UROGEN I and III each contain eight carboxyl groups as side chains, four of which are acetate ($–CH_2COOH$) and four of which are propionate, ($–CH_2–CH_2–COOH$) moieties (Fig. 149-2). The soluble cytosolic enzyme UROGEN decarboxylase catalyzes the sequential decarboxylation of the four carboxyl groups of the acetate side chains to methyl groups to form COPROGEN (Fig. 149-2). Decarboxylation first occurs on ring D, after which the enzyme turns around to decarboxylate rings A, B, and C in a clockwise fashion. This converts the original 8-carboxyl porphyrinogen (UROGEN I or III) first to 7-carboxyl, then to 6-carboxyl, and then to 5-carboxyl porphyrinogen. The 5-carboxyl porphyrinogen can then undergo decarboxylation of its last acetyl group to form the 4-carboxyl porphyrinogen that is known as coproporphyrinogen (COPROGEN I or III) (Fig. 149-2). These intermediates are also referred to as hepta-, hexa-, penta-, and tetracarboxylate porphyrinogens. As discussed above, COPROGEN I cannot be further metabolized to heme. The human enzyme purified from erythrocytes has a molecular mass of about 42 kDa. The human cDNA for UROGEN decarboxylase has been isolated, and the deduced sequence is equivalent to 367 amino acids, consistent with the molecular mass and the amino acid composition of the purified protein. Human UROGEN decarboxylase is encoded by a single gene on 1p34 that contains 10 exons spread over 3 kb. [12]

UROGEN decarboxylase activity is reduced in the liver of patients with porphyria cutanea tarda (PCT) and hepatoerythropoietic porphyria (HEP). Approximately 20 percent of patients with PCT have a 50 percent decrease in UROGEN decarboxylase concentration in all tissues; this form of PCT is inherited as an autosomal dominant trait with low penetrance (type II PCT). Multiple mutations of UROGEN decarboxylase (at least 30) have been identified that either decrease the stability of the enzyme or produce defective pre-mRNA splicing. [1], [12], [13], [14] and [15] In type I PCT, also known as the sporadic form, the enzyme deficiency is limited to the liver. Type II PCT is a disease in which the enzyme is deficient in all tissues, although penetrance is low and relatively few patients have a family history of skin symptoms. [14] There is also a rare type III PCT in which the activity and concentration of the erythrocyte enzyme is normal suggesting that an autosomal gene, not necessarily at the UROGEN decarboxylase locus, could influence the expression of this form of PCT. [16] Normal amounts of mRNA for the enzyme are present in type II PCT, and a splice-site mutation has been

found in at least one pedigree with type II PCT that causes a deletion of exon 6 from the mRNA. [17] The resulting protein is shorter than the normal protein, missing the amino acids encoded by exon 6, and this aberrant protein lacks catalytic activity and is rapidly degraded.

In HEP, UROGEN decarboxylase activity is usually 5 to 10 percent of normal, and patients are either homozygotes or compound heterozygotes for mutations of the UROGEN decarboxylase gene. One mutation occurring in HEP homozygotes is also associated with overt PCT in heterozygotes. [18] A mutation that has been identified in some, but not all, families with HEP is a 281 (Gly-Glu) shift. [13], [14], [19]

Coproporphyrinogen Oxidase

This is a mitochondrial enzyme located in the intermembrane space.

COPROGEN III has four carboxyl groups, each of which is part of a propionate side chain. COPROGEN oxidase, a mitochondrial enzyme of molecular mass 74 kDa, catalyzes the sequential oxidative removal of the carboxyl group from two of the propionate groups, forming first 3-carboxyl porphyrinogen, or harderoporphyrinogen (HARDEROGEN), and then 2-carboxylporphyrinogen, or protoporphyrinogen IX (PROTOGEN) (Fig. 149-2). Southern analysis of human restriction fragments suggests the presence of a single gene located on chromosome 3q12. [20] The COPROGEN oxidase gene spans 14 kb and consists of seven exons and six introns. Multiple mutations have been found in patients with heterozygous and homozygous HCP. These include point mutations resulting in base substitutions or exon skipping.

A unique modification of normal heme synthesis can occur in PCT. No additional enzymes or enzymatic reactions are involved, but there is a reversal in the sequence of action of the enzymes UROGEN decarboxylase and COPROGEN oxidase. UROGEN decarboxylase normally acts on 5-carboxylporphyrinogen to decarboxylate the final remaining acetate group, forming a tetracarboxyl porphyrinogen known as COPROGEN III (Fig. 149-1). This is subsequently converted to PROTOGEN by COPROGEN oxidase (Fig. 149-1 and Fig. 149-2). However, in PCT where UROGEN decarboxylase is deficient, COPROGEN oxidase may first oxidatively decarboxylate a propionate group on 5-carboxylporphyrinogen to form dehydroisocoproporphyrinogen (Fig. 149-1). The acetyl group on dehydroisocoproporphyrinogen can be decarboxylated by UROGEN decarboxylase to form HARDEROGEN, resulting in diversion back into the normal heme synthesis pathway (Fig. 149-1). Alternatively, dehydroisocoproporphyrinogen can undergo hydration to isocoproporphyrinogen (Fig. 149-1). These steps rarely, if ever, occur during the normal process of heme synthesis, but become important in certain of the porphyrias such as PCT, where they provide one explanation for the increased isocoproporphyrin (ISOCOPRO) characteristically found in the feces of patients with this disease.

Protoporphyrinogen Oxidase

The oxidation of PROTOGEN IX to PROTO is catalyzed by the enzyme PROTOGEN oxidase, an integral protein of the inner mitochondrial membrane (Fig. 149-1 and Fig. 149-2). This reaction can also occur nonenzymatically, but the enzyme appears to be necessary for heme synthesis to proceed at a normal rate. This reaction leads to the removal of six hydrogens from PROTOGEN IX. PROTOGEN oxidase activity is reduced in patients with VP. Multiple mutations have been identified, one of which (R59W) is the founder gene underlying the high incidence of the disorder in South Africa. PROTOGEN oxidase isolated from rat liver mitochondria has a molecular mass of 51 kDa and requires molecular oxygen to catalyze the oxidation of PROTOGEN to PROTO. The human PROTOGEN oxidase gene has been mapped to chromosome 1q22–23 and consists of 13 exons spanning 8 kb. [21] Northern blot analyses from a variety of tissues indicate that there is a single transcript of 1.8 kb encoding a protein of 477 bp.

Ferrochelatase

The final step in the formation of heme, the incorporation of ferrous iron (Fe^{2+} into PROTO, is catalyzed by the enzyme ferrochelatase located at the matrix face of the inner mitochondrial membrane (Fig. 149-1 and Fig. 149-2). This enzyme is also referred to as heme synthase or proto-heme-ferro-lyase. Unlike other enzymes in the heme biosynthesis pathway, that require reduced forms of the porphyrins (porphyrinogens) as substrates, ferrochelatase uses oxidized PROTOGEN. This lysine-rich enzyme has a molecular mass of 63 kDa and a pH optimum of 7.8. Ferrochelatase activity is decreased in various tissues of patients with EPP.

The cDNA for human ferrochelatase has also been cloned, sequenced, and shown to have 88 percent identity to the mouse enzyme. Human ferrochelatase mRNA is encoded by a single nuclear gene that spans about 45 kb of chromosomal DNA. The gene is located on chromosome 18q and consists of 11 exons and 10 introns. Molecular genetic studies conducted in patients with EPP reveal approximately 30 mutations of various types of which exon deletions are the most common, resulting in encoding of truncated proteins that would be expected to have little or no catalytic activity. It is of interest that expression of these mutations in bacteria identified a common loss of the iron–sulfur metal center essential for catalytic activity. A C?T transition at position -23 in intron 1 is detectable in all EPP patients, as well as in some normals, suggesting that individuals with EPP are heterozygous for mutations of the enzyme. Recent studies show that the penetrance of EPP is modulated by expression of wild-type ferrochelatase that contains an intronic single nucleotide polymorphism that results in aberrantly spliced mRNA that is degraded by a nonsense-mediated decay mechanism. [22] Slight variations in expression of the normal allele may be decisive in determining clinical expression of EPP. The end product of the pathway, ferrous-PROTO (FePROTO) or heme, diffuses out of the mitochondrion into the cytoplasm, where it is available to function as a prosthetic group by combining with appropriate apoproteins (Fig. 149-3 and Fig. 149-4). Heme thus controls its own synthesis based upon the needs of the cell.

It is important to emphasize that porphyrinogens (reduced porphyrins) are the true intermediates in heme synthesis. The irreversibly oxidized porphyrins, with the exception of PROTO, do not function as substrates for the enzymes of the pathway. These porphyrins exhibit an absorption spectrum with a major peak in the 400 nm region, the so-called Soret band, and smaller absorption peaks between 580 and 650 nm. These oxidized porphyrins induce photodynamic effects in

skin tissue and subcellular components when exposed to ultraviolet and short visible light (360 to 420 nm) or red wavelengths (640 to 700 nm). Thus, porphyrins are actually heme pathway by-products, which are of special interest to dermatologists because of their unique photosensitizing properties.

PATHOPHYSIOLOGY OF CUTANEOUS LESIONS IN THE PORPHYRIAS

A common cutaneous manifestation of the porphyrias is photosensitivity; it is observed in patients with several of these disorders (EP, EPP, PCT, VP, HCP, and HEP) in whom plasma and tissue porphyrins are increased. Patients with AIP, in whom only nonphotosensitizing porphyrin precursors (ALA, PBG) are formed in substantially increased amounts, do not have photosensitivity nor do any of the four patients reported with ALA dehydratase-deficiency porphyria.

Patients with the erythropoietic types of porphyria frequently complain of an intense burning sensation and pruritus following exposure to sunlight. A priming effect of sun exposure on cutaneous photosensitivity in EPP has been described in which a threshold exposure on one day that evokes virtually no reaction seems to augment the response to subsequent sun exposure on the following day. [23] The cause of this is unknown, but the phenomenon suggests that repair of damage to skin by photosensitized porphyrins may be prolonged. These subjective symptoms are notably absent in patients with the chronic hepatic porphyrias such as PCT and VP. Although there is some information about the pathophysiology of photosensitivity and sclerodermoid skin changes in the chronic hepatic porphyrias, the causes of the pigmentary alterations and hypertrichosis seen in these patients remain to be elucidated.

Porphyrins have certain unique photobiologic and spectroscopic properties. The metal-chelated porphyrins (e.g., heme or FePROTO) show no fluorescence. Porphyrins that are chelated to other paramagnetic metals, such as Mn^{2+}, Co^{2+}, or Zn^{2+} (e.g., chlorophyll, ZnPROTO), also do not fluoresce. This is the reason that patients with lead intoxication, in which ZnPROTO is elevated, do not have photosensitivity. However, metal-free porphyrins (e.g., URO, COPRO, PROTO) in acidic solutions show a major absorption peak in the 400- to 410-nm region (Soret band); they also exhibit four additional absorption bands with decreasing intensity between 500 and 700 nm. Exposure of porphyrins to the Soret band spectra results in two major fluorescence emission peaks at the 600- to 610-nm and 640- to 660-nm regions (Table 149-4).

Porphyrin	Excitation (nm)	Emission (nm)	Fluorescent Porphyrins
Erythropoietic porphyria (EP)	398	619	URO I, COPRO I
Erythropoietic protoporphyria (EPP)	409	634	PROTO
Porphyria cutanea tarda (PCT)	398	619	URO I, III, COPRO III
Variegate porphyria (VP)	405	626	COPRO III, PROTO
Acute intermittent porphyria (AIP)	398	619	URO III
Hereditary coproporphyria (HCP)	398	619	COPRO III
Hepatoerythropoietic porphyria (HEP)	398	619	URO I

TABLE 149-4 **Fluorescence Characteristics of Porphyrin-Containing Plasma Diluted with 1:10 Phosphate Buffered Solution**

Although there is no single, clearly defined pathway that can currently explain the photosensitization evoked by porphyrins and light, there are a number of potential cellular and soluble factors that could be responsible. Among them, reactive oxygen species (ROS), certain cells (erythrocytes, mast cells, polymorphonuclear cells, and fibroblasts), and soluble mediators (the complement system, factor XII–dependent pathways, and the eicosanoids), as well as matrix metalloproteinases will be discussed (Table 149-5). It is likely that interactions among these factors will prove to be responsible for the pathogenesis of the cutaneous lesions in the porphyrias.

TABLE 149-5 **Factors Contributing to the Development of Cutaneous Lesions in Porphyrias**

Reactive Oxygen Species

Porphyrins such as URO, COPRO, and PROTO absorb light intensely around 400 nm and in the longer visible range between 580 and 650 nm. Absorption results in the generation of “excited” state porphyrin molecules (Fig. 149-5). The initial excited state porphyrin generated has an extremely short half-life of less than 0.01 µs. Singlet excited-state porphyrins may spontaneously convert to a triplet, another excited state that has a lower energy level but a longer half-life (in the order of microseconds to milliseconds). Because of their long half-life, triplet-state porphyrins are more likely to react with biologic substrates and are likely candidates to mediate most porphyrin-associated photobiologic reactions. Excited-state porphyrin molecules ultimately must return to their normal ground states by releasing their absorbed energy in the form of light (fluorescence is emitted by singlet-state molecules and phosphorescence by triplet states), heat, or by transferring energy to cell constituents (cell membranes, organelles, proteins, DNA) (Fig. 149-6 and Fig. 149-7).

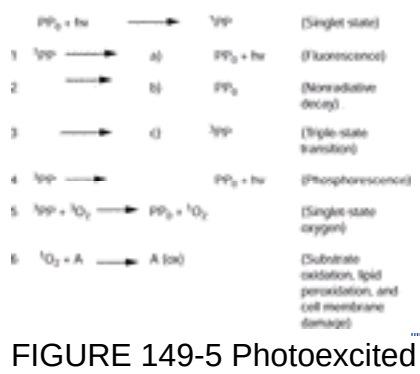

FIGURE 149-5 Photoexcited porphyrins release energy in a variety of ways when returning to their ground state, and these may contribute to damaging reactions in biologic systems.

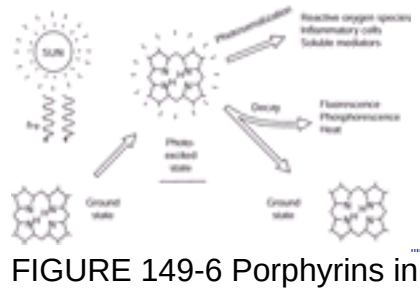

FIGURE 149-6 Porphyrins in ground state upon absorption of radiant energy (h *v*) undergo transition to photoexcited states. The photoexcited porphyrins generate reactive oxygen species, damaging cells by release of proinflammatory mediators; in turn, these may contribute to damaging reactions in biologic systems such as skin.

FIGURE 149-7 Photoexcited porphyrins in their triplet state transfer the absorbed energy to exygen (O_2) molecules, thereby producing reactive oxygen species ($^1O_2$, $\cdot O_2^{\cdot-}$, ·OH, and lipid peroxides). These reactive oxygen species interact with cell membranes to cause tissue damage.

Excited porphyrins in their singlet and triplet states can also transfer their absorbed energy to oxygen molecules thereby creating reactive “excited” oxygen states. Cellular and tissue damage induced by photoactivated porphyrins is believed to occur primarily as a result of the formation of reactive singlet oxygen ($^1O_2$), as illustrated in Fig. 149-5 and Fig. 149-7. [24] Various forms of ROS capable of causing tissue damage are known to exist, including singlet oxygen ($^1O_2$) and superoxide anion ($O_2^{\cdot-}$). In some cases, the sensitized porphyrin may react with oxygen to yield hydrogen peroxide (H_2O_2) or with water to form hydroxyl radicals ($^{\cdot}OH$). Those processes in which activated oxygen species play a role in photosensitization are referred to as photodynamic reactions. Most of the porphyrin-mediated cutaneous photosensitization reactions are essentially photodynamic and can be minimized or prevented if reactive oxygen is eliminated from the reaction system through inactivation processes known as quenching or scavenging.

Although these concepts regarding excited porphyrins and ROS are valid in simple systems, their applicability to complex tissues such as the skin remains to be established. Several hypotheses have been advanced regarding the mechanism of porphyrin-induced photosensitivity. One hypothesis involves the transfer of energy from excited species of oxygen to water or to lipids, creating hydrogen and/or lipid peroxides. These peroxides, in turn, can evoke damage in lipid-rich cellular membranes (Fig. 149-7). Evidence for this type of reaction has come from the demonstration of porphyrin-UV–induced cross-linkage of proteins within RBC membranes and destruction of fibroblast membrane sulfhydryl groups. If such damage occurs in plasma membranes in cells in or adjacent to the skin, it could result in tissue destruction and possibly explain the photosensitivity seen in the cutaneous porphyrias. It has been shown that photoexcitation of PROTO-enriched RBC results in the formation of hydrogen peroxide and lipid peroxides, each of which would be highly destructive to lipid-rich membranous structures. There is evidence in RBC of peroxidation of cholesterol groups in the cell membrane resulting in hemolysis following exposure to UV radiation and PROTO.

Several other studies have also supported the participation of ROS in porphyrin-induced phototoxicity. The release of inflammatory mediators from mast cells induced by photoexcited PROTO can be suppressed by catalase, which inactivates hydrogen peroxide by converting it to water and oxygen. [25] Singlet oxygen mediates porphyrin-induced photodamage to hepatic and epidermal microsomal cytochrome P450. [26] Porphyrin and radiation-induced damage of lysosomal and mitochondrial membranes also occur. DNA exposed to visible light and hematoporphyrin manifests selective degradation of the guanine moiety. In vivo, beta-carotene, a scavenger of singlet oxygen, is effective in diminishing the severity of cutaneous photosensitivity in patients with EPP. [27] In a murine model, it was demonstrated that xanthine oxidase–generated $O_2^{\cdot-}$ also plays a significant role in the development of the phototoxicity induced by HPD. [28]

Erythrocytes

Photoexcited PROTO elicits peroxidation of cholesterol groups in erythrocyte membranes, whereas URO or COPRO have no such effect. This difference, which is also true of mast cells, polymorphonuclear leukocytes, and fibroblasts, most likely relates to variations in lipid-water partitioning of the different porphyrins, which may relate to their polarity. The lipophilic PROTO, a 2-carboxyl porphyrin, is more damaging to lipid-rich membranes as compared to the more water-soluble COPRO and URO.

Mast Cells

Mast cell degranulation occurs in the exposed skin of patients with EPP. [29] Irradiation of PROTO-treated mast cells in vitro induces release of mast cell–derived mediators, although exposure to lower doses of PROTO and radiation results in inhibition of secretagogue-induced histamine release from these cells. [30] In contrast, no mediator release is detectable when cells are radiated in the presence of URO. These findings may help to explain the differences in the clinical presentation of patients with EPP and PCT. The elevated PROTO in patients with EPP may induce the release of mast cell mediators in vivo following sun exposure, resulting in painful, pruritic erythema and edema. The absence of these changes in patients with PCT may be explained by the apparent inability of photoexcited URO to damage cutaneous mast cells.

Phototoxicity is associated with elevated serum histamine levels and dermal mast cell degranulation, [31] and the phototoxic response can be suppressed by pretreatment with antihistamines (H_1 blockers) or by intradermal injection of a mast cell secretagogue (compound 48/80). [32]

Polymorphonuclear Cells

Exposure of human polymorphonuclear leukocytes (PMNs) to PROTO and radiation in vitro results in membrane damage, whereas photoexcited URO induces no such alterations. These results are strikingly similar to those obtained in studies with mast cells (see above). In an animal model, the porphyrin-induced phototoxic response was associated with a dermal PMN infiltrate, [31] and the phototoxicity was markedly suppressed in leukopenic animals. [32] These results appear to suggest that PMNs may be necessary but not sufficient for porphyrin-induced phototoxicity.

Fibroblasts

Differential phototoxic effects of various porphyrins have also been verified in studies using dermal fibroblasts. An increase in collagen biosynthesis is observed following incubation of fibroblasts with URO. [33] This effect is independent of irradiation and may partly explain the sclerodermoid changes observed in patients with PCT, which can occur in sun-exposed and in sun-protected areas. In contrast, PROTO induces photolysis of fibroblasts in vitro. [34]

The Complement System

The participation of the complement system in porphyrin-induced phototoxicity was initially suggested by immunofluorescent studies identifying selected complement components localized near vessel walls at the dermal–epidermal junction in patients with cutaneous porphyria. In addition to endothelial cell damage, histologic changes consistent with those mediated by complement activation products, that is, mast cell degranulation and infiltration of PMNs, are observed during the acute phase of photosensitivity in the skin of patients with EPP. [29] In vitro irradiation of sera obtained from patients with EPP and PCT results in complement activation. [35] In animal models, porphyrin-induced phototoxicity is associated with complement activation and is suppressed in complement-depleted animals, as well as in animals congenitally deficient in the fifth component of complement. [36] Generation of complement-derived chemotactic activity is also seen following exposure of the skin of patients with EPP and PCT to Soret band radiation. [37]

Factor XII–Dependent Pathways of Coagulation

Activation of Hageman factor–dependent pathways in the presence of PROTO has been demonstrated in vitro. [38], [39] In contrast, neither URO nor COPRO induces such activation. Whether this activation, which is independent of irradiation, contributes to the pathogenesis of porphyrin-induced phototoxicity remains to be determined.

The Eicosanoids

Porphyrins and radiation affect eicosanoid metabolism. Incubation of mouse peritoneal macrophages or radiation-induced fibrosarcoma tumor cells in vitro with hematoporphyrin-derivative PHOTOFRIN II, followed by 630-nm radiation, results in dose-dependent generation of prostaglandin E_2 (PGE_2). [39]

Matrix Metalloproteinases

Photoexcited URO coordinately induces interstitial collagenase [matrix metalloproteinase (MMP)-1], 72-kDa type IV collagenase (MMP-2), and stromelysin-1 (MMP-3) in human dermal fibroblasts in vitro. [40] The induction of the MMPs by porphyrin photosensitization suggests that blistering could be due to activation/release of these enzymes.

Cutaneous phototoxicity in porphyrias is directly related to the interaction of porphyrins with light of the Soret and other bands, resulting in the generation of ROS; in turn, this can induce lipid peroxidation and cell membrane alterations. Release of mediators and enzymes from cells such as mast cells and PMNs contributes to the inflammatory response; the reaction relates to the effects of porphyrins on the complement system, factor XII–dependent pathways, and the

eicosanoids. Variations in solubility influenced by the lipid-water partitioning of porphyrins may account for the striking patterns of the skin findings observed in various types of porphyria.

CLASSIFICATION OF THE PORPHYRIAS

Most classifications of the porphyrias are based on the primary site of expression of the specific enzymatic defect, thereby distinguishing erythropoietic and hepatic forms. However, an alternative approach is to classify the porphyrias as acute and nonacute, thereby categorizing patients with or without acute neurologic attacks. It should be pointed out that VP and HCP also should be considered as neurocutaneous porphyrias because they can manifest neurologic signs and cutaneous manifestations (Table 149-6).

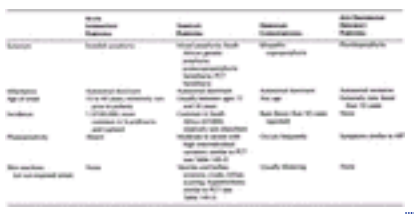

TABLE 149-6 **Overview and Summary of the Features of the Acute Porphyrias**

An acute porphyric attack can present a constellation of symptoms and signs, among them, intense abdominal pain; vomiting; electrolyte dysregulation (hyponatremia); constipation; tachycardia; hypertension; muscle pain and weakness; seizures; paresis of the upper and lower extremities; paralysis; and a variety of other neurologic and psychiatric symptoms. These myriad clinical manifestations inevitably mimic other diseases, thereby challenging the diagnostic acumen of even experienced physicians, particularly because the porphyrias are rare disorders. It is known that acute porphyric attacks can be precipitated by a variety of external factors, in particular porphyrinogenic drugs, alcohol, hormonal fluctuations, and diminished caloric intake from dieting or fasting. [41] Yet in practice, it is often impossible to identify the causative agent of an acute crisis in an individual patient. Timely diagnosis of an acute porphyric attack can be lifesaving because several complications may have fatal consequences if not recognized and treated. As an example, in a patient with episodic abdominal pain, treatment with analgesics may prolong or aggravate the attack. Diffuse abdominal pain can mimic acute appendicitis, diverticulitis, or other painful gastroenterologic disorders that may necessitate surgical intervention. After administration of certain drugs (e.g., barbiturates), or during general anesthesia, acute attacks can be exacerbated. [2] The acute porphyric attack is associated with several complications that are potentially life-threatening. Of these, muscle paralysis is particularly problematic. This can range from mild paralysis of small muscle groups to flaccid paralysis of multiple muscle groups that may result in paraplegia and respiratory compromise. These findings may be accompanied by severe sensory loss and amyotrophy. In some cases, paralysis may progress rapidly and can affect cranial nerves or develop into a pseudo–Guillain-Barré syndrome.

ACUTE AND NONACUTE PORPHYRIAS

The acute porphyrias include AIP, VP, HCP, and ALA dehydratase deficiency porphyria or plumboporphyria (Table 149-6). [3] Although AIP is the most prevalent form of acute porphyria worldwide, in some countries, other acute forms may predominate, as is the case for VP in Chile. In addition to neurovisceral symptoms, individuals suffering from VP or HCP can also present with cutaneous findings, including increased photosensitivity, abnormal skin fragility, bullous skin eruptions on sun-exposed areas, erosions, chronic scarring, and postinflammatory pigmentary change. Thus, VP and HCP are also referred to as neurocutaneous porphyrias, to distinguish them from AIP and ALA dehydratase deficiency porphyria that have no cutaneous abnormalities. [3]

The nonacute porphyrias consist of PCT, the most prevalent type of porphyria overall, EPP, CEP, and HEP, the recessively inherited variant of PCT (Table 149-7). [3] The nonacute porphyrias can present with different types of cutaneous findings, including mild to severe photosensitivity, increased skin fragility, vesicles and bullae, burning and stinging, edema, pruritus, hypertrichosis, scarring, hyperpigmentation, and mild to severe scarring changes. [3] It is of interest that alcohol and estrogens, which can trigger acute porphyric attacks in AIP, VP and HCP, can also exacerbate PCT although acute attacks do not occur in this disease.

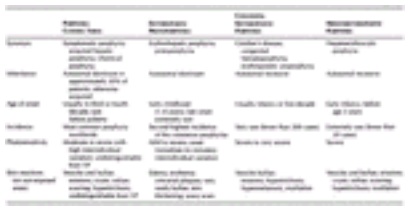

TABLE 149-7 **Overview and Summary of the Features of the Nonacute Porphyrias**

ACUTE INTERMITTENT PORPHYRIA (AIP) (Table 149-6)

Etiology

Several excellent reviews summarize the clinical and biochemical features of AIP. [1], [42], [43] The disease may affect the peripheral, autonomic, or central nervous systems with neuropathic symptoms and dysfunction. Increased hepatic ALA synthase is a characteristic finding in AIP, as it is in the acute hepatic porphyrias. [44] It is now clear that the enzyme PBG

deaminase, which converts PBG to UROGEN I, is deficient in various tissues of affected individuals and latent carriers of the disease. This helps to explain the excessive ALA and PBG excretion of AIP. PBG deaminase activity in AIP is approximately 50 percent of that in unaffected normal individuals, consistent with an autosomal dominant mode of inheritance. Diminished PBG deaminase partially blocks heme synthesis, which, in turn, decreases the regulatory heme pool and leads to derepression of ALA synthase mRNA synthesis. Fewer than 10 percent of latent carriers of the PBG deaminase defect ever express the clinical phenotype. The gene defect alone seems to be inconsequential unless the individual is exposed to additional triggering factors, of which certain drugs that induce hepatic cytochrome P-450s (CYPs), are particularly important (see Table 149-8).

Amidopyrine	Hydralazine
Aminoglutethimide	Isopropylmeprobamate
Aminopyrine	Mephenytoin
Amphetamines	Meprobamate
Antipyrine	Methyldopa
Barbiturates	Methylprylon
Bemegride	N-butylscopolammonium bromide
Carbamazepine	Nalidixic acid
Carbromal	Nikethamide
Chloromethazone	Nitrazepam
Chloropropamide	Nortriptyline
Chloroquine	Novobiocin
Danazol	Pargyline
Dapsone	Pentazocine
Diclophenac	Pentylenetetrazole
Diethylpropione	Phenoxybenzamine
Diphenylhydantoin	Phenylbutazone
Dramamine	Primadone
Enflurane	Pyrazinamide
Ergot preparation	Rifampin
Erythromycin	Sedormid
Ethchlorvynol	Succinimides
Ethinamate	Sulfonamides
Ethosuximide	Sulfonethylmethane
Ethyl alcohol	Sulfonylureas
Fentanyl	Synthetic estrogens, progestins
Furosemide	Theophylline
Furpwne	Tolazamide
Glutethimide	Tolbutamide
Griseofulvin	Trimethadione
Halothane	Valproic acid
Heavy metals	

TABLE 149-8 **Examples of Drugs Potentially Hazardous in Patients with the Acute Hepatic Porphyrias**

Epidemiology

AIP is an autosomal dominant disease that rarely, if ever, manifests before puberty. Most published series emphasize the female predominance of affected patients, ranging from ratios of 1.5 to 2.0:1 The incidence in the human population is approximately 1.5:100,000 in most areas of the world. However, in Scandinavia, particularly Lapland, the incidence is much higher (1:1000).

Clinical Manifestations (See Table 149-6)

The clinical signs and symptoms of AIP may be related to the effects of porphyrin precursors or heme depletion in the autonomic nervous system. The acute attack is characterized by abdominal pain and neurologic and psychiatric symptoms that can mimic various disorders. Attacks are often precipitated by ingestion of drugs such as those listed in (Table 149-8). Acute attacks of AIP are accompanied by seizures, especially in patients with hyponatremia resulting from vomiting and inappropriate fluid therapy.

There are no cutaneous lesions related to photosensitivity in AIP. This is logical as the abnormal excretion pattern of the disease consists mostly of the porphyrin precursors ALA and PBG, which are not photosensitizers.

These patients usually have abdominal pain (80 to 90 percent) during an acute attack (between attacks patients are often completely symptom free). The pain may be diffuse or localized and is often intermittent and spastic. Vomiting and constipation are frequently associated. Mild fever and leukocytosis may occur, making differential diagnosis extremely difficult. This is one reason many patients with AIP undergo repeated exploratory laparotomies before the diagnosis is finally established.

Peripheral neuropathy is a major part of the clinical syndrome in many patients varying from sensory (localized pain) to motor (weakness progressing to generalized flaccid paralysis). Patients may succumb to the disease, usually as a result of respiratory failure, or may improve slowly, although residual muscle weakness frequently persists for extended periods.

Laboratory Findings

The primary gene defect in AIP results in PBG deaminase deficiency, which causes excessive urinary excretion of ALA and PBG. Urinary porphyrins may also be elevated (Table 149-3). Urinary excretion of ALA and PBG as high as 100 mg/24 h may occur during an acute attack. During clinical remission of the disease, urinary excretion of ALA and PBG decreases, but usually remains above normal values. This is in contrast to patients with VP who often exhibit normal urinary excretion of ALA and PBG between acute attacks.

Two rapid screening tests are available to test freshly voided urine for increased PBG. The first is simply to expose the urine to bright sunlight for several hours. Darkening to a deep red color suggests that PBG is present but does not prove it. (Porphobilin, another dark pigment, can also be photocatalytically formed in urine.) The second rapid screening test, known as the Hoesch test, is also a simple procedure for detecting excessive urinary PBG. To 2 mL of Ehrlich's reagent (3 g of *p*-dimethylaminobenzaldehyde dissolved in 125 mL of acetic acid and 24 mL of perchloric acid) 2 drops of fresh urine are added. A uniform cherry-red color of the sample indicates a positive reaction. This test is based upon the formation of a chromogen by PBG and Ehrlich's aldehyde reagent that produces a red pigment with strong absorbance at 552 nm. The well-known Watson-Schwartz test is based on this same principle, but it is often not helpful. In patients with suspected AIP, quantitative 24-h measurement of urinary ALA and PBG using ion-exchange chromatography or

high-performance liquid chromatography is essential. [44]

Histopathology

Histopathologic findings of skin are unremarkable.

Differential Diagnosis

The clinical manifestations of AIP are so variable and resemble so many different diseases that Waldenström has used the term *little imitator* to describe it. Excellent reviews have summarized the differential clinical features of AIP. [1], [43]

Treatment

Although there is still no specific treatment for AIP, several therapeutic modalities have been used, including glucose loading (2 L of 20% glucose over 24 h in divided doses of 500 mL through a central venous line). [43], [45] Administration of a gonadotropin-releasing hormone analogue has also been recommended. [46] Infusion of hematin in the form of heme arginate (Normosang, Orphan Europe, Paris, or Panhematin, Abbott Laboratories, N. Chicago, IL) is effective in shortening attacks. [43] Precipitating factors such as drugs (Table 149-8), sex steroid hormones, and starvation should be avoided. AIP patients should wear medical warning bracelets and be given lists of drugs to avoid. Table 149-9 lists drugs thought to be safe for AIP patients.

Acetaminophen	Insulin
Adrenaline	Labetalol
Amitryptyline	Lithium
Aspirin	Mandelate
Atropine	Methenamide
Bromide	Naproxen
Cephalosporins	Narcotic analgesics
Chloralhydrates	Neostigmine
Chloramphenicol	Nitrofurantoin
Chlordiazepoxide	Nitrous oxide
Colchicine	Oxazepam
Digoxin	Penicillin and derivatives
Diphenhydramine	Phenothiazines
EDTA	Propranolol
Ether	Prostigmine
Glucocorticoids	Rauwolfia alkaloids
Guanethidine	Streptomycin
Heparin	Succinylcholine
Hyocine	Tetracycline
Hypocine	Thiouracil
Ibuprofin	Thyroxine
Indomethacin	

EDTA, Ethylenediaminetetraacetic acid

TABLE 149-9 **Drugs Considered to Be Safe (or Probably Safe) in Patients with the Acute Hepatic Porphyrias**

VARIEGATE PORPHYRIA (VP) (See Table 149-6)

Etiology

The disease is most prevalent in South Africa, but occurs worldwide.

ALA synthase is elevated in the liver of patients with VP, just as it is in those patients with AIP. This is a nonspecific finding because it occurs in each of the acute hepatic porphyrias. A 50 percent decrease in PROTOGEN oxidase activity is now recognized as the primary enzyme defect in VP. [47], [48] The enzyme acts specifically on PROTOGEN IX, the penultimate step in heme synthesis, and cannot catalyze the oxidation of COPROGEN I or III or UROGEN I.

Epidemiology

This form of porphyria is quite common among the white and so-called Cape-Coloured South Africans because of the "founder" effect described above. A high proportion of the present white population is descended from a pair of early Dutch settlers who immigrated to South Africa from Holland in 1688. The disease is inherited as an autosomal dominant trait, and the incidence in South Africa is the highest in the world, approximately 1:300 individuals in the white population.

The cutaneous manifestations of PCT and VP are for the most part indistinguishable. Among the native black population of South Africa, typical PCT without associated acute attacks also occurs. There is apparently no family history, and porphyrin excretion patterns are as for PCT, not VP. In South Africa, excessive intake of home-brewed spirits (Kaffir beer) and dietary iron overload from cooking vessels are considered important factors in the development of this disease. Thus, VP occurring in the descendants of the Dutch immigrants of South Africa is quite distinct from the PCT seen in the native black population. Finally, Dean pointed out that the group he designated as Cape-Coloured who are descendants of white European and Indian immigrants who intermarried with black natives, may have VP and PCT in the same family. [49] Factors that precipitate or lead to activation of AIP also appear to induce VP (various drugs, starvation, etc.). All patients with suspected PCT should be screened for VP because VP has a life-threatening potential, and death can follow the ingestion of these drugs.

Clinical Manifestations

The clinical manifestations of VP include those of AIP and PCT, either or both of which may occur in the same individual. In general, females have more frequent acute attacks typical of AIP and males are more likely to have the cutaneous lesions of PCT. Two major differences between VP and PCT are (1) the skin reactions which usually develop at an earlier age (second and third decades) as compared to PCT (fourth and fifth decades) and (2) the neurovisceral symptomatology. The clinical features of VP are (1) positive personal or family history of chronic skin involvement with or without attacks of abdominal pain, constipation, vomiting, muscle weakness, and neuropsychiatric manifestations of

stupor and coma; and (2) photocutaneous lesions associated with minor mechanical trauma. The skin lesions of VP are indistinguishable from those of PCT. These include bullae, erosions, or ulcers following minor trauma of light-exposed skin (Fig. 149-8). Hyperpigmentation, milia, hypertrichosis, and increased skin fragility are also seen. They appear to be more common in the hot climate of South Africa and are less frequently seen in cold climates. Blisters are often blood-tinged, heal slowly, and form milia with some scarring. Occasionally, the patient gives a history of acute sun sensitivity occurring during or soon after a period of exposure; this may include burning, erythema, and edema. In the chronic state, the skin changes may include thickening and scarring (Fig. 149-9A). Some authors believe that melanin pigmentation may reduce the severity of the photocutaneous findings (Fig. 149-9B). The skin manifestations do not correlate with the acute attacks in most patients. These clinical and biochemical features are usually seen after puberty, except in the homozygous patients who may develop signs and symptoms at or shortly after birth These patients frequently manifest short stature and small hands with shortening of the digits. [50]

FIGURE 149-8 A case of variegate porphyria. *A*. Blisters, crusted erosions, and pigmentary changes over the dorsa of the hands and fingers. *B*. Close-up view of index finger shows an intact blister with milia and pigmentary changes. *C*. Healing phase shows milia (*arrows*) and pigmentary changes. *D.* Large bullae of dorsum of foot and toes. *Note:* Patients with porphyria cutanea tarda have indistinguishable cutaneous findings.

FIGURE 149-9 Variegate porphyria. *A*. A peculiar leathery thickening of skin of the face of a patient chronically exposed to strong sunlight. A similar appearance has been noted in South African patients with erythropoietic protoporphyria. (*Courtesy of GH Findlay, MD, FP Scott, MD, and DJ Cripps, MD: Br J Dermatol 78:69, 1966.*) *B*. A South African pigmented patient showing less severe photodamage; the melanin appears to be photoprotective.

Laboratory Findings

Urinary ALA and PBG are elevated during acute attacks of VP (when the Watson-Schwartz test may be positive) but characteristically fall to normal levels between attacks (see Table 149-3), whereas in AIP patients, the urinary ALA and PBG are elevated, both during and between attacks. Another distinguishing feature of the two disorders is stool porphyrin excretion. Asymptomatic patients with VP usually, but not always, have marked elevations of stool PROTO and COPRO between attacks. These may fluctuate somewhat during acute attacks. PROTO typically exceeds COPRO. In AIP, fecal porphyrins are not elevated between attacks and usually increase only slightly during attacks. It is said that certain patterns of fecal and urinary porphyrin excretion may help in distinguishing VP from PCT. URO in the urine is only moderately elevated in VP whereas urinary COPRO is often higher. This is in marked contrast to active PCT where the reverse is seen, that is, urinary URO is much higher than COPRO. Again in VP, fecal porphyrins exceed 500 µg/g dry weight in >90 percent of patients, whereas in PCT this amount of stool porphyrin is excreted by only 1 percent of patients. Furthermore, the ratio of stool PROTO to COPRO in VP usually exceeds 1.5:1, whereas in PCT the ratio is almost always <1:1 because of the increased ISOCOPRO content characteristic of this disease. Stool porphyrin excretion patterns consistent with both VP and PCT have been found in different members of single families. [51] These types of findings led to the suggestion that measurement of bile porphyrins may be decisive in confirming a diagnosis of VP when excretory porphyrin patterns are ambiguous. Saline-diluted plasma specimens from patients with VP have characteristic fluorescence emission spectra (626-nm emission peak) that can be used to differentiate this disease from other forms of acute porphyria, PCT, EPP, and lead poisoning (Table 149-4). [52]

Histopathology

The skin lesions of VP are indistinguishable from those of PCT (see PCT below).

Differential Diagnosis

The differential diagnosis of VP should be considered from two perspectives. Acute attacks of abdominal pain and neurologic signs and symptoms are identical to those described for AIP. Fecal and biliary PROTO and COPRO determinations and plasma fluorescence spectra are decisive in making the diagnosis. The skin lesions of VP are identical to those of PCT, and, as such, the differential diagnosis includes the bullous diseases as well as other photosensitivity disorders. In HCP there may be identical acute attacks, but markedly elevated fecal COPRO III is diagnostic for this disease. HEP must also be considered, but this usually begins in childhood and is characterized by markedly deficient erythrocyte UROGEN decarboxylase and elevated erythrocyte PROTO, as well as increased stool ISOCOPRO. The presence of skin lesions rules out AIP. The determination of urinary ALA and PBG concentrations may help to rule out PCT and HEP. Screening of family members by measuring fecal porphyrins may also be helpful in differentiating VP and PCT.

Treatment

Preventive treatment of VP is identical to that described in AIP: avoidance of inducing drugs (see Table 149-8). Glucose loading and hematin infusions have also been used with ill-defined success. Phlebotomy and the antimalarials are not effective.

HEREDITARY COPROPORPHYRIA (See Table 149-6)

Etiology

HCP is an autosomal dominant disorder caused by mutations in the gene encoding COPROGEN oxidase. [53] This results in increased excretion of COPRO in the urine and stool.

Epidemiology

The disease appears to occur worldwide and, like AIP, to have a female preponderance and probably also an autosomal dominant inheritance. Fewer than 50 cases have been reported. A patient with HCP who developed AIDS has been reported. [54] As mentioned above, an extremely rare form of porphyria, known as harderoporphyria, appears to be a variant of HCP in which COPROGEN oxidase activity is very low (10 percent of control values). [55] This disease has been identified in three siblings.

Clinical Manifestations

The acute attacks are similar to those of AIP, and neurovisceral symptomatology predominates in HCP. This includes abdominal pain, vomiting, constipation, neuropathies, and psychiatric symptoms. The oral hypoglycemic agent glipizide has been reported to exacerbate a coproporphyria-like syndrome that was reversible following discontinuation of the drug. Cutaneous photosensitivity occurs in 20 percent of cases and resembles that seen in PCT and VP. [44] In general, it appears that this disorder is not associated with acute attacks as severe as those of AIP or VP.

Laboratory Findings

HCP is characterized by increased excretion of COPRO III in urine and feces. Markedly elevated (usually 10- to 100-fold) fecal COPRO, more than 90 percent of which is the III isomer, is present at all times in these patients. In addition, the feces may also contain increased amounts of hepta-, hexa-, and pentacarboxylic porphyrins. Urinary COPRO III is also raised, as are ALA and PBG, during attacks. The latter may be normal between attacks.

Histopathology

No histology has been reported.

Differential Diagnosis

Acute attacks are similar to those of AIP. The differential diagnosis rests on stool porphyrin determinations and measurement of COPROGEN oxidase in fibroblasts or leukocytes testing for mutations in the COPROGEN oxidase gene can also be performed. The skin lesions resemble those seen in PCT and VP. Fecal predominance of COPRO III is more suggestive of HCP than VP, in which PROTO and COPRO are usually increased.

Treatment

Avoidance of inducing drugs, glucose loading, and hematin infusions may be helpful.

ALA DEHYDRATASE DEFICIENCY PORPHYRIA (See Table 149-6)

This is a rare type of acute hepatic porphyria, and only a few patients have been reported. [5], [7] Clinically, these patients

have symptoms similar to AIP, and no skin lesions have been noted. Stress and ethanol ingestion reportedly precipitate attacks. The patients have erythrocyte ALA dehydratase activity that is <5 percent of normal. Although it has been suggested that ALA dehydratase deficiency porphyria may represent a homozygous ALA dehydratase defect, cloning of a mutant ALA dehydratase cDNA in a patient showed that the patient was doubly heterozygous for two independent mutant alleles of ALA dehydratase. [7]

In the few patients studied, the urinary porphyrin profile revealed elevated ALA, COPRO, and, to a lesser extent, URO. Fecal porphyrins revealed mildly elevated COPRO and PROTO in one patient, elevated COPRO in another, and a normal profile in two others. Erythrocyte PROTO was elevated in all patients. Increases of plasma ALA, COPRO, and PROTO have been reported. The porphyrin excretion pattern in these patients is unexplained.

TREATMENT OF THE ACUTE ATTACKS IN THE ACUTE PORPHYRIAS

Until recently, therapeutic interventions in the acute porphyrias were only partially effective and often limited to preventive measures and supportive care. Nowadays, most patients experiencing an acute attack can be treated successfully and life-threatening complications like paralysis, respiratory failure, and coma can be avoided if a timely diagnosis is made and appropriate aggressive treatment is implemented immediately. The importance of rapid intervention is illustrated by the fact that untreated or inappropriately treated patients suffering an acute porphyric crisis may have a 10 to 15 percent risk of mortality. Today, with mechanism-based therapeutic intervention the mortality rate of the acute attack has decreased to approximately 2 percent. Once the diagnosis of an acute porphyric attack has been confirmed, treatment should be initiated quickly and one approach involves four steps:

First, all potentially porphyrinogenic drugs should be stopped immediately and the patient should be monitored carefully and admitted to an intensive care unit if necessary. Virtually all drugs should be considered as posing a risk of exacerbating or prolonging an acute attack and several guidelines have been developed in an effort to categorize drugs as relatively “safe” or “unsafe” in patients with acute porphyria. [41] In addition to guidelines published in medical journals, extensive information about drugs and their safety in porphyria patients can also be obtained on the World Wide Web, for example, at www.uct.ac.za/depts/liver/index%20porphyria.htm, www.uq.edu.au/porphyria or http://www.knowdeep.org/porphyria/

Second, symptomatic treatment of neurovisceral manifestations like abdominal pain, vomiting, tachycardia, and seizures should be initiated promptly. Here we provide some recommendations for the symptomatic treatment of patients suffering from acute porphyric attacks. These are based on personal experience as well as on recommendations from different sources and include:

Symptom/Sign	Treatment
Abdominal pain	Acetylsalicylic acid; morphine
Vomiting	Chlorpromazine; promethazine
Hypertension and tachycardia	Propranolol
Hyponatremia	Electrolyte balance; saline infusions
Convulsions	Gabapentin
Constipation	Neostigmine

Third, the management of an acute attack can be initiated with the intravenous infusion of high doses of carbohydrates, preferably 400 to 500 g of glucose/24 h. This can be achieved by administration of 2 L of a 20% glucose solution or 1 L of a 40% solution. Simultaneously, diuresis should be induced by administration of furosemide with careful monitoring of serum electrolytes. Patients experiencing an acute attack are often unable to eat or drink because of severe nausea and recurrent vomiting. The rationale for high-dose glucose is based on experimental evidence showing that carbohydrates suppress the induction of ALA synthase, the first and rate-limiting enzyme of the heme biosynthetic pathway. Unfortunately, in many patients this regimen is only partially helpful.

Fourth, intravenous administration of heme arginate (Normosang), currently not FDA approved, is the most efficient method to suppress heme synthesis. The rationale for this approach is based on administering high doses of the end-product heme, which helps to repress the synthesis of ALA synthase. The early hematin preparations had the disadvantage of being very unstable. Furthermore, intravenous administration of these compounds was associated with a high risk of thrombophlebitis. A newer derivative, heme arginate, consists of human hemin and L-arginine as an additive to increase the solubility and stability of the product. In contrast to the older hematin preparations, heme arginate does not induce any significant changes in coagulation and fibrinolysis, and the frequency of thrombophlebitis, as well as the overall rate of side effects is markedly reduced. [56] Heme arginate exerts its specific action by correcting the underlying heme deficiency and restoring the negative feedback control of heme on ALA synthase, thereby decreasing the excessive hepatic production of porphyrins and porphyrin precursors. Heme arginate should be administered intravenously as a short infusion in a dosage of 3 mg/kg body weight/day over a period of 4 days. Cautious continued administration can be continued if the attack is not aborted; however, use of use heme arginate for more than 7 days is not recommended.

PREVENTION OF THE ACUTE ATTACKS IN THE ACUTE PORPHYRIAS

An important goal in porphyria therapy is the prevention of acute attacks. Therefore, all putative risk factors should be strictly eliminated. Patients should be advised to avoid fasting or dieting, to be abstinent of alcohol and to avoid the

intake of porphyrinogenic drugs, such as barbiturates, sulfonamides, and estrogens, to name several. [41], [44] By using appropriate screening procedures, asymptomatic carriers of an enzyme deficiency should be identified in the family of a patient suffering from an acute porphyria. In this context, it is important to define the inheritance patterns, as well as to identify mutations in the genes encoding for heme pathway enzymes that characterize these disorders.

The identification of mutations in the respective genes has greatly enhanced our understanding of the porphyrias. Once a mutation has been identified in a patient suffering from porphyria, the detection of asymptomatic gene carriers within the patient's family is easily accomplished by using standard molecular biologic techniques. In the acute porphyrias, the identification of these “silent” carriers is the first and most important step in the prevention of life-threatening acute attacks. Genetic analysis provides an effective way to make an early diagnosis thereby enhancing the likelihood of providing patients and asymptomatic gene carriers in their family with advice regarding the avoidance of precipitating factors.

PORPHYRIA CUTANEA TARDA (PCT) (See Table 149-7)

Etiology

PCT is caused by either an inherited or acquired deficiency of UROGEN decarboxylase, the fifth enzyme in the heme pathway. [12] UROGEN decarboxylase is present as a single copy per haploid genome and encodes a polypeptide of 42 kDa containing 10 exons within approximately 3 kb of DNA. The gene has been mapped to chromosome 1p34. The enzyme is cytosolic and catalyzes the sequential oxidative decarboxylation of the four acetic acid side chains of UROGEN to yield the tetracarboxylic COPROGEN. The UROGEN III isomer is most efficiently decarboxylated by the enzyme.

Most classifications of PCT separate the disorder into at least two broad categories, both associated with decreased UROGEN decarboxylase activity: (1) PCT-symptomatic, or sporadic (also referred to as acquired or type I); and (2) PCT-hereditary, or type II. In symptomatic (sporadic) PCT, the enzyme is deficient only in the liver, which could be explained either by a different gene defect restricted to the liver or by exposure to chemicals that selectively inhibit the hepatic but not the RBC enzyme (Table 149-10). Some of these substances (e.g., alcohol and estrogen) may provoke porphyria only in selected individuals, and others (e.g., hexachlorobenzene) in practically all exposed individuals.

Ethyl alcohol	2,3,7,8-Tetrachlorodibenzo-*p*-dioxin (TCDD)
Estrogenic hormones	Polychlorinated biphenyls (PCB)
Hexachlorobenzene (HCB)	Herbicides 2,4-dichloro- and trichlorophenoxyacetic acid
Chlorinated phenols	
Iron	

TABLE 149-10 **Drugs and Chemicals Associated with the Clinical Expression of Porphyria Cutanea Tarda**

In hereditary (type II) PCT, UROGEN decarboxylase is decreased approximately 50 percent in all tissues, including RBC and cultured skin fibroblasts. [14], [16] The defect is inherited in an autosomal dominant manner. Decreased enzyme concentration appears to follow a bimodal distribution, suggesting two overlapping groups of patients: a large group (>80 percent) with normal UROGEN decarboxylase concentration, and a small group (<20 percent) in whom the amount of detectable enzyme is about half normal. Some patients with type II PCT were found to have UROGEN decarboxylase activity at the lower end of the normal range. Penetrance of type II PCT is relatively low (approximately 20 percent), so that the majority of individuals with the inherited enzyme defect do not manifest the disease, suggesting that additional genetic or nongenetic factors are needed for disease expression.

On the other hand, it is important to emphasize that not every patient with a positive family history of PCT will have type II disease. Several patients have been described who had one or more relatives with type I PCT but with normal RBC UROGEN decarboxylase concentrations. [57] These patients could either have inherited some form of UROGEN decarboxylase that is immunochemically indistinguishable from the normal enzyme but which is uniquely susceptible to inhibition in the liver, or they may have a second inherited enzyme deficiency unrelated to UROGEN decarboxylase. These possibilities require further investigation. Some investigators designate this latter category of PCT as type III. [16]

It is likely that patients who were initially reported as having hereditary PCT actually had VP, an autosomal dominant disorder. PCT and VP may occur in different members of the same family, so-called dual porphyria. [51] Another form of dual porphyria in which PCT and AIP coexist has been described. [58]

The most frequently incriminated agents that contribute to the development of PCT (type I, acquired, or sporadic) are alcohol, estrogens, iron, viral infections (hepatitis C and HIV), polychlorinated hydrocarbons, particularly hexachlorobenzene (HCB) and 2,3,7,8-tetrachlorodibenzo- *p*-dioxin (TCDD), and hemodialysis in patients with renal failure. Each of these precipitating factors is discussed briefly below.

ALCOHOL Heavy alcohol intake is known to exacerbate PCT. Ethanol induces hepatic ALA synthase in patients with PCT. Erythrocyte UROGEN decarboxylase activity is diminished in healthy subjects following acute ethanol ingestion and in chronic alcoholics. Ethanol can also inhibit the activity of other enzymes in the heme pathway, including ferrochelatase and ALA dehydratase. Chronic alcoholism leads to suppression of erythropoiesis and increased absorption of dietary iron, perhaps linked to inherited mutations associated with hemochromatosis (see below). The fact that ALA synthase is increased in patients with hepatic cirrhosis without porphyria raises questions concerning the relevance of alcohol effects on ALA synthase in the clinical expression of PCT. [59]
ESTROGENS The widespread use of estrogens as contraceptive agents or as hormone supplements for postmenopausal replacement therapy in females and as adjunctive hormonal therapy in males with prostatic carcinoma is associated with PCT. The mechanism of the estrogen effect on the expression of PCT is not established.

Diethylstilbestrol, an estrogen, induces hepatic ALA synthase, but this would not explain the distinctive porphyrin excretion pattern found in PCT. The vast majority of patients receiving estrogens do not manifest the biochemical abnormalities associated with PCT.

HEXACHLOROBENZENE This fungicide caused an “epidemic” of a PCT-like syndrome in southeastern Turkey in the 1950s. [60] It was added as a preservative to wheat intended for planting, but, because of a famine, several thousand individuals of diverse ethnic origin, mostly children, ingested the seed wheat and subsequently developed typical PCT. More than 4000 cases of this syndrome were reported from 1956 to 1961. The porphyrin excretion pattern and the cutaneous findings in these patients were similar to those seen in PCT evoked by ethanol or estrogens. The outbreak of PCT in Turkey caused by ingestion of hexachlorobenzene (HCB) indicated that the disease could occur in nongenetically predisposed individuals. Twenty-five years after onset, the most common clinical findings in these HCB-poisoned individuals were those of chronic porphyria, including sclerodermoid scarring (84 percent), hyperpigmentation (78 percent), hirsutism (49 percent), thyromegaly, and increased skin fragility (38 percent). [61] A painless arthritis was seen in two of three affected individuals, and a variety of neurologic signs and symptoms were seen in the majority. Stool and urine porphyrins remained elevated in many patients. Studies show that the chronic administration of HCB to experimental animals produces excessive porphyrin accumulation in the liver in a pattern quite similar to that seen in PCT in humans. These data are consistent with the hypothesis that chlorinated hydrocarbons, such as HCB, or their metabolites inhibit hepatic UROGEN decarboxylase, leading to excessive hepatic storage of URO and other acetate substituted porphyrins. Experimental studies also show that HCB can inactivate UROGEN decarboxylase by abolishing catalytic activity without changing the amount of immunoreactive enzyme protein. [62] Chemical porphyria, similar to PCT, is caused by other chlorinated hydrocarbons such as the polychlorinated biphenyls (PCBs) and TCDD, a by-product in the synthesis of the herbicide 2,4,5-trichlorophenoxyacetic acid. Additional studies on the porphyrinogenic effects of HCB, dioxin, and PCBs suggest that metabolic activation of the compounds mediated by cytochrome P450 1A2 and involving iron-mediated ROS is associated with an attack on the catalytic site of UROGEN decarboxylase. [14], [63]

2,3,7,8-TETRACHLORODIBENZO- *p*-DIOXIN TCDD is a toxic environmental pollutant chemical. Among its numerous effects are chloracne, liver damage, and hepatic porphyria in experimental animals, and perhaps also in humans. The hepatic porphyrinogenic effect of TCDD can be abolished in mice by first depleting them of iron. Furthermore, it is known that highly inbred mouse strains vary in their susceptibility to induction of hepatic porphyria by TCDD, indicating that the porphyrogenic effect of this hydrocarbon is modulated by as yet undefined genetic factors.

IRON Serum iron and ferritin concentrations are elevated or in the upper range of normal in PCT, confirming the important role of iron in the pathogenesis of the disease. [64] Hepatic iron overload accompanies clinical PCT in practically all cases, and elevation of plasma iron is found in one-third to one-half of patients. In PCT, the quantity of iron that can be mobilized by phlebotomy indicates that total iron stores are approximately twice normal. Ferrokinetic studies in patients with PCT are said to be normal. The long remissions that follow repeated phlebotomy and the apparent ineffectiveness of this treatment if supplemental iron is administered concomitantly suggest that iron plays a role in the excessive hepatic porphyrin production of PCT. PCT is particularly common where alcoholism and iron overload occur together. The role of iron in the pathogenesis of PCT is complex, and several hypotheses have been proposed to explain it. Iron may directly inhibit UROGEN decarboxylase. However, studies with purified UROGEN decarboxylase prepared from human erythrocytes show that the purified enzyme is not inhibited by Fe^{2+} or Fe^{3+}. [65] Chronic iron overload can produce peroxidative damage to lipid-rich mitochondrial and microsomal membranes in the liver of experimental animals, but the relationship of this toxic effect to changes in hepatic heme synthesis has not been clearly defined. An increased frequency of the hemochromatosis C282Y mutation in a gene encoding for the HLA class I–like protein HFE has been found in British patients with sporadic PCT. [66] This mutation is responsible for much of the iron overload in populations of European descent. A second mutation in the HFE gene *H63D* may also be associated with PCT in some populations. [67] PCT is rare in heterozygotes for each of these mutations, but 20 percent of British patients with PCT are *C282Y* homozygotes. *C282Y* homozygosity is an important susceptibility factor for both type I and type II PCT. [13] Iron may have a permissive effect on the inhibition by halogenated hydrocarbons of UROGEN decarboxylase, and it can also enhance the induction response of hepatic ALA synthase to drugs. Although such an iron-augmented increase in ALA synthase activity could lead to enhanced porphyrinogenesis, this alone would not explain the porphyrin excretion pattern seen in PCT. Addition of ferrous iron to liver in vitro causes a marked increase in porphyrin synthesis and inhibits UROGEN III synthase activity providing an explanation for the URO isomer I excess characteristic of PCT. More recently, a mouse model of type II PCT was developed in which one allele of UROGEN decarboxylase is disrupted and these animals are then bred to mice homozygous for HFE disruption. [68] These animals develop a PCT-like phenotype.

VIRAL INFECTIONS There is an association between PCT and hepatitis C virus (HCV) infections and combined HCV and HIV infections. [69] The role of these viral infections in the pathogenesis of PCT is unclear, although some connection with the hemochromatosis mutation *H63D* has been suggested. [14] It is possible that the connection is fortuitous and secondary to nonspecific hepatotoxic effects of these viruses. From these known effects of alcohol, estrogens, chlorinated hydrocarbons, iron, and viral infections on the heme pathway, it is clear that each of these could contribute to the excessive hepatic porphyrinogenesis characteristic of PCT. There is growing evidence that hepatic siderosis is the critical pathologic event in PCT and that the other agents somehow intensify the ability of iron to attack the catalytic site of UROGEN decarboxylase. The clinical expression of PCT is therefore dependent upon the interaction of a number of factors, both genetic and environmental. However, it is important to note that the ingestion of drugs associated with inducing attacks of the acute hepatic porphyrias (see Table 149-8) has not been reported to exacerbate PCT.

Epidemiology

PCT occurs throughout the world, and it is the most common of all the porphyrias. The disease most often begins in middle-aged individuals but can develop earlier. Prior to the widespread use of oral contraceptives, PCT developed predominantly in males and most now believe that the sex incidence is approximately equal. The rising incidence of PCT in females is probably a result of the widespread ingestion of estrogens in oral contraceptives or in hormone supplements. It should be noted that males treated with estrogens, for example, as adjunctive therapy for carcinoma of the prostate, have also developed PCT.

Clinical Manifestations

Vesicles and bullae followed by erosions and crusting occur predominantly in areas subject to repeated trauma (see Fig. 149-8). There is increased skin fragility, usually on the dorsa of the hands, but occasionally on the feet as well (Fig. 149-8D). The traumatized skin becomes crusted and, as the lesions resolve, areas of scarring may ensue. Numerous small milia can develop, particularly on the fingers and hands. These are pearly white to yellow, spherical subepidermal inclusions 1 to 5 mm in diameter and, characteristically, they are present in each of the hepatic porphyrias with cutaneous photosensitivity (PCT and VP) (Fig. 149-8C, Fig. 149-10, and Fig. 149-11). Although the cutaneous lesions are primarily seen on the light-exposed areas, patients are often unaware that sunlight plays a role in producing their lesions because the acute photosensitivity, so characteristic of the erythropoietic porphyrias, is rare in PCT. However, most patients do recognize that their skin condition worsens in the spring and summer and seems to improve in the fall and winter. Porphyrin excretion in PCT appears to increase in summer months and decrease in winter months.

FIGURE 149-10 A case of porphyria cutanea tarda showing bullae filled with clear fluid. Elsewhere are remnants of blisters, and on the second metacarpophalangeal joint are small milia.

FIGURE 149-11 Periorbital and malar violaceous coloration, hyperpigmentation, and hypertrichosis. Bullae, crusts, and scars are seen on the dorsa of the hands.

Other skin changes seen in PCT include hyperpigmentation and hypopigmentation that may be mottled, resembling chloasma. There may be an associated purplish red (“heliotrope”) suffusion of the central part of the face, particularly involving the periorbital areas, which may bear a striking resemblance to the plethora seen in polycythemia rubra vera (Fig. 149-12). This is not seen in the porphyrias of bone marrow origin.

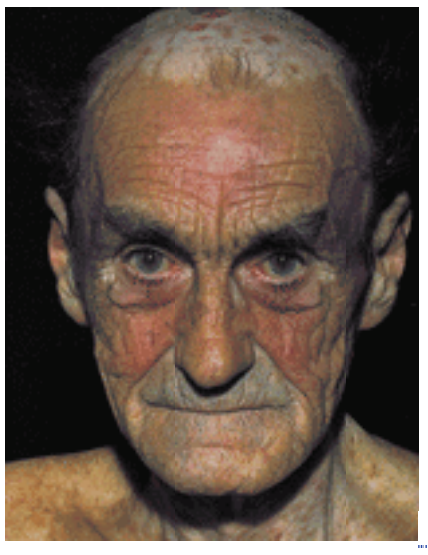

FIGURE 149-12 Porphyria cutanea tarda. Purple-red suffusion (“heliotrope”) of central facial skin is most pronounced in the periorbital and frontal areas.

Hypertrichosis (nonvirilizing) is a useful diagnostic sign that often brings the female patient to the dermatologist (Fig. 149-13). Facial hypertrichosis develops gradually and is more apparent in females. The hair may vary in texture between fine and coarse, and in color between light and dark. These hairs are particularly prominent along the temples and the cheeks but may occasionally involve the trunk and extremities in severe cases. Such hair may continue to grow, darken, and thicken, particularly on the cheeks, the forehead between the eyes, and at the hairline of the scalp. Males may complain that shaving is more difficult and that the growth pattern of their beard has changed. Hypertrichosis may be the presenting symptom in women, and a particularly severe form of hypertrichosis may occur in some children with PCT. In the reports of HCB poisoning in Turkey, some of the children were described as “monkey-like” because of marked hypertrichosis. [70] The mechanism of this phenomenon is unknown; androgen levels are reported to be normal. It is possible that surface receptors or growth factors for hair bulb keratinocytes are activated by the dual action of light and

porphyrins. The hypertrichosis of PCT usually improves slowly following appropriate treatment.

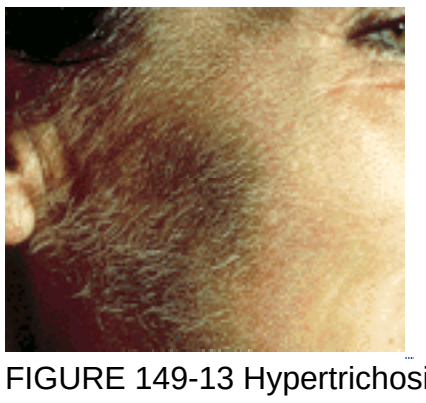

FIGURE 149-13 Hypertrichosis in a female with PCT; mostly pronounced on the zygomatic and malar skin.

Sclerodermoid plaques can occur in PCT and in HEP. These typically develop on both light-exposed and light-protected body areas (Fig. 149-14 and Fig. 149-15). These are usually scattered, waxy yellow to white, indurated plaques that closely resemble, both clinically and histopathologically, morphea or scleroderma. There is some evidence to indicate that PCT may occur concomitantly with true scleroderma, but this seems to be quite rare. As discussed earlier, URO I stimulates collagen synthesis in human skin fibroblasts. [33] In some patients, calcification has developed in these sclerodermoid plaques, necessitating excision and grafting.

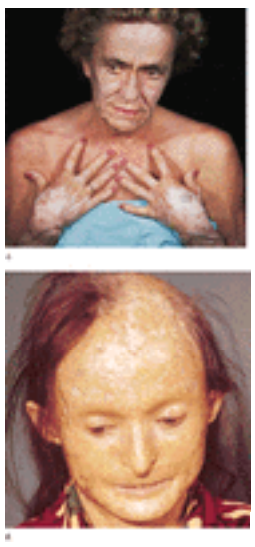

FIGURE 149-14 *A*. Porphyria cutanea tarda. The patient exhibits marked photoaging changes on the face and depigmented scars on the dorsa of the hands. *B*. Sclerodermoid thickening, shrinkage of facial and scalp skin with ulcerations and scars in a patient with hepatoerythropoietic porphyria where these sclerodermoid changes are particularly pronounced.

FIGURE 149-15 Porphyria cutanea tarda. Shiny sclerodermoid plaques on the chest.

PCT–like syndromes are occasionally seen in association with hepatic tumors and lupus erythematosus. Subepidermal bullous dermatoses mimicking PCT clinically and histologically have been described (see “ Pseudoporphyria” below). A number of cases of true PCT have occurred in patients with renal failure undergoing hemodialysis. Confirmation of the diagnosis rests on detection of markedly elevated plasma porphyrins (usually 5- to 100-fold) and increased ISOCOPRO in the feces.

PSEUDOPORPHYRIA (BULLOUS PHOTOSENSITIVITY)

Pseudoporphyria describes patients who clinically exhibit cutaneous manifestations of PCT without the characteristic abnormal porphyrin profile. This disorder may develop in association with ingestion of certain drugs such as furosemide, nalidixic acid, tetracycline, naproxen, pyridoxine, and isotretinoin. In the drug-induced type of pseudoporphyria, the

blistering process is subepidermal with little or no dermal inflammation. Staining with periodic acid–Schiff (PAS) reveals little or no deposition around upper dermal blood vessels and capillary walls. Indirect immunofluorescence studies conducted on split skin reveal no dermal deposition of fluorescent material in pseudoporphyria. Direct immunofluorescence studies have shown patchy granular deposition of IgG and C3 at the basement membrane zone in pseudoporphyria, PCT, and in epidermolysis bullosa acquisita (EBA).

A bullous dermatosis that is morphologically and histologically indistinguishable from PCT has also been observed in patients with chronic renal failure receiving maintenance hemodialysis. Such patients have moderately elevated plasma porphyrins (two- to fourfold) secondary to impaired renal clearance as well as diminished clearance through dialysis filters.

Laboratory Findings

Virtually all patients with PCT have excessive total body iron stores manifested as increased serum iron, ferritin, and/or hepatocellular iron. Occasionally, there is mild erythrocytosis. An abnormal glucose tolerance test occurs in a minority of patients.

Patients with PCT excrete increased amounts of porphyrins in the urine, which rarely may exhibit characteristic pink-red fluorescence when examined with a Wood's lamp. The porphyrin excretion pattern of PCT has three main features: (1) increased urinary excretion of URO and of other acetate-substituted porphyrins; (2) a distinctive pattern of excretion of isomer series I and III porphyrins; and (3) increased excretion of fecal ISOCOPRO. [14] PCT patients excrete greatly increased amounts of urinary 8-carboxyl URO as well as porphyrins with 7-, 6-, and 5-carboxyl groups; 4-carboxyl porphyrin (COPRO) is also increased but to a lesser extent than URO, and rarely surpasses 600 µg/24 h (see Table 149-3). In PCT, the hepatic UROGEN decarboxylase deficiency results in the accumulation of 5-carboxylporphyrinogen III (Fig. 149-1 and Fig. 149-2). This can be used as a substrate by the enzyme COPROGEN oxidase and it forms dehydroisocoproporphyrinogen, which, in turn, is oxidized to ISOCOPRO, resulting in the characteristic elevation of this compound in the feces of these patients.

The 8-carboxyl URO and 7-carboxyl porphyrins are the predominant urinary porphyrins in PCT (>90 percent of total porphyrins). The urinary porphyrin excretion pattern is a mixture of type I and type III isomers. URO is approximately 60 percent type I isomer and 40 percent type III; the 7- and 6-carboxyl porphyrins are >90 percent type III and <10 percent type I isomer; the 5- and 4-carboxyl porphyrins are approximately 50 percent each isomer. This distinctive isomer pattern is found consistently in patients with PCT.

In general, only trace amounts of URO are present in the stools of normal individuals. The porphyrin content of stool is increased in PCT and consists primarily of ISOCOPRO (type III), 7-carboxyl porphyrin, and lesser amounts of URO and COPRO. The total daily 24-h fecal porphyrin excretion may exceed total urinary porphyrin excretion.

The ratio of URO to COPRO in the urine is often helpful in differentiating PCT and VP. Thus, in PCT, the URO/COPRO ratio is usually >3:˜1, whereas in VP the ratio is usually <1:˜1. Occasionally, 24-h urine porphyrins will be normal or only slightly increased in a patient with the cutaneous findings of PCT. This should alert the physician to evaluate stool porphyrins as these are elevated in patients with VP (see “ Variegate Porphyria” above).

The constellation of clinical and laboratory findings often suffices to make the tentative diagnosis of PCT. Suspected PCT can frequently be confirmed by acidifying a random urine sample with a few drops of 10% hydrochloric acid or acetic acid and looking for orange-red fluorescence.

It should be emphasized that patients with clinical signs of PCT may have a negative urine fluorescent screening test for porphyrins. In such patients, it is absolutely essential to obtain plasma porphyrin levels and perform quantitative 24-h urine URO and COPRO determinations and stool PROTO and COPRO determinations, preferably by using high-performance liquid chromatography, which often permit differentiation of PCT from VP. However, some patients with VP will have normal fecal porphyrin excretion, and bile porphyrin measurements may be helpful in evaluating such patients.

Biochemical tests for liver function may be performed to identify liver disease. Elevated serum transaminases and ?-glutamyltranspeptidase levels may occur. Serum iron and ferritin concentrations may be elevated. The measurement of erythrocyte UROGEN decarboxylase is useful for detection of patients with type II PCT. Mutational analysis is an essential part of evaluating these patients (see below).

Histopathology

The characteristic histopathologic finding in PCT is a subepidermal blister (Fig. 149-16). Bullae characteristically show a corrugated, undulating base that has been termed festooned. [71] There is little or no inflammatory infiltrate. Periodic acid–Schiff stain reveals a mild degree of thickening of the papillary vessel wall, not nearly so marked as that seen in patients with EPP. Reticulin staining demonstrates slight proliferation of fibers along the basement membrane. Direct immunofluorescence studies reveal deposition of C3 and IgG in a granular pattern at the dermal–epidermal junction and in and around vessel walls in affected individuals. These changes are most apparent in sun-exposed areas of patients with active disease and high urinary porphyrin excretion, and they decrease substantially in patients after appropriate treatment. It is also possible that the deposition of immunoglobulins and complement is a nonspecific result of injury to the cutaneous tissue. The locus of damage to the upper dermal vessels and the dermal–epidermal junction suggests that damage to these areas evoked by porphyrin photosensitivity may be responsible for the unique skin fragility seen in PCT. Increased porphyrin concentrations are found in the skin of patients with PCT. With rare exception, blisters have not been induced by phototesting; however, erythema and delayed edema have been induced in the skin of patients with

PCT. [72]

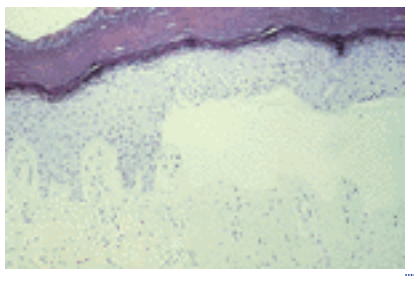

FIGURE 149-16 Porphyria cutanea tarda: subepidermal blistering in a late lesion. There is virtually no inflammatory response, but the form of the dermal papillae is partially preserved.

Differential Diagnosis

Other dermatoses that can be confused with PCT include VP, HEP, HCP, pseudoporphyria, scleroderma, and epidermolysis bullosa acquisita. Each of these can be differentiated on histopathologic grounds, by immunofluorescence tests, or by appropriate porphyrin studies. Careful evaluation of urine, stool, plasma, or bile porphyrins will almost always permit confirmation of the diagnosis of PCT. It should be emphasized that patients with PCT are not prone to the acute life-threatening attacks characteristic of the acute hepatic porphyrias. A very limited number of drugs and chemicals, particularly alcohol, estrogens, and selected halogenated hydrocarbons, seem capable of eliciting the disease in susceptible individuals (Table 149-10). Drugs such as barbiturates, which are contraindicated in AIP, have been administered to PCT patients without untoward effect. Nonsteroidal anti-inflammatory drugs such as naproxen, antibiotics such as the tetracyclines and nalidixic acid, and a variety of other agents may rarely produce clinical signs of a bullous photosensitivity closely resembling PCT (see " Pseudoporphyria" above). VP has skin lesions identical to PCT. However, in VP, stool PROTO and COPRO excretion is usually increased (PROTO>COPRO), and urinary porphyrin levels are only moderately increased (COPRO>URO). In PCT, stool ISOCOPRO is elevated, and total urinary porphyrin (URO>COPRO) is much higher than that observed in VP.

Treatment

Initially, a careful history should be taken in an effort to identify an environmental toxin (e.g., alcohol, estrogen, or chlorinated hydrocarbon) that may have triggered the disease. If HCV or HIV infection is present, these should be managed appropriately. Elimination of toxin exposure alone may result in gradual improvement. However, in most patients with PCT, more aggressive treatment is usually appropriate to accelerate therapeutic benefit and this currently consists of either repeated phlebotomy [14] or orally administered antimalarials, either chloroquine or hydroxychloroquine, or a combination of both. Other forms of treatment that have been described include administration of iron chelators [73] and the oral administration of cholestyramine. [74]

PHLEBOTOMY Phlebotomy is the treatment of choice for PCT. Numerous reports emphasize the safety and efficacy of this form of therapy, [75] which was introduced by Ippen in 1961. Phlebotomy is effective because it depletes the excessive hepatic iron stores characteristic of PCT. Biochemical remission of PCT has occurred in patients treated with phlebotomy who had iron overload, as well as in patients with quantitatively normal iron stores. Replenishment of iron following phlebotomy-induced remission of PCT has resulted in biochemical and clinical exacerbation of the disease. Abstinence from the porphyrinogenic agent alone, especially alcohol, may induce a clinical and biochemical remission, although this may take months to years. [75] The efficacy of phlebotomy may relate to several effects:

1. Iron effect on ALA synthase. Iron can enhance the induction response of ALA synthase to drugs and the hepatic porphyrinogenic response to HCB in experimental animals, and its depletion could render ALA synthase less inducible and thereby diminish hepatic porphyrinogenesis.
2. Iron depletion effects on other heme pathway enzymes. Ferrous iron inhibits UROGEN decarboxylase and increases the rate of hepatic porphyrin synthesis from ALA or PBG, suggesting that removal of iron can allow UROGEN decarboxylase activity to return to normal and/or reduce excessive porphyrinogenesis. This concept has been verified by the creation of genetically engineered mice in which iron overload inhibits the enzyme.
3. Iron effects on hepatic lipid peroxidation secondary to ROS. Iron depletion could reverse this response of the liver to iron overload.
4. Iron effects on oxidation of URO. Removal of iron could result in a diminished capacity of the ferrous metal to irreversibly oxidize the UROGEN substrate to nonmetabolizable porphyrins.

Phlebotomy is carried out as an ambulatory procedure. The total amount of blood removed varies widely, usually ranging from 1500 to 12,000 mL. It is most convenient to use plastic blood-drawing bags available in any blood bank. Approximately 500 mL of blood is removed at weekly or biweekly intervals until the hemoglobin decreases to approximately 10 g/dL or until the serum iron drops to 50 to 60 µg/dL. Some authors believe that phlebotomies should be continued until serum ferritin falls to the lower range of normal. Patients are strongly encouraged to discontinue or decrease exposure to porphyrinogenic agents because this usually hastens clinical and biochemical remission. It is particularly important to reassure the patient that clinical improvement may not become apparent for variable intervals after beginning the phlebotomies. Porphyrin excretion continues to fall long after phlebotomies are discontinued. It has been shown that in more than 90 percent of patients treated with regular phlebotomy, urinary URO excretion reaches normal levels (<100 µg/24 h) after 5 to 12 months. [75] Blistering is the first sign to disappear, followed by improvement in skin fragility and in hypertrichosis over a period of 3 to 18 months. Even sclerodermoid changes can resolve slowly, although this may take several years. There is little or no published information on long-term follow-up of treatment, but most relapsed patients have again responded to repeated courses of phlebotomies. The length of remission induced by

phlebotomy varies widely and ranges from 6 months to more than 10 years. At least 10 to 20 percent of patients will relapse within 1 year. Phlebotomy is a safe, effective, and relatively simple form of therapy with minimum associated morbidity. A few patients may complain of mild to moderate fatigue and weakness during the treatment period, but this usually resolves as the hemoglobin returns to normal. Phlebotomy remains the treatment of choice for uncomplicated PCT.

ANTIMALARIALS In some patients, phlebotomy is not recommended or is contraindicated owing to the presence of anemia or cardiopulmonary disorders or HIV infection. In such cases low-dose antimalarial therapy may be useful. The antimalarial aminoquinolines chloroquine (Aralen) and hydroxychloroquine (Plaquenil) have been recommended for treating PCT. In 1957, it was first suggested that chloroquine was useful in treating PCT. [76] The cutaneous signs of the disease cleared within 1 year in one patient who received 500 mg daily for several months. However, such doses will trigger severe hepatotoxicity in many PCT patients and this is no longer an acceptable approach. Experience with low doses shows that this is an effective approach. The clinical and biochemical remission of PCT obtained with chloroquine appears to be identical in all respects to that evoked by phlebotomy. However, it has been reported that rapid relapse occurred in several patients treated with hydroxychloroquine. There is a marked increase in urinary URO excretion in patients receiving higher doses of the antimalarial. The effect of chloroquine may relate to formation of water-soluble drug-porphyrin complexes that are then excreted from the liver. It is possible that chloroquine chelates iron in the hepatocyte and that the bound iron is then eliminated. [77] Use of low-dose (125 mg twice weekly) chloroquine therapy in PCT obviates the drug's hepatotoxic effect. [78] Remission of the disease was obtained in a single patient who received 50 mg of chloroquine twice weekly for 7 months. Additional studies confirmed good results in seven of eight PCT patients treated with chloroquine sulfate (330 mg base) twice weekly for several months. [77] Low-dose chloroquine (125 mg twice weekly for 8 to 18 months) was employed successfully in more than 100 patients with PCT. [79] Liver function tests and urinary porphyrins are monitored quarterly, and the medication continued until urinary URO is <100 µg/24 h. This usually requires 6 to 12 months of treatment. Studies comparing the therapeutic efficacy of phlebotomy with that of low-dose chloroquine suggest that they are equally efficacious. The combination of phlebotomy and chloroquine treatment may reduce the severity of the hepatotoxic response to chloroquine and also accelerate remission of the disease. Patients are treated with a series of one to four phlebotomies prior to starting chloroquine (250 mg daily for 7 days). The procedure is repeated when signs of biochemical or clinical relapse develop, which may occur in 1 to 2 years. It should be emphasized that despite the tendency of the antimalarials to evoke hepatotoxic responses in patients with PCT, there is no evidence to suggest that the changes in hepatocellular pathology characteristic of PCT worsen as a result of treatment with these drugs. The antimalarials may cause retinopathy, and the low-dose regimen helps to minimize the risk of this complication. Pretreatment and semiannual ophthalmologic examinations should be obtained on patients treated with these drugs. In patients with PCT and chronic renal failure, standard phlebotomy and antimalarial therapy are not feasible. The combination of high-dose recombinant erythropoietin and small-volume phlebotomy has been successful in selected patients. [80]

ERYTHROPOIETIC PROTOPORPHYRIA (EPP) (See Table 149-7)

Etiology

The specific defective enzyme in EPP is ferrochelatase, which is decreased in RBCs, mitogen-stimulated lymphocytes, and cultured skin fibroblasts of patients and unaffected carriers. [81] Because the activity of ferrochelatase in cultured skin fibroblasts of EPP patients is only 10 to 25 percent of normal, questions have been raised about the dominant inheritance of the disease. In one study several families with EPP were examined with respect to the mode of inheritance and on the basis of erythrocyte ferrochelatase activity this was said to be either autosomal dominant or recessive. [81]

Epidemiology

Although the exact incidence of EPP is unknown, it has been reported with increasing frequency since 1961, indicating that it is likely the most common cutaneous porphyria except for PCT. Studies from one laboratory performing diagnostic tests for RBC porphyrins in patients with suspected cutaneous photosensitivity indicated that 8 percent of such samples demonstrate elevated RBC PROTO levels diagnostic of EPP. The disease has been reported from many countries around the world, and it is likely that no ethnic group is spared.

Clinical Manifestations

The disease begins early in life and is characterized by cutaneous photosensitivity and by elevated PROTO in RBC, feces, and plasma; there is no excess porphyrin excretion in the urine except in the setting of hepatic failure. The acute episodes of cutaneous photosensitivity include burning, stinging (smarting), and pruritus in light-exposed skin, particularly of the nose, cheeks, and dorsal aspects of the hands. These are followed by erythema, edema (Fig. 149-17), urticarial lesions, and, less commonly, purpura. Photosensitivity may occur within minutes of sun exposure; it is often seasonal, starting early in the spring, continuing through the summer, and diminishing in the winter. The skin lesions often resolve slowly, leaving small, atrophic, waxy or pitted scars (Fig. 149-18). There may be some pursing of perioral skin (pseudorhagades). The skin of the knuckles and fingers, particularly over the metacarpophalangeal and interphalangeal joints, often appears thickened, wrinkled, and waxy, suggesting a premature aging (so-called old knuckles in a child). This subtle change is pathognomonic, particularly in children. Superficial scarring on the bridge of the nose and small circular shallow scars may be seen on the face. Vesicular or bullous lesions rarely occur in EPP in temperate climates, although they have occurred in patients exposed to tropical sunlight. The porphyrin abnormality persists throughout life, although some patients seem to be less symptomatic as they get older.

FIGURE 149-17 A case of erythropoietic protoporphyria showing swelling and purpura on dorsa of hands resulting from exposure to solar radiation.

FIGURE 149-18 *A*. One hour after exposure to sunlight, the face of this 35-year-old female is edematous, erythematous, and there is purpura on the forehead, cheeks, and nose. The patient experiences severe burning sensations. *B*. *A* 15-year-old patient with erythropoietic protoporphyria with severe sensitivity to sunlight. The nose, lower lip, and chin show erythematous, in part erosive, and crusted lesions. Nose and cheeks show erythematous lesions, a few small slightly depressed scars, and peculiar waxy thickening of skin. Linear scars are seen between the nose and mouth.

Controversy exists concerning the tissue origin of the excessive PROTO. Some authors have shown that RBC PROTO levels alone are sufficient to explain the increased levels of PROTO, [82] whereas others have suggested that hepatic PROTO production contributes to the excessively high levels of circulating PROTO. [83]

Associated findings are few in most patients with EPP. There is no erythrodontia, hypertrichosis, milia, sclerodermoid change, or hyperpigmentation. Hemolytic anemia is decidedly uncommon, although approximately 11 percent of patients with EPP have a mild anemia of unknown cause.

Gallstones have been reported in some patients with EPP at a relatively early age; in one series, 12 percent of patients had cholelithiasis, of whom three underwent cholecystectomy. [84]

Light microscopy of liver biopsies has revealed slight portal and periportal fibrosis and deposition of brown pigment, which may occlude bile canaliculi and ducts; it is also present in hepatocytes, in Kupffer cells, and in periportal macrophages. The pigment is birefringent on polarization microscopy. Hepatocytes may also contain cytoplasmic or mitochondrial inclusions, which at the ultrastructural level appear as needle-like crystals (Maltese crosses), probably caused by precipitated PROTO (Fig. 149-19). Biliary excretion of PROTO is coupled to secretion of phospholipid, translocated from the inner to outer canalicular membrane leaflet by the mdr2P glycoprotein. PROTO excretion from the liver requires bile acids and excessive amounts of the porphyrin inhibit its transport out of the hepatocyte.

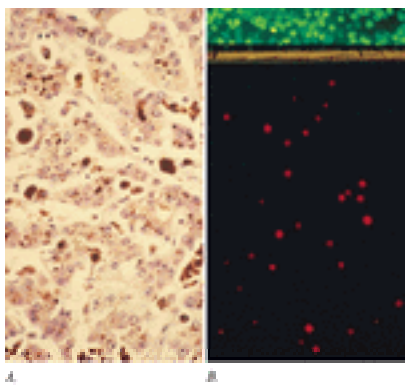

FIGURE 149-19 *A*. Brown pigment deposits in the liver tissue found in bile canaliculi, hepatocytes, and Kupffer cells. *B*. Bright-red fluorescence in red blood cells of a fresh smear of an EPP patient. Where all red blood cells contained in this smear are revealed by green fluorescence only (*top*), a few RBC contain increased amounts of protoporphyrins and thus fluorescence in red (*bottom*).

The huge increase in hepatic throughput of PROTO overwhelms the liver's excretory capacity in a small percentage of patients with EPP. This may be aggravated by hemolysis of PROTO-laden RBCs creating a vicious cycle of increased erythropoiesis and increased PROTO loading of the liver. Terminal hepatic failure has been reported in approximately 5 percent of patients. [85] All these individuals were jaundiced, had hepatic cirrhosis, and died in hepatic coma or as a consequence of portal hypertension. Some patients with end-stage liver disease may develop axonal neuropathy resembling that in the acute hepatic porphyrias despite normal serum ALA and PBG. Risk factors for EPP-associated hepatic failure remain unknown, but it is likely that the deposits of crystalline PROTO lead to hepatocyte injury. Experimental studies show that perfusion of rat liver with PROTO induces a dose-dependent cholestasis that could contribute to the hepatotoxic effect of PROTO. Liver failure has also occurred in two siblings who inherited EPP in an autosomal recessive pattern as compound heterozygotes, suggesting that this genotype may augment the risk of this complication. [86] However, this has been disputed because there are cases in which compound heterozygotes have had

normal liver function and cases in which heterozygotes developed liver failure. [87]

Laboratory Findings

The diagnosis of EPP is based on the detection of elevated free PROTO in the RBCs and/or feces (see Table 149-3 and Table 149-7). In addition, there may be increased plasma PROTO, increased fecal COPRO, and, occasionally, slightly increased RBC COPRO. In patients with deteriorating hepatic function, the fecal excretion of PROTO may decrease as plasma levels and cutaneous photosensitivity increase. Examination of a blood smear under a fluorescent microscope reveals red-fluorescing RBCs (5 to 30 percent). This fluorescence is often transient and quite light sensitive, thus the procedure should be carried out in subdued light or preferably in the dark. A rapid quantitative microfluorometric assay for free erythrocyte and plasma PROTO has been developed that is useful as a screening test for suspected EPP. Finger-prick samples of blood collected on filter paper are used for this test. In one series of 32 patients with EPP, the RBC PROTO levels ranged from 131 to 1617 µg/dL of RBC (normal <90 µg/dL of RBC). [88]

The photosensitizing activity of porphyrins is most probably related to the light absorption and emission characteristics of these tetrapyrroles that results in the generation of reactive oxygen species (see Fig. 149-5 and Fig. 149-7). Irradiation of PROTO-enriched RBCs enhances egress of the porphyrin suggesting that sun exposure may augment skin concentrations of PROTO in these patients. Unchelated (metal-free) PROTO is the photosensitizer in EPP, as evidenced by data from studies designed to explain the perplexing observation that in lead poisoning and in iron-deficiency anemia, RBC PROTO levels are similar to those found in EPP, but cutaneous photosensitivity does not occur. In these nonphotosensitizing disorders, the excessive PROTO is probably chelated with zinc and bound to globin chains in the RBC, which renders it incapable of diffusing into the plasma and then into cutaneous tissue, explaining why plasma PROTO is not elevated in these nonphotosensitizing disorders. In EPP, however, the majority of the excessive PROTO is probably unchelated or free. Free PROTO can diffuse out of the RBCs and is detectable in the plasma of patients with EPP who manifest cutaneous photosensitivity. In one study, a patient with sideroblastic anemia had marked increases in free PROTO, both in the RBCs and in the plasma, but had no cutaneous photosensitivity. [89] Because ferrochelatase activity was normal in this patient, it is possible that the excessive free PROTO was either chelated with zinc or readily converted to heme in the skin, thereby precluding cutaneous accumulation of PROTO and associated photosensitivity. It has also been suggested that the infrequency of hemolytic anemia in EPP is due to the unique capacity of PROTO to move out of the RBCs and to bind to albumin in the plasma. The porphyrin does not remain within the lipid-rich red cell membrane sufficiently long for light exposure to cause damage, and serum albumin has a potent inhibitory effect on photohemolysis in EPP.

Histopathology

Immediately following irradiation, endothelial cell damage, mast cell degranulation, and PMN cells are seen in the dermis. [29] In sun-exposed areas, there is often marked eosinophilic homogenization and thickening of vessels in the papillary dermis as a result of the accumulation of an amorphous, homogeneous, slightly basophilic (hyaline-like) substance in and around the vessel walls. The perivascular deposits of concentric eosinophilic layers of hyaline-like material stain strongly positive with PAS and are diastase positive (see Fig. 149-20). Histochemical studies suggest that this material may be a neutral glycoprotein with smaller amounts of acid mucopolysaccharide and lipids. The histologic findings are similar to those of lipoid proteinosis (hyalinosis cutis et mucosae). Electron microscopic studies in EPP show that the amorphous material consists of a multilayered partially fragmented basement membrane and finely fibrillar material of moderate density that permeates and surrounds the vessel walls. Other studies show that type IV collagen and laminin, as well as amyloid P and fibronectin, are deposited in the walls of dermal blood vessels. [90]

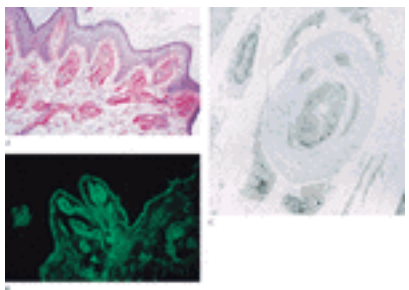

FIGURE 149-20 *A*. A biopsy of light-exposed skin from a patient with erythropoietic protoporphyria. There is marked thickening of the blood vessel walls of the upper dermis, which are surrounded by a hyaline-like material that stains brightly red with the PAS stain. *B*. Direct immunofluorescence reveals that the PAS-positive stain around papillary vessels contains immunoglobulins of classes. Immunoglobulins are also deposited along the dermal-epidermal junction. *C*. Electron micrograph of biopsy of chronically exposed skin from a patient with erythropoietic protoporphyria. Multiple concentric basal laminae surrounding dermal blood vessels and finely fibrillar material admixed with amorphous masses within perivascular tissue are shown.

Differential Diagnosis

EPP must be differentiated from other causes of photosensitivity, primarily hydroa aestivale, polymorphous light eruption (PMLE), idiopathic solar urticaria, and other types of porphyria. Contact dermatitis and angioedema should also be considered. In PMLE, the lesions are characteristically papules, plaques, and papulovesicles. A family history of photosensitivity is less common. Burning and smarting of the skin during or soon after sun exposure is unusual in PMLE, whereas it is a common occurrence in EPP. Porphyrin profile and skin biopsy with PAS staining may also be helpful in differentiating between PMLE and EPP. Idiopathic solar urticaria can be easily differentiated from EPP; it is not associated with elevated RBC or fecal PROTO. Contact dermatitis may involve non–light-exposed areas such as the skin folds and the submental areas. Patch testing with suspected allergens and negative porphyrin values help to differentiate

this condition. The lesions of angioedema may occur anywhere on the body, including the mucous membranes. Because discomfort is often disproportionate to visible lesions, EPP has been confused with psychoneurosis and malingering. This problem in differential diagnosis is readily solved by porphyrin determinations. Erythrocyte coproporphyrin (ECP), an extremely rare condition, should also be considered in the differential diagnosis. Clinically, it resembles EPP and could only be diagnosed by chromatographic study of RBC porphyrins.

Treatment

The treatment of photosensitivity in EPP has been aided by the use of the orally administered antioxidant beta-carotene. Topical sunscreens, particularly products containing titanium or zinc oxides, as well as dihydroxyacetone, that deposits in the stratum corneum forming a brown-tan pigment that absorbs in the UVA-Soret border, antimalarial drugs, cholestyramine, and vitamins E and C have all been suggested but are of unproven benefit. Beta-carotene (60 to 180 mg per day by mouth) has been found helpful in preventing or minimizing the symptoms of skin photosensitivity reactions of EPP. [27], [91] One hundred twelve of 133 patients (84 percent) claimed to triple their tolerance to sunlight after an adequate course of beta-carotene exceeding 2 months. The therapeutic effectiveness of the drug has been confirmed by several groups of investigators. These results are, however, based on limited controlled laboratory testing and on uncontrolled clinical impressions; the one controlled clinical trial failed to confirm the therapeutic effectiveness of beta-carotene although the adequacy of the dosage has been questioned. [92] To achieve optimal photoprotection, serum carotene levels should be maintained at a minimum of 600 µg/dL. In adult patients, this can usually be achieved by oral administration of two to six capsules of 30 mg each per day, which will produce serum carotene levels of 600 to 800 µg/dL after 4 to 6 weeks of therapy. Children younger than 12 years of age may receive 30 to 90 mg daily. Because maximum effectiveness may not occur until 1 to 2 months after initiating therapy, patients should receive therapy in early spring through the fall season (February to October in the northern hemisphere). The drug is remarkably well tolerated at these doses, and there are no known toxic systemic effects of beta-carotene. Occasionally, diarrhea occurs in a small number of patients. Orange or rusty discoloration of stools is common and is not an indication for discontinuing treatment. The only other side effect of note is the visible yellowing of the skin that occurs as a result of carotenoderma and this is more noticeable on the palms and soles.

The mechanism of the photoprotective effect of beta-carotene is not precisely known. Beta-carotene does not function as a sunscreen; it is capable of quenching excited singlet oxygen and of trapping free radicals formed by the interaction of light with PROTO and molecular oxygen. Another antioxidant, the amino acid cysteine, improves photosensitivity. [93] Hematin infusions may decrease the production of heme temporarily and are associated with a decrease in fecal and plasma PROTO in some patients. [82] The use of RBC exchange with autologous washed cells has also been explored for its ability to induce clinical and biochemical remission of EPP. Such therapy resulted in a marked decrease in photosensitivity associated with a decline in free erythrocyte PROTO levels. Management of the hepatic failure is particularly challenging. Orally administered bile salts have been used in an effort to diminish the enterohepatic circulation of the excessive PROTO and to enhance the capacity of the liver to clear excess PROTO. Another approach was reported using large amounts of orally administered iron in a patient with EPP who manifested incipient hepatic failure as well as elevated erythrocyte and plasma PROTO levels and concomitant iron deficiency anemia. [94] Oral iron therapy exacerbated the disease in another patient. [95] Liver transplantation has also been used successfully. [96] Future therapy could include replacement of defective ferrochelatase. [97] The feasibility of obtaining detectable levels of the enzyme in fibroblasts from EPP patients by adding the cDNA for normal ferrochelatase employing a retroviral vector has been demonstrated. [98] Gene replacement has been achieved in a mouse model of EPP in which ex vivo preselection of hematopoietic stem cells transduced with a polycistronic retrovirus expressing human ferrochelatase resulted in complete correction of skin photosensitivity. [99]

CONGENITAL ERYTHROPOIETIC PORPHYRIA (Table 149-7)

Etiology

Congenital erythropoietic porphyria (CEP) is an autosomal recessive inborn error of metabolism that results from variably deficient activity of UROGEN III synthase, the fourth enzyme in the heme synthetic pathway. This results in accumulation of hydroxymethylbilane that converts spontaneously to UROGEN I.

Epidemiology

CEP has been observed to occur in countries around the world. Fewer than 200 cases had been reported until 1992. Nearly all begin in childhood and only a few in adults. CEP also occurs in a number of mammals, including swine, cattle, and cats, and studies in these animal models have greatly aided research in this disease.

Clinical Manifestations

The disease usually presents itself in the first few months of life with moderate to severe cutaneous photosensitivity associated with pinkish red urine. [100] CEP causes the most mutilating skin lesions of any of the porphyrias. The photosensitivity is a result of the excessive URO I and COPRO I in RBCs, plasma, and skin, which may result in photolysis of porphyrin-rich cells.

The skin manifestations include skin fragility and vesicles and bullae, which may contain pink fluorescent fluid. Secondary infection, delayed healing, and scar formation may occur. This may lead to loss of acral tissue, such as the tips of the ears, the nose, and fingers (Fig. 149-21A and Fig. 149-21B), and facial mutilation. Hirsutism, with long, dark, lanugo-like hair, may occur and is particularly evident in light-exposed areas such as the face, neck, and extremities. The scalp may develop a cicatrizing alopecia. Other chronic findings include eye changes (photophobia, keratoconjunctivitis, ectropion, symblepharon, and even loss of vision) and irregular hyper- and hypopigmentation of the skin. Erythrodontia (red-stained teeth) is a common finding in both deciduous and permanent teeth and is virtually pathognomonic of CEP.

The urine also fluoresces reddish pink (Fig 149-21C).

FIGURE 149-21 Two cases of congenital erythropoietic porphyria (Günther's diease). *A,B*. Severe scarring damage of the ear and nose cartilage, hair loss, and discolored teeth. *(Courtesy of A Wiskemann, MD, and J Kimmig, MD.) C*. Burgundy red urine of a patient with congenital porphyria.

In addition, splenomegaly, porphyrin-rich gallstones, and fluorescent bone marrow normoblasts are often observed. Hemolytic anemia associated with shortened erythrocyte lifespan and hypersplenism (36 versus 120 days) is seen. Whether the hemolytic anemia is a result of “photohemolysis” of circulating porphyrin-laden erythrocytes or to an associated intracorpuscular red cell defect is unresolved.

Laboratory Findings

The primary defect in CEP involves a decreased activity of UROGEN III synthase that results in accumulation and increased excretion of predominantly type I porphyrins in the tissues. The pink to burgundy red color of the urine from excess URO I is often visible on inspection Marrow normoblasts exhibit relatively stable fluorescence and contain markedly elevated URO I, COPRO I, and PROTO. Urinary excretion of ALA and PBG is normal. COPRO I may be present in large amounts in the feces. Table 149-3 summarizes typical biochemical findings of CEP.

Histopathology

The bullous lesions of CEP are subepidermal with minimal degrees of inflammation. Thickening of collagen bundles may be seen in areas of scarring. Perivascular deposits of porphyrin can be found when the unstained sections of skin or liver are viewed with a fluorescence microscope.

Differential Diagnosis

The diagnosis of CEP can usually be made from the early onset of severe cutaneous photosensitivity associated with red fluorescent urine and erythrodontia. Distinguishing CEP from other congenital types of photodermatoses is important. Cutaneous findings in patients with xeroderma pigmentosum, epidermolysis bullosa, hydroa vacciniforme, and bullous pemphigoid may mimic those in patients with CEP, but the porphyrin profiles of the former conditions are completely normal. Patients with chronic hepatic porphyrias such as PCT and VP can be differentiated from patients with CEP by the normal PROTO content of their erythrocytes. The cutaneous manifestations of HEP may be strikingly similar to those of CEP, and measurement of the enzymes UROGEN III cosynthase (decreased in CEP) and UROGEN decarboxylase (decreased in HEP) distinguishes one from the other. The dual occurrence of HCP and CEP in a single patient who inherited the HCP trait from her mother and the CEP trait from both of her parents has been reported. [101]

Treatment

The treatment of CEP is essentially preventive and symptomatic and includes avoidance of sun exposure, surveillance of the anemia, and treatment of recurrent skin infections. Protection from sunlight is absolutely essential and this alone may be of substantial benefit. Patients should be instructed to wear broad-brimmed hats and other photoprotective clothing. Topical sunscreens are relatively little used as the only ones effective at wavelengths greater than 400 nm are light opaque [sun protection factor (SPF) >30] and contain zinc oxide or titanium dioxide. Newer formulations with improved cosmetic properties may be helpful. The efficacy of oral administration of beta-carotene (120 to 180 mg daily) in CEP is not proven. Splenectomy because of intractable hemolytic anemia has occasionally resulted in marked improvement both in the anemia and in cutaneous photosensitivity. Suppression of erythropoiesis by transfusion of packed erythrocytes causes a marked decrease in porphyrin production and excretion; however, iron overload is a drawback. Oral treatment of a single patient with activated charcoal (60 g three times a day) for 9 months was found to lower the porphyrin levels in plasma and skin and there was complete remission of photosensitivity during the treatment period. [102] Charcoal is thought to interfere with the enterohepatic recirculation of the porphyrin and thereby enhance porphyrin clearance from the body. However, this beneficial effect has been disputed. [103] Allogeneic bone marrow transplantation has been curative for a small number of patients. [104]

HEPATOERYTHROPOIETIC PORPHYRIA (HEP) (Table 149-7)

Etiology

HEP is caused by homozygous deficiency of UROGEN decarboxylase; in some cases, this is the result of inheritance of a mutant allele from each parent (compound heterozygote), while in other cases, it is the result of being a homozygous form of type II PCT. The primary enzyme defect is a profound deficiency of UROGEN decarboxylase activity. [12] Measurement of the enzyme in hemolyzed whole blood or skin fibroblasts from three unrelated patients with the disease showed that it was 7 to 8 percent of normal levels. The father of one HEP patient was heterozygous for the same enzyme defect, suggesting that patients with HEP are homozygous for the gene that causes PCT. There is no evidence, as yet, that clinical expression of HEP is related to exposure to environmental drugs or chemicals, as is true for PCT. In one family clinical, biochemical, and enzymatic studies of three generations, in which a second-generation 31-year-old male

was shown to have HEP, revealed that both of the proband's parents and each of his three children had a moderate deficiency of UROGEN decarboxylase. [105]

Epidemiology

Patients with HEP have been reported in Europe and America.

Clinical Manifestations

This disease is usually manifest in early childhood, with dark urine being the most frequently observed sign. Severe cutaneous photosensitivity includes blistering and pruritus. The photosensitivity seems to diminish with age and is followed by hypertrichosis, hyperpigmentation, and scleroderma-like scarring similar to that seen in Günther's disease. Ocular manifestations include ectropion associated with cutaneous sclerosis and scleromalacia perforans. Splenomegaly has occurred in a small percentage of affected individuals, particularly after the age of 10 years, and hemolytic anemia has been documented as well. In some patients, liver function tests have been abnormal, but serum iron and iron binding are normal. In summary, the clinical manifestations of HEP resemble a combination of EP and PCT.

Laboratory Findings

Elevated urinary URO (I and III) and 7-carboxyl porphyrins (>90 percent III), elevated fecal COPRO and ISOCOPRO, and elevated RBC PROTO (zinc-chelated) have been observed in all patients. These findings suggest that there is abnormal porphyrin synthesis in both the liver and the bone marrow. In contrast to PCT patients, serum iron concentrations are usually normal in HEP.

Histopathology

Skin biopsies have shown subepidermal bullae resembling those occurring in PCT. PAS-positive material is seen in and around dermal capillaries.

Differential Diagnosis

The differential diagnosis is that of childhood porphyria and includes CEP, PCT, and EPP. CEP manifests erythrodontia and mutilating scarring, whereas EPP often presents with acute photosensitivity. Unlike CEP, in which increased RBC URO is a characteristic finding, in HEP there is elevated RBC PROTO of the zinc-chelated type. The urinary porphyrin pattern is similar to that found in PCT, with high URO (URO/COPRO ratio >5:˜1). The elevated PROTO in RBC helps to distinguish HEP from PCT. Urinary porphyrin analysis can differentiate HEP and EPP because urinary porphyrins are normal in EPP.

Treatment

There is no known treatment aside from careful photoprotection.

ABNORMAL PORPHYRIN PROFILE AND SIDEROBLASTIC ANEMIA

Some cases of sideroblastic anemia may be associated with an abnormal porphyrin profile. [106] These patients may have photosensitivity closely resembling that of EPP and they subsequently develop sideroblastic anemia; in some patients, the two conditions may develop within a few months of each other. All patients have elevated PROTO in RBC and/or plasma; many also have elevated stool PROTO levels. Urinary COPRO and URO are also elevated. The activities of ferrochelatase and, less frequently, of ALA synthase may be decreased. Chromosomal abnormalities, which include deletions in chromosomes 18 and 20, have been described.

MOLECULAR GENETIC RESEARCH STRATEGIES FOR THE PORPHYRIAS

In the various types of porphyrias, discrepancies between clinical findings and the results of biochemical tests or enzyme essays often lead to doubtful or incorrect diagnoses. In the case of the acute porphyrias, this can have fatal consequences for the patient if an accurate diagnosis is not established in a timely manner.

ANIMAL MODELS AND FUTURE OPTIONS FOR GENE THERAPY

Recently, animal models for EPP and PCT were described. [68], [99], [107] These models afford unique opportunities to explore the pathogenesis of these types of porphyria using in vivo models, and to study the feasibility of achieving phenotypic reversion by gene therapy. Retrovirus-mediated gene transfer of human ferrochelatase cDNA into deficient fibroblasts from an EPP patient has been achieved. [98] In transduced cells, ferrochelatase catalytic activity increased from 7 to 550 percent of the normal value, and partial metabolic correction of the phenotype was demonstrated. In CEP, correction of the underlying enzymatic defect in cultured cells was also accomplished by retrovirus-mediated gene transfer leading to partial normalization. [108] Excessive porphyrin levels in the transduced cells were reduced to normal These investigations demonstrate the potential utility of somatic stem cell gene therapy for the treatment of different types of porphyrias.

FUTURE PROSPECTS

The various human porphyrias often present with overlapping clinical and laboratory findings making precise diagnosis a challenging proposition, especially in the acute porphyrias. The clinical signs and symptoms are highly variable in

different patients and even in the same patient at different times. Biochemical analyses of urinary and/or fecal porphyrins/precursors often display overlapping values. These methods, as well as the measurement of enzymatic activities in fibroblasts or lymphocytes, are somewhat imprecise, and it is not uncommon to find values that do not distinguish between clinically unaffected gene carriers (so-called “silent” carriers), and normal controls. The identification of “silent” carriers within families suffering from the acute porphyrias is the first and foremost step toward the prevention of life-threatening acute attacks. Once a DNA-based diagnosis is made, patients and their families can be provided with genetic counseling and with advice regarding the avoidance of precipitating factors (Fig. 149-22). In case of a life-threatening acute attack, a prior genetic diagnosis permits the attending physician to begin appropriate treatment immediately. [44]

XANTHOMATA, HYPERLIPIDEMIA, AND DYSLIPOPROTEINEMIAS

Lipoproteins are small spherical particles that transport lipids in the circulation. The major lipids carried in lipoproteins include cholesterol, triglycerides, and phospholipids. An elevation of serum lipid levels is called *hyperlipidemia,* or *hyperlipoproteinemia,* whereas *dyslipoproteinemia* signifies abnormalities in serum lipoproteins, whether or not serum lipid levels are elevated. Several disorders of lipoprotein metabolism promote coronary atherosclerosis, the precursor of coronary heart disease (CHD). The infiltration and deposition of lipoproteins into tissues, however, is not limited to the arterial tree. Lipoproteins can enter the skin, subcutaneous tissues, and tendons, and lipids can accumulate to produce xanthomata. Different species of lipoproteins typically produce different types of xanthomata, and the pattern of xanthomata provides important clues to the type of hyperlipoproteinemia (or dyslipoproteinemia) present.

Clinical Findings

Xanthomata, although caused by many individual metabolic and physiologic defects that are described in this chapter, present in four major forms: tendinous, planar, tuberous, and eruptive. There are characteristic clinical phenotypes associated with specific metabolic defects. The older clinical and pathologic literature has been thoughtfully reviewed by Parker. [1]

Tendinous xanthomata are firm subcutaneous nodules found in fascia, ligaments, the extensor tendons of the hands, knees, and elbows, and the Achilles tendons. Planar xanthomata are yellow macules, soft papules, or plaques. These lesions are found commonly on the upper eyelids (xanthelasma palpebrarum) and frequently on the palms. Tuberous xanthomata are yellow to reddish nodules that are frequently localized to the extensor surfaces of the elbows, knees, knuckles, and buttocks. Eruptive xanthomata are suddenly appearing, multiple, reddish yellow papules that are arranged in crops on the extensor surface of the extremities and the buttocks. Table 150-1 shows the association of different clinical xanthomata with disorders of lipoprotein metabolism.

TABLE 150-1 **Associations of Visible Xanthomata and Lipid Infiltrates with Lipoprotein Disorders**

LIPOPROTEINS AND THEIR METABOLISM

Chylomicrons (Fig. 150-1)

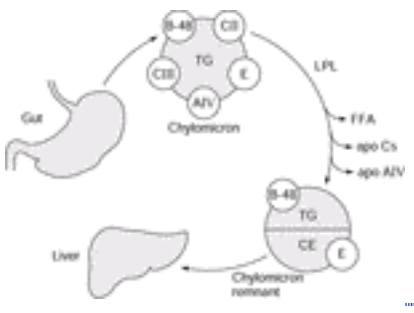

FIGURE 150-1 Metabolism of chylomicrons (see text for details).

Most dietary lipid is triacylglycerol (triglyceride). In the intestine, triglycerides are hydrolyzed by pancreatic lipase into fatty acids and monoglycerides, which are solubilized by the bile and taken up by the intestinal mucosa. In the enterocyte, fatty acids and monoglycerides are resynthesized into triglycerides and are incorporated into lipoproteins called *chylomicrons*. An enterocyte protein, microsomal lipid transfer protein, transfers the triglycerides into these chylomicron particles that have an inner core of triglycerides plus small amounts of cholesterol ester and a surface coat composed of unesterified cholesterol, phospholipids, and proteins (apolipoproteins). The major apolipoprotein of chylomicrons is apo B-48; other apolipoproteins are named apo C-II, apo C-III, apo E, apo A-I, and apo A-IV. All these apolipoproteins play special roles in the metabolism of chylomicrons.

Chylomicrons are secreted into the intestinal lymph and enter the systemic circulation through the thoracic duct, passing into the capillary bed of the peripheral circulation, where they come into contact with lipoprotein lipase (LPL). This enzyme, located on the endothelial surfaces of capillaries, hydrolyzes the triglycerides of chylomicrons into fatty acids. Several other surface components of chylomicrons are lost to the circulation during triglyceride lipolysis. When most triglycerides of chylomicrons have been hydrolyzed by LPL, a residual particle (chylomicron remnant) returns to the circulation. The core lipid of chylomicron remnants contains large amounts of cholesterol ester. These chylomicron remnants disappear quickly from the circulation in the liver, facilitated by the presence of apo Es.

Very Low Density Lipoproteins

Another class of triglyceride-rich lipoproteins is derived from the liver. This class includes the very low density lipoproteins (VLDLs). The VLDL particles contain less triglyceride than chylomicrons but relatively more cholesterol. Their synthesis in hepatocytes is analogous to chylomicron synthesis in enterocytes. In contrast to chylomicrons, however, VLDL particles contain apo B-100 as their major apolipoprotein; they also have apo Cs and apo Es. The total amount of triglyceride secreted daily associated with VLDL is only about one-fourth that entering through chylomicrons from the typical American diet. Newly secreted VLDL particles are named *nascent VLDLs*.

Like chylomicrons, circulating VLDLs pass into the peripheral circulation, where they interact with LPI, which hydrolyzes most of the VLDL triglycerides (Fig. 150-2). After much of the triglyceride is removed, a residual particle, called a *VLDL remnant,* returns to the circulation. Once VLDL remnants are formed, they have two fates. About half of VLDL remnants are removed directly by hepatic uptake facilitated by apo E. A portion of VLDL remnant uptake occurs via receptors for low-density lipoproteins (LDLs). These receptors are located on the surfaces of liver cells, where they bind both to apo E and apo B-100 but not to apo B-48. When VLDL remnants attach to liver cells, many are internalized and degraded; however, a portion of these particles interacts with hepatic triglyceride lipase, which removes residual triglycerides and converts them into LDL (Fig. 150-3). Newly formed LDL particles are released from hepatocytes and returned to the circulation.

FIGURE 150-2 Metabolism of very low density lipoproteins (VLDL) (see text for details).

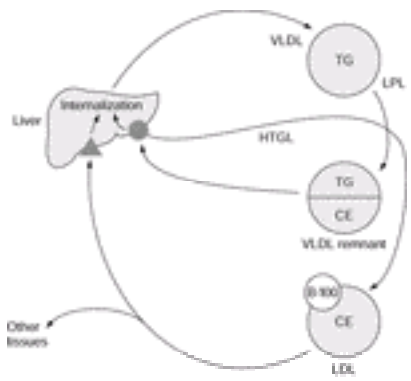

FIGURE 150-3 Metabolism of low-density lipoproteins (LDL) (see text for details).

Low-Density Lipoproteins (LDL)

LDL particles carry most of the cholesterol present in the fasting serum. LDLs are smaller than VLDLs and contain mostly cholesterol esters in their lipid cores. The only apolipoprotein associated with LDL is apo B-100. Removal rates of LDL from the circulation are slower than for VLDL; hence there is a tendency for LDL particles to accumulate in serum, which explains why serum LDL concentrations typically exceed those of VLDL. About three-fourths of circulating LDL is removed through LDL receptors on liver cells. Lesser amounts of LDL are cleared via nonreceptor pathways or by extrahepatic tissues. When LDL particles bind to LDL receptors, they are internalized and pass into lysosomes, where they are degraded.

High-Density Lipoproteins

High-density lipoproteins (HDLs) have unique properties and seem to perform a “cleanup” function. During lipid transport through triglyceride-rich lipoproteins (chylomicrons and VLDL), many component molecules are released to the circulation (Fig. 150-4). They are taken up by HDL particles and are either removed from the circulation or recycled to triglyceride-rich lipoproteins. Components of triglyceride-rich lipoproteins transferred to HDL during their catabolism include unesterified (free) cholesterol, phospholipids, apo Cs, apo Es, apo As, and small amounts of triglyceride. Some apo A-I and apo A-II molecules on HDL are derived by direct secretion from the liver. Excess unesterified (free) cholesterol in the membranes of peripheral tissue cells also may be taken up by HDL. This uptake is the first step of a process called *reverse cholesterol transport;* the process is so named because cholesterol synthesized in peripheral tissues is eventually returned to the liver for its disposal from the body. All these components may be removed from the circulation through direct tissue uptake of HDL; alternatively, apo Cs, apo Es, and cholesterol esters can be shuttled back to nascent triglyceride-rich lipoprotein for reutilization in their catabolism.

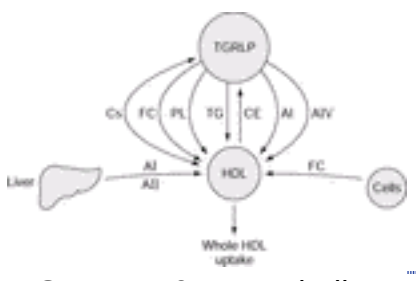

FIGURE 150-4 Metabolism of high-density lipoproteins (HDL) (see text for details).

HYPERCHOLESTEROLEMIA

The term *hypercholesterolemia* is usually taken to mean an increase in serum LDL-cholesterol concentrations. LDL has been identified as the major atherogenic lipoprotein by the National Cholesterol Education Program (NCEP). [2], [3] A large body of evidence—epidemiologic studies, animal models, clinical forms of hypercholesterolemia, tissue culture studies, and clinical trials—supports the concept that elevated serum LDL concentrations are atherogenic and a major cause of CHD. The NCEP has classified both total cholesterol and LDL-cholesterol levels in terms of risk for CHD. [2], [3] Approximate comparable values for total cholesterol and LDL-cholesterol are shown in Table 150-2. In the discussion to follow, severe forms of hypercholesterolemia will be considered first. These forms illustrate clearly the mechanisms of hypercholesterolemia, and they are commonly accompanied by xanthomata.

TABLE 150-2 **Classification of Total Cholesterol and Low-Density Lipoprotein (LDL) Cholesterol**

Familial Hypercholesterolemia

The primary defect in familial hypercholesterolemia (FH) is a genetic deficiency of LDL receptors. [4] Normally, two functional alleles encoding for LDL receptors are inherited—one from each parent. Both inherited LDL receptors function in removal of LDL from the circulation. The synthesis and expression of cell surface receptors are a multistep process. Defects occurring at any of these multiple steps can produce the clinical picture of FH. [5] In some cases, the functional activity of the receptor produced by a defective allele is zero; in other cases, mutations in the receptor gene or

associated genes produce defective receptor function.

In rare individuals, approximately 1 per 1 million persons in the general population, defective alleles for the LDL receptors are inherited from each parent. These doubly affected persons thus have homozygous FH. [5] They have either no LDL receptor activity or very low activity. Their serum LDL-cholesterol levels are markedly elevated, often in the range of 800 to 1000 mg/dL. They commonly develop CHD or other forms of atherosclerotic disease before their teenage years. Patients with homozygous FH usually have severe xanthomatosis.

Multiple types of xanthomata are found (Fig. 150-5). These include tuberous xanthomata (especially over the elbows), subperiosteal xanthomata (below the knees and over the olecranon process), tendon xanthomata (especially in the Achilles tendon and in the extensor tendon of the hand), and elevated xanthomatous plaques (over the extremities, buttocks, and hands). The rate of xanthoma deposition and growth is associated with the duration and severity of the LDL elevation.

FIGURE 150-5 Xanthomata typical of homozygous familial hypercholesterolemia.

Several forms of therapy have been proposed for homozygous FH. Since LDL receptor function is largely absent, drugs that act by enhancing LDL receptor activity produce little benefit. Such agents include bile acid sequestrants and lower doses of HMG-coenzyme A (HMG-CoA) reductase inhibitors (statins). High doses of statins, however, may cause moderate reductions in LDL-cholesterol levels in homozygous FH patients, probably by partial inhibition of VLDL secretion. A more radical approach to treatment of homozygous FH is liver transplantation. [6] This procedure supplies normal LDL receptors from the donor liver and markedly lowers LDL levels. A more practical approach is to remove LDL periodically from the circulation by plasmapheresis or LDL-apheresis. [7] The latter approach employs a variety of LDL-binding agents and is currently the preferred therapy.

As noted, the more common form of FH is heterozygous FH. This condition occurs from inheritance of a single abnormal allele for the LDL receptor. Serum LDL-cholesterol levels are approximately twice normal. The prevalence of heterozygous FH is about 1 in 500 people. Men with heterozygous FH commonly develop CHD in their thirties and forties; affected women typically manifest CHD in their fifties and sixties. In contrast to patients with homozygous FH, heterozygotes only rarely show tuberous xanthomata; tendon xanthomata, however, are common (Fig. 150-6). In fact, the majority of patients with tendon xanthomata will be found to have heterozygous FH. Less common causes of tendon xanthomata are discussed below.

FIGURE 150-6 Tendon xanthomata typical of heterozygous familial hypercholesterolemia. Similar xanthomata occur in patients with familial defective apolipoprotein B-100, cerebrontindinous xanthomatosis, and sitosterolemia.

Statins have proven to be effective drugs for treatment of heterozygous FH. [8] These agents inhibits HMG-CoA reductase, the rate-limiting enzyme in cholesterol synthesis. [9] A reduction in cellular cholesterol content sends a signal to the nucleus of the cell to stimulate the synthesis of LDL receptors. In patients with heterozygous FH, the one functional allele for the LDL receptor is “upregulated” by statin therapy; this supplies more LDL receptors and reduces serum LDL levels.

All statins have a similar mechanism of action, although the dose required to produce a given LDL-cholesterol lowering varies among the drugs. The frequency of side effects appears to correlate with LDL-lowering efficacy; i.e., higher doses cause more side effects. The major side effects of statins are myopathy and hepatotoxicity. These side effects are relatively rare but increase in frequency with increasing doses. The risk for myopathy is increased substantially when the statin is given with either a fibric acid (e.g., gemfibrozil) or cyclosporine. In patients with heterozygous FH, the lowering of LDL-cholesterol levels can be enhanced substantially by combining a statin with a bile acid sequestrant (e.g., cholestyramine or colestipol). In addition, statins prevent the synthesis of isoprenoid intermediates such as farnesylpyrophosphate and geranylpyrophosphate, which are posttranslational modifications of many cell signaling proteins. [10] There are several case reports of lichenoid drug eruptions associated with statins. [11]

Familial Defective Apolipoprotein B-100

Familial defective apolipoprotein B-100 (FDB) is another cause of moderately severe hypercholesterolemia. [12], [13] In this condition, the primary structure of apo B-100 is defective, and apo B binds poorly to LDL receptors. As a result, serum LDL levels are raised. Patients with FDB frequently resemble those with heterozygous FH except that they typically have somewhat lower LDL-cholesterol levels. Most patients with FDB are heterozygotes, and only half their LDL particles are defective in binding to LDL receptors. Rare patients are homozygous and have more severe hypercholesterolemia, although usually not to the degree seen in patients with homozygous FH. Some patients with heterozygous FDB develop tendon xanthomata that are identical in appearance to those associated with heterozygous FH. Patients with FDB are prone to premature CHD, [14] and their hypercholesterolemia usually responds well to statin therapy.

Moderate Hypercholesterolemia

Most patients with primary hypercholesterolemia have only moderate elevations of serum LDL-cholesterol levels (e.g., 160–219 mg/dL). Multiple mechanisms appear to underlie primary moderate hypercholesterolemia; these include reductions in LDL receptor activity, overproduction of lipoproteins containing apo B-100, and enrichment of LDL particles with cholesterol ester. [15], [16] Approximately 20 percent of American adults have moderate hypercholesterolemia. [2], [3] These persons are at increased risk for premature CHD, although less so than are those with severe forms of genetic hypercholesterolemia (i.e., FH and FDB). Patients with moderate hypercholesterolemia rarely have xanthomata, although one such patient with severe xanthomata in the Achilles tendons has been studied. [17] Presumably, tissue susceptibility in patients of this type combines with moderately high LDL levels to produce xanthomata.

CHYLOMICRONEMIA

Another severe form of hyperlipidemia is one in which triglyceride levels are markedly elevated. When triglyceride levels are below 500 mg/dL, most of the triglycerides are carried in VLDLs. At higher concentrations, chylomicrons begin to accumulate in the serum. Some patients manifest severe chylomicronemia begin to accumulate in the serum. Some patients manifest severe chylomicronemia with triglyceride levels ranging from 1000 to 10,000 mg/dL. These marked elevations result from either severe genetic defects in triglyceride metabolism or moderate genetic defects combined with aggravating acquired factors. Eruptive xanthomata are often associated with lipemia retinalis and pancreatitis.

Lipoprotein Lipase Deficiency

Rare (1 per million population) patients are homozygous for genetic defects in LPL function. [18] A large series of mutations in the *LPL* gene that prevent the normal function of LPL has been identified. Patients who are homozygous for LPL defects typically manifest severe chylomicronemia. Triglyceride levels can be severely elevated from birth. When serum triglyceride concentrations exceed 2000 mg/dL, patients are at high risk for developing acute pancreatitis. Triglyceride levels in this range are often associated with eruptive skin xanthomata (Fig. 150-7). These lesions are white to yellow papules on a slightly erythematous base. Sometimes they coalesce to form larger cutaneous plaques. Typical locations are over the buttocks, shoulders, and extensor surfaces of the extremities. Their rapid appearance usually signifies a striking rise of triglyceride concentrations. In this syndrome, only eruptive xanthomata occur. Patients with LPL deficiency generally are not at increased risk for CHD; the prevailing view has been that chylomicrons are too large to filter into the arterial wall to initiate atherogenesis. Although a few patients with LPL deficiency have manifested some atherosclerosis, premature CHD is rare. Patients who are heterozygous for LPL deficiency either have normal serum triglycerides or have mild hypertriglyceridemia.

FIGURE 150-7 Eruptive skin xanthomata characteristic of severe chylomicronemia.

There are no available drugs that can effectively treat the severe chylomicronemia of LPL deficiency. The most effective management is through dietary modification. The formation of chylomicrons can be curtailed by reducing the fat content of the diet. The intake of dietary fat should be reduced to less than 10 percent of total calories. Medium- chain triglycerides (MCTs) can be used as a substitute for dietary fat. The fatty acids of MCT are not incorporated into chylomicrons; thus 10 to 15 percent of total calories can be safely consumed as MCTs. The goal of therapy is to keep total triglyceride levels below 1500 mg/dL, which will greatly reduce the risk for pancreatitis.

Apo C-II Deficiency

Apo C-II is carried on triglyceride-rich lipoproteins and is required for activation of LPL. Rare patients have a congenital absense of apo C-II. These patients develop severe chylomicronemia resembling that developed with LPL deficiency. [19] They also manifest skin xanthomata identical to those of patients deficient in LPL. Treatment of chylomicronemia associated with apo C-II deficiency is the same as in patients with LPL deficiency.

Chylomicronemia Combined with Endogenous Hypertriglyceridemia (Type 5 Hyperlipoproteinemia)

This disorder is defined by combined elevations in levels of chylomicrons and VLDL. Most cases appear to result from a dual defect in triglyceride metabolism, namely, overproduction of VLDL and defective lipolysis of triglyceride-rich lipoproteins. [20] Both abnormalities can have multiple causes. Overproduction of VLDL is commonly due to obesity and may be accentuated by non-insulin-dependent diabetes mellitus. There is growing evidence that hepatic overproduction of VLDL is frequently the result of insulin resistance; the latter, in turn, can be due to either a primary metabolic abnormality or obesity. Defective lipolysis of triglyceride-rich lipoproteins can occur in the heterozygous state for LPL mutations or from functional reduction of LPL activity. [18] Recent evidence also suggests that high serum levels of apo C-III, an inhibitor of LPL activity, also can cause defective lipolysis. [21] Elevated serum apo C-III levels may be secondary to insulin resistance. [22] Thus insulin resistance appears to cause both overproduction of VLDL and defective lipolysis of triglycerides in VLDL and chylomicrons; both defects are characteristic of type 5 hyperlipoproteinemia. [20] Patients with type 5 hyperlipoproteinemia appear to be at increased risk for CHD, and they commonly manifest peripheral arterial disease. The risk for acute pancreatitis rises sharply when triglyceride levels exceed 2000 mg/dL. At this triglyceride level, eruptive skin xanthomata also commonly appear. Treatment of type 5 hyperlipoproteinemia consists of a very low fat diet (<10 percent of total calories as fat) and fibric acids (e.g., gemfibrozil). In addition, weight reduction in obese patients will reduce triglyceride levels, as will improved glucose control in diabetic patients.

DEFECTIVE METABOLISM OF LIPOPROTEIN REMNANTS (DYSBETALIPOPROTEINEMIA)

Dysbetalipoproteinemia (type 3 hyperlipoproteinemia) denotes a category of lipid disorders defined by accumulation in serum of remnant lipoproteins, i.e., chylomicron remnants and VLDL remnants. [23] The usual abnormality is the presence of an abnormal isoform of apo E, named apo E2. Normal isoforms are apo E3 and apo E4; these isoforms promote remnant uptake by the liver. When apo E2 is present, especially in the homozygous form of the disease, remnant uptake is impaired; as a result, remnant lipoproteins are removed slowly and accumulate in the serum. Isolated homozygous apo E2 typically produces mild remnant accumulation but not categorical hyperlipidemia.

However, hyperlipidemia of the dysbetalipoproteinemic type can develop when lipoprotein metabolism is otherwise disturbed, i.e., in patients with obesity, diabetes mellitus, or endogenous hypertriglyceridemia. Typically, in hyperlipidemic patients with dysbetalipoproteinemia, serum concentrations of cholesterol and triglycerides are about equally raised. The cholesterol-to-triglyceride ratio in the VLDL fraction usually exceeds 0.30. A definite diagnosis of dysbetalipoproteinemia is made by identifying the apo E2 isoform.

Hyperlipidemic patients with dysbetalipoproteinemia are at increased risk for CHD and often have peripheral arterial disease. About two-thirds of these patients have tuberoeruptive and tuberous xanthomata (Fig. 150-8). Also, they have a characteristic lipid deposition in the creases of the palms of the hands (xanthoma striata palmaris) (Fig. 150-8B and Fig. 150-9). Occasionally, patients manifest tendon xanthomata and xanthelasma. Some patients with dysbetalipoproteinemia exhibit tuberous xanthomata in the absence of raised serum levels of total cholesterol and triglyceride; in these patients, tissue susceptibility combined with increased remnant lipoproteins appears to be responsible for tuberous xanthomata. Tuberous xanthomata of the hands have been observed in two normolipidemic patients who were homozygous for apo E2. In one patient, xanthomata apparently developed in the fingers because of heavy manual labor [24]; the other tuberous xanthomata resulted from the presence of apo E2 combined with a form of histiocytosis. The hyperlipidemia in most patients with dysbetalipoproteinemia is responsive to fibric acids or nicotinic acid; however, if total cholesterol levels are markedly raised, statin therapy is more effective. Reducing serum lipids with drug therapy often causes xanthomata to regress.

FIGURE 150-8 Tuberoeruptive and tuberous xanthomata typical of familial dysbetalipoproteinemia. *A*. Knee *B.* Palm.

FIGURE 150-9 Xanthoma striata palmaris characteristic of familial dysbetalipoproteinemia.

DEFECTS IN HDL METABOLISM

Tangier Disease

This rare condition is characterized by profound deficiency of serum HDL. [25] The catabolism of HDL appears to be markedly increased in Tangier disease, which noticeably lowers serum HDL concentrations; the reasons for this excessive catabolism of HDL are unknown. Tangier homozygotes manifest accumulation of cholesterol esters in tonsils, spleen, lymph nodes, bone narrow, skin, thymus, and intestinal mucosa. These accumulations most commonly produce tonsillar hyperplasia, mild lymphadenopathy, and splenomegaly. Older patients with Tangier disease often develop CHD. Despite widespread tissue accumulation of cholesterol esters, skin xanthomata are not prominent.

HDL Deficiency with Plane Xanthomata

Mutations in apo A-I can reduce its synthesis and produce HDL deficiency. [26] In some cases, there is a concomitant defect in synthesis of apo C-III and apo A-IV. When the latter defects are present, complex abnormalities are present in lipoprotein metabolism, and affected patients are prone to premature CHD. Patients with defects limited to synthesis of apo A-I may manifest plane xanthomata. [27] It is uncertain whether these patients are prone to premature CHD; however, they do not appear to develop fulminant atherosclerosis, as do patients with homozygous FH.

LCAT Deficiency Syndrome

Lecithin-cholesterol acyl transferase (LCAT) is an enzyme responsible for esterification of cholesterol in plasma. Congenital defects in LCAT synthesis produce abnormalities in the metabolism of HDL and other lipoproteins. [28] Several such congenital defects have been discovered that produce related syndromes of varying degrees of clinical severity. The major clinical features include corneal infiltrates and opacity, anemia, and proteinemia. Xanthomatous deposits of the skin or tendons have not been reported with LCAT deficiency syndromes.

DISORDERS OF STEROL METABOLISM

Cerebrotendinous Xanthomatosis

Cerebrotendinous xanthomatosis (CTX) is a rare recessive disorder in which xanthomata occur in the tendons and brain. [29], [30] The genetic abnormality is a defect in the conversion of cholesterol into bile acids in the liver due to mutations in sterol 27-hydroxylase. A by-product of this defect is an increased synthesis of the sterol cholestanol.

Accumulation of this abnormal sterol in the serum apparently is responsible for xanthomata in the brain and tendons. Cerebroxanthomatosis causes several neurologic manifestations. Patients with CTX also appear to be at increased risk for CHD. Treatment consists of replacement of the bile acid pool with oral chenodeoxycholic acid. This therapy reduces cholestanol synthesis and has been reported to alleviate neurologic symptoms.

Sitosterolemia (Phytosterolemia)

This rare autosomal recessive disorder results from accumulation of plant sterols in the serum. [29] The major plant sterol in the serum is ß-sitosterol; other plant sterols are increased as well, but to a lesser extent. The molecular defect in sitosterolemia is unknown; however, the metabolic abnormality appears to be a defective transfer of sterols into bile for

excretion. [31] This defect causes retention of both cholesterol and plant sterols in the liver; in turn, serum cholesterol and plant sterol levels are raised. Early in life, serum cholesterol levels are extremely elevated, similar to those of homozygous FH. Hence sitosterolemia has been called *pseudohomozygous FH*. Later in life, cholesterol levels decline, but serum sitosterol levels remain elevated. Tendon xanthomata are common in sitosterolemia; they resemble those of patients with heterozygous FH. Seemingly, elevated serum sitosterol concentrations of a few milligrams per deciliter promote xanthoma formation, even without significant hypercholesterolemia. Treatment of sitosterolemia consists of a reduced intake of cholesterol and plant sterols. In addition, bile acid sequestrants promote conversion of cholesterol into bile acids and reduce serum levels of cholesterol.

DYSPROTEINEMIAS

A number of forms of dysglobulinemia or paraproteinemias are accompanied by diffuse plane xanthomata that typically are yellow-orange macules or slightly raised plaques over the eyelids, neck, and trunk. [32] Diffuse plane xanthomata have been reported in multiple myeloma, monoclonal gammopathy, cryoglobulinemia, leukemia, lymphoma, eosinophilic granulomatosis, and rheumatoid arthritis. The mechanism of production of xanthomata is typically the formation of a complex between a paraprotein and a particular lipoprotein species. Cellular uptake of these complexes by macrophages in the skin produces plane xanthomata.

BILIARY OBSTRUCTION

Prolonged obstruction of the biliary tree leads to accumulation of cholesterol in the serum. Causes include primary biliary cirrhosis and secondary biliary obstruction. Serum cholesterol is high in unesterified cholesterol, which leads to the formation of an abnormal lipoprotein called *lipoprotein X*. Besides having hypercholesterolemia, patients with prolonged biliary obstruction usually manifest jaundice, pruritus, and hyperpigmentation of the skin. Prolonged hypercholesterolemia leads to plane xanthomata (beige-orange plaques on hands, feet, and trunk), xanthelasma, and occasionally, tuberous xanthomata.

REFERENCES

Fabry disease, an inborn error of glycosphingolipid metabolism, results from the defective activity of the lysosomal enzyme, a-galactosidase A. The enzymatic defect, transmitted by an X-linked recessive gene, leads to the progressive deposition of neutral glycosphingolipids (predominantly globotriaosylceramide) with terminal a-galactosyl moieties in most visceral tissues and fluids of the body (Fig. 151-1). The birefringent glycosphingolipids are deposited in the lysosomes of the vascular endothelium; in perithelial and smooth muscle cells of the cardiovascular-renal system; in reticuloendothelial, myocardial, and connective tissue cells of the cornea, kidney, and other tissues; and in ganglion and perineural cells of the autonomic nervous system.

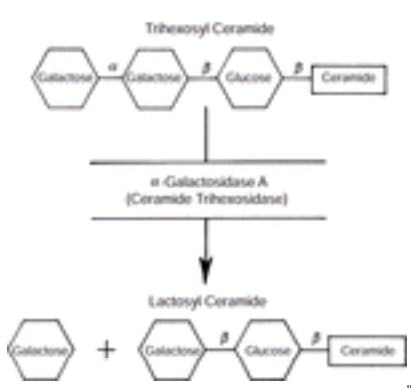

FIGURE 151-1 The metabolic defect in Fabry disease. Defective a-galactosidase A activity results in the accumulation of its major glycosphingolipid substrate, trihexosyl ceramide, which is also termed globotriaosylceramide.

Clinically, classically affected males, who have very little or undetectable a-galactosidase A activity, have a characteristic skin lesion of angiokeratoma corporis diffusum universale. They also have acroparesthesias, episodic crises of excruciating pain, corneal and lenticular opacities, hypohidrosis, and cardiac and renal dysfunction. Death usually occurs in adult life from renal, cardiac, or cerebral complications of their vascular disease.

In contrast, males with residual a-galactosidase A activity (1 to 5 percent of normal) have milder manifestations. These “cardiac variants” lack vascular endothelial glycolipid deposition and do not have angiokeratoma, acroparesthesias, hypohidrosis, or lenticular/corneal opacities. They present in mid- to late adulthood with left ventricular hypertrophy, cardiomegaly, mitral insufficiency, and/or conduction abnormalities. They may have proteinuria, but do not develop renal insufficiency.

Carrier females for the classic phenotype are asymptomatic or have only mild disease manifestations. Most carriers show the characteristic corneal opacities. Rarely, female carriers may develop disease manifestations as severe as those of affected males because of random X-chromosome inactivation.

HISTORICAL ASPECTS

In 1898, two dermatologists, Anderson [1] in England and Fabry [2] in Germany, independently described the first patients with angiokeratoma corporis diffusum. Fabry originally made the diagnosis of purpura nodularis in a 13-year-old male, whom he followed over the next 30 years (Fig. 151-2). He documented the presence of albuminemia; further described the cutaneous lesions, noting the presence of small vessel aneurysms; [3] and subsequently classified his case as one of angiokeratoma corporis diffusum, a designation that has persisted. Scriba definitively established the lipid nature of the storage material, [4] and Hornbostel and Scriba were the first to confirm the diagnosis histologically by demonstrating the refractile lipid deposits in the vessels of a skin biopsy specimen. [5] Opitz and colleagues documented the X-linked recessive inheritance of the disorder by pedigree analysis. [6]

FIGURE 151-2 Distribution of angiokeratoma in the 30-year-old classically affected male originally described by Fabry. [2]

In 1963, Sweeley and Klionsky isolated and characterized the two major accumulated neutral glycosphingolipids—globotriaosylceramide Gal-Gal-Glc-Cer (GL-3) and galabiosylceramide Gal-Gal-Cer (GL-2)—from an affected male's kidney obtained at autopsy, establishing Fabry disease as a sphingolipidosis. [7] Subsequent chemical analyses of various Fabry tissues and fluids have demonstrated the marked accumulation of GL-3 and, to a lesser extent, GL-2. [5], [6], [7] and [8] In addition, blood group B substances, glycosphingolipids with terminal a-galactosyl moieties, accumulate in affected individuals with B or AB blood types. [9]

In 1967, Brady and associates demonstrated that the enzymatic defect was the defective activity of ceramide trihexosidase, a lysosomal galactosyl hydrolase required for the catabolism of GL-3 and GL-2 [10] (see Fig. 151-1). Kint characterized the defective enzymatic activity as an a-galactosyl hydrolase (designated a-galactosidase A). [11] The accumulated glycosphingolipid substances, including blood group B substances, all had a-linked terminal galactosyl residues. The elucidation of the specific enzymatic defect permitted the enzymatic diagnosis of affected males, the identification of carrier females, [12] and the prenatal diagnosis of affected males. [13] The molecular cloning of the full-length cDNA and entire gene encoding human a-galactosidase A has resulted in the characterization of the various mutations that produce the classical and variant forms of the disease, and it has provided accurate carrier diagnosis. [14], [15] Recent Phase 1, 1/2, 2, and 3 clinical trials have demonstrated the safety and efficacy of recombinant a-galactosidase A replacement. [16], [17], [18] and [19]

In keeping with the terminology applied to other lipidoses and for the benefit of information retrieval, it would seem advisable to retain the commonly used eponym and to append the specific enzymatic defect. Thus, an appropriate designation is *Fabry disease: a-galactosidase A deficiency.* Other comprehensive reviews on the clinical, pathologic, biochemical, and genetic aspects of the disease are available. [20]

CLINICAL MANIFESTATIONS

Classically Affected Males

The major clinical manifestations of Fabry disease result from the progressive deposition of GL-3 in the vascular endothelium (Table 151-1). Onset of the disease usually occurs during childhood or adolescence with periodic crises of severe pain in the extremities (acroparesthesias), the appearance of vascular cutaneous lesions (angiokeratoma), hypohidrosis, and the characteristic corneal and lenticular opacities. With advancing age, the progressive accumulation leads to early demise because of renal, cardiac, or cerebrovascular involvement.

Manifestation	Classical Type	"Cardiac Variant"*
Clinical onset (yr)	4–8 yr	> 40 yr
Average age of death (yr)	41 yr	> 60 yr
Angiokeratoma	++	–
Acroparesthesia	++	–
Hypohidrosis/anhidrosis	++	–
Corneal/lenticular opacity	+	–
Heart	Ischemia/MI	LVH/cardiomyopathy
Brain	TIA/strokes	–
Kidney	Renal failure	Mild proteinuria
Residual α-Gal A activity	< 1%	1%–3%

*All in a hemizygote (male) patient. LVH = left ventricular hypertrophy. TIA = transient ischemic attack. + = present. – = absent.

TABLE 151-1 **Major Clinical Manifestations in Males Affected with the Classical and "Cardiac Variant" Phenotype of Fabry Disease**

PAIN The single most debilitating early symptom of Fabry disease is the pain, of which there are two types: (1) episodic "crises" consisting of agonizing, burning pain, initially in the palms and soles, and (2) a nagging, constant discomfort in the hands and feet, characterized by burning, tingling paresthesias. Exercise, fatigue, emotional stress, or rapid climatic changes in temperature and humidity usually trigger the painful crises. Attacks of abdominal or flank pain may simulate appendicitis or renal colic. With increasing age, the periodic crises usually decrease in frequency and severity; however, in some patients, they may occur more frequently, and the pain can be so excruciating that the patient may contemplate suicide. The common association of the pain with a low-grade fever and an elevated erythrocyte sedimentation rate has frequently led to the misdiagnosis of rheumatic fever, neurosis, or erythromyalgia. [21] In addition to these intermittent crises, most patients complain of a nagging, constant burning, tingling in their hands and feet. These acroparesthesias may occur daily, usually during late afternoon, and may represent an attenuated form of the excruciating episodic crises. However, 10 to 20 percent of older patients deny any history of Fabry crises or acroparesthesias.

SKIN LESIONS With age, there is a progressive increase in the number and size of the cutaneous vascular lesions of Fabry disease. Classically, the angiokeratomas develop slowly as clusters of individual, punctate, dark red to blue-black angiectases in the superficial layers of the skin (Fig. 151-3 and Fig. 151-4). The lesions may be flat or slightly raised, and they do not blanch with pressure; larger lesions may be hyperkeratotic. The clusters of lesions are most dense between the umbilicus and the knees and have a tendency toward bilateral symmetry. The hips, back, thighs, buttocks, penis, and scrotum are most commonly involved, but there is a wide variation in the pattern of distribution and density of the lesions. Involvement of the oral mucosa and conjunctiva is common, and involvement of other mucosal areas may also occur. There are some variants without the characteristic skin lesions. [22], [23], [24] and [25] Although it may not be easy to detect the angiectases in some patients, careful examination of the skin, especially the scrotum and umbilicus, may reveal the presence of isolated lesions. In addition to these vascular lesions, anhidrosis or, more commonly, hypohidrosis is an early and almost constant finding.

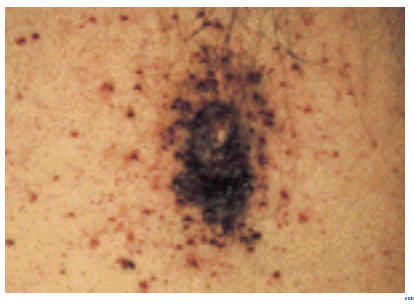

FIGURE 151-3 Clusters of dark red angiokeratomas in an affected male with Fabry disease.

FIGURE 151-4 Angiokeratomas in a 28-year-old affected male with Fabry disease. Note the "swimsuit" distribution.

CARDIAC, CEREBRAL, AND RENAL VASCULAR MANIFESTATIONS The infiltration of glycosphingolipid progresses in the vascular system with increasing age. Cardiac disease, including anginal chest pain, myocardial infiltration, ischemia and infarction, mitral valve prolapse, congestive heart failure, hypertension, mitral insufficiency, and cardiac enlargement, occurs in most affected males. [26], [27], [28], [29], [30], [31] and [32] Systemic hypertension related to vascular involvement of renal parenchymal vessels may accentuate these findings. Hypertrophic obstructive cardiomyopathy, and myocardial infarction secondary to occlusion of the coronary arteries by glycolipid deposition, have been reported. [33], [34] Resulting primarily from multifocal small vessel involvement, cerebrovascular manifestations may include thromboses, basilar artery ischemia and aneurysm, seizures, hemiplegia, hemianesthesia, aphasia, labyrinthine disorders, or frank cerebral hemorrhage. Personality changes and psychotic behavior may become manifest with increasing age. Severe neurologic signs may be present without evidence of major thrombosis and are presumably due to multifocal small vessel occlusive disease. [28], [29], [30], [31] and [32] Progressive glycosphingolipid deposition in the kidney results in proteinuria, with gradual deterioration of renal function and development of azotemia in middle age. During childhood and adolescence, protein, casts, red cells, and desquamated kidney and urinary tract cells may appear in the urine. Polarization microscopy reveals birefringent lipid globules with characteristic Maltese crosses free in the urine and within desquamated urinary sediment cells (Fig. 151-5). With age, renal impairment progresses to significant proteinuria, isosthenuria (specific gravities of 1.008 to 1.012), and alterations of other renal tubular functions. Gradual deterioration of renal function and the development of azotemia usually occur in the third to fourth decades of life, although renal failure has occurred in the second decade. [20] Death most often results from uremia, unless the patient undergoes chronic hemodialysis or renal transplantation. The mean age at death of a series of affected males who were not treated for uremia was 41 years, [35] but occasionally an affected individual has survived into his early 60s.

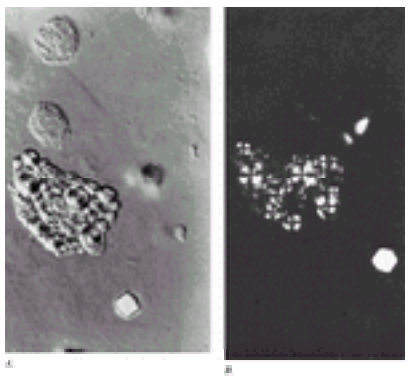

FIGURE 151-5 Photomicrographs of the urinary sediment from a male classically affected by Fabry disease, showing lipid accumulation by interference microscopy (*A*) and polarization light microscopy (*B*). Note that Maltese crosses are visible under polarization.

OCULAR FEATURES Ocular involvement is most prominent in the cornea, lens, conjunctiva, and retina. [36] A characteristic corneal opacity, observed only on slit-lamp microscopy, is evident in males with the disease and in most heterozygous females (Fig. 151-6). The earliest lesion is a diffuse haziness in the subepithelial layer. In more advanced cases, the opacities appear as whorled streaks that extend from a central vortex to the periphery of the cornea. Typically, the whorllike opacities are cream-colored; however, they range from white to golden brown. They are generally inferior and may be very faint. An indistinguishable, drug-induced phenocopy of the Fabry corneal dystrophy occurs in patients on long-term therapy with chloroquine or amiodarone (see " Genetics").

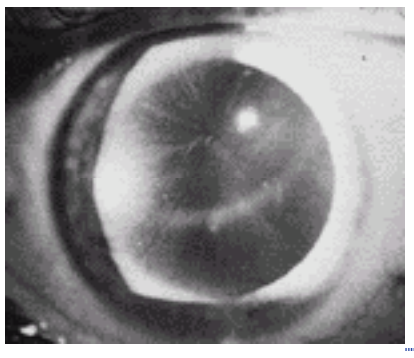

FIGURE 151-6 Corneal opacity observed on slit-lamp microscopy in a Fabry disease carrier female. The corneal involvement results from subepithelial glycosphingolipid deposition.

There are two specific types of lenticular changes. A granular anterior capsular or subcapsular deposit occurs in about one-third of affected males, but rarely in carrier females. Typically, these lenticular opacities are bilateral and inferior in position. They frequently appear in a propeller-like distribution, that is, wedge-shaped with their bases near the lenticular equator and aligned radially with the apices toward the center of the anterior capsule. A second, possibly unique to Fabry disease, lenticular opacity has occurred in both affected males and carrier females. [37] It may be the first ocular manifestation to appear. Posterior and linear, the opacity appears as a whitish, almost translucent, spokelike deposit of fine granular material on or near the posterior cortex. This unusual opacity has been termed the Fabry cataract [36] and is best seen by retroillumination. Conjunctival and retinal vascular lesions are common and represent part of the diffuse systemic vascular involvement. These vascular lesions occur early in life in normotensive individuals and are characterized by mild to marked tortuosity of the conjunctival and retinal vessels. There is an aneurysmal dilation of thin-walled venules as well as angulation and segmental, sausage-like dilatation of veins typically seen on the inferior bulbar conjunctiva. As the disease progresses, the development of hypertension and uremia may produce retinal changes. Neither the vascular lesions in the conjunctiva and retina nor the corneal dystrophy impair vision. However, acute visual loss has occurred in affected males as a result of unilateral total central retinal artery occlusion. [36]

OTHER CLINICAL FEATURES Because of the widespread visceral distribution of the glycosphingolipid deposits, signs and symptoms of this disorder arise in many other organs and systems. Patients have had chronic bronchitis, wheezing respiration, or dyspnea with alveolar capillary block. Older affected males may experience changes in pulmonary function, such as significant airflow obstruction, reduced diffusing capacity, and a reduction in the V_{max25} values. In affected males, airway obstruction occurs commonly, regardless of smoking history, and increases with age, most likely because of fixed narrowing of the airways by accumulated glycosphingolipid. [38] Lymphedema of the legs may be present in adulthood without hypoproteinemia, varices, or any clinically manifest vascular disease. Presumably, the lymphedema reflects the progressive glycosphingolipid deposition in the lymphatic vessels and lymph nodes. Many patients have varicose leg veins and hemorrhoids. Priapism has also been associated with Fabry disease. Episodic diarrhea and, to a lesser extent, nausea, vomiting, and flank pain, are the most common gastrointestinal complaints. These symptoms may be related to the deposition of glycosphingolipid in intestinal small vessels and in the autonomic ganglia of the bowel. Anemia is probably due to decreased red blood cell survival. Patients may have a decreased serum iron concentration, normal red blood cell fragility, and an elevated reticulocyte count. [20] Lipid-laden, foamy-appearing macrophages are present in the bone marrow. Many affected males appear to have retarded growth or delayed puberty and sparse, fine facial and body hair. In some kindreds, an acromegalic-like appearance has been described. Affected individuals may complain of fatigue and weakness and may be incapacitated for prolonged periods.

Cardiac Variants

Affected males with this variant phenotype of Fabry disease are essentially asymptomatic at ages when classically affected males would be severely affected or would have died of the disease [20] (see Table 151-1). In contrast to patients with the classic phenotype, who have very low or nondetectable a-galactosidase A activity, these variants have residual enzyme activity compatible with their milder phenotypes. Patients present with late-onset cardiac or cardiopulmonary disease including cardiomegaly, typically involving the left ventricular wall and interventricular septum, and electrocardiographic abnormalities consistent with a cardiomyopathy. [28], [39] Others have had hypertrophic cardiomyopathy or myocardial infarctions. Most had mild proteinuria. They had been essentially asymptomatic during most of their lives and did not experience the early classic manifestations, including acroparesthesia, angiokeratoma,

corneal and lenticular opacities, and hypohidrosis. In most of these cases, it was the onset of cardiac manifestations that led to the diagnosis.

Carrier Females

The clinical course of Fabry disease and the prognosis of affected males and carrier females differ significantly. [20] Many carrier females experience little difficulty in adult life at ages when affected males already have severe renal or cardiac involvement, although with increasing age some manifest minor symptoms of the disease. Approximately 30 percent of carrier females have a few isolated skin lesions; about 20 to 30 percent have acroparesthesias, particularly in adolescence; and about 70 to 80 percent have the whorllike corneal dystrophy.

Renal findings in carrier females include hyposthenuria (i.e., the occurrence of erythrocytes, leukocytes, and granular and hyaline casts in the urinary sediment), proteinuria, and other signs of renal impairment. In some carrier females, cardiac involvement will develop with advanced age. However, a few carrier females have disease as severe as that observed in classically affected males. In contrast, obligate carriers (daughters of affected males) may have no clinical manifestations with normal levels of leukocyte a-galactosidase A and urinary sediment glycosphingolipids. [40] Indeed, asymptomatic and symptomatic monozygotic female twins have been described. [41] Such markedly variable expression is expected in female carriers for X-linked diseases because of random X-chromosome inactivation (see " Genetics").

PATHOLOGY

Morphologically, Fabry disease is characterized by widespread tissue deposits of crystalline glycosphingolipids that show birefringence with typical Maltese crosses under polarization microscopy (see Fig. 151-5). Although deposits of glycosphingolipid may occur in all areas of the body, they occur predominantly in the lysosomes of endothelial, perithelial, and smooth muscle cells of blood vessels and, to a lesser degree, in the histiocytic and reticular cells of connective tissue. Lipid deposits are also prominent in the epithelial cells of the cornea, as well as in the glomeruli and tubules of the kidney, in the muscle fibers of the heart, and in the ganglion cells of the autonomic system.

Pathology of the Skin

The skin lesions are telangiectases or small superficial angiomas (Fig. 151-7). After a silent period, cumulative vascular damage leads eventually to clinically apparent and progressive angiectases. [42], [43] The early pathologic changes in the vascular endothelium and perithelium have been observed in the clinically normal skin from a 1-year-old affected male. [44]

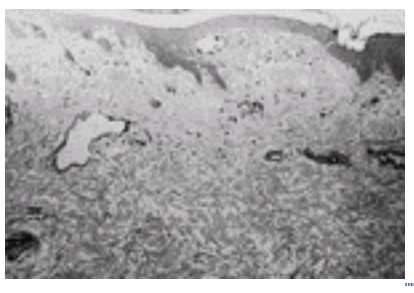

FIGURE 151-7 Telangiectatic vessels in the dermis that are typical of the changes in the skin seen with Fabry disease.

The capillaries, venules, and arterioles of those with classic Fabry disease contain pathologic lipid deposits in the endothelium, perithelium, and smooth muscle. There is marked dilatation of the capillaries of the dermal papillae. Deeper vessels show less dilatation and aneurysm formation. Lipid stores have been evident in arrectores pilorum muscles, gingival tissues, sweat gland epithelium, and perineural cells. [44], [45]

The fully developed classic lesions are usually located in the upper dermis, where they may produce the elevation, flattening, or hypertrophy of the epithelium. The larger lesions may have a slight to moderate keratosis, hence the term *angiokeratoma*.

Pathology of Other Systems

KIDNEY The earliest lesions in the kidney are due to the accumulation of glycosphingolipid in endothelial and epithelial cells of the glomerulus and of Bowman's space, and in the epithelium of the loops of Henle and of distal tubules. Lipid-laden distal tubular epithelial cells desquamate and may be detectable in the urinary sediment (see Fig. 151-5). Concurrently, the involvement of renal blood vessels progresses and often becomes extensive. An early finding is the presence of arterial fibrinoid deposits, which may result from the necrosis of severely involved muscular cells. Other histologic changes in the kidney are the sequelae of nonspecific, end-stage renal disease.

NERVOUS SYSTEM The vascular involvement of the nervous system, which is also prominent in Fabry disease, [46] presumably accounts for the observation of minor electroencephalographic and electromyographic abnormalities in these patients. In addition, vascular ischemia and lipid deposition in the perineurium may cause the peripheral nerve conduction abnormalities of slowed conduction velocities and distal latency, respectively. In both affected males and carrier females, glycosphingolipid deposition in nervous system tissue appears to be limited to the perineural sheath cells of peripheral nerves, neurons of the peripheral and central autonomic nervous system, and certain primary neurons of somatic afferent pathways. Qualitative and quantitative studies of peripheral sensory neurons in sural nerves and spinal ganglia have shown preferential loss of small myelinated and unmyelinated fibers, as well as small cell bodies of spinal ganglia. [47] Fabry disease may involve multiple brainstem centers. [47] Hemisphere involvement has been evident in the amygdaloid, hypothalamic, and hippocampal nuclei. Lipid storage in neuronal cells of the anterior and posterior lobes of

the pituitary has been observed. Detailed reviews of the neurologic findings are available. [48], [49]
EYE Histologically, there are abnormal glycosphingolipid deposits in endothelial, perivascular, and smooth muscle cells of all ocular and orbital vessels, in smooth muscle of the iris and ciliary body, in perineural cells, and in connective tissue of the lens and cornea. [50] Researchers have localized inclusions in the epithelium of the conjunctiva, cornea, and lens. Electron microscopy shows inclusions to be in the basal layer of conjunctival epithelial cells as well as in the surface epithelium. There may be hyperplasia and edema of corneal epithelial cells. Bowman's membrane appears normal, and no deposits appear in the stroma or endothelium. The whorllike corneal dystrophic pattern may result from the formation of a series of subepithelial ridges or from the reduplication of the basement membrane.
HEART The progressive deposition of glycosphingolipid in myocardial cells and valvular fibroblasts appears to be a primary cause of cardiac disease in affected males and some carrier females. [51], [52] Most commonly, the left atrium and ventricle are enlarged, and the ventricular walls and septum are markedly thickened; right atrial and ventricular dilatation and enlargement are variable findings. Within the myocardial cells, there is extensive glycosphingolipid deposition around the nucleus and between myofibrils.

Histochemistry and Ultrastructure

The accumulated glycosphingolipids can be stained in frozen sections with lipid-soluble dyes and may be removed from tissues by the process of dehydration and embedding in paraffin. If lipid-solubilizing procedures are used, empty vacuoles are observed on light microscopy. Most of the lipid crystals are retained through alcohol dehydration but are lost on exposure to xylene or pyridine. Improved fixation of the lipid deposits can be achieved with 1% calcium formol. A comparison of various fixation and embedding techniques to preserve the storage material has been reported. [53]

A modified periodic acid–Schiff (PAS) stain specific for neutral glycosphingolipids [54] and a positive test for sphingosine [55] have served to confirm the chemical identification of the accumulated glycosphingolipids. The levels of peroxidase- or fluorescence-labeled *Banderiaea simplicifolia* lectin, which is specific for a- *D*-galactosyl residues, and antiglobotriaosylceramide antibodies also have been used to stain the glycosphingolipid substrates selectively. [53], [56], [57]

At high resolution, a typical pattern of concentric or lamellar inclusions with alternating light- and dark-staining bands is evident (Fig. 151-8). The periodicity of these bands has been reported variably as 40 to 50 Å, 50 to 60 Å, 60 to 65 Å, or as great as 98 Å. The electron-dense component is 20 to 30 Å in thickness. These inclusions have coarser periods of 150 to 200 Å.

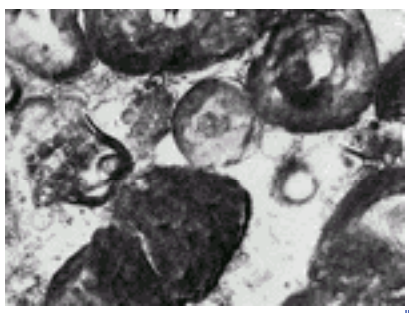

FIGURE 151-8 Electron photomicrograph of a section of the mitral valve from an affected male with Fabry disease, showing the concentric lamellar inclusions in lysosomes of fibrocytes. (*Courtesy of HL Sharp, MD.*)

BIOCHEMICAL GENETICS OF FABRY DISEASE

The deficient activity of the lysosomal enzyme a-galactosidase A results in the accumulation of glycosphingolipids with terminal a-galactosyl moieties in most visceral tissues and body fluids. The predominant glycosphingolipid accumulated is globotriaosylceramide or galactosyl-(a1 ? 4)-galactosyl-(ß1 ? 4)-glycosyl-(ß1 ? 1')-ceramide. A second neutral glycosphingolipid, galabiosylceramide [Gal(a1 ? 4)Gal(ß1 ? 1')Cer, also accumulates in Fabry disease–affected males to abnormally high concentrations. The deposition of galabiosylceramide, however, appears to be tissue-specific, because this substrate has been detected only in the kidney, pancreas, right heart, lung, and urinary sediment. In addition, the blood group B–specific substances, which have terminal a-galactosyl moieties [Gal(a1 ? 3)Gal(2 ? 1a-Fuc) (ß1 ? 3)GlcNAc(ß1 ? 3)Gal(ß1? 4)Glc(ß1 ? 1')Cer] and the blood group B1 glycosphingolipid [Gal(a1 ? 3)Gal(2 ? 1aFuc)(ß1 ? 4)GlcNAc(ß1 ? 3)Gal(ß1 ? 4)Glc(ß1 ?1')Cer], accumulate in patients who have the blood group B antigens. Thus, affected males and carrier females who have blood group B or AB accumulate four major glycosphingolipid substrates (and generally have a more rapid disease course), whereas patients with A or O blood groups accumulate globotriaosylceramide and galabiosylceramide.

Human a-galactosidase A is a homodimeric glycoprotein with native and subunit molecular masses of ˜101 and ˜46 kDa. The enzyme has a pH optimum of 4.6 and hydrolyzes the a-linked galactosyl moieties from glycolipids and glycopeptides. Isoelectric focusing studies of the enzyme from various sources reveal multiple forms with pI values ranging from 4.2 to 5.1, owing to glycoforms with varying sialylation and phosphorylation. [58] The a-galactosidase A subunit in cultured fibroblasts is normally synthesized as a precursor glycopeptide of ˜50 kDa. After cleavage of the signal peptide and carbohydrate modifications in the Golgi apparatus and lysosomes, the mature enzyme subunits of ˜46 kDa form the active, homodimeric enzyme, which contains complex, hybrid, and high-mannose type oligosaccharide moieties. The transport to the lysosome is dependent on mannose-6-phosphate receptors. Reviews of glycosphingolipid metabolism, the biochemistry of a-galactosidase A, and the metabolic defect in Fabry disease are available. [20]

As noted earlier, classically affected males with Fabry disease have no detectable a-galactosidase A activity. Studies of a-galactosidase biosynthesis have demonstrated several types of enzyme defects, suggesting allelic heterogeneity, including gene rearrangements and point mutations that affect a-galactosidase A synthesis, maturation, and stability. [20] In

contrast to classically affected males, those with atypical or cardiac variants of the disease have residual a-galactosidase A activity, consistent with the attenuation or absence of the characteristic clinical manifestations. [20]

Based on studies with synthetic substrates, two activities initially thought to represent a-galactosidase isozymes were detected and designated a-galactosidases A and B. [59] The two “isozymes” were separable by electrophoresis, isoelectric focusing, and ion exchange chromatography. Subsequently, the demonstration that polyclonal antibodies against a-galactosidase A or B did not cross-react with the other enzyme, [60] that only a-galactosidase A activity was deficient in affected males with Fabry disease, and that the genes for a-galactosidases A and B occurred on different chromosomes [20], [61] clearly established the genetic distinction between these enzymes. Thus, it was not surprising when a-galactosidase B was shown in 1977 to be an a- *N*-acetylgalactosaminidase, a homodimeric glycoprotein that hydrolyzed artificial and natural substrates with terminal a- *N*-acetylgalactosaminyl moieties. [60] The a-galactosidase B gene has been subsequently identified and characterized. [61], [62]

PATHOPHYSIOLOGY

The pattern of glycosphingolipid deposition in Fabry disease, particularly its predilection for vascular endothelial and smooth muscle cells, is different from that seen in other glycosphingolipidoses. [63] However, the origin of the accumulated glycosphingolipid substrates in Fabry disease has not been fully clarified. Certainly, there is a significant contribution from the endogenous synthesis and subsequent lysosomal accumulation of terminal a-galactosyl–containing glycosphingolipids after autophagy of cellular membranous material with these lipid substrates. Endogenous metabolism is likely to be the major source of substrate accumulation in avascular sites, such as the cornea, and in neural cells, which are presumably protected from the increased circulating levels of GL-3 by the blood-brain barrier. In addition, the turnover of GL-3 and particularly its precursor, globotriaosylceramide (globoside), which are present in higher concentrations in normal renal tissue than in any other tissue, is presumably responsible for the endogenous renal deposition of the Fabry substrate.

The unique cellular and tissue distribution of accumulated GL-3 suggests that a significant intracellular contribution may be derived by the endocytosis or diffusion of GL-3 from the circulation, where the concentration in affected males is three- to tenfold higher than that in healthy individuals. Circulating GL-3 is transported primarily in the low-density lipoprotein (LDL) and high-density lipoprotein (HDL) fractions. In plasma from affected males, the accumulated GL-3 is distributed in the LDL and HDL fractions in proportions similar to those in normal plasma, approximately 60 and 30 percent, respectively.

The finding that little, if any, substrate deposition occurs in Fabry hepatocytes (in contrast to the accumulation in Kupffer cells) supports the contention that GL-3 synthesized by the hepatocyte is associated with lipoprotein and secreted as a complex. In support of this concept is the fact that patients with hypercholesterolemia have proportional plasma elevations of both LDL and neutral glycosphingolipids, including GL-3. The circulating GL-3 then presumably gains access to vascular endothelial and smooth muscle cells throughout the body by the high-affinity lipoprotein receptor–mediated uptake pathway. Deposits in other tissues may also be derived to a lesser extent from receptor-independent diffusion or by nonabsorptive endocytosis of globoside- or GL-3–lipoprotein complexes from the plasma. Because the lysosomes in all cells are deficient in the a-galactosidase A activity needed to degrade the accumulated glycosphingolipids, they accumulate within extended multivesicular bodies or, in more advanced stages, as free intracytoplasmic masses, which may lead to cellular dysfunction or degeneration. In addition to hepatocyte biosynthesis, bone marrow synthesizes glycosphingolipids and incorporates them into the membranes of the formed blood elements.

It has been postulated that erythrocyte globoside (GalNAc-Gal-Gal-Glc-Cer), the predominant glycosphingolipid of erythrocytes and the catabolic precursor of GL-3, may be another major metabolic source of the circulating pathogenic lipid. Globoside is presumably released into the circulation from senescent erythrocytes and is subsequently catabolized (most likely in the spleen) to GL-3. In Fabry disease, the GL-3 cannot be metabolized and may be partly released into the circulation, where it can be incorporated into both HDL and LDL fractions and/or rapidly cleared by the liver, as intravenously administered neutral glycosphingolipids are known to be. Thus, the turnover of erythrocyte and other membrane glycosphingolipids may contribute significantly to the substrate load in Fabry disease. In addition, a minor amount of GL-3 may be “excreted” into the circulation from the secondary lysosomes of various cell types throughout the body. Because the glycosphingolipid cannot be catabolized in the circulation, it would slowly accumulate at a rate reflecting the turnover of various cells, the contribution from exocytosis, lipoprotein uptake, or diffusion.

The metabolism of at least two related compounds also is abnormal in Fabry disease, as demonstrated by the accumulation of galabiosylceramide, Gal-Gal-Cer, and the blood group B antigenic substances. Affected males and carrier females who are blood group type B or AB appear to be more severely affected, presumably because of the additional accumulation of B-specific glycosphingolipids. [20]

Thus, the total amount of glycosphingolipid stored in a given tissue depends on time, the rate of accumulation from intracellular and circulatory sources, the possibilities for excretion, the individual's ABO blood type, and the presence or absence of residual a-galactosidase A activity. The pattern of glycosphingolipid accumulation, predominantly in the cardiovascular-renal system, best correlates pathophysiologically with the major clinical manifestations of the disease.

Pathophysiology of the Vasculature

Narrowing, dilatation, motor unresponsiveness, and instability of blood vessels are major features of the altered physiology associated with Fabry disease. The swollen vascular endothelial cells, often accompanied by endothelial proliferation, encroach on the lumen, causing a focal increase of intraluminal pressure, dilatation, and angiectases, as well as peripheral ischemia or frank infarction. Such changes are frequently the precursors of thromboses and infarcts of

the brain and other tissues. Muscle and peripheral nerve ischemia may contribute to the pain or fatigue. [64]

There may be progressive aneurysmal dilatation of the weakened vascular walls. This process is apparent in the retinal and conjunctival vessels and in the transition from normality to telangiectasia and frank angiokeratoma in the skin.

Observed alterations of vasomotor control may reflect either the vascular lesions themselves or the extensive glycosphingolipid deposits in autonomic ganglia and perineural sheath cells. The blood vessels in both affected males and carrier females demonstrate an impaired ability to constrict, and those in the more severely affected males show, in addition, an inability to dilate. Such a combined vascular and neural lesion may also explain the clinically observed temperature intolerance. [65]

Pathophysiology of Other Systems

NERVOUS SYSTEM The involvement of peripheral and central autonomic nerve cells may be responsible for the paresthesias, pain, hypohidrosis, gastrointestinal symptoms (e.g., nausea and diarrhea), and a variety of vague neurologic signs and symptoms. Fukuhara and associates found marked degeneration of the secretory and myoepithelial cells of sweat glands by electron microscopy and proposed that the hypohidrosis was due to local lipid deposition rather than autonomic nervous system involvement. [64] The episodic fevers may be related to lesions of the hypothalamus. The observations of a selective decrease in the number of unmyelinated and small myelinated fibers in peripheral nerves [48], [66] suggest that the selective damage to these fibers may account for the pain and hypohidrosis in this disorder. Sympathetic and parasympathetic dysfunction, particularly in distal cutaneous responses, has been evident. Alternatively, it has been suggested that the lipid deposition in the vasa nervorum may lead to the acroparesthesias, rather than the involvement of the autonomic nervous system. [64]
KIDNEY The observed abnormalities in renal function associated with Fabry disease have their basis in lesions of the nephron and of the renal vasculature, and possibly of the posterior pituitary and hypothalamus as well. Early glycosphingolipid deposits antedate clinical signs and symptoms. Alteration of the glomerular epithelial cells and their foot processes or increased desquamation of lipid-laden tubular epithelial cells may explain the observed mild proteinuria. [56] Loss of renal concentrating ability with polyuria and polydipsia may occur well in advance of a significant decrease in glomerular filtration or evidence of renal failure. The defect in concentrating ability may be due to decreased water permeability of the distal tubules and collecting ducts secondary to lipid deposition. The later and more severe renal changes are the result of vascular lesions and of hypertension.
HEART The progressive deposition of glycosphingolipids in the myocardial cells, the valvular fibroblasts, and the coronary vessels is the primary cause of cardiac disease in males with Fabry disease and some carrier females. [34] The left ventricular myocardium and the mitral valve are the sites of the most marked lipid deposition in the heart. The marked deposition of GL-3 in the coronary arteries leads to myocardial ischemia and frank infarction. [34]
OTHER INVOLVEMENT Pulmonary symptoms of Fabry disease have been attributed to the involvement of lung vasculature or of bronchial and mucous gland epithelium. [38] The airflow obstruction may be due to the loss of elastic recoil secondary to lipid deposition in lung parenchyma. The lymphedema presumably results from lymphatic obstruction or venous insufficiency secondary to lipid-laden endothelial cells.

Abnormal Distribution in Tissues

Increased concentrations of globotriaosylceramide have occurred in all tissues except erythrocytes, [67], [68] which indicates that the catabolism of these glycosphingolipids involves most tissues. In one affected male, the level of glycosphingolipid accumulation was 30- to 300-fold higher than normal levels. [68] The greatest levels of accumulation were evident in the kidney, lymph nodes, vessels, prostate, and autonomic ganglia. A comparison of globotriaosylceramide accumulation in various tissues showed that affected males had markedly increased levels in the kidney, whereas a carrier female had the highest accumulation in the heart. [69] Accumulation of galabiosylceramide has been reported to occur only in the kidney, pancreas, heart, lungs, and urinary sediment. [7], [8], [51], [68]

MOLECULAR GENETICS OF a-GALACTOSIDASE A AND FABRY DISEASE

a-Galactosidase A Gene and Transcript

Human a-galactosidase A is encoded by a single housekeeping gene, which has been localized to the chromosomal region Xq22.1. [70] The 12-kb a-galactosidase A gene has been completely sequenced. [14], [15] It contains 7 exons, ranging from 92 to 291 bp, and 6 introns, ranging from 0.2 to 3.8 kb. The gene is remarkably rich in *Alu* repetitive sequences with nine intronic repeats and three repeats in the immediate 3' flanking region; these sequences represent ˜30 percent of the 12 kb gene, or ˜ 1 *Alu* /kb. The full-length 1437-bp a-galactosidase A cDNA encodes a precursor peptide of 429 amino acids, including a 31-residue signal peptide. The mature 398 amino acid subunit contains four *N*-glycosylation consensus sequences [14]

a-Galactosidase A is synthesized as a precursor peptide of 50 kDa that is processed to the mature lysosomal subunit of 46 kDa. The transport to the lysosome is dependent on mannose-6-phosphate receptors. The enzyme functions as a homodimer.

Molecular Pathology of Fabry Disease

The isolation of the gene encoding a-galactosidase A was a major advance that has provided (1) precise patient diagnosis, carrier identification, and prenatal diagnosis; (2) understanding of the nature of the mutations causing the classic and variant forms of the disease; and (3) the means to develop molecular-based therapies, including enzyme and gene replacement.

Studies of the a-galactosidase A mutations in unrelated Fabry families have identified a variety of lesions underlying the molecular genetic heterogeneity of the disease. To date, more than 300 a-galactosidase A mutations have been identified. [71] Classically affected males have a variety of mutations, including large and small gene rearrangements, splicing defects, and missense or nonsense mutations. [72], [73] and [74] In contrast, most of those with cardiac variants of Fabry disease have missense mutations that express residual a-galactosidase A activity, including I91T, R112H, F113L, N215S, M296I, R301Q, and G328R. [72] Of note, the N215S mutation occurred in several unrelated cardiac variants.

Most mutations occur only in a single pedigree (private mutation). However, mutations at CpG dinucleotides have been found in unrelated families of different ethnic or geographic backgrounds. Haplotype analysis of mutant alleles that occurred in two or more families revealed that those with rare novel alleles were probably related, whereas those with mutations involving CpG dinucleotide “hot spots” were not. [74]

The fact that most Fabry disease patients have private mutations limits efforts to establish genotype/phenotype correlations, as attempts to predict the phenotype require more extensive clinical information from unrelated patients with the same genotype. Of interest, three mutations (R112H, R301Q, and G328R) have been identified in patients with the classic disease and the cardiac variant phenotypes, suggesting that other modifying factors are involved in disease expression. [74]

GENETICS

Mode of Inheritance

Fabry disease is transmitted by an X-linked recessive gene, located at Xq22.1 (see “ Molecular Genetics of a-Galactosidase A and Fabry Disease ”) that normally encodes the gene product, a-galactosidase A. The prevalence of Fabry disease has not been determined; the disease is rare, and it is estimated that the incidence is about 1:40,000 to 60,000 males. [20], [75] Of the more than 400 described cases of affected males, most are white; however, cases have occurred in blacks, Latin Americans, Native Americans, Egyptians, and Asians. The Fabry gene is highly penetrant in males. Clinical onset is variable; the disease usually appears during childhood, but may not appear until the second or third decade. Both intrafamilial and interfamilial variations in the clinical expression have been reported, the intrafamilial being less than the interfamilial variation.

Expressivity in the carrier female is variable. Although proven carriers may be completely asymptomatic throughout a normal life span, several carrier females have experienced complete clinical and biochemical expression of the disease, as severe as in affected males. [20] The markedly variable expression of the Fabry gene in carrier females is anticipated for X-linked enzymatic deficiencies by the random X-chromosome inactivation hypothesis, which predicts that carrier females for X-linked enzymatic defects will leave two populations of cells, one with mutant and the other with normal enzymatic activity. Two such populations have been isolated from individual cultured skin fibroblasts from obligate carriers, one with normal and the other with defective a-galactosidase A activities. [76]

Phenocopies

A phenocopy is a mimic or simulation of a specific genetic trait that is usually the result of environmental factors and, thus, is not inherited. There are two such phenocopies for Fabry disease, one that mimics the characteristic corneal opacity and another that causes renal functional and ultrastructural changes resembling those in affected males. Because suspicion of the diagnosis of Fabry disease often arises from an eye examination or renal evaluation for proteinuria, these phenocopies have significant diagnostic import.

The whorllike keratopathy of Fabry disease is readily distinguishable from the corneal opacities of other lysosomal storage diseases, but is clinically and ultrastructurally identical to the corneal dystrophy associated with long-term chloroquine therapy. [77] Chloroquine has been shown to concentrate rapidly in lysosomes, increase the intralysosomal pH, decrease the activity of specific lysosomal hydrolases, alter the rate of proteolysis, and cause the formation of lysosomal inclusions. Based on these findings, it has been proposed that chloroquine-induced keratopathy results from the pH inactivation of lysosomal a-galactosidase A and the subsequent accumulation of GL-3. In support of this concept is the finding that corneal a-galactosidase A is more sensitive to increasing pH in vitro than other lysosomal hydrolases. More recently, amiodarone has also been shown to cause a phenocopy of Fabry disease keratopathy; although presumed to be similar to that of chloroquine, the mechanism underlying the amiodarone-induced pathology has not been elucidated. [78]

Another tissue-specific phenocopy of Fabry disease occurs in individuals who are environmentally exposed to silica dust. There are descriptions of the pulmonary complications of silicolipoproteinosis, but the renal manifestations of proteinuria and lipiduria have received little attention. Ultrastructural examination of renal tissue from these individuals has revealed the typical electron-dense lamellar inclusions in the lysosomes of glomerular epithelial and endothelial cells, and proximal and distal tubular cells as observed in Fabry disease. [79] The levels of a-galactosidase A and urinary sediment glycosphingolipids were normal in one such patient. [79] Although the mechanism responsible for the silica-induced phenocopy is unknown, the finding of such lesions in biopsied renal tissue warrants the inclusion of silicosis as well as Fabry disease in the differential diagnosis.

Genetic Counseling

All families that have a member with Fabry disease should have an opportunity to receive genetic counseling. Inheritance of the Fabry gene from both affected males and carrier females should be addressed, because both genotypes transmit the gene. All sons of affected males will be unaffected, but all daughters will be obligate carriers of the gene. Carrier

females have a 50 percent chance of transmitting the gene to sons who will have the disease and a 50 percent chance of transmitting the gene to daughters who will be carriers. On the average, therefore, half the sons of carrier females will have the disease, and half the daughters will be carriers. All possible carriers among close female relatives should undergo clinical examination, biochemical studies, and mutation analysis for carrier identification. Fabry disease has been detected antenatally from cultured fetal cells and amniotic fluid obtained by amniocentesis, as well as from chorionic villus samples (see " Prenatal Diagnosis").

DIAGNOSIS

Clinical Evaluation

The history and the observation of the characteristic skin lesions and/or corneal dystrophy generally lead to the clinical diagnosis of Fabry disease. The most common childhood symptom before the appearance of the cutaneous lesions is recurrent fever in association with pain in the hands and feet. The disorder has often been misdiagnosed as rheumatic fever, neurosis, erythromyalgia, or collagen vascular disease.

The differential diagnosis of the cutaneous lesions must exclude the angiokeratoma of Fordyce, angiokeratoma of Mibelli, and angiokeratoma circumscriptum, none of which have the typical histologic or ultrastructural pathology of the Fabry lesion (see Fig. 151-3 and Fig. 151-4). Angiokeratomas of Fordyce are similar in appearance to those of Fabry disease, but are limited to the scrotum and usually appear after age 30. Angiokeratomas of Mibelli are warty lesions on the exterior surfaces of extremities in young adults; they are associated with chilblains. Angiokeratoma circumscriptum or naeviformis, which can occur anywhere on the body, is clinically and histologically similar to those of Fordyce and is not associated with chilblains.

Angiokeratomas reportedly similar to or indistinguishable from the clinical appearance and distribution of the cutaneous lesions in Fabry disease have occurred in patients with other lysosomal storage diseases, including fucosidosis, sialidosis (a-neuraminidase deficiency with or without a-galactosidase deficiency), adult-type ß-galactosidase deficiency, aspartylglucosaminuria (a lysosomal disorder that presents with mental retardation and some features of the mucopolysaccharidoses), and an adult-onset variant of a- *N*-acetylgalactosaminidase deficiency. Ultrastructural examination of these lesions reveals lysosomal substrate deposition that differs in the fine structural appearance of the respective storage material. In addition, some patients with classically appearing angiokeratoma, but no other clinical symptoms or morphologic evidence of lysosomal storage, have normal levels of a-galactosidase A and other lysosomal hydrolase activities. Clinical and pathologic details of the differential diagnosis of the skin lesion are available in reviews. [31], [80], [81]

A presumptive diagnosis of Fabry disease in affected males can be made through the findings of a careful ophthalmologic examination, the demonstration of the birefringent inclusions in the urinary sediment, or the results of skin biopsy. The observation of the characteristic corneal dystrophy on slit-lamp examination should aid in the diagnosis. Biopsied skin will reveal the refractile lipid inclusions (Maltese crosses) in blood vessels. [44] Lipid-containing macrophages may also be evident in bone marrow aspirates. Women suspected of being heterozygous carriers of the Fabry gene should undergo a careful examination for evidence of the characteristic corneal opacity on slit-lamp microscopy and for isolated skin lesions, particularly on the breasts, back, trunk, and posterolateral thighs. The histologic finding of lipid-laden cells in biopsied skin, tissues, or in the urinary sediment may also be helpful in diagnosis.

Biochemical Confirmation

The diagnosis of Fabry disease should be confirmed biochemically by the demonstration of deficient a-galactosidase A activities in plasma or serum, leukocytes, biopsied tissues, or cultured cells. [12] Alternatively, multiprocedural glycosphingolipid analyses can demonstrate theincreased levels of GL-3 in urinary sediment, plasma, or cultured skin fibroblasts (Table 151-2). [8]

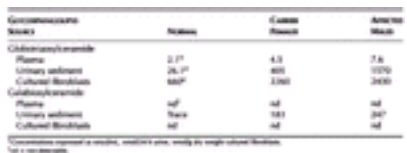

TABLE 151-2 **Mean Concentration of Globotriaosylceramide and Galabiosylceramide in Various Sources from Normal Individuals and Affected Males and Carrier Females with Fabry Disease** [8], [67], [80]

Although low or intermediate levels of a-galactosidase A activity in various tissues and their products identify many obligate carrier females, the biochemical identification of female carriers of the Fabry gene is problematic because of random X-chromosome inactivation. Thus, carriers can express levels of enzymatic activity ranging from essentially zero to normal, consistent with reports of obligate carrier females with normal a-galactosidase A activity and no keratopathy. [40] If carrier females have borderline or normal levels of enzymatic activity, then their recognition requires the identification of the specific molecular mutation present in affected males in the pedigree.

Molecular Diagnosis of Female Carriers

For families in which a specific a-galactosidase A gene lesion has been identified, carrier detection is specific. However, there are no common a-galactosidase A mutations that cause this disease, and almost every unrelated family in which a member has Fabry disease has a different mutation, [72], [74], [82], [83] necessitating a mutation study of the entire coding

region in each family. In informative families without an identified mutation, linkage analysis is possible by using intragenic single nucleotide polymorphisms and/or simple sequence repeat polymorphisms closely linked to the a-galactosidase A gene. [84]

Prenatal Diagnosis

An assay of a-galactosidase A activity in chorionic villi obtained at 9 to 10 weeks of pregnancy or a culture of amniotic cells obtained by amniocentesis at approximately 15 weeks of pregnancy permits the prenatal diagnosis of Fabry disease. [13], [85], [86] The minimum requirement for the diagnosis in a male fetus is the demonstration of deficient a-galactosidase A activity and an XY karyotype. Molecular studies by direct mutation testing or indirect studies by linkage analysis further confirm the diagnosis.

P>Biochemical and ultrastructural studies of tissues from fetuses with Fabry disease, consistent with the prenatal diagnosis, showed the a-galactosidase A activity to be defective in all tissues studied; [86] furthermore, there were increased concentrations of globotriaosylceramide in all tissues analyzed, with the exception of neural tissues. [87] Histologic and light microscopic examinations of various tissues were unremarkable, but ultrastructural examination revealed electron-dense concentric lamellar inclusions in the lysosomes of vascular endothelium, myocardial cells, renal tubules, and epithelial and endothelial cells of renal glomeruli. [86], [87]

TREATMENT

Medical Management

In Fabry disease, the chronicity of the clinical events causes severe debilitation and incapacity that extends over years. The single most debilitating and morbid aspect of Fabry disease is the excruciating pain. The pathophysiologic events that cause the incapacitating episodes of pain or the chronic burning acroparesthesias have not been clarified. With the exception of centrally acting narcotic analgesics, which have been only partially effective, conventional analgesic agents have not been successful in controlling the pain. However, the prophylactic administration of low maintenance dosages of diphenylhydantoin can provide relief from the periodic crises of excruciating pain and constant discomfort in affected males and symptomatic carriers. [21] Carbamazepine also provides pain relief. [88] The combination of diphenylhydantoin and carbamazepine can be used if either is not effective. Recently, gabapentin (Neurontin) has been used to prevent pain. [20]

Care of patients with regard to cardiac, pulmonary, and central nervous system manifestations remains nonspecific and symptomatic. Obstructive lung disease occurs in older affected males and carrier females, with more severe impairment in smokers; therefore, patients should be discouraged from smoking.

Renal Transplantation

Because renal insufficiency is the most frequent and serious late complication in patients classically affected by Fabry disease, chronic hemodialysis and/or renal transplantation have become lifesaving procedures. The first renal transplant in a patient with Fabry disease was performed in 1967. [89] Contrary to an unfavorable early report, [90] experience has supported the clear benefit of transplantation for patients with this disease. [91] In fact, recent reviews of the registries of the European Renal Association–European Dialysis and Transplantation Association and the United States Renal Data System suggest excellent outcomes for renal transplantation in Fabry disease. [91], [92] For example, when 93 patients who received transplants during the 10-year period from 1988 to 1998 were compared to a matched control group, transplant recipients with Fabry disease had equivalent, if not better, 5-year patient (82 versus 83 percent) and graft (67 versus 75 percent) survival results, respectively. Also, immune function in Fabry disease–affected males has been shown to be similar to that in other uremic patients, obviating any immunologic contraindication to transplantation in this disease. [93]

Successful transplantation corrects renal function, and the engrafted kidney will remain histologically free of glycosphingolipid deposition because the normal a-galactosidase A activity in the allograft will catabolize endogenous renal glycosphingolipid substrates. Rarely, electron microscopy of transplanted cadaveric kidneys has detected isolated glycosphingolipid deposits as small myelin figures in vascular endothelial cells. These endothelial cells were derived from the recipient and were deficient in a-galactosidase A. [53]

Transplantation of kidneys from Fabry carriers, which already may contain significant substrate deposition, should be avoided. In one reported case, transplantation of an allograft from a carrier to an affected male relative resulted in decreased renal function (serum creatinine, 3.0 mg/dL) 5 years later. [94] A kidney donated by a carrier female to her unaffected daughter showed glycolipid deposition in podocytes 7 years after transplantation. Although these deposits were not extensive, their persistence suggests that the uptake of the recipient's circulating normal enzyme by podocytes was minimal. [95] Therefore, it is essential to screen all potential related donors in order to exclude affected males and carrier females for the Fabry gene. Because enzyme analysis does not reliably detect carriers, it is necessary to demonstrate the absence of the specific a-galactosidase A mutation or disease haplotype in females who are potential donors.

In addition to its role in the treatment of the renal failure associated with Fabry disease, kidney transplantation has been undertaken to determine if the allograft could provide normal a-galactosidase A for substrate metabolism. [96] Hypothetically, the normal kidney might metabolize the accumulated substrate either by uptake and catabolism within the allograft or by the release of the active enzyme into the circulation for uptake and metabolism in other tissues, such as the vascular endothelium. Although biochemical and/or clinical improvement was initially reported, [96] no clear biochemical effect could be demonstrated. Several patients with successful engraftment who survived for 10 to 15 years have expired from complications of vascular disease [97] or other unrelated disorders. [98] Thus, the use of renal allografts to alter the rate

of progressive systemic substrate accumulation is not effective, and patients with allografts should consider enzyme replacement therapy to prevent the late cardiac and cerebrovascular complications of Fabry disease.

Enzyme Replacement Therapy

Early studies of enzyme replacement in Fabry disease indicated the feasibility of this therapeutic approach. [99], [100] and [101] However, the limiting obstacles were the inability to produce sufficient amounts of purified normal enzyme and the lack of an animal model in which to evaluate the pharmacokinetics and pharmacodynamics required for the design of clinical trials.

PRECLINICAL STUDIES IN FABRY MICE: PROOF OF CONCEPT The isolation of the human a-galactosidase A cDNA [14] and its high-level expression in CHO cells made it possible to overcome early obstacles to enzyme replacement therapy. [102] It provided a source of selectively secreted recombinant human enzyme that was highly sialylated and had mannose-6-phosphate residues for lysosomal targeting. In addition, the generation of an a-galactosidase A knockout mouse permitted the evaluation of enzyme replacement in an animal model of Fabry disease. [103], [104] With these advances, preclinical studies of four recombinant human a-galactosidase A glycoforms were performed in the enzyme-deficient mice. The pharmacokinetics and biodistributions were determined for the glycoforms, which differed in sialic acid and mannose-6-phosphate content. [103] Normal (or higher) enzymatic activity levels were reconstituted in the liver, spleen, heart, lung, and kidney following eight every other day doses of 10 mg/kg of the highly sialylated glycoform, a-galactosidase A-1. Four days later, a-galactosidase A-1 activity continued in the liver and spleen at 30 and 10 percent of that recovered at 1 h postinjection, respectively. Furthermore, GL-3 was cleared from the liver, heart, spleen, kidney, and plasma in a dose-dependent manner. These preclinical animal studies provided “proof of concept,” as well as the pharmacokinetic and pharmacodynamic data critical for the design of clinical trials of enzyme replacement.
PHASE 1 AND 1/2 CLINICAL TRIALS The preclinical studies served as the basis for Phase 1 and Phase 1/2 clinical trials. [18] A Phase 1/2 open-label, dose-escalation study involved 15 classically affected males who received five doses of recombinant human a-galactosidase A. [16] The enzyme was well tolerated, and rapid, marked reductions in plasma and tissue GL-3 were observed biochemically, histologically, and ultrastructurally. Mean GL-3 content was decreased 84 percent in the liver (n = 13), was markedly reduced in the kidney in 4 of 5 patients, and was modestly lowered in the endomyocardium of 4 of 7 patients. In addition, GL-3 deposits were cleared to near normal or were markedly reduced in the vascular endothelium of the liver, skin, heart, and kidney. These patients reported improvements in the level of pain, ability to sweat, and quality of life. Four patients experienced mild-to-moderate infusion reactions that were managed conservatively. Of the 15 patients, 8 (53 percent) developed IgG antibodies to a-galactosidase A; however, the antibodies were not neutralizing. These results provided dose-response data and explored possible primary efficacy endpoints for a Phase 3 pivotal trial.
PHASE 2 AND PHASE 3 CLINICAL TRIALS A single-center, double-blind, placebo-controlled Phase 2 trial of a-galactosidase A replacement involved 26 patients at a dosage of 0.2 mg/kg every 2 weeks for 6 months. [19] “Pain at its worst” in treated patients decreased significantly compared to no significant change in the placebo group. Mean creatinine clearance also was significantly improved; however, one placebo-treated patient went into renal failure. The Phase 3 trial was a multinational, double-blind, randomized, placebo-controlled trial involving 58 patients and eight centers in four countries. [17] Each patient received an infusion of 1 mg/kg of recombinant a-galactosidase A or placebo every 2 weeks for 20 weeks. The primary efficacy endpoint was the clearance of stored GL-3 in the vascular endothelium of the kidney, the organ of greatest morbidity in Fabry disease. Twenty of 29 (69 percent) patients treated with the enzyme achieved the primary endpoint (i.e., essentially normal renal vascular endothelial cells as determined by histologic examination; scored normal or near normal, on a 0-3 seventy scale), while 8 of the other 9 treated patients all had decreased renal vascular GL-3 deposits. The ninth patient's posttreatment biopsy was lost. In contrast, no patient receiving the placebo cleared the renal endothelial GL-3 deposits. These results were highly significant ($p < 0.001$). Compared to the levels found in the placebo group, the amount of GL-3 decreased significantly in the heart ($p < 0.001$) and the skin ($p < 0.001$) in response to the enzyme infusions. Clearance of plasma GL-3 was directly correlated with renal endothelial glycosphingolipid clearance; patients receiving the enzyme cleared the accumulated GL-3 in the circulation. The enzyme infusions were well tolerated, and the adverse event profiles of both groups were comparable, with the exception of transient mild-to-moderate infusion reactions in the enzyme-treated group, which were managed conservatively. Of the 29 enzyme-treated patients, 24 (83 percent) developed IgG antibodies, as might be expected for patients classically affected by Fabry disease who have essentially no native a-galactosidase A activity and are cross-reacting immunologic material (CRIM)–negative for the enzyme protein. However, seroconversion did not influence the efficacy of treatment. When the Phase 3 trial was completed, all 58 patients enrolled in an open-label extension study. All 29 enzyme-treated patients continued enzyme therapy, while all 29 patients originally randomized to the placebo group now received enzyme therapy. After 6 months of treatment, all 22 former placebo patients who underwent biopsies had cleared the GL-3 deposits from their renal vascular endothelial cells (as determined histologically). After 12 months of enzyme treatment, 22 of 23 patients who had optional renal biopsies retained their 0 scores for renal vascular endothelial GL-3 clearance. In total, 44 of 45 patients (98 percent) who received enzyme treatment for 6 or 12 months achieved 0 scores, indicating that the enzyme effectively cleared the renal vascular endothelial GL-3 deposits. Similar results (i.e., 0 scores) were found for GL-3 clearance in skin (96 percent) and heart (75 percent) in the extension study. Thus, the results of the extension study confirmed the results of the double-blind Phase 3 trial and demonstrated that the patients treated with enzyme for 12 months had continued GL-3 clearance from the vascular endothelium in the kidney, heart, and skin, the key sites of pathology in this disease. In addition, histologic examination of other renal, cardiac, and skin cell types revealed complete or partial clearance of accumulated GL-3. These findings further demonstrated the efficacy and safety of a-galactosidase A replacement in Fabry disease. On the basis of these findings, the European Agency for Evaluation of Medical Products has approved a-galactosidase A replacement therapy for Fabry disease, and approval by the Food and Drug Administration is pending. Because this disease is inborn, and because GL-3 accumulation begins in utero, treatment should begin in early childhood as soon as practical. In addition, transplanted or dialysis patients should receive enzyme therapy to treat or to prevent the morbidity and mortality associated with their progressive cardiac and cerebrovascular disease. After years of research, development, and evaluation, specific treatment for patients with Fabry disease may be available.

REFERENCES

Lipoid proteinosis is an uncommon, recessive autosomal disorder linked to loss of function mutations in the extracellular matrix protein 1 gene. [1] It is characterized by noninflammatory persistent papules on the skin and mucous membranes. The accumulation of a basement membrane–like material in various connective tissues produces the papules. The detailed pathogenesis of the disease is not yet clear. Therapy is mainly symptomatic. [2]

HISTORICAL ASPECTS

In 1929, two Viennese, E. Urbach and C. Wiethe, a dermatologist and an otorhinolaryngologist, described an entity that they called lipoidosis cutis et mucosae on the basis of histologic investigations that demonstrated the deposition, in skin and mucous membranes, of a lipoid material associated with protein. [3] The initial name was later modified to lipoid proteinosis to avoid confusion with other lipoidoses. This syndrome is also called hyalinosis cutis et mucosae and may be referred to as Urbach-Wiethe disease eponymously.

INHERITANCE

Parental consanguinity, affected siblings, and equal numbers of male and female patients suggest autosomal recessive transmission of lipoid proteinosis. Most of the reported patients have a European background, and more than half of them belong to or are related to the Germanic linguistic group. Interesting studies performed in the Afrikaaner population of South Africa suggest that most of the reported cases in that country derive from descendants of a brother and a sister who immigrated to South Africa from Germany in the middle of the seventeenth century.

Using DNA from three affected siblings in a consanguineous Saudi Arabian family, the group of J. McGrath performed a genome-wide linkage analysis and mapped the disorder to 1q21. [1] The same linkage also appeared in five other families. Using the candidate gene approach, the group identified six different homozygous loss-of-function mutations in the extracellular matrix protein 1 gene (*ECM1*) and a reduction of ECM1 immunostaining in lipoid proteinosis skin. Knowing the defect did not solve the pathogenesis of the disorder, because the biologic function of ECM1 and its shorter splice variant are not yet known.

CLINICAL PRESENTATION

The first clinical sign of lipoid proteinosis is often hoarseness, caused by infiltration of the laryngeal mucosa that has developed by birth or in early childhood. Skin lesions usually appear shortly afterward or simultaneously. An intercurrent event as benign as, for example, vaccination may precipitate the clinical signs.

Location of Lesions

Patients with lipoid proteinosis may have papular, nodular, or diffuse yellow, waxy infiltrates on the face, the axillae, and the scrotum. Skin lesions resembling pitted acne scars may appear not only on the face, but also in nonacneogenic regions. Other lesions of the face resemble solar elastosis because the deposition of yellow material induces a marked thickening of the skin with deep wrinkles (Fig. 152-1). The classic and most easily recognizable sign, although not always present, is the beaded arrangement of waxy papules along the eyelids (see Fig. 152-1).

FIGURE 152-1 Lipoid proteinosis. Note the beaded arrangement of waxy papules along the margin of both eyelids and the pseudo solar elastosis of the cheeks and forehead. (*Courtesy of O. Braun-Falco, Munich.*)

Lesions on the scalp may occur and cause alopecia. Lesions on non–sun-exposed skin can be present, as well as alterations of the mucous membranes. The tongue is often firm, and its mobility may be limited (Fig. 152-2). The tonsils and other areas in the oral cavity may be infiltrated. A yellow discoloration of the lips is characteristic (see Fig. 152-2). Traumatized skin lesions may ooze and become hyperkeratotic.

FIGURE 152-2 Discoloration of the lips in lipoid proteinosis. Limitation of mobility of the tongue is related to infiltration of the frenulum. (*Courtesy of O. Braun-Falco, Munich.*)

The palm and dorsum of the hands (Fig. 152-3A and Fig. 152-3B), elbows, knees (Fig. 154-4), and buttocks may also show signs of hyperkeratosis, possibly related to frequent trauma in these locations.

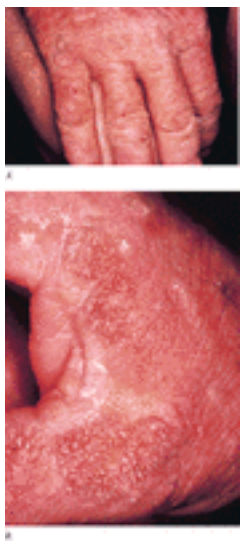

FIGURE 152-3 Hyperkeratotic papular lesions on dorsum of hands (*A*), interdigital web, and the sides of the fingers (*B*) in lipoid proteinosis.

FIGURE 152-4 Verrucous nodular lesions on the knee in lipoid proteinosis.

Involvement of Other Organs

Recurrent parotitis associated with lipoid proteinosis is related to occlusion of the salivary canal. The teeth are abnormal in almost 30 percent of patients; often, for example, patients lack permanent upper lateral incisors. Except for lesions in the oropharyngeal cavity, alterations of the digestive tract are uncommon and reported only as autopsy findings in a few patients. The respiratory tract may be involved by infiltration of the vocal cords and obstruction.

A bilateral, intracranial, bean-shaped suprasellar calcification appears in 50 percent of the patients, but not all of these patients present with epilepsy or any other signs of cerebral dysfunction. This calcification occurs in blood vessels of the hippocampal portions of the temporal lobes. Abnormalities of the peripheral nervous system are uncommon; four South African patients had peripheral nervous system lesions that may have been due to congenital analgesia.

Infiltration of the eyelids induces malpositioning of the eyelashes, causing corneal ulceration. Alopecia of the eyelashes

and eyebrows occurs. Focal degeneration of the macula has been evident in one-third of the examined patients.

Cardiac, endocrine, and urogenital disorders have been seen, but are not clearly a part of the spectrum of this disease.

Microscopic examination shows deposition of hyaline material around the blood vessels in internal organs. It indicates that the defect is a generalized disease. These changes appear to be asymptomatic.

CLINICAL COURSE AND PROGNOSIS

Except for the risk of respiratory obstruction that it carries for infants, lipoid proteinosis is compatible with a normal life span. Lesions of the upper respiratory tract may cause problems in patients with tracheotomy or disease of the trachea. The disfiguring lesions and the permanent hoarseness seriously impair the quality of life, however.

LABORATORY FINDINGS

No laboratory finding is typical of lipoid proteinosis. In some patients, glucose metabolism is abnormal. Porphyrins, liver function, protein electrophoresis, lipids, and lipoproteins are normal in the classic form of the disease. There may be signs of chronic or acute inflammation (increased alpha $_2$ or gamma globulins). Elevated serum calcium occurs rarely.

DIFFERENTIAL DIAGNOSIS

It is necessary to differentiate lipoid proteinosis from other diseases related to the deposition of amorphous material in the dermis. The differential diagnosis applies at both clinical and histopathologic levels.

Porphyria, especially erythropoietic protoporphyria, shows deposition of a PAS-positive material around the blood vessels, primarily in sun-exposed areas. Because light sensitivity is not a feature of lipoid proteinosis, the observation of lesions in non–sun-exposed sites aids the diagnosis. The pathologist should be aware of the site of the biopsy for differential diagnosis.

Lipid deposition in the various forms of xanthomatosis is rarely a problem of differential diagnosis. Furthermore, xanthoma cells never occur in lipoid proteinosis.

Amyloidosis may resemble lipoid proteinosis. Often, however, the development of amyloidosis is more progressive and may involve the kidneys, heart, and other tissues. Amyloid deposition may occur in the skin of lipoid proteinosis patients. The clinical presentation of diabetic microangiopathy is often different from that of lipoid proteinosis, but the pathologic picture may be confusing.

Acquired lipoid proteinosis in a patient with monoclonal immunoglobulinopathy has been reported. This form of the syndrome can be differentiated by immunoelectrophoresis of the plasma proteins.

MORPHOLOGIC, BIOCHEMICAL, AND GENETIC FINDINGS

The main manifestations of lipoid proteinosis are related to the deposition of an amorphous or laminated material in the connective tissues. The location and the immunohistochemical nature of the deposit support its relation to components of the basement membrane zone. It displays a PAS-positive reaction that resists digestion by enzymes and contains collagen type IV and laminin. The deposition of this material is progressive and often takes place next to cells that are known to synthesize a basement membrane.

Little is known about the initial stage of the disease. Most often, biopsy specimens collected from obvious lesions show deposition of the amorphous eosinophilic material initially around walls of the small and medium-sized blood vessels in the papillary dermis, with a pronounced “onion-skin” proliferation of the adventitia. [4] The hyaline material also appears around the smooth muscle cells of the arrectores pilorum and ultimately involves the surrounding dermis of the sweat glands. The development of these lesions may also involve the myoepithelial cells. The amount of amorphous material increases with time to progressively encase the adnexae, filling up the dermis and pushing aside most of the normal collagen bundles (Fig. 152-5).

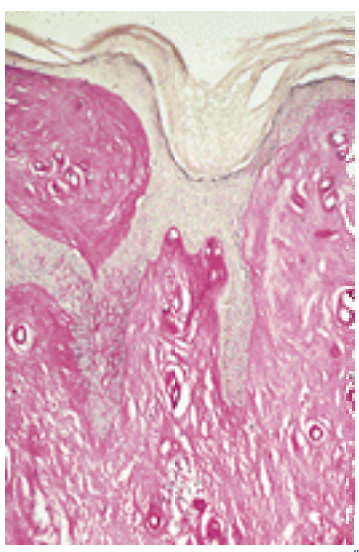

FIGURE 152-5 Extensive deposition of a PAS-positive material in the papillary dermis of a pitted acne scar lesion in

lipoid proteinosis.

By electron microscopy, the deposit seems to be composed of small granules and short filaments of low electron density, 3 to 5 nm in diameter. Electron-dense bodies (mineralized) appear around the sweat glands. Lysosomal inclusions, similar to those found in Farber disease, have been seen in the cutaneous lesions and normal skin of two unrelated patients. [5] A storage disease was considered as the mechanism for the disorder. [6]

The deposit in lipoid proteinosis is composed mainly of noncollagen protein, although the concentric layers of basement membrane–like material contain collagen types III and IV and laminin, as shown by immunodetection. A portion of this material, solubilized by reduction and injected to produce antibodies in rabbits, induced antibodies that recognize antigens also detectable in normal skin. This indicates that the disease may be related to the overproduction or the lack of degradation of a normal component of the human skin.

The lipid nature of the deposit remains controversial. Solubilization in various solvents gave nonreproducible results. The deposit stains with lipophilic agents, suggesting that unsaturated hydrophobic lipids may be present.

Exons 6 and 7 are the most common sites for mutations, and consanguinity has been present in most cases reported to date. [7]

THERAPY

There is presently no effective therapy. Topical glucocorticoids have been extensively used with beneficial effect.

Some patients have undergone plastic surgery and dermabrasion to remove lesions. The value of these therapies is questionable, because trauma has seemed to increase the deposition of the pathologic material. Some benefit has, however, been reported.

CALCIUM

Calcium is involved in many physiologic processes. It is key to skeletal muscle and myocardial contraction, neurotransmission, and blood coagulation. In addition, it is the primary mineral in the bony skeleton. On the cellular level its diverse functions include transmission of information into and between cells, regulation of plasma membrane potential, and exocytosis. Only over the last 20 years has its effect on skin been fully appreciated. Calcium was first discovered to influence epidermal cell growth and differentiation in 1980, when it was shown that growth and differentiation of mouse epidermal cells in culture depended on extracellular calcium. [1] In cell culture, keratinocytes proliferate rapidly in low calcium conditions, but do not differentiate. With higher concentrations of extracellular calcium, keratinocytes begin to differentiate and express markers of terminal differentiation, such as transglutaminase activity and involucrin. Calcium also plays an integral role in modulating cell–cell adhesion. The function of the cadherin family of cell–cell adhesion molecules is calcium dependent, and mutations in plasma membrane calcium pumps were recently found to cause the acantholytic disorders Darier's disease and Hailey-Hailey disease. [2], [3]

REGULATORY HORMONES

Parathyroid Hormone

Parathyroid hormone (PTH) is an 84-amino acid, single-chain polypeptide that is synthesized in the parathyroid glands. Under normal conditions, a decrease in the serum concentration of ionized calcium results in an increase in PTH production, whereas an increase in the serum concentration of ionized calcium results in a decrease in PTH production. An increased PTH plasma concentration causes an increase in plasma calcium concentration by its direct effects on the kidney and bone and its indirect effects on the intestine. In the kidney, PTH increases renal tubular reabsorption of calcium and increases renal clearance of phosphate. PTH also acts directly on the bone to increase the plasma calcium concentration. It does this acutely by mobilizing calcium from bone into the extracellular fluid. Osteocytes and osteoblasts are the presumed target cells for this effect. PTH also stimulates osteoclastic bone resorption, possibly by stimulating osteoblasts to release factors that activate osteoclasts. PTH together with a decreased plasma phosphate concentration stimulates 1a-hydroxylase activity in the kidney, causing an increase in the plasma concentration of $1,25(OH)_2D_3$. $1,25(OH)_2D_3$ increases intestinal absorption of calcium.

Many malignant cells, particularly those derived from squamous epithelia, produce the PTH-like peptide that is responsible for the humoral hypercalcemia of malignancy. Cultured nonmalignant human keratinocytes also produce a similar protein called parathyroid hormone–related peptide (PTHrP). The existence of receptors that recognize PTH and PTH-like peptides on dermal fibroblasts suggests that PTH and keratinocyte-produced PTHrP may contribute to normal skin physiology.

The levels of PTH are elevated in some patients with keratinization disorders, [4] such as ichthyosis vulgaris, lamellar ichthyosis/nonbullous congenital ichthyosiform erythroderma, pityriasis rubra pilaris, ichthyosis linearis circumflexa, and Darier's disease. The cause and significance of this elevation are unknown.

Calcitonin

Calcitonin is a 32-amino acid polypeptide that is produced by parafollicular or C cells of the thyroid gland. Calcium is the primary stimulant for calcitonin secretion. Calcitonin lowers the serum calcium concentration, primarily through osteoclast inhibition, but whether it plays a major role in serum calcium metabolism in vivo is unclear.

Vitamin D

Vitamin D_3, or cholecalciferol, is a secosteroid formed by the opening of the beta ring of 7-dehydrocholesterol. In humans, this formation occurs in the basal layer of the epidermis. [5] First there is a UVB-mediated conversion of 7-dehydrocholesterol to previtamin D_3. Previtamin D_3 then undergoes thermal isomerization to form vitamin D_3.

Vitamin D_3 is inert. To become biologically active, it must first be hydroxylated at carbon position 25 in the liver and then at carbon position 1a by the enzyme 1a-hydroxylase in the kidney. 1a-Hydroxylase is tightly regulated. PTH and calcitonin increase its activity, whereas calcium, phosphate, and $1,25(OH)_2D_3$ inhibit it.

$1,25(OH)_2D_3$, like PTH, increases the concentration of plasma calcium. Its primary action is to stimulate the active transport of calcium across the intestine. $1,25(OH)_2D_3$ also increases the plasma calcium concentration by mobilizing calcium from bone. The simultaneous presence of PTH appears to be necessary for this effect.

$1,25(OH)_2D_3$ not only is important in calcium regulation but also plays a major role in the growth and differentiation of tissues, including skin. Receptors for $1,25(OH)_2D_3$ are present on epidermal keratinocytes, pilosebaceous structures, and in the dermis. In human keratinocyte cultures, $1,25(OH)_2D_3$ causes a dose-dependent decrease in proliferation, an increase in morphologic differentiation, and an increase in the terminal differentiation markers transglutaminase activity and involucrin. [6] Cultured human keratinocytes can convert $25(OH)D_3$ to $1,25(OH)_2D_3$, suggesting that the epidermis may regulate its own growth and differentiation by endogenously produced $1,25(OH)_2D_3$. [6] The mechanism by which $1,25(OH)_2D_3$ may induce differentiation of epidermal cells may be through calcium, because calcium is required for terminal differentiation of keratinocytes. $1,25(OH)_2D_3$ may facilitate calcium entry into cells and, through induction of calcium-binding proteins, facilitate the ability of calcium to regulate various cellular processes. [6] In addition, $1,25(OH)_2D_3$ may effect terminal differentiation hormonally.

ABERRANT CALCIFICATION AND OSSIFICATION

Despite the careful regulation of serum calcium, calcification and ossification of cutaneous and subcutaneous tissues may occur. Calcification is the deposition of insoluble calcium salts; when it occurs in cutaneous tissues it is known as *calcinosis cutis*. Ossification is the formation of true bony tissue by the deposition of calcium and phosphorus in a proteinaceous matrix as hydroxyapatite crystals. Cutaneous calcification may be divided into four major categories: dystrophic, metastatic, idiopathic, and iatrogenic (Table 153-1). Dystrophic calcification is the most common type of calcinosis cutis and occurs as a result of local tissue injury or abnormalities. Although calcium and phosphate metabolism and serum levels are normal, local tissue abnormalities, such as alterations in collagen, elastin, or subcutaneous fat may precipitate calcification. The internal organs usually remain unaffected. Metastatic calcification is the precipitation of calcium salts in normal tissue secondary to an underlying defect in calcium and/or phosphate metabolism. The calcification is usually widespread and affects predominantly blood vessels, kidneys, lungs, and gastric mucosa. Cutaneous and subcutaneous tissues also may be involved. All patients presenting with signs of metastatic calcification should receive a calcium and phosphate metabolic evaluation. Idiopathic calcification occurs without identifiable underlying tissue abnormalities or abnormal calcium and/or phosphate metabolism. Cutaneous calcification also may be iatrogenic. Cutaneous ossification most commonly occurs secondary to local tissue alteration or preexisting calcification. Any calcifying disorder of the skin may ossify secondarily. On rare occasions, primary cutaneous ossification may occur without underlying tissue abnormalities or preexisting calcification (Table 153-2).

DYSTROPHIC CALCIFICATION

Connective Tissue Diseases

Dystrophic calcification frequently occurs in connective tissue diseases. Scleroderma and CREST syndrome (*c*alcinosis cutis, *R*aynaud's phenomenon, *e*sophageal dysfunction, *s*clerodactyly, *t*elangiectasia) are notable examples that are frequently associated with calcinosis cutis. In these disorders, nodules and plaques of calcium deposits may occur in the skin, subcutaneous tissue, muscle, or tendons, usually at least 10 years after disease onset. The calcium deposits most commonly occur on the upper extremities, especially on the fingers and wrists, but may occur in any area subject to trauma or motion. As the calcifications enlarge, they may ulcerate and exude a chalky material. Long-term diltiazem therapy has been used successfully in patients with calcinosis cutis associated with scleroderma or CREST syndrome. [7]

Dystrophic calcification also occurs in dermatomyositis. It is more commonly associated with juvenile rather than adult-onset dermatomyositis, occurring in 44 to 70 percent of children as opposed to 20 percent of adults. [8] The calcification tends to occur 2 to 3 years after disease onset. The subcutaneous calcified nodules most frequently appear on the elbows, knees, shoulders, and buttocks. The calcium deposits may be painful and can ulcerate. They also may exude a chalky material, form sinuses, and become chronically infected. Particularly in children, calcium salt deposition may become quite extensive, progressing along fascial planes of skin and muscle, forming an “exoskeleton,” and leading to significant morbidity and mortality. Calcinosis cutis in dermatomyositis is difficult to treat; however, if the patient survives long enough, the calcified nodules may improve spontaneously. A diet low in calcium and phosphate along with aluminum hydroxide may arrest or facilitate regression of the calcified nodules. [9] Disodium etidronate has also been used with some success, and intralesional glucocorticoids may have limited use. [10], [11] Diltiazem and colchicine have been reported to improve the calcinosis cutis in some patients. [12], [13] Because high levels of vitamin K–dependent ?-carboxyglutamic acid have been found in involved tissue of patients with calcinosis cutis, some investigators have treated patients with low-dose warfarin and found that it decreased the amount of extraskeletal ossification as measured by bone scan. [14] However, because none of the patients showed clinical improvement, this treatment has largely been abandoned. In advanced cases, glucocorticoid or immunosuppressant therapy may be attempted. Occasionally, calcium deposits must be removed surgically to clear sinus tracts, ulcers, or chronic infections.

Although uncommon, calcinosis cutis has been described in systemic lupus erythematosus, [15] subacute cutaneous lupus, [16] and discoid lupus erythematosus. [17]

Panniculitis

Pancreatic enzyme panniculitis is a type of lobular panniculitis that commonly demonstrates dystrophic calcification. Pancreatic enzyme panniculitis occurs in patients with pancreatitis or pancreatic adenocarcinoma and is presumably caused by the action of liberated pancreatic enzymes on subcutaneous fat. The fatty acids formed by lipolysis may combine with calcium and form calcium soap.

In subcutaneous fat necrosis of the newborn, erythematous, well-defined nodules and plaques occur during the first few weeks of life over the cheeks, back, buttocks, and extremities. The affected infants are generally otherwise healthy, and the nodules and plaques usually clear spontaneously. Occasionally, the lesions calcify, and in a small subset of patients symptomatic hypercalcemia may develop. [18]

Panniculitis may occur with connective tissue diseases and, like their cutaneous counterparts, may show dystrophic calcification. Lupus profundus and panniculitis associated with dermatomyositis may show calcification.

Inherited Disorders

Dystrophic calcification occurs in patients with pseudoxanthoma elasticum (PXE). PXE is a hereditary disorder of elastin tissue characterized by progressive calcification of elastin fibers, primarily within the skin, Bruch's membrane of the retina, and the cardiovascular system. The gene responsible for causing PXE was recently mapped to chromosome 16p13.1 and was identified as the ABC-C6 gene. [19] Although its exact function is unknown, this gene is thought to play a critical role in transmembrane transport. Most patients with PXE have normal calcium-phosphate metabolism, but a few have been identified who have abnormal calcium, phosphate, and/or vitamin D metabolism. Patients in this subset may develop metastatic calcification in the form of calcified or ossified tumors, calcification of the falx cerebri, and arterial calcification. [20], [21]

Ehlers-Danlos syndrome (EDS) is a group of inherited disorders of fibrillar collagen metabolism. Mutations in the *COL5A1, COL5A2,* and *COL5A3* genes encoding for collagen precursor proteins have been identified in some patients with classic forms of EDS. [22], [23] and [24] The skin characteristically shows hyperelasticity and fragility with formation of pseudotumors and large gaping scars. In addition, particularly in EDS type I, subcutaneous calcified spheroids may appear. Subcutaneous spheroids are thought to represent calcified ischemic fat lobules. Calcification of healing surgical incisions has also been reported in patients with Ehlers-Danlos syndrome. [25]

Werner's syndrome is an inherited disorder that leads to premature aging. The skin and subcutaneous tissues are often scleroderma-like in appearance and may show calcification. In one study, 12 of 24 patients with Werner's syndrome had soft tissue calcification. [26]

Calcinosis cutis presenting as numerous, small, yellow papules on the extremities has also been reported to occur in

association with Rothmund-Thomson syndrome. [27]

Porphyria Cutanea Tarda

Dystrophic calcification has been observed in patients with porphyria cutanea tarda (PCT). Sclerodermoid plaques with dystrophic calcification have occurred on the preauricular area, scalp, neck, and dorsa of the hands. [28] In one case report, a 78-year-old male with PCT developed extensive sclerodermoid changes with ulcerations on his torso, upper arms, and back. [29] The ulcerations contained transepidermally eliminated sheets of calcification.

Cutaneous Neoplasms

Dystrophic calcification occurs in association with a variety of benign and malignant cutaneous neoplasms. Often the neoplasms also show ossification in the surrounding stroma.

Pilomatricomas are the most common cutaneous neoplasms that manifest calcification and ossification. Recently, activating mutations in the adherens junction protein ß-catenin have been identified in a series of sporadic cases of pilomatricomas. [30] Approximately 75 percent of pilomatricomas show calcification and 15 to 20 percent show ossification. Some pilomatricomas perforate and exude a chalky material containing calcium. Ossification usually occurs within the connective tissue adjacent to the shadow cells, probably through metaplasia of fibroblasts into osteoblasts.

Other neoplasms reportedly are associated with calcification and ossification. Twenty-five percent of pilar cysts show foci of calcification, and approximately 20 percent of basal cell carcinomas show calcification. [31], [32] Intradermal nevi may infrequently show ossification, probably as a result of inflammation or folliculitis. [33] Mixed tumors (chondroid syringomas) may also show calcification and ossification. However, unlike other neoplasms, the ossification occurs within the tumor via ossification of the chondroid cells, much like endochondral bone formation occurring in the epiphyses of bones. Although rare, ossification has also been described in desmoplastic malignant melanomas and atypical fibroxanthomas. [34], [35] Other neoplasms rarely associated with ossification include pyogenic granulomas, hemangiomas, neurilemomas, trichoepitheliomas, and seborrheic keratoses.

Infections

Infectious agents may produce enough cutaneous damage to cause dystrophic calcification. Parasitic infections that may result in calcinosis cutis include onchocerciasis, [36] caused by the filaria *Onchocerca volvulus,* and cysticercosis, caused by the tapeworm *Taenia solium*. Calcinosis cutis has been reported as a complication of intrauterine herpes simplex infection. [37]

Trauma

Dystrophic calcification has been reported in a variety of settings where local tissue injury occurs, such as in scarring caused by burns, trauma, neonatal heel sticks, and surgery. One case report described calcification in abdominal keloids. [38]

METASTATIC CALCIFICATION

Chronic Renal Failure

Metastatic calcification most commonly occurs in chronic renal failure and takes the form of either benign nodular calcification or calciphylaxis. In chronic renal failure, decreased clearance of phosphate results in hyperphosphatemia. In addition, the impaired production of $1,25(OH)_2D_3$ results in a decrease in calcium absorption from the intestine and decreased serum calcium levels. The hypocalcemia results in increased PTH production and secondary hyperparathyroidism. Elevated levels of PTH cause bone resorption and mobilization of calcium and phosphate into the serum, leading to normalization of the serum calcium concentration but marked hyperphosphatemia. If the solubility product of calcium and phosphate is exceeded, metastatic calcification may occur. In benign nodular calcification, the calcifications typically occur at periarticular sites, and their size and number tend to correlate with the degree of hyperphosphatemia. The lesions disappear with normalization of calcium and phosphate levels.

Calciphylaxis is a life-threatening disorder characterized by progressive vascular calcification, soft tissue necrosis, and ischemic necrosis of the skin. Clinically it presents as firm, extremely painful, well-demarcated, violaceous plaques associated with soft tissue necrosis and ulceration (Fig. 153-1). The lesions may occur anywhere, but the lower extremities are most frequently involved. [39] The mortality rate is estimated to be approximately 80 percent. Histopathologically, there is medial calcification of small and medium-sized arteries with intimal hyperplasia, primarily in dermal and subcutaneous tissues. Calciphylaxis occurs almost exclusively in patients with a history of chronic renal failure and prolonged secondary hyperparathyroidism. However, there exist rare reports of the occurrence of calciphylaxis in the absence of renal failure. [40] Most of the patients reported are female, and there may be an association with obesity and poor nutritional status. [41], [42] Calciphylaxis is considered a type of metastatic calcification, although the calcium and phosphate solubility product is not elevated in all patients.

FIGURE 153-1 Calciphylaxis. The lesions develop as violaceous plaques that may progress to necrotic ulcers, as shown in this patient.

The pathogenesis of calciphylaxis is unknown. One theory is based on Selye's experimental animal studies in which calciphylaxis was induced in rats by exposing them to a sensitizing agent, such as PTH, dihydrotachysterol, or vitamin D, and then exposing them to a challenging agent, such as metallic salts, egg albumin, or glucocorticoids. [43] Whether or not Selye's studies are applicable to calciphylaxis in humans has been the subject of debate. In Selye's report, the clinical description of the treated rats differs from the clinical appearance of calciphylaxis in humans, and the histopathology was massive calcium deposition within connective tissue and not medial calcification of arteries.

Some patients with calciphylaxis have decreased protein C function. Protein C is a potent anticoagulant synthesized in the liver that inhibits clotting factors V and VIII. Quantitative or functional protein C deficiency leads to hypercoagulable states. Whether this plays a direct role in the pathogenesis of calciphylaxis or is a marker for a coagulation defect that predisposes a subset of these patients to calciphylaxis is unknown. Some investigators believe that patients with calciphylaxis have underlying small vessel disease, perhaps related to the etiology of their renal failure, and that this condition, in conjunction with high serum levels of PTH, predisposes them to medial calcification of small and medium arteries and to soft tissue necrosis. A recent report suggests that microorganisms may play a role in soft tissue calcification. [44]

Treatment of calciphylaxis is primarily supportive. Appropriate wound care with careful débridement of necrotic tissue and monitoring for infection are important. Oral phosphate binding therapy may be helpful in cases associated with hyperphosphatemia. Although it has not been studied in a controlled fashion, parathyroidectomy may help some patients. A total parathyroidectomy can be undertaken with autotransplantation of one gland in the forearm. The transplanted gland can be removed later if the patient's hyperparathyroidism persists. Hyperbaric oxygen therapy and systemic glucocorticoids followed by cimetidine have been anecdotally reported to be of some benefit. [45], [46] One case report demonstrated improvement with low-calcium dialysis. [47] Anticoagulant therapy does not appear to alter prognosis.

Hypervitaminosis D

Chronic ingestion of vitamin D in supraphysiologic doses (50,000 to 100,000 units per day) may produce hypervitaminosis D. The initial signs and symptoms of hypervitaminosis D are attributable to hypercalcemia and hypercalcuria and include weakness, lethargy, headache, nausea, and polyuria. Metastatic calcification may also occur.

Milk-Alkali Syndrome

Milk-alkali syndrome is characterized by excessive ingestion of calcium-containing foods or antacids, leading to hypercalcemia. Complications other than the acute manifestations of hypercalcemia include irreversible renal failure, nephrocalcinosis, and subcutaneous calcification, occurring predominantly in periarticular tissues.

Other Disorders

Other systemic disorders associated with hypercalcemia and/or hyperphosphatemia are reported to cause metastatic calcification. These disorders include the neoplasms associated with bony destruction, such as lymphoma, leukemia, multiple myeloma, and metastatic carcinoma. Sarcoidosis is also associated with metastatic calcification.

IDIOPATHIC CALCIFICATION

Calcified nodules characterize idiopathic calcification of the scrotum. The lesions usually appear in otherwise healthy males and tend to increase in size and number with time. Eventually, they may break down and exude a chalky material. Controversy exists over the etiology of this disorder. Many believe idiopathic calcification of the scrotum is truly idiopathic; others maintain that calcified scrotal nodules are inflamed or ruptured epidermoid cysts that undergo dystrophic calcification. Excision of the lesions is the treatment of choice, although patients may continue to develop nodules at other sites. Idiopathic calcification of the penis, vulva, and breast has also been reported.

Tumoral calcinosis is a disorder characterized by the deposition of calcific masses around major joints, such as hips, shoulders, elbows, and knees. It generally occurs in otherwise healthy adolescents. The masses are intramuscular or subcutaneous and may enlarge to sizes causing significant impairment of joint function. Usually the overlying skin is normal, but associated ulceration and calcinosis cutis may occur. Familial occurrences among siblings and associated hyperphosphatemia in a subset of patients have led some investigators to postulate that tumoral calcinosis is a form of metastatic calcification caused by an inborn error in phosphate metabolism. Others disagree because hyperphosphatemia is not a universal finding and the calcification occurs only in periarticular regions. Surgical excision is the treatment of choice, but phosphate deprivation has met with some success.

Subepidermal calcified nodules appear on the exposed areas of the head and the extremities. They may be congenital or acquired and typically appear as hard, 3- to 11-mm solitary lesions, although multiple lesions may occur. Some

investigators believe the lesions represent calcified sweat gland hamartomas.

Reports have described the appearance of milia-like idiopathic calcinosis cutis on the dorsa of hands and forearms of patients with Down's syndrome. [48] Some of the calcifications were associated with lesional or palpebral syringomas.

IATROGENIC CALCIFICATION

Cutaneous calcification may be iatrogenic. Calcinosis cutis is a complication of intravenous calcium chloride and calcium gluconate therapy. With extravasation of the calcium solution, calcified nodules may appear, probably as a result of an elevated tissue concentration of calcium and tissue damage at the site of the extravasated calcium solution. [49] Minor trauma and prolonged contact with calcium salts can lead to calcinosis cutis in a variety of settings. [50] It has occurred in patients undergoing electroencephalography who had prolonged contact with saturated calcium chloride electrode paste. Recently, a number of patients were reported as developing cutaneous calcification of skin graft donor sites after the application of calcium alginate dressings. [51] Transient deposits of calcium in the skin and other soft tissues have also been reported after liver transplantation. [52] It is hypothesized that these transient deposits are caused by the large amounts of calcium- and citrate-containing blood products used during surgery combined with metabolic abnormalities in the perioperative period.

PRIMARY OSSIFICATION

Primary ossification of cutaneous and subcutaneous tissues rarely occurs without any underlying tissue abnormality or preexisting calcification. In addition to miliary osteoma of the face, there are four well-described ossifying syndromes: fibrodysplasia ossificans progressiva, Albright's hereditary osteodystrophy, progressive osseous heteroplasia, and platelike osteoma cutis. Other primary ossification disorders reported in the literature, such as isolated osteoma or widespread osteoma, probably are variants of the above or represent a group of poorly described primary ossification disorders.

Miliary osteoma cutis of the face most commonly occurs as multiple small, firm nodules on the faces of young women with a history of acne vulgaris. There are, however, reports of multiple miliary osteoma cutis in older patients without acne vulgaris or other underlying skin disease. [53]

Fibrodysplasia ossificans progressiva (FOP) is an autosomal dominant syndrome characterized by the progressive ossification of deep connective tissues leading to significant morbidity and mortality. [54] Ossification is of the endochondral type, and involvement of the skin occurs as a result of direct extension from underlying tissues. Dysmorphic great toes are a characteristic feature of FOP. Other features include abnormal phalanges of the hands, deafness, baldness, and mental retardation. Although the genetic defect remains unknown, linkage analysis studies have identified potential loci at 17q21 and 4q27–31. Genes involved in the bone morphogenesis protein-signaling pathways are located in these regions. [55], [56]

Albright's hereditary osteodystrophy, progressive osseous heteroplasia, and platelike osteoma cutis are three closely related syndromes that are characterized by intramembranous bone formation in skin. Mutations in the gene encoding for the a subunit of the stimulatory G protein of adenyl cyclase have been identified in all three of these disorders. [57], [58] and [59] In addition, families have been described in which some members have platelike osteoma cutis while other members have progressive osseous heteroplasia. [60] How differing mutations in the same gene give rise to clinically distinct syndromes remains to be elucidated.

Albright's hereditary osteodystrophy is an X-linked or autosomal dominantly inherited syndrome characterized by the ossification of cutaneous and subcutaneous tissues in childhood. The ossification can occur anywhere on the body. Albright's hereditary osteodystrophy generally follows a limited course, and significant deformity and physical impairment are rare. Patients typically have brachydactyly, dimpling over the metacarpophalangeal joints (Albright's sign), obesity, round or moon facies, and mental retardation. Most patients have a deficient end-organ response to PTH or “pseudohypoparathyroidism” with hypocalcemia, hyperphosphatemia, and elevated levels of PTH. Other patients have “pseudo-pseudohypoparathyroidism” with normal serum levels of calcium and phosphorus.

Progressive osseous heteroplasia is characterized by progressive ossification of skin and deep tissues during infancy or childhood. [61] Most reported patients are female, although a small number of male patients have also been described. Ossification usually begins in the dermis and progresses to involve deeper tissues, such as muscle, as well as overlying skin. Skin involvement has been described as a papular eruption resembling “rice grains” and having a “gritty” consistency. Unlike Albright's hereditary osteodystrophy or fibrodysplasia ossificans progressiva, there are no associated dysmorphic features. Secondary orthopedic problems, such as limb-length discrepancy or ankylosis of the joint, arise if the cutaneous ossification is severe enough to limit motion.

Worret and Burgdorf first described platelike osteoma cutis in a 4-month-old infant who had a slowly spreading bony plate in the dermis on the lateral thigh and knee. [62] In addition, they described 12 other patients with similar findings. On the basis of these cases, they coined the term *platelike osteoma cutis* and proposed the following as diagnostic criteria: lesion present at birth or within first year of life; no evidence of abnormal calcium or phosphorus metabolism; no history of infection, trauma, or other predisposing events; and the presence of at least one bony plate with or without other cutaneous osteomas. After their report, many patients with various findings were described under the heading of platelike osteoma cutis. It is likely, however, that many of these patients actually had progressive osseous heteroplasia or another undefined ossification disorder. Platelike osteoma cutis is currently used to describe patients with a more limited, nonprogressive form of cutaneous ossification. Evidence is beginning to suggest that platelike osteoma cutis and progressive osseous heteroplasia may represent different ends of the spectrum of the same disorder.

REFERENCES

Heritable disorders of connective tissue are generalized defects caused by mutations in the genes for components of connective tissues or in enzymes modifying them. They involve many tissues, reflecting organ distribution of those components. Virtually all are inherited in a straightforward Mendelian pattern.

THE EHLERS-DANLOS SYNDROMES

The Ehlers-Danlos syndromes (EDS) are a genetically, biochemically, and clinically diverse group of disorders having joint laxity and dermal features in common. [1], [2] and [3] Prior classifications of EDS included up to 11 disorders. Recently a simplified classification was proposed that takes into account increasing clinical experience and recent advances in our understanding of the molecular pathogenesis of these disorders. Table 154-1 provides the new classification and its relationship to the most recent prior classification in 1988. [2], [4] For all forms of EDS, combined prevalence estimates of 1 in 5000 have been made. [5]

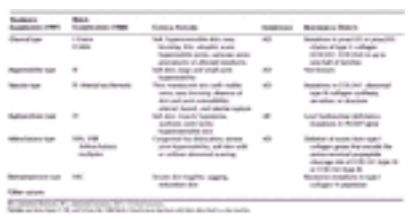

TABLE 154-1 **The Ehlers-Danlos Syndromes: Clinical Subtypes and Associated Defects**

The clinical features and molecular pathogenesis of each type of EDS will be discussed separately. All forms have generalized joint hypermobility as a feature (Fig. 154-1). Determination of hypermobility in adults and adolescents can be assessed using the scale derived by Beighton (Table 154-2). [6]

FIGURE 154-1 Ehlers-Danlos syndrome. Hyperextensibility of digits and Beighton's sign is demonstrated (see also Table 154-1).

Exam	Right	Left
Passive dorsiflexion of the fifth finger beyond 90 degrees	1	1
Passive apposition of the thumbs to the flexor aspect of the forearm (Beighton sign)	1	1
Hyperextension of the elbow beyond 10 degrees	1	1
Hyperextension of the knees beyond 10 degrees	1	1
Forward flexion of the trunk with knees fully extended so the palms of the hand rest flat on the floor	1	

A score of 5/9 or greater defines hypermobility.

TABLE 154-2 **Beighton Criteria for Joint Hypermobility**

The Classical Type

The *classical* form of Ehlers-Danlos syndrome is characterized by joint laxity, hyperextensibility of skin, and poor wound healing. The skin is soft and velvety and can be stretched easily (Fig. 154-2). The dermis is fragile and is easily bruised. Scars after trauma or surgical procedures are thin and atrophic and may stretch considerably after healing (Fig. 154-3). The more severely affected individuals have scars with a characteristic “cigarette paper” appearance. Molluscoid pseudotumors are present at the extensor surfaces of joints, in the foot, and on the shins (Fig. 154-4). Approximately half of affected individuals with Ehlers-Danlos syndrome I had been delivered up to 1 month prematurely because of premature rupture of fetal membranes. A significant number of individuals with EDS have cardiac abnormalities. Mitral valve prolapse is particularly common in the *vascular* form of EDS (type IV), [7] but can be seen in all types. Aortic root dilatation with occasional rupture has been reported in the classical and *hypermobile* form of EDS (types I to III). [8], [9] Musculoskeletal features seen in Ehlers-Danlos syndrome type I include joint hyperextensibility in all patients and a fairly high frequency of scoliosis and pes planus. The joint hypermobility can lead to the onset of osteoarthritis in the third or fourth decade.

FIGURE 154-2 Classical Ehlers-Danlos syndrome. Dermal elasticity is demonstrated. Unlike cutis laxa, the skin returns to original shape after stretching.

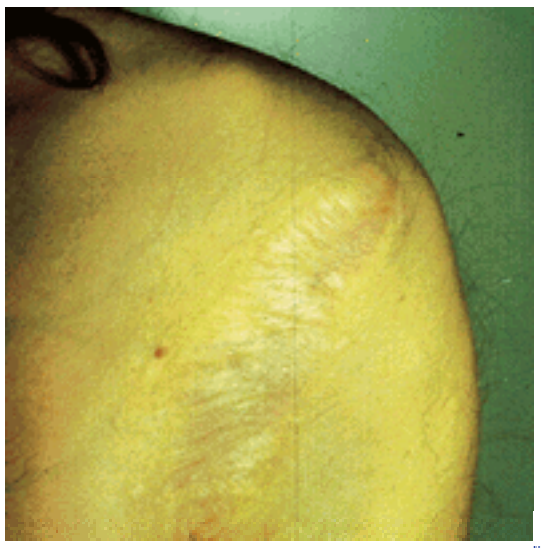

FIGURE 154-3 Classical Ehlers-Danlos syndrome. Widened, “cigarette-paper” scar is demonstrated. After a good primary repair of a injury after an automobile accident, the scar stretched out in the 6 months after the injury.

FIGURE 154-4 Classical Ehlers-Danlos syndrome. Chronic discolored scars and pseudotumors on knees and shins.

Ehlers-Danlos syndrome types I and II are autosomal dominant, single gene disorders. Ultrastructural findings show thickened collagen fibrils in skin; so-called cauliflower deformities of collagen fibrils have been reported as well. Mutations in the proa1(V) and proa2(V) chains of type V collagen are the most common cause of the classical type of Ehlers-Danlos syndrome, accounting for up to 50 percent of cases. [10], [11], [12], [13], [14], [15], [16] and [17] At least one other locus is involved, because several families are discordant for linkage to both COL5A1 and COL5A2. [14], [18]

The Hypermobile Type

This form of Ehlers-Danlos syndrome (EDS) was called type III in earlier classifications. It is characterized primarily by hyperextensibility of large and small joints, and soft velvety skin. Individuals with Ehlers-Danlos syndrome type III have near-normal scarring, but may have stretchy skin. Molluscoid pseudotumors are absent. As discussed above, a significant number of individuals with both the classical form and the hypermobile form have dilatation and/or rupture of the ascending aorta. Musculoskeletal features seen in the classical form of Ehlers-Danlos syndrome, such as scoliosis and pes planus, are also common. Musculoskeletal pain is a prominent feature of hypermobile EDS. The genetic basis of this form of EDS is unknown, and diagnosis is made on the basis of clinical criteria. [4]

The Vascular Type

This form represents a refined definition of Ehlers-Danlos syndrome type IV in that it is limited to those patients with dominant mutations in the gene for the proa1(III) chain of type III collagen. Patients with this condition often have a characteristic facies that is characterized by a thin nose, thin upper lip, and a hollowed out appearance under the eyes, which may also appear discolored (Fig. 154-5). The skin is thin, with easy bruisability; scar formation is usually normal. [19] In fair-skinned individuals, subcutaneous vasculature is easily visible beneath the skin (Fig. 154-6). Affected individuals are at high risk for life-threatening rupture of the large intestine and medium-sized arteries. [20] The most common sites of arterial rupture are the mesenchymal arteries in the abdomen, the splenic artery, renal arteries, and the descending aorta. There may also be an increased incidence of stroke. Another life-threatening complication is uterine rupture in the peripartum period. The vascular form of EDS is caused by abnormal synthesis, structure, or secretion of type III collagen. [3], [19], [21] Multiexon deletions, single-point mutations, and splicing defects have all been described, and no particular mutation type has been associated with more severe clinical effects. [20] Testing for this form of EDS can be reliably accomplished by analysis of type III procollagen and collagen chains harvested from cultured dermal fibroblasts.

FIGURE 154-5 Vascular Ehlers-Danlos syndrome. Characteristic facial features include thin nose, thin upper lip, and a hollowed out appearance under the eyes, which may also appear discolored.

FIGURE 154-6 Vascular Ehlers-Danlos syndrome. Venous pattern apparent in a fair-skinned individual.

The Kyphoscoliosis Type

The cardinal features of the *kyphoscoliosis* type of EDS, formerly called Ehlers-Danlos syndrome type VI, are neonatal onset of joint laxity, kyphoscoliosis, and hypotonia. [22] Ocular fragility, which was observed in the original reports, was found in only a minority of patients. Skin fragility, easy bruisability, and dermal hyperextensibility occurred to some extent in most patients, although they are much less prominent features than in patients with the classical form of EDS. Individuals with the kyphoscoliosis form of EDS, like those with the vascular form, are at risk of having a potentially

catastrophic arterial rupture. Most patients have radiologically detectable osteopenia, but pathologic fractures are rare.

This form of EDS is caused by a deficiency of lysyl hydroxylase (PLOD: procollagen lysyl 2-oxoglutarate 5 dioxygenase).[23] All patients with the kyphoscoliosis form of EDS have decreased hydroxylysine content in dermal tissues.[24] Many of the cross-links that normally occur between adjacent collagen monomers within a fibril begin as chemical modifications of hydroxylysyl residues. Therefore, although hydroxylysine-deficient collagen is efficiently secreted from cells, it is not capable of normal cross-linking. The deficiency is highly tissue- and collagen type-specific, apparently affecting only type I and III collagens.[25] Several patients have been reported who have defects at both PLOD alleles. Hautula and coworkers[26] reported homozygosity for an intragenic duplication of exons 9 to 15 in two patients, which appears to be the only common mutant allele, with an allele frequency of 19.1 percent in families with Ehlers-Danlos syndrome VI.[27] There appears to be a rare subtype that is clinically indistinguishable but has normal lysyl hydroxylase activity and normal hydroxylysyl content in skin.[28]

Although enzymatic testing for lysyl hydroxylase activity in cultured fibroblasts is available as a diagnostic test, measurement of the ratio of urinary excretion of pyridinium cross-links has become widely used as a screen for this disorder. Affected individuals demonstrate a narrow range of deoxypyridinoline: pyridinoline ratios that are at least one order of magnitude greater than age-matched controls.[29], [30] This method shows great promise in providing a rapid, inexpensive diagnostic test for this type of Ehlers-Danlos syndrome.

The Arthrochalasia Type

This rare form of Ehlers-Danlos syndrome, which corresponds to Ehlers-Danlos syndrome types VIIA and VIIIB in previous classifications, is characterized by extreme joint laxity, multiple joint dislocations, and congenital hip dislocations that are difficult to repair surgically. Dermal features include tissue fragility and widened scars; these dermal findings are less prominent than in the classical form of EDS.

The biochemical defect that results in this form of Ehlers-Danlos syndrome is the failure to accomplish the normal cleavage of the amino-terminal propeptide of type I collagen in all tissues. Electron micrographs of collagen fibrils from skin of a patient with this disorder show abnormal collagen fibrils that are irregular in outline and vary widely in diameter. Patients have autosomal dominant mutations that remove the exon containing the N-peptidase recognition sequence in proa1(I) (type A) or proa2(I) (type B) chains. This recognition sequence is contained in exon 6 of both COL1A1 and COL1A2, which are highly homologous and have well-conserved intron–exon boundaries. The molecular mechanism is almost always a mutation that disrupts the splice acceptor or splice donor sequences 5' or 3' to exon 6, causing removal of that exon during processing of mRNA.[1], [3], [31] Confirmation of the diagnosis is accomplished by electrophoretic demonstration of pNa1(I) or pNa2(I) chains extracted from dermal collagen or harvested from cultured skin fibroblasts. Direct demonstration of exon 6 skipping in cDNAs of COL1A1 or COL1A2 can be performed, followed by mutation analysis.

The Dermatosparaxis Type

This very rare form of Ehlers-Danlos syndrome, which corresponds to Ehlers-Danlos syndrome type VIIC in previous classifications, is characterized by striking dermal fragility. The skin is lax but not stretchy, and joint dislocation is usually not a feature of this disorder. Infants have been reported with premature rupture of membranes, and umbilical/inguinal hernias occur as well. The biochemical defect that results in this form of Ehlers-Danlos syndrome is the failure to cleave off the amino-terminal propeptide of type I collagen, due to deficiency of type I collagen N-peptidase.[32] In skin, procollagen metabolites that contain the N-propeptides are present, and cultured dermal fibroblasts secrete procollagens in which the N-propeptide, but not the C-propeptide, is retained.

Tenascin Deficiency

Deficiency of tenascin X results in a relatively rare variant of EDS that appears to be intermediate in severity between the classical and hypermobile forms, but with autosomal recessive inheritance.[33] Tenascin deficiency has been identified in approximately 3 percent of patients with classical EDS.[34]

Clinical Manifestations of EDS

SKIN In classical EDS, the dermal fragility associated with the severe classical form of Ehlers-Danlos syndrome presents special problems. When the skin splits from trauma, it is relatively painless and does not bleed excessively, but the wounds tend to gape. The wound margins tend to retract and heal slowly. Dehiscence is common, and complete wound breakdown may require repeated suturing. Alternatively, the skin may appear to hold the stitches well initially, but the wound may fall apart after sutures are removed. Wide, thin papyraceous scars develop, with eventual stretching of scars over several months. Thin, atrophic, darkly pigmented scars form as a consequence of intradermal or subdermal hematomatas, and occur mainly at pressure points (Fig. 154-4). Failure of dermal sutures prevents close apposition of wound edges. Healing is slow and wound dehiscence is common. An increased frequency of infection accompanies this slow healing. Scars may darken, and gradual stretching and widening may take place over a long period of time. During the initial healing, adhesive tapes and steri strips may help support the skin, but they will not be able to prevent spreading of scars, which occurs over many months. Retention sutures tied at a distance from the incision may help, and adhesive strips may be used to support the skin during scar formation. A significant number of patients will eventually present for scar revision; excision of hyperpigmented scars from elbows and knees is the most common cosmetic operation. In some cases, skin grafts may be necessary to repair extensive scarring on the shin. Early adolescence is probably the best time for this surgery, because additional traumatic events are less likely. Pseudotumors are easily removed from the elbows and knees, but those related to bursae over the heels are often diffusely involved with the underlying tissues and may be difficult to excise.
CARDIOVASCULAR There have been numerous reports of cardiac and aortic abnormalities in the Ehlers-Danlos

syndromes, including aortic and mitral valve prolapse or incompetence, aortic root dilatation (ARD), and aortic dissection/rupture. [22], [35], [36] A recent prevalence study of aortic root dilatation in a combined population of classical and hypermobile EDS patients indicated that 29 percent of EDS patients had ARD, and initial screening of all EDS patients by echocardiography was recommended. [9] The most commonly affected site was the sinus of Valsalva. ARD was more frequent in classical EDS than in hypermobile EDS. At present, there are no reliable data on rates of progression or frequency of serious complications. Aortic valve incompetence, aortic rupture and dissection do occur, but appear to do so far less commonly than in Marfan syndrome. Beta-blocker therapy with agents such as atenolol has been attempted in individual cases, but too few data exist to determine whether therapy is indicated or effective. Patients with the vascular form (Ehlers-Danlos syndrome IV) and the kyphoscoliotic form (type VI) of Ehlers-Danlos syndrome also have increased incidence of mitral valve prolapse and aortic abnormalities. The aortic disease in these forms may be more prevalent than that found in the other forms of Ehlers-Danlos syndrome; the disease is different in its location. Rupture and/or dissection of the aorta, when it occurs, is usually at or distal to the mid-aortic arch and extends distally. The major cause of mortality and severe complications in vascular EDS is rupture of medium-sized arteries, with the renal, splenic, and inferior mesenteric arteries being the most commonly affected. Arterial rupture generally occurs in the third, fourth, and fifth decades, and is the major cause of reduced life span in patients with this disorder. There is no good evidence that dissection and rupture of aorta or arteries is preceded by dilation, as is nearly always true for Marfan syndrome and probably true for the other forms of Ehlers-Danlos syndrome. [9], [35]

MUSCULOSKELETAL Joint dislocations are a relatively frequent complication of any form of Ehlers-Danlos syndrome. The joints most commonly affected are the shoulders, hip, patellae, temporomandibular joints, and digits. Congenital dislocation of the hip is a hallmark of the arthrochalasia form (Ehlers-Danlos syndrome VIIA and VIIB); however, it also occurs in the classical (Ehlers-Danlos syndrome I) and the vascular (Ehlers-Danlos syndrome IV) forms. Chronic pain is a major manifestation of the Ehlers-Danlos syndrome. Although it is seen in all forms, it is most common and most debilitating in the hypermobile form (Ehlers-Danlos syndrome III). The origin of this pain is not well understood. There is acute pain from dislocations and subluxations and from soft tissue injury. Many individuals with Ehlers-Danlos syndrome present with significant joint pain; many have been previously evaluated for inflammatory arthritis. However, the pain is not associated with erythema or point tenderness, and only rarely with swelling. For most patients, chronic pain began in at least one location during childhood. Chronic pain is frequently compounded by secondary depression. [37] With the exception of congenital dislocation of the hip, joint dislocations in Ehlers-Danlos syndrome either spontaneously resolve or can usually be corrected by closed reduction. Orthopedic procedures designed to reduce ligamentous laxity and therefore prevent recurrent dislocations have been generally unsatisfactory. Shoulder surgery has been particularly unsuccessful, [38] while procedures to reduce temporomandibular dislocation may be more successful. Surgery to prevent patellar dislocation is usually only temporarily successful. The most productive avenue of therapy involves a triad of anticipatory guidance, pain management, and physical therapy. Avoidance of standing or working on hardened floors for long periods and the wearing of supportive, cushioned shoes reduces foot, knee, hip, and back pain. Nonsteroidal anti-inflammatory drugs (NSAIDs) or COX-2 inhibitors may bring temporary relief; none are demonstrably superior. The relevant issue is the best-tolerated drug at the least cost. Other medications that may be used include fixed combination products (NSAID/opioid), or single-entity opioids, and tricyclic antidepressants. Hydrotherapy and behavioral and/or cognitive coping strategies may also be tried to improve pain. Physical therapy, particularly that directed at strengthening the shoulder girdle, has lowered the frequency of shoulder dislocations in individuals with chronic or recurrent dislocation. A regular exercise program may be helpful for strengthening muscles, helping to stabilize the joints and relieve stress. Some patients use orthopedic devices such as orthotics and braces.

OTHER CLINICAL MANIFESTATIONS Pregnant women with EDS should be referred to high-risk obstetric practices when possible, because of increased pregnancy risks. Women with the vascular form of EDS are at relatively high risk for catastrophic uterine rupture in the perinatal period. In addition, pregnancy is a period of increased risk of vascular rupture. Premature rupture of fetal membranes may occur because of abnormal membranes of a fetus with classical EDS, or because of premature cervical dilatation, typically occurring between 32 and 37 weeks gestation. Bowel rupture is a serious complication that is limited to the vascular form. [39] Diverticulosis with chronic inflammation can occur in all forms of EDS.

MARFAN SYNDROME

Marfan syndrome is an autosomal dominant generalized disorder of connective tissue that has primary manifestations in the skeletal, ocular, and cardiovascular systems. Premature death in Marfan syndrome is a result of its cardiovascular complications: proximal aortic dilatation associated with aortic valve incompetence, aortic rupture, or aortic dissection. The incidence of Marfan syndrome is approximately 1 in 10,000 live births. Approximately one-third of cases are new mutations without a clear family history. Patients with Marfan syndrome may have major abnormalities, primarily in three organ systems: in the eye—most characteristically dislocation of the lenses; in the skeletal system—excessive length of extremities, loose-jointedness, kyphoscoliosis, and anterior chest deformity; and in the cardiovascular system—most characteristically aortic aneurysm and mitral valve redundancy (reviewed by Godfrey [40]. Skin manifestations consist of striae distensae, a common finding, and elastosis perforans serpiginosa, a rare finding.

Clinical Manifestations

SKELETAL The skeletal features, particularly the long, narrow extremities, figured prominently in Marfan's initial description, in 1896, of the syndrome that now bears his name. Patients with Marfan syndrome are usually taller than their same-sex siblings. There is skeletal disproportion, with the most consistent and reliable measure being an abnormally low ratio of the upper segment to the lower segment (Fig. 154-7A and Fig. 154-7B). The segments are measured below and above the top of the pubic symphysis. In practice, two measurements are made with the patient standing: height and lower segment (top of the pubic symphysis to the floor). In adult whites, the mean ratio is about 0.92, and in adult blacks it is about 0.87. The excessive length of the extremities is responsible for the abnormally low upper-segment-to-lower-segment ratio (US:LS) in Marfan syndrome. Shortening of the trunk by kyphoscoliosis exaggerates the low US:LS. When kyphoscoliosis is more than minimal, the US:LS should not used. Another abnormal measurement includes the comparison of the arm span (fingertip to fingertip) with height; the arm span is usually longer by several centimeters. The ribs appear to undergo the same excessive longitudinal growth, as do the bones of the extremities. Depression of the sternum (pectus excavatum) or projection (pectus carinatum) or an asymmetric deformity

of the anterior chest results (Fig. 154-8).

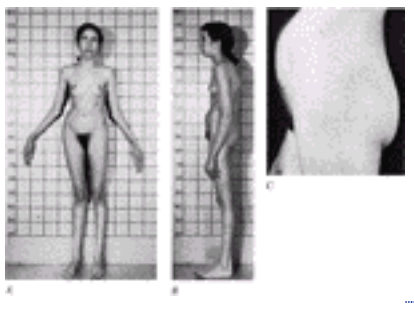

FIGURE 154-7 Marfan syndrome. Frontal (*A*) and lateral views (*B*) of a 15-year-old girl with Marfan syndrome. Note the tall stature, arachnodactyly, kyphoscoliosis, round shoulders, and strabismus. *C.* Striae distensae over the hips in the same patient.

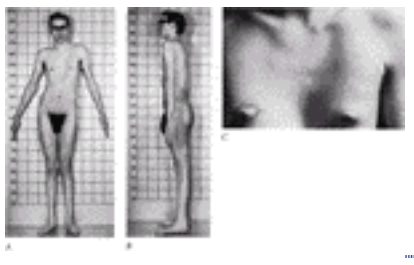

FIGURE 154-8 Marfan syndrome. Frontal (*A*) and lateral views (*B*) of a 20-year-old boy with Marfan syndrome. Note the tall stature, depressed sternum, scoliosis, and arachnodactyly. The father and a younger brother were also affected. This patient falls among the approximately 30 percent who do not have ectopia lentis. His brother, however, did have ectopia lentis. *C.* Striae distensae over the pectoral and deltoid areas.

Joint hyperextensibility is present in some, but not all, patients with Marfan syndrome. Flat-footedness, hyperextensibility at the knees (genu recurvatum) and elbows, and occasional dislocation of joints are manifestations of the loose-jointedness. Because of joint hyperextensibility and long, narrow extremities, the patient is often able to touch his or her umbilicus with the right hand passed around the back and approaching the umbilicus from the left. A relatively narrow palm of the hand with a long thumb and hyperextensibility is the basis of Steinberg's sign: the thumb propped across the palm extends well beyond the ulnar margin of the hand.

OCULAR Virtually all patients with Marfan syndrome have myopia as the result of an abnormally long anterior-posterior axis of the orbit and relatively flat corneas. In addition, approximately 70 percent of affected patients have ectopia lentis with the lens usually displaced upward. In an examination after the dilatation of the pupil, the margin of the lens is usually visible in the lower part of the pupil. Dislocation of the lens into the anterior chamber or trapping of the lens in the pupil sometimes occurs, and acute glaucoma may result. Detection of mild ectopia lentis requires full dilation of the pupils and slit lamp examination for redundancy of the suspensory ligament of the lens. Therefore, clinical exclusion of ectopia lentis in an individual suspected of having Marfan syndrome must include a slit lamp exam after dilation of the pupils. Detachment of the retina is also an ocular component of Marfan syndrome. Mild ectopia lentis can be treated by drugs that cause pupillary constriction. Contact lenses have been successful in treating patients with Marfan syndrome and high myopia. Others may require a combination of contact lenses and spectacles. More severe ectopic lentis requires lensectomy, in order to avoid glaucoma. Various procedures used to correct the flat cornea by reshaping should be avoided in patients with Marfan syndrome.

CARDIOVASCULAR The cardiovascular manifestations of Marfan syndrome are by far the most severe, and account for the overwhelming majority of morbidity associated with this disorder. The two major cardiovascular manifestations are mitral valve prolapse (MVP) and aortic root dilatation. MVP is a consequence of the redundancy of the valve leaflets, the stretching of the chordae tendineae, and dilation of the valve annulus. The prevalence of MVP in Marfan syndrome increases with age. Mitral valve prolapse can occasionally be associated with abnormal electrocardiograms, but these changes are no different than those found in individuals in the general population with MVP. Dilatation of the proximal aorta is progressive and, in some cases, may even occur in utero. Dilatation is first seen in the sinuses of Valsalva. Dilatation during life is often discontinuous and unpredictable. In general, dilatation of the aorta is more likely to occur in patients who have dilatation early in life or who have undergone rapid dilatation in the past. Patients with Marfan syndrome should be monitored on a yearly basis, as aortic complications of Marfan syndrome do not occur in aortas that are normal for age, or in adults in aortas less than 40 mm in diameter. The aortic pathology of Marfan syndrome is almost always in the proximal aorta; distal pathology is usually a result of forward progression of a dissecting lesion. Management of aortic disease in Marfan syndrome calls for lifestyle management, beta-blockers, and aortic repair. Patients with aortic dilatation are encouraged to avoid caffeine, stressful circumstances, and vigorous exercise. Beta-adrenergic blockade has been a mainstay of medical therapy for Marfan syndrome for many years, although it is based only on a single clinical trial. [41] Current recommendations are that all patients with Marfan syndrome be considered for beta-blocker therapy, except for those with significant asthma, Raynaud's phenomenon, and severe diabetes. Successful surgical repair of or replacement of an incompetent aortic valve and dilated proximal aorta has led to dramatic improvements in longevity in these patients. Current recommendations are that patients undergo aortic valve repair or replacement when the aortic sinuses dilate to 50 mm. Early use of either a valve-saving aortic repair or composite graft placement is now prudent because of significant improvements in the success of these procedures and the well-known difficulties in managing an acute aortic dissection in Marfan patients.

SKIN Most patients with Marfan syndrome have striae distensae, particularly in the pectoral and deltoid areas and over the buttocks, thighs, breasts and abdomen [42] (Fig. 154-7C), and thighs. In addition, incisional and inguinal hernias are common.

OTHER FEATURES A high-arched palate and crowding of the anterior teeth are common manifestations of the syndrome. Pulmonary manifestations include cystic changes, emphysema, and spontaneous pneumothorax. The skeletal musculature is often underdeveloped and hypotonic. Dural ectasia, due to stretching of the spinal dural meninges may cause radicular pain due to neural root compression.

Genetic Defect

Approximately 80 percent of patients with Marfan syndrome have a positive family history; in the rest, the syndrome results from de novo mutations in the sperm or ova of the parents. Thereafter, the syndrome is inherited as an autosomal dominant condition. Marfan syndrome is caused by heterozygous mutations in the gene for fibrillin (FBN1), a major constitutive element of extracellular matrix microfibrils throughout the body. Discovered in 1986, [43] fibrillin is abundant in tissues prominently affected with Marfan syndrome—the ascending aorta, suspensory ligament of the lens, periosteum, and skin. Prefibrillin is a 2871-residue protein with 5 distinct structural domains. The largest of these, comprising 75 percent of the protein, is a series of 46 EGF domains, which were originally observed in human epidermal growth factor. Most of the EGF domains are calcium-binding. [44] These EGF repeats are interrupted by eight cysteine motifs that resemble that found in latent TGF-ß–binding protein type 1 (LTBP-1). Initial studies showed that there was dramatically decreased binding of fluorescent antibodies to fibrillin in skin and dermal fibroblast matrix in patients with Marfan syndrome, [45] and the decreased antifibrillin staining cosegregated with the Marfan clinical phenotype in several Marfan families. Linkage studies by several investigators mapped Marfan syndrome to 15q21.1, which was also found to be the chromosomal locus of the fibrillin-1 (*FBN1*) gene. [46]

Over 80 mutations in the fibrillin-1 gene have been reported, nearly all of which occur only within a single family. [47], [48] Mutations have been reported over the entire coding region of the gene. Some, but not all, mutations result in the classical features of Marfan syndrome, and a few genotype-phenotype correlations are possible. Most missense mutations in the EGF domains result in the classic form of the disease. Patients with dramatic structural rearrangements such as exon skipping (approximately 10 percent of the total) have comparatively severe forms of the disease. Patients with mutations that lead to premature stop codons and reduced mRNA transcripts from the mutant allele have a surprisingly wide range of clinical severity, which is unlike the clear differences seen between osteogenesis imperfecta patients with dominant-negative mutations and loss-of-function mutations (null alleles).

It has also become apparent that genetic alterations in *FBN1* produce a spectrum of clinical abnormalities well beyond the classic Marfan phenotype, the so-called fibrillopathies. [49], [50], [51] and [52] The spectrum includes the severe neonatal Marfan phenotype at one end, extending to isolated aortic root dilatation or marfanoid skeletal features lacking cardiovascular involvement or ectopia lentis at the other.

HOMOCYSTINURIA

By definition, homocystinuria is a biochemical abnormality, not a specific disease entity. By far the most common cause of this condition is a deficiency of the enzyme *cystathionine-beta-synthase* (CBS) because of recessive mutations in its gene. Much less common causes of homocystinuria are defects in *5,10 methylenetetrahydrofolate reductase* activity, heritable vitamin B_{12} deficiency as a result of absorption abnormalities (Imerslund syndrome), and *transcobalamin II* deficiency, leading to defective cellular uptake of vitamin B_{12} (for review, see Mudd et al. [53].

The major clinical manifestations of CBS deficiency include dolichostenomelia, ectopia lentis, and chest and spinal deformities; the eye, spinal, and chest wall deformities make it superficially similar to Marfan syndrome, but generalized osteoporosis, arteriovenous thrombosis, and mental retardation are prominent features that allow relatively easy discrimination from Marfan syndrome. The cutaneous manifestations include malar flush, thin hair and skin, and cutis reticulata.

Clinical Manifestations

CARDIOVASCULAR The most serious and life-threatening complication of CBS deficiency is arterial and venous thrombosis. The cumulative risk of thrombosis in patients is approximately 25 percent. Acute occlusion of the coronary arteries can cause myocardial infarction; renal occlusion can cause severe hypertension; occlusion of carotid or cerebral arteries can cause stroke; and ophthalmic artery occlusion can cause blindness. Thrombotic complications in the venous system include renal or portal vein thrombosis and pulmonary embolism. These manifestations are usually seen in the homozygous state with the full-blown clinical syndrome. Although there have been suggestions in the literature that heterozygotes for a mutation at the cystathionine-beta-synthase locus may be at increased risk for myocardial infarction, the data are inconclusive. The vascular complications of homocystinuria are the cause of increased mortality in these patients. At least 20 percent of patients die prematurely from thrombotic complications.
OCULAR Most patients with homocystinuria have ectopia lentis in the first decade of life. Unlike Marfan syndrome, in which ectopia lentis is stable well before age 2 years, ectopia lentis is progressive in cystathionine-beta-synthase deficiency. Rupture of the sclera and retinal detachment has also been reported. Nearly all patients have significant myopia.
SKELETAL Patients with homocystinuria have the same asthenic habitus as those seen with Marfan syndrome and have a high incidence of scoliosis, thoracic asymmetry, and pectus excavatum. However, joint hyperextensibility is not a feature of this disorder; more characteristic is mild joint limitation. There is an increased incidence of pathologic fractures in patients with homocystinuria because of generalized osteopenia.
SKIN A prominent malar flush has been reported in many patients, which is most easily seen after vigorous exercise or after cold exposure. The dermis is usually fair and thin, and livedo reticularis is commonly seen on the extremities. In patients with deep venous thromboses, collateral venous channels are visible through the skin. Hair is often thinned and fair. Treatment may cause hair to darken.
OTHER FEATURES Mental retardation is a common but variable feature of CBS deficiency. About one-fifth of untreated patients have grand mal seizures. In addition, a survey reported that slightly more than 50 percent of the patients with documented CBS deficiency had psychiatric disorders such as depression, chronic behavioral disorders, obsessive-compulsive disorder, and other personality disorders. [54]

Metabolic Defect

CBS catalyzes the condensation of homocysteine and serine; in its absence, homocysteine is converted to homocystine, which is greatly increased in blood and appears in urine. Some homocysteine is converted back to methionine, which is also elevated in blood and urine. Cystine, which normally is supplied to the body by metabolism of methionine, becomes an essential amino acid in patients with CBS deficiency. There is considerable controversy over the mechanisms by which CBS and elevated homocysteine cause the clotting abnormality and the connective tissue findings characteristic of homocystinuria. With regard to the clotting abnormality, experimental work suggests that elevated homocysteine alters the aggregation of platelets, is toxic to endothelial surfaces, or alters the activity of soluble factors that regulate thrombosis, such as antithrombin III, but no widely accepted general explanation has taken hold.

The pathogenesis of the connective tissue abnormalities, including ectopia lentis, osteoporosis, and the vertebral and thoracic abnormalities, may be related to elevated homocystine levels, which inhibit cross-linking of collagen. Harris and Sjoerdsma [55] demonstrated a decrease of cross-linking of collagen in skin from two patients with homocystinuria. Specifically, they found an excess of monomeric collagen relative to the amount of dimerized collagen chains in reducing gels. The mechanism for decreased cross-linking in vivo is unknown. It might be in the earliest step in cross-linking, which is catalyzed by lysyl oxidase, or in later steps, which serve to mature the cross-links. The biologic basis for mental retardation and psychiatric disturbance in patients with homocystinuria is also unknown.

Genetics

The great majority of patients with homocystinuria have primary deficiency of CBS. A minority have an acquired (dietary) deficiency of cobalamin or heritable disorders that prevent conversion of dietary cobalamin to its biologically active forms; rarely, some have defects that cause decreased availability of 5-methyltetrahydrofolate, which is also required in the metabolism of methionine.

The clinical syndrome of homocystinuria caused by CBS deficiency is inherited as an autosomal recessive trait, based on segregation analysis of a number of families, on the increased incidence of homocystinuria in consanguineous matings, and on the finding of intermediate decreases of cystathionine-beta-synthase activity in liver biopsy specimens from parents of some patients. The gene for cystathionine-beta-synthase has been isolated and localized to the long arm of chromosome 21 (21q22.3). [56] Molecular analysis of the CBS locus has identified several mutant alleles in patients with homocystinuria. Substitution of serine for glycine at amino acid position 370 (G370S) is the most common mutation in northern European populations, but most patients are compound heterozygotes for rare mutant alleles. [57]

Treatment

It has been well documented that approximately one-half of patients with clinical CBS deficiency, respond to very high doses of pyridoxine (250 to 500 mg/day) with decreases of methionine in plasma and virtual elimination of homocysteine from urine. [53] Pyridoxine treatment, if initiated in infancy, significantly reduces the risk of thrombosis, grand mal seizures, and mental retardation. Increases in responsiveness are likely caused by increased production of pyridoxal-5'-phosphate, the active form of vitamin B_6 that is the cofactor for CBS. Sensitivity to pyridoxine is constant in affected sibs and only occurs in the presence of residual CBS activity. Specific CBS mutations predict pyridoxine responsiveness. [53]

PSEUDOXANTHOMA ELASTICUM

Pseudoxanthoma elasticum (PXE) is a heritable disorder characterized by progressive mineralization and fragmentation of elastic fibers in various tissues, involving skin (flexural sites), eye (angioid streaks and retinal defects) and cardiovascular system (hypertension, gastrointestinal bleeding, and vascular disease). The disease prevalence is estimated at 1 in 100,000 and it can be inherited as an autosomal dominant or autosomal recessive trait, with considerable morbidity and mortality. The pathogenesis of the disease was not known until recently, when the gene for PXE was mapped to chromosome 16p and its underlying molecular defect was elucidated.

Clinical Manifestations

PXE usually involves the skin, Bruch's membrane of the eye, and vascular tissues. Cases with involvement of other systems have been reported, including urinary tract and pulmonary tissues. The mortality and morbidity of PXE is dependent on the extent of extracutaneous involvement, especially the extent of vascular disease. PXE has been reported in all ethnic groups with average age of onset being 13.5 years. It is unclear whether the known female predominance (female-to-male ratio = 2:1) represents bias of ascertainment or whether there is a true gender-determined difference in disease penetrance.

SKIN Typically, yellowish papules giving a “plucked chicken” appearance in flexural skin begin in childhood. [58] However, their presence is usually not noted until adolescence or even later adulthood, because of their asymptomatic nature. Early diagnosis of this disease allows early recognition of ocular and cardiovascular manifestations reducing potential major complications. Skin involvement of PXE is of cosmetic concern. Commonly involved areas include antecubital, popliteal, inguinal, neck, axillae, and periumbilical areas, as well as oral, vaginal, and rectal mucosa (Fig. 154-9). Involvement may be progressive and the disease may ultimately involve the entire skin. In time, the skin may become soft, lax, wrinkled, and hang in folds, particularly in the neck, axillae, and groin. Patients usually present to their physicians with those lesions because of asymptomatic, cosmetic concern. Careful examination and differential diagnosis are warranted as is a skin biopsy.

FIGURE 154-9 Pseudoxanthoma elasticum. Papules on the neck. There is a distinct yellowish hue. Loose, thickened skin with a pebbled appearance on the neck.

The characteristic histology consists of fragmentation and calcification of elastic fibers in the middle and lower third of the dermis (Fig. 154-10). The normal elastic fibers may also be pathologically altered, staining blue because of their high calcium content. Skin defects of PXE usually remain unchanged throughout life. Elastosis perforans serpiginosa may coexist with PXE. Molecular studies can be done to confirm the clinical diagnosis and to help recognize asymptomatic patients with a positive family history.

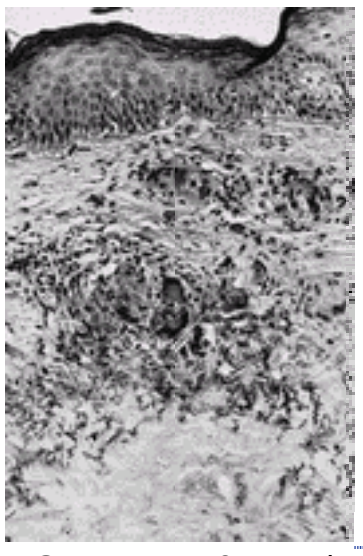

FIGURE 154-10 Pseudoxanthoma elasticum. The pathology affects the connective tissue of most of the reticular dermis. Even in routine hematoxylin and eosin preparations one may see the tightly, but irregularly coiled, basophilic elastic fibers. The collagen associated with the fibrils is also abnormal; the broad collagen bundles so characteristic of the reticular dermis are replaced by irregular and rather confluent collagen fibrils. (*Micrograph by Wallace H. Clark, Jr., MD.*)

OCULAR The characteristic ocular defects of PXE are angioid streaks of the retina, which are reddish-brown curvilinear bands radiating from the optic disk. Angioid streaks result from calcification of the elastic fibers in Bruch's membrane of the retina, with cracking and fissuring in its outer portion, the lamina elasticum. About 85 percent of the patients with PXE may have those lesions identified on routine ophthalmologic examination. The angioid streak is usually present bilaterally and is often first noted between the ages of 20 and 40 years, typically many years after the onset of cutaneous lesions. They may progress slowly or remain stationary for years. Angioid streaks are often mistaken for blood vessels, though they are irregular and generally wider. Early recognition of ocular defects is critically important because laser repair may be sight sparing. Fibrovascular ingrowth in the retina may lead to retinal hemorrhages, and may progress to the stage of retinal detachment and vision loss, worsening with each hemorrhage. Peripheral vision is often spared. Other ocular lesions may be present earlier than angioid streaks, such as the “leopard spotting” of the posterior pole of the retina, which may be concurrent with the onset of skin lesions and is characterized as yellowish speckled mottling. [59]
CARDIOVASCULAR Cardiovascular complications occur primarily in affected adults, but occasionally occur in children. Calcification of the elastic media of blood vessels with subsequent intimal proliferation leads to a variety of physical findings and to serious complications of PXE. Intermittent claudication is the most common cardiovascular manifestation and the one that presents the earliest. In adults, peripheral pulses are often severely diminished. Angina pectoris or abdominal angina may become incapacitating. Hypertension, caused by renal artery involvement, is three times more common in patients with PXE than in the general population. Severe coronary artery disease may cause early myocardial infarction. Mitral valve prolapse has a higher prevalence in PXE than the general population, [60] and cerebral artery involvement has also been reported. Seizures occur more frequently than in the general population because of the cerebral involvement. [61] Subarachnoid hemorrhage has been a major cause of death.
OTHER CLINICAL FEATURES Gastrointestinal hemorrhage, apparently caused by the fragility of calcified submucosal vessels, is the most significant vascular complication of PXE and it is usually gastric in origin. Hemorrhage may occur early in the disease progression and is often the presenting sign, presenting without warning in the second to fourth decade of life. Approximately 10 to 15 percent of patients with PXE have a gastrointestinal hemorrhage at some point in their lives. Depending on its severity, hospitalization, blood transfusion, and surgery may be necessary. Lung involvement has been seen, but rarely. Bleeding may occur in the urinary tract, and the patient presents with hematuria. Pregnancy is uncomplicated and thus not contraindicated in these patients, but there is an increased risk of miscarriage in the first trimester. [62]

Molecular Defect

At the pathologic level, PXE is known to be caused by progressive calcification and fragmentation of elastic fibers. The gene responsible for PXE has been localized to chromosome 16p13.1, and it encodes an ATP-binding cassette (ABC) subfamily C member 6 (ABCC6) transporter. [63], [64], [65] and [66] *ABCC6* consists of 31 exons spanning 75 kb and encodes a 165-kDa transmembrane protein.

Many mutations have been detected in *ABCC6* that are associated with both recessive and dominant forms of PXE. [63], [64], [65] and [66] PXE shows several distinct patterns of inheritance, including autosomal dominant forms and autosomal

recessive forms. Autosomal recessive inheritance occurs far more frequently, in approximately 90 percent of patients. Although most mutations appear to be unique variants, two disease-causing alleles occur frequently in apparently unrelated individuals. *R1141X* has been found predominantly in Europe at a frequency of 28.4 percent (overall, 18.8 percent). *ABCC6del23–29* occurred at an overall frequency of 12.9 percent and was most prevalent in patients from the United States (28.4 percent). These results suggested that *R1141X* and *ABCC6del23–29* might be derived regionally from founder alleles. [66] predominantly expressed in both the liver and kidney. [67] The precise function of the ABCC6 transported is unknown, and the genotype-phenotype relationship between *ABCC6* mutation and pathologic changes in PXE tissues remains to be elucidated.

CUTIS LAXA (GENERALIZED ELASTOLYSIS)

Cutis laxa describes a group of rare disorders that have in common loose, redundant skin and widespread manifestations in other organs. Autosomal dominant, autosomal recessive, and X-linked recessive forms of cutis laxa are recognized. [21], [68], [69] The dominant form of cutis laxa is primarily a cosmetic problem and the prognosis is good. Onset may be delayed and appear to be an acquired defect. One autosomal recessive form of cutis laxa is associated with severe cardiorespiratory complications and early death. Another less-severe form is characterized by growth retardation, developmental delay, and ligamentous laxity. [70] X-linked cutis laxa is characterized by mild joint laxity, bladder diverticula, hernias, and cranial occipital exostoses or horns. [69], [71] Acquired forms of cutis laxa have been reported, often following an ill-defined febrile illness. [72], [73] Other inherited disorders with cutis laxa as an associated feature include DeBarsy syndrome, Patterson syndrome, “wrinkly skin” syndrome, geroderma osteodysplastica, PXE, and SCARF (skeletal abnormalities, cutis laxa, craniostenosis, psychomotor) syndrome. Cutis laxa may also be associated with amyloidosis and plasma cell dyscrasias.

Clinical Manifestations

The clinical presentation of cutis laxa shows considerable heterogeneity. In both inherited and acquired forms, internal organs can be involved. As a rule, the autosomal dominant form of cutis laxa has primarily skin involvement. The autosomal recessive and X-linked forms are often associated with more severe multisystem complications that include emphysema, diaphragmatic hernia, and gastrointestinal and genitourinary diverticula. The most severe manifestation of cutis laxa is progressive emphysema, which may result in early death from cor pulmonale. Cutis laxa has been reported in all ethnic groups and, except for the X-linked recessive form, it affects men and women equally. Congenital onset is indicative of a heritable, autosomal recessive or X-linked form of cutis laxa; later onset is consistent with either a heritable or acquired form.

SKIN Skin lesions may occur in newborn infants. This is then called the “congenital” form of cutis laxa. Onset may be delayed, and thus the disease may appear to be an acquired defect. Many cases of acquired cutis laxa have developed after a febrile illness and/or inflammatory skin diseases such as lupus erythematous, urticaria, eczema, erythema multiforme, vesicular eruption, amyloidosis, and angioedema, as well as reactions to penicillin, or other drugs. Cutis laxa may affect any portion of body, but it often causes attention when it is present with loose appearance around the face, neck, shoulders, and thighs. In all forms of cutis laxa, the skin gives the appearance of being too large for the rest of the body. [74] At birth, the skin may be noticeably soft, loose, and hyperextensible. It tends to sag in the areas where the skin is normally loose, for example, around the face and eyes (Fig. 154-11). The skin may be excessively wrinkled and appears prematurely aged. Children with severe cutis laxa may have characteristic facial features known as the “bloodhound” look, an aged appearance with sagging jowls. At birth, the skin may be noticeably soft and loose; in contrast to the skin of EDS, it returns very slowly to its normal position after being stretched. Skin fragility, easy bruisability, joint hypermobility, and poor wound healing are not usually associated with cutis laxa. Cosmetic surgery can ordinarily be undertaken without complications. Histologically, elastic tissues are reduced in quantity and altered in morphology throughout dermis. The findings are highly variable and only imperfectly reflect clinical heterogeneity. [75]

FIGURE 154-11 Cutis laxa. The skin hangs in loose folds, giving the appearance of premature aging.

OTHER CLINICAL FEATURES The X-linked form of cutis laxa is known as the occipital horn syndrome because of occipital exostoses. [76] Characteristic facial features include inverted lower eyelids, a hooked nose, inverted nostrils, a short columella, and a long upper lip. The cry of an affected infant may be hoarse, and a low-pitched voice is often associated with redundancy of the vocal cords. Diagnostic skeletal features of this condition can be identified radiologically and include short flat clavicles, fused carpal bones, and occipital horns, which may not be present until a few years of age. This form is the only cutis laxa phenotype that has joint laxity as a feature. The autosomal recessive form of cutis laxa is often associated with severe internal complications, such as genitourinary and gastrointestinal diverticula. Chronic diarrhea is a widely reported complication and secondary kidney damage may be noted because of urinary tract obstruction as a consequence of diverticula. The most serious complications are diaphragmatic hernia and

emphysema, which may lead to cor pulmonale and death in first few years of life. Rare cardiovascular features include aortic dilatation with secondary cardiomegaly and congestive heart failure. Rectal prolapse, diaphragmatic atony, pneumothorax, peripheral pulmonary stenosis and aortic dilatation have also been reported. Facial features include down-slanting palpebral fissures, broad/flat nose, and large ears. [74] The autosomal dominant form of cutis laxa usually has a mild presentation and a benign clinical course. The phenotype is usually limited to skin involvement with few, if any, systemic complications. Cosmetic concerns are major issue for medical care.

Medical Management

There is no known medical treatment to prevent disease progression. Dapsone has been used with success in controlling acute swelling of the affected skin in acquired cutis laxa. [77] Surgical correction of redundant skin folds, rectal prolapse, or any hernias are temporarily beneficial and can be undertaken without major complication. [78] Regular evaluation of internal organ involvement is important in prevention and management of major complications.

Molecular Defect

Because of histologic abnormalities in elastin quantity or structure in virtually all forms of cutis laxa, investigations into the molecular pathogenesis have focused on genetic mutations that result in alterations in the structure, or processing of elastin in the extracellular matrix. The genetic heterogeneity of cutis laxa reflects the fact that several genes are required for normal elastin biosynthesis and function.

Elastin (see Chap. 15) is one of several matrix components responsible for the properties of reversible deformability in many tissues including the skin, lungs, and large blood vessels. The human elastin gene (*ELN*) is 45 kb in length and has been mapped to 7q11.2. [79], [80] Elastin initially is synthesized as individual tropoelastin molecules that are aligned on a network of elastic fibers. This alignment is stabilized by the formation of intermolecular cross-links that are mediated by the copper-dependent enzyme lysyl oxidase. Reduced lysyl oxidase activity [69] and a generalized abnormality in copper metabolism has long been described in patients with X-linked cutis laxa. [76] Recently, mutations were found in the gene encoding ATP7A, a member of the P-type ATPase family responsible for copper transport. [81], [82] and [83] ATP7A mediates copper transport from the gastrointestinal tract, efflux of excess copper from cells, and delivery of intracellular stores of copper to cuproenzymes. Lysyl oxidase deficiency has been also reported in the patients with autosomal recessive form of cutis laxa, [84] but its molecular basis remain unclear. More recently, elastin gene mutations that result in abnormal tropoelastin and abnormal elastic fibbers were reported in autosomal dominant cutis laxa. [80], [85]

CONCLUSION
REFERENCES

A group of heritable diseases with differing clinical features share the common characteristics of in vitro or in vivo cellular hypersensitivity to damage by certain physical or chemical agents (Table 155-1). Diseases with autosomal recessive, X-linked, and autosomal dominant inheritance fall in this group. These diseases include xeroderma pigmentosum, Cockayne syndrome, trichothiodystrophy, Bloom syndrome, Fanconi anemia, dyskeratosis congenita, basal cell nevus syndrome, ataxia-telangiectasia, and familial melanoma with dysplastic nevi. Clinical abnormalities involve the cutaneous, ocular, nervous, immune, hemopoietic, skeletal, and gastrointestinal systems. Some are associated with increased incidence of neoplasia.

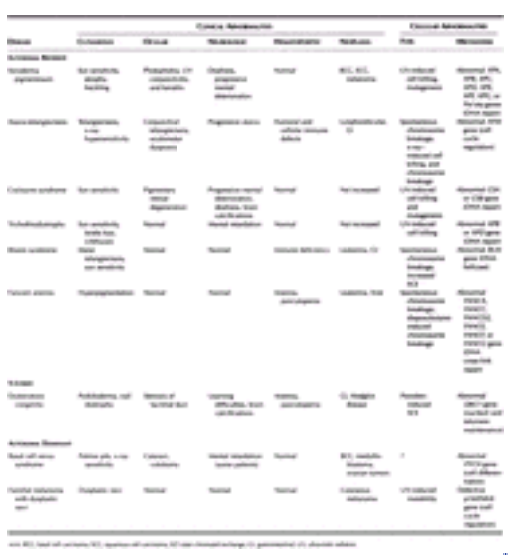

TABLE 155-1 **Heritable Diseases with Cellular Hypersensitivity**

Several have a major feature of progressive degeneration of previously normal bodily function.

The cellular hypersensitivity is often of diagnostic utility. Further, it may suggest pathogenic mechanisms and measures for therapeutic or prophylactic intervention. The molecular basis of the cellular hypersensitivity is currently being clarified in some of these disorders.

In this chapter the clinical features and laboratory abnormalities of the first six of the heritable diseases with cellular hypersensitivity listed above are presented. Basal cell nevus syndrome, ataxia-telangiectasia, and familial melanoma with dysplastic nevi are reviewed in Chap. 82, Chap. 92, and Chap. 191. The diseases are discussed in terms of the systems affected, the cellular hypersensitivity, and the relevance of the cellular abnormality to the clinical symptoms. The

major tests used to measure cellular hypersensitivity and to assess DNA repair are described in Chap. 35.

XERODERMA PIGMENTOSUM

Xeroderma pigmentosum (XP) serves as the prototype heritable disease with increased sensitivity to cellular injury. [1], [2] and [3] XP is an autosomal recessive disease with sun sensitivity, photophobia, early onset of freckling, and subsequent neoplastic changes on sun-exposed surfaces. There is cellular hypersensitivity to ultraviolet (UV) radiation and to certain chemicals in association with abnormal DNA repair. Some of the patients have progressive neurologic degeneration.

Frequency

Xeroderma pigmentosum occurs with an estimated frequency of 1 in 1 million persons in the United States. It is more common in Japan and the Middle East. Patients have been reported worldwide in all races, including whites, Asians, blacks, and Native Americans. [1] Consanguinity is common.

Clinical Features

SKIN Approximately half the patients with XP have a history of acute sunburn reaction on minimal UV exposure. The other patients apparently tan normally without excessive burning. In all patients, numerous freckle-like hyperpigmented macules appear (Fig. 155-1). The median age of onset of the cutaneous symptoms is between 1 and 2 years [1] (Fig. 155-2). These abnormalities are strikingly limited to sun-exposed areas (see Fig. 155-1E). Continued sun exposure causes the patient's skin to become dry and parchment-like, with increased pigmentation, hence the name *xeroderma pigmentosum* (“dry pigmented skin”) (see Fig. 155-1A). Premalignant actinic keratoses develop at an early age (see Fig. 155-1B). XP is an example of accelerated photoaging. The appearance of sun-exposed skin in children with XP is similar to that occurring in farmers and sailors after many years of extreme sun exposure.

FIGURE 155-1 Xeroderma pigmentosum. *A.* Pigmentary changes, atrophy, dryness, and cheilitis in a 16-year-old patient. *B.* Cheek of a 14-year-old patient with pigmented macules of varying size and intensity, actinic keratosis, basal cell carcinoma, and a surgical scar. *C.* Corneal clouding, prominent conjunctival blood vasculature, and loss of lashes. *D.* A 26-year-old patient with deafness and mental retardation. (Note hearing aid.) *E.* Myriads of pigmented macules of varying size and intensity and scattered achromic areas on the back, with marked sparing of sun-protected buttocks of a 14-year-old patient.

CANCER Patients with XP under 20 years of age have a greater than 1000-fold increased risk of cutaneous basal cell or squamous cell carcinoma or melanoma. [1], [4] The median age of onset of nonmelanoma skin cancer reported in patients with XP was 8 years. This 50-year reduction in comparison with the general population is an indication of the importance of DNA repair in protection from skin cancer in normal individuals (see Fig. 155-2). Multiple primary cutaneous neoplasms, including melanomas, occur commonly in XP patients.

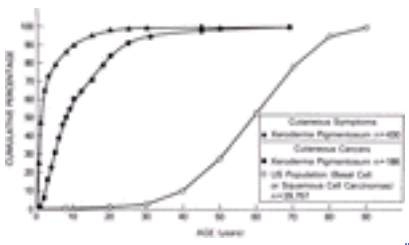

FIGURE 155-2 Xeroderma pigmentosum. Age at onset of clinical symptoms and skin cancers. Age at onset of cutaneous symptoms (generally sun sensitivity or pigmentation) was reported for 430 patients. Age at first skin cancer was reported for 186 patients and is compared with the age distribution for 29,757 patients with basal cell carcinoma or squamous cell carcinoma in the U.S. general population. There is a 50-year reduction in age of onset of skin cancer in the XP patients compared with the U.S. general population. (*From* Ref. [1].)

Review of the world literature has revealed a substantial number of cases of oral cavity neoplasms, particularly squamous cell carcinoma of the tip of the tongue—a presumed sun-exposed location. Brain (sarcoma and medulloblastoma), central nervous system (astrocytoma of the spinal cord), lung, uterine, breast, pancreatic, gastric, renal, and testicular tumors and leukemias have been reported in a few patients with XP. [1], [4], [5] Overall, these reports suggest an approximate 10- to 20-fold increase in internal neoplasms in XP.

EYES Ocular abnormalities are almost as common as the cutaneous abnormalities and are an important feature of XP [1], [4] (see Fig. 155-1C). The posterior portion of the eye (retina) is shielded from UV radiation by the anterior portion (lids, cornea, and conjunctiva). Clinical findings are strikingly limited to these anterior, UV-exposed structures. Photophobia is often present and may be associated with prominent conjunctival injection. Continued UV exposure of the eye may result

in severe keratitis leading to corneal opacification and vascularization. The lids develop increased pigmentation and loss of lashes. Atrophy of the skin of the lids results in ectropion, entropion, or in severe cases, complete loss of the lids. Benign conjunctival inflammatory masses or papillomas of the lids may be present. Epithelioma, squamous cell carcinoma, and melanoma of UV-exposed portions of the eye are common. The ocular manifestations may be more severe in black patients. [6]

NEUROLOGIC SYSTEM Neurologic abnormalities have been reported in approximately 30 percent of the patients. [1], [4], [7] The onset may be early in infancy or, in some patients, delayed until the second decade. The neurologic abnormalities may be mild (e.g., isolated hyporeflexia) or severe, with progressive mental retardation, sensorineural deafness (beginning with high-frequency hearing loss), spasticity, or seizures (see Fig. 155-1D). The most severe form, known as the *De Sanctis-Cacchione syndrome,* involves the cutaneous and ocular manifestations of classic XP plus additional neurologic and somatic abnormalities, including microcephaly, progressive mental deterioration, low intelligence, hyporeflexia or areflexia, choreoathetosis, ataxia, spasticity, Achilles tendon shortening leading to eventual quadraparesis, dwarfism, and immature sexual development. The complete De Sanctis-Cacchione syndrome has been recognized in very few patients; however, many patients with XP have one or more of its neurologic features. In clinical practice, deep tendon reflex testing and routine audiometry usually can serve as a screen for the presence of XP-associated neurologic abnormalities. The predominant neuropathologic abnormality found at autopsy in patients with neurologic symptoms was loss (or absence) of neurons, particularly in the cerebrum and cerebellum. There is evidence for a primary axonal degeneration in these patients. [7]

Laboratory Abnormalities

There have been no consistent routine clinical laboratory abnormalities in patients with XP. Tests of cellular hypersensitivity to UV damage, however, have shown uniformly abnormal results. [2], [3] One XP patient was reported with hypoglycinemia. [8]

CELLULAR HYPERSENSITIVITY Cultured cells from patients with XP generally grow normally when not exposed to damaging agents. The population growth rate or single-cell colony-forming ability is reduced to a greater extent than normal, however, following exposure to UV radiation. A range of post-UV colony-forming abilities has been found with fibroblasts from patients, some having extremely low post-UV colony-forming ability and others having nearly normal survival [2], [3] (see also Chap. 35). XP fibroblasts are deficient in their ability to repair some UV-damaged viruses or plasmids to a functionally active state. [2], [3] These host cell reactivation assays have detected an abnormality in every form of XP tested. UV-irradiated XP fibroblasts produce more mutations per survivor than normal fibroblasts. XP cells also introduce more mutations into UV-damaged plasmids than do normal cells. [9] This post-UV hypermutability is believed to be the basis of the increased frequency of sunlight-induced somatic mutations that lead to cancer in XP patients. [10]

CHROMOSOME ABNORMALITIES XP cells generally are found to have a normal karyotype without excessive chromosome breakage or increased sister chromatid exchanges. Following exposure to UV radiation, however, abnormally large increases in chromosome breakage and in sister chromatid exchanges have been observed. [11] The extent of this induced abnormality varies in different patients.

DNA REPAIR In 1968, hypersensitivity of cultured XP cells to UV damage was reported by Cleaver [12] to be the result of defective DNA repair. He found defective UV-induced repair replication, indicating a defect in the nucleotide excision repair system. Most XP cells have a normal response to treatment with x-rays, indicating the specificity of the DNA repair defect. The defective genes for the seven excision repair–defective forms of XP have been cloned, [3], [13] and their functions are being investigated (see Chap. 35).

COMPLEMENTATION GROUPS Genetic heterogeneity among the XP DNA repair defects was found by fusing cultured fibroblasts from different patients and defining complementation groups (see discussion in Chap. 35). Up to 2002, seven such DNA excision repair–deficient complementation groups have been identified (named *XP-A* to *XP-G*), and the corresponding genes have been identified [2], [3], [13] (Table 155-2). Additional patients with clinical XP but normal DNA excision repair have been called *XP variants*. Studies of cellular hypersensitivity revealed a slightly increased sensitivity to UV-induced inhibition of cell growth that was potentiated by caffeine. Cells from XP-variant patients were reported recently to have a defect in an error-prone DNA polymerase (pol ?) that bypasses unrepaired DNA damage. [14], [15]

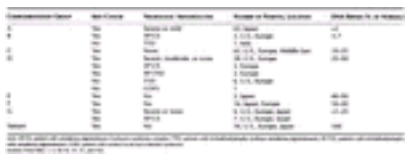

TABLE 155-2 **Xeroderma Pigmentosum: Characteristics of DNA Repair Complementation Groups**

PRENATAL DIAGNOSIS This has been reported by measuring UV-induced unscheduled DNA synthesis in cultured amniotic fluid cells [16] and, more recently, by use of DNA diagnosis of trophoblast cells obtained early in pregnancy. [17]

DRUG AND CHEMICAL HYPERSENSITIVITY A number of DNA-damaging agents other than UV radiation have been found to yield hypersensitive responses with XP cells. These agents include drugs (psoralens, chlorpromazine), cancer chemotherapeutic agents (cisplatin, carmustine), and chemical carcinogens (benzo[*a*]pyrene derivatives). Presumably, these agents induce DNA damage whose repair involves portions of the DNA repair pathways that are defective in XP. [18]

Treatment

Management of patients with XP is based on early diagnosis, lifelong protection from UV radiation exposure, and early detection and treatment of neoplasms. Diagnosis rests on recognition of the characteristic clinical features and is confirmed by laboratory tests of cellular hypersensitivity.

SUN PROTECTION Patients should be educated to protect all body surfaces from UV radiation by wearing protective clothing and UV-absorbing glasses and long hair styles. They should adopt a lifestyle to minimize UV exposure and use

sunscreens with high sun protective factor (SPF) ratings (minimum SPF 15) daily. Cells from patients with XP are hypersensitive to killing by UVC, UVB, and UVA. Patients should be examined frequently by a family member who has been instructed in recognition of cutaneous neoplasms. A set of color photographs of the entire skin surface with close-ups of lesions (including a ruler) is often extremely useful to both the patient and the physician in detecting new lesions. A physician should examine patients at frequent intervals (about every 3 to 6 months depending on severity of skin disease). Premalignant lesions such as actinic keratoses may be treated by freezing with liquid nitrogen or with topical 5-fluorouracil. Larger areas have been treated with therapeutic dermatome shaving or dermabrasion to remove the more damaged superficial epidermal layers. [19], [20], [21] and [22] This procedure permits repopulation by relatively UV-shielded cells from the follicles and glands. Since cells from patients with XP are also hypersensitive to environmental mutagens such as benzo[*a*]pyrene found in cigarette smoke, prudence dictates that patients should be protected against these agents. One of our patients who smoked cigarettes for more than 10 years died of bronchogenic carcinoma of the lungs at age 35. [4]

CANCERS Cutaneous neoplasms are treated in the same manner as in patients who do not have XP. This involves electrodesiccation and curettage, surgical excision, or chemosurgery. Since multiple surgical procedures are often necessary, removal of undamaged skin should be minimized. Extremely severe cases have been treated by excision of large portions of the facial surface and grafting with uninvolved skin. [19], [20], [21] and [22] Most patients with XP are not abnormally sensitive to therapeutic x-rays, and XP patients have responded normally to full doses of therapeutic x-radiation for treatment of inoperable neoplasms. [5] However, cultured cells from a few XP-G patients were found to be hypersensitive to x-rays, [23] so when x-ray therapy is indicated, an initial small dose is advisable to test for clinical hypersensitivity. High-dose oral isotretinoin has been shown to be effective in preventing new neoplasms in patients with multiple skin cancers. [24] Because of its toxicity (hepatic, hyperlipidemic, teratogenic, calcification of ligaments and tendons, premature closure of the epiphyses), oral isotretinoin should be reserved for patients with XP who have had multiple skin cancers. A bacterial DNA repair enzyme, den V T4 endonuclease, in a topical liposome-containing preparation has been reported to reduce the frequency of new actinic keratoses and basal cell carcinomas in XP patients in one research study. [25] As of 2002, this treatment has not yet been approved by the U.S. Food and Drug Administration (FDA).

EYES The eyes should be protected by wearing UV-absorbing glasses with side shields. Methyl cellulose eye drops or soft contact lenses have been used to keep the cornea moist and to protect against mechanical trauma in patients with deformed eyelids. Corneal transplantation has restored vision in patients with severe keratitis with corneal opacity. Neoplasms of the lids, conjunctiva, and cornea are usually treated surgically. [26], [27] and [28]

Clinical-Laboratory Correlations

Patients with XP are hypersensitive to UV radiation, as are their cultured cells. Cutaneous and ocular abnormalities are strikingly limited to UV-exposed areas and usually spare such UV-shielded locations as the axillae, buttocks, and retina. The fact that black patients with XP have an increased frequency of skin cancer indicates that a normally functioning DNA repair system provides greater protection against skin cancer than does the natural pigmentation of black skin.

COMPLEMENTATION GROUPS At least eight different molecular defects are associated with the clinical abnormalities recognized as XP, as indicated by the existence of seven DNA excision repair–deficient complementation groups (A to G) and the variant form (see Table 155-2). A discussion of the cloned XP genes and their function can be found in Chap. 35. There is a complex relationship among the DNA repair genes and clinical disease (Fig. 155-3). These 11 genes are associated with at least 7 different clinical phenotypes. A clinical phenotype can be associated with defects in each of several genes. Conversely, mutations in one gene can be associated with several different clinical phenotypes. These complex relationships and the roles of DNA repair genes in regulation of transcription and in immune functions are under intense investigation.

FIGURE 155-3 Relationship of clinical disorders and molecular defects in DNA repair diseases. Seven clinical phenotypes of DNA repair diseases have been recognized (*red rectangles*). Defects in 11 DNA repair genes have been associated with these clinical phenotypes (*gray ovals*). Mutations in different DNA repair genes can be associated with the same clinical phenotype. Similarly, different mutations in one DNA repair gene can be associated with different clinical phenotypes. For example, mutations in the *XPD* gene have been associated with XP, with XP with neurologic abnormalities, with the XP-CS complex, with TTD, with XP-TTD, or with COFS (cerebro-oculo-facio-skeletal syndrome).

Complementation group A contains patients with the most severe neurologic and somatic abnormalities (the De Sanctis-Cacchione syndrome) as well as patients with minimal or no neurologic abnormalities [3] (see Table 155-2 and Fig. 155-3). This form is seen in the United States, Europe, and the Middle East. It is the most common form of XP in Japan. Approximately 90 percent of Japanese XP-A patients have the same single-base-substitution mutation in this gene. [29] This finding has served as the basis for development of a rapid diagnostic assay for Japanese XP-A patients (including prenatal diagnosis) using polymerase chain reaction analysis of a small sample of DNA. [17] Complementation group B (see Table 155-2; Fig. 155-3 and Fig. 155-4) is composed of three patients in two kindreds who had the cutaneous abnormalities characteristic of XP (including neoplasms) in conjunction with neurologic and ocular abnormalities typical of Cockayne syndrome (CS). [3] Surprisingly, a patient with trichothiodystrophy (TTD) also was found to have a defect in the *XPB* gene.

FIGURE 155-4 Xeroderma pigmentosum–Cockayne syndrome complex. (*A*) A 28-year-old patient (XP11BE) in XP complementation group B with cutaneous changes of xeroderma pigmentosum, including pigmentary changes and atrophy. She has the beaklike nose and loss of subcutaneous tissue typical of Cockayne syndrome. (*B*) The patient is of short stature (less than 4 ft tall). Her mother, an obligate heterozygote, is clinically normal.

Patients in complementation group C, with rare exceptions, have XP with skin and ocular involvement but without neurologic abnormalities [3], [30] (see Table 155-2 and Fig. 155-3). This is the most common group in the United States, Europe, and Egypt but has been found rarely in Japan. Patients in complementation group D have been described with six different clinical phenotypes (see Table 155-2 and Fig. 155-3). They may have cutaneous XP with late onset of neurologic abnormalities in their second decade of life or XP with no neurologic abnormalities. [3], [31] Two XP-D patients have been reported with clinical symptoms of both XP and CS. Cells from patients with a photosensitive form of TTD (without XP) also were assigned to XP complementation group D. Two patients were reported with combined symptoms of both TTD and XP (one patient had a skin cancer) and mutations in the *XPD* gene. [32] Finally, a patient with cerebro-oculo-facio-skeletal (COFS) syndrome had a mutation in the *XPD* gene. [33] Complementation group E was found in one kindred in Europe and several in Japan [3], [34] (see Table 155-2 and Fig. 155-3). These patients had relatively mild cutaneous abnormalities without neurologic involvement. Complementation group F patients have been found mainly in Japan [35], [36] (see Table 155-2 and Fig. 155-3). These patients have mild clinical symptoms without neurologic abnormalities or skin cancer. The residual rate of DNA repair, however, is very low (only 10–20 percent of normal). Thirteen patients in XP complementation group G have been identified in the United States, Europe, and Japan [37] (see Table 155-2; Fig. 155-3 and Fig. 155-5). There is a large variation in clinical features among these patients. Several patients with mutations in the *XPG* gene had clinical features of both XP and severe CS with cachexia and death in the first decade (see Fig. 155-5). Other patients with different mutations in the same gene had no neurologic abnormalities. Fibroblasts from one of the patients were found to be hypersensitive to killing by x-rays as well as by UV radiation. [23]

FIGURE 155-5 Severe and mild XP-G patients. (*Upper left*) Patient XP82DC at 3 years of age has deep set eyes characteristic of Cockayne syndrome and irregular lentiginous pigmentation on her face characteristic of XP indicating the XP-CS complex. (*Lower left*) Patient XP82DC at 3 years has characteristic XP pigmented lesions present on her forearms and dorsa of hands along with thin, translucent skin with readily visible veins. The small size of her hands is apparent in comparison with the hands of her mother. (*Middle column, top*) Patient XP65BE at age 6 months experienced severe sunburn of her face on minimal sun exposure. Erythema and swelling are seen on skin of forehead, cheeks, and periorbital area. (*Middle column, middle*) Patient XP65BE at age 9 months shows erythema and peeling of skin of malar area of face following sun exposure. (*Middle column, bottom*) Patient XP65BE at age 4.5 years shows pigmentary changes on her nose, malar area, and other portions of the face. (*Upper right*) Patient XP65BE at age 4.5 years shows blistering sunburn on upper thigh. Note spared area above knee where sunscreen was applied. (*Lower right*) Patient XP65BE at age 14 years shows minimal pigmentary changes on face and sparing of neck and hand. She used measures to protect her skin from sun exposure. (*From* Ref. 37.)

XP-variant cells have normal DNA nucleotide excision repair and thus do not fall into any of the complementation groups of cells with defective DNA excision repair [3] (see Table 155-2 and Fig. 155-3). There is, however, a defect in an error-prone DNA polymerase, pol ? [14], [15], [38] (see Chap. 35). XP-variant patients have been identified in the United States, Europe, and Japan. [3] Most XP-variant patients have clinical XP with no neurologic abnormalities. The cutaneous and ocular abnormalities have been severe in some patients and mild in others. A family with four affected individuals was described in Germany. The affected individuals had extensive sun exposure and late onset of cutaneous cancers. They originally had been thought to represent a separate disorder (pigmented xerodermoid). Subsequent laboratory studies showed the findings typical of XP variants.

ENVIRONMENTAL-GENETIC INTERACTION The cutaneous and ocular changes in patients with XP are consistent with the notion that repeated insults by environmental agents, particularly UV radiation, produce repeated bouts of DNA damage. Because of defective DNA repair, this damage results in cell death, diminished cell growth, or somatic cell mutations. Through mechanisms that are not completely understood, these cellular alterations lead to atrophy, hyper- and hypopigmentation, and telangiectasia, as well as to a 1000-fold increase in malignant neoplasms. Thus XP provides strong support for the somatic mutation theory of carcinogenesis. In addition, rigorous protection from UV radiation from early infancy in a few patients has been shown to prevent most of the serious cutaneous and ocular abnormalities. Some patients with XP demonstrate progressive neurologic degeneration (see Fig. 155-1 and Fig. 155-5). Severely affected patients lose their ability to walk and talk. Histologically, the picture is of a primary neuronal degeneration with loss (or absence) of neurons without evidence of vascular abnormality, deposition of abnormal material, or inflammatory reaction. It has been hypothesized, in analogy to the cutaneous degenerative changes, that the neurologic degeneration is a manifestation of unrepaired DNA damage. Since mature neurons do not divide, unrepaired DNA damage would lead to cell death without replacement by other neurons. This process would lead to progressive loss of neurologic function. The

specific cause of such damage, whether by exogenous or endogenous agents, and the explanation of why some neurons are more severely affected than others are not known. The severity of the neurologic symptoms in patients with XP with associated neurologic disease has been shown to correlate with the UV sensitivity of their skin fibroblasts. [7]

HETEROZYGOTES XP heterozygotes (parents and some other relatives) are carriers of the gene for XP but are clinically normal. There is limited epidemiologic evidence to indicate that such persons have an increased risk of developing skin cancer. [39] Most tests of cell function or DNA repair yield normal responses with cells from XP heterozygotes. A nonspecific test of hypersensitivity to x-ray–induced chromosome breakage has been reported to be abnormal with cells from obligate heterozygotes for XP. [40] Cloning of the defective genes in different XP complementation groups should provide a direct assay for detection of XP heterozygotes.

PATIENT SUPPORT GROUP The Xeroderma Pigmentosum Society is an educational, advocacy, and support organization for helping patients with XP and their families. The society's address is Xeroderma Pigmentosum Society, Inc., Box 4759, Poughkeepsie, NY 12602-4759 USA;Web site: http://www.xps.org/; e-mail: http://xps@xps.org/; telephone: toll-free (877) XPS-CURE (877-977-2873). The booklet “Understanding Xeroderma Pigmentosum,” prepared by the National Institutes of Health, is available on the Internet at http://www.cc.nih.gov/ccc/patient_education/pepubs/xeroderma.pdf. This booklet provides information about XP written in plain English. It may be useful for patients, their families, educators, students, health professionals, media inquiries, and others interested in learning more about XP. A Web site listing disease-causing mutations in XP and CS genes has been established: http://xpmutations.org/.

COCKAYNE SYNDROME

CS is a very rare autosomal recessive degenerative disease with cutaneous, ocular, neurologic, and somatic abnormalities [41], [42] (see Table 155-1). A review published in 1992 described 140 cases reported in the literature. [43]

Clinical Features

In 1936, Cockayne described a syndrome characterized by cachectic dwarfism, deafness, and pigmentary retinal degeneration with a characteristic “salt and pepper” appearance of the retina. The skin had photosensitivity without the excessive pigmentary abnormalities seen in XP. There was marked loss of subcutaneous fat, resulting in a “wizened” appearance with typical “bird-headed” facies and prominent “Mickey Mouse” ears. Other ocular findings included cataracts and optic atrophy. [44] Neurologic abnormalities, in addition to deafness, include peripheral neuropathy, normal pressure hydrocephalus, and microcephaly. Birth weight and early development are usually normal. The disease onset is usually in the second year of life with slowly progressive neurologic degeneration. Intellectual deterioration may be nonuniform, with some functions preserved better than others. A severe infantile form has been described, [45], [46] as well as a milder form with late onset. COFS syndrome [33], [47], [48] with microcephaly and severe mental retardation and CAMFAK syndrome of congenital cataracts, microcephaly, failure to thrive, and kyphoscoliosis [49] have some similar features. CS is not associated with an increased incidence of neoplasia.

Laboratory Abnormalities

Clinical laboratory testing often shows sensorineural deafness, neuropathic electromyogram, and slow motor nerve conduction velocity. [3], [7], [41], [43], [45], [50] The electroencephalogram may be abnormal, and x-ray examination may show thickened skull and microcephaly. Computed tomography (CT) may be diagnostically useful in the detection of normal-pressure hydrocephalus and showing calcification of the basal ganglia and other structures (Fig. 155-6). Magnetic resonance imaging (MRI) of the brain shows atrophy and dysmyelination of the cerebrum and cerebellum. Bone age is usually normal. Height and weight are usually well below the third percentile for the age.

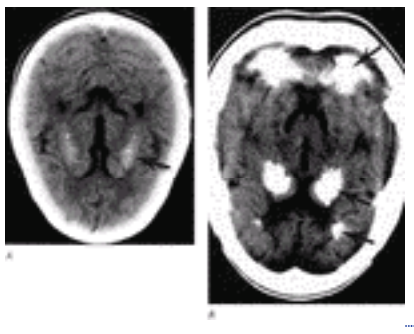

FIGURE 155-6 Cockayne syndrome. Calcification of brain visualized on CT scan. *A.* A 2-year-old patient with bilateral calcification of basal ganglia (*arrow*). *B.* A 15-year-old patient with extensive calcification involving basal ganglia, cerebellum, and cerebral hemispheres (*arrows*).

CELLULAR HYPERSENSITIVITY As with XP, cultured cells (fibroblasts or lymphocytes) from patients with CS are hypersensitive to UV-induced inhibition of growth and colony-forming ability. [3], [51] Host cell reactivation of UV-damaged adenovirus or plasmids is reduced, although generally to a lesser extent than in XP.

CHROMOSOME ABNORMALITIES Chromosome karyotype and sister chromatid exchange frequency are usually normal in untreated cells. UV treatment of CS cells results in a greater than normal increase in sister chromatid exchanges and a delayed recovery of chromosome damage after near-UV light exposure. In CS, the usual tests of DNA excision repair are normal. CS cells are defective in repair of actively transcribing genes. [3] There is also evidence that CS cells are unable to repair photoproducts of the cyclobutane dimer type but are able to repair nondimer photoproducts. [52] CS cells have a prolonged decrease in the rate of RNA synthesis following UV irradiation. There are two complementation groups (A and B) in CS (see Fig. 155-3), and their genes have been cloned. Patients with defects in *CSA* or *CSB* genes have similar clinical features. [51] A patient with COFS syndrome was reported with a defect in *CSB* [48] and another with a defect in *XPD*. [33]

PRENATAL DIAGNOSIS Prenatal diagnosis of CS has been performed [53] based on the delay in recovery of post-UV RNA synthesis and the increased cell killing by UV radiation.

Clinical-Laboratory Correlation

CS, like XP, is a disease of progressive neurologic degeneration. Pathologically, CS shows abnormal (dys)myelinization of neurons, whereas XP shows primary axonal degeneration. These findings are consistent with the theory that the myelin-producing cells in CS or neurons in XP are damaged repeatedly but do not recover fully and die. [7] Since mature neurons cannot divide, the dead neurons are not replaced, resulting in progressive loss of neurologic functioning. As in XP, the cause of this damage in CS and the reason for the precise anatomic location of the damage are not known.

Despite similar UV hypersensitivity to cell killing in CS as in XP, patients with CS do not have an increased frequency of cutaneous (or internal) neoplasia. The few patients with CS in the literature with multiple skin cancers also had XP (the XP-CS complex; see below). Thus cellular UV hypersensitivity does not necessarily result in increased neoplasia. The neoplastic process may be related more closely to the DNA excision repair defects present in XP (e.g., defective global genome repair) but absent in CS.

Patient Support Group

There is an educational, advocacy, and support organization for helping patients with CS and their families: The Share and Care Cockayne Syndrome Network, Inc., Box 570618, Dallas, TX 75357; Web site: http://www.cockayne-syndrome.org/.

XERODERMA PIGMENTOSUM–COCKAYNE SYNDROME COMPLEX

Twelve patients with CS have been found to have, in addition, clinical features of XP. [7], [37] These features include freckling on sun-exposed skin and cutaneous neoplasms (see Fig. 155-4). Cells from these XP-CS patients have reduced DNA excision repair characteristic of XP. Clinically, these patients may be distinguished from XP patients with neurologic abnormalities by the presence of the CS features of pigmentary retinal degeneration, calcification of the basal ganglia, normal-pressure hydrocephalus, and hyperreflexia. Cells from patients with this complex have been found to have mutations in three different XP genes: *XPB, XPD,* and *XPG,* [37], [51] demonstrating that several different genes are implicated in this disorder (see Table 155-2 and Fig. 155-3).

TRICHOTHIODYSTROPHY

Patients with trichothiodystrophy (TTD), [54] also called *Tay syndrome* or *IBIDS syndrome,* have ichthyosis, sulfur-deficient brittle hair, intellectual impairment, decreased fertility, and short stature. Some patients are also photosensitive (PIBIDS) (see Table 155-1 and Chap. 51 and Chap. 71). TTD is not associated with cancer. It is autosomal recessive, and affected families have been described in Italy [55] and elsewhere. TTD may be part of a group of similar rare disorders known variously as *Amish brittle hair syndrome, Sabinas brittle hair syndrome,* or *Pollitt syndrome;* they all have low cystine content of hair and in addition may have brittle nails, cataracts, hypogonadism, microcephaly, or ataxia. Patients may have abnormal brain myelin on MRI, a finding similar to that in CS. [56] A few patients have been described with both XP and TTD who have mutations in the *XPD* gene. One of these XP/TTD patients developed skin cancer at a early age. [32]

Laboratory Abnormalities

Diagnosis is based on microscopic observation of broken hair shafts with characteristic light and dark bands visible in polarized light (“tiger tail”), although this may not be present at birth. The sulfur content of the hairs is reduced due to low cystine content. It is not known whether other proteins also have low sulfur content. Fibroblasts from some TTD patients with photosensitivity (PIBIDS) (see Chap. 51 and Chap. 71) have been found to have similar abnormalities to fibroblasts from patients with XP in complementation group D [31], [51] or B, [57] whereas others form a unique TTD complementation group (see Fig. 155-3). The cells are hypersensitive to killing by UV radiation and have reduced unscheduled DNA synthesis. Fibroblasts from TTD patients without sun sensitivity have normal UV survival and normal unscheduled DNA synthesis.

BLOOM SYNDROME

Bloom syndrome (BS) is an autosomal recessive disease characterized by sun sensitivity, facial telangiectasia, short stature, and immunodeficiency [58] (see Table 155-1). Patients have an increased frequency of various internal neoplasms, including acute leukemia and carcinomas of skin, breast, and gastrointestinal tract. About 250 patients have been recognized. BS is most frequent among Ashkenazi Jews, in whom the carrier rate has been estimated as 1 in 100. [59]

Clinical Features

Facial erythema and telangiectasia superficially resembling lupus erythematosus are often present within the first few weeks after birth in the malar area, on the nose, and around the ears. [58] Sun exposure accentuates these abnormalities and may induce bullae, bleeding, and crusting of the lips and eyelids. The telangiectatic lesions often involve the ears and dorsa of the hands but characteristically spare the trunk, buttocks, and lower extremities. The intensity of the facial lesions may vary from minimal telangiectasia around the lips to severe erythema of the malar area, cheeks, and nose (Fig. 155-7). Café-au-lait spots are common, at times accompanied by adjacent depigmented areas.

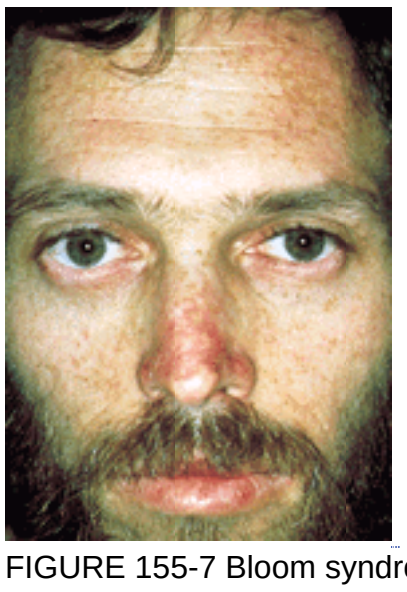

FIGURE 155-7 Bloom syndrome. Prominent telangiectasia in malar distribution.

Affected children generally are born at full term but are of low birth weight, averaging approximately 2000 g. Patients are well proportioned but small. Adult height is usually under 150 cm. Patients have a long, narrow head with a characteristic facies consisting of a narrow, prominent nose, relatively hypoplastic malar areas, and a receding chin. Major skeletal abnormalities are unusual, neurologic abnormalities are uncommon, and intelligence is generally normal.

Patients with BS are predisposed to multiple severe infections of the respiratory or gastrointestinal tracts. There is a tendency for the frequency of infections to decrease with advancing age. There is immune dysfunction. Diabetes mellitus is common. Sexual development generally appears to be normal, but male infertility due to defective sperm is the rule.

Approximately 20 percent of patients with BS develop neoplasms. [58] Half occur before age 20 years. Patients with BS have been estimated to have a 150- to 300-fold increased frequency of development of lymphatic and nonlymphatic leukemia, lymphosarcoma, lymphoma, and carcinoma of the oral cavity and digestive system.

Laboratory Studies

Laboratory studies of immunity have shown diminished immunoglobulin levels, reduced cellular proliferative response to mitogens, and decreased proliferation in the mixed leukocyte reaction.

CHROMOSOME ABNORMALITIES BS cells have a characteristic elevated frequency of chromosome abnormalities, accompanied by a markedly elevated rate of spontaneous sister chromatid exchanges (see Chap. 35) and spontaneous hypermutability of circulating blood cells. [11], [60], [61] The chromosome abnormalities include a high frequency of chromosomal breakage and rearrangements. The most characteristic of these aberrations, the quadriradial configuration, was found in 0.5 to 14.0 percent of all dividing phytohemagglutinin-stimulated lymphocytes from patients with BS. [61] Quadriradials are believed to be the result of a rearrangement before the onset of mitosis resulting from the exchange of chromatid segments of two homologous chromosomes. The quadriradial is almost never found in cells from normal individuals. Increased sister chromatid exchanges and the presence of quadriradials are considered essential for the diagnosis of BS. BS cells show an abnormally large increase in chromosome aberrations when treated with x-rays in the G_2 phase of the cell cycle. [62]

CELL KILLING AND MUTAGENESIS There are a few reports of cellular hypersensitivity to agents such as UVB, but this has not been a consistent finding. BS cells were reported to have an eight- to tenfold increase in the spontaneous mutation rate and a 50- to 100-fold increase in frequency of in vivo mutations at the *glycophorin A* (MN blood group) locus, hypermutability at a tandem-repeat locus, and a 100-fold increase in hypoxanthine-guanine phosphoribosyltransferase (*HGPRT*) mutations.

BLOOM SYNDROME GENE The defective gene in BS (*BLM*) [63], [64] was identified on chromosome 15q26.1 as a helicase that serves to unwind DNA. A founder deletion/insertion mutation in the *BLM* gene was identified in Ashkenazi Jews at a frequency of about 1 percent. [59], [65] This mutation may be used for DNA diagnosis of BS patients and carriers among Ashkenazi Jews.

Clinical-Laboratory Correlation

The clinical diagnosis of BS is confirmed by the findings of increased spontaneous sister chromatid exchanges and increased spontaneous chromosome breakage, including the presence of quadriradials. The high frequency of neoplasia in BS may be related to the chromosome breakage or the immune deficiency, as in ataxia-telangiectasia. The observation of an increased spontaneous mutation rate in cultured cells suggests that somatic mutations may play a role in the neoplasia. Homologous chromosome exchange (as in quadriradials) or genetic recombination may be a mechanism whereby heterozygous (recessive) traits become homozygous within somatic cells and thereby result in mutation or neoplasia.

The defective gene in BS is a helicase that functions to unwind DNA. DNA helicases also have been implicated in Werner syndrome, Rothmund Thompson syndrome, and XP complementation groups B and D. [64]

FANCONI ANEMIA

Fanconi anemia (FA) is an autosomal recessive disease with progressive loss of all the formed elements of the blood (pancytopenia) (see Table 155-1). Patients also may have malformations of the heart, kidney, or limbs, although about

one-third may not have congenital malformations. [66], [67] Internal neoplasms such as leukemia occur with greatly increased frequency. [68] Blood cells show increased spontaneous chromosome breakage. More than 700 patients have been reported to the International Fanconi Anemia Registry. [67]

Clinical Features

Cutaneous abnormalities are present in almost 80 percent of patients. [69] Hyperpigmentation is present from birth or early childhood and is diffuse and accentuated over the neck, joints, and trunk. Café-au-lait spots and achromic lesions are present. Following repeated blood transfusions, hyperpigmentation due to iron overloading may be present.

Hemopoietic manifestations usually have their onset before age 10 years. These consist of a hypocellular bone marrow with progressive decrease in the number of circulating platelets, granulocytes, and erythrocytes. Of 129 patients with FA, 66 percent had skeletal malformations. [66] These included aplasia or hypoplasia of the thumb, metacarpals, or radius; less frequently, hip dislocation or scoliosis were reported. [70] About 60 percent of the patients had short stature; most had low birth weight. Malformations of other organ systems also were observed: 28 percent of the patients had renal deformities, including renal aplasia and horseshoe kidney; 21 percent had ocular abnormalities, including strabismus and microphthalmia; and 20 percent had hypogonadism. CNS abnormalities (hyperreflexia and mild mental retardation) were observed in fewer than 20 percent of the patients, and deafness due to deformities of the ear anatomy was present in fewer than 10 percent. Heart defects (patent ductus arteriosus, aortic stenosis, auricular septum defect) were observed in eight patients.

Patients with FA have a high incidence of neoplasia, particularly nonlymphatic leukemia. [68] The frequency of acute myelogenous leukemia has been reported to be elevated 15,000-fold. [71] The course is often progressively downhill, with death from infection, hemorrhage, or neoplasia. Bone marrow transplantation has been attempted in more than 200 patients. [72], [73]

Laboratory Abnormalities

Clinical laboratory abnormalities reflect the bone marrow failure. There is a hypocellular marrow with thrombocytoplasia, leukopenia, and anemia.

CHROMOSOME ABNORMALITIES FA is associated with a high frequency of spontaneous chromosomal abnormalities, [60] including gaps, breaks, and translocations. With FA cells, the chromosomal abnormalities are increased to a greater extent than with normal cells following treatment with diepoxybutane, [74], [75] mitomycin C, psoralen plus UVA (PUVA), or isonicotinic acid hydrazide (INH), and chromosome abnormalities persist longer than normal after damage by x-irradiation in the G_2 phase of the cell cycle. [62]

CELL KILLING The colony-forming ability of cultured fibroblasts is hypersensitive to inhibition by treatment with agents that form cross-links in DNA. These include mitomycin C, busulfan, nitrogen mustard, PUVA, and cisplatin. [76] Colony-forming ability has a normal response to killing by UV radiation. The mechanism of the cellular hypersensitivity to DNA cross-linking agents is thought to involve defective DNA repair. A detailed understanding of this defect has not yet been attained.

FANCONI ANEMIA GENE Eight FA complementation groups have been described. [76], [77], [78] and [79] The genes for six of the FA complementation groups have been cloned. There is variability of the clinical phenotype and genotype. Mutations were detected in cloned genes in 169 patients. [80] FA-G patients had more severe cytopenia and a higher incidence of leukemia. Somatic abnormalities were less prevalent in FA-C. Founder mutations were described in Israel [65] and among Afrikaners in South Africa. [81]

HETEROZYGOTES Cells from heterozygous carriers of FA have an abnormal chromosomal response to damage with diepoxybutane or nitrogen mustard intermediate between the homozygotes and normal individuals. The carrier frequency of a particular base-substitution mutation in the *FAC* gene is greater than 1 percent among Ashkenazi Jews and thus may be used for carrier detection. [75]

PRENATAL DIAGNOSIS The chromosomal aberrations induced by diepoxybutane have been used successfully as a test for prenatal diagnosis of FA. [82] Many more chromosome aberrations are induced by diepoxybutane in cultured amniotic fluid cells from fetuses with FA than from normal fetuses.

Clinical-Laboratory Correlation

FA is a progressive degenerative disease with major involvement of the hematologic system. There is a high frequency of spontaneous chromosomal breakage in association with a high rate of neoplasia, particularly nonlymphatic leukemia. Immunodeficiency is not prominent. Cells are hypersensitive to killing and to induction of chromosome aberrations by DNA cross-linking agents. Six of the defective genes have been cloned recently.

At present, incorporating these diverse observations into a unitary theory involves considerable speculation: The progressive nature of the disease is similar to XP and ataxia-telangiectasia and suggests the presence of accumulated cellular damage. “Spontaneous” chromosomal breakage may be a manifestation of this damage. The neoplasia may be related to the chromosome breakage. When considering two diseases with spontaneous chromosome breakage (FA and ataxia-telangiectasia), lymphoid leukemia is absent in FA and predominant in ataxia-telangiectasia. In contrast, nonlymphoid leukemia predominates in FA and is absent in ataxia-telangiectasia. Thus other modifying factors, perhaps the immune defects in ataxia-telangiectasia, may be at work.

Registry

Patients may get information from several support groups. The Fanconi Anemia Research Fund, Inc., 1801 Willamette

St., Suite 200, Eugene, OR 97401; telephone: 1-541-687-4658 or 800-828-4891; fax: 1-541-687- 0548; e-mail: http://info@fanconi.org/ ; Web site: http://www.fanconi.org/. There also is an organization in Canada: Fanconi Canada, P.O. Box 38157, Toronto, Ontario M5N 3A9, Canada; phone: 416-489-6393; fax: 416-489-6393; e-mail: http://admin@fanconicanada.org/ ; Web site: http://www.fanconicanada.org/.

DYSKERATOSIS CONGENITA

Dyskeratosis congenita, the Zinsser-Engman-Cole syndrome, is an X-linked multisystem disease with cutaneous, mucosal, ocular, gastrointestinal, and hematologic abnormalities and an increased incidence of cancer (see Table 155-1). More than 100 cases are recorded in the literature, including some female cases. [83] A registry at Hammersmith Hospital in London recruited 46 families having 83 affected patients, including 76 males. [84] Patients have been reported from the United States, Europe, Japan, China, and India.

Clinical Features

The most common features are a triad of reticulated hyperpigmentation, dystrophic nails, and mucosal leukoplakia. [83], [84] and [85] During the first decade of life, patients develop reticulated poikiloderma of sun-exposed areas with hyperpigmentation and, occasionally, bullae. Nail dystrophy is present in virtually all patients, beginning at approximately age 2 to 5 years. The nails initially split easily and then develop longitudinal ridging with irregular free edges. Eventually, the nails become smaller, resulting in rudiments remaining. The fingernails are usually involved before the toenails. Other skin abnormalities include atrophic, wrinkled skin over the dorsum of hands and feet and hyperhidrosis and hyperkeratosis of palms and soles with disappearance of dermal ridges (absence of fingerprints).

Leukoplakia may be present in any mucosal site. The oral mucosa is the most frequent, but leukoplakia is also found in the urethra, glans penis, vagina, and rectum. Lingual hyperkeratosis may be present. Mucosal surfaces such as the esophagus, urethra, and lacrimal duct may become constricted and stenotic, resulting in dysphagia, dysuria, and epiphora. Multiple dental caries and early loss of teeth are common. Progressive pulmonary disease, including infections and fibrosis (and cirrhosis in some patients), was reported in 19 percent of affected males. [84] About 20 percent of patients had learning difficulties or mental retardation. [84]

There is an increased incidence of neoplasia, particularly squamous cell carcinoma of the mouth, rectum, cervix, vagina, esophagus, and skin. A large British kindred had Hodgkin's disease and adenocarcinoma of the pancreas. [86] Several patients had multiple primary neoplasms; most neoplasms occurred in the third or fourth decade. However, a gastric carcinoma was reported in an adolescent. Like FA, although hypoplasia is the main abnormality seen in bone marrow, there is a predisposition to both myelodysplasia and acute myeloid leukemia in patients with dyskeratosis congenita. [84]

The majority (93 percent) of patients developed bone marrow failure, which was the main cause (71 percent) of early death. [84] About half the patients (21 of 41) developed pancytopenia below the age of 10 years with a hematologic picture similar to FA. Patients have been treated with bone marrow transplantation. [87]

Laboratory Studies

Immune function has been studied in only a small number of patients. Defects in immunoglobulin levels and in cell-mediated immunity were found in some patients.

There have been several reports of intracranial calcifications, especially of the basal ganglia. [88], [89] These are also seen in CS.

Chromosomes are usually normal in untreated cells; however, chromosomal abnormalities have been found in fibroblasts and bone marrow cells from a few patients. [90], [91] The leukoplakia cells may show chromosomal changes presaging malignancy.

Clinical-Laboratory Correlation

A gene for dyskeratosis congenita (*DKC1*), which has been cloned, [92], [93] is located on the q28 region of the X chromosome. The protein, dyskerin, has a nucleolar function and a role in telomere maintenance and aging. [94], [95], [96], [97] and [98] Mutations in the *DKC1* gene have been detected in affected patients. [92], [99], [100] There is also evidence for an autosomal form with affected females. [84], [101], [102]

Dyskeratosis congenita, like FA, is associated with anemia and increased incidence of neoplasia. However, patients with dyskeratosis congenita do not have the developmental malformations or spontaneous chromosomal breakage seen in FA. In both disorders there is a suggestion of an abnormal chromosomal response to the DNA cross-linking induced by psoralens.

CONCLUSION

Increased sensitivity to some physical and chemical agents has been recognized in a number of heritable diseases in recent years (see Table 155-1). Clinical hypersensitivity to sunlight is manifested by a corresponding cellular hypersensitivity in XP, CS, and TTD. Ataxia-telangiectasia has a corresponding hypersensitivity to x-radiation. In patients with XP, CS, and the XP-CS complex and in some patients with TTD and COFS, the cellular hypersensitivity has been shown to be related to defective DNA repair.

Spontaneous chromosomal breakage is a feature of BS, FA, and ataxia-telangiectasia. There has been remarkable progress in identifying and cloning the genes responsible for ataxia-telangiectasia, XP, CS, TTD, BS, Werner syndrome, Rothmund-Thompson syndrome, dyskeratosis congenita, and FA. These genes may be useful for DNA diagnosis. Understanding their functioning should provide insights into the mechanism of disease and may provide opportunities for new therapeutic approaches.

Although these heritable diseases are rare, it can be calculated that carriers of the affected genes comprise several percent of the general population. These individuals are usually free of clinical symptoms. However, epidemiologic studies have suggested that they may have an increased risk of neoplasia. In particular, heterozygous carriers of ataxia-telangiectasia, who represent 1 to 2 percent of the general population, may have an increased risk of death from cancer. [103] There is a similar suggestion that persons heterozygous for XP have an increased risk of developing skin cancer. [39] Many of these individuals may be at an increased risk from exposure to environmental agents. As the defective genes are identified, molecular biologic techniques should permit carrier identification. Similarly, common polymorphisms in DNA repair genes may be associated with increased cancer risk. [104] Thus, there are implications for cancer control, preventive medicine, and occupational medicine.

Hematologic Diseases

CUTANEOUS SIGNS AND SYMPTOMS ASSOCIATED WITH HEMATOLOGIC DISEASES
Pallor
Flushing and Erythroderma (Generalized Erythema)
Cyanosis
Jaundice
Infiltrative Lesions/Extramedullary Hematopoiesis
HEMOSTASIS AND THE DIFFERENTIAL DIAGNOSIS OF PURPURA
Hemostasis
Differential Diagnosis of Purpura

REFERENCES

Hematology includes the study of blood and blood-forming tissues. Given the large number and variety of hematologic disorders, it is not surprising that mucocutaneous manifestations of hematologic disorders are common. Many hematologic malignancies and malignancy-mimicking diseases can involve the skin through tumor infiltration (specific lesions), and some of these may present preferentially in the skin. These conditions, such as T and B cell cutaneous lymphomas, other leukemias and lymphomas, plasma cell dyscrasias, and Langerhans and non-Langerhans histiocytoses, are discussed in other chapters. Likewise, patients with serious or chronic hematologic diseases are often at risk for complications of therapy, especially chemotherapy, certain cytokine therapies, radiation therapy, or marrow transplantation. Any of these interventions may affect skin and mucous membranes; these associations are also discussed elsewhere.

The first major section of this chapter is directed toward nonspecific (non–tumor-containing) cutaneous findings that may be associated with hematologic disorders. Although the ready availability of laboratory testing has made early recognition of such conditions as anemia and polycythemia common and much less dependent on physical findings, cutaneous associations still may aid in the diagnosis of a hematologic condition or complicate its management. A comprehensive listing of these associations is presented in Table 156-1. Selected associations are covered in more detail in the text.

Download image in PDF format

TABLE 156-1 **Cutaneous Findings with Hematologic Associations** [32], [33], [34] and [35]

The second section of the chapter focuses on the differential diagnosis of purpura with an emphasis on those subsets of purpura with important underlying hematologic abnormalities.

CUTANEOUS SIGNS AND SYMPTOMS ASSOCIATED WITH HEMATOLOGIC DISEASES

Pallor

Cutaneous pallor results from a drop in the hemoglobin content of the cutaneous microvasculature. This decrease can occur either with a drop in the overall cutaneous blood flow as a result of emotion, epinephrine, cold exposure, or shock, or with physiologic adjustments to severe anemia.

Patients with acute severe anemia usually present with constitutional signs and symptoms such as dyspnea on exertion and occasionally at rest, faintness, dizziness, or hypotension and shock secondary to hypovolemia. Such acute severe anemia most commonly follows major bleeding or brisk hemolysis. Malaise and fatigue are also common, although with nutritional anemias these symptoms may be much more evident in retrospect after replacement therapy. Patients whose severe anemia develops more slowly often have surprisingly few complaints, presumably because of gradual physiologic adaptation.

A measurable increase in the resting cardiac output does not occur until the hemoglobin concentration is below 7 g/dL, and clinical signs of cardiac hyperactivity are not usually present until the hemoglobin concentration reaches even lower levels. [1] In human chronic anemia, oxygenation of oxygen-sensitive areas such as brain, heart, and muscle is maintained by a selective increase in blood flow, at the expense of perfusion to less oxygen-sensitive tissues, especially skin and kidneys. [1] Although vasoconstriction and oxygen deprivation in the subcutaneous tissue seem well tolerated, they are partly responsible for the anemic pallor. In the fully opened hand, the palmar creases appear pink until the hemoglobin level is less than 7 g/dL. [2]

Severe anemia due to marrow failure, fibrosis, or infiltration is typically accompanied by infections or bleeding secondary to associated neutropenia or thrombocytopenia. Development of a chronic anemia with the hemoglobin concentration below 7 g/dL and no other cytopenias is usually slow and caused by nutritional deficiencies or severe hypothyroidism, each of which may produce distinctive clinical syndromes. In any patient with anemia, examination of the peripheral blood smear can reveal important clues to the pathogenesis of the anemia. [3] Further testing (including Coombs' tests for antibody-mediated hemolysis; specific assays for vitamin B_{12}, folate, or iron; or a bone marrow aspirate or biopsy) generally leads to a correct diagnosis.

IRON DEFICIENCY Fatigue, irritability, and headaches are common complaints of individuals with iron-deficiency anemia. The severity of symptoms correlates poorly with the blood hemoglobin concentration. [4] The depletion of storage iron, and often of tissue iron, precedes the appearance of anemia. Some of the symptoms of iron deficiency may be a result of impaired function of iron-containing enzymes or proteins other than hemoglobin. For example, headache, paresthesia, and a burning sensation of the tongue are symptoms of iron deficiency that are likely caused by tissue cell iron depletion. Pica, the craving to eat substances such as dirt, clay, ice, laundry starch, salt, or cardboard, is a classic manifestation of iron deficiency and is usually cured promptly by iron therapy. [4] The physical findings of iron-deficiency anemia, in their approximate order of frequency, include pallor, glossitis (smooth, red tongue), stomatitis, and angular cheilitis. [4] Skin dryness and coarsening; brittle nails; and dry, fine, and brittle hair may also occur. Koilonychia (spooning of nails) is now rare. Retinal hemorrhages and exudates occur in patients with severe anemia (hemoglobin =5 g/dL), and proliferative retinopathy may accelerate in diabetic patients who are iron-deficient. The differential diagnosis of microcytic anemias includes the thalassemias and some other hemoglobinopathies, chronic inflammatory disorders, benign or malignant neoplasms, chemical blockade of heme synthesis (lead, pyrazinamide, isoniazid), and sideroblastic anemias. [4] Although serum levels of iron, iron-binding capacity (transferrin), and ferritin are useful in the diagnosis of iron deficiency, none of these is uniformly reliable when compared to stainable iron in marrow biopsies. For example, serum iron levels characteristically drop in patients after an acute myocardial infarction, with acute or chronic inflammatory disorders, or with malignancies, despite marrow evidence of sufficient iron. [4] Likewise, even in iron-deficient individuals, disorders such as hepatitis, chronic inflammatory diseases (e.g., rheumatoid arthritis, chronic infections), chronic renal disease, and malignancies can elevate serum ferritin into the normal range. Therefore, as with all laboratory values, the proper interpretation of serum indices of iron stores requires correlation with the clinical setting.

MEGALOBLASTIC ANEMIAS Megaloblastic anemias result from impaired DNA synthesis. [5] The most common causes of megaloblastic anemia are folate or cobalamin (vitamin B_{12}) deficiency. Acute megaloblastic anemia can result from nitrous oxide exposure or severe illness combined with extensive transfusion, dialysis, total parenteral nutrition, or exposure to weak folate antagonists (e.g., trimethoprim). Other causes of more chronic megaloblastosis include certain medications (especially antimetabolites, inhibitors of dihydrofolate reductase or deoxynucleotide synthesis, some anticonvulsants, oral contraceptives) and a variety of inborn metabolic errors. Megaloblastic anemias share certain clinical features. The slowly developing anemia produces few symptoms until the hematocrit is severely depressed. Symptoms of weakness, palpitation, fatigue, light-headedness, and shortness of breath are a result of anemia. Hyperbilirubinemia secondary to ineffective erythropoiesis with hemolysis can lead to mild jaundice. Severe anemic pallor and slight jaundice combine to produce a lemon-yellow skin color. Hyperpigmentation is common, particularly in dark-skinned individuals, in both folate- and vitamin B_{12}-deficient patients. [6] In the latter, the hyperpigmentation frequently localizes to the face, hands, and feet, but occasionally only to the fingers. [7] Poikilodermatous pigmentary change has also been described in vitamin B_{12} deficiency; replacement typically reverses the hyperpigmentation. When pernicious anemia is the etiology, there is an increased incidence of vitiligo and of premature graying. [8] Cheilosis and atrophy of filiform papillae of the tongue may develop with folate or cobalamin deficiency. Leukopenia and thrombocytopenia may occur but are seldom severe enough to be symptomatic. Characteristic findings on peripheral blood smear are red cell oval macrocytosis and neutrophil hypersegmentation. Folate deficiency typically results from poor nutrition (common in elderly, poor, or alcoholic individuals), from decreased absorption (such as with sprue), or from increased metabolic requirements because of pregnancy or increased cell turnover (chronic hemolytic anemia, exfoliative dermatoses). [5], [9] Cobalamin deficiency results from impaired absorption or decreased intake of vitamin B_{12}. Dietary deficiency is uncommon but is most likely to develop in vegetarians who avoid dairy products, eggs, and B_{12} supplements (vegans). Impaired absorption is usually the cause of cobalamin deficiency and may be a result of gastric causes (pernicious anemia, gastrectomy, Zollinger-Ellison syndrome), intestinal causes (ileal resection or disease, blind loop syndrome, fish tapeworm), or pancreatic insufficiency. The most common disorder of impaired vitamin B_{12} absorption is pernicious anemia, an autoimmune disease of insidious onset producing gastric atrophy and impaired intrinsic factor production. Absorption of cobalamin is severely impaired by the absence of intrinsic factor. In addition to anti-(gastric) parietal cell antibodies, many patients with pernicious anemia also develop antibodies to intrinsic factor or the intrinsic factor–cobalamin complex. Antiparietal cell antibodies occur in 90 percent of patients with pernicious anemia, but also in 60 percent of patients with other forms of atrophic gastritis, and in 5 percent of a random 30- to 60-year-old population. Although anti-intrinsic factor antibodies are found in only approximately 70 percent of patients with pernicious anemia, they are highly specific for this condition. Other autoimmune diseases occurring more often than expected in patients with pernicious anemia include thyroid disease, type I diabetes, hypoparathyroidism, Addison's disease, postpartum hypophysitis, ulcerative colitis, vitiligo, acquired agammaglobulinemia, and certain forms of infertility. [5], [8] The hematologic manifestations of vitamin B_{12} or folate deficiency are indistinguishable, but it is critical to determine the deficient nutrient because of the often serious neurologic complications of severe vitamin B_{12} deficiency. With folate deficiency, physiologic replacement of folate (200 µg daily) should result in a full hematologic response, while a pharmacologic dose of folate (5 mg daily) corrects the hematologic abnormalities of cobalamin deficiency. [8] However, this replacement should not be used as a diagnostic test to distinguish the two, because any folate replacement may accelerate the neurologic damage of cobalamin deficiency. [8] Neurologic complications include paresthesia in the feet and fingers; changes in vibratory sense and proprioception; and progression to spastic ataxia, somnolence, altered taste, smell, and vision, dementia, psychotic depression, or paranoid schizophrenia. [5] In some patients, the neurologic findings may appear in the absence of megaloblastic changes. Because numbness and dysesthesia are perceived by some patients as skin problems, it is possible that a patient might present with these findings to a dermatologist.

ANEMIA OF ENDOCRINE DISORDERS Pituitary deficiency, adrenal dysfunction, gonadal dysfunction, and thyroid

dysfunction are the endocrine disorders in which hormonal deficiency is most likely to lead to anemia. The absence of androgen in men is followed by a drop in hemoglobin levels to those of women. The lowest hemoglobin levels are associated with myxedema, which may present with dry, coarse, and scaly skin and anemia. Hemoglobin levels in hypothyroidism are seldom below 8 to 9 g/dL. [10] Uncomplicated thyroid hormone deficiency produces a normochromic, normocytic anemia. However, for reasons only partly understood, iron deficiency frequently accompanies severe hypothyroidism, producing a hypochromic and microcytic anemia. To further complicate matters, pernicious anemia, with vitamin B_{12} deficiency and a megaloblastic anemia, is also associated with autoimmune thyroid disease at a rate higher than chance alone.

Flushing and Erythroderma (Generalized Erythema)

Just as emotional factors or cold may trigger cutaneous vasoconstriction and pallor, so may emotion or heat stimulate vasodilatation and flushing. Rosacea or actinic damage can cause facial redness. Rarely, the POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, M protein, and skin changes) with idiopathic flushing may mimic carcinoid syndrome. [11] Patients with cutaneous mastocytosis may also develop flushing episodes lasting =30 min, unlike the typical carcinoid flush of =10 min. [12] Widespread erythroderma occurs in cutaneous T cell lymphoma, in some cases of chronic lymphocytic leukemia, in lymphocytic lymphoma, and, rarely, in angioimmunoblastic lymphadenopathy or hypereosinophilic syndrome. [13], [14] and [15] The skin is often involved, sometimes severely enough to produce erythroderma, in both acute and chronic graft-versus-host disease.

A sustained increase in red cell production leads to an increase in both hematocrit and blood volume, directly raising blood viscosity and vascular volume. In turn, these are responsible for many of the signs and symptoms of polycythemia. [1] A ruddy cyanosis or acrocyanosis is seen in conditions associated with abnormally high levels of hemoglobin and sluggish flow of deoxygenated blood through dilated cutaneous vessels. An increased red cell mass may be compensatory, as in chronic hypoxic states, or primary, as in polycythemia vera.

POLYCYTHEMIA VERA Ruddy cyanosis or plethora is probably the best known cutaneous finding in polycythemia vera (PV), but patients with this myeloproliferative disease may present to the dermatologist with a variety of cutaneous findings. This disorder involves all hematopoietic stem cell lines, even though erythroid proliferation is usually dominant. It occurs most commonly after age 50 years. [16] Bleeding and thrombosis are frequent and often serious complications of this disease, including stroke and Budd-Chiari syndrome (hepatic vein occlusion). A cerebral event may precede the diagnosis of PV in up to 35 percent of patients. Signs and symptoms involving the peripheral vasculature are frequent (34 to 62 percent), including peripheral vascular disease (6 to 22 percent), erythromelalgia (18 percent), peripheral gangrene (16 percent), deep venous thrombosis (7 to 13 percent), digital artery occlusion (7.5 percent), Raynaud's phenomenon (1 to 3 percent), and leg ulcers (2 percent). Erythromelalgia, a syndrome of burning erythema in the feet or hands triggered by warmth, may precede the diagnosis of PV by several years (Table 156-1). PV-associated erythromelalgia is probably caused by the platelet abnormalities that occur in PV, may result in cutaneous necrosis, and should respond well to treatment with aspirin. Other possible cutaneous findings include paresthesia (29 percent) and pruritus (14 to 50 percent). [16], [17] Aquagenic pruritus is distinct from various forms of water-related urticaria, is characterized by intense itching after water exposure without visible skin changes, and is usually of unknown origin. Recognized associations include PV and rarely myelodysplastic syndromes or juvenile xanthogranuloma. [18], [19] and [20] The pruritus is often sudden in onset after a warm bath or shower and must be distinguished from transient pruritus after bathing or aquagenic pruritus of the elderly. True aquagenic pruritus is characterized by intense, constant, disabling, and often progressive symptoms. [19] There is no clear relationship between the degree of pruritus and the severity of the disease, with roughly 20 percent of patients continuing to itch despite adequate control of their PV. [17] Although the pathogenesis of pruritus has been tied to elevated blood and urine histamine levels, H_1 antagonists are generally of little value. Occasional patients may respond to aspirin, cholestyramine, H_2 receptor antagonists, oral iron, or PUVA. [17] Recombinant interferon-a may be an effective therapy in PV, and in one study provided greater than 50 percent improvement in pruritus control in 77 percent of patients. [17] Suberythemal UVB and PUVA may also induce at least temporary remissions. [19] The diagnosis of PV depends on an increased red cell mass (=36 mL/kg in males or =32 mL/kg in females) and arterial O_2 saturation (=92 percent). In addition, patients must have either splenomegaly or any two numerically defined minor criteria, which include thrombocytosis, leukocytosis, an elevated leukocyte alkaline phosphatase level, and a greatly elevated serum vitamin B_{12}-binding capacity. [16] Phlebotomy is the treatment of choice for relief of symptoms of hypervolemia and hyperviscosity, but it does not relieve pruritus or thrombocytosis. Beyond phlebotomy, there is no single best treatment for PV. Myelosuppressive therapy or radioactive phosphorus (^{32}P) is indicated to reduce the incidence of thrombosis, but may be complicated by the development of acute leukemia or other secondary malignancies.

Cyanosis

In patients with normal hemoglobin levels, peripheral cyanosis indicates at least 5 g/dL of reduced hemoglobin in capillary blood. Peripheral cyanosis has multiple etiologies, including vasoconstriction with resulting slow acral flow. Only central cyanosis (tongue and sublingual region) reliably indicates significant arterial deoxygenation or altered hemoglobin. Cyanosis is best observed in fluorescent lighting. Thin skin areas are the best places to look for cyanosis; in adults, these areas include the lips, earlobes, nail beds, and oral mucous membranes; in newborns, these areas include the highly vascular palms and heels. However, multiracial studies suggest that the tongue is the most sensitive site for detection of central cyanosis.

Lingual cyanosis as the earliest manifestation of central cyanosis is reliably detectable at a level of 3.4 g/dL of reduced arterial hemoglobin, resulting in a level of 5 g/dL of reduced capillary hemoglobin. The total concentration of hemoglobin determines the level of arterial deoxygenation that this lower limit of detectable cyanosis represents. For example, in a patient with a hemoglobin of 15 g/dL, 3.4 g/dL corresponds to an SaO_2 of 77 percent and a PaO_2 of 43 mmHg. This same level of reduced hemoglobin in a patient with 12 g/dL hemoglobin corresponds to a PaO_2 of 39 mmHg. A severely

anemic patient with a hemoglobin of =7 g/dL may never manifest cyanosis despite fatal hypoxia. In contrast, a polycythemic patient with 18 g/dL hemoglobin and 3.4 g/dL of reduced hemoglobin will develop central cyanosis with an SaO_2 of 84 percent and a PaO_2 of 49 mmHg. Because cyanosis depends on the absolute amount of reduced hemoglobin, patients with PV can easily manifest peripheral cyanosis despite normal arterial saturation, which explains their ruddy cyanosis.

Central cyanosis in an individual with normal hemoglobin levels and an acceptable PaO_2 implies an abnormal hemoglobin level or a related problem. These include inherited methemoglobinemia (hemoglobin M), toxic methemoglobinemia, inherited NADH-diaphorase (cytochrome b5 reductase) deficiency, cytochrome b5 deficiency, acquired sulfhemoglobinemia, and low oxygen-affinity hemoglobins. [21]

Methemoglobin occurs naturally as 1 percent of total hemoglobin. At a 1.5-g/dL concentration (roughly 10 percent in men), cyanosis is easily detectable. At 20 percent, a chocolate cyanosis is seen, turning the tongue and sublingual area brown. Levels >60 percent methemoglobin are a medical emergency and should be treated with IV methylene blue or exchange transfusion. Many medications may cause elevated levels of methemoglobin, including dapsone, phenazopyridine (Pyridium), sulfamethoxazole, nitroglycerin, nitrites, and the local anesthetics benzocaine and prilocaine. [21] Nitrates in drinking water and aniline dyes in diapers are important and easily overlooked causes of this condition in infants. [21] NADH-diaphorase deficiency and the very rare cytochrome b5 deficiency impair the ability of the red cells to reduce iron to the divalent form, thereby increasing the formation of methemoglobin.

Sulfhemoglobin produces cyanosis at levels of only 0.5 g/dL capillary blood and cannot be reversed. Medications (especially sulfonamides, phenacetin, acetanilid, and phenazopyridine) are the usual cause of sulfhemoglobinemia, but this condition has occurred independent of drug use in association with chronic constipation and with purging.

Hemoglobins with altered oxygen affinity produce cyanosis through different mechanisms, but the predominant abnormalities are either lowered oxygen affinity with higher levels of reduced hemoglobin, or increased formation of methemoglobin. Cyanosis of the ears or fingertips is observed after exposure to cold in some individuals with cryoglobulins or cold agglutinins. Raynaud's phenomenon and acrocyanosis are nonhematologic causes of peripheral cyanosis with characteristic clinical presentations.

Jaundice

Jaundice is caused by staining of the skin by bile pigment. Bilirubin glucuronide (direct-reacting or conjugated bilirubin) stains the skin more readily than does the unconjugated form. [2] Jaundice of the skin may not be visible if the bilirubin level is below 2 to 3 mg/dL. Unconjugated hyperbilirubinemia suggests hemolytic anemia or inefficient hematopoiesis, as in megaloblastosis. Usually, total bilirubin is only modestly increased (<5 mg/dL), with unconjugated bilirubin comprising at least 85 percent of the total amount. [22] Urinary urobilinogen is increased regularly, but bile is not detected in the urine unless serum conjugated bilirubin is increased. Usually, serum-haptoglobin levels are low, and lactate dehydrogenase (LDH) levels are elevated. Hemoglobinuria is encountered in rare patients with hyperacute hemolysis who develop significant hemoglobinemia.

Infiltrative Lesions/Extramedullary Hematopoiesis

Specific (tumor-containing) lesions occur in many leukemias, lymphomas, and related disorders and are detailed elsewhere. Some of these same conditions induce non–tumor-containing extramedullary hematopoiesis, with the skin being an occasional and sometimes presenting site. Lesions of extramedullary hematopoiesis may present as red, pink, or violaceous papules or plaques, hemangioma-like nodules, bullae, or leg ulcerations; they may occasionally be surrounded by a hemorrhagic border. [23] Such extramedullary hematopoiesis usually occurs in idiopathic myelofibrosis, but rarely has been seen in other myeloproliferative diseases. Neonatal cases are associated with congenital infections, erythroblastosis fetalis, and, even more rarely, conditions such as twin transfusion syndrome. [23]

HEMOSTASIS AND THE DIFFERENTIAL DIAGNOSIS OF PURPURA

Hemostasis

Hemostasis is divided into two components: primary and secondary. Primary hemostasis depends both on vasoconstriction of the injured vessel and on the development of a platelet plug at the site of injury. Primary hemostasis is a critical homeostatic mechanism for repair of small defects and is a sufficient mechanism for most focal injury in the microcirculation. Because it is richly endowed with microcirculatory vessels, presumably in part to support its heat exchange function, the skin is a sensitive early warning site for problems in primary hemostasis, especially with problems in platelet function or numbers. Defects larger than those that can be sealed by a platelet plug alone and defects in larger vessels require secondary hemostasis. Secondary hemostasis involves the cascade pathway of coagulation factors and results in fibrin clot reinforcement for the platelet plug. Whereas platelet problems are an important cause of purpuric skin lesions, defects or deficiency of a single procoagulant clotting factor are an uncommon cause of cutaneous hemorrhage, usually leading instead to soft tissue hemorrhage, particularly into joints.

Differential Diagnosis of Purpura

The differential diagnosis of purpura can be confusing, and etiologies encompass hematologic, rheumatologic, dermatologic, infectious, and traumatic entities. Although it is the pathogenesis or etiology of the purpura that we usually most want to know, many approaches to the differential diagnosis of purpura begin with classifications by etiology. To circumvent this requirement, we must understand what the morphology of purpura can reveal about its likely pathogenesis. At the most basic level, purpura in the skin can be caused by simple hemorrhage, inflammatory hemorrhage, or microvascular occlusion with ischemic hemorrhage. Careful inspection of purpuric lesions is essential for

the sorting of lesions clinically into one of these fundamental categories as well as for providing an initial focus for history taking, further clinical examination, and laboratory assessment.

Morphologic differentiation can be extremely helpful in sorting through the differential diagnosis, but this approach requires a definition of terms not always used in a standard fashion and the addition of terms to categorize important morphologic subsets not previously distinguished. In this chapter, *purpura* refers to visible hemorrhage in skin or mucous membranes. Morphologic subsets of purpura include petechia (pl. petechiae), ecchymosis (pl. ecchymoses), contusions (bruises), classic palpable purpura, target lesions, inflammatory retiform purpura, and noninflammatory retiform purpura. [24]

The morphologic diagnosis of purpura begins with three P's: Is the lesion *purpuric,* is it *primary,* and is it *palpable*? For a lesion to qualify as purpuric, it must have a color that is compatible with hemorrhage—usually some shade of red, blue, or purple, but sometimes yellow-brown, green, or black—and at least some of this color must persist on compression of the skin. If the vessels are compressible, and if the color is caused by red cells that are free to move, then the color should completely blanch on compression. False-positive results occur if the lesion contains tortuous vessels that kink or constrict each other on compression, or if the lesion is difficult to compress sufficiently because of lesional firmness or because it is located in an area of dermis overlying a particularly soft subcutis, such as on the abdomen.

Red cells that have extravasated or are trapped within thrombi or vascular plugs are not free to move, and therefore some of the color persists on compression. In addition to defining purpura, compression of a lesion can be used to determine the ratio of erythema to hemorrhage. A lesion due solely to the erythema of inflammation or flushing should blanch completely. A lesion consisting of some inflammation and some hemorrhage, such as vasculitis, should blanch partially. A lesion of simple hemorrhage or extravasation of red cells, or one related to ischemic or thrombotic hemorrhage, usually has no blanchable component. Lesions caused by microvascular occlusion alone appear to induce visible purpura through ischemic extravasation of red cells around the vessel, inasmuch as thrombosis within the dermal microvasculature itself is too small to be seen directly.

The color of lesions provides additional clues. Red implies saturated hemoglobin, whereas blue implies desaturated hemoglobin. Usually, color because of blood flow is red, whereas color because of hemorrhage is blue. However, hemorrhage may remain bright red even without an inflammatory component, most often when small and superficial—for example, petechial hemorrhage. Presumably, it is possible for the hemoglobin in the extravasated cells to remain saturated through simple diffusion of oxygen from the dermis or through the epidermis. Likewise, slow flow in the skin commonly produces the bluish-purple discoloration of livedo reticularis. The term *livedo reticularis* should be limited to a completely blanchable, netlike discoloration of the skin; defined in this way, livedo reticularis is a sign of slowed or restricted cutaneous blood flow. Cyanosis, discussed previously, is another nonpurpuric cause of bluish discoloration.

Next, one must decide whether purpura is primary, that is, caused by the same process that induces the lesion. With simple extravasation, the entire visible lesion is solely a result of red cells in the dermis, resulting in macular, nonerythematous (nonblanching) purpura. In contrast, a mosquito bite is not a clinically evident hemorrhagic event for most people, but sufficient scratching can induce purpura in such a lesion. This purpura is secondary and not primary. Vasculitis as a vessel-directed injury can induce both a papule and hemorrhage as part of the same vessel injury, producing a primary purpura lesion.

Palpability must be evaluated. Red cells alone do not determine palpability, because simple hemorrhage in the dermis is usually not palpable. Extravasation of blood into or beneath the panniculus can produce a palpable hematoma, which may or may not be purpuric (the overlying dermis may or may not show visible hemorrhage). Edema confers palpability to purpuric lesions, usually secondary to inflammation but sometimes to occlusion with preceding microvascular ischemia.

Finally, a very important morphologic feature is the presence of retiform or branching features. Retiform (branching, stellate) purpura without inflammation suggests microvascular occlusion as the etiology of the lesion, whereas prominent erythema in early retiform lesions suggests vasculitis caused by either IgA or mixed–vessel-size inflammatory syndromes. [24], [25] It is presumed that the reticulate, livedoid, or stellate patterning of such lesions is caused by the same microvascular anatomy of the skin responsible for the localization of the livedo reticularis pattern in slow-flow states. Figure 156-1 summarizes this bedside approach to purpura.

FIGURE 156-1 Algorithm for assessing purpura.

NONPALPABLE PURPURA Petechial, nonpalpable hemorrhage in the skin and mucous membranes raises concerns about two general categories of hematologic syndromes: hemostatically relevant thrombocytopenia, usually less than

50,000 platelets per microliter, and abnormal platelet function (Table 156-2). There are also nonhematologic causes of nonpalpable petechial hemorrhage. The most common include spiking elevations of intravascular pressure (e.g., straining during childbirth, repetitive vomiting, and paroxysmal coughing), which usually result in petechial hemorrhage above the clavicles, chronic elevation of venular pressure (e.g. stasis), increased transmural pressure gradients (e.g., high altitudes), and the syndromes of chronic pigmented purpura. The clinical features of the chronic pigmented purpuras typically include clustered petechiae within patches of orange-brown discoloration. This color results from a mix of mild erythema with hyperpigmentation from hemosiderin and melanin in dermis. The subsets of chronic pigmented purpuras or pigmented purpuric dermatoses are discussed in Chap. 176. Occasionally, viral syndromes may present with widespread petechiae, which in some patients are not palpable. Enteroviral syndromes seem most likely to produce this outcome. Rarely, benign hypergammaglobulinemic purpura of Waldenström can present as nonpalpable petechiae.

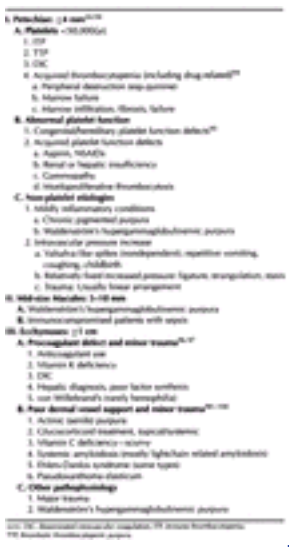

TABLE 156-2 **Partial Diffferential Diagnosis of Nonpalpable, Nonretiform Purpura by Size of Lesion**

Macular hemorrhage >4 mm and <1 cm in diameter (intermediate or indeterminate hemorrhage) can be a result of most of the causes of either petechial or ecchymotic hemorrhage. Laboratory studies are therefore less directed, and physicians must screen for both platelet and procoagulant problems. Patients who are immunocompromised may have little or no inflammatory response to organisms, and therefore septic lesions may not be palpable in these patients. Another disorder that often presents with similar-sized macular lesions is benign hypergammaglobulinemic purpura of Waldenström. [26] This syndrome is seen most characteristically as an idiopathic syndrome in young women, with recurring crops of macular hemorrhage, most often on the legs, frequently after exercise or prolonged standing. In women middle-aged and older, it may be associated with Sjögren's or sicca syndrome, lupus, rheumatoid arthritis, or, rarely, a lymphoproliferative syndrome or monoclonal gammopathy. [26] A polyclonal gammopathy is the typical finding, but the most distinctive finding is an IgG or IgA rheumatoid factor that may be monoclonal and that acts to form 12- to 15-s immune complexes on analytic ultracentrifugation. Standard tests for rheumatoid factor detect only IgM rheumatoid factor and are of no help in diagnosing this syndrome. Ecchymoses have multiple etiologies and are probably the most common form of hemorrhage (Table 156-2). They are almost always localized by minor trauma and therefore typically develop in areas prone to trauma (dorsum of hand, pretibial area, extensor forearm, lateral or anterior thighs) and in a geometric pattern, usually linear or rectangular (Fig. 156-2 and Fig. 156-3). Petechial hemorrhage arranged linearly, often with skip areas, may have the same significance as ecchymoses, especially when the petechiae are themselves asymmetric or linear rather than symmetric and round. Easy bruising is a common complaint, most often because of the dermal effects of chronic sun injury, glucocorticoids, or (in some geographic areas) scurvy. In some individuals, usually women, no abnormalities may be found after detailed study, leaving the etiology uncertain. Less commonly, ecchymoses may result from a mild hereditary bleeding disorder.

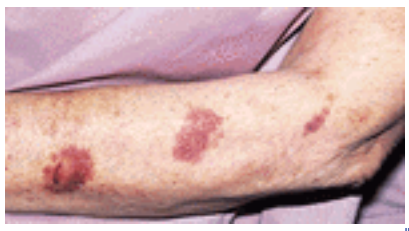

FIGURE 156-2 Nonpalpable ecchymoses in a patient on chronic oral glucocorticoid therapy. Note the rectangular and linear lesions that suggest the minor trauma component. (*From Piette,* [37] *with permission.*)

FIGURE 156-3 Close-up of one of the ecchymotic areas shown in Fig. 156-2, showing a linear traumatic injury with surrounding ecchymosis. (*From Piette,* [37] *with permission.*)

Contusions and hematomas are usually a result of trauma significant enough to be remembered. Such lesions are often swollen and therefore palpable and tender; they may also show erythema or abrasions, depending on the degree of trauma. Determining the age of ecchymoses and contusions can be a critical aspect of forensic medicine and in suspected abuse, but recent studies have suggested that dating hemorrhage is far less precise than reported earlier. [27], [28] A bruise may become more prominent with the passage of hours or days as a result of continued bleeding from the ruptured vessels or of a delay in reaching the surface because of deflection by fascial planes and other anatomic

structures. Additionally, bruises may move under gravity, such as those related to a laceration on the upper forehead. The subcutaneous hemorrhage can slide downward over the eyebrow ridge and appear in the orbit, to give a “black eye.” Similarly, a bruise of the upper arm or thigh may surface lower around the elbow or knee. Another factor in the delayed prominence of hemorrhage is hemolysis of the extravasated cells, inasmuch as free hemoglobin stains tissues more diffusely than intact red blood cells. Chemical degradation of hemoglobin into hemosiderin, biliverdin, and bilirubin causes a sequence of color changes from purple or bluish brown, to greenish brown or green, and finally to yellow before completely fading. Variables affecting color changes in bruising include the size of the extravasation (a larger bruise may contain more color changes due to delay in resolution from the margin inward), the age and constitution of the individual (severely sun-damaged skin resolves purpura much more slowly), and individual idiosyncrasies such as persistent coagulation defects. Hemosiderin does not usually appear within the first 2 or 3 days. Hematoidin, another breakdown product of blood pigment, can appear in old bruises and in hematomas after the first week. The capillaries of the subcutaneous tissues make the greatest contribution to bruising. Data are sparse regarding the reliability of wound dating by appearance. In experiments with cattle, the sequence of color development is red from 15 min to 2 days (due to red cells and free hemoglobin), green on days 3 and 4, and yellow and orange from days 4 to 6 (due to bilirubin). In humans, a long-standing consensus has been that red, blue, and purple are early colors; greens show after 4 to 7 days; and yellow color is delayed until after the seventh day. Recent studies challenge this consensus with the demonstration that red, blue, purple, or black coloration can develop from within 1 h of bruising up to 21 days. [27], [28] A bruise with yellow color is at least 18 h old in any individual, although the development of a yellow color occurs significantly faster in persons younger than 65 years of age. [27]

PALPABLE OR RETIFORM PURPURA The differential diagnosis of inflammatory hemorrhage, including vasculitis, is extensive. Summarized in Table 156-3, such syndromes are discussed elsewhere in this text. Figure 156-4, Figure 156-5, and Figure 156-6 provide examples of classic palpable purpura, target lesions, and inflammatory retiform purpura.

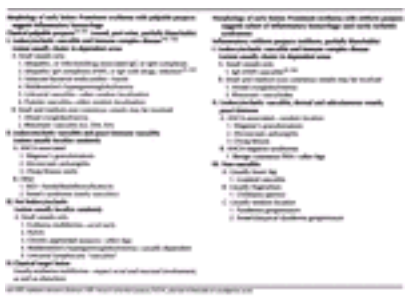

TABLE 156-3 **Partial Differential Diagnosis of Palpable or Retiform Purpura with Prominent Early Erythema by Lesion, Shape, and Degree of Erythema**

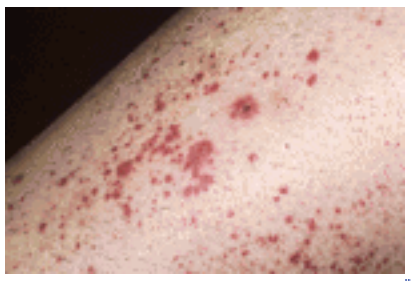

FIGURE 156-4 Classic palpable purpura on the leg of a patient with IgA vasculitis. Partial blanching of an early lesion on compression supports the clinical impression of inflammatory hemorrhage.

FIGURE 156-5 Target lesions with central hemorrhage in a patient with erythema multiforme (EM). Unfortunately, many patients with EM do not develop target lesions, and some may develop lesions clinically identical to those in Fig. 156-4.

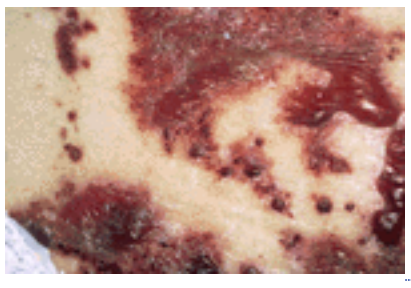

FIGURE 156-6 Inflammatory retiform palpable purpura in a patient with IgA vasculitis. The initial erythematous phase is still present but fading in these lesions.

It is critical to distinguish vascular injury in which inflammation predominates from processes in which microvascular thrombosis or occlusion is the primary mechanism. Table 156-4 summarizes the major differential possibilities for microvascular occlusion, characterized clinically by noninflammatory retiform (branching, stellate) purpura or by large

areas of purpura/necrosis with minimal early erythema (Fig. 156-7) and histologically by bland (noninflammatory) occlusion of dermal vessels. An important, but nonpurpuric presentation of cutaneous microvascular occlusion includes the development of painful atrophie blanche (livedoid vasculitis)-like ulcers or porcelain white scars, especially on the legs. Such lesions may develop secondary to occlusion in patients with primary atrophie blanche, in some patients with antiphospholipid antibody syndrome, either primary or secondary to lupus, or with severe anemia with high reticulocyte counts (especially sickle cell disease or thalassemias). Syndromes important in cutaneous microvascular occlusion have been reviewed. [29]

TABLE 156-4 **Differential Diagnosis of Palpable or Retiform Purpura with Minimal Early Erythema by Lesion, Shape, and Degree of Erythema**

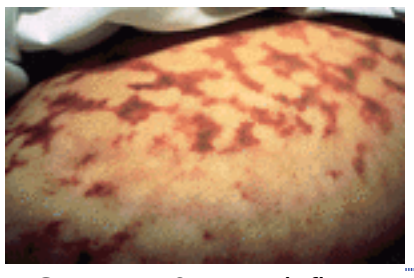

FIGURE 156-7 Noninflammatory retiform palpable purpura on the thigh in a patient with disseminated intravascular coagulation secondary to sepsis. None of the lesional color faded on compression. The biopsy showed multiple dermal vessels occluded by clot without inflammation.

Medicine has seen important advances in understanding hypercoagulable states in recent years, especially in the areas of the protein C–thrombomodulin pathway, factor V Leiden, antiphospholipid antibody syndrome, and homocystinuria. [30], [31] It is important to recognize that the causes of microvascular thrombosis or occlusion overlap with, but are not identical to, the causes of thrombotic disorders of larger vessels. For example, antithrombin III deficiency is an important risk factor for large-vein thrombosis but is rarely responsible for occlusion of the dermal microvasculature. Likewise, cryoglobulins can cause dermal vessel occlusion in acral areas but do not occlude major veins. Therefore, expertise in this area of cutaneous disease can be critical not only in interpreting the cutaneous changes but also in suggesting likely individual syndromes responsible for occlusion. The proper interpretation of morphologic findings of purpura can be an important aid in the timely and accurate evaluation of causes of cutaneous hemorrhage.

HISTORICAL ASPECTS

The earliest descriptions of cutaneous T cell lymphomas (CTCL) appeared during the era of descriptive dermatology when the great French clinicians recognized the distinctive features of this disease. Alibert observed the unique features in the early 1800s and coined the term *mycosis fungoides* (MF). Later in the nineteenth century there were descriptions of the patch, plaque, and tumor stages of MF. By using sheep red blood cell rosetting these disorders could be unified as being malignancies of T lymphocytes. Sheep red cell rosetting was the first marker for T cells and is now known to be related to expression of CD2. As research tools were applied, it was discovered that there were cutaneous B cell lymphomas, ?d cutaneous lymphomas and NK lymphomas. Cutaneous homing lymphocytes include T cells, B cells, and subsets thereof. Cutaneous T cells are a dynamic population with distinct cell surface markers. Subsequent work clearly shows that the malignant cells of CTCL are cutaneous T cells, providing the unifying concept for lymphomas of cutaneous T cells. Thus, the concept of the old clinical entity MF has been expanded to the spectrum of CTCL including non-MF cutaneous T cell lymphomas. Whereas all forms of MF are CTCL, not all CTCLs are MF. [1] Table 157-1 lists the distinct variants of CTCL.

I. Mycosis fungoides variants
  A. Classic mycosis fungoides
  B. Clincopathologic syndromes
    1. Hypopigmented
    2. Granulomatous slack skin
    3. Pagetoid reticulosis
    4. Pigmented purpuria
    5. Alopecia mucinosa
    6. Follicular
    7. Adnexotropic
  C. Immunophenotypic syndromes
    1. CD8+
    2. Gamma-delta+
    3. NK T cell
  D. Erythrodermas
    1. Sézary syndrome
    2. Erythrodermic MF
    3. Erythrodermic CTCL
  E. Tumors of mycosis fungoides
II. Nonmycosis fungoides CTCL
  A. CD30+ and CD30−
  B. Large vs. small vs. mixed cell type
  C. Angiocentric
  D. Lipotropic (subcutaneous)

CTCL = cutaneous T cell lymphoma; MF = mycosis fungoides; NK = natural killer

TABLE 157-1 **Distinct Variants of CTCL**

EPIDEMIOLOGY

The difficulty in determining the changing epidemiology of CTCL relates to the restriction of study patient groups to tertiary centers that accrue patients in a nonrandom manner. Although early epidemiologic studies reported a substantial increase in the incidence of MF before the early 1980s, [2] a more recent study that used a substantially larger database with a longer interval of time showed that the incidence rate has stabilized, at an average rate of 0.3 per 10^5 person-years. [3] The data were derived from cancer registries that participated in the Surveillance, Epidemiology, and End Results (SEER) program data of the National Cancer Institute from 1973 through 1992. Among racial groups, the

incidence rate of MF is highest among blacks and lowest among Asians. Males are twice as likely to get MF than are females, and this is consistent among racial groups. Underregistration was identified as a potential problem in their data because most MF patients are treated as outpatients. The often indolent nature of the disease further hinders diagnosis, as patients die of other causes before CTCL progresses to an advanced stage.

The mortality rate of MF has declined. [4] Data were obtained from death certificates reported to the National Center for Health Statistics for the United States during the period 1979 to 1991. The mortality rate was found to be 0.064 per 10 [5] person-years and the rate ratio for men versus women was 1.8 overall. Identical to the incidence rate, the mortality rate was highest among blacks and lowest among Asians. But the overall mortality rate declined approximately 22 percent during the period studied. A Swedish study also showed a decrease in mortality rates between 1961 and 1980. [5] Those declines in mortality rates can be attributed to improved diagnostic techniques, early diagnosis, and rapid treatment of MF.

The same SEER data were used for the period between 1973 to 1992 to evaluate the trend in survival among MF patients. [4] This study identified important prognostic factors as age, and race and a larger group of patients (1633) were followed for a substantially longer period of time (greater than 10,000 person-years). It was found that advanced age and black race were associated with poorer prognosis and there was improvement in survival rates over the 20-year period studied. The data showed that when patients survived 11 years after diagnosis of their disease, it was unlikely they were going to die because of MF.

In a study of long-term outcome of patients with generalized patches and/or plaques of MF (T2, see below), 24 percent of patients had disease progression and 20 percent eventually died of advanced disease. [6] Younger patients had a better disease-specific prognosis than older patients and presence of lymphadenopathy at the time of diagnosis did not indicate poorer long-term outcome. Lack of complete response to initial therapy and lymphadenopathy at diagnosis were predictive of disease progression.

Patients with limited, early stage disease (T1) have no significant difference between observed and expected survival. [7] As expected, the relative survival of patients with CTCL decreases with increasing disease stage. In this study, the 10-year relative survival rates were calculated for 489 patients: T2 = 67.4 percent, T3 = 39.2 percent, and T4 = 41 percent. Lymphadenopathy at time of diagnosis had an unfavorable impact on prognosis, conflicting with other studies where it was shown not to impact long-term outcome.

Uniform standards for diagnosing and staging CTCL patients are necessary in order to determine the true epidemiologic statistics and significance of this disease. Dermatologists must take an example from oncologists in regards to staging a patient with CTCL. The stage at initial presentation must be maintained for each patient whether their disease improves or progresses so that data collection accurately represents the CTCL patient population. It is important to adhere to the oncologic principle that the patient's stage will not change, although their disease status may. In addition, consistent reporting to local cancer registries will lead to more complete data for CTCL. These changes will result in more reliable statistics including incidence, prognosis and mortality rates.

ETIOLOGY

For many years, CTCL was thought of as a disease of chronic antigen stimulation in which an initial inflammatory response in the epidermis leads to T cell proliferation and, finally, to the emergence of a malignant clone. Despite much effort to identify a unifying antigen in this disease, the etiology remains unknown.

A viral etiology for CTCL was an attractive hypothesis given the cutaneous similarities with adult T cell lymphoma/leukemia(ATL), associated with human T cell lymphotrophic virus type I (HTLV-1) infection. The results of studies to determine an association between CTCL and HTLV-1 are contradictory. An early study reported a partially deleted HTLV-1 provirus in a cell line established from a patient with MF detected by polymerase chain reaction (PCR) analysis. However, studies have been done in American and European populations that find no association of MF with HTLV-1 infection. PCR, Southern blot, and reverse transcriptase assays have been used, but no HTLV-1 has been demonstrated. These data suggest that HTLV-1 does not play an important role in the etiology of CTCL and that the only reason for screening patients for antibodies is when one suspects the diagnosis of ATL, not MF. Epstein-Barr virus (EBV) has also been proposed as a pathogen. Given its association with other lymphoproliferative disorders and lymphomas, such as Burkitt's lymphoma, its connection seemed logical. The possibility that EBV infection can lead to the proliferation and activation of T cells in the epidermis has been suggested, but this has not yet been definitively proven.

Bacterial infections have also been implicated in CTCL. One group suggested an association of *Staphylococcus aureus*. [8] Of the CTCL patients studied, 75 percent had a positive staphylococcus culture from the blood or skin with half of these cultures positive for *S. aureus* carrying enterotoxin genes, such as toxic shock toxin-1. The patients with positive blood cultures had Sézary syndrome or progressive plaque and tumor MF but only four had monoclonal expansion of a specific Vß gene. This study suggested that *S. aureus* superantigen enterotoxins could provide or potentiate lymphocytic infiltration and chronic antigenic stimulation leading to T cell clonal expansion in CTCL.

It has been suggested that occupational risk factors also play a causative role in CTCL, because an indolent dermatitis often precedes the diagnosis. Exposure to carcinogens in the work environment can provide the chronic antigenic stimulation needed to initiate clonal expansion. An occupational exposure to chemicals considered hazardous was recorded in 30 percent of patients in the Mycosis Fungoides Study Group [7]. However, a case control study in California and Washington State demonstrated no correlation between MF and occupation or chemical exposure. [9]

Even though the hypothesis that CTCL is a disease due to chronic antigenic stimulation with ultimate emergence of a malignant T cell clone remains well established, the etiology of CTCL, including the discovery of some possible initiating

events, has yet to be determined.

PATHOPHYSIOLOGY (See also Chap. 23 and Chap. 28)

The clinical entities encompassed by the term *cutaneous T cell lymphoma* share several components, including a T cell clonal population, a modulated antitumor response, and an epidermal microenvironment.

CTCL is a malignancy of skin-homing T cells thta are best delineated from other T cells by a unique cell surface receptor called *cutaneous lymphocyte-associated antigen* (CLA). CLA is expressed on memory T cells that have the ability to home to the skin by binding to E-selectin, which is expressed on vascular endothelial cells and superinduced during cutaneous inflammation. As these T cells circulate through high endothelial venules, they respond to yet unknown signals from the epidermis by tethering and rolling on P-selectin and E-selectin and, finally, extravasating into inflamed skin.

CLA is a cell surface glycoprotein that is defined by its reactivity with a monoclonal antibody, HECA-452. It was recently discovered that CLA is actually an inducible carbohydrate modification of a ubiquitously expressed T cell surface protein, P-selectin glycoprotein ligand-1 (PSGL-1). CLA is produced by a posttranslational modification of PSGL-1 by a(1,3)-fucosyltransferase (FucT VII) that is found in lymphocytes that bind E-selectin.

CLA is also expressed on cells of myeloid lineage, including monocytes, neutrophils and dendritic cells. Less than 20 percent of peripheral T cells express CLA, suggesting that these cells can be readily recruited to the skin. More than 85 percent of T cells participating in a cutaneous inflammatory response express CLA. However, CLA-expressing lymphocytes are not found in inflammatory infiltrates in the kidney, synovium, or other tissues. In vitro studies show that CLA can be induced in all peripheral blood T cells populations, implying that all T cells have the capacity to home to the skin, depending on yet undetermined regulatory signals. [10]

The second similarity unifying CTCLs is the presence of a modulated antitumor response. Lesions of CTCL often have a CD8+ T cell component. Once thought to be innocent bystanders in the epidermis, we now have data defining the responsibility of CD8+ T cells in the antitumor response. The first insight into defects in the integrity of normal T cell function in advanced CTCL patients came from observations in patients who had been treated with extracorporeal photochemotherapy (see Chap. 266). Responding patients had significantly lower CD4/CD8 T cell ratios and higher absolute numbers of CD8+ T cells in their peripheral blood at the outset of treatment than did nonresponders. [11] In general, skin biopsies of MF lesions in early stages (T1 and T2) harbor a higher proportion of CD8+ cells as compared to lesions in advanced stages. Improved long-term prognosis was correlated with the presence of these CD8+ tumor-infiltrating lymphocytes (TIL) in MF. [12] It is now believed that these CD8+ cytotoxic T cells play an important part in the pathogenesis of CTCL, mainly in mediating an antitumor response.

One possible mechanism for this antitumor response may be mediated through the Fas/FasL pathway, which can also provide neoplasms with immune privilege and protection. Fas receptor and Fas ligand (FasL) are transmembrane proteins of the tumor necrosis factor (TNF) family and are expressed on cells of lymphoid and myeloid lineage. Upon binding of the ligand to the receptor, a cascade of events occurs leading to apoptosis. In melanoma, loss of Fas expression by tumor cells has been correlated with tumor progression suggesting that absence of this apoptotic initiator mediator leads to immunosurveillance escape. In other tumor models, the converse has been demonstrated. Expression of FasL on tumor cells can trigger apoptosis in cytotoxic T cells that express Fas, thereby providing a counterattack to the immune response and evading destruction itself.

Aberrations of the Fas/FasL pathway have been studied in CTCL. Immunohistochemical studies of Fas and FasL expression in frozen and paraffin-embedded skin biopsies of CTCL patients demonstrated loss of Fas expression in advanced MF and aggressive forms of CTCL and strong expression in early stages of MF. The Fas/FasL pathway may contribute to the immunosuppression seen in MF patients and provide immune advantage/privilege to tumor cells, rendering them immunologically tolerant.

The third unifying concept in the pathophysiology of CTCL is the participation of the epidermis as a microenvironment for malignant cells (see Chap. 23). Within the skin, cytokines have an important role in maintaining the milieu and initiating immune responses (see also Chap. 26). It is well established that patients with CTCL have variable production and response to T_H1 and T_H2 cytokines. Early studies that measured the mRNA levels of T_H1 and T_H2 cytokines showed that, at any stage of disease, IL-5 and IL-4 mRNA, T_H2 cytokines, could be found with the persistence of T_H2 cytokine mRNA in skin more frequent in tumor stage. The decline in interferon (IFN)-? and predominance in T_H2 cytokines might be responsible for loss of immunosurveillance, allowing CTCL to progress.

Other cytokines are also likely to play a role in the pathogenesis of CTCL. Culture studies and immunohistochemical studies on skin biopsies demonstrate the presence of interleukin (IL)-15 and IL-7 in CTCL patients. IL-7 is a cytokine, produced by keratinocytes, which has been identified as a T cell growth factor. IL-15, also produced in the skin by keratinocytes, has functional properties similar to IL-2, a growth-stimulating cytokine for both B and T cells and a potent T cell chemoattractant.

To better define the microenvironment and cellular components of the epidermis, a new technique of micromanipulation to obtain single immunolabeled T cells in tissue sections followed by single-cell PCR was developed. [13] By using this technique, the exact localization and immunophenotype of clonal and nonclonal (likely reactive) T cells in the different skin compartments can be determined. Once the single cells were obtained, their genetic material could be precisely analyzed by PCR without reactive T cell component contamination. This allowed insight into the microanatomic preferences of the tumor cells. In addition, these techniques are simply done on skin punch biopsies of patients at any stage of disease. Initial experiments with single-cell micromanipulation found that clonal CD4+ T cells, especially in early stages of CTCL, were localized to the epidermis and that nonclonal CD4+ T cells had a preference for the dermis rather than the epidermis. This suggests that the polyclonal CD4+ T cells in the subepidermal infiltrate establish a barrier of

lymphocyte-mediated antitumor response. Further investigations using this novel technique will bring us closer to an understanding of the unique epidermal sanctuary that harbors, preserves, and perpetuates CTCL.

For many years, the role of oncogenes and tumor-suppressor genes in the pathogenesis of CTCL have been investigated, but the data are inconsistent and nonconclusive. A recent allelotyping study was performed to identify the chromosomal regions of allelic loss and sites of tumor-suppressor genes in MF. [14] Loss of heterozygosity (LOH) was present in 45 percent of MF patients and in 67 percent of Sézary syndrome patients with no significant difference in age at diagnosis or number of treatment received by the patients with LOH and those without. In all stages of disease, LOH on 1p and 9p was found, implicating tumor-suppressor genes such as p73, TAL1, p15, and p16 in early stages of MF. LOH on 17p and 10q were restricted to patients with advanced disease, suggesting that Fas, PTEN, and p53 could be important in disease progression.

CLINICAL MANIFESTATIONS

The clinical syndromes of CTCL, as listed in Table 157-1, are as varied as the functions of cutaneous T cells. The major components of the disease (discussed above) interplay to varying degrees of intensity to produce lesions and the clinical entities can be categorized by their clinical, pathologic, and/or immunopathologic features. The most commonly encountered type of CTCL is the mycosis fungoides spectrum. The other syndromes are often referred to as the nonmycosis fungoides types of CTCL. The nonmalignant conditions often confused with CTCL are discussed in the chapters on parapsoriasis (Chap. 47) and cutaneous pseudolymphomas (Chap. 159). Other systemic lymphomas with skin infiltrations are discussed in Chap. 158.

Clinical Features

Malignant skin-homing T cells growing primarily in the skin give rise to several clinical patterns. In general, the process begins with flat lesions (macules and patches). These erythematous patches, as shown in Fig. 157-1, are often associated with inflammation and pruritus. The diagnosis is elusive as the lymphomatous cells are mature helper T cells and the lesions have an admixture of cell types that suggests an inflammatory etiology. These nondiagnostic patches can persist for years or resolve spontaneously. The lymphoma's affinity for the skin persists throughout all but the final stages of the disease. Invasion of the epidermis is typically associated with the clinical changes of scaling and pruritus. As the cells proliferate, lesions become firmer and more varied in their surface and contour (plaques). The clinical progression of the disease then proceeds at variable rates with the development of cutaneous nodules and tumors or erythroderma.

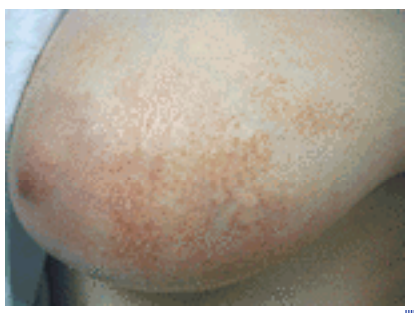

FIGURE 157-1 Patch lesion of cutaneous T cell lymphoma with poikiloderma and scale in a typical location on the breast.

Mycosis Fungoides and Variants

PATCH AND PLAQUE STAGE MYCOSIS FUNGOIDES In early patch stage MF, there are single or multiple, erythematous, scaly macules and patches that vary in size and are usually well defined. The color of the lesions may vary from orange to a dusky violet-red. The distribution classically favors non–sun-exposed sites with the “bathing trunk” and intertriginous areas predominant early in the course of the disease. The eruption may be intensely pruritic or asymptomatic and occasionally may be transitory, disappearing spontaneously without scarring. Diagnosis at this stage may be difficult. Often a patient will recall a preceding “chronic dermatitis” for 10 to 20 years that may have been considered to be therapeutically resistant contact dermatitis, atopic dermatitis, psoriasis, or eczema. Of 211 patients studied by the Mycosis Fungoides Cooperative Study Group, 77 percent were reported to have had antecedent, noninfectious skin conditions, 32 percent of which were diagnosed as dermatitis, not otherwise specified. [15] In any patient with a dermatosis that is refractory to the usual modalities of treatment, multiple biopsies should be taken to pursue a diagnosis. Patches may last for months or years before progressing to the plaque stage, or plaques may arise de novo. Plaques arise as sharply demarcated, scaly, elevated lesions that are dusky red to violaceous in color and variably indurated (Fig. 157-2, Fig. 157-3, Fig. 157-4, and Fig. 157-5). Lesions in this stage may regress spontaneously or may coalesce to form large plaques with annular, arcuate, or serpiginous borders, and may clear centrally with disease activity remaining at the periphery of the lesion. There may be hyper- or hypopigmentation and poikiloderma (see Fig. 157-1).

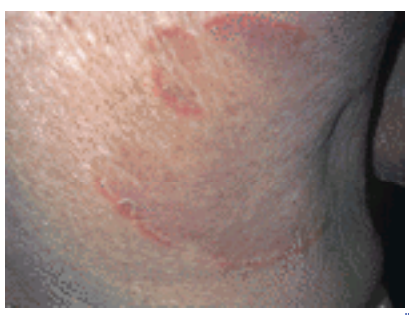

FIGURE 157-2 Large plaque/patch of cutaneous T cell lymphoma on the right flank. Annular and arcuate configurations on the border with more atrophy centrally.

FIGURE 157-3 Patches and plaques of cutaneous T cell lymphoma on the back and arm.

FIGURE 157-4 Confluent plaques with scaling and developing nodules.

FIGURE 157-5 Polymorphic nature of mycosis fungoides type of cutaneous T cell lymphoma. On the right buttock is a large violaceous plaque while further down the thigh is a pink psoriasiform annular lesion. Smaller atrophic lesions can also be noted in the surrounding skin.

Hypopigmented mycosis fungoides Patients with dark skin develop hypopigmented mycosis fungoides, a variant of patch MF. In darker-skinned individuals, this may be the most common presentation the disease. Patients respond to therapy by repigmenting, and a relapse often presents as hypopigmentation. [16]

Pigmented purpura Close examination of the skin in patients with a diagnosis of CTCL often reveals lesions of capillaritis. Some patients may present with pigmented purpura, and CTCL is found on biopsy. These lesions respond to skin-directed therapy (SDT) for CTCL. The distinction between CTCL pigmented purpura and Schamberg's disease can be made by using the diagnostic guidelines noted below. Thus, pigmented purpuric lesions, as shown in Fig. 157-6, occurring in a distribution typical of mycosis fungoides with patches >4 cm in size, should be biopsied. [17]

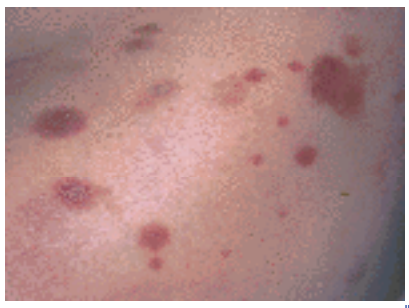

FIGURE 157-6 In the pigmented purpuric variant of mycosis fungoides, the lesions are the typical size of mycosis fungoides lesions, but are distributed in areas that are not usually affected by pigmented purpura, as shown here in the periaxillary skin. (*Photo courtesy of Kathy Zug, MD.*)

Granulomatous CTCL and slack skin This is a constellation of unique clinical and histologic findings. [18] It is not infrequent that granulomatous changes are encountered in the histology of CTCL. At the extreme end of this spectrum, however, is a distinctive syndrome called granulomatous slack skin, which is discussed in Chap. 158.

Pagetoid reticulosis (Woringer-Kolopp disease) Pagetoid reticulosis is another cutaneous presentation of CTCL (see

Fig. 157-7) that typically presents as a chronic solitary plaque. [19] The eponym Woringer-Kolopp is typically applied to patients with uni- or oligolesional disease (see Chap. 158). The long duration, slow growth, and benign nature of the disease are not typical of a lymphoma. There is a disseminated form that is much more aggressive. [20]

FIGURE 157-7 A solitary papulosquamous lesion on an extremity, as shown here, on the hand, is the most common presentation of the Woringer-Kolopp variant of pagetoid reticulosis.

Alopecia mucinosa The clinical picture that is produced by the T cell infiltrative disease known as follicular mucinosis is referred to as *alopecia mucinosa*. It was first described as grouped follicular papules or red, raised, boggy, occasionally nodular plaques. In hair-bearing areas, alopecia may be the presenting sign (Fig. 157-8). Lesions may be isolated or multiple. The eruption presents as indurated papules or plaques with follicular accentuation. [21] An attempt to assess the malignant potential of follicular mucinosis reveals the enigmatic nature of this condition which is discussed further in Chap. 158.

FIGURE 157-8 Alopecia mucinosa. Note the follicular localization and the resulting hair loss.

Adnexotropic CTCL The cutaneous infiltrates of CTCL may display an affinity for the adnexal structures of the skin. As noted above, follicular infiltration with CTCL cells may be accompanied by mucin production within the follicular epithelium. However, follicular infiltration has been recognized as occurring without the signs or findings of follicular mucinosis and this variant is called the follicular mycosis fungoides type of CTCL (Fig. 157-9). The clinical features include follicular-based, erythematous papules and alopecia. Pruritus may also accompany lesions. Plaquelike lesions may result from the accumulation of follicular papules. Additionally, CTCL infiltrates can be centered on the eccrine structures producing multiple small papules, as shown in Fig. 157-10. Anhidrosis and compromise of the eccrine system in lesional skin may often be subtle to detect. [22]

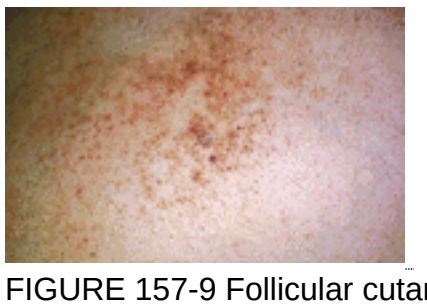

FIGURE 157-9 Follicular cutaneous T cell lymphoma (CTCL) begins as perifollicular papules that group to create lesions typical (>4 cm) in size for CTCL. Alopecia in affected areas is common.

FIGURE 157-10 Adnexotropic cutaneous T cell lymphoma is clinically similar to the follicular disease shown in Fig. 157-9; the lesions are groups of periadnexal infiltrates that are ˜2-mm papules. Individual papules may coalesce to form plaques.

IMMUNOPHENOTYPIC SYNDROMES

Suppressor T cell lymphoma (CD8+ lymphoma) There are at least two variants of this suppressor T cell lymphoma, one of which differs from patch/plaque disease only by the immunophenotypic difference. There is a distinctive clinical subtype that is rapidly progressive with formation of nodules that ulcerate (Fig. 157-11). The distribution is diffuse with involvement of palmar/plantar surfaces. The two subtypes of CD8+ lymphoma differ by other immunophenotypic markers. The aggressive subtype has a low expression of CD2 and a high expression of CD7, whereas the more chronic variant has the exact opposite pattern (see also Chap. 158). [23]

FIGURE 157-11 Multiple papulonodular lesions of aggressive suppressor T cell lymphomas.

Gamma-delta T cell lymphoma The malignant cell in the vast majority of CTCL patients expresses the surface proteins CD3+ and CD4+, with only rare CD3+ CD8+ cases reported. Even more rare are “double-negative” (CD3+, CD4–, CD8–) CTCL cases. These malignant cells express the ?d T cell receptor instead of the aß receptor. ?d T cells have been demonstrated in normal murine epidermis, but have not been found in human skin The immunologic repertoire of such double-negative cells includes the ability to lyse target cells. There often is pronounced epidermal necrosis in conjunction with the ?d tumor cell epidermotropic infiltrates suggesting that the malignant cells participate in keratinocyte lysis. Marked epidermal necrosis in such a patient progressed to ulcerations following an attempt to initiate interferon therapy. [24] There is another variant of this disease that has deep dermal and subcutaneous infiltrates (see “ CTCL Tumors” below). Subcutaneous, lipotropic infiltrates of ?d lymphoma are invariably accompanied by excessive ?-interferon production and the hemophagocytic syndrome. [25]

Cutaneous natural killer cell lymphomas Natural killer (NK) cell activity is traditionally associated with the cell surface expression of the CD56 marker. Expression of CD56 in cutaneous lymphomas occurs with T cell–derived lymphomas and lymphomas that do not have a T cell origin. The NK-expressing T cell lymphomas are clinically indistinguishable from the NK lymphomas that do not express other T cell markers. Morphologically, the T cell–derived NK lymphomas tend to have large granular lymphocytes. The lesions vary from erythematous papules to tumors with ulceration, as shown in Fig. 157-12. In general, these lymphomas are aggressive with median survival after diagnosis rarely exceeding 15 months. The presence of extracutaneous disease is quite common. [26]

FIGURE 157-12 In natural killer (NK) T cell lymphoma there is minimal epidermotropism to produce scaling and patchlike lesions. As a result, papules, nodules, and ulcers (as shown here) are the more typical clinical findings.

ERYTHRODERMIC VARIANTS Erythroderma may start de novo or follow mycosis fungoides. Some patients with the erythrodermic form of CTCL develop tumors. The skin is diffusely bright red with readily apparent scaling, but there may be characteristic symmetric islands of uninvolved skin (Fig. 157-13). There may be sparing of the areas of skin that are frequently folded, such as the abdomen, antecubital, axillary areas. This sparing produces a finding often called the “deck chair” or “folded luggage” sign, as shown in Fig. 157-14. Differential diagnosis includes pityriasis rubra pilaris, as well as erythroderma secondary to psoriasis, atopic dermatitis, seborrheic dermatitis, and drug eruption. Involvement of the face may lead to leonine facies with marked accentuation of facial folds (Fig. 157-15). The differential diagnosis of this presentation includes lepromatous leprosy, sarcoidosis, and leishmaniasis. The patient may complain of fever, chills, weight loss, malaise, insomnia secondary to the overwhelming pruritus, and poor body temperature homeostasis. There may be hyperkeratosis, scaling and fissuring of palms and soles, alopecia, ectropion, nail dystrophy, and ankle edema with the integument being shiny and hidebound. These changes result in pain on walking and extreme difficulty with manual dexterity. Such patients become cutaneous cripples, being severely debilitated by the skin manifestations of this fatal disease. Pruritus is often intense, resulting in excoriation, exudation and secondary changes that may dominate the clinical picture.

FIGURE 157-13 Cutaneous T cell lymphoma erythroderma (Sézary syndrome). Note coppery redness, infiltration of skin

as reflected by increased skin folds and scaling.

FIGURE 157-14 In patients with cutaneous T cell lymphoma and erythroderma, there may be sparing of areas where the skin folds, as shown here. This finding is often called the “deck chair” or “folded luggage” sign.

FIGURE 157-15 Leonine facies characterized by infiltrated plaques of cutaneous T cell lymphoma.

The nomenclature for erythrodermic phases of CTCL varies. One workshop has proposed that erythroderma should be defined by 80 percent body surface area involvement with ill-defined borders (Fig. 157-13) and patients with a preexisting history of mycosis fungoides should be separated out as the syndrome of “erythrodermic mycosis fungoides.” For the diagnosis of Sézary syndrome, [27] the patient should be erythrodermic, with a biopsy consistent with CTCL, evidence of >5 per 100 lymphocytes having cerebriform nuclei (“Sézary cells”) on peripheral blood smear review, and corroborating evidence of CTCL in the peripheral blood (either a positive gene rearrangement study or elevated CD4/CD8 ratio). Patients lacking the atypia on the peripheral blood smear or the corroborating evidence are considered as having erythrodermic CTCL. The hematologic evaluation of patients has improved from the era of Sézary when the syndrome he described was characterized by the peripheral blood appearance of “monster cells.” As the disease progresses, the normal lymphocytes are destroyed before the leukocytosis appears. By the time the Sézary syndrome appears, there is very little normal immunity left. Indeed, Sézary's patients died from infectious complications, not from progressive disease.

CTCL TUMORS

T cell lymphomas of the skin can give rise to nodular lesions that are deep, protuberant, or ulcerating, as shown in Fig. 157-16, Fig. 157-17, and Fig. 157-18. The classification of a patient presenting with tumors of CTCL is partly guided by history and mostly guided by the dermatopathologic interpretation.

FIGURE 157-16 Tumor stage cutaneous T cell lymphoma. Large tumor on the cheek.

FIGURE 157-17 Cutaneous T cell lymphoma. Ulcerated, infected tumor on the digit.

FIGURE 157-18 A mixture of plaque and tumor stage lesions on the face of a cutaneous T cell lymphoma patient. *A.* Patch and plaque on the cheek and infected centrofacial ulcer. *B.* Ulcerated nodules on the trunk and (*C*) annular and crusted tumors/ulcers on the legs.

MYCOSIS FUNGOIDES TUMORS The tumor stage may occur anywhere, but tumors have a predilection for the face and body folds: axillae, groin, antecubital fossae, and, in women, the inframammary area. These may occur in preexisting plaques or patches of CTCL, which suggests the development of a vertical growth phase (Fig. 157-18). At this point, the neoplastic cells behave in a more biologically malignant manner, with vertical spread that leads to the clinical appearance of an expanding dermal nodule (Fig. 157-16). De novo occurrence suggests metastatic spread by cells of a malignant T cell clone. The nodules are reddish brown or purplish red and smooth-surfaced, but they often ulcerate and may become secondarily infected (see Fig. 157-17). Growth rate is variable, and ulceration may occur. Spontaneous resolution of tumors is occasionally observed. Patients with tumors tend to have a more aggressive form of the disease than patients with patch and plaque disease. In this respect, it is of interest that one study used the depth of the infiltrate as a prognostic guide similar to the Breslow depth of melanomas. The differential diagnosis of CTCL includes those processes that produce violaceous nodules that may or may not ulcerate. This extensive differential diagnosis includes tumors of other cell lines (B cell lymphoma or leukemia), carcinoma cutis, sarcoidosis, and infectious etiologies such as deep fungi, atypical mycobacteria, or leprosy.

NONMYCOSIS FUNGOIDES CTCL TUMORS The categorization of tumor stage CTCL is made on clinical and histologic features. If the patient had a previous diagnosis of mycosis fungoides or if there is concomitant epidermotropism typical of this subset, then the best assignation is mycosis fungoides tumor. If tumor mycosis fungoides is the initial presentation of the disease, the patient is often referred to as having the “tumeur d'emblee” variant. Tumors in patients without a previous history or without accompanying histologic features of mycosis fungoides are best termed *nonmycosis fungoides CTCL tumors*. The rest of the categorization depends on histologic features. Cellular morphology is important, and these tumor patients can be subdivided into large, small, and pleomorphic categories based on the cytomorphology. If angiotropism or lipotropism is present, then this is added as a descriptor. CD30 expression is also recorded in the characterization of a non-mycosis fungoides CTCL.

CD30+ (Ki-1) lymphoma versus CD30- lymphoma The typical clinical appearance is that of a tumor stage lesion with central ulceration. The CD30+ lymphomas have been traditionally thought of as having a better prognosis than CD30- lymphomas. A perplexing feature of CD30+ lymphomas is a tendency to spontaneous resolution, although there is also a tendency to progress to an aggressive malignant lymphoma. The unpredictable course of this condition has led to uncertainty in its therapy. Aggressive radiotherapy with or without follow-up chemotherapy is recommended. Follow-up studies suggest that systemic polychemotherapy as initial treatment does not result in higher cure rates or less relapses when compared to local ablative therapy. [28]

SMALL CELL VERSUS LARGE CELL VERSUS PLEOMORPHIC T CELL CUTANEOUS LYMPHOMA These entities are histologically separable from other cutaneous T cell lymphomas. The histologic differentiation of large and small cells is discussed in the section on histology. However, the reproducibility of cutaneous lymphoma staging by the small cell–large cell dichotomy is variable, and as yet there has not been a clear definition of the prognosis based on these classification criteria. Nonetheless, the degree of cellular atypia should be recorded at the time of diagnosis and relapse. [29]

ANGIOCENTRIC CUTANEOUS T CELL LYMPHOMA This syndrome was first labeled as malignant angioendotheliomatosis. It was recognized as a progressive, fatal condition that begins typically with reddish-brown patches of plaques. Frequently, these appear on the head, and there may be progression to aggressive central nervous system involvement. The histology demonstrates atypical cells inside blood vessels. [29]

SUBCUTANEOUS (LIPOTROPIC, PANNICULOTROPIC) CTCL This variant typically has the deepest infiltrates of atypical cells with involvement of the septa and lobules of the subcutaneous fat. Not surprisingly, it is the most aggressive disease variant with the worst prognosis. This disease typically presents de novo, without any preceding patch or plaque mycosis fungoides. The initial lesions appear as inflammatory nodules and there is often considerable difficulty distinguishing this from inflammatory panniculitides. Ulceration of the lesions is not uncommon. There are two features that are distinct for subcutaneous CTCL. One is that the malignant cell frequently expresses the ?d T cell receptor. The other is that these cells often induce variable degrees of the hemophagocytic syndrome. [25] In this condition, cytokines that are presumably produced by the malignant cells induce macrophages to engulf and destroy normal

hematologic components including platelets, erythrocytes, and neutrophils. As a result, subcutaneous CTCL is frequently accompanied by anemia, thrombocytopenia, and granulocytopenia. These complications often result in the terminal events of patients suffering from this rare variant. It is important to emphasize that, as the immunopathogenesis of the hemophagocytic syndrome is further understood, specific cytokine therapy to reverse this complication may be just as important as debulking the tumor burden.

Dual Lymphoid Neoplasia of the Skin

This represents a collection of syndromes characterized by combined B cell and T cell lymphoproliferative disorders with skin lesions. [30] One hypothesis is that there is an increased risk of second malignancies in CTCL patients. Another hypothesis is chronic B cell stimulation from malignant T_H2 cells selecting out a clonal proliferation of B cells, which become malignant. Possibly, there is a mutation in a lymphoma-suppressor gene that allows both B- and T-derived cells to proliferate beyond normal regulatory controls. In support of this concept is the aforementioned study showing an increase in hematologic malignancies in relatives of CTCL patients. One must also consider the mutagenic properties of therapy used to treat the initial lymphoproliferative condition as a potential cause of the second malignancy. In patients with this dual lymphoid neoplasia, biopsies for immunophenotyping provide the only reliable way to distinguish between the entities present on the skin.

PATIENT ASSESSMENT (LABORATORY FINDINGS)

The evaluation of the CTCL patient (Table 157-2 and Table 157-3) focuses on the three major features of CTCL that affect outcome: tumor burden, the degree of atypia in the malignant cells, and the immunocompetence of the patient. Of these three components, tumor-burden assessments also play a role in the follow-up of patients on therapy. The realm of the cutaneous T cell includes the skin, lymph nodes, and peripheral blood. Samples of these can be evaluated for tumor burden, the degree of histologic atypia, and for determining where the patient's immune system is on the spectrum from immunocompetent to immunosenescent. Tumor burden can be reliably assessed in the skin, blood, and lymph nodes. Increasing involvement of each of these sites by lymphoma correlates with decreasing survival. Another evaluable feature of CTCL is the degree of transformation of the malignant cells. This “anaplastic nature” of the lymphoma cells also correlates with poor prognosis. Finally, the immunologic competence of the patient must be taken into account. Some of the immunologic responses crucial to the survival of CTCL patients are an intact antitumor response and effective antimicrobial defenses.

	Tissue Biopsies	Stains	Immune Status
Skin	Skin scan Biopsy depth Cytotyping	H&E Stripes Phenotyping	Phenotyping
Blood	CBC Phenotyping Cytotyping	Smear	Phenotyping
Lymph node	CT scan Cytotyping H&E Stripes	H&E Stripes	Architecture phenotyping

*The three rows are the three tissues available for assessing the parameters listed in columns. The assessment of atypia and immune status are dates as the rows of presentation for prognostic information. The measures of tumor burden are charted specially only to assess the impact of therapy.
CBC = complete blood cell count; H&E = hematoxylin and eosin.

Skin Evaluation

IDENTITY OF THE MALIGNANT CELL POPULATION After a diagnosis of CTCL is made, skin biopsies are used to provide an immunophenotypic and immunogenotypic description of the malignant cells. Immunogenotyping on skin biopsies is best done with the PCR technique. The majority of the mycosis fungoides variants can be adequately studied with a shave biopsy. In a study of epidermal samples versus dermal samples in mycosis fungoides, the malignant clone could be more readily detected in the epidermal samples. [31] This reflects the preference of the malignant cells for the epidermis and the dilution of the malignant clone in a reactive infiltrate in the dermis. Another value of performing the PCR test at the time of diagnosis is that if this technique is to be used on any other tissues, it is best to know whether or not the patient is one of the 15 percent false negatives by PCR testing. [32] If the clone is not detectable in involved skin, there is no value in studying other tissues or skin at other times unless new primers for the PCR technique become available.
TUMOR BURDEN A parameter of CTCL that has significant prognostic value is the extent and type of skin involvement evident on the physical examination. For this reason, the Mycosis Fungoides Cooperative Study Group, in 1975, adopted a modified TNM classification system. [15] This was further modified by the Cutaneous T Cell Lymphoma Workshop and is shown in Table 157-4 and Table 157-5. Staging of the disease using this classification is done at the time of diagnosis and, as discussed earlier, the stage of a patient does not change. As the skin lesions on an individual may change over time, it is common to use the T system as a way to denote this, recognizing that the stage (I to IV) of an individual never changes. This classification grades lesions as patch/plaque(T1 and T2), tumor (T3), and erythroderma (T4), To assist in the day-to-day management of CTCL patients, there are standard target lesion and body surface area assessments available. Whole-body photography is a useful adjunct in skin tumor-burden assessments.

Classification	Description
T: Skin	
T_0	Lesions clinically and/or histopathologically suggestive of CTCL
T_1	Limited plaques, papules, or eczematous patches covering <10% of the skin surface
T_2	Generalized plaques, papules, or erythematous patches covering ≥10% of the skin surface
T_3	Tumors(≥1)
T_4	Generalized erythroderma
N: Lymph nodes	
N_0	No palpable adenopathy, lymph node pathology negative for CTCL
N_1	Palpable adenopathy, lymph node pathology negative for CTCL
N_2	No palpable adenopathy, lymph node pathology positive for CTCL
N_3	Palpable adenopathy, lymph node pathology positive for CTCL
B: Peripheral blood	
B_0	Atypical circulating cells not present (<5%)
B_1	Atypical circulating cells present (>5%); record total white blood cell count, total lymphocyte count, and number of atypical cells/100 lymphocytes
M: Visceral organs	
M_0	No visceral organ involvement
M_1	Visceral involvement (must have pathology confirmation and organ involved should be specified)

TABLE 157-4 **Staging of Cutaneous T Cell Lymphoma: TNM Classification**

Stage	Classification		
	T	N	M
IA	1	0	0
IB	2	0	0
IIA	1,2	1	0
IIB	3	0,1	0
III	4	0,1	0
IVA	1–4	2,3	0
IVB	1–4	0–3	1

TABLE 157-5 **Staging Classification of CTCL**

The skin biopsy can also be used in tumor-burden assessment. Tumors should be confirmed and defined by biopsy. The use of the skin biopsy in staging patients has been explored. One study measured the thickness of cutaneous infiltration from the granular layer to the lower limit of the infiltrate. The depth of infiltrate correlated with morbidity. [33]
ATYPIA OF THE CTCL CELLS Skin biopsies can also assess the degree of transformation in the cellular infiltrate. Atypical cells with enlarged pale nuclei, prominent nucleoli, or loss of T cell markers portend a worse prognosis and a tendency to be refractory to therapy. Routine histology and immunophenotyping are necessary studies to evaluate the degree of atypia in the skin. In a study of immunophenotypic anomalies associated with transformation, there were more abnormalities by immunoperoxidase in patients with aggressive transformed lymphoma. [34]
IMMUNOCOMPETENCE OF THE PATIENT Immunophenotyping is routinely performed on skin biopsies in the workup of CTCL patients. As mentioned earlier, several studies have noted correlations between immunophenotyping and stage of disease. [12] As the disease progresses, there are fewer CD8 cells in the tissue and the CD4/CD8 ratio in tissue increases. Other clinical clues to impairment of cutaneous immunity are the presence of yeast, tinea, and herpetic infections along with a tendency to develop cutaneous malignancies.

Lymph Nodes

In early disease, the lymph node has the appearance of dermatopathic lymphadenopathy, which is a histologic picture seen also in chronic dermatoses. This reactive hyperplasia is characterized by increase in size of the germinal follicles, with proliferation of histiocytes containing lipids, melanin, or hemosiderin. Because CTCL is usually present in the skin for some time prior to lymph node biopsy, dermatopathic lymphadenopathy is nearly always present. With progression of the disease, atypical lymphoid cells with deeply indented (cerebriform) nuclei and relatively scant cytoplasm accumulate focally in the T cell areas of the lymph node, that is the paracortical area, superimposed on the dermatopathic changes. With time, these atypical cells proliferate and expand throughout the node and eventually efface the architecture. Lymph node biopsies are performed primarily to confirm the presence of disease (and to rule out other etiologies), to look for large cell transformation, and to evaluate the architecture. PCR testing is not that valuable because most lymph nodes should have CTCL cells trafficking through them in the normal recirculation of lymphocytes.

TUMOR BURDEN The incidence of lymphadenopathy by physical examination increases with the stage of cutaneous involvement. Lymphadenopathy, whether histologically dermatopathic lymphadenopathy (N1) or infiltration by CTCL (N2, N3), is a sign of poor prognosis. In practice, enlarged nodes are biopsied at initial staging or if adenopathy develops in progressive disease. Just the presence of a clinically enlarged node has prognostic importance, [35] with these patients having lower survival rates than those patients without adenopathy. The best measure of lymph node tumor burden is a CT scan of affected node groups. [36] Enlarged nodes can be measured to an accuracy of 0.1 cm, and periodic reassessments can provide evidence as to the efficacy of therapy.
ATYPIA The impact of the anaplastic histology on survival was demonstrated in a review of lymph node biopsies. In that series, 195 lymph node biopsies were graded into three categories. Patients with lymph nodes containing malignant lymphocytes that were small cells with hyperchromatic nuclei had a median survival of 40 months. Those patients with lymph nodes containing CTCL cells that were larger with pale nuclei had a median survival of 9 months. A third category of patients with lymph nodes containing a mixture of these cell types had median survival between these two extremes (26 months). [37]
IMMUNOCOMPETENCE The only reflection of immunocompetence is a normal lymph node architecture in the face of regional disease. This is intuitively associated with a better outcome than if the node were effaced by malignant cells. [37]

Peripheral Blood

In CTCL patients with limited patch/plaque disease, it has long been suspected that malignant T cells have hematogenously spread to different sites despite the fact that conventional techniques were unable to detect a circulating component of the disease. The lymphocyte recirculation pathway model would predict that malignant cells are continuously moving from the skin to lymph nodes, and from there to the vascular system. Even the earliest phases of the

disease should be characterized by malignant cells in both the peripheral vasculature and lymph nodes. Utilizing PCR with primers for T cell receptor (TCR) rearrangements, it is possible to detect clonal T cell populations in patients with limited cutaneous disease. [38] In no way, however, does this finding change the stage of a patient. To assign clinical importance to this observation, a quantitative method to assess the numbers of circulating malignant T cells must be developed so that survival can be correlated with increments of circulating cells.

TUMOR BURDEN A routine complete blood count may reveal a markedly elevated lymphocyte count and provide a readily measurable parameter of tumor burden in the peripheral blood. Circulating CTCL cells are often indistinguishable from circulating mature T cells. A variety of tests are available to assess tumor burden, and these have been compared to determine sensitivity. To assess the magnitude of peripheral blood involvement, a panel of antibodies has been developed that recognizes different segments of the variable sections of the beta chain of the TCR. Normally, none of the variable region antibodies react with more than 5 percent of circulating peripheral blood lymphocytes. A clonal expansion in the peripheral blood compartment can readily be detected if one of the existing framework antibodies reacts with that clone. Results with these antibodies in leukemic patients have provided a point of reference for comparing readily available tests. [39] An elevated CD4/CD8 ratio is indicative of disease expansion into this compartment. Thus, flow cytometry for CD4 and CD8 should be a component of the staging of all patients with >T1 CTCL. The rapidity and ease of applying this technology also makes it applicable for following patients. The “memory cell” marker CD45RO is expressed on the majority of leukemic CTCL cells. An elevated level of CD45RO-expressing lymphocytes in the peripheral blood may indicate the magnitude of peripheral blood involvement by CTCL. Another widely used combination of markers is to assess the percentage of circulating T cells that express CD4 yet lack expression of CD7. Circulating CTCL cells in overtly leukemic patients are frequently CD4+ CD7–, although some patients will have malignant cells that express CD7. [40] A practical approach for the use of these varied tests begins with the complete blood count for total lymphocyte count, eosinophil count, and for overt lymphocyte nuclear abnormalities. A flow cytometry panel should initially include CD3, CD4, CD8, and CD45RO. Any elevation of the CD4/CD8 ratio or elevation of the percentage of CD45RO would select patients in whom gene rearrangement studies could confirm leukemic disease if the malignant clone can be detected using PCR primers on the skin infiltrate.
ATYPIA “CELLULES MONSTREUSES” OF SÉZARY Previously, the presence of more than 5 percent circulating cells with hyperconvoluted nuclei was used to define blood involvement because it was associated with a poor prognosis. Sézary cell analysis in the peripheral blood has been documented to change during the course of the day and to vary dramatically between observers. As a result, there is tremendous subjective input in assessing the blood smear. Sézary described circulating atypical lymphocytes in patients with erythroderma. The estimation of Sézary cell percentage was the only technology available for blood testing in the decades preceding the more reproducible antibody and gene testing. The nuclei of these cells are hyperchromatic and hyperconvoluted when compared to their nonmalignant counterparts. Sézary cells, which represent activated T cells, can be seen in inflammatory dermatoses, and Sézary cells appear in large numbers in the Dilantin hypersensitivity syndrome (see Chap. 159). At least 100 lymphocytes are counted to determine the percentage of cells showing the Sézary phenomenon. Although the enumeration of Sézary cells has variability, there is prognostic information in the determination of whether there are large, low, or no numbers of circulating Sézary cells.
IMMUNOCOMPETENCE The immunocompetence of the CTCL patient, especially with regards to the antitumor response, has recently become the focus of many studies. The poor prognosis traditionally associated with hyperleukocytic CTCL cannot simply be a consequence of the presence of circulating CTCL cells, since these cells are now detectable in patients at all stages of disease. [38] In fact, it is compromise of the immune system that is the most common cause of mortality in CTCL patients, including the original patients described by Sézary, who died of infection. Thus, an assessment of a patient's immunologic competence should yield important information regarding prognosis. As mentioned previously, this is now possible through the use of antibodies to various TCR variable regions, which can be clone-specific. These antibodies can enumerate malignant T cells in the peripheral blood of selected patients. This allows the numbers of nonmalignant T cells to be determined by subtraction of the malignant T cell number from the total T cell pool. By using this methodology in six patients with advanced CTCL, it was observed that the nonmalignant T cell population was decreased in some patients to the same level as that seen with advanced HIV disease. [39] Even though antibodies that recognize all CTCL clones are not available, the normal T cell population can also be estimated by measurement of the CD8+ population. Increases in the CD4/CD8 ratio and decreases in the numbers of CD8+ T cells are readily assessed by flow cytometry as measures of the immunocompetence of the patient. Assessing normal immunity by flow cytometry is a rapid and reproducible staging technique. Knowledge of a patient's immunocompetence affects the management of a CTCL patient. For instance, because of the increased risk of second malignancies, [41] symptoms or physical findings should be pursued with this predisposition to malignancy in mind. Antibiotic prophylaxis should also be considered in patients with advanced stage disease.

Staging

The heterogeneity in lymphomas of cutaneous T cells is reflected in the varied clinical outcomes that occur: cure, persistent disease, death by complication, death. Attempts to predict outcome have been complicated by our incomplete understanding of the disease components. Many of these components have been identified and can be incorporated into the patient's evaluation (Table 157-3).

What are those features that can predict outcome at the time of presentation? Tumor burden plays a role, and unilesional CTCL has the best outcome. [42] As the degree of cellular atypia increases, prognosis decreases. Immunocompetence affects outcome and confers responsiveness to some therapies. [11] Understanding CTCL can refine patient evaluation and prediction of outcome. What needs to be done with the parameters of CTCL is to determine their relative weight of importance and their degree of independence from other variables. Predicting the outcome of an individual patient with CTCL utilizes all of the information available from the staging workup. There are many rough guidelines on what to expect with CTCL. In general, the worse the skin, the worse the prognosis as discussed above.

In the modified TNM system, T0 represents skin lesions that are clinically and/or histopathologically suggestive of CTCL but the biopsy is not clearly diagnostic. Repeat skin biopsies are recommended at intervals for these patients. T1 to T4 represent skin lesions whose biopsies are diagnostic of CTCL. Whole-body mapping is performed with the palmar

surface of the hand representing about 1 percent of the skin surface. When more than one type of lesion exists, the most advanced is used for staging, although both are recorded. For example, a patient with generalized plaques and a tumor would be T3, whereas a patient with generalized erythroderma and a tumor would be T4. In addition to body surface area assessment, it is useful to select several “target lesions” at baseline and to query the patient with a CTCL related questionnaire to help assess objective and subjective responses to therapies. The methodology for these assessments is available utilizing methods found in clinical trials for CTCL. [43]

Table 157-4 and Table 157-5 show the staging classification used at diagnosis. Stage I patients are those whose lesions are confined to the skin without clinical adenopathy stage IIA patients are those with plaques and adenopathy and stage IIB patients are those with skin tumors with or without clinical adenopathy but, by definition, lymph node biopsies are negative. Stage III patients have generalized erythroderma with or without adenopathy, but node biopsy is nondiagnostic by definition. Stage IV patients have biopsy-proved CTCL of lymph nodes (IVA) or visceral organs (IVB) with a skin stage (T1 to T4) and any node stage (N0 to N3).

Disease in Other Tissues

Further evaluation of specific organ systems is indicated when involvement is suggested by history, examination, or routine tests. However, further routine invasive staging procedures are not indicated. Once the disease process becomes extracutaneous, any organ may be involved (Table 157-6). Widespread CTCL is commonly found at autopsy, but clinically apparent extracutaneous disease is detected much less often. Considering the varied sites of dissemination, it is not surprising that symptomatic disease has been identified in vivo in virtually every organ system. Survival is directly related, therefore, to the type of skin involvement and the presence or absence of extracutaneous disease.

Organ System	Manifestation
Pulmonary	Parenchymal nodules
	Pulmonary infiltrates
	Pleural effusion
	Mediastinal and/or hilar adenopathy
Ocular	Intraocular disease—optic nerve, retina, choroid
	Extraocular disease—lid, conjunctiva cornea
Skeletal	Solitary or numerous osteolytic lesions
	Diffuse osteoporosis
	Arthritis
Oral	Infiltrated lesions, Manifested as raised or eroded areas on lips, buccal mucosa, tonge, larynx
Nervous	Intracerebral tumor mass
	Leptomeningeal disease
	Peripheral neuropathy
	Cerebral hemorrhage
	Progressive multifocal leukoencephalopathy
Gastrointestinal	Diarrhea
	Ascites
	Hemorrhage
	Perforation
Cardiovascular	Congestive cardiac failure
	Cardiac arrhythmias
Renal	Progressive renal failure
Hematologic	Eosinophilia
	Monocytosis
	Monoclonal paraproteinemia
	Cryoglobulinemia

TABLE 157-6 **Extracutaneous Manifestation of CTCL**

Bone marrow involvement by CTCL is uncommon but increases with the stage of disease. Thus, the absence of involvement of marrow in the presence of increased circulating lymphocytes and skin lesions suggests a diagnosis of CTCL.

Pulmonary involvement is present in 40 to 60 percent of CTCL patients at autopsy, but antemortem recognition occurs uncommonly; it may or may not be symptomatic. On chest x-ray, pulmonary disease may be manifest as parenchymal nodules, pleural effusions, mediastinal and/or hilar adenopathy, diffuse parenchymal infiltrates, or patchy areas of consolidation. Parenchymal nodules are the most often observed abnormality and are variable in size, poorly marginated, and usually bilateral. Pulmonary infiltrates are also usually bilateral and are symmetric, interstitial, and involve the lower portions of the lungs. Pleural effusion with atypical T cells has also been reported. Differential diagnosis of such radiographic findings includes infections, drug-related infiltrates, and other primary or metastatic neoplasms. Most patients have extensive and progressive extracutaneous disease by the time pulmonary disease becomes apparent. [44]

Bone involvement is seen in 30 to 40 percent of patients at autopsy but is generally not apparent antemortem. Radiographic evidence of bone involvement includes osteolytic lesions and pathologic fractures. [45] Infiltration of the synovium may produce an inflammatory polyarthritis. [46]

Other sites of clinical involvement by CTCL are the oral cavity and the upper respiratory tract, gastrointestinal tract, heart, kidney (rarely), eye and the brain, leptomeninges, and the peripheral nervous system. [47], [48], [49] and [50] Magnetic resonance imaging and spinal fluid analysis for Sézary cells are often useful in confirming central nervous system involvement.

PATHOLOGY

The role of histopathology in CTCL patient management is in making the diagnosis, confirming a change in T status (e.g., from patch to tumor), and in the evaluation of relapse. In performing the biopsies, it is often best to have the patient abstain from any topical or systemic therapy for at least 4 weeks prior to biopsy. There are many components that can contribute to the pathologic diagnosis of mycosis fungoides and the CTCL variants. [51], [52] and [53] Rarely are all of these components present in the same location as the biopsy. The classic findings are characterized by finding lymphocytes with hyperchromatic and hyperconvoluted nuclei that cluster in the epidermis in microabscesses (Pautrier type) as shown in Fig. 157-19. The classical dermal infiltrate underneath this would be mostly mononuclear cells with deeply indented nuclei along with a mixed inflammatory response of lymphocytes, plasma cells, and eosinophils (Fig. 157-20).

Frequently, the epidermal lymphocytes appear larger than the dermal lymphocytes. In the absence of these findings the diagnosis of mycosis fungoides can be suggested by a constellation of findings. The epidermotropic lymphocytes in patch and plaque MF biopsies (Fig. 157-21) are often accompanied by minimal spongiosis. These solitary epidermotropic cells often have a lacunae that develops while processing the biopsy and the cells appear to have a halo around them (halo cells). Lymphocytes can often appear to be lined up along the dermal–epidermal junction awaiting entry to the epidermis. In the dermis, as shown in Fig. 157-22 there can be a lichenoid or perivascular infiltrate with mononuclear cells that may or may not be atypical, that is, with pleomorphic, hyperchromatic, convoluted nuclei. Also, there is often is a lamellar ibroplasia in the papillary dermis. As the patches become more plaquelike clinically, there is an increasing lichenoid quality of the infiltrate. The epidermis itself may be histologically normal, atrophic, or psoriasiform. A classic biopsy of plaque MF contains a lichenoid and perivascular infiltrate with epidermotropic cells. In America and Europe, studies with panels of pathologists have demonstrated that there is a significant disagreement between pathologic opinions on any particular slide. [54], [55]

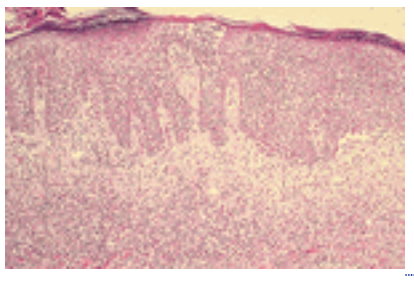

FIGURE 157-19 Dense mononuclear cell infiltrate extending from the papillary dermis into the epidermis. The epidermis is completely permeated be these cells, which form a Pautrier's abscess.

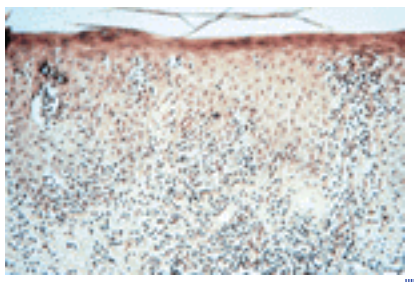

FIGURE 157-20 There is epidermotropism with a dermal infiltrate that contains many cell types.

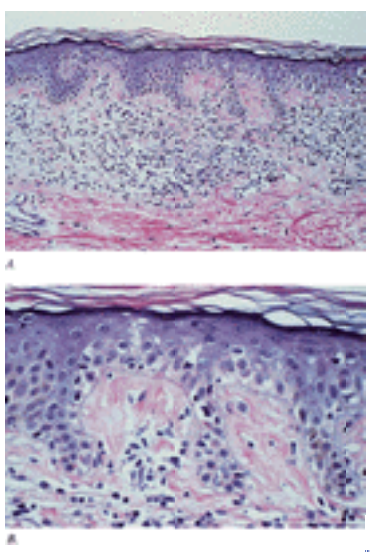

FIGURE 157-21 Patch stage of CTCL. *A*. Single atypical mononuclear cells in epidermis with sparse superficial perivascular infiltrate in papillary dermis. H&E stained section. *B.* High-power view of atypical cells in epidermis of same section.

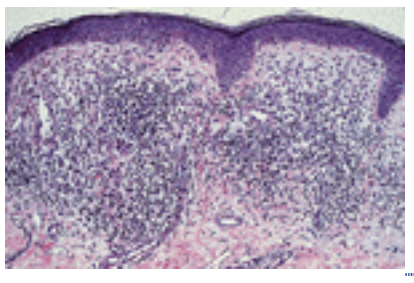

FIGURE 157-22 Plaque of CTCL. There are scattered cells in the epidermis and a dense bandlike infiltrate of lymphocytes in the dermis.

Many of the CTCL variants are defined by their histologic features. In pagetoid reticulosis, the lymphomatous cells show a pronounced epidermotropism. The histology of the disease is diagnostic but should not be confused with Paget's disease or pagetoid melanoma. In follicular mucinosis, the epithelial cells of the sebaceous glands and outer root sheaths are disrupted with formation of cystic spaces and mucin deposition (Fig. 157-23). [21] For diagnosing follicular CTCL, the pathologist will often orient the epithelial lining horizontally because the findings are similar to the features

above except that the invasion of the epidermis is limited to the follicular epithelium.

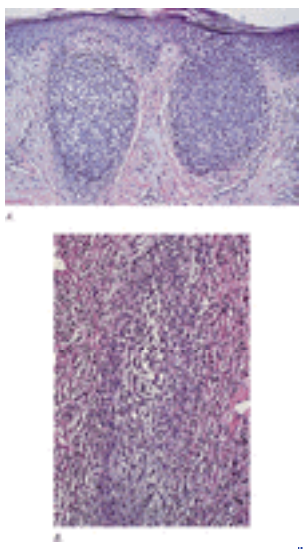

FIGURE 157-23 Follicular mucinosis (alopecia mucinosa). *A*. Outer root sheath of hair follicle is disrupted with formation of cystic spaces and mucin deposition. H&E stained section. *B*. High-power view of disrupted outer root sheath at base of hair follicle.

The histology of the erythrodermic stage is extremely variable. The development of erythroderma is characterized by perivascular accumulation of lymphocytes. Multiple biopsies are needed to make the diagnosis because of the marked variability in epidermotropism and infiltrate density. Secondary changes such as psoriasiform hyperplasia from chronic scratching can also dominate the histology.

In tumors (Fig. 157-24), two histologic appearances may be observed. In some patients, a polymorphous infiltrate is present, similar to that seen in the plaque stage, but the infiltrate is denser and extends into subcutaneous fat. In areas where tumors originated in plaques, the epidermis may show typical epidermotropism, but in other areas may show no involvement, even with the presence of a grenz zone in the upper dermis (an area of sparing between infiltrating lymphocytes and the basement membrane of the epidermis). In other patients, the infiltrate is monomorphous, composed almost exclusively of tumor cells. Epidermotropism is not a prominent feature in these tumors. There may be varying degrees of transformation. Tumors are frequently accompanied by transformation where cells and their nuclei are larger with hyperchromatic nuclei, prominent nucleoli, and frequent mitotic figures. As discussed above, histologic features important for diagnosis and classification of the tumor include concomitant findings of epidermotropism, cytomorphology (large cell, small cell, or pleiotropic), angiotropism, lipotropism, and CD30 expression.

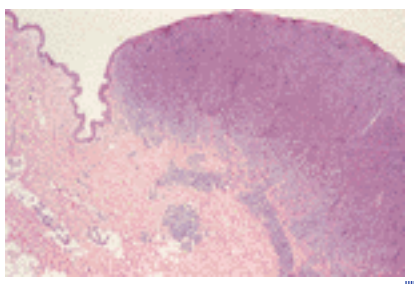

FIGURE 157-24 Low-power view of a CTCL tumor. The dense infiltrate extends deep into the dermis.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of CTCL still rests on having compatible clinical and histopathologic features. Although T cell clonal infiltrates can be demonstrated in the skin by using the PCR techniques previously described, clonality can also occur in the nonmalignant eruption of Mucha-Habermann disease (PLEVA) (see also Chap. 159). It should not, therefore, be equated with malignancy. The diagnosis of CTCL rests on the combination of the appropriate clinical lesion and histology. For the most common type of CTCL, mycosis fungoides, it is possible to weigh the strength of diagnosis with a scoring system that equally rates lesion morphology, distribution, and histology (as discussed above).

The diagnosis of cutaneous T cell lymphoma is often made in evaluating cutaneous lesions initially thought to represent some banal dermatosis. The index of clinical suspicion for CTCL is heightened if a particular skin eruption is refractory to therapy. Chronic inflammatory eruptions on the skin may be mimicked by lymphoma. Epidermotropic infiltrates can produce findings similar to eczema, psoriasis, erythroderma, pityriasis rubra pilaris, lichen planus, drug eruptions, photosensitivity, pompholyx, vitiligo, annular erythemas, seborrheic dermatitis, intertrigo, tinea, and alopecia. Dermal infiltrates may mimic urticaria, vasculitis, annular erythemas, purpura, insect bites. Subcutaneous lymphoma may present like erythema nodosum, leg ulcers, or pyoderma gangrenosum.

As discussed earlier, there have been no standard guidelines for the diagnosis of CTCL, lending variability to the patient populations reported from different centers. Working groups have developed a practical format to assist in standardizing the diagnosis of mycosis fungoides, by far the most common variant of CTCL.

The diagnostic format uses input derived from the physical exam (lesion morphology and distribution) and integrates this with the biopsy and ancillary studies as shown in Table 157-7. The lesion morphology can be considered as meeting major criteria (arcuate lesions with scale, poikilodermatous patches, and plaques with atrophy), and minor criteria

(erythema, papulosquamous plaques, alopecia, hypopigmentation). Lesions atypical for mycosis fungoides are those with the finger-like lesions of digitate dermatosis. The distribution of lesions can also be used to assess the strength of diagnosis of mycosis fungoides. Again, there are major and minor criteria. Major criteria for distribution are lesions on the buttocks, breasts, and intertriginous regions. Minor criteria are lesions on the trunk or extremities. The biopsy is frequently signed out by the dermatopathologist as typical of mycosis fungoides or as consistent with the diagnosis of mycosis fungoides. The former is regarded as a major criterion and the latter as a minor criterion.

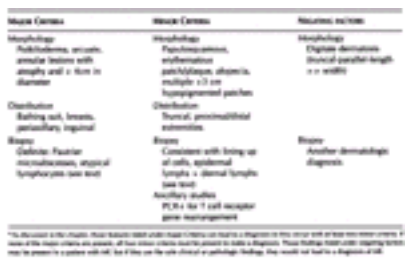

TABLE 157-7 **Guidelines for Diagnosing Patients with T1, T2 Mycosis Fungoides Type of CTCL**

How can these assessments be integrated into the practice of dermatology? For those patients with two major criteria, the diagnosis is firm. For those with anything weaker than three minor criteria the diagnosis of mycosis fungoides should not be made. The role for new technology in making the diagnosis of mycosis fungoides is limited to those cases with three minor criteria. PLEVA and digitate disease may have clonal populations but these would not be assessed as lesions appearing consistent with, in a distribution consistent with, or with a biopsy that meets major criteria for mycosis fungoides. In those borderline cases where the PCR is negative and a diagnosis cannot be made, subsequent followup and repeat biopsies may eventually document an evolving case of mycosis fungoides.

TREATMENT

Every successful strategy in managing CTCL begins with goals, tumor-burden assessments, questionnaires, and a timetable. The primary goals of therapy are to improve the quality of life, to prolong life and to cure. With a chronic disease like CTCL surrogate markers are a necessity and tumor burden is still the best surrogate marker for survival. Tumor-burden measurements and measures of palliation are the markers most commonly utilized. Skin score systems and health-assessment questionnaires that assess both discrete and global manifestations of the disease have also provided disease activity measurements. [43] The first staging of CTCL was done on the basis of skin involvement in a multicenter project by the Mycosis Fungoides Cooperative Group. [15] The T staging provided the only underpinning for linking tumor burden with survival in that from limited patch to 100 percent involvement, the more the skin was involved, the worse the prognosis. In addition to skin staging, there are other factors, previously discussed, that contribute to the heterogeneity of CTCL. This heterogeneity has undermined the utility of the TNM staging system. Markers such as CD8 expression in biopsies have yet to be adopted as staging tools. Currently, skin scores provide measures of objective responses to therapy and questionnaires guide the assessment of subjective responses to therapy. It has not been shown that the reduction of a patient from a T3 to a T1 is accompanied by any benefit in survival, yet it is also recognized that cure is unattainable unless the patient is first in remission with a skin score of 0 by whatever skin scoring system is used. Thus, remission is the first step toward achieving a cure.

There are a few principles that help guide therapy strategies. Excellent long-term results have been reported with the localized therapy of localized disease. [7], [42] More widespread disease requires total skin or systemic therapy. However, it is not known at what percentage of skin surface involvement it becomes imperative to treat the entire skin. Onced a remission is achieved, maintenance therapy has a role in preventing relapse. Because many patients will have therapies that span decades, it is also important to minimize exposure to therapies that have cumulative toxicities on keratinocytes (i.e., mutagens) or the bone marrow.

With the above mentioned principles, one can approach the therapy of a given patient based on the patient's clinical presentation. The therapies discussed later are presented roughly in the same order as summarized in Table 157-8. The clinical presentation of the patient can be matched up with a successful therapy modality for both the remittive phase of therapy and the maintenance therapy. For patients with several types of lesions, priority is given to those further down the column on the left in the table. For example, a patient with patches and tumors would be approached as tumors until those lesions are cleared. The therapies utilized to help a patient with CTCL can be best categorized into skin directed therapies, biological response modifiers, cytotoxic therapies, and combination therapies. Within each category, the individual modalities have unique properties that are discussed in the context of how these modalities are used.

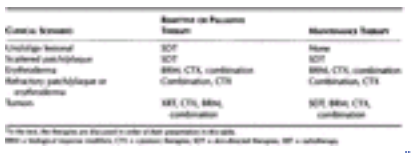

TABLE 157-8 **Matching Treatment Modalities with Clinical Scenarios***

Uni/Oligo Lesional CTCL: Skin-Directed Therapy

The modalities considered for inducing a remission of uni/oligo lesional disease are spot x-ray therapy (XRT), topical chemotherapy with carmustine (BCNU), and topical retinoid therapy with bexarotene. Topical glucocorticoid therapy is discussed below. Spot radiotherapy [42] is the most reliable and rapid method of inducing a remission of localized CTCL.

There is widespread availability of radiotherapy and most lesions, no matter where they occur on the body (e.g., eyelid, buttock crease, ear) can be treated with this modality. There are no compliance problems, with each session performed by professional radiotherapists. The toxicity is minimal acutely, but the chronic toxicity of radiation dermatitis and cutaneous malignancy encourages the conservative use of this modality.

The limitations of topical BCNU therapy are the systemic toxicity from absorption of this chemotherapeutic agent and the local irritant response. As a result, topical carmustine is primarily used for limited body surface area. The initial protocols for using BCNU involved an alcohol-based solution kept in the refrigerator. However, ointment based protocols are now more common. BCNU can be easily made up in 20 mg%, 30 mg%, or 40 mg% ointments in petrolatum. Patients typically apply BCNU ointment at night and wash it off in the morning. Locally, there may be a dose-responsive irritation and/or hyperpigmentation that appear over the 8 to 20 weeks needed to clear lesions. Monitoring includes complete blood counts every 2 weeks looking for marrow suppression. The cumulative toxicity of BCNU is primarily structural damage with skin thinning and telangiectasias. Reliable and compliant patients are needed for this therapy to succeed. [56]

Similarly, the limitations of topical bexarotene gel are primarily due to the dose-responsive irritant response. Hence, bexarotene gel is typically used for <15 percent body surface area, as was the case in most of the patients in the pivotal trial that led to its approval. The gel is commercially available in a 1% formulation so that dose intensity is varied by the frequency of application. Patients typically initiate therapy with nightly lesional applications of bexarotene gel. After a week, the frequency is increased to twice daily and the patient cautioned about an irritant dermatitis at the site of the lesions. Complete clearance of lesions will usually occur after 12 to 16 weeks of therapy. Irritant responses can be managed by decreasing the frequency of application. [57] Successful topical bexarotene therapy also requires a compliant patient willing to put up with the irritating properties of this vitamin A derivative.

Disseminated Patch/Plaque Disease

Cutaneous T-cells recirculate through the vascular system, capable of patrolling the entire skin. When CTCL lesions are scattered about the skin, the most successful treatment strategies are those that treat the entire skin so as to extend the antilymphoma effect to the entire realm of the cutaneous T cell. Because recirculating CTCL cells are detectable even in limited disease, there are recirculating cells capable of recapitulating the disease. These cells provide some of the basis for using maintenance therapy following a complete response in the management of a patient with disseminated patch/plaque disease. The total skin treatment modalities most commonly used as first-line therapy against disseminated patch/plaque disease are phototherapies, topical chemotherapy, and total skin electron-beam radiotherapy.

PHOTOTHERAPIES (See also Chap. 266) Administration of oral 8-methoxypsoralen and UVA radiation can produce a definite clinical response and complete remissions of long duration in patients with patch/plaque CTCL. [58] PUVA therapy requires regular treatments, initially three to four times a week for up to 3 months or until remission occurs. The follow up of a patient on PUVA for CTCL includes an assessment to be sure there is some mild degree of phototoxicity. Otherwise, there may be insufficient dosing of either the psoralen or the UVA light. Risks of the treatment include possible induction of cutaneous epithelial neoplasms and cataract formation. Therefore, all patients should be observed closely and checked regularly for development of skin cancer. In addition, patients are advised to protect their eyes for 24 h following PUVA therapy and to have annual ophthalmologic examinations. These precautions should be enforced early because PUVA is a therapy that may continue for years as a maintenance treatment. Even after poor responses with conventional therapy, patients have had complete clearing of the skin with PUVA. [58], [59] However, maintenance therapy may be needed, as shown by the prolongation of clinical remission with continued PUVA. [60] For this reason, a gradual taper of therapy from thrice weekly to one session every 2 to 4 weeks after the patient has a stable remission is typical. UVB and narrow band ultraviolet B (NBUVB) are both effective for CTCL. [61] These phototherapies are more convenient for patients although their efficacy, especially for plaque disease, may not be as great as PUVA. Patch CTCL can often be completely cleared with UVB or NBUVB. A complete response can typically be induced with three to five treatment sessions per week. After a complete response has occurred, phototherapy can be continued on a maintenance schedule initially at once per week. The acute toxicities are primarily due to phototoxicity and the chronic toxicity is the increased risk for cutaneous malignancy.
TOTAL-SKIN TOPICAL CHEMOTHERAPY This consists of nitrogen mustard (mechlorethamine hydrochloride) that is applied as either an ointment base or as a freshly prepared aqueous solution. [62] As an initial dose, 10 mg of the drug is dissolved in approximately 50 mL of tap water. The entire volume is then applied to the whole body surface by the patient. The patient should wear protective plastic gloves while applying the solution. A delayed hypersensitivity reaction may complicate treatment and it is possible to desensitize patients, although their confidence in the therapy may be compromised. Ointment-based mechlorethamine, typically 10 mg% in ointment, may be less sensitizing and is stable on the shelf over a long period of time. Other side effects from mechlorethamine hydrochloride therapy, besides hypersensitivity reactions and primary irritant reactions, include the development of second cutaneous malignancies [63] and hypo- and hyperpigmentation (Fig, 157-25). This method is relatively easy for the patient to use at home, but daily whole-body application is required with maintenance therapy once remission is induced.

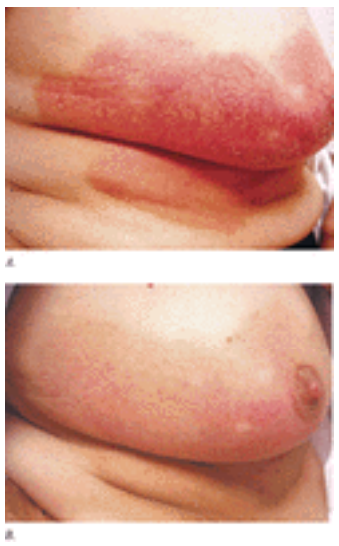

FIGURE 157-25 Typical lesions of mycosis fungoides on the breast before (*A*) daily total skin topical nitrogen mustard therapy. (*B*) After 3 months of therapy the lesions are starting to clear with residual hyperpigmentation.

TOTAL-SKIN RADIATION THERAPY The radiosensitivity of cutaneous lymphomas has been therapeutically exploited by total-skin electron-beam (TSEB) radiation. [64] Because electrons penetrate only to the upper dermis, electron-beam therapy may be used without systemic effect. The limited penetration of the electrons is advantageous in that it spares the mucous membranes, bone marrow, gastrointestinal tract, and other vital internal organs. Only those portions of the skin that are directly exposed to the beam are radiated. Therefore, palms, soles, scalp, axillae, and perineum may need separate exposure to ensure total-body treatment. The eyelids are routinely covered with lead eye shields to protect the cornea and lens from the effects of radiation. If the eyelids are involved, 5-mm–thick contact lenses are worn between the lid and cornea within the conjunctival sac. Nail shields may also be used to prevent anonychia. Whole-body electron-beam irradiation brings about complete remission in 80 to 95 percent of patients. The relapse rate is highest in the later stages of CTCL, that is, in those patients with tumors, lymphadenopathy, and visceral involvement. Patients with limited plaque disease had the best relapse-free rate (42 percent at 10 years). Most relapses occurred within the first year after completion of therapy and were very rare after 3 years. The median disease-free interval was greater than 3 years in the limited plaque group, approximately 1 year for patients with generalized plaque or erythrodermic disease, and less than 6 months for patients with cutaneous tumors. The total dose of irradiation is important, and a dose of 30 cGy (3000 rad) or more gives better complete remission rates and disease-free survival than do lower ones. The major disadvantages are that this type of therapy requires a specialized center, and takes up to 3 months for complete treatment. Local side effects include alopecia, atrophy of sweat glands and skin generally, radiodermatitis, and edema. When the total dose is highly fractionated, these complications are minimized and often avoided. The question is what is the maximum radiation tolerance of the skin? With the highly fractionated approach, patients can receive a second course of electron beam therapy of 36 cGy (3600 rad) to reinduce a remission. As the total radiation dose increases, so does the risk of squamous cell carcinoma and radiodermatitis. Small-field or spot orthovoltage radiotherapy using soft x-rays (60 to 100 kV with half-value layers of 1 to 1.5 mm Al) fractionated to doses of 0.75 to 5 cGy (75 to 500 rad) and total doses of 8 to 15 cGy (800 to 1500 rad) will adequately eliminate most lesions. In many patients, a second or even third complete course of total-skin electron-beam radiation can be safely administered. [65] The strategy of using electron beam for repeat courses requires the use of a highly fractionated dose of 1 Gy per dose.

MAINTENANCE THERAPY AND TOPICAL STEROID THERAPY The concept of treating normal skin evolved from the clinical experiences with skin directed therapies. There are two components to this: treatment of normal skin during remittive SDT and the treatment of normal skin during the remission maintenance phase. Topical chemotherapy, PUVA, and TSEB all involve the exposure of normal skin as an integral component of their success in achieving remission. [66] This success reflects the ability of the therapy to interrupt the critical skin based phase of the life cycle of a recirculating CTCL cell. Once a remission has been achieved, normal skin can be maintained with lower doses and frequencies of the therapies used to clear it. Maintenance therapies have been described with PUVA, [58] total-skin nitrogen mustard, [67] extracorporeal photochemotherapy, [68] and interferon. [69] The most commonly used maintenance therapy is PUVA (see Chap. 266) or UVB. As a maintenance therapy, PUVA is initially administered at once-weekly frequencies until 1 year has passed. At this point, the schedule is changed every other week for another year, every third week for a year and finally every fourth week for 2 years. At this point, the patient should have been in remission for 5 years. Consideration should be given to stopping therapy at this point. Cures are defined as 8 years disease free off all therapy. This definition arose from experience with nitrogen mustard and with total-skin electron-beam radiotherapy showing that after a patient achieves a remission off therapy of 5 to 8 years, late relapse is extremely rare. This would imply that malignant cutaneous T cells recirculate without lesions for up to 5 years. With 5 years of intermittent PUVA, it is less likely that one of these cells will survive, but it is still possible. After a patient is off therapy, they should not be considered a cure unless they stay clear for 8 years after stopping therapy. The management of suspected relapse often includes topical glucocorticoids and reflects the critical role this modality can play in the management of suspicious lesions. Early in the course of CTCL and in the recapitulation of the disease in a patient in remission, the T cell activation process can be blunted by the aggressive use of topical glucocorticoids. Indeed, most patients have a history of using these agents before a firm diagnosis is made. A regimen for treating early lesions of mycosis fungoides involves twice daily applications of a class I topical glucocorticoids for 8 weeks. [70] This regimen is one of the first-line modalities for suspected relapse and it can help identify which patients need to undergo a 4-week “wash-out” before repeat biopsies are performed.

Erythroderma

The erythrodermas of CTCL represent florid immune dysfunctions that result in total-skin redness, scaling, and discomfort. It is not surprising that immune-based therapies take the forefront in the management of these disorders. The three major biologic response modifiers (BRMs) used in the treatment of CTCL are oral retinoids, intravenous extracorporeal photochemotherapy (ECP), and subcutaneous injections of interferon-a. In the clinical trials of these agents, patients have undergone monotherapy of what has usually been heavily pretreated refractory disease. In practice, these are often used first line as monotherapy in erythroderma and combination therapies are incorporated if

there is an incomplete response. With these agents, partial responses are more common than complete responses. Thus, if the goal is remission, a combination therapy is more common than monotherapy. If the goal is palliation, monotherapies with BRMs are often sufficient. The BRMs differ in terms of their administration, side effects, interactions with other therapy modalities, and their availability.

RETINOID THERAPY (See Chap. 257) The first-generation retinoids such as isotretinoin have an impact on CTCL. The more CTCL-specific retinoid, bexarotene, selectively binds the retinoid X receptor, whereas the other available retinoids have less-specific binding patterns. In the monotherapy trials, bexarotene was dosed at 300 mg/m ^{2} (average dose, 450 to 675 mg per day, taken as capsules with the evening meal). Responses were seen at all phases of the disease: plaques, erythroderma, and tumors. Responses paralleled the secondary endpoints: decreases in overall body surface area involvement, overall tumor aggregate area, and improvement in pruritus. Erythrodermic patients may experience increased desquamation during the first few weeks of oral bexarotene therapy. Improvement typically occurs by week 12 of therapy. [71] Although there appeared to be a dose-response relationship with respect to efficacy, the higher doses were also associated with a higher rate of adverse events and dose-limited toxicities. The most common were hyperlipidemia/hypercholesterolemia and neutropenia. Elevations in the lipids occurred rapidly, within 2 to 4 weeks, and were associated with serious, but reversible, pancreatitis. Institution of monitoring lipids and use of lipid-lowering drugs were helpful in controlling the lipid levels. Dose reductions of bexarotene capsules were also required in some patients. Drug interactions of oral bexarotene with gemfibrozil and warfarin have been observed. Patients started on bexarotene develop central hypothyroidism with low thyroid-stimulating hormone (TSH) and free thyroxine levels within weeks of starting the medication. Symptoms of hypothyroidism may be subtle because they include symptoms of fatigue and feeling cold that may be attributed to CTCL. Supplementation with levothyroxine while patients were on bexarotene alleviates the symptoms and improves tolerance to treatment. The condition was reversible within weeks of stopping therapy. There is no immunosuppression with bexarotene therapy. Patients on bexarotene typically have monthly monitoring visits to follow lipid, liver, and thyroid parameters.

EXTRACORPOREAL PHOTOCHEMOTHERAPY (See Chap. 266) ECP therapy involves the photoinactivation of a portion of a patient's lymphocyte compartment with 8-methoxypsoralen (8-MOP) in the presence of ultraviolet A light, followed by reinfusion of these cells. The treatment is performed via an intravenous line feeding into a photoinactivation device that typically requires the patient to be recumbent for 3 h. Treatments are conducted on two consecutive days every 4 weeks. Erythrodermic CTCL is manageable with ECP monotherapy, [11] but other stages have not been rigorously studied with monotherapy. In a multicenter study of erythrodermic CTCL patients, approximately one-fourth had a complete response, one-fourth had no response, and the remainder had partial responses. However, it is clear that even a partial response can improve the quality of life of these patients. Improvement may begin as early as 6 weeks into therapy, and yet some patients do not completely clear until 12 months after starting therapy. There were occasional temporary responses immediately following a 2-day cycle of therapy. On average, after 4 to 6 months there was typically a gradual and permanent decrease in erythema, scaling, and pruritus. Patients often notice more subtle changes such as the return of body hair, loss of rigors, and a return of the ability to sweat. Partial responses may also decrease the morbidity these patients suffer in terms of infectious complications. More heavily involved and inflamed skin is more readily colonized, providing both a reservoir and access point for microbes to invade the host. Thus, cutaneous improvement can also minimize complications of CTCL. The clinical experiences with ECP for CTCL suggest that the therapeutic response may well be based in the immune system. One feature is that when less than 5 percent of the malignant lymphocyte pool is photoinactivated with 8-MOP/UVA, there can be clinical responses, with more than 95 percent of the malignant lymphocytes disappearing over time. It also appears that most immunocompetent patients respond. Patients heavily pretreated, with longer disease durations, had less of a response. Also, patients with more normal CD8+ lymphocyte levels were responsive to ECP. [11] In one study, total-skin electron beam was combined with ECP in T3 and T4 patients. By comparing the SDT+BRM group to historic controls who underwent electron-beam radiotherapy at the same institution, the impact of ECP was demonstrable in the significantly longer survival of patients in the SDT+BRM group. [68]

a-INTERFERON The most studied interferon has been a, but clinical trials have also been done with ß- and ?-interferon in the treatment of CTCL. The initial studies with a-interferon showed complete responses varying from 10 to 27 percent with durations less than 6 months as a monotherapy. Again, the heterogeneity of the disease and the pretreatments patients undergo affect outcomes to make comparisons with other modalities impossible. a-Interferon is typically started at 3 million units (MU) three times a week and can be increased to a maximally tolerated dose, typically in the range of 12 MU per day. Like the other BRMs, the response to interferon is gradual, with 3 to 6 months being needed to determine the maximal response. [72] After patients achieve a maximal response, interferon can be lowered to a maintenance dose of 1 MU daily. All interferons have similar toxicities. The initial week of interferon is complicated by a flulike illness that may be accompanied by fever, myalgia, fatigue, and listlessness. As this wears off, patients are often left with a slight feeling of chronic fatigue. The long-term toxicity that causes most concern is neurologic: depression, neuropathy, dementia, and myelopathy. There are autoimmune phenomena that may occur such as proteinuria, thrombocytopenia, and anemia. Monitoring of interferon therapy includes blood counts and urinalysis along with questionnaires assessing the impact on the quality of life. The combined modality therapies that use interferon in the management of erythrodermas include ECP and retinoids. If monotherapy of erythroderma produces a partial response, the addition of either of these agents can induce the desired goals of either complete response or increased palliation.

Refractory Patch-Plaque or Erythroderma

COMBINATION THERAPY As mentioned above, the BRMs induce complete remissions as a monotherapy in only a minority of cases. As also noted, the SDTs are occasionally ineffective at completely clearing the disease. Thus, a practical combination of these two treatment strategies was inevitable. The role of interferon in CTCL has been primarily as a BRM that enhances PUVA therapy. Patients with extensive plaque stage CTCL that does not clear with PUVA have been shown to go into remission when interferon injections were started. The interferon could be tapered and PUVA used as a maintenance therapy. [73] Similar to psoriasis, the combination of retinoids with PUVA therapy can be synergistic in the therapy of patch/plaque disease. The successful strategy of combining a BRM with a debulking treatment is understandable in the context of the previous discussion of the pathogenesis of CTCL. The malignant cells are the source of some, if not all, of the immunosuppressive features of progressive CTCL. By reducing the number of cells, contributions to the immunosuppression would decrease and the immune-enhancing therapies would have a greater

chance of success.

CYTOTOXIC THERAPY Cytotoxic agents are often beneficial in the management of a patient with CTCL. The major problem with cytotoxic therapy has been that the malignant T cells of CTCL are virtually identical to other mature T cells in their sensitivity to these agents. Thus, traditional cytotoxic therapy is often complicated by side effects that are more frequent in CTCL patients treated with traditional chemotherapy. [74] To exploit the benefits of cytotoxic therapy, several successful strategies have been developed. Targeting cytotoxic therapy can be accomplished with the fusion toxins. These recombinant proteins have portions that preferentially bind actively growing T cells and portions that deliver cytotoxicity to these cells. Another strategy is to utilize chronic low dose oral chemotherapy. These well-tolerated agents can be administered for months to years if necessary to help control symptoms and, at times, to induce a complete response.

LOW-DOSE ORAL CHEMOTHERAPY Chlorambucil and methotrexate have been the most frequently used agents in daily low-dose chemotherapy of CTCL. [75] Typically, chlorambucil is combined with prednisone (40 mg prednisone and 4 mg chlorambucil per day). If no hematologic toxicity is noted, the chlorambucil can be increased in 2 mg increments. Once the maximum response is achieved, the prednisone is tapered to a long-term tolerable dose of 20 mg every other day. Once-weekly methotrexate has also been used in doses from 20 to 60 mg per week. [76] Patients with refractory plaque and erythroderma have benefited from weekly methotrexate, palliative responses are reliable but complete responses are rare.

DENILEUKIN DIFTITOX Denileukin diftitox (DD) is a fusion protein, a unique cytotoxic therapeutic agent that targets specific receptors on CTCL cells while minimizing damage to normal cells not expressing the receptor. DD uses both the cytotoxic action of diphtheria toxin and the cell-targeting ability of interleukin (IL)-2 to selectively damage CTCL cells. DD is approved in the United States for the treatment of patients with persistent or recurrent CTCL. There is some controversy as to whether it is necessary to have the high-affinity IL-2 receptor present at the levels of detection by immunoperoxidase in order for this therapy to work, because many immunoperoxidase CD25- patients have responded. DD is administered at doses of either 9 or 18 µg/kg per day IV over 20 min daily for 5 consecutive days every 3 weeks. Patients may experience infusion-related fever and chills requiring subsequent prolongation of infusion time and the addition of premedications. The safety and efficacy of DD in patients with CTCL whose malignant cells express the CD25 component of the IL-2 receptor was examined in a phase III trial of 71 patients who had failed a median of 5 prior therapies. DD was administered at two doses: 9 µg/kg per day or 18 µg/kg per day for 5 consecutive days. The overall response rate was 30 percent, with a 10 percent complete remission rate. Patients with more advanced disease (stage IIB or higher) had a greater likelihood of response at the higher dose. The median time to response was 6 weeks. A common toxicity is a reversible elevation of liver enzymes that reaches a peak during the week following an infusion. This will usually return to normal by the start of the second infusion and any subsequent elevations are of a lower magnitude. Thus, patients with cachexia, hypoalbuminemia, and hepatic abnormalities are at increased risk for toxicity from DD. The most frequent grade IV (most severe) toxicity of DD was edema from the vascular leak syndrome. No premedication was available for this during the clinical trial because it could have potentially interfered with the disease activity assessments. One of the most valuable parameters for measuring the vascular leak syndrome was to have the patient do daily weights during DD therapy. A sudden weight gain is good evidence of capillary leak. Patients receiving DD are currently dosed with the same regimens of intravenous corticosteroids that are used with other intravenous biologic therapies, typically for all 5 days of the infusion. The time to response with DD is relatively quick and after three cycles of therapy, responders will be evident. In responders, the next step is to maximize that response with continued therapy cycles. [77]

GEMCITABINE Gemcitabine is a pyrimidine antimetabolite with a low-toxicity profile. This is typically administered at a dose of 1.2 g/m ^{2} intravenously over 30 min for three doses over a 1-month period. These monthly treatment cycles can be repeated if efficacy is observed. Approximately half of the patients treated with this regimen show a palliative response and treatment is well tolerated with mild hematologic toxicity and no nausea or vomiting. [78]

MULTIAGENT CHEMOTHERAPY Chemotherapy is mostly palliative in the management of CTCL. Palliation has been obtained with a variety of multiagent regimens. Combination chemotherapy produces high objective response rates (up to 85 percent overall) but the duration of remission varies widely. Consequently, it should be emphasized that various combinations of agents may induce significant clinical responses and apparent remission in some cases, but no regimen has been shown to be curative for advanced disease. Systemic high-dose chemotherapy is most often used as a palliative agent in advanced disease. Most patients in advanced stages will exhibit some degree of steroid sensitivity, which makes the glucocorticoids a usual component of therapy. The combination regimen of cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) is one of the safer, better-tolerated regimens for advanced CTCL. [79]

Tumors

Tumors of CTCL are a heterogenous group as discussed above. The initial therapy of tumors is usually with radiotherapy given the high response rates. For patients with disseminated tumors, total-skin electron-beam radiotherapy (as discussed earlier) is needed. Given the aggressive nature of tumor disease, patients cleared with radiotherapy typically undergo maintenance therapy (see above) once remission is achieved. Given the finite tolerance of the skin for radiotherapy, relapsing tumors are frequently treated with the previously discussed chemotherapy or combination therapy regimens discussed in the section on refractory patch/plaque disease. Cytotoxic therapy typically begins with denileukin diftitox infusions to get debulking of the lymphoma without compromise of bone marrow or immune status. If there is no response, CHOP or gemcitabine infusions are useful but often require hematologic support for bone marrow suppression and close monitoring for infections. The propensity for infection is increased in patients with indwelling catheters that are often used for chemotherapy infusions. These are easily seeded from the low-level bacteremias that result from the compromised skin of patients with CTCL, especially those with erosions and ulcers. Following the induction of a complete response with any of these modalities it is worthwhile pursuing a course of maintenance therapy although only the use of nitrogen mustard, ECP, interferon, or PUVA (as discussed previously in the section on maintenance therapy) have been reported as useful following total-skin electron-beam radiotherapy.

SECONDARY SKIN INVOLVEMENT IN LYMPHOID NEOPLASIAS

REFERENCES

Systemic lymphomas represent a heterogeneous group of neoplastic diseases of the lymphoid tissue. Definition and classification of these entities are rapidly changing as knowledge grows. Currently, lymphoid neoplasias are best classified by the World Health Organization (WHO) Classification of Neoplastic Diseases of the Hematopoietic and Lymphoid Tissues [1] (Table 158-1), which primarily categorizes the entities according to lineage and, subsequently, according to a combination of morphology, immunophenotype, genetic features, and clinical syndromes.

TABLE 158-1 **WHO Classification of Neoplastic Diseases of the Hematopoietic and Lymphoid Tissues**

Infiltration of the skin may represent the first manifestation of the lymphoma (primary cutaneous lymphoma) or may occur as skin involvement of a primary extracutaneous lymphoma (secondary cutaneous lymphoma). Primary cutaneous lymphomas are defined as clonal proliferations of skin-infiltrating B/T lymphocytes primarily (at least during the first 6 months) presenting in the cutaneous compartment (see Chap. 157). [2], [3] They show a considerable variation in clinical presentation, histology, immunophenotype, and prognosis. Following the group of primary gastrointestinal lymphomas, they form the second most common group of extranodal lymphomas. [4] The annual incidence is estimated to be between 0.5 and 1 per 100,000. [5] Secondary cutaneous lymphomas are rarely seen and show a clinically uniform picture despite their different histopathologic and morphologic features.

Differentiation of primary and secondary skin involvement has prognostic relevance. [6] Differences in the expression of oncogenes, viral sequences, and adhesion molecules, as well as the presence of specific translocations, further support the view that primary cutaneous lymphomas represent a clinically and biologically distinct lymphoma group. This fact is taken into account by the proposal of the Cutaneous Lymphoma Study Group of the European Organization for Research and Treatment of Cancer (EORTC). Based on clinical presentation, histology, immunophenotype, and prognosis, primary cutaneous T cell lymphomas and primary cutaneous B cell lymphomas are classified into distinct disease entities with an indolent, intermediate, or aggressive clinical course (Table 158-2).

TABLE 158-2 **EORTC Classification for Cutaneous Lymphomas**

The unifying concept that considers all T cell lymphomas of the skin to be variations of a single pathogenetic process called cutaneous T cell lymphoma (CTCL) [7] has attracted considerable interest in disorders whose historically developed names were known mainly to the dermatologic community. However, the group of cutaneous T cell lymphoma is too heterogeneous to be pooled into a single pathogenetic concept. The major entities covered by the term CTCL are described in Chap. 157, and for reasons of completeness, some overlap with this chapter is unavoidable.

The EORTC classification provides the basis for this chapter. No consideration is given here to the etiology and pathogenesis of cutaneous malignant lymphomas, because only limited data exist despite very active research.

PRIMARY CUTANEOUS T CELL LYMPHOMAS

Mycosis Fungoides and Associated Indolent T Cell Lymphoma of the Skin

MYCOSIS FUNGOIDES Mycosis fungoides is defined as an epidermotropic cutaneous T cell lymphoma, which is extensively discussed in Chap. 157. The cases forming primary tumors, previously described as mycosis fungoides *d'emblée,* are classified according to their cytologic and immunophenotypic characteristics. [8]

MYCOSIS FUNGOIDES-ASSOCIATED FOLLICULAR MUCINOSIS Mycosis fungoides-associated follicular mucinosis represents a distinct variant of mycosis fungoides with preferential involvement of head and neck by folliculotropic T cell infiltrates, and mucinous degeneration of the hair follicles. This is also discussed in Chap. 157. Follicular papules, indurated plaques, and tumors, which usually involve the head and neck region, constitute the typical clinical appearance. The occurrence of alopecia, pruritus, and secondary bacterial infections is common. The folliculotropism of the infiltrating lymphocytes is histologically prominent. Medium-sized to large hyperchromatic cells with cerebriform nuclei form dermal infiltrates and invade the follicular epithelium, which is accompanied by a mucinous degeneration of the adnexal structures. A considerable number of eosinophils and plasma cells can be observed within the infiltrates. The neoplastic T cells express a phenotype identical to that of mycosis fungoides. Because epidermotropism can be absent in some cases, mycosis fungoides-associated follicular mucinosis may be incorrectly classified as pleomorphic T cell lymphoma of the skin. Recognition of the typical folliculotropism ensures the diagnosis.

PAGETOID RETICULOSIS (See also Chap. 157)

Definition Pagetoid reticulosis is regarded as a distinct type of cutaneous T cell lymphoma that is characterized by the presence of localized patches or plaques with an intraepidermal proliferation of neoplastic cells. Two types of the disease are described: [9], [10] The localized Woringer-Kolopp type [11] presents almost exclusively in males and is associated with an excellent prognosis (disease-related 5-year survival of 100 percent). The disseminated Ketron-Goodman type [12] mostly affects elderly people. Because the disseminated type behaves like classical mycosis fungoides, only the localized variant should be referred to as pagetoid reticulosis.

Clinical manifestations Patients develop slowly enlarging hyperkeratotic or psoriasiform plaques, most often localized on the distal extremities (Fig. 158-1). Extracutaneous dissemination has not been observed.

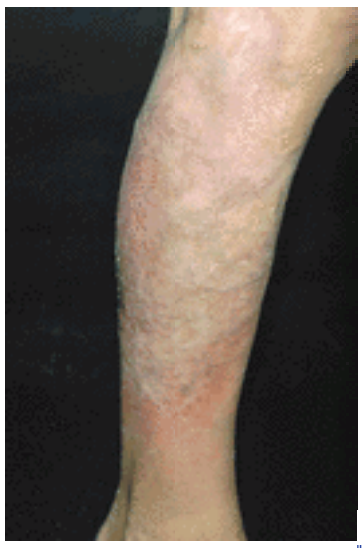

FIGURE 158-1 Pagetoid reticulosis. Hyperkeratotic plaque localized on the lower leg of a male patient.

Pathology The histologic picture resembles the pattern of Paget's disease. Acanthosis and spongelike disaggregation of the epidermis are caused by a dense, strongly epidermotropic infiltrate of large atypical mononuclear cells. These cells show medium-sized to large, sometimes hyperchromatic, nuclei and a clear cytoplasm. Immunophenotyping reveals the tumor cells to be CD3+, CD4+, CD8- or CD3+, CD4-, CD8+; whereas CD30 positivity is inconsistently observed. [13], [14] The strong expression of cutaneous lymphocyte antigen and a ^{E} ß $_{7}$, an adhesion molecule interacting with E-cadherin on epithelial cells, might be the basis of the prominent epidermotropism of the neoplastic cells. [15] A characteristic feature of pagetoid reticulosis is the variable loss of the CD2, CD5, and CD45 surface antigens.

Diagnosis and differential diagnosis The localized variant must be distinguished from hypertrophic lichen planus or Bowen's disease.

Treatment and prognosis Localized pagetoid reticulosis is best treated with x-rays or excision. Widespread generalized pagetoid reticulosis will respond to PUVA treatment combined with retinoids or interferon-a. The localized Woringer-Kolopp type presents with an excellent prognosis of a disease-related 5-year survival of 100 percent.

Primary Cutaneous CD30+ Lymphoproliferative Disorders

CD30+ CUTANEOUS LARGE CELL LYMPHOMA

Definition This is a cutaneous lymphoma consisting of large tumor cells that in majority express the CD30 antigen, with no evidence or history of lymphomatoid papulosis, mycosis fungoides or another type of primary cutaneous T cell lymphoma. Irrespective of the morphology of the tumor cells (anaplastic, immunoblastic or pleomorphic large cells) the clinical presentation and behavior are identical.

Clinical manifestations CD30+ cutaneous large cell lymphomas occur in adults, rarely in children and adolescents, with a male-to-female ratio of 1.5:1. The clinical picture is characterized by the solitary or locoregional occurrence of reddish to brownish nodules and tumors, which frequently tend to ulcerate (Fig. 158-2A). Although observed in roughly 25 percent of the patients, secondary involvement of the regional lymph nodes is not necessarily associated with an unfavorable prognosis. [16]

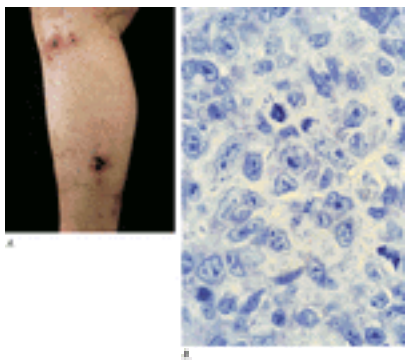

FIGURE 158-2 CD30+ cutaneous large cell lymphoma. *A.* Localized nodules, partially with ulcerations. *B.* Pleomorphic large cell lymphoma T cell infiltrate.

Pathology A nodular or diffuse nonepidermotropic infiltrate of large cells is seen in the dermis (Fig. 158-2B). In the majority of cases, the neoplastic cells show an anaplastic morphology with oval or irregularly shaped nuclei, prominent nucleoli, and an abundant cytoplasm. Less commonly, a pleomorphic or immunoblastic appearance is observed. Atypical mitotic figures are frequent. In the periphery of the lesions, inflammatory cells (T cells, eosinophils, and neutrophils) are present, sometimes imitating the histologic picture seen in lymphomatoid papulosis. By definition, at least 75 percent of the large cells are CD30+. Additionally, they express a CD4+ phenotype with variable loss of pan-T cell antigens such as CD2, CD3, and CD5. Cases with CD8+ neoplastic cells occur rarely. Unlike nodal CD30+ lymphomas, CD30+ large cell lymphomas of the skin are negative for CD15 and epithelial membrane antigen (EMA).
Diagnosis and differential diagnosis Clinicopathologic correlation is crucial. The histologic picture may suggest lymphomatoid papulosis (see Chap. 159), but lesions of CD30+ cutaneous large cell lymphoma are clinically larger and localized and they do not tend to disappear spontaneously. CD30 positivity of at least 75 percent of the large cells excludes a CD30- T cell lymphoma.
Treatment and prognosis In cases of solitary or localized skin lesions, radiotherapy is the preferred mode of treatment. Successful treatment with PUVA in combination with interferon-a has been reported. In cases of more generalized skin lesions or in cases of extracutaneous dissemination, multiagent chemotherapy should be considered. [17] In contrast to extracutaneous large cell lymphomas, CD30+ cutaneous large cell lymphomas of the skin have a favorable prognosis with a disease-related 5-year survival rate of 90 percent.

LYMPHOMATOID PAPULOSIS

Definition Lymphomatoid papulosis is a chronic recurrent, self-healing papulonodular skin eruption with histologic features that suggest cutaneous T cell lymphoma. Because this entity is not unanimously regarded as a lymphoid neoplasia, it is discussed in Chap. 159.

Aggressive Primary Cutaneous T Cell Lymphomas

SÉZARY SYNDROME

Definition Sézary syndrome is defined by the triad of erythroderma, generalized lymphadenopathy, and the presence of neoplastic T cells (Sézary cells) in skin, lymph nodes, and peripheral blood. The disease is discussed in Chap. 157.

CD30- CUTANEOUS LARGE CELL LYMPHOMA

Definition CD30- cutaneous large cell lymphoma is characterized by the occurrence of skin lesions consisting of CD30- large neoplastic T cells without prior or concurrent mycosis fungoides. Although the histologic appearance may be identical to that of classical mycosis fungoides undergoing transformation into large cell lymphoma, the absence of prior or concurrent patches or plaques represents the decisive criterion.
Clinical manifestations Patients present with solitary, localized or generalized plaques, nodules, or tumors of a reddish to brownish color (Fig. 158-3). Generalization of the lesions is more common than in CD30+ cutaneous large T cell lymphoma, and sometimes occurs at the onset of the disease.

FIGURE 158-3 CD30- cutaneous large cell lymphoma. Localized tumors of a reddish to brownish color on the face of a male patient.

Pathology Variable numbers of medium-sized to large pleomorphic T cells infiltrate the dermis and/or subcutis in a nodular or diffuse pattern. In rare cases, the neoplastic cells may show an immunoblastic morphology. By definition, large cells represent at least 30 percent of the total infiltrate. Epidermotropism, as well as angiocentricity, may occur in some cases. Immunophenotyping reveals CD30 expression to be negative or restricted to a few scattered cells. Neoplastic

cells show an aberrant CD4+ phenotype with variable loss of pan-T cell antigens.
Diagnosis and differential diagnosis Absence of prior or concurrent patches or plaques excludes transformed mycosis fungoides.
Treatment and prognosis Multiagent chemotherapy is the treatment of choice. Radiotherapy may be considered as initial treatment only in patients with solitary or localized disease. CD30- cutaneous large cell lymphomas show an aggressive clinical behavior with a disease-related 5-year survival of 15 percent.

Provisional Entities of Primary Cutaneous T Cell Lymphomas

In addition to the above-mentioned diseases, a number of provisional entities was included in the EORTC classification system. These primary cutaneous T cell lymphomas display characteristic histologic features, but no distinct clinical presentation and/or outcome has been defined so far.

PLEOMORPHIC SMALL/MEDIUM-SIZED CUTANEOUS T CELL LYMPHOMA
Definition A neoplastic proliferation of pleomorphic small- or medium-sized T cells in the skin without any clinical signs of classical mycosis fungoides defines the pleomorphic small/medium-sized cutaneous T cell lymphoma.
Clinical manifestations Patients present with one or several red-purplish papules or nodules at any location. Because histologic differentiation from mycosis fungoides and from mycosis fungoides-associated follicular mucinosis can raise problems, the absence of patches and plaques in pleomorphic small/medium-sized cutaneous T cell lymphoma is the decisive criterion.
Pathology Histologically, a dense, diffuse or nodular infiltrate containing small- to medium-sized pleomorphic cells is observed within the dermis and sometimes the subcutis. Epidermotropism may be present. The neoplastic cells express a helper T cell phenotype with frequent loss of pan-T cell markers. In some cases that show a more aggressive clinical course, expression of CD8+ is observed.
Diagnosis and differential diagnosis Demonstration of an aberrant phenotype and of T cell clonality, as well as predominance of pleomorphic T cells in the infiltrate, serve as useful criteria for the exclusion of pseudolymphomas, which often show an identical histologic pattern. Mycosis fungoides is excluded by the absence of a dominant cerebriform tumor cell population.
Therapy and prognosis In the case of solitary or localized lesions, radiotherapy is the preferred mode of action. PUVA treatment, possibly in combination with interferon-a, is useful in cases with disseminated lesions. A 5-year survival rate between 60 and 90 percent is reported for this type of lymphoma. [18], [19]
GRANULOMATOUS SLACK SKIN (See Chap. 157)
Definition Granulomatous slack skin represents a rare primary cutaneous T cell lymphoma characterized by the slow development of folded lax skin and granulomatous infiltrates with clonal T cells. Currently, only limited data concerning the clinical behavior of granulomatous slack skin are available, but in our opinion, this entity is better categorized as a variant of mycosis fungoides.
Clinical manifestations Patients develop large poikilodermatous and infiltrated areas, predominantly involving the axillary region and the groins. The lesions subsequently become atrophic and develop skin folds, caused by an elastolysis within the entire dermis (Fig. 158-4). Males are predominantly affected, and in about 30 percent of the cases, an association with Hodgkin's disease is observed. [20]

FIGURE 158-4 Granulomatous slack skin. Note skin folds due to secondary elastolysis.

Histopathology Light microscopy reveals a dense granulomatous infiltrate in the dermis. Apart from small atypical cells with cerebriform nuclei, macrophages, as well as numerous multinucleated giant T cells, occur [21] and palisade around necrobiotic areas where, destruction of the elastic tissue is observed. The neoplastic cells express a CD3+ CD4+ CD8- phenotype.
Therapy and prognosis Radiotherapy may be effective, but experience is still limited. Rapid recurrences after surgical excision have been reported. [22] Most patients have an indolent clinical course similar to that of mycosis fungoides, but the association with Hodgkin's disease has to be considered.
CYTOTOXIC LYMPHOMAS OF THE SKIN
Definition Cytotoxic lymphomas of the skin are peripheral natural killer (NK)/T cell lymphomas, which express cytotoxic proteins, that is, T cell–induced antigen (TIA), granzyme A/B, and perforin and are frequently associated with an aggressive clinical course. Although subcutaneous panniculitis-like T cell lymphoma, nasal-type NK/T cell lymphoma, CD8+ cutaneous T cell lymphoma, and nonhepatosplenic ?d-positive T cell lymphoma have been described, subentities still have to be defined. Because the EORTC classification includes subcutaneous panniculitis-like T cell lymphoma as primary cutaneous lymphoma, we describe the four entities mentioned in this context. Subcutaneous panniculitis-like T cell lymphoma is characterized by subcutaneous nodules and plaques, which usually involve legs and, less commonly, the trunk. [23] Patients often present B cell symptoms, that is, weight loss, fever, and fatigue, which are due to a frequently associated hemophagocytic syndrome. The histologic picture presents with subcutaneous infiltrates simulating a panniculitis. Infiltrates contain a mixture of neoplastic pleomorphic cells of various sizes and macrophages. Usually,

tumor cell necrosis, karyorrhexis, and erythrophagocytosis are found. By means of immunophenotyping, the neoplastic cells express CD3, CD43, CD45RO, TIA-1, perforin, granzyme B, and either T cell receptor aß (75 percent) or ?d (25 percent). Despite aggressive chemotherapy, the disease shows a rapidly progressive course and the prognosis is generally poor, although dissemination into extracutaneous sites rarely occurs. A small number of patients with aß expression may show an indolent clinical course with spontaneous regression. [24] Nasal-type NK/T cell lymphoma represents the prototype of cytotoxic lymphomas. It either affects the naso-oropharynx, which leads to destruction of the nasal region (former description: lethal midline granuloma), or manifests in skin, subcutis, lungs, viscera, and testes. Skin lesions enclose subcutaneous tumors, erythematous plaques, ulcers or an exanthema with macules and papules. The clinical course is often aggravated by a hemophagocytic syndrome with pancytopenia. [25] The histologic picture resembles that of subcutaneous panniculitis-like T cell lymphoma, but neoplastic cells strongly express CD56 and are characteristically positive for Epstein-Barr virus. Despite aggressive chemotherapy, the disease is often lethal within months. CD8+ cutaneous T cell lymphoma is clinically characterized by patches, plaques, papulonodules, and tumors mimicking disseminated pagetoid reticulosis and by a metastatic spread to unusual sites, that is, lung, testis, central nervous system, and oral cavity, but not to the lymph nodes. Histologically, bandlike infiltrates consisting of pleomorphic lymphocytes or immunoblasts are observed, displaying a diffuse infiltration of an acanthotic epidermis with variable degrees of spongiosis, intraepidermal blistering, and necrosis. The neoplastic cells express the Ki-67 antigen at a high frequency and are positive for CD3, CD8, CD7, CD45RA, and TIA, whereas CD2 and CD5 are frequently lost. Expression of TIA identifies these lymphomas derived from a cytotoxic T cell subset. [26] Despite multiagent chemotherapy, the disease shows an aggressive course with a median survival of 32 months. Nonhepatosplenic ?d-positive T cell lymphoma encompasses the peripheral T cell lymphomas with a T cell receptor ?d phenotype. The definition overlaps with subcutaneous panniculitis-like T cell lymphoma, nasal-type NK/T cell lymphoma and pagetoid reticulosis.
Staging Staging of cutaneous T cell lymphoma includes examination of the entire skin, chest x-ray, and ultrasonography of abdominal organs and peripheral lymph nodes (cervical, axillary, and inguinal). Blood investigations comprise complete blood cell count, lactate dehydrogenase level, sedimentation rate, and T cell clonality. A biopsy has to be taken from representative skin lesions and from enlarged lymph nodes. Staging may be completed by CT scan and/or histologic investigation of suspicious lymph nodes and/or visceral organs. Staging examination should be repeated at relapse and every 12 months (chest x-ray every 2 to 3 years). The aforementioned investigations allow for the assignment to the TNM system (Table 158-3). Although prognostic value and applicability of TNM staging in different cutaneous T cell lymphomas is controversial, the TNM scheme [27] directs the decision-making process toward an appropriate therapeutic regimen in most cutaneous T cell lymphomas.

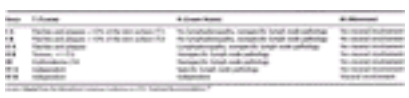

TABLE 158-3 **TNM Staging of Cutaneous Lymphomas**

Treatment Multiple strategies have been proposed to treat the different types of cutaneous T cell lymphomas. These strategies include skin-targeted therapies such as photo(chemo)therapy (e.g., psoralen plus UVA [PUVA]), [28] combination of photochemotherapy and IFN-a [29] or retinoids, topical application of nitrogen mustard [30] or chlormustine (BCNU), [31] and radiochemotherapy including total skin electron-beam irradiation. [32] Surgical excision is preferred for solitary or localized skin lesions. Oral chemotherapy is effective in cases of lymphomatoid papulosis (methotrexate [33]), Sézary syndrome (methotrexate, [34], [35] chlorambucil, and prednisone [36]) or pleomorphic small/medium-sized cutaneous T cell lymphoma (cyclophosphamide). PUVA and extracorporeal photopheresis (ECP) are effective in Sézary syndrome and in extensive skin disease in mycosis fungoides. [37] In case of unequivocal lymph node or secondary visceral involvement, as well as in the case of CD30- cutaneous large cell lymphoma or widespread cutaneous involvement, multiagent chemotherapy is indicated. However, none of these regimens have shown a curative effect. Therefore, therapy of cutaneous T cell lymphoma should be adapted to the stage of the disease. [38]

PRIMARY CUTANEOUS B CELL LYMPHOMAS

Indolent Variants

FOLLICLE CENTER CELL LYMPHOMA

Definition Primary cutaneous follicle center lymphoma can be defined as a neoplasm of clonal centrocytes (small and large cleaved follicle center cells) and centroblasts (large follicle center cells with prominent nucleoli) with or without formation of follicular centers. [39], [40]
Clinical manifestations Patients present symptoms such as nonscaling, solitary or grouped papules, and thick plaques or tumors, and, occasionally, an annular erythema can be observed in the surrounding area (Fig. 158-5). A typical symptom is the occurrence of lesions in a circumscribed area of the head and neck region.

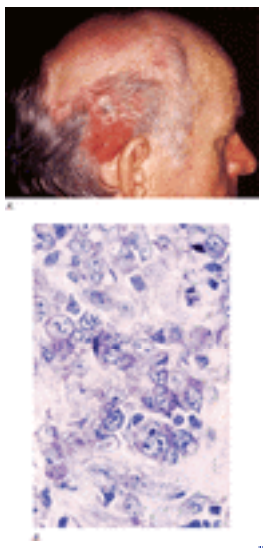

FIGURE 158-5 Cutaneous follicle center cell lymphoma. *A.* Tumor in the head area surrounded by erythema. *B.* The

cellular infiltrate consists of a mixture of centrocytes, a number of centroblasts, and reactive T cells.

Pathology The histologic picture is characterized by a nodular or diffuse infiltrate, composed of centrocytes, a small number of centroblasts, and large numbers of reactive T lymphocytes. The infiltrate spares the epidermis and remnants of reactive follicle centers can be observed in some cases. At the more advanced stage of lesions, the number of centroblasts increases and a monotonous infiltrate of large follicle center cells is evident. The typical phenotype of the neoplastic cells is CD19+ CD20+ CD22+ CD79A+. By molecular genetic analysis, clonal immunoglobulin rearrangements can be detected. However, unlike nodular follicular lymphomas, the t(14;18) translocation is not present and bcl-2 protein is expressed only in a minority of cases.
Therapy and prognosis Radiotherapy is the preferred mode of treatment. Chemotherapy should be considered only in rare cases with more generalized skin lesions. Single lesions can be excised. [41] Immune therapies such as IFN-a and interleukin-2 or monoclonal antibodies against CD20 may be beneficial in cases with disseminated lesions. With an estimated 5-year survival of 97 percent, the follicle center cell lymphoma is classified as an indolent entity of primary cutaneous B cell lymphomas. In untreated patients, the skin lesions increase in size over the years, but extracutaneous dissemination is uncommon.

IMMUNOCYTOMA/MARGINAL ZONE LYMPHOMA

Definition The cutaneous immunocytoma/marginal zone lymphoma is defined as a neoplastic proliferation of small lymphocytes, lymphoplasmacytoid cells and plasma cells, which are initially localized in the marginal zone of a follicular center. [42], [43] It is still controversial whether or not marginal zone lymphoma of the skin represents a defined entity or should be grouped together with immunocytoma of the skin. [44]
Clinical manifestations Patients present with solitary or multiple papules and nodules, which occur with preferential location on the trunk and extremities.
Pathology Diffuse or nodular infiltrates of small lymphocytes, lymphoplasmacytoid cells and plasma cells are observed in the dermis and typically spare the epidermis. The neoplastic cells express monotypic immunoglobulin and CD79, but are CD5-. A clonal rearrangement of the immunoglobulin genes can be detected in most cases. However, specific translocations have not yet been demonstrated.
Therapy and prognosis Radiotherapy is the treatment of choice. Immune therapies such as IFN-a and interleukin-2 or monoclonal antibodies against CD20 may be administered in cases with disseminated lesions. This entity is classified as an indolent form of cutaneous B cell lymphoma, with an estimated 5-year survival of close to 100 percent.

Primary Cutaneous B Cell Lymphomas with Intermediate Course

LARGE B CELL LYMPHOMA OF THE LEG

Definition This entity shows an intermediate clinical course and is defined by tumors composed of large T cells, which present exclusively on the legs (Fig. 158-6). [45]

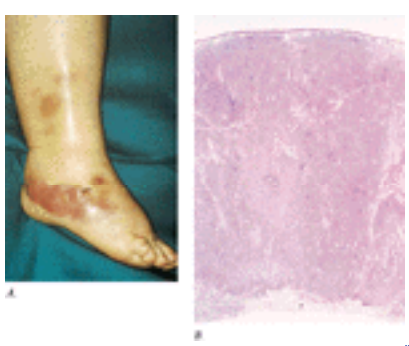

FIGURE 158-6 Large B-cell lymphoma of the leg. *A.* Nodules and tumors on the right leg 3 months after disease onset. The patient died 5 months later. *B.* The same patient. Diffuse infiltrate of large B cells with centroblasts, large centrocytes, and numerous immunoblasts.

Clinical manifestations The tumors show a red to bluish color and affect one or both lower legs of, preferentially, female patients over 70 years of age.
Pathology The histologic picture is characterized by diffuse infiltrates of large B cells in the dermis without any epidermotropism; small cells and admixed reactive cells only rarely occur. The immunophenotype of the tumor cells is CD19+, CD20+, CD22+, CD79A+. Strong expression of the BCL2 protein is found, and a clonal immunoglobulin rearrangement is detected in most cases.
Therapy and prognosis In cases of solitary or localized skin lesions, radiotherapy may be undertaken; in all other cases and when progression is observed, multiagent chemotherapy should be administered. The prognosis is less favorable with a 5-year survival of 46 to 58 percent.

Provisional Entities of Primary Cutaneous B Cell Lymphomas

In addition to the clearly defined primary cutaneous B cell lymphomas mentioned above, provisional entities have been included in the EORTC classification.

The intravascular cutaneous B cell lymphoma (CBCL) is defined by clusters of large neoplastic T cells within dermal and subcutaneous blood vessels. [46] Occasionally, slight extravascular infiltrates of atypical cells are observed. Clinically, red to bluish, indurated plaques can be observed on the legs or trunk; sometimes a panniculitis-like pattern can be seen. Multiagent chemotherapy is the preferred mode of treatment.

Cutaneous plasmacytoma is defined as a rare type of CBCL with a clonal proliferation of plasma cells, primarily developing in the skin. [47] Clinically, solitary or multiple red to bluish nodules occur without any predilection of the skin. The histologic picture is characterized by dermal infiltrates of major plasma cells, expressing monotypic immunoglobulin and CD38 but lacking expression of CD20 and LCA. Radiotherapy or surgical excision is recommended.

STAGING Staging of cutaneous B cell lymphoma includes examination of the entire integument, chest x-ray,

ultrasonography of abdominal organs and lymph nodes (cervical, axillary, and inguinal), and bone marrow biopsy. A complete blood cell count, lactate dehydrogenase level, sedimentation rate, serum and immune electrophoresis, *Borrelia* serology, and B cell clonality are ordered for most patients. In the case of pathologic findings, staging is completed by CT scan and/or histologic investigation of suspect lymph nodes and/or visceral organs. Staging examination should be repeated at relapse and every 12 months (chest x-ray every 2 to 3 years, bone marrow biopsy at relapse only).
TREATMENT SUMMARY Treatment of primary cutaneous B cell lymphomas should be adapted to the favorable prognosis of these entities, in particular the follicle center cell lymphoma and immunocytoma. Because no curative regimen has been defined so far, therapy depends on entity and the dissemination of the cutaneous lesions. [48] In the case of solitary lesions, complete excision of the tumor is the treatment of choice, and, in addition, local irradiation (single dosage: 3 to 4 Gy; total dosage: 20 to 40 Gy), by x-ray or electron beam can be considered. By using this regimen, long-lasting remissions can be observed. [49] As local treatment, intralesional application of cisplatin has also been found to induce long-lasting, complete remissions, in the case of solitary lesions. [50] In the case of indolent cutaneous B cell lymphomas with disseminated lesions, immunotherapeutic regimens, including the combined application of IFN-a and interleukin-2 [51] or the application of anti-CD20 antibodies, are evaluated for their efficacy. Systemic treatment regimens are recommended in the case of large B cell lymphomas of the leg, the occurrence of multiple lesions in other cutaneous B cell lymphomas, as well as in the presence of secondary extracutaneous manifestations. Polychemotherapy (6 cycles of CHOP [cyclophosphamide, hydroxydaunomycin, Oncovin (vincristine), and prednisone], COP [cyclophosphamide, Oncovin (vincristine), and prednisone] or MACOP [methotrexate-leucovorin, Adriamycin, cyclophosphamide, Oncovin (vincristine), prednisone]) is administered. [52] After complete remission, maintenance therapy with IFN-a may be applied for a period of 1 year. Alternatively, administration of a COP polychemotherapy with longer cycle intervals of 4 to 12 weeks is possible. For stage IV disease, combined myeloablative chemotherapy and irradiation with subsequent autologous bone marrow transplantation can be taken into consideration, although only a small number of cases have been treated by this regimen so far.

SECONDARY SKIN INVOLVEMENT IN LYMPHOID NEOPLASIAS

Secondary skin involvement in lymphoid neoplasias is rarely observed and defines advanced stages with a poor prognosis. In such cases, skin lesions are caused by specific infiltrations of neoplastic cells or by nonspecific inflammatory processes.

Specific infiltrates appear as nodules, tumors, plaques, or diffuse infiltrations. Diffuse nonepidermotropic infiltrates predominated by the neoplastic cell type characterize the pathologic picture. Definition of the lymphoma subtype depends upon immunophenotyping of the neoplastic cells.

Nonspecific skin lesions are more frequently observed and develop in about 30 percent of all patients. Signs include pruritus, purpura, mouth ulcers, and erythroderma. In addition, Sweet's syndrome (see Chap. 94 and Chap. 184), pyoderma gangrenosum, and drug reactions have been described.

Table 158-4 summarizes lymphoid neoplasias, in which secondary skin involvement has been described.

REFERENCES

Cutaneous pseudolymphoma is a term used to describe skin lesions that bear a clinical and/or histopathologic resemblance to lymphoma. Over the years, a wide variety of designations have been included in this category. Some of these represent outdated synonyms, some refer to variants of the same entity, and some are misnomers for diseases now recognized to be true lymphomas. The pseudolymphomas that are discussed in this chapter can be organized into several distinct entities based on their lymphoid subset composition, pattern of cutaneous infiltration, and associated clinical findings (see Table 159-1).

TABLE 159-1 **Classification of Cutaneous Pseudolymphomas**

THE ASSOCIATION BETWEEN PSEUDOLYMPHOMAS AND LYMPHOMAS

One of the most challenging issues concerning cutaneous pseudolymphomas has been the nature of their relationship to true lymphomas. Many patients with cutaneous B cell lymphoma (CBCL) present with a history of prior biopsies diagnosed as cutaneous lymphoid hyperplasia (CLH) or *atypical CLH*. Patients with disorders such as lymphomatoid papulosis, lymphomatoid granulomatosis, and angioimmunoblastic lymphadenopathy with dysproteinemia (AILD) have an increased risk of developing various forms of overt lymphoma. [1], [2], [3] and [4] The advent of molecular biologic methods for determining B cell or T cell clonality by analyzing immunoglobulin or T cell receptor gene rearrangements, respectively, has provided important insights into the relationship between pseudolymphomas and lymphomas. [2], [3] and [4] It appears that many forms of cutaneous pseudolymphoma represent the benign end of a lymphoproliferative continuum eventuating in true lymphoma at its malignant extreme (see Table 159-2). In between lies a spectrum of intermediate disorders that are often difficult to classify unless one is cognizant of this spectral paradigm. In some cases, such as the CLH-CBCL spectrum, lesions range from polyclonal CLH at the benign extreme, through an intermediate form known as clonal CLH, to overt CBCL at the malignant extreme. In other instances, such as the lymphomatoid papulosis–CD30+ lymphoma spectrum, dominant clonality is already present in most cases at the clinically benign end of the spectrum. The most compelling evidence for the validity of this spectral concept is that case studies verify that the same dominant lymphoid clone is involved in the clonal pseudolymphomatous precursor and the subsequent overt lymphoma when they arise in the same individual. This relationship between overt neoplasia and clonal precursor lesions is not unique to cutaneous pseudolymphomas. It is also seen in the connection between other forms of extranodal lymphoid hyperplasia and overt lymphoma, and in the relationship between monoclonal gammopathy of uncertain significance (formerly termed *benign monoclonal gammopathy*) and subsequent B cell malignancies.

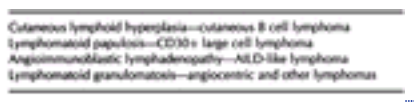

TABLE 159-2 **Pseudolymphoma—Lymphoma Disease Spectra**

The spectral paradigm for cutaneous pseudolymphomas and associated lymphomas has several important implications for their diagnosis, management, and pathogenesis. First, because some cases will exhibit lesions at an intermediate point along their lymphoproliferative continuum, they may be difficult to classify neatly into a specific disease entity. It is probably more important to recognize that they belong to a particular disease spectrum because it is the spectrum that is often the most relevant factor for determining optimal therapy, as well as the magnitude and nature of the subsequent lymphoma risk. Second, because many patients with cutaneous pseudolymphomas are at increased risk for a clonally

related lymphoma, they should maintain regular clinical follow-up, and all reasonable attempts should be made to eradicate or suppress their disease. Third, patients with pseudolymphomas probably have underlying abnormalities in the regulation of lymphoid proliferation and/or clearance (e.g., via apoptosis). Clonal evolution and concomitant clinical disease progression are likely to occur through a sequence of somatic mutations that act through these mechanisms to confer progressively increasing autonomy to the dominant lymphoid clone. Elucidating these pathogenetic mechanisms will be important not only for developing novel therapies for cutaneous pseudolymphomas, but also for improving the treatment of analogous lymphoproliferative disorders occurring in other organ systems.

EVALUATION OF PATIENTS WITH PSEUDOLYMPHOMA

Although the details of the workup of individual patients will vary with the specific type of pseudolymphoma being considered, certain data are generally important for establishing the correct diagnosis, identifying potential causative factors, and ruling out an underlying lymphoma. The clinical history should include duration and symptomatology of lesions; nature and pace of clinical progression; past treatment; local or systemic exposure to foreign antigens, including medications; personal or family history of other lymphoproliferative disorders; and a review of systems focusing on so-called lymphoma B symptoms, such as fever of unknown origin, unexplained weight loss, night sweats, fatigue, and malaise. A general physical examination is important, with special attention to the type and distribution of skin lesions and to the status of peripheral lymph nodes, liver, and spleen. A complete blood count with differential review, general chemistry panel, and a chest radiograph are screening tests that help to exclude extracutaneous involvement. Lesional skin biopsy is an essential part of the diagnostic evaluation. Topical and systemic glucocorticoids should be discontinued if possible about 4 weeks prior to biopsy because these agents can attenuate lymphoid infiltrates and thereby confound their interpretation. Skin specimens should be large enough and deep enough to ensure representative sampling and to provide adequate tissue for routine histopathology, immunohistology, and molecular biologic studies. As with squamoproliferative skin lesions, the most diagnostic areas within cutaneous lymphoid infiltrates are often their deepest portions (Fig. 159-1 and Fig. 159-2). To be cost-effective, it is often possible to perform these biopsy studies in a sequential fashion, proceeding to the next test only if a firm diagnosis cannot be made based on the results of preceding analyses. However, rigorous characterization of a pseudolymphomatous infiltrate requires the full complement of these assays. If there is only a solitary lesion, it is generally best to obtain all biopsy material simultaneously because inflammatory changes induced by the initial biopsy may interfere with the interpretation of subsequent specimens from the same locale.

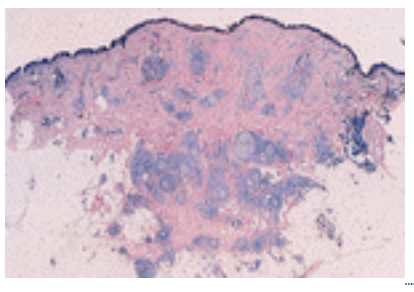

FIGURE 159-1 Cutaneous lymphoid hyperplasia. Infiltrate is wedge-shaped and tapers out in its deeper portions. Note reactive lymphoid follicles containing pale germinal centers (see Fig. 159-8).

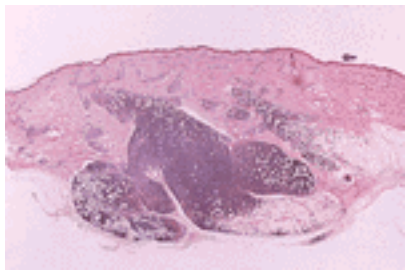

FIGURE 159-2 Cutaneous lymphoma. Infiltrate is dense and does not taper out in its deeper portions.

In the event that there is still uncertainty as to whether the lymphoid infiltrate represents a pseudolymphoma or a lymphoma, additional workup can be helpful. This includes computed tomographic (CT) scans of the chest, abdomen, and pelvis, as well as bone marrow aspiration and biopsy. Abnormally enlarged lymph nodes identified by physical examination or radiography can be biopsied and evaluated as described above for skin lesions. The author has seen patients with atypical cutaneous B cell infiltrates, presenting as only one or a few skin lesions, whose workup was otherwise unremarkable until radiographic scans of deep lymph nodes or bone marrow sampling demonstrated that they actually had advanced stage B cell lymphoma with minor skin involvement.

CUTANEOUS LYMPHOID HYPERPLASIA

CLH is characterized by a relatively dense lymphoid infiltrate, centered in the reticular dermis, that is usually B cell rich and may resemble lymphoma clinically and/or histopathologically. Many terms refer to this type of pseudolymphoma, including *Spiegler-Fendt sarcoid, lymphocytoma cutis, lymphadenosis benigna cutis,* and *cutaneous lymphoplasia*. CLH is the preferred term because it accurately describes the underlying pathophysiology of the lesion and is unlikely to be confused with terms used to describe various forms of cutaneous lymphoma. [2], [4], [5], [6] and [7]

CLH presents most commonly as a solitary nodule but it can also appear as a localized array of nodules, plaques, or papules. Generalized forms occur rarely. Adults and children may be affected, females more commonly than males. The head, neck, extremities, breasts, and genitalia are common sites (Fig. 159-3, Fig. 159-4, Fig. 159-5, and Fig. 159-6). Lesions have a doughy to firm consistency and range from red-brown to violaceous in color. Lesions secondary to

arthropod bites can be pruritic, ulcerated, or crusted. Occasionally, reactive lymphadenopathy may be present in the area of regional lymphatic drainage. The clinical differential diagnosis includes granuloma faciale, angiolymphoid hyperplasia with eosinophilia (ALHE, see below), nodular secondary syphilis, lymphoma, leukemia, Merkel cell tumor, and metastatic carcinoma. The *hydantoin-associated pseudolymphoma syndrome* is caused by anticonvulsant drugs such as phenytoin. This syndrome involves fever, lymphadenopathy, hepatosplenomegaly, arthralgia, eosinophilia, and generalized cutaneous macules and papules or, rarely, nodules. [4], [5] Nodules may contain aggregates of large lymphoid cells worrisome for lymphoma; however, both B and T cells are polyclonal. Subcutaneous lymph nodes may exhibit reactive follicular hyperplasia or atypical features suggestive of lymphoma. The macular and papular lesions of this syndrome share histopathologic features with hypersensitivity reactions to other drugs. *Acral pseudolymphomatous angiokeratoma of children (APACHE)* presents as a unilateral eruption of angiomatous papules on the extremities. [8] There is a dense lymphoid infiltrate associated with histiocytes, plasma cells, and prominent, thickened capillaries. This disorder is probably a variant of CLH secondary to arthropod bites. *Large cell lymphocytoma,* originally reported as a cutaneous pseudolymphoma, most likely represents a mixed cell or large cell form of primary CBCL. [2]

FIGURE 159-4 Cutaneous lymphoid hyperplasia. Involvement of the breast in a patient with elevated titers of antibodies against *Borrelia burgdorferi* spirochetes.

FIGURE 159-5 Cutaneous lymphoid hyperplasia. Multiple lesions of nodular scabies involving the genitalia.

FIGURE 159-6 Cutaneous lymphoid hyperplasia. Lymphomatoid drug reaction manifest as a generalized papulonodular eruption in a patient who was taking various neuroleptics.

In most cases, CLH is idiopathic; however, some lesions are associated with exposure to foreign antigens from arthropods (bites, stings, infestations), infections (herpes zoster, *Borrelia burgdorferi*), tattoos, acupuncture, trauma, gold jewelry, vaccinations, hyposensitization injections, or medications (Fig. 159-4, Fig. 159-5, and Fig. 159-6). [2], [4], [5], [6] and [7] Medications include phenytoin, carbamazepine, phenobarbital, beta blockers, calcium channel blockers, angiotensin-converting enzyme inhibitors, allopurinol, D-penicillamine, penicillin, mexiletine chloride, cyclosporine, and agents that inhibit binding of histamine to H_1, H_2, or H_{1c} receptors. These drugs include conventional H_1 and H_2 antagonists, as well as tricyclic and nontricyclic antidepressants and phenothiazines. Rather than being the target of an immune response themselves, it has been proposed that these latter agents may alter lymphocyte reactivity in a way that promotes a CLH response to other antigens in occasional individuals. [9]

Histopathologic examination of CLH lesions reveals a dense, nodular or diffuse lymphoid infiltrate that is concentrated in the reticular dermis (Fig. 159-1). It tends to be top-heavy and to taper out in the lower dermis, although more widespread dermal infiltration with extension into the subcutis can sometimes be seen. In most cases, the epidermis is normal and separated from the underlying infiltrate by a narrow Grenz zone of uninvolved papillary dermis. Occasionally, the

epidermis may exhibit variable degrees of hyperkeratosis, parakeratosis, acanthosis, dyskeratosis, spongiosis, and basal vacuolar degeneration. Arthropod reactions may show prominent epidermal hyperplasia or ulceration. Rarely, retained mouth parts may be seen associated with foreign-body granulomatous reactions. The dermal infiltrate is composed primarily of small mature lymphocytes, with a minor component of large lymphoid cells containing large, pale vesicular nuclei with small nucleoli (Fig. 159-7). Fewer than half of cases exhibit well-defined reactive lymphoid follicles discernible in routinely stained sections (Fig. 159-2 and Fig. 159-8). These B cell follicles may be either primary or secondary. The former are composed of homogeneous small lymphocytes, whereas the latter are compartmentalized into a peripheral mantle zone of small lymphocytes surrounding a germinal center composed of a heterogeneous mixture of small and large lymphoid cells, with cleaved and noncleaved nuclei, known as centrocytes and centroblasts. Also present in germinal centers are tingible-body macrophages, so named because they contain phagocytized debris from apoptotic lymphoid cells. Mitotic figures may be numerous within germinal centers but are usually uncommon elsewhere in the infiltrate. Various types of histiocytes, including macrophages, dermal dendritic cells, and Langerhans cells, are scattered throughout the infiltrate in variable proportions. Capillary hyperplasia and endothelial swelling are often present. Other cells are sometimes admixed, including plasma cells, eosinophils, mast cells, neutrophils, and histiocytic giant cells. The first two are particularly common in arthropod reactions such as nodular scabies (Fig. 159-9).

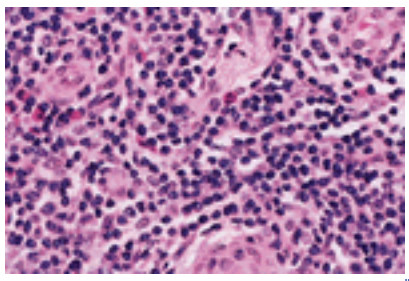

FIGURE 159-7 Cutaneous lymphoid hyperplasia. Infiltrate consists predominantly of small lymphocytes with an admixture of large lymphoid cells, histiocytes, and eosinophils.

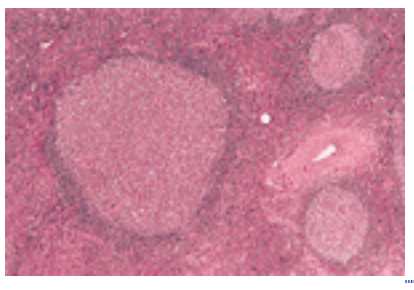

FIGURE 159-8 Cutaneous lymphoid hyperplasia. Lymphoid follicles in the dermis contain pale germinal centers surrounded by darker mantle zones.

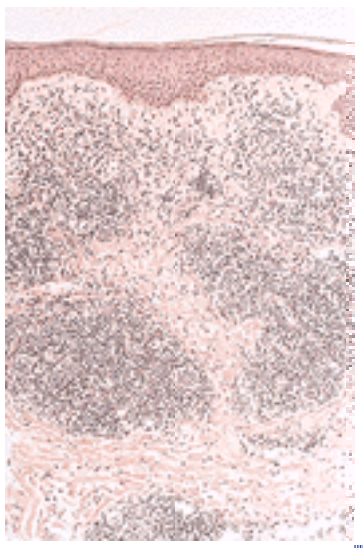

FIGURE 159-9 Cutaneous lymphoid hyperplasia. Nodular scabies. Patchy dense infiltrate composed of small lymphocytes, histiocytes, eosinophils, and plasma cells.

CLH is just one special case of extranodal lymphoid hyperplasia that may occur in a variety of organ systems. In their most well developed form, these extranodal reactions recreate the immunoarchitectural features of reactive follicular lymphoid hyperplasia occurring in lymphoid tissues. CLH is generally a B cell–predominant or mixed B cell/T cell disorder. B cells may be organized into primary or secondary lymphoid follicles, simple clusters devoid of the follicular dendritic cell network seen in B cell follicles, or may be randomly scattered throughout the infiltrate (Fig. 159-10). [7] A defining immunophenotypic feature of CLH is that the small, nongerminal center B cells and plasma cells are polytypic, that is instead of restriction to only one type of immunoglobulin light chain, there is a mixture of ?-positive and ?-positive cells. The follicular dendritic cell networks in lymphoid follicles coexpress both immunoglobulin light chains because of the polytypic nature of the immunoglobulins bound to these networks (Fig. 159-11). The larger germinal center B cells are also polytypic but generally have very low levels of immunoglobulin expression, which is obscured by the more intense staining of the follicular dendritic cell networks in which they are enmeshed. Consistent with their role as a site of antigen selection and apoptosis, reactive germinal centers are negative for the bcl-2 oncoprotein. [2]

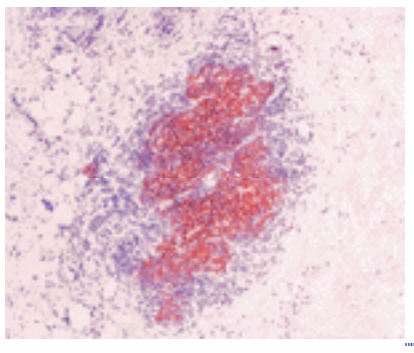

FIGURE 159-10 Cutaneous lymphoid hyperplasia. Reactive lymphoid follicle contains B cells (blue) enmeshed in a network of follicular dendritic cells (red). Frozen section immunoperoxidase-stained using the anti-DRC (dendritic reticulum cell) monoclonal antibody.

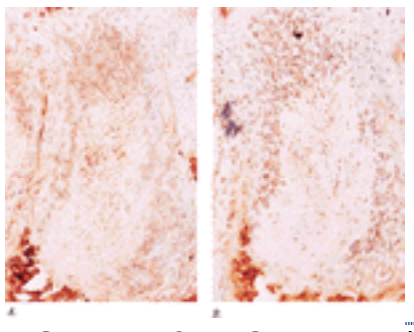

FIGURE 159-11 Cutaneous lymphoid hyperplasia. Reactive lymphoid follicle contains a germinal center surrounded by a mantle zone composed of a mixture of B cells that express either (*A*) ?-immunoglobulin light chain or (*B*) ?-immunoglobulin light chain. Note that the central follicular dendritic cell network stains positive for both light chains because polytypic immunoglobulins are bound to its surface.

Some observers classify CLH into follicular and diffuse variants based on the identification of lymphoid follicles in routinely stained sections. This distinction is probably not relevant biologically because most of the apparently diffuse cases also exhibit B cell follicles when examined immunohistologically. T cells are also present in all cases of CLH. They are found in small numbers within lymphoid follicles but are concentrated mainly between follicles, constituting an interfollicular T cell domain. This imparts an overall compartmentalization of B and T cells in CLH lesions. The CD4+ T cell subset predominates over the CD8+ subset. There is a normal pattern of T cell–antigen expression except that CD7 may be moderately deficient sometimes, being expressed by only 20 to 40 percent of T cells. Germinal center B cells, mantle zone B cells, interfollicular B cells, and plasma cells also express the same complement of cell surface differentiation antigens expressed by their counterparts in reactive lymphoid tissues.

In contrast to most nodal follicular B cell lymphomas (see Chap. 158), the t(14;18) translocation, which results in inappropriate expression of the bcl-2 oncoprotein, is absent in CLH. [2], [3], [10] Molecular biologic studies show that 5 to 33 percent of CLH cases defined by clinicopathologic and immunohistologic criteria contain occult dominant immunoglobulin gene rearrangements, indicating the presence of a dominant B cell clone. [2], [11], [12], [13], [14] and [15] These cases, known as clonal CLH, have progressed in some cases to overt B cell lymphoma exhibiting the same dominant B cell clone. These findings support the view that CLH, clonal CLH, and primary cutaneous B cell lymphoma exist as points along a continuum of cutaneous B cell lymphoproliferative disorders (Table 159-2). Progression across this spectrum of diseases clearly occurs in some cases, most likely as the result of serial mutations within the dominant B cell clone. This implies that patients with persistent CLH require regular monitoring for the development of lymphoma. Clonal T cell receptor gene rearrangements have also been detected in up to one-third of CLH cases. [15] This may represent an expanded reactive T cell clone within the CLH infiltrate. Evidence for this has been observed in HIV-related CLH. [16] Other less likely possibilities include an abortive T cell lymphoma or an evolving B cell lymphoma bearing T cell receptor gene rearrangements.

A principal challenge in the differential diagnosis of CLH is its distinction from CBCL of either diffuse or follicular types (see Chap. 158). [2], [3], [4] and [5], [17] The most common variant of CBCL is the diffuse large cell lymphoma, which is readily distinguished from follicular CLH on the basis of its diffuse architecture and monomorphous large cell composition. Differentiating follicular CLH from follicular CBCL can be difficult (Fig. 159-12). Follicular CBCL tends to be more bottom heavy with adnexal infiltration and lymphoid follicles lacking the cellular heterogeneity, zonation, and macrophages typical of reactive follicles. Immunophenotyping shows the neoplastic B cell follicles are either monotypic or immunoglobulin-negative. Cases involving cutaneous lymphoid infiltrates that are hard to classify, or that contain a dominant lymphoid clone, often benefit from a staging workup as described above. In those instances representing lymphoma, workup will sometimes reveal extracutaneous involvement, biopsies of which may be easier to diagnose as lymphoma. Staging also provides useful prognostic data and is essential for appropriate management of patients with overt lymphoma.

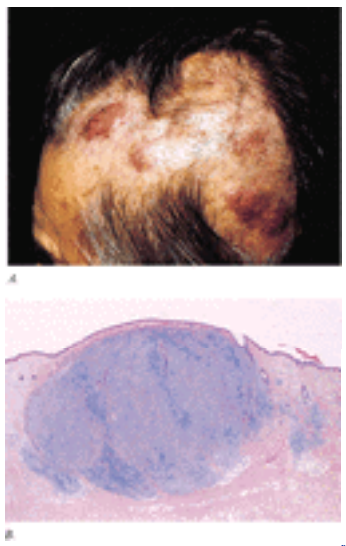

FIGURE 159-12 Cutaneous follicular B cell lymphoma. *A.* Red-brown nodules on the scalp. *B.* Dense expansile lymphoid infiltrate containing poorly circumscribed neoplastic lymphoid follicles with confluence.

CLH must also be distinguished from lymphocytic infiltrates such as chronic lymphocytic leukemia, deep figurate erythemas, polymorphous light eruption, discoid lupus erythematosus, and Jessner's lymphocytic infiltration of the skin (LIS). All of these disorders tend to produce perivascular, and sometimes periadnexal, infiltrates whose density is far less than that of the nodular or diffuse infiltrates typical of CLH. With the exception of chronic lymphocytic leukemia, these are all T cell disorders. Chronic lymphocytic leukemia is a B cell disorder that exhibits monotypic immunoglobulin and CD5 expression and involves the blood and bone marrow. CLH lesions rich in plasma cells must be distinguished from those of secondary syphilis, plasmacytoma, myeloma, and immunocytoma. The infiltrate in secondary syphilis is generally richer in plasma cells or histiocytes than small lymphocytes and is associated with epidermal hyperplasia, an interface inflammatory component, and positive serology. The plasma cells in plasmacytoma and myeloma are monotypic and tend to exhibit mitotic figures, atypia, immaturity, and multinucleated forms. Monotypic immunoglobulin is also present in the tumor cells of primary cutaneous immunocytoma. This B cell neoplasm is also known as marginal zone lymphoma, mucosa-associated lymphoid tissue (MALT)-type lymphoma, and low-grade SALT B cell lymphoma. [1], [2] and [3] It is composed of varying proportions of small lymphocytes, plasmacytoid lymphocytes, plasma cells, and marginal zone-like B cells. The latter have monocytoid features with a halo of cytoplasm visible around their nuclei. These cells often surround clusters of small lymphocytes, imparting a “reverse reactive follicle” appearance with smaller cells centrally and the larger monocytoid cells peripherally.

It should be noted that typical reactive lymphoid follicles with germinal centers are not specific for CLH. They can be seen in some lymphomas (e.g., marginal zone lymphoma), Kimura's disease, ALHE (see below), Castleman's disease, inflammatory pseudotumor of the skin, and morphea and as part of the host response to tumors such as basal cell carcinoma. The broad histopathologic differential diagnosis of CLH also includes histiocytoses, especially Rosai-Dorfman disease (sinus histiocytosis with massive lymphadenopathy; see Chap. 161), as well as so-called small round cell tumors such as Merkel cell carcinoma (see Chap. 86), oat cell carcinoma, neuroblastoma, and Ewing's sarcoma.

In the less common T cell CLH, there are only rare B cells. [2], [4], [5], [18], [19] and [20] Lesions may be idiopathic or secondary to drugs or arthropods. Sparse to moderate epidermotropism by atypical lymphoid cells may be seen. The dermal infiltrate has a nodular or diffuse pattern and may contain cerebriform cells, immunoblasts, and histiocytes mixed with a preponderance of small mature lymphocytes. The histiocytes are sometimes numerous enough to impart a vaguely granulomatous appearance. [20] The author has seen one such case presenting as multiple nodules on the trunk and extremities that was associated with rheumatoid arthritis and eventuated in T cell lymphoma. Differentiation between T cell CLH and T cell lymphomas relies on the fact that most cases of mycosis fungoides exhibit marked epidermotropism, and most nonmycosis fungoides cutaneous T cell lymphomas are either diffuse large cell or mixed cell types, although a pleomorphic small cell type occurs rarely. Many T cell lymphomas show loss of one or more T cell antigens, and most have monoclonal T cell receptor gene rearrangements. Progression to T cell lymphoma has been reported in occasional patients with T cell CLH. [18], [19]

CLH lesions may resolve spontaneously or persist indefinitely. Nodular scabies (Fig. 159-5 and Fig. 159-9) is a well-recognized form of persistent CLH. Solitary lesions sometimes regress after biopsy or may be eradicated by excision. Those lesions secondary to drugs usually regress when the offending agent is withdrawn. CLH related to *B. burgdorferi* (lymphocytoma cutis; see Chap. 203) responds to antibiotic therapy, as do some cases of idiopathic CLH. Glucocorticoids (topical, intralesional, systemic), cryotherapy, antimalarials, minocycline, and radiation therapy have all been used with variable success. The latter is particularly effective but is usually regarded as a last resort. Local or distant recurrence can occur following any of these treatments. Cases of atypical CLH that cannot be distinguished from lymphoma are usually treated as localized lymphoma after staging rules out extracutaneous disease. Treatment typically involves local radiation therapy that may be preceded by excision of the lesion.

KIMURA'S DISEASE

Kimura's disease presents as a solitary or multiple nodules up to 10 cm in diameter centered in the subcutis, most commonly involving the head of a young to middle-aged adult. [21], [22] and [23] Peripheral eosinophilia and regional lymphadenopathy are characteristic. Histopathologically, the dermis and/or subcutis exhibit hyperplasia of small blood vessels lined by plump endothelial cells similar to those present in the high endothelial venules of lymphoid tissues. These venules are a major point of lymphocyte trafficking between the blood and the paracortical T cell domain of lymph nodes. Surrounding these hyperplastic vessels is a dense infiltrate composed of small lymphocytes, plasma cells, histiocytes, and eosinophils. The latter are typically prominent but may be absent in some cases. There are usually multiple secondary lymphoid follicles with prominent germinal centers, particularly in the subcutaneous lesions. It is

possible that Kimura's disease represents a florid, deep-seated form of the same basic pathogenetic process that gives rise to classic CLH.

There is controversy regarding whether Kimura's disease and ALHE are variants of the same disorder or separate clinicopathologic entities. [21], [22] and [23] The terms *epithelioid hemangioma* and *pseudopyogenic granuloma* have been used as synonyms for ALHE (Fig. 159-13). Some regard ALHE essentially as a malformation of blood vessels caused by an underlying arteriovenous shunt. They consider the CLH-like aspects of the lesional infiltrate to be a secondary feature. Proponents of ALHE as a separate disorder argue that, relative to Kimura's disease, ALHE lesions tend to be smaller (Fig. 159-13A) and exhibit a more prominent vascular hyperplasia, characterized by small blood vessels lined by plump endothelial cells with abundant cytoplasm and sometimes atypical nuclei (Fig. 159-13B). In addition, there is often evidence of arteriovenous anastomoses, the lymphoid infiltrate is less extensive, secondary lymphoid follicles are present only in a minority of cases, and lymphadenopathy is absent.

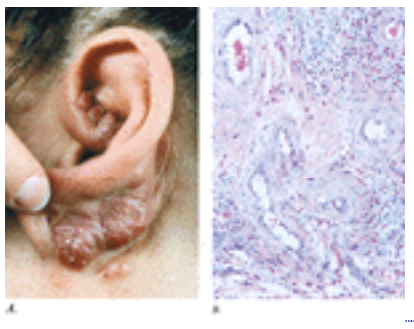

FIGURE 159-13 Angiolymphoid hyperplasia with eosinophilia. *A.* Clinically there are soft, confluent papular lesions typically located in the auricular region. *B.* Histologically blood vessels are lined by plump endothelial cells protruding into the lumen; there is vascular hyperplasia with thickened vascular walls, lymphocytic infiltrates, and prominent eosinophilia.

CASTLEMAN'S DISEASE

Castleman's disease is also known *as angiofollicular lymphoid hyperplasia* or *giant lymph node hyperplasia*. [24], [25], [26] and [27] It is a lymphoproliferative disorder that most often presents as an isolated mediastinal mass, although a multicentric form of the disease also exists. Rarely, it may present as a solitary subcutaneous or cutaneous tumor in various locations. Surgical excision is effective therapy, and the clinical course is usually favorable. Castleman's disease may be associated with *p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *M* protein, and *s*kin changes, the POEMS syndrome. [28] Studies of multicentric Castleman's disease demonstrate increased levels of lesional and circulating interleukins 1ß and 6, suggesting that cytokine abnormalities may mediate the systemic manifestations of POEMS syndrome. [28], [29] Castleman's disease occurring in the setting of HIV infection is associated with human herpesvirus type-8, [30] which has also been detected in Kaposi's sarcoma (see Chap. 104), and primary effusion lymphomas.

Two histopathologic variants of Castleman's disease exist. The more common hyaline vascular variant exhibits small, concentrically whorled, lymphoid follicles surrounded by small lymphocytes arranged in a concentric, onion-skin pattern. An extensive proliferation of capillaries is present between follicles. The rarer plasma cell variant exhibits large, hyperplastic secondary lymphoid follicles associated with a highly vascular interfollicular zone rich in plasma cells. The differential diagnosis of subcutaneous Castleman's disease includes eosinophil-poor ALHE, Kimura's disease, plasmacytoma, myeloma, CLH, and follicular types of CBCL. All of these diseases lack the characteristic features of the lymphoid follicles seen in the two histopathologic variants of Castleman's disease. These disorders also lack prominent vascular hyperplasia, except for ALHE and Kimura's disease whose characteristic endothelial cells aid their recognition. Plasmacytoma and myeloma contain dense sheets of atypical plasma cells and differ in their associated clinical findings. CLH is usually centered in the dermis rather than the subcutis. Most cutaneous lymphomas have a diffuse, monomorphous appearance. The rare follicular types of CBCL have distinctive features, as summarized in the CLH section.

PSEUDO-MYCOSIS FUNGOIDES (See also Chap. 157)

Pseudo-T cell lymphomas with a bandlike or mycosis fungoides–like histopathologic pattern may arise spontaneously; as a T cell infiltrate coexisting with B cell chronic lymphocytic leukemia; as a rare variant of the eruption of lymphocyte recovery (which occurs in the setting of leukocyte reconstitution after iatrogenic marrow aplasia); or in association with ingestion of various drugs including hydantoins, carbamazepine, propylvalerate, dexchlorpheniramine maleate (Polaramine), and other antihistamines. [2], [4], [5], [9], [20] The lesions present clinically as one or a few plaques on the trunk or extremities. Occasionally, several plaques or a Sézary-like syndrome develop. Histopathologically, there is a papillary dermal, bandlike infiltrate containing mostly small- and medium-sized atypical lymphocytes with clefted and cerebriform nuclei. Moderate numbers of histiocytes are admixed, but eosinophils and plasma cells are rare. The dermal–epidermal junction is obscured, and there is no Grenz zone. The overlying epidermis may be hyperplastic and/or may contain a sparse to moderate atypical lymphoid infiltrate; however, relative to mycosis fungoides, epidermotropism is typically far less prominent and Pautrier's microabcess-like cell aggregates are rare. The differentiation of these pseudolymphomas from mycosis fungoides is aided by their tendency toward minimal epidermotropism in many cases, the small number of lesions, and resolution following drug discontinuation and/or local therapy with excision or topical glucocorticoids.

Lichenoid drug eruptions, caused by agents such as gold, thiazides, and antimalarials, may also bear a histopathologic resemblance to atrophic forms of large plaque parapsoriasis and overt mycosis fungoides when they result in a bandlike, dermal lymphoid infiltrate that involves an atrophic epidermis. As in mycosis fungoides, eosinophils and plasma cells may also be present. However, these lesions lack lymphoid atypia, exhibit the clinical features of typical lichenoid drug

rashes, and regress eventually following discontinuation of the causative agent. Poikilodermatous skin lesions of collagen vascular diseases and genodermatoses are distinguished from mycosis fungoides by their associated clinical and laboratory findings; sparser infiltrates lacking atypia; and, for collagen vascular diseases, dermal mucin, thickened epidermal basement membranes, and characteristic epidermal alterations. Chronic radiodermatitis may resemble poikilodermatous mycosis fungoides clinically but is distinguished by clinical history, sparse infiltrate, keratinocyte atypia, dermal fibrosis, and loss of adnexa. Some cases of secondary syphilis may also mimic mycosis fungoides by virtue of showing a dense, bandlike, upper dermal infiltrate that obscures the dermal–epidermal junction and invades a nonspongiotic epidermis. However, the infiltrate contains more plasma cells and fewer lymphocytes than expected in mycosis fungoides; there is no lymphoid atypia; there may be neutrophils in the epidermis; and there is a deep perivascular extension of the infiltrate that is unusual in mycosis fungoides except in the tumor phase. Furthermore, the patient's history, clinical appearance of lesions, serology, and response to antibiotic therapy will facilitate the correct diagnosis.

Three other disorders that may mimic mycosis fungoides/Sézary syndrome clinically and/or pathologically include follicular mucinosis, lymphomatoid contact dermatitis, and actinic reticuloid. Because of their distinctive features, each is discussed separately below.

FOLLICULAR MUCINOSIS (See also Chap. 157 and Chap. 158)

Follicular mucinosis, also referred to as alopecia mucinosa, presents as variably pruritic, pink to yellow-white follicular papules or red boggy plaques that result in alopecia when they involve hairy areas such as the scalp. [2], [3], [4], [5], [31] Three clinical variants exist: (1) one or a few lesions that usually present on the head or neck of a child and resolve spontaneously within a few years; (2) generalized lesions in older individuals that may persist or recur indefinitely; and (3) follicular mucinosis secondary to other disorders, usually mycosis fungoides but occasionally Sézary syndrome, other skin lymphomas, discoid lupus, or ALHE. It has been proposed that follicular mucinosis secondary to mycosis fungoides should be termed *follicular mycosis fungoides* because the degree of mucinosis can vary among cases and even in the same case over time. [32] Follicular mucinosis may occur as an isolated disease but has also arisen in patients with chronic lymphocytic leukemia, Hodgkin's disease, and Kaposi's sarcoma. Histopathologic examination reveals a variably dense, dermal lymphoid infiltrate that surrounds hair follicles and infiltrates their epithelia. Histiocytes and sometimes eosinophils are admixed. The hair follicles contain pools of acid mucopolysaccharides associated with follicular disruption. In cases of mycosis fungoides with secondary follicular mucinosis, characteristic tumor cells are present in the follicular epithelium, epidermis, and/or dermis. Atypical lymphocytes are unusual in primary alopecia mucinosa and reportedly do not form Pautrier's microabscesses; however, some observers have found it difficult to differentiate these two disorders, especially when the primary form presents as generalized plaques. Eosinophils have been reported in both primary and secondary types. [33] Dominant T cell clones have been detected in some cases of primary follicular mucinosis as well as in mycosis fungoides–related follicular mucinosis, indicating that the primary form is a lymphoproliferative disorder that cannot be distinguished from mycosis fungoides merely on the basis of monoclonality. [2], [3], [32] Treatment options include topical and systemic PUVA, topical and intralesional glucocorticoids, retinoids, topical nitrogen mustard, and radiation therapy.

LYMPHOMATOID CONTACT DERMATITIS

This condition was described originally in four patients with persistent allergic contact dermatitis proven by patch tests. [34] The clinical and histopathologic changes in the lesions are said to resemble those of mycosis fungoides.

Clinically, lymphomatoid contact dermatitis is characterized by generalized, pruritic, red, scaly papules and plaques that may become confluent (Fig. 159-14) with resultant exfoliative erythroderma. Patch tests for a variety of common allergens, such as ethylenediamine dihydrochloride, may be positive.

FIGURE 159-14 Lymphomatoid contact dermatitis. Erythematous papules and plaques on the forehead. Patch test with local anesthetics was positive.

Histopathologically, lymphomatoid contact dermatitis contains foci of spongiosis, simulating the appearance of cutaneous T cell lymphomas. It must be differentiated from mycosis fungoides (Fig. 159-15), usually on the basis of changes within the epidermis; specifically, in mycosis fungoides more atypical lymphocytes have a tendency to form Pautrier's microabscesses in the epidermis. Frequently there is edema in the papillary dermis of lymphomatoid contact dermatitis, a finding that is absent from mycosis fungoides. Immunohistopathologic investigations indicate that lymphomatoid contact dermatitis represents a T cell pseudolymphoma. Examination of the cells in the infiltrate by electron microscopy reveals many atypical lymphocytes with cerebriform nuclei like those of mycosis fungoides.

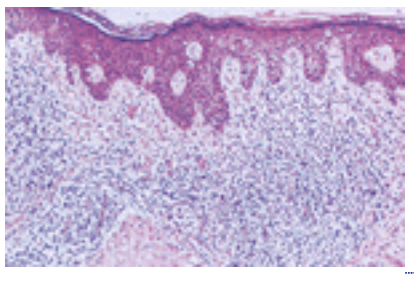

FIGURE 159-15 Lymphomatoid contact dermatitis. Dense bandlike infiltrate in the upper part of the dermis and spongiotic foci in the epidermis (“spongiotic simulator” of mycosis fungoides).

Although lymphomatoid contact dermatitis has been reported, albeit rarely, to evolve into lymphoma, it is more likely that those patients had lymphoma from the outset.

A thorough search for the offending antigen by way of patch tests is necessary if the process of lymphomatoid contact dermatitis is to be interrupted. Avoidance of the responsible allergens leads to eventual resolution of the condition, aided by topical application of glucocorticoids.

ACTINIC RETICULOID (See also Chap. 135 and Chap. 136)

Actinic reticuloid, a chronic inflammatory condition that tends to affect older men, is a consequence of persistent photoallergic sensitivity. [35], [36] and [37] It may be regarded as the most severe expression of chronic actinic dermatitis. The clinical and histopathologic aspects of actinic retinoid have been described as resembling those of T cell lymphoma.

Clinical examination reveals red-purple, sometimes scaly, lichenoid papules and plaques situated almost entirely on sites exposed to sunlight. In some patients, there are nodules, and generalized erythroderma may develop. The facies may be leonine with deep furrows in markedly thickened skin (Fig. 159-16), strikingly similar to the facies of patients with lymphomas and leukemias. Alopecia may be diffuse as a consequence of prolonged, vigorous rubbing. Pruritus is generally severe and intractable. Generalized lymphadenopathy is common. Differentiation of actinic reticuloid from T cell lymphoma may be difficult clinically, especially because circulating Sézary-like cells are found in the peripheral blood in approximately 10 percent of cases of actinic retinoid.

FIGURE 159-16 Actinic reticuloid. Markedly thickened and erythematous skin with deep furrows and lichenoid papules on the face.

Patients with actinic reticuloid are sensitive to both short- and long-wave ultraviolet radiation, and occasionally to visible light. Fluorescent light is said to sometimes lead to exacerbation of the disease. The minimal erythema dose is lower than normal in patients with actinic reticuloid. Some evidence suggests that photosensitivity in actinic reticuloid is related to allergic contact dermatitis (compositae plants, rubber components, potassium dichromate, and fragrance material). In rare instances, exposure to halogenated salicylanilides has been demonstrated in patients with actinic reticuloid.

Histopathologically, actinic reticuloid consists of moderately dense, superficial and deep, perivascular, mixed-cell infiltrates of lymphocytes, histiocytes, plasma cells, mast cells, and eosinophils. Atypical mononuclear cells with hyperchromatic, lobulated nuclei have been reported by some observers. The infiltrate is patchy and may be bandlike in the upper part of the dermis. The papillary dermis is thickened by coarse bundles of collagen in vertical streaks perpendicular to the skin surface and parallel to the rete ridges. Often plump, stellate, multinucleated fibroblasts are present in the thickened papillary dermis. The epidermis often shows psoriasiform hyperplasia. The constellation of changes in the papillary dermis and epidermis just enumerated are indubitable evidence of prolonged rubbing of skin, that is lichen simplex chronicus. Solitary lymphocytes may be found within a spongiotic epidermis.

The presence of IgE+ cells with a dendritic morphology (Langerhans cells) associated with elevated serum IgE levels are notable features. [38] Electron microscopy reveals cells that resemble Lutzner cells and Langerhans cells. In contrast to mycosis fungoides, which is almost always a tumor of CD4+ T cells, there is a predominance of CD8+ T cells in the lesional skin and blood of most patients with actinic reticuloid. [39] This difference and the photosensitivity help to distinguish actinic reticuloid from mycosis fungoides. Furthermore, the histopathologic changes of actinic reticuloid can be differentiated from those of mycosis fungoides because the former has features of lichen simplex chronicus

superimposed on a persistent photoallergic dermatitis. The latter is an epidermotropic form of lymphoma.

The development of lymphoma in the course of actinic reticuloid has been reported. [36] T cell receptor gene rearrangement analysis has not shown evidence of dominant clonality. [38], [40] Frequently a chronic course is observed in actinic reticuloid. The condition does not usually respond to conventional therapy such as systemic glucocorticoids, chloroquine, or beta-carotene. Total avoidance of light can lead to improvement, but that is a long-term endeavor and not a solution. Treatment modalities include PUVA and UVB phototherapy, azathioprine, cyclosporine, and danazol. [36] Prescription of sun-protective agents and avoidance of contact allergens are crucial.

LYMPHOMATOID PAPULOSIS (See also Chap. 48)

Lymphomatoid papulosis often bears a close clinical resemblance to pityriasis lichenoides et varioliformis acuta (PLEVA). [2], [41] It usually presents as generalized crops of red to red-brown papules and/or nodules that develop scales, vesicles, pustules, crusts, or ulcers prior to their spontaneous resolution within several weeks of onset (Fig. 159-17). Lesions in different stages of clinical evolution are present concurrently (Fig. 159-17A). Burned-out lesions may exhibit varioliform scarring or postinflammatory hyper- or hypopigmentation. Sometimes lesions arise and regress without appreciable epidermal changes. Occasionally, the lesions are regionalized or few in number and may sometimes appear as plaques. In addition to the acute and chronic forms of pityriasis lichenoides, the clinical differential diagnosis includes arthropod bites, cutaneous lymphomas, and histiocytoses. Both sexes are affected, with a wide age range and a peak incidence in middle age. Patients with lymphomatoid papulosis have about a 20 percent risk of developing mycosis fungoides, large cell lymphoma, and/or Hodgkin's disease. In some instances, these diseases precede the onset of lymphomatoid papulosis.

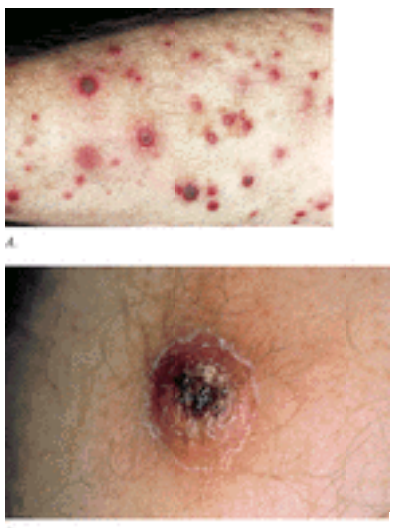

FIGURE 159-17 Lymphomatoid papulosis. *A*. Papular papulonecrotic and modular skin lesions. Note various stages of development are present at the same time (*courtesy of W. Sterry, MD*). *B*. Lymphomatoid papulosis. Crusted erythematous papulonodule.

Histopathologic examination reveals a wedge-shaped, top-heavy, atypical lymphoid infiltrate associated with epidermal destruction. [2], [3], [4] and [5], [42], [43] Epidermal changes depend on the stage of lesional evolution. Initially, they are minimal, but subsequently lymphoid infiltration, spongiosis, necrosis, and formation of vesicles, pustules, crusts, or ulcers supervene. The atypical lymphoid cells are large and mixed with banal lymphocytes and sometimes neutrophils and eosinophils. The large atypical cells vary from a small minority to a great majority of the total lymphoid infiltrate. They are classified into two cytologic types that may exist concurrently or serially in various lesions in individual cases (Fig. 159-18). [3] Type A cells resemble Reed-Sternberg cells and their mononuclear variants as seen in Hodgkin's disease. Type B cells resemble the larger tumor cells in mycosis fungoides and exhibit hyperchromatic, irregular nuclei. These cells are found in type A and B lesions, respectively. When type A cells form diffuse sheets without many admixed inflammatory cells, the lesions are referred to as type C. Mitotic figures may be numerous and abnormal. Extravasation of erythrocytes is a frequent finding. A minority of cases exhibit lymphocytic vasculitis, but true fibrinoid necrosis is rare.

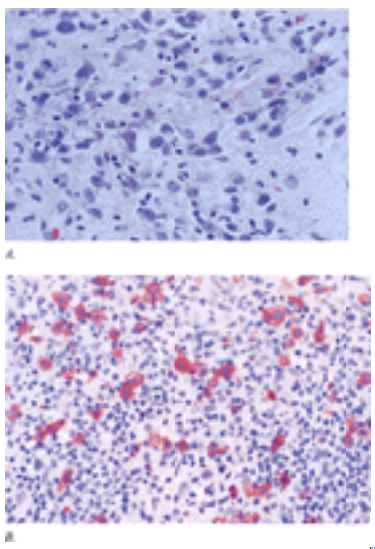

FIGURE 159-18 A. Lymphomatoid papulosis. Dermal infiltrate contains several large lymphoid cells with nuclei containing evenly dispersed chromatin and variably prominent nucleoli (so-called type A cells). B. Type A with large

CD30+ T cells (red) among admixed inflammatory cells (*B courtesy of Wolfram Sterry MD*).

Immunohistologic studies reveal a predominantly T cell infiltrate, with the CD4+ subset outnumbering the CD8+ subset. [2], [3], [4] and [5], [42], [43] As with most cutaneous lymphoid infiltrates, macrophages and histiocytic dendritic cells are admixed. Lymphomatoid papulosis lesions have two distinctive immunophenotypic features: (1) the type A large atypical cells are CD25+, CD30+, and sometimes CD15+, analogous to the Reed-Sternberg cells of Hodgkin's disease; and (2) there is often deficiency of one or more T cell antigens, analogous to the phenotypic abnormalities seen in many T cell lymphomas. Type A lymphomatoid papulosis and cutaneous CD30+ large cell lymphomas generally express a T_H2 cytokine pattern (interleukins 4, 5, and 10). [44] Molecular biologic studies of T cell receptor gene rearrangements show that most cases of lymphomatoid papulosis are dominant clonal T cell disorders. [2], [3], [4] and [5], [43] /SUP>, [44], [45] and [46] Furthermore, studies of patients with lymphomatoid papulosis and one or more of the lymphomas with which it is associated have generally shown the same dominant clonal T cell receptor gene rearrangement in each disease in individual cases. [2], [47], [48] This indicates that these clinicopathologically distinct diseases all arise as subclones of a common precursor T cell clone. The exact mechanism by which these subclones develop is currently under investigation. Existing evidence suggests somatic mutations in genes that confer a proliferation or survival advantage, such as the transforming growth factor ß type II receptor or p53. [49], [50] Lymph node–based CD30+ large cell lymphomas often contain a t(2;5)(p23;q35) translocation that results in inappropriate expression of the anaplastic lymphoma kinase gene, which is believed to be involved in their pathogenesis. This translocation has been seen in some pediatric cases with primary skin involvement. [51] In contrast, CD30+ primary skin diseases in adults rarely exhibit this translocation, suggesting that usually they arise by a different mechanism. [52]

The characteristic clinicopathologic and immunophenotypic features of lymphomatoid papulosis allow its differentiation from classic cases of mycosis fungoides. The latter presents as persistent patches or plaques containing a superficial, bandlike, atypical lymphoid infiltrate with Pautrier's microabscesses and few or no CD30+ cells. As noted earlier in this chapter, lymphomatoid papulosis exists on a continuum with CD30+ large cell lymphoma. As a consequence, there are causes that are difficult to classify because they have the clinical features of lymphomatoid papulosis and the histopathologic features of large cell lymphoma, or vice versa. The exact designation given to such cases is less important than the recognition that they belong to this disease spectrum. There is also debate as to whether lymphomatoid papulosis is part of the pityriasis lichenoides disease spectrum. [2], [41] Some observers allow a few atypical lymphoid cells in lesions that they diagnose as PLEVA. Others regard such cases as lymphomatoid papulosis. In favor of a connection between these diseases are the following: (1) individuals have been reported who exhibited lesions of PLEVA and lymphomatoid papulosis either concurrently or serially; (2) dominant T cell clonality has been documented in many cases of PLEVA and pityriasis lichenoides chronica, as well as lymphomatoid papulosis; and (3) some cases of both PLEVA and pityriasis lichenoides chronica have been associated with mycosis fungoides. [41], [45], [46], [53], [54], [55] and [56]

There are certain other uncommon cutaneous lymphoproliferative disorders with the capacity for spontaneous resolution that might be regarded as part of the lymphomatoid papulosis–lymphoma spectrum. These include *primary cutaneous Hodgkin's disease* and *regressing atypical histiocytosis*. Patients with the very rare primary cutaneous Hodgkin's disease disorder develop one or a few slowly evolving cutaneous nodules that may ulcerate or self-heal and bear a close histopathologic and immunophenotypic resemblance to Hodgkin's disease. [57] However, in contrast to the rarely occurring secondary cutaneous involvement by classic Hodgkin's disease, systemic workup is negative. [58] Cutaneous recurrence or progression to nodal involvement is possible, even years after radiation or chemotherapy. Regressing atypical histiocytosis presents with skin nodules that may spontaneously regress and exhibit an extensive dermal infiltrate of large atypical CD30+ lymphoid cells with pleomorphic nuclei, prominent nucleoli, and abundant cytoplasm. [59] These cases are now recognized to be CD30+ anaplastic large cell lymphomas, and the old terminology should be dropped.

Lymphomatoid panniculitis is a diagnosis that has been given to rare patients who develop tender, spontaneously regressing nodules, centered in the subcutis, with a septal panniculitis containing large atypical lymphoid cells morphologically similar to those in classic lymphomatoid papulosis. Lymphocytic vasculitis may also be present. At least one case has been associated with systemic lupus erythematosus. Although disease may be persistent, progression to systemic lymphoma has not been observed within a few years, and lesions can be suppressed with small doses of prednisone. The differential diagnosis includes lupus panniculitis, subcutaneous panniculitic T cell lymphoma, anaplastic large cell lymphoma, and angiocentric T cell lymphoma. Some of these lymphomas have been preceded for several years by spontaneously resolving subcutaneous nodules, suggesting that a condition analogous to cutaneous lymphomatoid papulosis exists in the subcutis. Recognizing that not all variants of the lymphomatoid papulosis spectrum exhibit the same clinicopathologic features, Macaulay, who first described the condition, proposed that the term *rhythmic paradoxical eruptions* be used as an umbrella designation for the whole array of idiopathic, spontaneously regressing atypical cutaneous lymphoid infiltrates. [60]

Even when unusual variants are excluded, the clinical course of classic lymphomatoid papulosis is highly variable. Some cases resolve without treatment in a few months. Others may persist for decades, sometimes marked by periods of complete remission lasting for years. Evolution to more aggressive lymphoproliferative disorders, such as CD30+ large cell lymphoma, is heralded by the development of larger lesions that are more persistent and contain sheets of large atypical cells. As noted earlier, mycosis fungoides and Hodgkin's disease may also develop. Because an association has rarely been observed between PLEVA and oral contraceptives, a trial discontinuation of such drugs may be warranted. Initial treatment with tetracycline or erythromycin is sometimes effective, presumably related to their anti-inflammatory properties. An effective treatment for this spectrum of diseases is low-dose oral methotrexate. [61] The vast majority of cases respond to weekly doses of about 10 to 25 mg within 1 month, including those classified as primary cutaneous CD30+ large cell lymphoma. This can spare such patients treatment with multiagent chemotherapy, although the latter may be required for those failing less intensive treatments. Other therapies for lymphomatoid papulosis have included PUVA, sulfones, retinoids, topical carmustine, topical and systemic glucocorticoids, and intralesional and systemic interferon-a2b. [43] Localized lesions may be managed effectively with radiation therapy.

ANGIOIMMUNOBLASTIC LYMPHADENOPATHY WITH DYSPROTEINEMIA

AILD, also known as *immunoblastic lymphadenopathy,* is a lymphoproliferative disorder that typically presents in the elderly as lymphadenopathy, hepatosplenomegaly, hypergammaglobulinemia, and anemia. [1], [2] and [3], [62], [63] Skin lesions arise in nearly half of the cases and often precede other clinical manifestations. They generally appear as a diffuse macular and papular eruption, although some of these are suspected drug reactions. Less often, petechiae, plaques, or nodules may develop. The clinical course may be chronic and marked by remissions, or patients may die acutely, often secondary to sepsis. AILD is considered to be a lymphoma in its own right by some. [1], [2] Progression to high-grade lymphoma occurs, usually diffuse large cell immunoblastic, of T cell or, less often, B cell type. [1], [2] AILD and AILD-like peripheral T cell lymphomas constitute the two ends of a lymphoproliferative disease continuum. Serial molecular biologic and karyotypic studies are consistent with the view that progression along the AILD-lymphoma spectrum involves the emergence of a dominant lymphoid clone from a polyclonal or oligoclonal background. [64], [65] Dominant clonal T cell receptor gene rearrangements are present in many cases of AILD and in all cases of AILD-like peripheral T cell lymphoma. [64], [65] The presence of clonal Epstein-Barr virus (EBV) genomes in many AILD-associated lymphomas suggests that this virus may play a role in the development of AILD-related lymphomas analogous to its role in other immunocompromised states. [66] Some AILD-associated lymphomas have shown increased levels of cytokines such as tumor necrosis factor a, lymphotoxin, and interleukins 1ß and 6. [67] These factors may contribute to the immune dysfunction seen in the AILD disease spectrum and may facilitate the proliferation of EBV-infected cells. Minimal levels of recombinase-activating genes 1 and 2 in most cases suggest that AILD is a disorder of genotypically mature lymphoid cells, that is, ones that have already completed antigen receptor gene rearrangement. [68]

The histopathologic features of cutaneous AILD lesions are generally nondiagnostic but may be suggestive in the appropriate clinical setting. The macular and papular lesions contain a perivascular and periadnexal dermal lymphocytic infiltrate mixed with plasma cells and occasional large immunoblasts. Vascular proliferation, lymphocytic vasculitis, and erythrocyte extravasation may be present. Occasionally, the infiltrate is composed primarily of plasma cells, plasmacytoid cells, and immunoblasts. Plaques and nodules may exhibit features ranging from nonnecrotizing lymphohistiocytic inflammation to dense, diffuse atypical lymphoid infiltrates, including those diagnostic of immunoblastic large cell lymphoma. Differential diagnosis may be challenging because of the nonspecific nature of many AILD lesions. Drug eruptions need to be excluded. AILD is differentiated from mycosis fungoides by its systemic manifestations and the absence of cerebriform T cells exhibiting epidermotropism. Fully evolved AILD-associated lymphomas involving the skin are uncommon but, when present, resemble other skin lymphomas of similar histopathologic type.

LYMPHOMATOID GRANULOMATOSIS

Lymphomatoid granulomatosis is a pulmonary lymphoproliferative disorder with systemic manifestations including cutaneous involvement. [1], [2], [69], [70] and [71] Skin lesions appear first in more than 10 percent of patients. Another 33 to 50 percent of patients develop skin involvement following the onset of pulmonary disease. The skin lesions are localized or generalized, sometimes symmetric, red to purple maculopapules, dermal nodules, or subcutaneous nodules. They may be pruritic or tender and resolve spontaneously, persist unchanged, or ulcerate. Skin involvement heralds a more aggressive clinical course, with a median survival time of only about 1 year.

Many patients with lymphomatoid granulomatosis die with overt systemic lymphoma because, in at least some cases, this disease appears to be the clinically benign end of a spectrum of angiocentric lymphoproliferative disorders that has angiocentric lymphoma as its malignant extreme. Some observers refer to this continuum as *angiocentric immunoproliferative lesions*. [1], [2], [72] Other observers suspect that past reports of lymphomatoid granulomatosis included a heterogeneous collection of pulmonary T cell lymphomas, B cell lymphomas, Hodgkin's disease, AILD, and the like. [73] Some overt angiocentric lymphomas arising in the setting of lymphomatoid granulomatosis have exhibited T cell differentiation and clonal T cell receptor gene rearrangements. [1], [2], [72] Other cases of lymphomatoid granulomatosis have shown evidence of dominant B cell clonality and EBV in atypical B cells within a T cell–predominant background. [74] This suggests that at least some cases of lymphomatoid granulomatosis may be analogous to so-called T cell–rich B cell lymphomas, and that the T cells may mount an angiodestructive response to EBV-infected clonal B cells. Angiocentric immunoproliferative lesions involving the midface, nasal cavity, paranasal sinuses, and/or upper aerodigestive tract have been referred to in the past as *lethal midline granuloma* or *polymorphic reticulosis*. [1], [2], [72]

Cutaneous lesions of lymphomatoid granulomatosis typically exhibit an angiocentric, polymorphous infiltrate of small lymphocytes, plasma cells, histiocytes, immunoblasts, and small and large atypical lymphoid cells. Sometimes eosinophils are admixed. T cells predominate. The blood vessels are surrounded and their walls are invaded by the infiltrate, which is often heaviest in the deep dermis or subcutis. There is usually sparing of the epidermis and adnexa, and Pautrier's microabscesses are absent. These features distinguish lymphomatoid granulomatosis from mycosis fungoides, which generally contains an epidermotropic infiltrate concentrated in the upper dermis. Lymphomatoid papulosis also exhibits a top-heavy, cutaneous lymphoid infiltrate with a distinct clinical presentation, including the absence of extracutaneous disease. Lymphomatoid granulomatosis is differentiated from Wegener's granulomatosis and allergic granulomatosis (Churg-Strauss disease) by the presence of leukocytoclastic vasculitis and well-formed granulomas in the latter two conditions, as well as by associated clinical findings. Cases of lymphomatoid granulomatosis that have evolved to overt angiocentric lymphoma show angiocentricity, angioinvasion, and necrosis combined with the features of diffuse mixed cell or large cell lymphoma.

LYMPHOCYTIC INFILTRATION OF THE SKIN

LIS, which was first described by Jessner and Kanof, [75] presents as one or more erythematous plaques or nodules, generally localized to only one or a few sites on the face, neck, upper trunk, or arms. [76], [77] Pustules, pruritus, and epidermal alterations are absent. Photoexacerbation may occur in a minority of patients according to some observers. The vast majority of cases occur in adults with a roughly equal gender ratio. LIS may respond favorably to topical or intralesional glucocorticoids, antimalarials, or thalidomide; however, a persistent, indurated variant has been described that may require systemic glucocorticoid therapy to achieve remission. The etiology of LIS is unknown. Some regard it as a distinct disease, whereas others consider it to be a variant of lupus erythematosus or, less commonly, polymorphous light eruption, CLH, or lymphocytic lymphoma. The course is chronic and may show periods of spontaneous remission and eventual resolution. Immunologic investigations have

shown decreased natural killer cell function as well as elevated circulating immune complexes, the level of which were reported to parallel disease activity. [78] Skin lesions known as *arcuate dermal erythema* may arise in female carriers of chronic granulomatous disease. These lesions resemble LIS clinically and microscopically.

Histopathologic examination reveals a superficial and deep, perivascular and variably periadnexal infiltrate of small mature lymphocytes, often with a minor admixture of histiocytes, plasmacytoid monocytes, and plasma cells. Lymphoid follicles and eosinophils are absent. The epidermis is unremarkable. Direct immunofluorescence is negative or nonspecific. Immunohistologic studies have demonstrated a predominantly HLA-DR–Leu-8+ T cell infiltrate with some B cells and histiocytes admixed. In contrast, most of the T cells in discoid lupus are HLA-DR+ Leu-8–. [79], [80] Initial studies indicate that the infiltrate is polyclonal. [2]

The differential diagnosis of LIS includes discoid lupus erythematosus, polymorphous light eruption, CLH, lymphocytic lymphoma and leukemia, deep figurate erythemas such as erythema chronicum migrans, and reticular erythematous mucinosis. Discoid lupus generally exhibits epidermal changes, an interface inflammatory component, and a lupus band on direct immunofluorescence. The tumid variant of discoid lupus is typified by abundant dermal mucin and subtle alterations at the dermal–epidermal interface. These changes are not seen in LIS. Antinuclear antibody panel and erythrocyte sedimentation rate are also normal. Polymorphous light eruption exhibits papillary dermal edema, which is absent in LIS. CLH contains nodular or diffuse, dermal lymphoid infiltrates that are much denser than the predominantly perivascular infiltrate of LIS. Furthermore, LIS lacks reactive B cell follicles. Well-differentiated or small lymphocytic lymphoma/leukemia is usually a monoclonal B cell process, and there is a peripheral lymphocytosis in the leukemic form of the disease. These findings are absent in LIS. Erythema chronicum migrans and some cases of CLH exhibit serologic evidence of active infection with *B. burgdorferi,* whereas this is rarely seen in LIS. Reticulated erythematous mucinosis has a reticulated clinical appearance, favors the trunk rather than the head and neck, and shows bipolar fibroblasts. These are not features of LIS.

REFERENCES

Langerhans cell histiocytosis (LCH), previously called histiocytosis X, is a disease of unknown cause characterized by the proliferation of a distinct cell type that is S-100 and CD1a positive and contains cytoplasmic Langerhans granules (LG). [1] LCH includes four main clinical forms: Letterer-Siwe disease (LSD), Hand-Schüller-Christian disease (HSCD), eosinophilic granuloma, and Hashimoto-Pritzker disease (HPD). [1], [2] and [3]

In 1953, Lichtenstein [4] integrated the three previously described clinical conditions LSD, HSCD, and eosinophilic granuloma into a single nosologic entity called histiocytosis X (HX); in 1978 Hashimoto and Pritzker [5] described self-healing reticulohistiocytosis, a condition characterized by nodular, self-healing lesions restricted to the skin. Basset and Nezelof [6] demonstrated that the proliferating cells present in the lesions of these conditions share the ultrastructural characteristics of Langerhans cells. Thus, these conditions are now designated as Langerhans cell histiocytosis. [7]

CLINICAL FINDINGS

Letterer-Siwe Disease

LSD is the acute, disseminated multisystemic form of LCH. LSD begins within the first 6 months of life in one-third of cases and before 2 years of age in most of the others. [1], [3] More than 20 congenital cases [3] and approximately 30 adult cases have been documented. [3], [8]

Cutaneous manifestations are very common in LSD. The cutaneous lesions are characteristic and may represent the earliest sign of the disease. The typical lesion is a small translucent papule, 1 to 2 mm in diameter, slightly raised, rose-yellow in color (Fig. 160-1A and Fig. 160-1B), and usually located on the trunk (Fig. 160-1A and Fig. 160-1C) and scalp (Fig. 160-1B). The lesions frequently show scaling (Fig. 160-1A) and may become crusted and ulcerate (Fig. 160-1C and Fig. 160-1D). Vesicles and pustules may occur, simulating eczema, miliaria, scabies, and varicella. Purpura represents a poor prognostic sign. [1], [3]

FIGURE 160-1 Langerhans cell histiocytosis, Letterer-Siwe disease. *A.* Abdominal area of infant with multiple yellowish erythematous papules covered by scale or crust. *B.* Seborrheic papules on the scalp mimicking seborrheic dermatitis. *C.* Infant with multiple ulcerated skin lesions on the trunk. *D.* Severe Letterer-Siwe disease with confluent erosive and crusted lesions forming ulcers; distension of abdomen reflects hepatosplenomegaly.

Cutaneous lesions appear in successive crops. The lesions tend to merge on the scalp, leading to a seborrheic dermatitis-like appearance, and on the folds (retroauricular, axillary, and genital), mimicking intertrigo. [1], [3], [9] In LSD, mucous membrane involvement, consisting of erosions and ulcerations, is rare. Nail changes including paronychia, nail

fold destruction, onycholysis, subungual hyperkeratosis, and purpuric striae of the nail bed (Fig. 160-2) are considered an unfavorable prognostic sign. Cutaneous manifestations in elderly patients (Fig. 160-3) are similar to those seen in LSD of early childhood. [3], [8]

FIGURE 160-2 Letterer-Siwe disease. All nails, save one, show purpuric striae of the nail bed. Nail changes are considered an unfavorable prognostic sign.

FIGURE 160-3 Letterer-Siwe disease in an 81-year-old woman. The diffuse papuloscaling and papulocrusted lesions on the trunk are similar to those seen in early childhood. Systemic involvement consists of hepatosplenomegaly and pulmonary lesions. (*From Caputo et al.,* [8] *with permission.*)

Systemic manifestations of LSD are variable. Pulmonary involvement can be detected in more than half of affected children. [1], [3] Functional symptoms consist of dyspnea, cyanosis, and pneumothorax. The lungs may show a classic "honeycomb" appearance (Fig. 160-4). Pulmonary lesions can be asymptomatic, but can also cause death. [10], [11] Hepatosplenomegaly is never the initial sign of the disease but is a frequent complication and is a prognostically unfavorable sign, particularly when accompanied by jaundice. [1], [3], [10], [11] Lymphadenopathy is rarely prominent but has been noted in 25 to 75 percent of fatal cases. [10], [11] In the later stages of the disease, bone lesions occur in about 60 percent of patients; [1], [2], [11] in addition, flat bones, vertebral bones, and cranial bones are more frequently involved. Osteolytic lesions, either asymptomatic or accompanied by pain and functional impairment, are generally multiple and appear gradually. Their presence is more frequent in cases with a favorable course. Teeth may be lost prematurely. Chronic otitis media is frequent. [3] Hemopoietic involvement is rare. [1], [2] and [3] When thrombocytopenia and severe anemia occur, death is almost certain. [2] Bone marrow involvement is characterized by the presence of numerous histiocytic cells. Fever is frequently present.

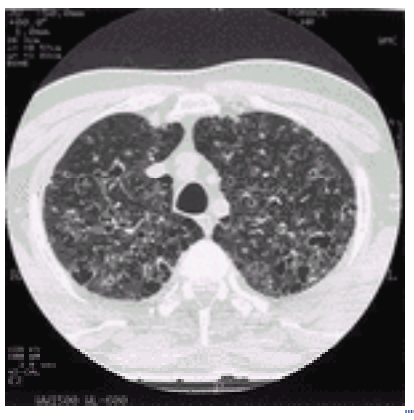

FIGURE 160-4 Letterer-Siwe disease. Bilateral involvement of lungs characterized by multiple cystic cavities (honeycomb appearance). (*Courtesy of E. De Juli, MD.*)

Hand-Schüller-Christian Disease

HSCD is the chronic, progressive, multifocal form of LCH. HSCD begins between the second and sixth year of life in 70 percent of cases and before the age of 30 years in 91 percent of cases. [1] The disorder is characterized by the four findings: bone lesions, diabetes insipidus, exophthalmos, and mucocutaneous lesions. [1], [2] and [3], [10], [11] Rarely are all four manifestations seen together in the same patient. [1]

Although the initial manifestations of HSCD most frequently are diabetes insipidus, otitis media, or skin lesions, [10] bone lesions are the most frequent manifestations of HSCD (80 percent of cases). They preferentially involve the calvaria, especially in the temporoparietal region, where the infiltrates lead to limited osteolytic foci that merge to typical “map” lesions (Fig. 160-5). Because osteolysis of the lower maxillary bones is also frequent, on x-ray, the teeth appear to be floating in the mouth. [3], [11] Bone lesions of the mastoidal region, which are usually painful but not tender, [2] may cause otitis media.

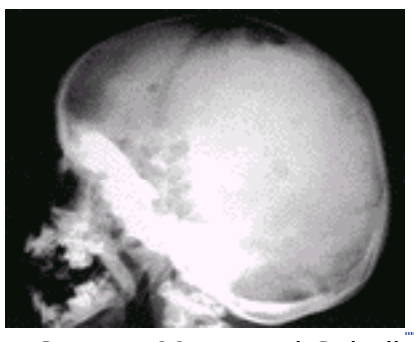

FIGURE 160-5 Hand-Schüller-Christian disease. X-ray of the skull shows well-circumscribed osteolytic areas with a typical “map” appearance.

Diabetes insipidus is present in more than 50 percent of cases and is easily controlled by vasopressin. It occurs more often in children and in patients with involvement of the skull and the orbits. [1], [3] Diabetes insipidus is considered a prognostically favorable symptom. Exophthalmos [1], [2] and [3] usually appears later; it is present in 10 to 30 percent of cases and may be unilateral or bilateral. Because it is infrequent, it has little diagnostic significance.

Mucocutaneous lesions occur in about one-third of the cases. In the early stage, cutaneous lesions are papular with the same morphologic characteristics as those observed in LSD. In the later phases, skin lesions are frequently grouped on the medial aspect of the chest (Fig. 160-6), back, and temporoparietal regions, [1], [10], [11] and they may become xanthomatous. [8] Occasionally, the lesions merge into plaques. The involvement of the large body folds may mimic intertrigo, while on the scalp the lesions may look like seborrheic dermatitis (Fig. 160-6) or folliculitis. Mucous membrane lesions are commonly noduloulcerative [3], [10], [11] and mainly involve the gingiva (Fig. 160-7) and the vulva.

FIGURE 160-6 Hand-Schüller-Christian disease. The papuloscaling and papulocrusted lesions show a typical distribution on the trunk and the scalp. The involvement of the face in the patient is unusual.

FIGURE 160-7 Hand-Schüller-Christian disease. Infiltrating lesions of the gingival tissue, frequently leading to loss of teeth.

Pulmonary infiltrates can be found in fewer than 20 percent of HSCD cases, and hepatomegaly and lymphadenopathy are rare. [1], [2], [3], [11]

Eosinophilic Granuloma

Eosinophilic granuloma is the localized, benign form of LCH. It occurs between the ages of 5 and 30 years and is more

common in males. [1], [3] The granulomatous lesions affect the bones in the following decreasing order of frequency: [12], [13] cranial vault, ribs, vertebral column, pelvis, scapulae, and long bones (Fig. 160-8). The onset is insidious. The osseous lesion is frequently single and may go undetected until spontaneous fracture and/or otitis media occur. When the lesions become symptomatic, there is localized pain, tenderness, and soft-tissue swelling.

FIGURE 160-8 Eosinophilic granuloma. The bones of the elbow reveal well-defined osteolytic lesions. These lesions manifest by swelling of soft tissue and localized pain.

Noduloulcerative mucocutaneous lesions [1], [3], [14], [15] are rare and preferentially involve the mucous membranes and the perigenital, perioral, or perianal regions (Fig. 160-9).

FIGURE 160-9 Eosinophilic granuloma. Noduloulcerative lesions in the vulva and on the perianal area. These lesions, although rare, are as unique as the bone lesions.

Hashimoto-Pritzker Disease

HPD, or congenital self-healing reticulohistiocytosis, [18] is the benign self-healing variant of LCH. HPD is usually present at birth or may appear during the first few days of life. [16], [17], [18], [19], [20] and [21] Typically, the disease is characterized by the eruption of multiple disseminated, elevated, firm, red-brown nodules (Fig. 160-10). [17] These lesions can grow in size and number in the first few weeks of life, and some may become quite large; they then form brown crusts, which are shed and occasionally leave whitish atrophic scars. In a few cases, solitary lesions have been reported (Fig. 160-11). [19], [22] The absence of mucous membrane lesions is a key feature of HPD. Systemic signs are usually absent except for occasional hepatomegaly. [18] No significant hematologic abnormalities have been observed. Physical and mental development is normal. The salient features of HPD are multiple or solitary papulonodular lesions, sparing of mucous membranes, absence of systemic involvement, and rapid spontaneous regression.

FIGURE 160-10 Hashimoto-Pritzker disease. Multiple, disseminated, elevated, firm red-brown or dark red nodules (multiple form) present at birth. *(From Bonifazi et al.,* [17] *with permission.)*

FIGURE 160-11 Hashimoto-Pritzker disease. Solitary nodule on the temple. The central crust is an expression of rapid spontaneous regression.

INCIDENCE

The annual incidence of LCH is estimated at 0.5 per 100,000 children in the United States [2], [8] and at 1 per 2 million children worldwide. [8] The male to female ratio is 1.8:1. [1]

COURSE AND PROGNOSIS

LCH presents a very wide clinical spectrum and runs a variable course; manifestations range from isolated self-healing lesions to generalized and fatal destructive disease. Classically, the course of LSD is rapid and fatal; for HSCD, it is protracted but progressive (and fatal in about 50 percent of untreated patients); for eosinophilic granuloma, it is chronic and benign; and for HPD, it is self-healing. [1] The most frequent causes of death are pulmonary and bone marrow involvement and intercurrent infections. [1], [9], [10], [11]

Single-system disease is usually associated with a good prognosis, whereas multisystem disease may be fatal. [9], [23], [24] and [25] However, some patients with LSD have been reported to recover spontaneously. [2]

The appearance of xanthomatous lesions in the course of LCH in children [9] and adults [3] is considered by some authors to be an expression of a shift from a disseminated subacute form (LSD) into a progressive chronic form (HSCD); [3] others believe that these lesions may represent a distinct clinical entity independent of the primary disease. [1]

The synchronous occurrence of HX with leukemias [26], [27], [28] and [29] may be interpreted as additional clinical evidence in favor of a common origin of monocytes and Langerhans cells.

Intercurrent infections (mainly candidiasis) are frequently observed in LSD. [1], [3], [9] Several staging systems have been proposed on the basis of prognostic factors derived from retrospective case studies. The age of patients at diagnosis, [23], [30] the number of organs involved, [24] and organ dysfunction [25] are the three main parameters on which the evaluation of prognosis is based. [2]

It is impossible to attribute prognostic significance to any single symptom, but jaundice, thrombocytopenia, anemia, hepatic failure, and nail involvement are considered unfavorable prognostic signs. [1], [24] A favorable prognosis can be ascribed to a small number of lesions, nodular lesions (as in HPD), their prompt resolution, and the involvement of only one organ system (skin or bones). [1], [24] Multisystem LCH in adults carries a better prognosis than in children. [3]

LABORATORY FINDINGS

The laboratory evaluation of a patient with LCH should include complete blood count, platelet count, prothrombin time, partial thromboplastin time, liver function tests, urinalysis, serum protein electrophoresis, T and B cell counts, T cell subset analysis for immunologic evaluation, chest x-ray, complete skeletal radiographic survey, and biopsy of the most accessible lesion. [2] In some cases, these examinations are also required: abdominal sonography, computed tomography of the head, pulmonary function tests, and bone marrow aspirate.

Lahey's concept of organ dysfunction [30], [31] may be evaluated as follows. Liver dysfunction is considered present if there is hypoproteinemia (<5.5 mg/dL total protein and/or <2.5 g/dL of albumin), or edema, or ascites, and/or hyperbilirubinemia (total serum bilirubin >1.5 mg/dL). Lung dysfunction is considered present if there is tachypnea and/or dyspnea, cyanosis, pneumothorax, or pleural effusion attributable to the disease rather than to infection. The presence of radiographic densities alone is not interpreted as evidence of dysfunction. Hemopoietic dysfunction is considered present if there is anemia (<10 g/dL hemoglobin not due to iron deficiency or superimposed infection), leukopenia (white blood count <4000/µL), or thrombocytopenia (<100,000 platelets/µL). The presence of excessive numbers of histiocytes in the marrow aspirate per se is not considered as evidence of dysfunction.

HISTOPATHOLOGIC, IMMUNOHISTOCHEMICAL, AND ULTRASTRUCTURAL FINDINGS

The unifying aspect of the entire spectrum of LCH lies in its pathologic features. The linking histologic element of the different lesions is the typical “LCH cell,” a cell easily identified and differentiated from the nonspecific elements of the infiltrate by its size and configuration. This cell is approximately four to five times larger than small lymphocytes; has an irregular and vesiculated nucleus; is often reniform (kidney shaped); and has abundant, slightly eosinophilic cytoplasm (Fig 160-12). [1], [2]

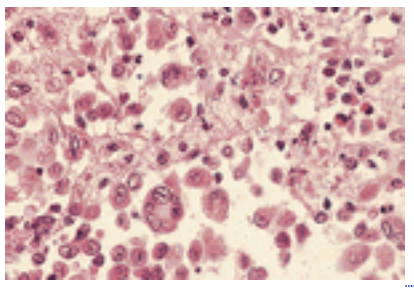

FIGURE 160-12 Langerhans cell histiocytosis. Proliferative reaction. A pure LCH cell infiltrate invades and destroys the epidermis.

The histologic patterns observed in LCH are of three types: [1], [3] proliferative, granulomatous, and xanthomatous. A proliferative reaction is seen in early papules. It consists of an extensive LCH cell infiltration in the upper dermis close to the epidermis, which soon becomes compressed, thinned, invaded, and even destroyed (Fig. 160-12). In the upper dermis, LCH cells are typically separated by edema, whereas in the lower dermis their cell membranes coalesce. In the deep dermis, the infiltrate is often localized around vessels and may invade the hypodermis. A few mitotic figures are occasionally found. [3] Cytologic examination of LCH cells is easily performed by scraping early papules. [1] The granulomatous reaction (Fig. 160-13) consists of an aggregation of LCH cells with some multinucleated histiocytes and a varying number of eosinophils, generally in clusters. Neutrophils, lymphocytes, and plasma cells may also be present in the infiltrate. This type of reaction is seen in the chronic stages of the disease. The xanthomatous reaction is encountered mainly in HSCD and consists of numerous foam cells intermingled with LCH cells and eosinophils (Fig. 160-14). Multinucleated giant cells are frequently seen. They are mainly of the foreign-body type but occasionally may have the appearance of Touton giant cells. Lipid accumulation is considered to be a late secondary phenomenon. [1], [3]

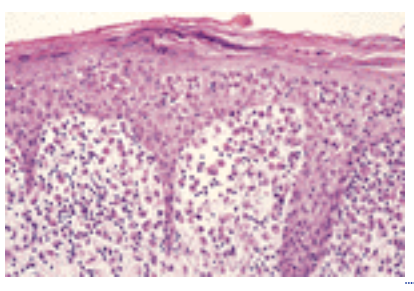

FIGURE 160-13 Langerhans cell histiocytosis. The granulomatous reaction consists of an aggregation of LCH cells with some multinucleated histiocytes, as well as with varying numbers of eosinophils, neutrophils, lymphocytes, and plasma cells. This type of reaction is seen in the chronic stage of the disease.

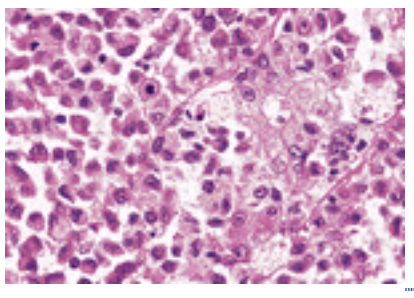

FIGURE 160-14 Langerhans cell histiocytosis. The xanthomatous reaction consists of numerous foam cells intermingled with LCH cells and is encountered mainly in Hand-Schüller-Christian disease. Mitotic figures are occasionally seen.

These different types of histologic reactions may be found simultaneously in the same patient, [1] and the visceral lesions present in LCH show the same three types of reactions observed in the skin. [2], [3]

In HPD, [16], [17], [18], [19], [20], [21] and [22] the infiltrate appears to consist mostly of large multinucleated giant cells intermingled with typical LCH cells. The cytoplasm of the giant cells is either acidophilic or has a “ground glass” appearance. It is usually localized in the mid- and deep dermis; occasionally, the epidermis may be infiltrated and ulcerated.

The LCH cells show the immunophenotype of normal Langerhans cells, expressing high levels of major histocompatibility complex (MHC) class II molecules, CD1a complex, CD4 molecules and S-100 protein; however, in contrast to Langerhans cells, LCH cells also express several macrophage-associated markers including CD11c, CDW32, and CD1, [3], [32], [33] and [34] Moreover, heterogeneity with respect to the expression of various cell markers has been reported. [33], [34] There are few reliable markers capable of distinguishing LCH cells from Langerhans cells of normal skin. Three markers, placental alkaline phosphatase (PLAP), peanut agglutinin (PNA), and interferon-gamma receptor (IFN-(R), are especially valuable in differentiating normal Langerhans cells from LCH cells. [35]

Electron microscopic studies show that approximately 50 percent of the histiocytes of LCH contain LG (Fig. 160-15). [36], [37]

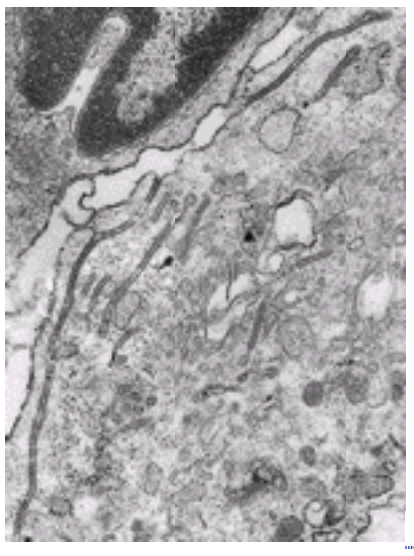

FIGURE 160-15 Langerhans cell histiocytosis. Electron microscopy. A LCH cell containing a large number of very long Langerhans granules.

In HPD, LCH cells are less numerous (10 to 25 percent of tumor cells) and may contain dense and regularly laminated bodies. [3]

ETIOPATHOGENESIS

The etiopathogenesis of LCH remains a mystery despite numerous investigative efforts. A reactive or neoplastic nature of LCH cells is debated. These features substantiate the reactive hypothesis: (1) LCH cells are highly differentiated; (2) histologically the granulomatous lesions resemble those seen in infections or foreign-body reactions, and (3) the possibility of spontaneous regression.

Favara [38] suggested these pathogenic steps: (1) viruses induce activation of histiocytes; (2) immunologic mechanisms produce the pathologic LC phenotype; and (3) a cytokine-mediated storm results in HX lesions.

Many viruses (human herpesvirus-6, cytomegalovirus, adenovirus, parvovirus) were suspected to play an etiologic role, but none have been proved to be responsible for the disease. [39]

The following observations substantiate the clonal neoplastic origin of LHC: [40], [41], [42] and [43] (1) bone marrow derivation and clonality of LCH cells, [42], [43] finding of familial cases of LCH, [44] chromosomal instability with an abnormality on chromosome 7, [45] and of p53 protein in LCH; [46] and (2) concurrence of LCH and a myelodysplastic marrow. [27], [28] and [29]

Two possible explanations have been proposed for the association of LCH and myelodysplasia. [43] The first is that the marrow dysplastic features are secondary to the infiltration of the marrow by LCH cells induced by cytokines and do not represent elements of a “true” myelodysplastic syndrome. A second possibility is that the abnormal marrow cells are related to the clonal LCH cells and are part of the disease process; that is, myelodysplastic cells could be arising from the same clonal cell (an anomalous pluripotent dendritic [Stein] cell line). This possibility raised the issue of whether LCH could be considered a “myeloid dendritic Stein cell disorder.” These findings suggest a genetic predisposition in LCH and stimulate the search for potential candidate genes in LCH.

DIFFERENTIAL DIAGNOSIS [47] (See also Chap. 161)

Skin lesions of disseminated LCH are similar to those of seborrheic dermatitis, moniliasis, and miliaria, but the presence of purpura suggests the diagnosis of LCH. When a condition thought to be banal, such as seborrheic dermatitis, does not respond to proper therapy, LCH should be suspected. The diagnosis can be confirmed promptly by a cytologic examination of the scrapings of an early papule.

In Darier-White disease (see Chap. 54), the lesions appear between ages 8 and 15 years, and the papules are hyperkeratotic and may involve the extremities. Lichen nitidus (see Chap. 50) is differentiated from LCH by the presence of shiny, skin-colored, nonscaling papules and the Koebner phenomenon, which does not occur in LCH. Chronic and persistent xanthomatous lesions of LCH must be differentiated from urticaria pigmentosa (see Chap. 163) and non-Langerhans cell histiocytosis (see Chap. 161). In urticaria pigmentosa, the lesions are macular, papular, or nodular, and wheal immediately after they have been rubbed.

Benign cephalic histiocytosis is characterized by flat dome-shaped nonscaling papules that preferentially involve the head. Here, the scalp, trunk, mucous membranes, and viscera are spared.

Histopathologic examination is necessary to differentiate some lesions of juvenile xanthogranuloma and xanthoma disseminatum from the xanthomatous lesions of LCH; in juvenile xanthogranuloma, bone lesions are not present, and in xanthoma disseminatum, cutaneous xanthomas are distributed symmetrically and tend to coalesce.

In sinus histiocytosis with massive lymphadenopathy, cervical lymphadenopathy is a prominent feature and is usually accompanied by fever, leukocytosis with neutrophilia, and polyclonal hypergammaglobulinemia. Papules of generalized eruptive histiocytosis are differentiated from those of LCH by absence of scales and crusts, a red-brown or red-blue color, and symmetric distribution.

The presence of violaceous plaques or nodules with patulous follicular ostia on the face distinguishes granuloma faciale

from eosinophilic granuloma. HPD must mainly be differentiated from nodular forms of LCH such as eosinophilic granuloma, juvenile xanthogranuloma, generalized eruptive histiocytosis, and urticaria pigmentosa. The distinction of HPD from nodular lesions present in the disseminated form of LCH may be difficult because of the histologic, ultrastructural, and immunologic similarities. HPD is distinctive in that the skin alone is involved and the lesions are rapidly self-healing. Nodular lesions of juvenile xanthogranuloma may be present at birth. However, they rapidly become yellow, do not tend to ulcerate, and heal spontaneously within several years but never in a few months. Histologically, the lesions are composed of foamy cells and multinuclear giant cells; S-100– and CD1a-positive cells are absent, and LG are not detected by electron microscopy.

Generalized eruptive histiocytosis consists of numerous, discrete papules appearing in successive crops and involving mainly the trunk and proximal limbs. The disease is rare in children and has never been seen at birth. Histologically, the infiltrate is monomorphous and the histiocytes are S-100 and CD1a negative and do not contain LG (see also Chap. 161). The absence of urtication and, histologically, of mast cells, rules out urticaria pigmentosa.

MANAGEMENT

Treatment strategies of LCH are chosen on the basis of the age of patients, extent of disease, and location of lesions (Table 160-1). [2], [19]

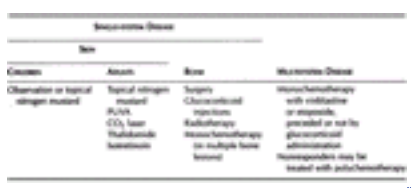

TABLE 160-1 **Treatment of Langerhans Cell Histiocytosis**

In “single-system disease” involving skin or bone, management is nonaggressive. In children with skin involvement only, observation is the best option; [9] if the lesions are persistent, topical nitrogen mustard may be an effective treatment. [48], [49] Therapy consists of application of nitrogen mustard diluted in water to a concentration of 20 mg/dL and applied daily for 5 days. Systemic glucocorticoids or antimitotic drugs are indicated in resistant cases. [9] In adults with skin involvement only, topical treatment with nitrogen mustard may be an effective treatment strategy. Significant improvement has been obtained with conventional PUVA treatment in a considerable number of cases. [50], [51] CO_2 laser therapy has been suggested in periorificial eosinophilic granuloma. [52] The use of thalidomide, at a dose of 100 mg per day for 1 month and then 50 mg per day for 1 or 2 months (see Chap. 264), may induce a remission of skin lesions. [53], [54] and [55] Usually the disease recurs after stopping treatment. The effect of thalidomide seems to be a result of its immunomodulatory and anti-inflammatory properties. In one case, a complete remission of skin lesions was obtained after oral isotretinoin therapy. The patient was treated with 1.5 mg/kg daily for a period of 8 months and remained free of recurrence and visceral involvement for 5 years. [56]

For patients with bone involvement only, surgery (excision or curettage) is the treatment of choice if the lesions are accessible. [2], [9], [57] In children, glucocorticoid injections into selected sites may avoid surgical trauma to developing teeth or the growth plate of long bones. [9] In adults, radiotherapy is indicated for involvement of vertebrae, the sella turcica, and weight-bearing bones with risk of spontaneous fracture. [2], [10] In children, radiotherapy must be reserved for cases that fail to respond to other measures in order to avoid the risk of long-term effects. [9] In the case of multiple bone lesions, monochemotherapy is suggested as with multiorgan involvement.

The management of patients with multisystem disease is controversial. [58] Currently, monochemotherapy with vinblastine or etoposide with or without glucocorticoids is probably the most suitable treatment. [59], [60] Vinblastine is given intravenously at doses of 0.1 to 0.2 mg/kg once weekly (6.5 mg/m ^{2}) for 1 to 3 months. Readministration of the alkaloid should be instituted only when new lesions appear. [1], [3], [59] Etoposide [60], [61] and [62] is administered at a dose of 200 mg/m ^{2} orally or intravenously for 3 consecutive days every 3 to 4 weeks for at least three to four courses. Etoposide gave approximately a 90 percent response rate in one study. [60] Both vinblastine and etoposide are well tolerated and cause only a few toxic effects. In case of relapses, retreatment with the same type of monochemotherapy may result in complete clearing in 60 percent of cases. [2] Finally, methylprednisolone (30 mg/kg intravenously on 3 consecutive days) may be the initial therapeutic approach.

Only nonresponders to monochemotherapy should be given multiagent regimens including vincristine, cyclophosphamide, doxorubicin, and chlorambucil. [2], [59], [63] In refractory and advanced cases of LCH, cyclosporine [64], [65] and interferon-a $_2$, [66] and 2-chlorodioxyadenosine (2CdA) [67] have been used. Allogenic bone marrow transplantation was successful in one child with a very poor prognosis. [68]

REFERENCES

Nonhistiocytoses X, [1] or non-Langerhans cell histiocytoses, are characterized by the proliferation of histiocytes that always lack Langerhans granules (LG) and are usually S-100 and CD1a negative. Nonhistiocytoses X include a series of nonaggressive, frequently self-healing diseases, affecting both children and adults. [2], [3]

JUVENILE XANTHOGRANULOMA

Definition and Historic Aspects

Juvenile xanthogranuloma (JXG) is a benign, self-healing disorder of infants, children, and, occasionally, adults, that is characterized by yellowish papulonodular lesions located in the skin and other organs in the absence of metabolic disorders and consisting of an infiltrate of histiocytes with a progressively greater degree of lipidation.

Nevoxanthoendothelioma [4] was the name first used, in 1912, to describe this disease. Because there was no evidence for a relationship to nevi or endothelial cells, in 1954, Helwig and Macknay [5] proposed the term *juvenile xanthogranuloma*. Laurb and Lain [6] reported the first case of JXG with visceral involvement in 1937; in 1949, Blank et al. [7] first described ocular involvement.

Incidence

JXG is the most common form of nonhistiocytosis X. [8] The author has observed 117 cases in the past 30 years. [3] There is no sexual or racial predilection.

Age of Onset

JXG appears within the first year of life in about 80 percent of cases; [2], [3] in 20 to 30 percent of cases, it is present at birth. [3] Approximately 25 adult cases are reported in the literature. [1], [3]

Clinical Findings

Two main clinical forms can be distinguished: a papular form and a nodular form. [2], [3] The papular form (Fig. 161-1) is characterized by numerous (up to 100), firm, hemispheric lesions, 2 to 5 mm in diameter, that are initially red-brown but quickly turn yellowish. These lesions are irregularly scattered throughout the skin but are located mainly on the upper part of the body. Mucous membrane involvement is rare. The nodular form (Fig. 161-2) is less frequent and occurs as one or a few lesions. Such nodules are generally round, 10 to 20 mm in diameter, translucent, red, tan or yellowish, and might show telangiectases on their surface. The term *giant JXH* indicates lesions larger than 2 cm. [3], [9] Mucous membrane lesions are more commonly seen in the nodular form than in the papular form. Both types of lesions are generally asymptomatic. Unusual clinical variants have been recently reported. [9] The mixed form is characterized by the simultaneous presence of both small and large nodules. The term *JXG en plaque* defines a group of JXG lesions with a tendency to coalesce into a plaque as the only expression of the disease. The subcutaneous form [3] consists of a solitary, deep-seated congenital or perinatal lesions, 1 to 2 cm in diameter, usually located on the head.

FIGURE 161-1 Juvenile xanthogranuloma. Papular form.

FIGURE 161-2 Juvenile xanthogranuloma. Nodular form.

Associations

Café au lait macules are noted in approximately 20 percent of patients with the papular form of JXG. [10] In this form, ocular involvement [11] is the most typical extracutaneous manifestation; it may precede or follow the cutaneous lesions. Such lesions are usually unilateral and may lead to hemorrhage and glaucoma. An extremely rare extracutaneous manifestation of the papular variant is central nervous system involvement. [12]

The nodular form of JXG may occasionally be related to systemic lesions of lungs, bones, kidneys, pericardium, colon, ovaries, and testes. [2], [3] Juvenile chronic myeloid leukemia has been observed in association with this variant of JXG. [3]

Histopathologic Findings

Early lesions are characterized by a monomorphous, non–lipid-containing histiocytic infiltrate [1], [2] and [3], [8] that occupies at least the upper half, and sometimes the entire thickness, of the dermis. Mature lesions (Fig. 161-3) contain foamy cells, foreign-body giant cells, and Touton giant cells, mainly distributed in the superficial dermis and on the border of the infiltrate. Lymphocytes, eosinophils, and neutrophils are variably associated. Older lesions may show fibrosis. In mature lesions, fat stains are positive. The histiocytes forming the infiltrate are CD15, CD36, CD116, and CD4 positive and S-100 negative.

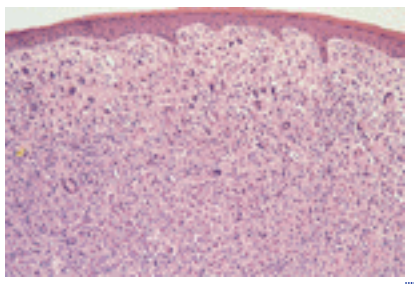

FIGURE 161-3 Juvenile xanthogranuloma. Histopathologic findings. A mature lesion containing foamy cells, foreign-body giant cells, and Touton giant cells.

Under the electron microscope, [2], [3] the histiocytes that characterize the early stage of the disease exhibit pleomorphic nuclei, are rich in pseudopods, and contain many elongated and irregular dense bodies.

Clusters of “comma-shaped bodies,” but no Langerhans cell granules (LG), can occasionally be observed electronmicroscopically. In older lesions, there is a predominance of foamy cells, the cytoplasm of which is completely filled with lipid vacuoles, cholesterol clefts, and myeloid bodies. The cells corresponding to Touton giant cells are extremely large and sometimes contain more than 10 nuclei. At their periphery, such cells are rich in lipid material, whereas in their center, mitochondria and lysosomes predominate.

Differential Diagnosis

JXG can be differentiated from nodular urticaria pigmentosa, in which lesions become urticarial immediately after rubbing and histologically have many mast cells. Benign cephalic histiocytosis (BCH) differs from JXG because its papular lesions are located only on the head and neck. Its infiltrate lacks foamy cells and multinucleated giant cells. Generalized eruptive histiocytoma (GEH) is not granulomatous, and lipidation of the cells never occurs; histiocytes are monomorphous and are rich in dense and regularly laminated bodies on electron microscopic examination. In self-healing reticulohistiocytoma, the cutaneous lesions persist for only the first few months of life and 10 to 25 percent of the cells are S-100 protein-positive and show LG. Tuberous xanthoma appears only in hyperlipidemic states. Papular xanthoma (PX) is distinguishable from JXG and xanthoma disseminatum (XD), from a histologic point of view, only because the primitive pure histiocytic phase is lacking. The nodular forms of histiocytosis X can be differentiated because of the different histologic, immunocytochemical, and ultrastructural characteristics (i.e., the presence of histiocytosis X cells, which are S-100 positive and contain LG). Single JXG may be clinically difficult to distinguish from a Spitz nevus, which is characterized by the presence of spindle and epithelial nevus cells. Histologically, however, they are distinct.

Course and Prognosis

The cutaneous lesions tend to flatten with time. Each lesion evolves separately; thus, lesions at different stages of evolution may be seen in the same patient. [1], [2] and [3] Both cutaneous and visceral lesions disappear spontaneously within 3 to 6 years. The patient's general health is not impaired, and physical and mental development is normal. Metabolic disturbances have not been identified. In the absence of associated conditions, prognosis is good.

GENERALIZED ERUPTIVE HISTIOCYTOSIS

Definition and Historic Aspects

GEH [13] is a papular, nonlipidic, self-healing histiocytosis affecting mainly adults. The first adult case of this disease was described, in 1963, by Winkelmann and Muller [13]; in 1987, Caputo et al. [14] reported a series of pediatric cases.

Incidence

GEH is an extremely rare disease. Approximately 30 cases have been described, of which 7 were in children. [3], [14]

Age of Onset

GEH may start at any age, with reports of starting ages ranging from 3 months to 58 years.

Clinical Findings

The skin lesions consist of an asymptomatic eruption of round or oval papules that are firm, dark red or dark blue, and range in size from 3 to 10 mm (Fig. 161-4). These lesions appear in successive crops and are usually numerous (hundreds). In adults, the lesions are symmetrically distributed and may involve mucous membranes, whereas in children, the lesions are irregularly scattered over the entire body and mucous membranes are spared. [14] No visceral lesions have been observed in either children or adults.

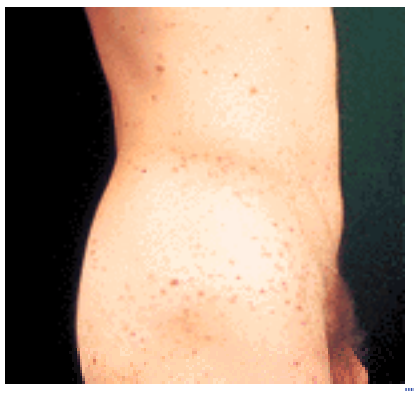

FIGURE 161-4 Generalized eruptive histiocytosis in an adult.

Histopathologic Findings

The lesions (Fig. 161-5) consist of a dense, monomorphous, histiocytic infiltrate in the papillary and midportion of the dermis, with a few lymphocytes. [14], [15] The histiocytes contain a nucleus with scanty chromatin and an abundant, light, poorly limited cytoplasm. These cells are often arranged in nests around vessels. Older lesions in children may contain foamy cells. [14]

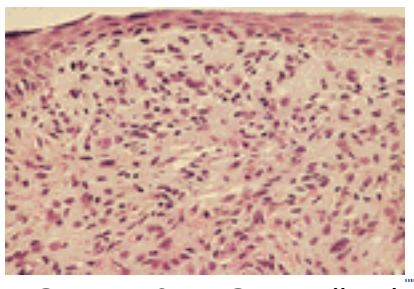

FIGURE 161-5 Generalized eruptive histiocytosis. Histopathologic findings. Dense monomorphous histiocytic infiltrate in the papillary and mid–dermis, intermingled with a few lymphocytes.

In all the cases studied by using immunologic techniques, [14] the histiocytes of the infiltrate were negative for S-100 protein and CD1a and positive for CD11b and CD4, except for the case described by Sigal-Nahum et al. [16] in which many cells of the infiltrate were S-100 negative and CD1a positive. Electron microscopy shows the tumor cells to contain a large number of dense and regularly laminated bodies, often clustered together. Occasionally, wormlike bodies are found, but LG are always absent. [2], [3], [14], [15]

Differential Diagnosis

JXG and PX can be excluded in view of the color of the lesions and the presence of both foamy cells and Touton giant cells. Multicentric reticulohistiocytosis can be ruled out because of the absence of arthritis and the lack of multinucleated giant cells. BCH has lesions localized on the face and affects only children; nevertheless, this disease may represent a problem in differential diagnosis because it is histologically closely related to GEH.

Histiocytosis X is easily excluded based on its clinical features and because of its typical histologic, immunocytochemical, and ultrastructural features.

Course and Prognosis

New crops of lesions may continue for years. Slowly the disease subsides spontaneously without a trace or leaving anetoderma-like macules. General health is always normal. Winkelmann [1] suggests that this syndrome could represent the primitive form of other, more developed, nonhistiocytoses X (JXG, PX, BCH, multicentric reticulohistiocytosis). The appearance of xanthomatous lesions in children with the disease [14] might support this hypothesis.

BENIGN CEPHALIC HISTIOCYTOSIS

Definition and Historic Aspects

BCH is self-healing, cutaneous, nonhistiocytosis X, characteristically occurring on the head, especially the face.

First described in 1971 by Gianotti et al., [17] it was named “histiocytosis with intracytoplasmic wormlike bodies” because of the presence of such structures in the cytoplasm. Ultrastructural examination of specimens from many different histiocytopathies has shown comma-shaped bodies. Therefore, the name benign cephalic histiocytosis was suggested, [2] focusing on its most typical clinical feature. The first two cases observed in the United States were reported in the mid-1980s. [18], [19]

Incidence

The condition is very rare. Over the past 3 decades, approximately 30 cases have been described. [3], [20], [21], [22] and [23] The incidence in boys and girls is about the same.

Age of Onset

The age of onset is 5 to 34 months (mean, 13.5 months).

Clinical Findings

The eruption consists of asymptomatic, slightly raised, round or oval, pinkish and brownish-yellow papules, 2 to 8 mm in diameter, localized first on the upper part of the face, mainly around the eyelids, forehead, and cheeks (Fig. 161-6). Other lesions subsequently appear over the entire head, the auricles (particularly on the posterior side), the occipital region, and the neck; a few other lesions may appear on the shoulders and arms. Mucous membranes and viscera are always spared. The number of lesions at the beginning of the disease varies considerably, from 2 to more than 100. New lesions continue to appear for many months.

FIGURE 161-6 Benign cephalic histiocytosis.

Histopathologic Findings

By conventional microscopy, [23] early lesions show a well-circumscribed infiltrate, closely attached to the lower surface of the epidermis, which is thin and flattened. Most of the cells in the infiltrate are histiocytes with pleomorphic nuclei, sparse chromatin, and barely recognizable, sometimes glassy, cytoplasm. Scattered or grouped lymphocytes and a few eosinophils are found among the histiocytes. Old lesions have few multinucleated giant cells with peripheral nuclei. The histiocytes are S-100 and CD1a negative and CD11b and CD4 positive. By electron microscopy, [2], [3], [17], [18], [20] many coated vesicles with a diameter ranging from 500 to 1500 nm are seen in all the histiocytes. Clusters of “comma-shaped bodies” are present in nearly one-fourth of the histiocytes. The comma-shaped bodies are formed by two electron-dense membranes of approximately 6 nm, separated by a light space of about 8 nm. Where the infiltrate is more dense, desmosome-like junctions may be observed among the histiocytes. These cells always lack LG.

Differential Diagnosis

BCH can be differentiated from JXG (particularly the small nodular type), in which the nodules are pleomorphic and not limited to the head and neck. Histologically, the latter nodules appear to be composed of many multinucleated giant cells and foamy cells. Electron microscopy demonstrates lipid droplets without limiting membranes in the cytoplasm of the macrophages. The nodular type of urticaria pigmentosa is distinguishable because of the wheal that follows rubbing;

mast cells are an obvious histopathologic marker. The lichenoid form of sarcoidosis can be diagnosed by its islands of epithelioid cells permeated and surrounded by reticulum fibers. GEH is distinguishable because of the age of onset (mainly adults) and the sites involved. Electron microscopy demonstrates many dense and regularly laminated bodies clustered together in the macrophages. PX can be differentiated because the lesions are widespread and show foamy cells and Touton giant cells, even in the early stage. Histiocytosis X, especially the chronic disseminated form (Hand-Schüller-Christian disease), is distinguishable because its papular lesions spread to the scalp and the trunk. Histopathology, S-100 protein staining, and electron microscopy confirm the diagnosis.

Course and Prognosis

Spontaneous regression of lesions occurs months to years after the onset of the eruption. Regression of lesions starts characteristically where papules first appeared. The papules begin to flatten and then, after a short period of hyperpigmentation, the lesions disappear without leaving scars. Both the mental and the physical development of the patients are normal.

SINUS HISTIOCYTOSIS WITH MASSIVE LYMPHADENOPATHY

Definition and Historic Aspects

Sinus histiocytosis with massive lymphadenopathy (SHML) [24], [25] is a benign, generally self-limited disease confined mainly to cervical lymph nodes. It is usually accompanied by fever, elevated erythrocyte sedimentation rate, leukocytosis with neutrophilia, and polyclonal hypergammaglobulinemia. Cutaneous manifestations are observed in approximately 10 percent of patients. [26], [27] and [28]

SHML was first described in 1969 by Rosai and Dorfman [24] (Rosai-Dorfman syndrome). Thawerani et al. [26] emphasized the cutaneous manifestations in 1978.

Incidence

SHML is a relatively rare disease; approximately 365 cases have been studied and followed. [29] The disease has a worldwide distribution with a predilection for blacks from Africa and the West Indies. There is no sexual predilection.

Age of Onset

Any age group may be affected, but 80 percent of cases occur in the first or second decades of life. [28], [29]

Clinical Findings

Cutaneous lesions are polymorphic (Fig. 161-7). [27], [28] They may occur as yellowish macules and patches, reddish-brown papules, plaques, and nodules that may become eroded or ulcerated. In one patient, [26] firm purple nodules and tumors as large as 10 cm in diameter were noted, but in most instances, the lesions are much smaller, multiple, widespread, and asymptomatic. A special presentation of SHML on the skin can be misinterpreted when periocular involvement results in a lobulated induration of the eyelids. [3] Cutaneous manifestations may be the initial presentation and sole presenting feature of the disease. [30] Massive, bilateral cervical lymphadenopathy, usually painless, is the hallmark of the condition. Less commonly, axillary, mediastinal, inguinal, and preauricular lymph nodes may be affected.

FIGURE 161-7 Sinus histiocytosis with massive lymphadenopathy.

Associations

Extranodal disease occurs in approximately 25 percent of patients [28] and may be the initial manifestation of the disorder. The extranodal noncutaneous sites most commonly affected are the eye, [3] upper respiratory tract, [30] liver, spleen, testes, skeleton, [31] and nervous system. [32] Fever, an elevated erythrocyte sedimentation rate, leukocytosis with neutrophilia, and polyclonal hypergammaglobulinemia are common (90 percent of tested patients). [29] Less-frequent findings include moderate anemia (60 percent), lymphopenia, elevated titers of Epstein-Barr virus, [29] and, in one case, elevated Klebsiella antibody titers. [28]

Histopathologic Findings

Histopathologically, [26], [28] the skin lesions are characterized by a dermal infiltrate composed predominantly of histiocytes with large vesicular nuclei and abundant pale cytoplasm. Some histiocytes are foamy, multinucleated, or both. Lymphophagocytosis has been described. Histiocytes are sometimes aggregated in clusters resembling lymph node sinuses. Lymphocytes, plasma cells, and polymorphonuclear leukocytes may be intermixed in the infiltrate. Recent reports [29] show that most of the histiocytes of SHML lesions are S-100 positive and CD1a negative. Electron microscopy [3] shows that most histiocytes forming the infiltrate are rich in phagosomes and may contain clusters of “comma-shaped bodies.” LG are absent.

Etiology

The cause of SHML remains obscure. Two main hypotheses have been proposed: a disturbance of cell-mediated immunity or a primary infection (Epstein-Barr virus, Klebsiella). [28], [29]

Differential Diagnosis

There is a broad differential diagnosis with many diseases, both proliferative and inflammatory, mainly based on histopathologic and immunologic findings. The histopathologic combination of histiocytes with abundant pale cytoplasm, a mixed-cell infiltrate, and karyophagocytosis is an important criterion of differentiation. The observation that histiocytes forming the infiltrate of SHML are mainly S-100 positive and CD1a negative, if confirmed, could be another distinctive feature of this disease.

Treatment

As a rule, because the vast majority of lesions of SHML heal spontaneously, no treatment is necessary. In rare instances, a space-occupying lesion will interfere with the function of an organ and then treatment with systemic glucocorticoids or with various chemotherapeutic regimens might be useful. [28]

Course and Prognosis

In most patients, SHML has a benign course [28] with spontaneous regression over a period of months to years. Usually the extranodal lesions regress first, whereas adenopathy may persist for years. [25] A worse prognosis results mainly from associated immunologic abnormalities. [33]

XANTHOMA DISSEMINATUM

Definition and Historic Aspects

XD, or Montgomery's syndrome, is a rare, benign, normolipemic form of histiocytoxanthomatosis affecting the skin and mucous membranes, and frequently associated with diabetes insipidus.

Montgomery and Osterberg, [34] in 1938, first recognized this distinct type of cutaneous xanthomatosis. Altman and Winkelmann [35] reviewed the literature and confirmed this syndrome.

Incidence

The condition is rare (about 100 published cases), [36], [37] affecting males more frequently than females. [34] The random nature of the disorder does not permit an exact evaluation of either familial involvement or morbidity.

Age of Onset

In approximately 60 percent of patients, onset is before age 25 years. [35]

Clinical Findings

The cutaneous manifestations consist of hundreds of papules that are red-brown at first and then become yellowish. They symmetrically involve the trunk, face, and proximal extremities and, in flexures and folds, tend quickly to merge, forming verrucous plaques (Fig. 161-8). [35], [37] In approximately 50 percent of the cases, [35], [36] xanthomatous lesions may also be observed on the mucous membranes of the mouth, pharynx, and larynx, and on the conjunctiva and cornea. Symptoms of dyspnea and dysphagia are not uncommon. Vasopressin-sensitive transitory diabetes insipidus may be present, [35], [36] but polyuria and polydipsia are generally mild. A normal lipid profile is present in this disease but, slightly elevated values of serum cholesterol or triglycerides have been found in a few cases. [36]

FIGURE 161-8 Xanthoma disseminatum.

Associations

Osteolytic lesions have been reported in only a few patients. [3] XD may be associated with multiple myeloma, Waldenström's macroglobulinemia, and monoclonal gammopathy. [3]

Histopathologic Findings

In the early stage, there is a mixture of histiocytes, foamy cells, and inflammatory cells; later, foamy cells predominate and Touton giant cells are frequently present. [36] (Fig. 161-9) Siderosis is often observed. The proliferating cells are S-100 and CD1a negative and, ultrastructurally, they are similar to those present in JXG and in PX, but the plasma membranes of foamy cells show many microvilli. [37] LG are absent.

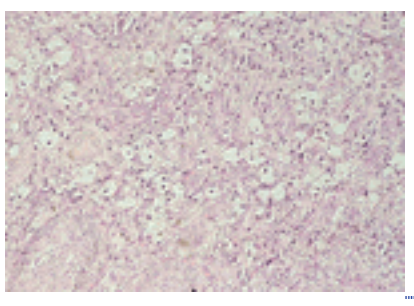

FIGURE 161-9 Xanthoma disseminatum. Histopathologic findings. The lesions are characterized by a mixture of histiocytes, inflammatory cells, and foamy cells. Touton giant cells are present.

Differential Diagnosis

In hyperlipemic xanthomatoses, lesions are more yellowish and their distribution is different. XD differs from PX in that lesions merge into plaques, there is mucous membrane involvement and associated diabetes insipidus. JXG mainly affects children, and the lesions do not merge into plaques; there may be visceral involvement, but diabetes insipidus is absent. Multicentric reticulohistiocytosis (see Chap. 162) occurs mainly in adults, is associated with destructive joint lesions, and is not self-limited. The lesions of GEH never contain lipids. In the chronic disseminated form of histiocytosis X (Hand-Schüller-Christian disease), papular lesions spread to the scalp and trunk and bone lesions are the most frequent manifestation. Histiocytosis X cells are S-100 and CD1a positive and contain LG.

Treatment

Treatment is usually not helpful. [35], [36] Systemic glucocorticoids and antimitotic agents have been used for the more disfiguring forms. Vasopressin is necessary for the associated diabetes insipidus.

Course and Prognosis

Based on the evolution and prognosis of reported cases, Caputo et al. [37] have distinguished three clinical variants of XD: a self-healing form, a persistent form, and a progressive form. The persistent form is the most frequent one. XD could represent the evolution of other, less-developed nonhistiocytoses such as generalized eruptive histiocytoses. [35], [38] Prognosis is usually good, but respiratory tract involvement may lead to dyspnea and dysphagia. Tracheotomy has been required in a few cases. [35]

PAPULAR XANTHOMA (See also Chap. 150)

Definition and Historic Aspects

PX is a normolipidemic papular xanthomatosis, histologically different from other normolipidemic xanthomatoses such as JXG and XD. This disease was first described by Winkelmann [1] in 1981 in adults. The first pediatric cases were reported

by Caputo et al. in 1990. [39]

Incidence

PX is a rare disorder; fewer than 20 cases have been described. [1], [39]

Age of Onset

The onset of PX in children is usually during the first year of life. [39] The disease seems to be more frequent in males.

Clinical Findings

PX is characterized by the eruption of 2- to 12-mm, rounded, yellowish, asymptomatic, papulonodular lesions in a generalized distribution with no tendency to merge into plaques (Fig. 161-10). Occasionally mucous membranes may be involved. No visceral involvement can be found; the lipid profile is normal; diabetes insipidus is absent.

FIGURE 161-10 Papular xanthoma in a child.

Histopathologic Findings

The lesions are composed almost entirely of foamy cells and Touton giant cells. There is no evidence of a primitive histiocytic phase and inflammatory cells are absent [1], [39]. The foamy cells are S-100 and CD1a negative. [39], [40] and [41] Ultrastructurally, [39], [40] the cytoplasm is completely filled with lipid vacuoles without a limiting membrane, myeloid bodies, and lysosomal inclusions. Neither LG nor “comma-shaped bodies” are found in these histiocytes.

Differential Diagnosis

PX differs from XD in that the lesions do not tend to merge into plaques and do not turn red-brown, the skin folds are spared, and there is no diabetes insipidus. Histologically, inflammatory cells are absent. JXG can be recognized by its pure primitive histiocytic phase and, in mature lesions, by the presence of inflammatory cells. Benign cephalic histiocytosis differs in localization and never shows lipidation. GEH does not have lipid-containing cells. PX is clinically and histologically difficult to differentiate from the xanthomatous lesions that may appear in histiocytosis X, but the history and the absence of lesions typical of histiocytosis X, the absence of S-100 positivity, and the absence of LG are discriminating findings. Although it is clinically and histologically indistinguishable from disseminated papular xanthomas with hyperlipoproteinemia, in this case, serum lipids provide the correct diagnosis.

Course and Prognosis

In most of the cases involving children, the lesions regressed within 1 to 5 years; [39] thus PX seems to be, at least in children, a self-healing xanthomatosis, but a progressive course has also been described in several cases. [40]

NECROBIOTIC XANTHOGRANULOMA

Definition

Kossard and Winkelmann, in 1980, were the first to recognize necrobiotic xanthogranuloma (NXG) as a distinct entity. [42] It is an inflammatory histiocytoxanthomatosis involving the dermis and subcutaneous tissue, primarily of the face and, less frequently, of the trunk and extremities. Clinically, the disorder is characterized by indurated yellow-red nodules or plaques, often ulcerated and histologically by xanthogranulomatous features with various amounts of necrobiosis or hyalin necrosis and the presence of lymphoid nodules. There is frequently paraproteinemia, and, occasionally, there are elevated erythrocyte sedimentation rate, cryoglobulinemia, anemia, and leukopenia. [3], [42], [43], [44], [45], [46], [47], [48] and [49]

Incidence

Approximately 60 cases are described in the literature. [48]

Age of Onset

The age of onset of NXG ranges from 17 to 85 years, and the disease has no sex predilection. [46]

Clinical Findings

Early cutaneous lesions consist of firm papulonodules varying in color from red-orange to violaceous or yellow. [42], [44], [46] These lesions slowly enlarge into plaques with well-demarcated edges, ranging in diameter size from a few centimeters to 25 cm. There is central atrophy with telangiectasias or areas of ulceration (Fig. 161-11). Most cases are asymptomatic, but pain or a burning sensation may be noted. [46] The lesions are usually multiple and involve, in order of frequency, the face, trunk, and extremities. The periorbital area is the site of predilection (85 percent of cases). [46] The oral mucosa is occasionally involved. [47] Hepato- and splenomegaly have been observed in approximately 20 percent of patients. [46]

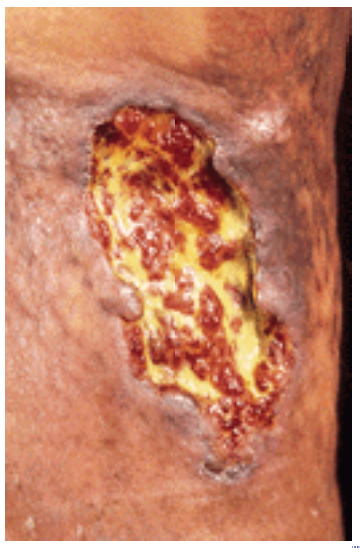

FIGURE 161-11 Necrobiotic xanthogranuloma on the calf. Note “granulomatous” periphery of the lesion, with central ulceration and necrotic material at the base.

Associations

NXG may be associated with myeloma, [43], [45], [49] arthropathy, [46] hypertension, [46] neuropathy, [46] neoplastic syndrome, [45] primary biliary cirrhosis, [44] and Graves' disease. [46]

Complications

The periorbital involvement may lead to important ocular complications such as lagophthalmos, conjunctivitis, keratitis, scleritis, uveitis, and corneal ulceration, and even to loss of ocular function. [45], [46]

Laboratory Findings

Ninety percent of patients have paraproteinemia (IgG ? or ?), while cryoglobulinemia has been found in about 40 percent of cases. [44], [45], [46] and [47] Other abnormal laboratory tests include an elevated sedimentation rate (57 percent), neutropenia (30 percent), leukopenia (35 percent), and decreased CH50 (47 percent).

Histopathologic Findings

The histopathologic picture of NXG is characteristic and consists of a granulomatous infiltrate involving the whole dermis and the subcutis and composed of a mixture of lymphocytes, epithelioid cells, foamy cells, and Touton giant cells. [43], [44], [45] and [46], [49] Areas of severe, clearly defined necrobiosis are sharply marginated from the surrounding granuloma. Cholesterol crystals may be located within the necrobiotic areas. Numerous, atypical, very large, bizarrely angulated, multinucleated giant cells may be seen adjacent to the areas of necrobiosis. Dense, well-defined lymphoid nodules, occasionally containing a germinal center, may be present in the dermis or subcutis. A Touton cell panniculitis may involve the entire fat lobules. Occasionally, a granulomatous infiltrate may surround some vessels.

Immunohistochemically, the cells constituting the infiltrate are CD15 and CD4 positive and CD1a and S-100 negative. [46], [49] Ultrastructurally, cells are rich in lipid droplets, cholesterol clefts, and myeloid bodies [49] and are similar to those observed in JXG.

Etiopathogenesis

Both the pathogenesis of NXG and its link to paraproteinemia are unclear.

Differential Diagnosis

The differential diagnosis of NXG includes necrobiosis lipoidica diabeticorum, granuloma annulare, XD, and multicentric reticulohistiocytosis. In necrobiosis lipoidica diabeticorum, facial and scalp lesions are exceptional and are not associated with any serum protein abnormalities but are associated with diabetes. Histologically, the necrobiotic changes and the granulomatous infiltrate are less prominent, lymphoid nodules are absent, and cholesterol clefts are rare. The subcutaneous form of granuloma annulare occurs mainly in children and does not tend to ulcerate. Giant cells are rare,

and lymphoid nodules and cholesterol clefts are absent. In XD, the large body folds are the main sites of predilection and the periorbicular lesions are less firm and infiltrated and do not tend to ulcerate.

In multicentric reticulohistiocytosis, the lesions do not tend to ulcerate and do not merge into plaques; they are frequently associated with severe arthropathy and histologically feature large histiocytes with a typical “ground glass” cytoplasm and no necrobiosis.

Treatment

Intermittent glucocorticoid treatment can induce partial response without complete disappearance of the lesions. [44] Low-dose alkylating agents, such as chlorambucil or melphalan, produced remission of the paraproteinemia and skin lesions in several cases [44], [45] and [46] but did not prevent the evolution to multiple myeloma. [45] Temporary remissions of skin lesions have been obtained with radiation therapy and with plasmapheresis. [50]

Course and Prognosis

NXG has a chronic, often progressive course that is characterized by the appearance of new lesions and ulcerations. [45], [46] The prognosis of patients is difficult to predict and depends on extracutaneous involvement, multiple myeloma, or visceral tumors.

PROGRESSIVE NODULAR HISTIOCYTOSIS

Definition and Historic Aspects

Progressive nodular histiocytosis (PNH) [51] is a histiocytic disorder of skin and mucous membranes with a progressively deforming course.

Incidence

P>The condition is extremely rare and effects both children and adults. [51], [52]

Clinical Findings

This disorder consists of the eruption of hundreds of lesions of two different types: superficial papules and deep nodules. [51], [52] and [53] The most common lesions are yellow to orange papules, 2 to 10 mm in diameter, that are randomly scattered on the body without localization in the flexural areas. These lesions may be present in the oral, laryngeal, and conjunctival mucosae. The deep lesions are dermal nodules ranging from 1 to 5 cm, with overlying telangiectasia, mainly located on the trunk. Café au lait spots, arthritis and diabetes insipidus are absent.

Associations

In one case, an association with hepatosplenomegaly, hypocholesterolemia, and chronic myeloid leukemia was observed. [54]

Histopathologic Findings

The pathologic features are that of a xanthogranuloma with a predominance of storiform, spindle-shaped histiocytes that are positive for macrophage/dendritic cell line markers (CD 68, HAM 56, and factor XIIIa) and are S-100 and CD1 negative. [53], [54] Electron microscopic examination revealed histiocytes with a large indented nucleus, and no LG were observed. [53]

Differential Diagnosis

Xanthoma disseminatum is easily ruled out if the flexural areas are spared and diabetes insipidus is absent.

Course and Prognosis

New lesions continue to develop during successive years with no sign of spontaneous involution. Despite the progressive nature of the lesions, patients remain in good health. [51], [52] and [53]

Etiopathogenesis

PNH is a progressive disease with no tendency to spontaneous involution as a consequence of a proliferation of mature spindle-shaped cells. It may represent an evolution of other non LC histiocytoses. [2]

Treatment

This disease is resistant to all forms of therapy. [54]

HEREDITARY PROGRESSIVE MUCINOUS HISTIOCYTOSIS

Definition and Historic Aspects

Hereditary progressive mucinous histiocytosis (HPMH) is a familial, benign, but progressive, non–LC-histiocytosis that affects women exclusively. [55], [56]

Incidence

The disease has been reported in 11 female patients from 4 different families and it is inherited most likely as an autosomal-dominant trait. [56], [57], [58], [59] and [60]

Clinical Findings

The cutaneous lesions consist of the eruption of numerous asymptomatic skin colored or red nodules, 2 to 15 mm in diameter, scattered over the entire body. [56], [57], [58], [59] and [60]

The number of the nodules increase gradually during life (several hundreds), and the lesions do not resolve spontaneously nor do they ulcerate or merge into plaques. The mucous membranes are always spared. The patients remain in good general health, and no visceral lesions have been reported. All laboratory investigations are normal.

Histopathologic Findings

Histopathologic examination reveals a well circumscribed dermal tumor consisting almost exclusively of oval or spindle-shaped histiocytes with large nuclei and abundant cytoplasm. [57], [58], [60] Staining with toluidine blue reveals marked metachromasia of histiocytes. An outstanding finding is the marked production of mucinous material, predominantly in long-standing tumors. [57], [58], [60] Immunohistochemical findings show positive labeling for vimentin, a $_1$-antitrypsin, a $_1$-antichymotrypsin, and lysozyme, while S-100, CD1a, and factor XIIIa are negative. [57], [58] and [59] Under the electron microscope, the cytoplasm of the histiocytes is filled with myeloid bodies and zebra-like bodies, and LG are absent. [57], [58], [59] and [60]

Differential Diagnosis

Clinically and histologically, HPMH is very similar to progressive nodular histiocytosis but differs by inheritance, female involvement, and the presence of mucinous material.

Course

The course is progressive but lesions remain confined to the skin.

Etiopathogenesis

It is not clear whether this disease is a proliferation, or an accumulation of macrophages caused by an unknown and persistent stimulus, or if it could be an inherited storage disease.

Treatment

No treatment is known.

REFERENCES

Multicentric reticulohistiocytosis is a rare disorder. Over the last 30-odd years only two comprehensive reviews have appeared, and they could not offer any clues as to the nature of this peculiar disease. [1], [2] No revealing details have been unraveled since that time. Unfortunately, there have been no new insights into the basis of the pathologic process.

Multicentric reticulohistiocytosis is a systemic granulomatous disease of unknown cause characterized by a distinct histopathology. Skin, mucosa, synovia, bone, and internal organs may be involved. Cutaneous nodules and destructive arthritis are the most prominent clinical features. Multicentric reticulohistiocytosis is a paraneoplastic process in a portion of the patients afflicted. Twenty-eight percent of patients with multicentric reticulohistiocytosis develop cancer. In 75 percent of these patients, multicentric reticulohistiocytosis preceded the diagnosis of cancer. [3]

HISTORICAL ASPECTS

In 1952, Caro and Senear [4] first studied histopathologic skin sections of a patient with the features of multicentric reticulohistiocytosis; they called the syndrome reticulohistiocytic granuloma. [4] Goltz and Laymon in 1954 created the term *multicentric reticulohistiocytosis,* which most authors now use, because of the multifocal origin and the systemic nature of the process. [5] At least a dozen synonyms appear in the literature, including lipoid dermatoarthritis, giant cell (reticulo)histiocytosis, (giant cell) reticulohistiocytoma, and nondiabetic cutaneous xanthomatosis. By the early 1950s, the entity of multicentric reticulohistiocytosis was established. [1]

EPIDEMIOLOGY

Fewer than 200 cases of multicentric reticulohistiocytosis have been reported, but many others may have gone undiagnosed. [6] There appears to be no geographic area of prevalence. White patients predominate, but this finding may merely reflect the higher number of reports from North America, Australia, and Europe. Patients of African, South American, Japanese, and American-Indian ancestry have also been identified. In one study, the disease affected a greater number of women than men [1]; in another, the distribution between the sexes was equal. [2] The mean age of onset is 43 years. After an average of 8 years, the disease becomes inactive. Children and adolescents may develop the disease, [7], [8], [9] and [10] and there has been one report of multicentric reticulohistiocytosis during pregnancy. [11]

During the past four decades, most investigators considered multicentric reticulohistiocytosis to be of histiocytic rather than lymphocytic origin. In 1996 Zelger and associates proposed a new concept of non–Langerhans cell histiocytoses, called it indeterminate cell histiocytosis, and included multicentric reticulohistiocytosis as an oncocytic type among more than a dozen types of these histiocytoses. [12], [13] These investigators claim that each of the mononuclear and multinucleate histiocytic types reveals characteristic, but as yet not diagnostic, immunophenotypic features. They consider the KiM1p marker (CD68 family) to be the most reliable marker of the non–Langerhans cell histiocytoses.

ETIOLOGY AND PATHOGENESIS

The etiology of multicentric reticulohistiocytosis remains obscure, and its pathogenesis can be only a matter of speculation. [1], [2] The hallmark of the disease is a granulomatous, proliferative process of histiocytes, some of which are multinucleated and laden with lipids. The stimulus is not known, and no specific metabolic defect has been found. There is no evidence of an infectious agent, and there are no convincing data on a compromise of the immune status of the host. Little, if any, evidence exists to permit the categorization of multicentric reticulohistiocytosis with disorders of deranged lipid metabolism.

CLINICAL MANIFESTATIONS

Skin and joint symptoms dominate the clinical picture. Almost two-thirds of patients note arthritis first; one-fifth note skin

nodules first; and in another fifth, skin and joint changes appear simultaneously. About half of the patients develop mucous membrane manifestations. [1]

Skin Changes

The face (particularly the nose and paranasal areas), hands (particularly the nail folds; Fig. 162-1), ears, forearms, scalp (especially behind the ears), neck, eyelids, [14] the limbus and the cornea, [15] and the trunk are involved in decreasing order of frequency. The hemispherical, nontender nodular lesions have a reddish-brown hue; they vary in size from a few millimeters to conglomerate nodules measuring several centimeters. Ulceration is uncommon. Erythema may precede the formation of nodules. Pruritus may be a prominent symptom.

FIGURE 162-1 Hands of a patient with active skin lesions of multicentric reticulohistiocytosis. Note the periungual array of some of the nodules. (*From Barrow and Holubar,* [1] *with permission of Hautarzt.*)

Articular Changes

There is symmetric involvement of the interphalangeal joints, knees, shoulders, wrists, hips, ankles, feet, elbows, and vertebral and temporomandibular joints, in decreasing order of frequency. The arthritis is destructive (arthritis mutilans); as a result of the damage to bone and cartilage, severe deformation ensues. The disease progresses rapidly in the beginning, tapers, and finally burns out. There is a marked discrepancy between the severity of the radiographic findings and the underlying bone destruction, and the relative mildness of the clinical symptoms. In far advanced cases, the fingers are considerably shortened, but can be pulled out to their full length, leading to such designations as *la main en lorgnette,* opera-glass hand, telescope fingers, and concertina hand. There is no periosteal reaction or osteoporosis. Spontaneous fracture of the femoral neck has been observed. [16]

Mucosal Changes

Roughly half the patients have mucosal lesions; these lesions may involve the lips, buccal mucosa, tongue, gingiva, nasal septum, larynx, and trachea. Physically, the nodules mimic those in the skin (Fig. 162-2).

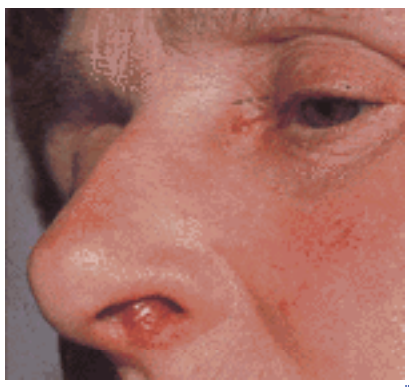

FIGURE 162-2 Mucocutaneous nodular infiltrate on the nasal mucosa and adjoining skin in a patient with multicentric reticulohistiocytosis.

Other Clinical Manifestations

Patients with multicentric reticulohistiocytosis may also exhibit xanthelasma, lesions along tendon sheaths, lesions in the myocardium and the lungs, adenopathy, pathologic fractures, hypertension, and hyperextensible joints. Kamel and associates reported a nodule in the muscles of the thoracic wall in 1996. [17] In some cases, it is impossible to substantiate a definitive diagnosis of multicentric reticulohistiocytosis, and the association of unusual findings may be fortuitous, as in patients with carpal tunnel syndrome, Dupuytren's contracture, and pleural effusion; cardiopulmonary complications; splenomegaly and pancytopenia; abnormal level of gamma heavy-chain paraprotein; and involvement of the salivary glands and pericardial effusion. Chevrant-Breton in her review cited reports of neurologic and (terminal) hematologic changes. [2]

LABORATORY FINDINGS

One report cites an association of multicentric reticulohistiocytosis with type IV hyperlipidemia [18]; another considers multicentric reticulohistiocytosis a lipid disorder with normolipidemic xanthomatosis. [19] These are chance findings. Otherwise, only nonspecific laboratory findings are present in individual cases: anemia, elevated sedimentation rate, leukocytosis, eosinophilia, hypo- and hypercholesterolemia, hypergammaglobulinemia, and the presence of cold

agglutinins and cryoglobulins.

Articular destruction due to oversecretion of cytokines, especially interleukin (IL)-1ß, IL-6, and tumor necrosis factor–a, has been reported. [16]

PATHOLOGY

Skin and Mucous Membranes

The histopathology of skin lesions is fairly uniform. [1], [2] Nonencapsulated and moderately well circumscribed, the nodules occupy the entire dermis or parts of it. Frequently, there is a narrow zone of noninfiltrated connective tissue between the infiltrates and the slightly atrophic epidermis.

Lesions consist of histiocytic cells that are irregular in size and shape (Fig. 162-3A). Many have transformed into multinucleated giant cells, generally not more than 250 nm in diameter, but occasionally larger (Fig. 162-3B). They may contain 20 or more aggregated nuclei with a distinct nuclear membrane and prominent nucleoli. The cytoplasm is slightly eosinophilic, has a granular appearance (“ground glass cytoplasm”), and may be foamy or show tiny vacuoles. There are no Touton giant cells.

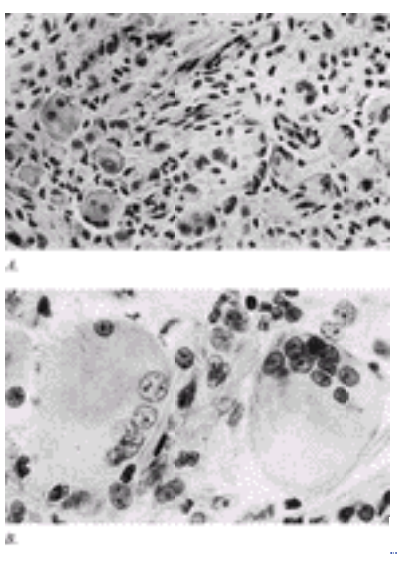

FIGURE 162-3 Microphotographs of a lesion from the patient shown in Fig. 162-1. Note histiocytic infiltrate (*A*) and multinucleated giant cells with aggregated nuclei and ground glass cytoplasm (*B*). (*From Holubar K, Mach K: Histiocytosis giganto-cellularis. Hautarzt 17:440, 1966, with permission of Hautarzt*.)

Multicentric reticulohistiocytosis nodules contain lymphocytes, which are more numerous in early lesions, and plasma cells, eosinophils, mast cells, and, occasionally, extravasated erythrocytes. As the age of the lesions increases, lymphocytes and giant cells decrease in number, fibroblasts appear, and fibrosis ensues. Lesions are well vascularized, and capillaries show endothelial hypertrophy. In places, histiocytes and giant cells have a perivascular arrangement. Elastic fibers are fragmented, clumped, and thickened, particularly in early lesions.

HISTOCHEMICAL INVESTIGATIONS The cytoplasm of histiocytes and giant cells is PAS-positive and hyaluronidase- and diastase-resistant, suggesting the presence of glycoproteins. It contains phospholipids, neutral fats, and iron. Biochemical studies have not revealed an isolated enzyme defect responsible for lipid accumulation.
ELECTRON MICROSCOPY There are no Langerhans cell granules in the histiocytic cells of multicentric reticulohistiocytosis. Both histiocytes and giant cells have lobulated nuclei with indented contours and margination of nuclear chromatin, an enlarged Golgi apparatus, and hyperplastic endoplasmic reticulum with dilated cysternae. Lipid-laden vacuoles are present, and numerous small, electron-dense, ovoid or rod-shaped cytoplasmic granules, up to 250 nm in size, may appear. These granules are positive for acid phosphatase, as are autophagic vacuoles. A characteristic feature is the complex interdigitation of the membranes of adjacent histiocytic cells. In addition, collagen phagocytosis has been observed, and intra- and extracellular fragments of collagen VI in histiocytes have been documented. [20] The histiocytes of multicentric reticulohistiocytosis have been characterized by their iron uptake, positivity of acid phosphatase, presence of unspecific esterase, and presence of lysozyme. The histopathology of synovial lesions is identical to that of skin lesions.

Lesions in Other Tissues

The morphology and localization of cutaneous nodules, the typical articular symptoms, and the radiographic findings (i.e., symmetric involvement of distal interphalangeal joints) are highly suggestive of multicentric reticulohistiocytosis, but histopathologic examination of a nodule permits the diagnosis. It is necessary to differentiate several disorders from multicentric reticulohistiocytosis: rheumatoid arthritis, the various types of xanthomas, Farber's disseminated lipogranulomatosis, lepromatous leprosy, lipoid proteinosis, sarcoidosis, histiocytosis X, juvenile and adult xanthogranuloma, solitary reticulohistiocytoma, generalized eruptive histiocytoma of Hashimoto and Pritzker, and Zayid and Farraj's familial histiocytic dermatoarthritis. Multicentric reticulohistiocytosis is not familial or congenital. The proposed grouping, still under discussion, into Langerhans and non-Langerhans types of histiocytic and lymphocytic proliferations may make many of these previously detailed diagnoses obsolete. [12], [13]

ASSOCIATED CONDITIONS

Possible concomitant diseases include thyroid disorders; tuberculosis; diabetes; hemoblastoses; systemic sclerosis and Sjögren's syndrome; cancer of the colon, breast, bronchus, cervix, ovary, and stomach; mesothelioma; and melanoma. [21], [22] An association with sarcoma and lymphomas has also been reported. The tumors may progress, and multicentric reticulohistiocytosis may remit; in contrast, multicentric reticulohistiocytosis may progress despite removal of the tumor. Although many investigators therefore remain skeptical about the alleged paraneoplastic nature of multicentric reticulohistiocytosis, there are enough questions to warrant a careful tumor search in all patients with the disease.

TREATMENT

Gianotti and Caputo stated that “treatment is usually not helpful.” [23] Glucocorticoids (administered also as pulse therapy); ACTH; antimalarials; salicylates; indomethacin; pyrazolone; clofibrate; penicillamine; and, increasingly, various antimitotic compounds, such as azathioprine, methotrexate, cyclophosphamide, cyclosporine, and nitrogen mustard (administered systemically and topically) have been used; but no controlled studies have been performed. Antimitotic agents appear to be a rational choice for therapy. However, because multicentric reticulohistiocytosis is a potentially paraneoplastic condition, antimetabolites and cytostatics may be harmful when malignancies are associated. Surgical measures have also been used.

COURSE AND PROGNOSIS

The skin nodules and arthritis associated with multicentric reticulohistiocytosis do not necessarily run in a parallel course. Articular changes may wax and wane, finally evolving into mutilating arthritis, whereas skin nodules may not appear at all or may erupt in successive crops with new infiltrates superimposed on older, regressing ones. The course of multicentric reticulohistiocytosis is capricious and unpredictable; about half of the patients will eventually suffer from prominent destructive arthritis. Most commonly, the disease burns out after 5 to 8 years, leaving the patient with severe articular deformations and disfigurement of the hands, face, and scalp.

Dean Metcalfe

The Mastocytosis Syndrome

ETIOLOGY AND PATHOGENESIS
CLINICAL FEATURES
DIAGNOSIS
TREATMENT
PROGNOSIS

REFERENCES

Mastocytosis is a condition characterized by mast cell hyperplasia in the bone marrow, liver, spleen, lymph nodes, gastrointestinal tract, and skin. Clinically, the disease is often accompanied by evidence of mast cell activation, which includes pruritus, flushing, urtication, abdominal pain, nausea, vomiting, diarrhea, bone pain, vascular instability, headache, and neuropsychiatric difficulties. Mastocytosis can occur at any age and demonstrates a slight male-to-female predominance (1.5:1.0). The prevalence of the disease is unknown, and familial occurrence appears unusual.

Mastocytosis is divided into clinicopathologic variants on the basis of clinical presentation, pathologic findings, and prognosis. Table 163-1 shows a consensus-based classification for mastocytosis. [1] Patients with cutaneous mastocytosis (CM) or indolent systemic mastocytosis (ISM) have a good prognosis, whereas patients with other variants have a less favorable outcome. Most children diagnosed with mastocytosis have CM with good prognosis. Mastocytosis is diagnosed on the basis of characteristic bone marrow findings plus at least one of the following minor criteria: (1) detection of a point mutation in *c-kit* at codon 816, (2) bone marrow mast cells that express CD2 and/or CD25, (3) a total serum tryptase of greater than 20 ng/mL, or (4) a tissue biopsy specimen in which more than 25 percent of mast cells have an atypical morphology. Mastocytosis may also be diagnosed when three of the four minor criteria are present. ISM is diagnosed when the criteria for mastocytosis are met and there is no evidence of an associated clonal hematologic disorder or of severe liver disease, hypersplenism, or significant lymphadenopathy. In most cases, patients with ISM are managed successfully with medications that provide symptomatic relief.

Cutaneous mastocytosis (CM)
Urticaria pigmentosa (UP)/maculopapular cutaneous mastocytosis (MPCM)
Typical UP
Plaque form
Nodular form
Telangiectasia macularis eruption perstans (TMEP)
Diffuse cutaneous mastocytosis (DCM)
Solitary mastocytoma of skin
Indolent systemic mastocytosis (ISM)
Systemic mastocytosis with an associated clonal hematologic non-mast cell lineage disease (SM-AHNMD)
Aggressive systemic mastocytosis (ASM)
Mast cell leukemia (MCL)
Mast cell sarcoma (MCS)
Extracutaneous mastocytoma

TABLE 163-1 **WHO Classification of Mastocytosis**

The second most common form of mastocytosis is systemic mastocytosis with an associated clonal hematologic non-mast cell lineage disease (SM-AHNMD). It is not often observed in children. In this group, examination of the bone marrow and peripheral blood reveals the hematologic abnormality. The prognosis for these patients is determined by the course of the associated hematologic disorder.

Patients with aggressive systemic mastocytosis (ASM) are usually adults. These patients have poor prognostic features, including impaired liver function, hypersplenism, and malabsorption, but they do not have a distinctive hematologic disorder or mast cell leukemia. There exists a subset of patients with ASM who have a distinct syndrome termed *lymphadenopathic mastocytosis with eosinophilia* because of the pronounced eosinophilia, hepatosplenomegaly, and lymphadenopathy. Patients with ASM have rapidly increasing mast cell numbers and are difficult to manage medically. Their prognosis is less favorable than that of patients with ISM.

Patients with mast cell leukemia (MCL) have numerous atypical immature mast cells in the bone marrow, and mast cells account for 10 percent or more of peripheral blood white cells. Mast cell sarcomas (MCS) are rare; they have localized destructive growth, and distant spread is possible. Mast cells in these tumors are highly atypical and immature. Extracutaneous mastocytomas are very rare, usually localized to the lung, and consist of mature mast cells.

ETIOLOGY AND PATHOGENESIS

Human mast cells originate from pluripotent CD34+, CD13+, CD117+ bone marrow cells [2] and circulate through the bloodstream [3] to specific sites in the body where they mature into fully granulated cells. The targeting of mast cells to defined locations appears to be determined by the sequential expression of cell surface adhesion molecules, predominantly members of the integrin family. [4]

The regulation of mast cell number and mast cell differentiation is under the control of factors produced both in the bone marrow and by cells in the tissues in which mast cells finally reside. For example, human mast cell differentiation depends on Kit ligand, also known as stem cell factor (SCF). Differentiation is inhibited by factors such as interferon gamma. [5] Final maturation and granule composition depend on factors produced in the tissue microenvironment, [6]

including SCF produced by fibroblasts and stromal cells. Inhibition of local production of SCF leads to mast cell apoptosis. [7]

The receptor for SCF is Kit. Mutations have now been identified in *c-kit* in peripheral blood cells and tissues from patients with mastocytosis. [8] These mutations are associated with enhanced receptor function and may contribute to the increase in mast cell number and disordered cell migration [8], [9] that is characteristic of mastocytosis. The first and most common mutation identified in patients with mastocytosis consists of an A to T substitution at codon 816 of *c-kit* mRNA that causes an aspartic acid to valine substitution. [8] The fact that this mutation can be found in multiple cell lineages suggests it takes place in a pluripotential stem cell, [10] and it appears to be a somatic mutation. This substitution, as well as others at codon 816, are observed in most adult patients with mastocytosis associated with a hematologic disorder and in patients with ISM. [11] Other mutations have now been described, including an inactivating mutation at codon 839 in some children with CM, which is of uncertain significance. Other genetic polymorphisms such as the Q576R polymorphism in the interleukin-4 receptor alpha chain may mitigate disease expression. [12] The relationship of these mutations to chromosomal abnormalities is unknown. However, fluorescent in situ hybridization has been used to identify trisomy 8 in five patients and trisomy 9 in one patient with unspecified patterns of mastocytosis. [13]

The systemic effects of mastocytosis are in large part the result of the increased production of mast cell mediators, which have effects both at the site of their production and remote from their origin, irrespective of the etiology of the increased burden of mast cells or the category of disease. Mast cell products are of three categories; all may circulate through the bloodstream and lymphatics to produce biologic effects in patients with mastocytosis (Table 163-2).

Mediators	Effects
Granule-associated	
Histamine	Pruritus, urticaria, increased vasopermeability, gastric hypersecretion, bronchoconstriction
Heparin	Local anticoagulation, osteoporosis
Lipid-derived	
Prostaglandin D_2	Vasodilation, bronchoconstriction
Cytokines	
TNF-α	Cachexia
Stem cell factor	Survival and proliferation of mast cells and mast cell progenitors
IL-6	Mast cell survival

Key: IL, interleukin; TNF, tumor necrosis factor.

TABLE 163-2 **Mast Cell Products Implicated in the Pathogenesis of Mastocytosis**

CLINICAL FEATURES

All categories of mastocytosis share clinical features that are caused by the excess production of mast cell-dependent mediators, although some aspects of disease may predominate in a specific category. The skin, gastrointestinal tract, lymph nodes, liver, spleen, bone marrow, and skeletal system contribute the most significant management problems. The respiratory tract and endocrine systems are seldom if ever involved. Also, patients with mastocytosis do not suffer from recurrent bacterial, fungal, or viral infections even though mast cells release mediators such as histamine that inhibit immune responses in vitro.

Urticaria pigmentosa (UP) is the most common skin manifestation of cutaneous disease in both children (Fig. 163-1) and adults (Fig. 163-2). It is seen in more than 90 percent of patients with ISM and in fewer than 50 percent of patients with SM-AHNMD or with ASM. The lesions of UP appear as small, yellow-tan to reddish-brown macules or slightly raised papules scattered over the body. The palms, soles, face, and scalp may be free of lesions. Mild trauma, including scratching or rubbing of the lesions, usually causes urtication and erythema around the macules; this is known as Darier's sign. UP is associated with a variable amount of pruritus, which may be exacerbated by changes in climatic temperature, skin friction, ingestion of hot beverages or spicy foods, ethanol, and certain drugs. The diagnosis is confirmed by characteristic skin histopathology. [14]

FIGURE 163-1 Urticaria pigmentosa in a child with cutaneous disease only.

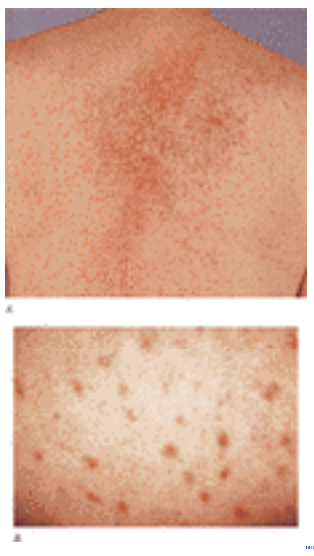

FIGURE 163-2 Urticaria pigmentosa in an adult with indolent systemic mastocytosis. *A*. Hundreds of lentigo-like macules are seen on the back of this adult. If vigorously rubbed, these lesions will show urtication and become erythematous, raised, and pruritic. *B*. Close-up.

Diffuse cutaneous mastocytosis (DCM) consists of a diffuse mast cell infiltration of the skin without discrete lesions. It usually occurs before the age of 3 years. The entire cutaneous integument is involved. The skin is normal to yellow-brown in color and is diffusely thickened. [14]

Solitary mastocytomas of the skin (Fig. 163-3) do occur but are rare. Their onset is generally before 6 months of age. In most cases, such lesions involute spontaneously.

FIGURE 163-3 Solitary mastocytoma. *A*. A tan macule is seen on the buttocks of an 18-month-old child. *B*. After the child's diaper was changed, the lesion became an urticarial plaque.

Young children with UP or DCM may have bullous eruptions with hemorrhage (Fig. 163-4). Blisters may erupt spontaneously or in association with infection or immunization. Blisters may occur at birth and thus are in the differential diagnosis of neonatal disorders with blisters.

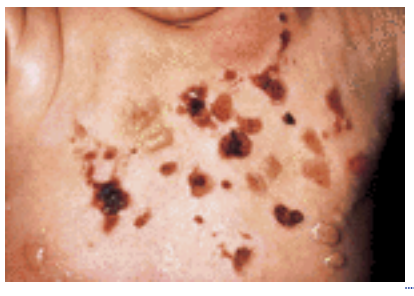

FIGURE 163-4 Bullous eruption on the back of a child with diffuse cutaneous mastocytosis and indolent mastocytosis.

Telangiectasia macularis eruptiva perstans (TMEP) is observed in fewer than 1 percent of patients with mastocytosis. It appears as tan to brown macules and patchy erythema. Telangiectasias are observed. This form of cutaneous disease in mastocytosis is observed exclusively in adults.

Both children and adults with mastocytosis may develop gastrointestinal disease. Gastric hypersecretion caused by elevated plasma histamine with resultant gastritis and peptic ulcer disease is the most common problem. [15] Diarrhea and abdominal pain are also common and are followed by the onset of malabsorption in a subset of patients with advanced disease. Roentgenographic abnormalities fall into three major categories: peptic ulcers; abnormal mucosal patterns such as mucosal edema, multiple nodular lesions, coarsened mucosal folds, or multiple polyps; and motility disturbances. Histologic sections of jejunal biopsies show moderate blunting of the villi; however, significant mast cell hyperplasia is uncommon.

Significant hepatic disease in adults with ISM is relatively infrequent, although liver function tests are somewhat above normal in about half of all patients with extracutaneous disease. [16] The most common chemical abnormality is an elevated level of alkaline phosphatase, which must be distinguished from bone-derived alkaline phosphatase (which may also be elevated). Serious manifestations of hepatic and splenic involvement, including portal hypertension and ascites associated with liver fibrosis, [16] are more common in patients who have SM-AHNMD or ASM.

Splenic involvement is also present in about half of patients with mastocytosis with evidence of systemic disease. [17] A peritrabecular distribution of mast cell infiltrates and fibrosis is most common. Eosinophilic infiltrates are also noted, as are areas of extramedullary hematopoiesis. Markedly increased splenic weights (greater than 700 g) generally occur in patients who fit into unfavorable categories of mastocytosis, that is, ASM or SM-AHNMD.

Bone marrow lesions usually consist of multifocal clusters or aggregates of tryptase-positive mast cells, often mixed with eosinophils, and T and B lymphocytes (Fig. 163-5). [1], [18] These lesions are rarely seen in children. [19] Alternatively, the diagnosis of mastocytosis may be made if more than 25 percent of mast cells are spindle-shaped, or have atypical morphology, and other criteria of mastocytosis (*c-kit* mutation at codon 816; CD2+ CD25+ mast cells; total serum tryptase >20 ng/mL) are met. Anemia, leukopenia, thrombocytopenia, and eosinophilia may occur in association with systemic disease and suggest SM-AHNMD, ASM, or MCL.

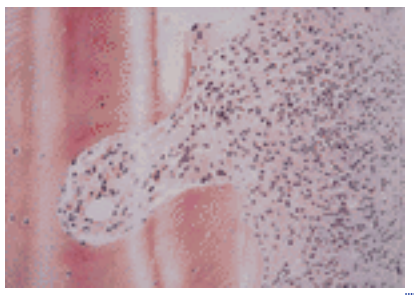

FIGURE 163-5 Bone marrow biopsy shows a characteristic lesion of systemic mastocytosis with peritrabecular infiltrates of mast cells and bony erosion. Mast cells are spindle-shaped, resembling fibroblasts or histiocytes.

Bone marrow infiltration with mast cells may induce bone changes that cause radiographically detectable lesions. The proximal long bones are most often affected, followed by the pelvis, ribs, and skull. Skeletal scintigraphy (bone scan) is more sensitive than a radiographic survey in detecting and locating active lesions. [20] Musculoskeletal pain affects 19 to 28 percent of patients. In patients with severe or advanced disease, pathologic fractures may occur.

Patients in every category of mastocytosis sometimes experience flushing or vascular collapse. In occasional patients, such reactions may be provoked by alcohol, aspirin, narcotics, iodinated contrast media, insect stings, exercise, or infections.

Neuropsychiatric abnormalities have been reported. [21], [22] Problems include decreased attention span, memory impairment, and irritability. Depression as a consequence of chronic disease or possibly mediated by mast cell products is a possibility.

DIAGNOSIS

The diagnosis of mastocytosis is suspected on clinical grounds and is confirmed by histology. Supporting evidence is derived from biochemical data (Table 163-3). [1] Mast cells may be overlooked on histologic sections, depending on the fixation and/or stain employed. The most useful stain for mast cells is tryptase, although metachromatic stains, such as toluidine blue and Giemsa; enzymatic stains, such as chloroacetate esterase and aminocaproate esterase; and avidin, which binds to heparin, also may be employed. [1], [23] These procedures highlight the granules in the cytoplasm of the mast cell, thereby facilitating identification. In trephine core bone marrow biopsies, decalcification interferes with subsequent attempts to visualize mast cell granules with metachromatic stains, thereby making tryptase the stain of choice.

Routine studies
Skin examination—gross and microscopic
Plasma tryptase
Bone marrow biopsy and aspiration
24-h urine for mediators
Additional studies as required by initial findings
Bone scan/skeletal survey
GI workup—upper GI series, small bowel x-ray, CT scan, endoscopy
EEG, neuropsychiatric workup

TABLE 163-3 **Consensus Diagnostic Workup for Mastocytosis Suspected on Clinical Grounds**

Most patients with mastocytosis have either UP or DCM, which can be recognized on physical examination. [14] These diagnoses should be confirmed by skin biopsy. Blind skin biopsies must be interpreted with caution because other skin conditions, including eczema and chronic urticaria, are associated with a two- to fourfold increase in dermal mast cells. [24]

In patients with UP, mast cells are found in increased numbers in the dermal papillae, particularly near blood vessels. [24] Mast cells may distribute in a bandlike infiltrate of the papillary dermis (Fig. 163-6) or appear as nodular infiltrates from the papillary dermis to subcutaneous tissues. Analysis of the relationship between mast cells and blood vessels has suggested that mast cells in patients with mastocytosis first increase in number around blood vessels and later appear in

tissues distant from vessels. [24] Mast cells may also be found in increased numbers in skin between lesions of UP. The greatest increases in mast cell number occur beneath UP macules and papules. On average, there is a 15- to 20-fold increase in mast cells beneath those lesions, but in occasional patients, only a two- to fourfold increase in mast cells is found. Two- to fourfold increases in mast cell number have also been documented in patients with recurrent episodes of anaphylaxis [24] at skin sites involved in scleroderma, [25] chronic urticaria, [26] and prolonged antigenic contact. [27] These observations document the need to correlate the gross skin examination with skin mast cell numbers and to avoid the diagnosis of UP solely on the basis of small increases in dermal mast cells. Cutaneous responses to intradermal histamine are unchanged in patients with UP. [28]

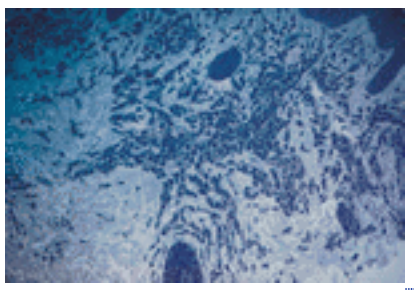

FIGURE 163-6 Mast cell hyperplasia in the dermis of a patient with systemic mastocytosis.

In patients with DCM, prominent bandlike infiltrates are present, which may be indistinguishable from some lesions of UP or from tissue obtained from mastocytomas. Cutaneous mast cell hyperplasia in patients with TMEP is present around the capillary venules of the superficial plexus.

Mastocytosis should be suspected in patients without skin lesions if they have one or more of the following: unexplained ulcer disease or malabsorption, radiographic or ^{99m}Tc bone scan abnormalities, hepatomegaly, splenomegaly, lymphadenopathy, peripheral blood abnormalities, or unexplained flushing or hypotension. Elevated levels of plasma [29], [30] or urinary histamine or histamine metabolites, [31] prostaglandin D_2 metabolites in the urine, [32] or plasma mast cell tryptase [33] are not diagnostic but do raise the index of suspicion of mastocytosis. Other surrogate markers of disease are serum interleukin (IL)-6 levels, [34] and soluble SCF receptor (CD117) and IL-2 receptor (CD25) levels. The levels of the latter receptors are highly correlated with the severity of bone marrow pathology. [35]

In the absence of skin lesions, patients suspected of having mastocytosis should have a bone marrow biopsy and aspirate for diagnosis and categorization of the type of mastocytosis. Adult patients with UP should also have this procedure, particularly if they have peripheral blood abnormalities, hepatomegaly, splenomegaly, or lymphadenopathy, to determine if they have mastocytosis with an associated hematologic disorder. Other tissue specimens, such as lymph nodes, spleen, liver, and gastrointestinal mucosa, define the extent of mast cell involvement, but are usually obtained only as dictated by necessity. For example, gastrointestinal biopsies are obtained only if a gastrointestinal workup is indicated, and lymph nodes are biopsied only if lymphoma is considered.

Patients suspected of having mastocytosis should have 24-h urine 5-hydroxyindoleacetic acid (5-HIAA) and urinary metanephrines measured to help eliminate the possibility of a carcinoid tumor or pheochromocytoma. The fact that patients with mastocytosis do not excrete increased amounts of 5-HIAA suggests that serotonin, present in the mast cells of some species, is not synthesized by human mast cells. Idiopathic anaphylaxis and flushing must also be ruled out. Patients with these disorders do not have histologic evidence of significant mast cell proliferation and should have normal plasma tryptase levels between episodes of anaphylaxis. [33]

TREATMENT

The primary objective of treatment in all categories of mastocytosis is to control mast cell mediator-induced signs and symptoms such as vascular collapse, gastric hypersecretion, gastrointestinal cramping, and pruritus. H_1 receptor antagonists such as hydroxyzine, loratadine, and fexofenadine are helpful in reducing pruritus, flushing, and tachycardia. If insufficient relief occurs, the addition of an H_2 antagonist such as ranitidine or cimetidine may be beneficial. However, many patients continue to complain of musculoskeletal pain, headaches, and flushing, resulting in part from the inability to block the effects of high levels of histamine with histamine antagonists and the presence of other mast cell mediators.

Disodium cromoglycate (cromolyn sodium) inhibits the degranulation of mast cells and may have some efficacy in the treatment of mastocytosis, particularly in relieving gastrointestinal complaints. [36] Cromolyn sodium does not lower plasma or urinary histamine levels in patients with mastocytosis. Both ketotifen and azelastine, antihistamines with mast cell-stabilizing properties, help by relieving the pruritus and whealing associated with mastocytosis. However, neither drug appears to offer an advantage over a standard antihistamine such as hydroxyzine. [37], [38]

Epinephrine is used to treat episodes of vascular collapse. Patients with such episodes should be prepared to self-administer this drug and have a plan for emergency management. If subcutaneous epinephrine is insufficient, intensive therapy for vascular collapse should be instituted. Patients with recurrent episodes of vascular collapse may be placed on H_1 and H_2 antihistamines to lessen the severity of attacks. Episodes of vascular collapse may be spontaneous but have also occurred after stings from insects or after administration of iodinated contrast media. In the latter case, premedication is recommended before such procedures.

Methoxsalen with long-wave ultraviolet radiation (PUVA) relieves pruritus and whealing after 1 to 2 months of treatment. [39], [40] Improvement is associated with a temporary decrease in dermal mast cells. Pruritus recurs within 3 to 6 months

after treatment is stopped. Photochemotherapy should be used only in instances of extensive cutaneous disease that do not respond to other forms of therapy. Some patients report a diminution in the number or intensity of cutaneous lesions after exposure to natural sunlight.

Topical glucocorticoids, such as 0.05 percent betamethasone dipropionate ointment, under plastic-film occlusion for 8 h per day over 8 to 12 weeks can be used to treat extensive cutaneous disease. Mast cell numbers decrease as the lesions clear. These lesions eventually recur after discontinuation of therapy, [41] although the treatment may lead to improvement in the cutaneous lesions for up to 1 year.

Treatment of gastrointestinal disease is directed to controlling peptic symptoms, diarrhea, and malabsorption. [15] Gastric acid hypersecretion leading to peptic symptoms and ulcerations is controlled with H_2 antagonists and proton pump inhibitors. Diarrhea is difficult to manage, and H_2 antagonists are generally not effective. Anticholinergics may give partial relief. In patients with severe malabsorption, systemic glucocorticoids have been effective. Ascites is difficult to control. Portal hypertension in one patient was successfully managed with a portacaval shunt. [42] Another patient with an exudative ascites was treated successfully with systemic glucocorticoid therapy. [43] Osteoporosis in patients with mastocytosis may be underrecognized. Recommended approaches to treatment include calcium supplementation, estrogen replacement in postmenopausal women, and the use of biphosphonates. [44]

Patients with SM-AHNMD are managed as dictated by the specific hematologic abnormality. Interferon-alpha 2b has been used to treat patients with SM-AHNMD or ASM with mixed results. [44] Some patients responded, but others did not. Various chemotherapeutic regimens for the treatment of aggressive forms of mastocytosis (ASM, MCL, some forms of SM-AHNMD) have been tried with limited success (reviewed in Ref. 44). One recent case report of the use of cladribine [45] suggests continued evolution in attempts to treat this disease. Tyrosine kinase inhibitors are under investigation, but some may not inhibit cells bearing the 816 mutation. [46] Chemotherapy has no place in the treatment of CM or ISM. Splenectomy may improve survival in patients with forms of mastocytosis that have a poor prognosis. [47] Radiotherapy has been used to treat refractory bone pain in advanced disease. [48] Bone marrow transplantation may be considered for gravely ill patients, although little is known about long-term prognosis after transplant.

PROGNOSIS

Prognosis must be addressed separately for each category of mastocytosis. A number of variables are associated with poor survival: constitutional symptoms, anemia, thrombocytopenia, abnormal liver function tests, a lobated mast cell nucleus, a low percentage of fat cells in the bone marrow biopsy, and an associated hematologic disorder. Other poor prognostic variables include absence of UP, male sex, absence of skin and bone symptoms, hepatomegaly, splenomegaly, and normal bone x-ray findings.

As a group, patients with CM or ISM have the best prognosis. Among children with isolated UP, at least 50 percent of cases reportedly resolve by adulthood. [49], [50] Furthermore, children born of mothers with ISM reportedly are free of disease. [51] Adults with UP usually progress gradually to systemic disease and rarely develop hematologic disease. [51] DCM is usually associated with ISM. Older patients with UP who experience fading of their lesions continue to exhibit bone marrow lesions typical of their diagnosis, whether ISM or SM-AHNMD. [52] Patients with SM-AHNMD have a variable course dependent on the prognosis of their hematologic disorder. With MCL, mean survival is generally less than 6 months. With ASM, mean survival is 2 to 4 years without therapy. The prognosis appears to improve with aggressive symptomatic management.

REFERENCES

Diseases of the skin and the alimentary tract or the skin and the hepatobiliary system frequently occur together. Just as a full physical examination should be part of a full dermatologic assessment, it is important to examine the skin in someone presenting with a gastrointestinal or liver problem.

Disorders of the pharynx, esophagus, stomach, pancreas, and intestines that may lead to skin changes include dysphagia, gastrointestinal bleeding, abdominal pain, and diarrhea and malabsorption. Skin changes may also occur in conjunction with liver disease. In some cases, pathologic processes affect both the skin and the liver. In some cases, skin disease is a cause of liver abnormalities; furthermore, drugs used to treat skin disease sometimes have an impact on the liver.

THE SKIN AND THE ALIMENTARY TRACT

Dysphagia

When dermatologic diseases extend into the pharynx and esophagus, as well as when the oro-oculogenital syndromes, esophageal cancer, and collagen vascular disease develop (Table 164-1), dysphagia may occur.

Rashes that may extend to the esophagus	Carcinoma of the esophagus
Infections	Iron deficiency
Blistering diseases, congenital and acquired	Dermatitis herpetiformis
Lichen planus	Tylosis
Darier's disease	Inorganic arsenic ingestion
Acanthosis nigricans	Collagen vascular diseases
Oro-oculo-genito-cutaneous syndromes	Systemic sclerosis
Stevens-Johnson syndrome	Dermatomyositis
Behçet's syndrome	

TABLE 164-1 **Skin Abnormalities That Occur with Dysphagia**

RASHES THAT EXTEND TO THE PHARYNX AND ESOPHAGUS
Infections Cutaneous and oral infections are discussed elsewhere (see Section 28, Section 29, and Section 30). Symptoms resulting from infections of the esophagus occur in patients who are taking oral and inhaled glucocorticoids or in those who have an immunodeficiency (e.g., AIDS; see Chap. 225). *Candida albicans* is the most frequent pathogen, although opportunistic viruses can also be responsible for infection.
Blistering diseases Extensive esophageal involvement with blisters, erosions, and strictures can occur in hereditary epidermolysis bullosa (see Chap. 65), particularly in the recessive dystrophic and junctional forms. Management of strictures includes esophageal dilatation, colonic interposition, and gastrostomy insertion to maintain adequate nutrition. [1] Acquired immunobullous disorders, such as pemphigus, bullous pemphigoid, acquired epidermolysis bullosa, and dermatitis herpetiformis, can affect mucosae (Fig. 164-1). Dysphagia is most troublesome in cicatricial pemphigoid (see Chap. 62). Half of the patients will have pharyngeal involvement and up to 13 percent esophageal involvement, usually of the upper esophagus, [2] with a risk of stricture formation requiring surgical dilatation.

FIGURE 164-1 Ulceration of the mouth in a patient with mucous membrane pemphigoid.

Other conditions Esophageal lichen planus has been reported only in women, typically middle-aged women, with oral involvement. Half have had strictures of the upper esophagus, but therapeutic dilatation can lead to a Koebner-like exacerbation of the stricture. [3] Esophageal involvement also occurs in Darier's disease, sometimes in association with esophageal carcinoma, [4] and in acanthosis nigricans.

ORO-OCULO-GENITO-CUTANEOUS SYNDROMES The mucosae may be extensively involved in Stevens-Johnson syndrome, toxic epidermal necrolysis (see Chap. 58), and Behçet's syndrome [5] (see Chap. 192). Isolated mucosal ulcers can occur at any point along the gastrointestinal tract. A typical site is the ileocecal region. Oral ulceration, occurring at least three times in a 12-month period, is usually evident on the nonkeratinized epithelium and can be difficult to distinguish from the mouth ulceration associated with Crohn's disease.

CARCINOMA OF THE ESOPHAGUS In the Plummer-Vinson (Paterson-Kelly) syndrome, a postcricoid web is associated with koilonychia, angular stomatitis, a sore tongue, and, usually, iron deficiency. Between 5 and 10 percent of patients with a postcricoid web develop carcinoma at the site. Tylosis is exceedingly rare, but 95 percent of those with tylosis eventually develop esophageal cancer. In two families, both tylosis and carcinoma of the esophagus were inherited as dominant traits. [6] Finally, inorganic arsenic is associated with malignancy. Non-melanoma skin cancers and palmoplantar keratoses are useful dermatologic markers.

COLLAGEN VASCULAR DISEASES Dysphagia occurs, particularly in systemic sclerosis and dermatomyositis (see Chap. 173 and Chap. 172). Up to 90 percent of patients with systemic sclerosis have gastrointestinal involvement, but this is subclinical in one-third. Dyspepsia due to gastroparesis is common; decreased peristalsis, esophageal dilation, and stricture formation occur and may require prokinetic agents or endoscopic dilatation, respectively. Gastric antral vascular ectasia is a rare manifestation that may cause significant bleeding. [7] In dermatomyositis and polymyositis, decreased esophageal motility and difficulty swallowing are indications for urgent treatment with the systemic administration of glucocorticoids and immunosuppressive drugs (see Chap. 172). Vasculitic ulcers in the mouth and pharynx infrequently occur in systemic lupus erythematosus (see Chap. 171).

Gastrointestinal Bleeding

Hematemesis, melena, or passing of fresh blood in the stools are signs of gastrointestinal bleeding. The skin may give diagnostic clues in a number of causes (Table 164-2), some of which may cause a change in bowel habit or abdominal pain (see " Abdominal Pain," below).

Congenital malformations of blood vessels	Kaposi's sarcoma
Hereditary hemorrhagic telangiectasia	Vasculitis
Blue rubber bleb nevi	Polyposis
Inherited defects of connective tissue	Ulcerative colitis and Crohn's disease
Ehlers-Danlos syndrome	Gastrointestinal tumors
Pseudoxanthoma elasticum	Drugs used to treat skin disease

TABLE 164-2 **Skin Abnormalities in Patients with Gastrointestinal Bleeding**

VASCULAR ABNORMALITIES The characteristic picture of hereditary hemorrhagic telangiectasia is of a familial pattern of epistaxis with telangiectases on mucosal surfaces (see Fig. 166-6) and arteriovenous malformations in multiple organs [8] (see Chap. 166). Hemorrhage from gastrointestinal lesions occurs in 10 to 40 percent of patients, usually from the stomach or duodenum, and at an average age of 55 years. Treatment includes low-dose estrogen/progestogen to reduce hemorrhage. Bipolar coagulation, argon, or neodymium:YAG laser ablation can be helpful in the treatment of local lesions. The benefits of embolization remain to be proven. Most cases of blue rubber bleb nevus syndrome are sporadic (see Chap. 103), but there are families with autosomal dominant inheritance. The venous malformations look and feel as their name suggests and project into the gut lumen, particularly that of the small intestine. In contrast to cutaneous lesions, they bleed easily, causing chronic anemia and, less commonly, acute hemorrhage. [9]

INHERITED DEFECTS OF CONNECTIVE TISSUE In the autosomal dominant vascular type of the Ehlers-Danlos syndrome, type IV, rupture of the bowel, often involving the sigmoid colon, accounts for one-quarter of all complications and 8 percent of all deaths. [10] Diverticula, and hiatus and inguinal hernias, may also occur (see Chap. 154). Thirteen percent of patients with pseudoxanthoma elasticum experience gastrointestinal bleeding, usually from the stomach. This bleeding is often the first clinical manifestation of the disease. Although treatment is conservative, surgery is effective when necessary. [11]

KAPOSI'S SARCOMA The gut, particularly the small intestine, is a common site for Kaposi's sarcoma (see Chap. 104). Involvement is commonly asymptomatic, but severe bleeding may occur.

DRUGS USED IN DERMATOLOGY Gastrointestinal bleeding in a patient with a dermatologic disease may be due to drug therapy. The systemic administration of glucocorticoids commonly causes dyspepsia; less commonly, it causes gastric erosions, ulceration, and hemorrhage. Methotrexate may cause enteritis, gastrointestinal ulceration, and hemorrhage.

Abdominal Pain

Skin signs may occasionally help in the diagnosis of abdominal pain (Table 164-3). Vasculitis, polyposis, inflammatory

bowel disease, and cancers have several possible dermatologic presentations.

Herpes zoster
Angioedema
Porphyria
Anderson-Fabry disease
Vasculitis
Henoch-Schönlein disease
Collagen vascular diseases

TABLE 164-3 **Skin Abnormalities in Patients with Abdominal Pain**

HERPES ZOSTER Involvement of the sensory roots of the vertebrae T6-L1 in herpes zoster may produce abdominal pain even before skin lesions appear. Occasionally, herpes zoster in the distribution of S2, S3, and S4 is associated with perineal pain and disturbances of urination and defecation (see Chap. 215).

ANGIOEDEMA Acute attacks of urticaria and angioedema may present as abdominal pain. Edema of the bowel wall and mucosal thickening, often in association with free peritoneal fluid, is evident ultrasonographically, which makes it possible to avoid unnecessary surgery in acute cases. [12] This is especially true in the autosomal dominant disorder hereditary angioedema where angioedema, usually without urticaria, may cause colicky abdominal pain and life-threatening laryngeal edema. Treatment of acute episodes is with injection of purified C1 inhibitor concentrate [13] (see Chap. 117).

VARIEGATE PORPHYRIA It is only in the rare variegate porphyria that skin involvement and attacks of abdominal pain coexist. The skin shows changes identical to those in porphyria cutanea tarda (see Chap. 149). Pregnancy or drugs such as estrogen and griseofulvin may precipitate acute attacks. Although the detection of urinary uroporphyrin and fecal protoporphyrin indicates the diagnosis, plasma fluorescence with emission maxima at 626 nm is more sensitive; it reveals the condition even in patients who are in remission. [14]

ANDERSON-FABRY DISEASE (ANGIOKERATOMA CORPORIS DIFFUSUM) A rare disease, Anderson-Fabry disease is an X-linked recessive multisystem lysosomal storage disorder caused by a deficiency of a-galactosidase A (see Chap. 151). Clinical signs and symptoms include severe, painful neuropathy; progressive renal, cardiovascular, and cerebrovascular dysfunction; and early death. Gastrointestinal symptoms include abdominal pain, postprandial cramps with delayed gastric emptying, and diarrhea. The diagnosis may be missed without the skin signs. Angiokeratomas may not appear until adolescence and, even then, can be subtle. Assay of a-galactosidase A is possible not only in established cases, but also before birth, and female carriers often identifiable. Treatment with intravenous infusions of a-galactosidase A is safe and efficacious. [15]

VASCULITIS (See Chap. 174 and Chap. 175.) Henoch-Schönlein purpura is palpable, especially on the legs and buttocks, and may occur in conjunction with joint swelling. Up to 76 percent of patients have gastrointestinal involvement, ranging from colicky abdominal pain, nausea, and vomiting to bloody diarrhea, intussusception, and pancreatitis. Renal involvement is common, especially in patients with bloody stools. [16] Upper gastrointestinal endoscopy reveals multiple raised erythematous lesions or ulceration that resolves after systemic treatment with glucocorticoids. [17] Acute involvement of vessels in the small and large intestine also occurs in collagen vascular diseases and may be fatal. Chronic obliteration of small intestinal vessels can result in malabsorption, and impairment of motility can cause abdominal pain. [7] Malignant atrophic papulosis is an idiopathic systemic obliterative vasculopathy (see Chap. 101). Recurrent crops of porcelain-white atrophic papules with an elevated erythematous border are the characteristic skin lesions. Gut vessels are involved in half of the cases, [18] and this involvement manifests itself clinically as bleeding, abdominal pain, diarrhea, malabsorption, and bowel perforation with peritonitis. Patients usually die of cerebrovascular bleeding or sepsis following perforation of the gut, but skin lesions may have been present for years with no other apparent disease.

POLYPOSIS True polyps are rare except in the colon and rectum. Polyp-like lesions that are hamartomatous or inflammatory occur in all parts of the gut. The term *hamartoma* implies a non-neoplastic tumor composed of tissue elements normally present in that organ. The hamartomatous polyposis syndromes (e.g., Peutz-Jeghers, Cronkhite-Canada) should be distinguished from the adenomatous polyposis syndromes (e.g., Gardner's). All may have dermatologic associations. In many of these syndromes, hamartomatous polyps of the gastrointestinal tract coexist with adenomas, and adenomas may develop within hamartomatous polyps. Either situation may contribute to the frequent occurrence of adenocarcinoma in most of these syndromes. [19]

Gardner's syndrome An autosomal dominant disorder, Gardner's syndrome is characterized by cutaneous cysts and premalignant adenomatous polyps, particularly in the colorectum. Duodenal and hepatic carcinoma has also occurred in conjunction with the disorder. The cutaneous lesions frequently predate the gastrointestinal lesions and include solitary or multiple epidermoid cysts, fibromas, lipomas, pilomatricomas, facial osteomas, and distinctive ocular lesions. [20] Regular colonoscopy is mandatory for patients at risk.

Peutz-Jeghers syndrome Like Gardner's syndrome, Peutz-Jeghers syndrome is an autosomal dominant condition. In the latter syndrome, small darkly pigmented macules occur around the mouth, on the lips and buccal mucosa, and on the digits (see Chap. 90). A histologically unique type of hamartomatous polyp occurs, mainly in the small intestine, which predisposes to recurrent intussusception in the majority of cases. Bleeding is relatively rare, but up to 2 percent of patients develop adenocarcinoma of the stomach, duodenum, and colon. [19] There is also an increased risk of malignancy in general.

Cronkhite-Canada syndrome In Cronkhite-Canada syndrome, a rare, nonfamilial disease, there is patchy alopecia and characteristic, but not diagnostic, nail changes or nail loss. Inflammatory polyps are present in the stomach and bowel, and abdominal pains with a severe protein-losing enteropathy are common. The hair and nail changes may precede the gastrointestinal symptoms. [19]

Neurofibromatosis type 1 Neurofibromas can involve any portion of the gastrointestinal tract (see Chap. 190). Leiomyomas and other tumors (both benign and malignant) also occur.

Ulcerative colitis Inflammatory polyposis occurs in ulcerative colitis. P> **INFLAMMATORY BOWEL DISEASE:**

ULCERATIVE COLITIS AND CROHN'S DISEASE Both ulcerative colitis and Crohn's disease can present with abdominal pain, gastrointestinal bleeding, or diarrhea. Ulcerative colitis predisposes to carcinoma of the colon. The skin complications of the two diseases are similar, although some occur with different frequencies; in particular, granulomas are much more common in Crohn's disease (Table 164-4).

Pyoderma gangrenosum
Erythema nodosum
Aphthous ulcers
Malnutrition
Rashes at ileostomy and colostomy sites
Metastatic cutaneous Crohn's disease

TABLE 164-4 **Skin Lesions in Ulcerative Colitis and Crohn's Disease**

Pyoderma gangrenosum (See Chap. 98.) Up to one-half of patients with pyoderma gangrenosum may have inflammatory bowel disease, although only 12 percent of patients with ulcerative colitis and 2 percent of patients with Crohn's disease will develop the condition. [21] The severity and extent of ulceration in pyoderma gangrenosum may be linked to the activity of the underlying disease, and pyoderma gangrenosum can heal with effective treatment of the underlying bowel disease.
Granulomas Oral granulomatous nodules are common in Crohn's disease, where they may coalesce to give a “cobblestone” appearance. Crohn's disease is one cause of granulomatous cheilitis (see Chap. 112), which may predate bowel disease by several years. Granulomas may also occur in the perineum, at colostomy and ileostomy sites (see Chap. 129), and in association with scars, sinuses, and fistulas. Very rarely, granulomas occur at sites not contiguous with the bowel, such as the trunk and limbs: the so-called “metastatic” cutaneous Crohn's disease. [22]
Erythema nodosum Ulcerative colitis and Crohn's disease are an uncommon cause of erythema nodosum.
Aphthous ulcers In inflammatory bowel disease or celiac disease, aphthous ulcers may be the presenting feature. Patients with both dermatitis herpetiformis and celiac disease are more likely to be affected than those with dermatitis herpetiformis alone. [23]
Malnutrition Signs of nutritional deficiencies can arise from inflammatory bowel disease or its treatment with elemental diets (see below).
Skin disorders in colostomy and ileostomy sites (See Chap. 129.)
PANCREATITIS Bruising of the skin around the umbilicus (Cullen's sign) or in the flanks (Grey Turner's sign) are well-known features of acute pancreatitis, but occur in less than 3 percent of cases. [24] Subcutaneous fat necrosis is even rarer. Chronic pancreatitis may cause tender, subcutaneous nodular areas of fat necrosis that may ulcerate (see Chap. 109).
GASTROINTESTINAL CANCER AND OTHER MALIGNANCIES Many skin changes occur in association with gastrointestinal malignancies. Dry skin (acquired ichthyosis) with cracking and eczematization (“eczema craquelé”) and hyperpigmentation may occur in malignancy, as well as in malabsorption syndromes (see below).
Metastases Any tumor may metastasize to the skin. The scalp is a common site. Metastases at the umbilicus (Sister Joseph nodules) occur, particularly with carcinoma of the stomach, colon, or ovary (Fig. 164-2).

FIGURE 164-2 Umbilical metastasis (Sister Joseph nodule) from intraabdominal adenocarcinoma.

Dermatomyositis (See Chap. 172.) Adult onset dermatomyositis is associated with underlying malignant disease in 32 percent of cases. [25] Pancreatic, gastric, and colorectal cancers are the third most common after bronchogenic and ovarian cancers in Europe and North America. In China, nasopharyngeal carcinoma is a common tumor and also frequently occurs in association with dermatomyositis. The rash and myopathy can regress after removal of the tumor, and, because 60 percent of patients develop cancer after the appearance of dermatomyositis, its recognition is potentially life-saving.
Acanthosis nigricans (See Chap. 185.) In two-thirds of patients with acanthosis nigricans and cancer, the tumor is gastric. The changes may regress if the tumor, usually an adenocarcinoma of the stomach or bowel, is removed.
Hypertrichosis lanuginosa Excessive growth of lanugo hair is a rare complication of gastrointestinal cancer (see Chap. 184).
Other skin changes Diverse cutaneous paraneoplastic syndromes may arise from underlying tumors. [26] They may precede, coincide with, or follow the diagnosis of cancer and often indicate a poor prognosis. They include reactive erythemas, such as erythema gyratum repens and necrolytic migratory erythema; the vascular dermatoses (Trousseau's syndrome); and papulosquamous disorders, including tripe palms (Fig 164-3), palmar hyperkeratosis, acquired ichthyosis, pityriasis rotunda, Bazex's syndrome, florid cutaneous papillomatosis, the sign of Leser-Trelat, and extramammary Paget's disease.

FIGURE 164-3 Patient with “tripe hands” due to adenocarcinoma of the jejunum.

Some gastrointestinal tumors have specific dermatologic signs. (See Carcinoma of the Esophagus, above.) For example, carcinoma of the stomach may result from atrophic gastritis and may lead to pernicious anemia. Patients with pernicious

anemia may develop vitiligo and alopecia areata. Small bowel tumors (see Chap. 170) produce a variety of hormones and vasoactive amines of which the best characterized is serotonin. The most common tumors are in the appendix, rectum, and ileum, where they are usually multiple. Episodic flushing (Fig. 164-4), wheezing, or diarrhea does not occur until the vasoactive amines reach the systemic circulation. Therefore, flushing usually indicates metastasis to the lymph nodes or liver or a primary tumor at a different site (e.g., lung or ovary). [27]

FIGURE 164-4 Facial rash in a patient with liver metastases from a carcinoid tumor of the small bowel.

One-third of patients with systemic mastocytosis have gastrointestinal involvement. Symptoms include nausea, vomiting, abdominal pain, malabsorption, diarrhea, esophagitis, esophageal strictures, peptic ulceration, and gastrointestinal bleeding (see Chap. 163). Patients with more aggressive disease may develop hepatosplenomegaly with ascites and lymphadenopathy. [28] Skin signs occur with the potentially malignant forms of adenomatous and hamartomatous polyposis and in ulcerative colitis. Paget's disease (see Chap. 87) in the perianal skin is often associated with an underlying carcinoma. The tumor is not always in adjacent tissue, but most commonly arises from rectal mucosa. Migratory superficial thrombophlebitis occurs in association with neoplasia, particularly carcinoma of the pancreas. Glucagonoma (see Chap. 184) is one of the amine precursor uptake and decarboxylation (APUD) cell tumors. Those that produce glucagon usually arise in the islet cells of the pancreas, are often malignant, and generally occur in association with a distinctive necrolytic migratory erythema.

Diarrhea and Malabsorption

Some of the skin associations of gastrointestinal disease that produce diarrhea have already been mentioned. If steatorrhea is present, the clinician should consider additional possibilities. Many skin changes occur in association with malabsorption—some as a result of it, some because of a disease process that affects the bowel as well as the skin. In addition, skin disease may be the cause of malabsorption.

SKIN CHANGES THAT RESULT FROM MALABSORPTION The various malabsorption syndromes have an impact on the skin and vice versa (Table 164-5). Skin changes due to malabsorption can be either nonspecific (e.g., those that occur as a result of wasting illnesses) or well defined (e.g., the rash of zinc deficiency) (see Chap. 146).

Skin changes due to malabsorption
Nonspecific
Acquired ichthyosis and pruritus
Hair and nail changes
Hyperpigmentation
Skin texture and elasticity
Eczematous and psoriatic rashes
Jejunoileal and jejunocolic anastomoses
Specific nutrients
Zinc
Essential fatty acids
Vitamins
Malabsorption due to skin disease
Dermatogenic enteropathy
Collagen vascular disease
Dermatitis herpetiformis and celiac disease

TABLE 164-5 **Malabsorption and Skin Disease**

Nonspecific cutaneous signs

Acquired Ichthyosis and Pruritus Ill health is often associated with pallid, dry, rough, scaly skin that is usually itchy. Eczema (asteatotic eczema, or eczema craquelé) may develop. The presence of this sign in patients with malabsorption, cancer, chronic renal disease, or chronic hepatic disease is nonspecific. Some patients itch without any visible abnormality of their skin.

HAIR (See Chap. 71.) Malnutrition or starvation causes hair to grow more slowly, fall out more easily, and become grey. The hair root diameter and the proportion of anagen hairs decrease. Lanugo hair may develop. Kwashiorkor, a form of protein-energy malnutrition, causes hair to become hypopigmented, varying from red-yellow to white, and curly. There may be alternating bands of pale and dark hair. [29] Total parenteral nutrition has been associated with hair loss and pigmentation of remaining hair. Type 2 vitamin D–dependent rickets is associated with alopecia totalis.

NAILS (See Chap. 72.) In conditions associated with malabsorption or starvation, nails grow more slowly, become brittle, and may develop fissures. [29], [30] Multiple pigmented bands may appear. Koilonychia in malnourished patients usually indicates iron deficiency, even without anemia (see below). White nails, thought to be due to selenium deficiency, have occurred with total parenteral nutrition.

SKIN COLOR Malabsorption or starvation can lead to hyperpigmentation, which is most pronounced on the face. Vitamin B_{12} deficiency causes pigmentation of the distal extremities in a glove and stocking distribution. The facial and limb eruption of pellagra can be deeply pigmented. Diffuse hyperpigmentation occurs in folate deficiency. Kwashiorkor produces generalized depigmentation.

SKIN TEXTURE AND ELASTICITY In the course of wasting diseases, the skin becomes thinner, dry, and less elastic. Vasoconstriction leads to a cold, cyanotic appearance.

JEJUNOILEAL AND JEJUNOCOLIC ANASTOMOSES Patients with gross obesity occasionally undergo treatment by gastric bypass or reduction. Dryness of the skin, hair loss, and inflammatory and vasculitic skin lesions have occurred,

together with recurrent fever and arthralgia. “Bowel bypass syndrome without bowel bypass” is recognized as the same constellation of symptoms, but with other gastrointestinal disorders. [31]

Cutaneous effects of malabsorption of specific nutrients (See Chap. 145.) Deficiencies in various nutrients can have cutaneous effects. [29] For example, vitamin deficiency can follow intestinal surgery, pancreatic disease, malabsorption syndromes, and malnutrition, including that associated with alcoholism. The effects of such deficiencies vary:

1. Vitamin A deficiency causes xerotic wrinkled skin covered with fine scales, occasionally accompanied by deep erosions (dermomalacia).
2. Deficiency of vitamin B_3 causes pellagra with its triad of diarrhea, dermatitis, and dementia. The cutaneous changes may overlap with essential fatty acid deficiency (see below).
3. Vitamin B_{12} (cyanocobalamin) deficiency is common in ileal malabsorption syndromes such as pancreatic disease and occurs rarely in dermatitis herpetiformis with a gluten-sensitive enteropathy. There is a symmetric “glove and stocking” hyperpigmentation, but a lemon yellow pallor to the skin elsewhere.
4. The follicular keratoses, hemorrhage, and corkscrew hairs associated with a vitamin C deficiency are described in Chapter 145.
5. Malabsorption of vitamin K occurs in obstructive jaundice and leads to impaired coagulation, resulting in cutaneous hemorrhage with ecchymoses and purpura.

Theoretically, drugs used for dermatologic diseases such as methotrexate, a folate antagonist, can exacerbate folic acid deficiency. A diffuse hyperpigmentation, cheilitis, and perineal ulceration or dermatitis can occur in deficiency states. Iron deficiency presents with angular stomatitis, smooth painful tongue, and fragile/brittle nails, which have longitudinal ridging and lamellation. In marked iron deficiency anemia koilonychia, a spoonlike convexity of the nails, develops. Hair changes include diffuse scalp alopecia with brittle, split hairs. All take a long time to resolve on replacement therapy. The association of pruritus with iron deficiency has not been conclusively demonstrated. Zinc deficiency can result from acrodermatitis enteropathica, malabsorption, or a lack of zinc in long-term parenteral nutrition (see Chap. 146). Acrodermatitis enteropathica usually presents at weaning or in very early infancy with dermatitic or vesicobullous lesions of the hands, on the feet, and around the mouth and anus, together with progressive alopecia and “failure to thrive.” Linoleic acid is metabolized to arachidonic acid, which is then converted to prostaglandins and leukotrienes. In linoleic acid deficiency, oleic acid is used as the substrate. Deficiency occurs due to malabsorption, malnutrition, bypass surgery for obesity, biliary disease, and, most important, parenteral nutrition. The epidermis becomes hyperkeratotic, resulting in diffuse xerosis, scale, and erythema with brittle nails and capillary fragility. Clinically, the topical application of linoleic acid, such as that found in sunflower seed oil, may improve the skin. There is diffuse hair loss with hyperpigmentation of remaining hair.

MALABSORPTION DUE TO SKIN DISEASE

Malabsorption in collagen vascular diseases Malabsorption can result from poor intestinal peristalsis in systemic sclerosis or chronic obliteration of mesenteric vessels in polyarteritis and other forms of vasculitis. Of patients with diffuse scleroderma and systemic sclerosis, 8 percent will develop malabsorption or recurrent intestinal pseudo-obstruction, usually within 3 years of disease onset. [32] Vasculopathy interferes with peristalsis and leads to malabsorption by allowing bacterial colonization higher up the bowel than is usual. In malabsorption syndromes that do not respond to antibiotic therapy, a small bowel biopsy may be appropriate. Resection or bypass surgery of affected segments or placement of enterostomy tubes for feeding or decompression may be necessary. [7]

Dermatitis herpetiformis The gastrointestinal associations of dermatitis herpetiformis, including celiac disease, malabsorption, and gastrointestinal lymphoma, are discussed in Chapter 67.

SKIN LESIONS DUE TO HEPATOBILIARY DISEASE

When skin lesions occur in association with liver disease, they are usually not specific to a particular hepatic pathology. The most florid cutaneous lesions generally appear in patients with chronic active hepatitis or alcoholic liver disease, but the changes seen in the skin, nails, and hair of patients with hepatobiliary disease may also occur in the absence of such disease or in association with physiologic states (Fig. 164-5). For example, spider nevi may occur in healthy children and in pregnant women. It is also possible for there to be no visible skin changes in patients with severe or advanced liver disease, and dramatic cutaneous manifestations may develop in those with minimal hepatic dysfunction. Severe itching may antedate other features of biliary cirrhosis by months or years.

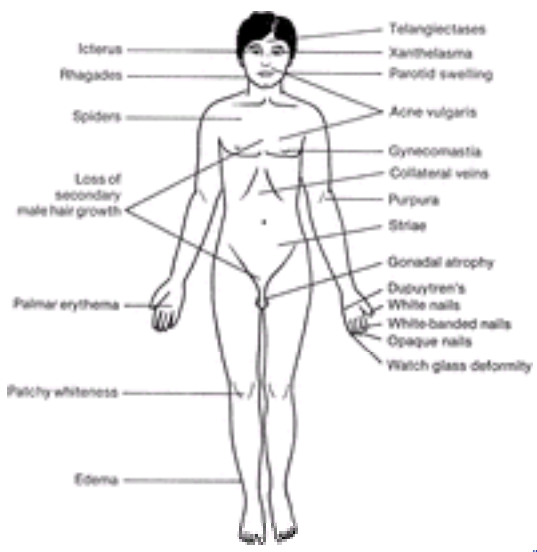

FIGURE 164-5 The main skin changes in liver disease.

Jaundice

In patients with jaundice, or icterus, the raised plasma level of bilirubin produces a generalized yellow or ocher coloration of the skin, mucous membranes, and other body tissues. Both jaundice and pigmentation are most prominent in disease states that produce extrahepatic biliary obstruction and in primary biliary cirrhosis. Involvement of the sclerae differentiates jaundice from other causes of skin pigmentation, including olive or sallow complexions, carotenemia, the yellow skin pigmentation produced by quinacrine and busulfan, and lycopenemia due to the ingestion of tomato juice.

PATHOGENESIS A functional classification of jaundice appears in Table 164-6. Jaundiced skin, varying in hue from faint golden to dark green-yellow, results from increased local cellular or connective tissue binding of bilirubin or its metabolites. Bilirubin has an affinity for elastin, but circulates almost exclusively as a tightly bound complex with albumin. Eighty-five percent of bilirubin comes from the degradation of heme, the remainder from other heme-containing proteins, such as myoglobin and cytochromes. Jaundice results from an imbalance between the tissue production and hepatic clearance of bilirubin.

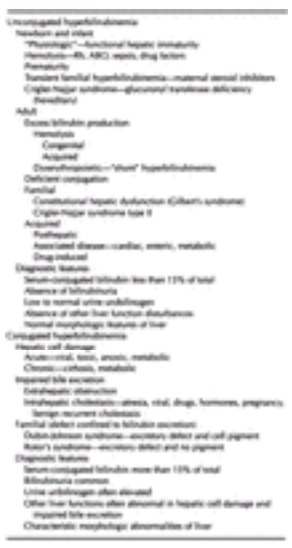

TABLE 164-6 **Functional Classification of Jaundice**

Tissue-serum equilibration is slow, and the intensity of clinical jaundice often fails to reflect the concurrent serum bilirubin level. Hyperbilirubinemia may, therefore, antedate the onset of detectable jaundice, and jaundice may persist despite falling or normal serum bilirubin levels. The correlation between skin color and serum pigment levels is especially poor in newborns. A further discrepancy between tissue and serum pigment levels in infants may result from the administration of drugs that uncouple protein-bound bilirubin and favor its passage into body tissues. [33] Clinically detectable jaundice appears when a sufficient amount of bilirubin has become tissue-bound, generally when total serum levels have exceeded 3.0 mg/dL in adults or 8.0 mg/dL in infants.

CLINICAL FEATURES Careful inspection of the sclerae or the mucous membrane of the soft palate in natural or bluish light are the best clinical methods for detecting jaundice. Prolonged and deep jaundice produces a greenish-tan quality. Degradation of bilirubin occurs with exposure to ultraviolet radiation, which is the rationale for phototherapy to prevent kernicterus in severe neonatal jaundice. The intensity of jaundice and levels of serum bilirubin in patients with biliary atresia, acquired bile duct obstruction, or defective bilirubin conjugation tend to stabilize despite continued pigment production. The urine becomes dark yellow and then brown as conjugated serum bilirubin rises. Hyperbilirubinemia is not a feature of unconjugated hyperbilirubinemic states. Because most of the brown color of normal feces is produced by urobilins derived from degradation of bilirubin in the intestine, the jaundice of impaired bilirubin excretion or bile obstruction is associated with “clay-colored” stools.

DIAGNOSIS The diagnosis of jaundice requires a methodical consideration of four important questions (see Table 164-6):

1. Is the jaundice due to biliary tree obstruction?
2. Is there evidence of chronic liver disease?
3. Are alcohol or drugs responsible?
4. Is there evidence of hemolysis?

A careful history and clinical examination should indicate the cause in 60 to 70 percent of cases; review of standard laboratory tests should afford a diagnosis in another 10 to 15 percent. [33] Additional investigations may include a liver ultrasound examination (especially if the clinician suspects an obstruction), abdominal computed tomography (which is not as accurate as ultrasonography in detecting cholelithiasis), and endoscopic investigation of the biliary tree and pancreatic ducts. In the absence of obstruction, serologic tests such as those for hepatitis or autoantibodies may be necessary

TREATMENT AND COURSE The jaundice of biliary obstruction resolves after the obstruction is relieved. Jaundice in patients with acute hepatitis resolves spontaneously. The jaundice of chronic liver disease may improve after transplantation. Jaundice in chronic active hepatitis and, occasionally, in acute alcoholic hepatitis, can decrease after glucocorticoid therapy. Neonatal jaundice may respond to phototherapy. Infants with the Crigler-Najjar syndrome, in which benign unconjugated hyperbilirubinemia occurs in association with otherwise normal liver function, have received treatment with a combination of phototherapy and microsomal enzyme inducers, such as phenobarbital. This treatment decreases hyperbilirubinemia. [34]

Melanosis and Other Pigmentary Changes

In addition to jaundice, both diffuse and circumscribed pigmentary changes may occur in chronic liver disease. A diffuse muddy gray color in patients with long-standing cirrhosis is due to basal cell melanin.

Melanosis is common in primary biliary cirrhosis and may be an early presenting sign. It initially involves exposed areas, but it gradually becomes generalized. Blotchy, circumscribed areas of dirty brown pigmentation are also occasionally evident. Accentuation of normal freckling and areolar pigmentation can occur. Localized linear pigmentation may appear in the creases of the fingers and palms. Pigmentation resembling chloasma may localize to the perioral and periorbital areas. Guttate hypomelanosis, a condition in which small white macules, sometimes with a central spider, appear on the skin of the buttocks, back, thighs, and forearms, may occur in cirrhosis and, rarely, in primary biliary cirrhosis. [35]

The generalized metallic gray or bronze-brown color of the skin in hemochromatosis is so striking that its alternative name is bronzed diabetes. There is accentuation over sun-exposed and traumatized skin, and occasionally there is buccal mucosal and conjunctival pigmentation. Clinical features alone may not distinguish alcoholic cirrhosis without iron overload from that of constitutional hemochromatosis. [36]

The yellow and orange lesions of dermal, subcutaneous, and tendon xanthomas and also xanthelasma are common in primary biliary cirrhosis and can be extensive (see Chap. 150).

With pellagra, lichenified, hyperpigmented skin in sun-exposed sites may develop in patients with alcoholic liver disease (see Chap. 145).

The etiology and pathogenesis of hyperpigmentation in chronic liver disease remains obscure. The cutaneous pigmentation in primary biliary cirrhosis is due predominantly to the presence of excess melanin with no stainable iron. In hemochromatosis, cutaneous pigmentation results not only from the presence of hemosiderin in the skin, but also from excess melanin. After phlebotomy, histologic siderosis and clinical skin pigmentation decrease, even though melanosis remains histologically.

The differential diagnosis of pigmentation includes primary adrenal insufficiency (Addison's disease) and some pituitary tumors that produce pigmentary changes of the skin and mucous membranes. Chronic diseases, such as lymphoma, tuberculosis, and malabsorption syndromes (see above), may produce both pigmentation and hepatic dysfunction.

Vascular Changes

Patients with chronic liver disease often have telangiectatic changes, mainly on light-exposed skin. Numerous tiny telangiectases sometimes give the impression of a diffuse, almost exanthematic redness. They are known as “dollar paper markings” after the small threads visible in paper money held up against the light. They fade on pressure with a glass slide and rarely pulsate.

SPIDER NEVUS Although it may also appear in alcoholics without liver involvement, the spider nevus, or spider angioma, is the most representative and classic vascular lesion of chronic liver disease. Clinically, it has a central arteriole represented by a red point, often slightly elevated, from which numerous small, twisted vessels radiate (Fig. 164-6). Spider nevi range in size from a pinhead to 2 cm. When sufficiently large, they can be seen or felt to pulsate, especially when pressed with a glass slide. Pressure over the central arteriole causes blanching of the whole lesion. Spider nevi are characterized by the abnormal permanent dilatation of end vessels. These are mainly end venules, although capillaries and arterioles of the subpapillary plexus can be involved. Histologically, spider nevi consist of a central ascending arteriole ending in a thin-walled ampulla beneath the epidermis from which small arterial branches radiate outward into the papillary dermis. [37]

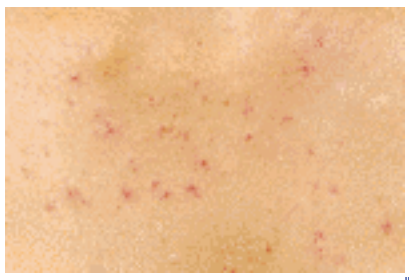

FIGURE 164-6 Spider nevi in a patient with cirrhosis.

Spider nevi are most common on the face, neck, forearms, hands, and upper part of the chest (i.e., over the region drained by the superior vena cava; see Fig. 164-6). Only rarely are they found in the mucous membranes of the nose, mouth, and pharynx. They may be seen in 10 to 15 percent of healthy adults and not infrequently in children, where they tend to affect the hands and fingers. They may appear in large numbers during pregnancy, but usually disappear after parturition. They may also be seen in patients who have thyrotoxicosis and in women who take oral contraceptives. In patients with liver disease, spider nevi may regress with improvement of the underlying condition, although they are more likely to persist. Spider nevi are more common in patients with alcoholic cirrhosis than in those with viral or idiopathic cirrhosis. In alcoholic cirrhosis, they are associated with the presence of esophageal varicosities, and their presence may be a useful predictive marker for the future risk of esophageal bleeds. [38] Traditionally, vascular spider nevi and palmar erythema (see below) have been attributed to estrogen excess, particularly because they also occur during pregnancy and because estrogens have an enlarging, dilating effect on the spiral arterioles of the endometrium. This would also explain the cutaneous spider nevi seen in men receiving estrogen therapy for prostatic cancer, although such nevi are very rare. Patients with nonalcoholic cirrhosis have been shown to have higher plasma estradiol:testosterone ratios and substance P levels than healthy controls do, and the substance P levels may have an etiopathogenic role. [39] In alcoholic cirrhosis patients, the presence of alcoholism and impaired liver function (elevated serum bilirubin) are both important predictors of the presence of spider nevi. [40]

PALMAR ERYTHEMA There are two clinical forms of palmar erythema or “liver palm.” In the first (Fig. 164-7), there is an exaggeration of normal mottling; the hands are warm and bright red, especially on the palm, the dorsae of the hands, the fingers, and the nail bases. In the second, there is well-demarcated redness of the hypothenar eminence that

gradually spreads to the fingertips and then to other areas of the palm. The soles of the feet may show similar changes.

FIGURE 164-7 Palmar erythema showing the characteristic blotchy redness.

The mottling blanches on pressure and, when a glass slide is pressed on the palm, it flushes synchronously with the pulse rate. Patients may complain of throbbing or tingling. “Liver palms” occur not only in liver disease, but also in pregnancy and thyrotoxicosis. An accompanying change in those with cirrhosis is atrophy of the muscles of the thenar and hypothenar eminence. This is of myogenic rather than neurogenic origin and not considered to be related to hormonal factors. [41]

OTHER VASCULAR CHANGES Corkscrew scleral vessels (tortuous small arteries that traverse the margins of the ocular sclerae) have developed in patients with chronic liver disease. Cardiac output frequently increases in patients with cirrhosis, and total peripheral resistance may decrease. Arteriovenous shunting may occur within the lungs (the hepatopulmonary syndrome [42], liver, and extremities. These arteriovenous malformations, including spider nevi, may regress after transplantation. [43] Portal-systemic collateral vessels may develop and may be an important clue to the existence of portal hypertension. Often, the umbilical vein is dilated and visible in the epigastrium, an occurrence more common than the well-recognized, but rare, caput medusae. Purpuric lesions, ranging from pinpoint-sized spots to large ecchymoses, occur mainly on the lower limbs. They are secondary both to acquired clotting defects such as thrombocytopenia and to vascular fragility. They may be transient and recurrent, and they are sometimes accompanied by follicular hyperkeratosis. [37] Bruising is common at venipuncture sites.

Hormone-Induced Changes of the Skin (See Chap. 169.)

With liver disease, loss of forearm, axillary, and pubic hair may occur in both sexes. Men may experience a decrease in the rate of growth of facial hair, pectoral alopecia, and female pubic hair distribution, as well as loss of libido, testicular atrophy, and oligospermia. Striae distensae occur in both men and women in association with chronic liver disease (Fig. 164-8). Gynecomastia, together with Dupuytren's contracture and swelling of the parotid gland, is also associated with cirrhosis. Many of these changes occur more commonly in those with alcoholic cirrhosis. Patients with chronic alcoholism also develop a “pseudo-Cushing's syndrome,” even in the absence of liver disease; signs include facial mooning, truncal obesity, and proximal muscle wasting. [37] These changes may regress if the patient discontinues the use of alcohol.

FIGURE 164-8 Widespread striae in a 16-year-old boy with chronic active hepatitis.

Cutaneous Manifestations of Primary Biliary Cirrhosis

The basis for a diagnosis of primary biliary cirrhosis is a typical clinical picture of a middle-aged female with jaundice and pruritus, liver function test results that suggest cholestasis, the presence of antimitochondrial antibodies, and histologic changes in the liver associated with inflammatory duct destruction with fibrosis and cirrhosis. Several cutaneous changes may be evident in addition to the skin changes usually associated with liver disease.

The combination of the CREST syndrome (i.e., *c*alcinosis cutis, *R*aynaud's phenomenon, *e*sophageal dysfunction, *s*clerodactyly, and *t*elangiectasia) and primary biliary cirrhosis occurs more often than would be expected by chance and has been termed Reynold's syndrome (see Chap. 173). Patients with this combination have a higher incidence of anticentromere antibodies (especially the antiprotein C isotype) and Sjögren's syndrome, as well as, to a lesser extent, calcinosis cutis and telangiectasia. [44]

Lichen planus has a well-recognized association with primary biliary cirrhosis and may occur in either the presence or the absence of penicillamine treatment for primary biliary cirrhosis (see Chap. 49). It can resolve following liver

transplantation. [45]

Cutaneous xanthomas also occur with primary biliary cirrhosis. Rarely, both lichenoid and xanthomatous changes appear in the same lesion [46] (see Chap. 150).

Miscellaneous Changes of the Skin

Porphyria cutanea tarda and erythropoietic protoporphyria are considered in Chapter 149. Liver disease is frequently associated with the former, and the latter may rarely seriously damage the liver.

Nail Changes in Liver Disease (See Chap. 72.)

The nails of many patients with liver disease are normal, and nail abnormalities are a less constant physical sign than spider nevi or liver palms. In patients with cirrhosis, however, a number of changes may occur: clubbing, curved nails, thickened nails, longitudinally ridged nails, white nails, watch-glass deformity, flattened nails, white bands, striations, and brittleness. [30]

Clubbing of the fingers is quite common in all forms of cirrhosis, especially primary biliary cirrhosis and chronic active hepatitis. Anatomically, there is an increased thickness of the nail bed. This is due to edematous infiltration of the soft parts of the terminal segment followed by hyperplasia of the dermal fibrovascular tissue with increased vascularity. [30]

White nails may occasionally be seen in healthy individuals or in association with systemic disease, including congestive heart failure, diabetes, cryoglobulinemia, Raynaud's syndrome, and systemic sclerosis. However, intensely white nails are characteristic of cirrhosis (Fig. 164-9 and Fig. 164-10), although their presence does not correlate with the severity of cirrhosis. Terry (after whom the sign is named) reported white nails in 82 of 100 patients with cirrhosis. [47] The reason for the whiteness, which does not alter with nail growth or with compression of digital vessels, is likely to be the opacity of the nail plate itself. In severe cases, the condition may affect all fingernails; almost the entire nail bed may show a ground glass–like opacity (see Fig. 164-10), although there may be a pink zone at the distal edge of the nail. Thumbs and forefingers are often most affected. The so-called watch-glass deformity may accompany white nails (see Fig. 164-9).

FIGURE 164-9 Flat white nails with slight convex watch-glass deformity, showing a distal pink band in a patient with liver disease.

FIGURE 164-10 Terry's white nails in a patient with cirrhosis.

Azure lunulae, a bluish color of the lunular portion of nails, occur in hepatolenticular degeneration (Wilson's disease). Azure lunulae and corneal changes resembling Kayser-Fleischer rings may also be evident in patients with argyria or following treatment with busulfan or antimalarials. [30]

The characteristic nail changes of lichen planus, including longitudinal ridging, pterygium formation, and permanent nail loss, occur both with and without skin changes in primary biliary cirrhosis (see Chap. 72).

Splinter hemorrhages and hypertrophic osteopathy also occur in cirrhosis. Flat or spoon nails are less common in patients with liver disease. The nails are flat or concave, pale in color, and frequently show longitudinal ridging. In hemochromatosis, koilonychia is probably the most common of the nail abnormalities, but it is not related to anemia. [30]

Itching

One of the most common and most distressing symptoms of hepatobiliary disease is pruritus. It may be mild and transient or so severe and prolonged that it dominates the clinical picture of the disease. Pruritus often complicates those conditions causing cholestasis, but less commonly occurs in diseases such as chronic hepatitis C infection in which cholestasis is not as clinically prominent. In viral hepatitis, itching is frequently missed as an early sign of the disease, but it occurs in the later, icteric phase. Some drugs, especially erythromycin, oral contraceptives, phenothiazines,

chlorpropamide, para-aminosalicylic acid, and nitrofurantoin, may also induce cholestasis accompanied by pruritus. Pruritus is the presenting symptom in more than 50 percent of cases of primary biliary cirrhosis and may precede jaundice by months or even years.

Itching in hepatobiliary disease may be transient or continuous and may occur without jaundice. Although usually most marked on the extremities, severe pruritus may affect the trunk; however, it only rarely involves the neck and face, and hardly ever involves the genitalia. Pruritus may be debilitating in patients with primary biliary cirrhosis, mechanical biliary obstruction, or intrahepatic obstruction. There is little correlation between the severity of cholestasis and the severity of perceived pruritus, and a spontaneous decrease in the intensity of pruritus may signal the development of hepatocellular failure rather than improvement. Scratching does not relieve the pruritus of cholestasis, and there may be no visible skin change except scratch marks and excoriations. In chronic pruritus of cholestasis, lichenified plaques or nodular prurigo occur. Histologically, the changes are nonspecific.

PATHOGENESIS OF PRURITUS (See Chap. 41.) The physiologic basis of the pruritus of cholestasis is still not completely understood. Although retained cutaneous bile acids have long been implicated, the poor correlation between the plasma level of bilirubin and the severity of pruritus, and the lack of convincing evidence that bile acids can induce the pathophysiologic changes of pruritus suggest that they do not have a direct role. However, the partial relief of itching by bile salt chelating resins and the disappearance of pruritus when liver cells fail suggest that the liver manufactures at least one of the agents contributing to pruritus. It is well recognized that opiate agonists such as morphine induce pruritus. Animal studies show that the intracerebral presence of morphine induces pruritus that is reversed by the opiate antagonist nalaxone, [48] confirming that opiate agonists induce scratching of central origin. In addition, the administration of the opioid antagonist nalmefene to patients with primary biliary cirrhosis produces a reaction similar to that of opiate withdrawal, and the injection of plasma from patients with primary biliary cirrhosis into monkeys produces pruritus. Taken together, these studies suggest that opioidergic tone increases in cholestasis. [48] These studies do not indicate which endogenous opioid receptor ligands may contribute to the pruritus of cholestasis or whether the agents responsible for increased opioidergic tone originate peripherally (e.g., in the liver) or centrally. They do, however, suggest less empirical therapies for the treatment of the pruritus of cholestasis.
MANAGEMENT Pruritus rapidly decreases when cholestasis secondary to mechanical bile duct obstruction is relieved. Drugs to relieve cholestasis such as ursodeoxycholic acid do not consistently relieve pruritus, nor do the anion exchange resins cholestyramine and cholestipol, which are thought to bind intestinal pruritogens and prevent them making their way to the skin. Hepatic enzyme inducers, including phenobarbital and rifampicin, may induce the metabolism of pruritogens: the latter has been shown to be relatively efficacious in randomized controlled trials. [49] Antihistamines or glucocorticoids given topically, although frequently prescribed, have not been proven to be efficacious. Trials of plasmapheresis and charcoal hemoperfusion are inconclusive. Sedatives, including phenobarbital, benzodiazepines, and sedating antihistamines, may help in patients prepared to tolerate the sedation. Neurotransmitter receptor antagonists such as oral nalmefene may be useful in the long-term control of the pruritus of cholestasis, [50] and naloxone administered IV has been shown to be efficacious for short-term use in a randomized controlled trial. [51] Naltrexone is an orally administered alternative, [52] but has been associated with hepatotoxicity. Miscellaneous therapies, including androgens, lidocaine, and ultraviolet light, are often tried in clinical practice.

Hepatitis and the Skin

Cutaneous striae may appear in patients with chronic hepatitis, whatever the underlying cause and even before glucocorticoid therapy (see Fig. 164-8). Pyoderma gangrenosum, urticaria, vasculitis, acne, scleroderma, and splinter nail hemorrhages occur, depending on the underlying cause of the hepatitis.

The clinical features of infection with the different hepatotrophic viruses that cause acute viral hepatitis are often so similar as to be indistinguishable. Specific diagnosis requires serologic testing. In the pre-icteric phase, nonspecific malaise, lethargy, nausea, and abdominal pain occur. In the early phase, a discrete, transient, maculopapular, urticarial, or petechial rash may develop, together with arthritis or arthralgia. These symptoms may worsen with the appearance of jaundice, dark urine, and pale stools. Malaise and fatigue may persist for some time after resolution of the disease.

Hepatitis A The transmission of the hepatitis A virus takes place via the fecal-oral route. In countries where sanitation conditions have improved, the mean age of exposure has increased, and the total infection rate has decreased. Clinical disease with jaundice in infants and young children is uncommon. Although relapses may occur, hepatitis A does not progress to chronic hepatitis.
HEPATITIS B The hepatitis B virus (HBV) is transmitted by percutaneous and permucosal routes. It is endemic in many countries, and even where it appears only sporadically, health care professionals are at risk. A recombinant DNA vaccine is available, but has been associated with cutaneous side effects. [53], [54] Five percent of HBV-infected subjects become carriers, and 90 percent of infants born of infected mothers develop chronic infection. There are four main cutaneous associations of hepatitis B: (1) a serum sickness–like syndrome, (2) cryoglobulinemia, (3) polyarteritis nodosa, and (4) papular acrodermatitis of childhood. The serum sickness–like syndrome occurs in approximately 5 to 15 percent of patients in the pre-icteric phase of acute hepatitis B infection. Urticaria may be the predominant or sole feature, but is usually accompanied by a low-grade fever, arthralgia of the peripheral joints, proteinuria, and hematuria. There may be vasculitis (see also Chap. 175). There are three types of cryoglobulinemia, identified according to the class of immunoglobulin that forms the cryoprecipitate (see Chap. 177). Both HBV and hepatitis C virus (HCV) infection are associated with cryoglobulinemia although HCV infection is more common. Mixed cryoglobulinemia in HCV infection is usually of type III, [55] and the cryoglobulinemia may indicate the presence of active viral replication. [56] Patients develop recurrent purpura, acrocyanosis, arthralgia, lymphadenopathy, peripheral neuropathy, and hepatosplenomegaly. Renal involvement is common. Histopathologically, there is a necrotizing vasculitis. Polyarteritis nodosa can occur in the acute phase of HBV infection, or it may not present for several years. Circulating immune complexes containing hepatitis B surface antigen (HBsAg) and immunoglobulin occur. Leukocytoclastic vasculitis may develop (see Chap. 174). Papular acrodermatitis (Gianotti-Crosti syndrome; see Chap. 143) usually affects children. The appearance of monomorphic, flat-topped, erythematous papules on the face and limbs is characteristic. This eruption is self-limited and asymptomatic in most, but may be accompanied by lymphadenopathy and anicteric acute HBV infection. [57] Other infectious agents and

immunizations have been implicated in papular acrodermatitis as well. [58] Sweet's syndrome (see Chap. 94) has recently been reported with both acute [61] and chronic HBV infection.

HEPATITIS C The majority of cases of posttransfusion hepatitis have been due to HCV infection, but screening has reduced the number of new cases dramatically. Cutaneous manifestations of acute and chronic HCV infection include leukocytoclastic vasculitis, usually due to cryoglobulinemia (see above); cutaneous necrosis; [56] pruritus; [60] acquired angioedema; [61] porphyria cutanea tarda; erythema nodosum; urticaria; erythema multiforme; and polyarteritis nodosa. [62] Lichen planus occurs more commonly in patients infected with HCV, although studies disagree on the incidence. [63] There is an increased frequency of the HLA-DR6 allele in Italian patients with HCV-associated oral lichen planus, [64] suggesting that host factors may play a part in this association.

Disorders That May Involve Both Skin and Liver

Many systemic diseases involve both the skin and the liver, but the changes may not be dependent on one another, do not always occur together, or may be separated by an interval of months or years. Table 164-7 contains a list of some of the more important ones.

Argininosuccinic aciduria	Porphyrias
Dermatomyositis	Porphyria cutanea tarda
Drug reactions	Variegate porphyria
Eruptive neonatal angiomatosis	Erythropoietic (erythrohepatic) porphyria
Graft-versus-host disease	Hereditary coproporphyria
Hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu disease)	Sarcoidosis
Histiocytoses	Syphilis
Immunodeficiency states	Systemic lupus erythematosus
Mastocytosis	Tuberous sclerosis
Mucocutaneous lymph node syndrome (Kawasaki disease)	Vinyl chloride disease

TABLE 164-7 **Disorders Involving Both Skin and Liver**

Argininosuccinic aciduria (see Chap. 147) is a rare autosomal recessive disorder characterized by ataxia, seizures, severe mental retardation, hepatomegaly with liver dysfunction, and brittle hair. Dermatomyositis (see Chap. 172) may be the presenting sign of an underlying cancer with primary [65] or secondary hepatic malignancy. In eruptive neonatal angiomatosis, multiple angiomas may occur anywhere on the skin surface; in addition, vascular lesions may occur in internal organs, including the liver. Both acute and chronic phases of graft-versus-host reactions may have prominent effects on both skin and liver, most commonly in patients receiving bone marrow transplants. In hereditary hemorrhagic telangiectasia, arteriovenous fistulas can cause shunting, and “cirrhosis” (i.e., multiple small telangiectatic hepatic vessels) occurs. [8] Several of the histiocytoses, including Langerhans cell histiocytosis (see Chap. 160) and malignant histiocytosis, may involve both skin and liver. Cytophagic histiocytic panniculitis has been associated with interferon-a therapy for chronic HCV infection [66] (see Chap. 109). Immunodeficiency states may result in multiple infections of skin and liver, some with specific cutaneous signs. Examples include congenital disorders (e.g., ataxia telangiectasia, Chediak-Higashi syndrome, chronic granulomatous disease) and acquired disorders (e.g., AIDS).

Hepatomegaly occurs in systemic mastocytosis [28] (see Chap. 163). In Kawasaki disease (see Chap. 204), children may develop upper abdominal pain associated with hepatobiliary changes, nonspecific elevation of liver enzyme levels due to vasculitic changes, or bile duct inflammation. [67] (See Chap. 149 for a detailed discussion of the porphyrias.)

Sarcoidal infiltration of the liver may accompany the cutaneous signs of sarcoidosis (see Chap. 183). Hepatic granulomas may also occur in tuberculosis, glandular fever, and syphilis, or as a side effect of drugs such as phenylbutazone, allopurinol, and the sulfonamides. True syphilitic hepatitis is rare and presents with pruritus and cholestatic jaundice.

Patients with systemic lupus erythematosus have a 25 to 50 percent chance of abnormal liver test results in their lifetime. [68] The most common cause is drug-induced hepatitis. Thrombotic conditions, including Budd-Chiari syndrome and veno-occlusive disease, occur with or without lupus anticoagulant. Rare abnormalities include nodular regenerative hyperplasia, perihepatitis, and hepatic or splenic rupture. Autoimmune hepatitis, primary biliary cirrhosis, [69] granulomatous hepatitis, cryptococcal infection, porphyria, or idiopathic portal hypertension [70] may also occur.

Cholestatic hepatitis occurs as a rare complication of Stevens-Johnson syndrome and may precede the skin signs. [71]

Angiomyolipomas are frequently seen on ultrasound examination of the livers of patients with tuberous sclerosis but are usually asymptomatic (see Chap. 189). Liver function abnormalities are common in patients with vinyl chloride disease and may be associated with hepatosplenomegaly, cirrhosis, and, rarely, angiosarcoma.

EFFECTS OF SKIN DISEASE ON THE LIVER

Several systemic complications occur as a consequence of skin disease, and some of them reflect abnormalities of hepatic function.

Extensive Loss of Skin

Patients may lose large areas of skin because of thermal burns, severe pemphigus, staphylococcal scalded skin syndrome, or toxic epidermal necrolysis. In experimental animal models, extensive thermal injury results in a halving of the hepatic arterial blood flow. [72] Postburn sepsis amplifies this injury and induces portal hypertension. This may in turn account for a gut barrier dysfunction (the so-called “dermatogenic enteropathy”), but research has not convincingly

demonstrated this relationship in humans with extensive skin disease.

Erythroderma

The systemic effects of erythroderma are considerable (see Chap. 44). Patients can develop hypothermia, hypoalbuminemia, hypovolemia, secondary sepsis, the initial stages of renal failure, and high-output cardiac failure with secondary effects on hepatic function. Death from sepsis, cardiac failure, adult respiratory distress syndrome, and capillary leak syndrome occur. [73]

Psoriasis (See Chap. 42.)

The high incidence of abnormalities of the liver architecture in patients with psoriasis has been attributed to alcohol misuse. Psoriasis is more common than expected in alcoholic cirrhosis than in cirrhosis due to other causes. [36], [74] Those who misuse alcohol are said to have a unique, acral, distribution of psoriasis. [36] Alcohol appears not only to trigger psoriasis, especially in men, but also to influence the course of the disease, as heavy drinkers have more severe, extensive, inflamed disease. Patients who decrease alcohol consumption may decrease the extent of their disease and increase their response to treatment. [74]

Dermatitis Herpetiformis

Results of liver function tests are sometimes abnormal in patients with dermatitis herpetiformis [75] and can also occur secondary to treatment or as a result of associated conditions [76] (see Chap. 67).

Cancers of the Skin

Primary cutaneous neoplasms, including melanoma, squamous cell carcinoma, Merkel cell tumor, and Kaposi's sarcoma, occasionally metastasize to the liver.

HEPATOTOXIC EFFECTS OF DRUGS USED IN THE TREATMENT OF SKIN DISEASE

Several drugs used in managing patients with skin disease are hepatotoxic (Table 164-8). Many others, such as antimalarials or terbinafine, warrant caution in patients with hepatic impairment.

Drug	Interaction	Side Effects
Azathioprine	Bullous disorders, dermatomyositis	Raised liver enzymes
Ciclosporin	Psoriasis, dermatitis	Raised liver enzymes
Cyproterone acetate	Hirsutism and virilization	May worsen preexisting dysfunction
Danazol	Hereditary angioedema	May worsen preexisting dysfunction and porphyria
Dapsone	Dermatitis herpetiformis, erythema elevatum diutinum, granuloma faciale, and others (Chap. 224)	May cause dapsone syndrome (rash, eosinophilia liver hepatitis). Avoid in porphyria
Griseofulvin	Fungal infections	May worsen preexisting liver disease
Ketoconazole	Fungal infections	Raised liver enzymes and hepatitis
Methotrexate	Psoriasis, sarcoidosis	Cirrhosis
Minocycline	Acne	Hepatitis
Retinoids	Acne, psoriasis, disorders of keratinization	Elevated liver enzymes, increases hepatotoxicity of methotrexate
Stanozolol	Hereditary angioedema	May worsen preexisting dysfunction and porphyria
Terbinafine	Fungal infections	Hepatitis

TABLE 164-8 **Hepatotoxic Drugs Used in the Treatment of Skin Disease**

Patients who have psoriasis and who are undergoing long-term treatment with methotrexate have a high frequency of liver fibrosis and cirrhosis, especially if their total doses exceed 1.5 g. Those with a history of alcohol misuse, impaired renal function, diabetes, and obesity are at higher risk. Diagnosis of fibrosis is histologic and requires liver biopsy. The morbidity of liver biopsy can be as high as 10 percent, and the mortality up to 0.1 percent. [77] In hepatic fibrosis, the synthesis of predominantly type III collagen is increased, and the amino-terminal propeptide of type III procollagen (PIIINP) is cleaved off and released into the circulation. Because it is now possible to measure serum PIIINP levels accurately, this test has become a valuable noninvasive marker of active hepatic fibrogenesis during methotrexate treatment of psoriasis. Thus, the number of liver biopsies taken in patients with normal serial serum PIIINP levels can be reduced to a minimum. [77]

Cutaneous Changes in Renal Disorders

CUTANEOUS MANIFESTATIONS OF CHRONIC RENAL FAILURE
General Skin Changes
Pruritus
Calcification
Bullous Disease of Hemodialysis
Acquired Perforating Dermatoses
NEPHROGENIC FIBROSING DERMOPATHY

REFERENCES

The protean cutaneous manifestations of renal disease are primarily encountered in patients with chronic renal failure (CRF). In contrast, although acute renal failure (ARF) causes uremia, hypertension, congestive heart failure, and other serious conditions, only two skin changes—edema and uremic frost—occur in the acute setting. Edema is a particular feature of ARF with nephrotic syndrome. Uremic frost results from eccrine deposition of urea crystals on the skin surface of individuals with severe uremia, and it is now rarely encountered because of the wide availability of acute hemodialysis.

CUTANEOUS MANIFESTATIONS OF CHRONIC RENAL FAILURE

General Skin Changes

The skin of patients with CRF is typically dry, often with ichthyosis-like scaling. This condition may result in part from altered vitamin A metabolism in CRF, [1] along with fluid volume shifts from dialysis. Skin color is also altered in CRF. The skin is pale (from anemia) and often exhibits a distinctive gray-yellow hue, because of the accumulation of carotenoid and nitrogenous pigments (urochromes) in the dermis. The nails also exhibit color changes. Lindsey's, or half-and-half, nails are normal in their distal 50 percent and white in the proximal 50 percent. The term *Terry's nails* has been applied to nails in which only the distal 20 percent is normal. These nail changes are fairly specific to CRF but may be encountered in patients with chronic liver disease and in healthy individuals.

Pruritus

Pruritus is frequently reported by patients with chronic end-stage renal disease. The incidence of renal pruritus is reported to approach 50 to 90 percent of patients undergoing hemodialysis. [2], [3], [4] and [5] Some patients complain of pruritus only during or soon after dialysis, whereas others report symptomatic exacerbation during this same period. [4] Although the etiology is poorly understood, localized and generalized forms of renal pruritus are likely caused by a combination of several mechanisms: increased serum levels of histamine, vitamin A, and parathyroid hormone (PTH); mast cell hyperplasia; peripheral polyneuropathy; and xerosis. [3], [5], [6] Clinically, the skin may appear normal or demonstrate a varied pattern of lichenified or hyperkeratotic lesions.

Treatment of renal pruritus is often empirical. Topical moisturizers alleviate pruritus associated with xerotic skin. Topical glucocorticoids and ultraviolet phototherapy are often used to suppress inflammation in treated areas. Topical capsaicin depletes substance P from nerve endings, thereby suppressing itch sensation. [6] Improving the efficacy of dialysis and/or changing the dialysate concentration may help to alleviate pruritus. [6], [7] Some patients have responded to treatments with intravenous lidocaine, heparin, and cholestyramine. [6] Surgical options include subtotal parathyroidectomy, electric needle stimulation, and renal transplantation. [2], [3], [6] De Marchi et al. [5] found erythropoietin to be effective in lowering plasma histamine concentrations with subsequent improvement in pruritus. Preliminary studies indicate that oral evening primrose oil and topical tacrolimus ointment may each have some therapeutic effect. [8], [9]

Calcification

Metastatic calcification of the skin in CRF results from secondary or tertiary hyperparathyroidism. Abnormally elevated levels of PTH may trigger deposition of crystalline calcium pyrophosphate in the dermis, subcutaneous fat, or arterial walls. [10] Vascular calcification is, in fact, very common in patients with long-term CRF, and is seldom symptomatic. Occasionally however, calcified vessels may thrombose acutely, resulting in a syndrome that has been called *calciphylaxis* (a term originally coined by the physiologist Selye, who experimentally induced abrupt calcification of tissues in animals). This is probably not the mechanism in the CRF-associated disorder. This acute thrombosis produces symmetrical livedo reticularis. Livedoid areas are excruciatingly painful due to ischemia, and they quickly become hemorrhagic and ulcerate (Fig. 165-1). Calciphylaxis is associated with a high mortality rate, particularly when the skin of the trunk is involved (as opposed to a somewhat better prognosis if skin infarction is limited to the extremities). [10] Laboratory evaluation usually demonstrates marked elevation of intact PTH. The serum calcium and phosphate levels, and the calcium-phosphate product (Ca mg/dL × PO_4 mg/dL) are frequently only minimally elevated and may be normal.

FIGURE 165-1 Calciphylaxis. (*Courtesy of Suzanne N. Granados, MD.*)

In addition to vascular calcification and calciphylaxis, nodular calcification may occur in the skin and fat of patients with CRF. These calcium deposits are identical to calcinosis cutis in other disorders, such as tumoral calcinosis or CREST (calcinosis cutis, Raynaud's phenomenon, esophageal dysfunction, sclerodactyly, and telangiectasia) syndrome. The involved skin may ulcerate, but this process occurs in subacute fashion, without livedo or ischemic pain. The prognosis for patients with this nonvascular form of calcification is excellent.

Treatment of calciphylaxis is extraordinarily difficult. Pain management, careful débridement of gangrenous tissue, and, especially, parathyroidectomy have been successful. [10], [11] However, no prospective trial of parathyroidectomy has been conducted, and convincing evidence of improved prognosis for patients with calciphylaxis after this procedure is lacking. Studies to evaluate the role of anticoagulation or thrombolytic therapy in calciphylaxis have yet to be conducted. The nonvascular form of CRF-associated calcinosis may be managed with surgical excision of calcific nodules and treatment of ulcers with hydrocolloid dressings and the like.

Bullous Disease of Hemodialysis

Porphyria cutanea tarda (PCT) has been described in patients with CRF undergoing hemodialysis. Although the etiology of this phenomenon is still unclear, inadequate clearance of plasma-bound porphyria precursors by urine excretion or hemodialysis may lead to porphyrin deposition in the skin manifested clinically as photosensitivity and subepidermal bullae. [12], [13] and [14] Patients undergoing hemodialysis may also produce or be exposed to compounds that alter normal heme synthesis. PCT has been reported both in a patient undergoing peritoneal dialysis [12] and in a patient undergoing hemodialysis after reactivation of hepatitis C virus infection. [15]

Bullous dermatosis of dialysis or pseudoporphyria may occur in 8 to 18 percent of patients undergoing hemodialysis. [12], [14], [16] This condition is often clinically indistinguishable from PCT with marked skin fragility and blister formation on sun-exposed skin. However, hypertrichosis is less common, and plasma porphyrin levels are typically normal. [12], [16] Pseudoporphyria may also occur in some patients taking tetracycline, nabumetone, nalidixic acid, furosemide, and phenytoin. [12]

Treatment of PCT or pseudoporphyria in most patients with CRF may be difficult. Phlebotomy can reduce iron levels in the liver, allowing new hepatic uroporphyrinogen decarboxylase to be formed. [17] However, patients with end-stage renal disease often have significant anemia and cannot tolerate phlebotomy. Intravenous erythropoietin may both lower total body iron stores and support phlebotomy as needed. [13], [17] Chloroquine effectively clears porphyrins from the liver. In patients with CRF, however, porphyrins may not be effectively cleared by hemodialysis or excreted in the urine. [14], [17] Deferoxamine may lower serum porphyrin levels in some patients. [13] Others may require renal transplantation to obtain complete resolution of symptoms. [13]

Acquired Perforating Dermatoses

Acquired perforating dermatosis can occur in association with CRF and diabetes mellitus. [18], [19] This condition, which occurs in up to 10 percent of patients undergoing hemodialysis, may be more common in blacks [18], [20], [21] and appears to be distinct from the four primary perforating disorders (elastosis perforans serpiginosa, Kyrle's disease, perforating folliculitis, and reactive perforating collagenosis). [19], [21] Clinically, patients develop hyperkeratotic papules with a central crust-filled crater on the trunk and extensor surfaces, often in a linear distribution. [21] Simultaneous transepidermal elimination of both collagen and elastic fibers has been detected. [20] The etiology of this process is unclear. Proposed mechanisms include diabetes microangiopathy, microtrauma caused by chronic pruritus, dysregulation of vitamin A or vitamin D metabolism, abnormality of collagen or elastic fibers, or local inflammation and connective tissue degradation caused by dermal microdeposition of substances such as uric acid and calcium pyrophosphate. [20], [22] However, we regard this entity as a secondary response to scratching associated with renal pruritus. Successful treatment depends on addressing the underlying etiology of pruritus. Topical and intralesional glucocorticoids, topical and systemic retinoids, cryotherapy, and ultraviolet light also may be helpful. [20], [21]

NEPHROGENIC FIBROSING DERMOPATHY

Nephrogenic fibrosing dermopathy (NFD), a recently described disorder, resembles scleromyxedema (see Chap. 187) in some of its aspects. [23], [24] To date, NFD has been found only in patients with renal disease. Most affected individuals have been on hemodialysis, and many have restarted dialysis after failure of a renal transplant. NFD also has been described in a few patients with ARF. Clinically, patients progressively develop erythematous, sclerotic dermal plaques on the arms and legs, with sparing of the head and neck. Pruritus is a common feature. The histopathology of NFD similarly resembles that of scleromyxedema, with proliferation of fibroblasts in the dermis and subcutaneous septae, accompanied by increased dermal and septal collagen and mucin. [24]

The etiology of NFD is unknown. The disorder has been described in clusters of patients from widely scattered dialysis centers in Europe and North America, prompting epidemiologic investigations that currently are ongoing. All patients described have had persistent disease (even though renal failure resolved in some cases). [23] There is no effective treatment.

Dermatomyositis
Systemic Sclerosis
Relapsing Polychondritis

REFERENCES

Descriptions of abnormalities of the skin in association with diseases of the heart and lungs are among those first recorded in medical antiquity. While many of these abnormalities are familiar and easily recognizable by the physician, others are unique and may remain a diagnostic challenge (Table 166-1). This chapter presents the cutaneous manifestations of selected cardiopulmonary diseases; in addition, interesting associations between the skin, heart, and lung are included.

Joint and connective tissue diseases	Watson syndrome
Rheumatoid arthritis	Neurofibromatosis
Systemic lupus erythematosus	Tuberous sclerosis
Reiter's syndrome	LEOPARD syndrome
Behçet's syndrome	LAMB syndrome
Systemic scleroderma	NAME syndrome
Dermatomyositis	Danoff syndrome
Rheumatic fever	Infectious diseases
Ehlers-Danlos syndrome	Varicella
Cutis laxa	Gonococcemia
Marfan's syndrome	Subacute and acute bacterial endocarditis
Periarteritis nodosa	Chagas' disease
Multicentric reticulohistiocytosis	Diphtheria
Metabolic diseases	Miscellaneous (protozoal, viral, rickettsial, and bacterial infections)
Hemochromatosis	Diseases of uncertain etiology
Amyloidosis	Sarcoidosis
Fabry's disease	Whipple's disease
Carcinoid tumors	Kawasaki disease
Myxedema	Degos' disease
Hyperlipidemias	
Hyperthyroidism	
Nevoid or genetic disorders	
Progressive lentigines (Moynahan syndrome)	

NOTE: See Table 166-4 for definitions of LEOPARD, LAMB, and NAME syndromes.

TABLE 166-1 **Diseases with Heart and Skin Involvement**

A number of situations in which the skin and the cardiopulmonary system are both involved are described elsewhere in this volume. These conditions include pruritus associated with cardiac failure or pulmonary insufficiency, pigmentary changes associated with hemochromatosis, or endocrine abnormalities (see Chap. 164, Chap. 169, respectively), the hyperlipidemias (see Chap. 150), mucocutaneous lymph node syndrome (see Chap. 204), lipoid proteinosis (see Chap. 152), and amyloidosis (see Chap. 148).

ALTERATIONS IN SKIN QUALITY

The skin may be warm in patients with erythroderma or exfoliative dermatitis as a result of shunting or increased metabolism with or without high-output congestive failure (see Chap. 44). Hyperthyroidism with increased cardiac output and vasodilation may also lead to increased skin temperature. Conversely, the temperature may be reduced in patients with hypothyroidism and low-output congestive failure secondary to atherosclerotic disease or myocardial infarction. Systemic amyloidosis may cause waxy induration of the skin, and when stroked the skin may become hemorrhagic ("pinch purpura") (see Chap. 148). Cardiac conduction disturbances, myocardial disease, and orthostatic hypotension are common.

Hyperelastic velvety skin that rebounds to the original position after being stretched, "cigarette-paper" scars, and hyperextensible joints are characteristic of the Ehlers-Danlos syndrome (see Chap. 154). Mitral and tricuspid prolapse, dilatation of the aorta and pulmonary artery, arterial rupture, a variety of congenital heart diseases, acute myocardial infarction, and panacinar emphysema may accompany this syndrome. [1] A progressive looseness of the skin with pendulous folds and droopy eyelids can be a clue to cutis laxa (see Chap. 154). This condition may be associated with generalized hyperelastosis that may cause aortic dilatation and rupture, congestive heart failure, or cor pulmonale with pulmonary artery stenosis and progressive emphysema. The skin of patients with pseudoxanthoma elasticum (see Chap. 154) is thick, lax, and yellowish, especially over the axillae, antecubital area, and neck. The skin around the mouth may sag. Yellow patches may occur on mucous membranes, especially the labia. The arteries may be calcified, and the aortic and mitral valves thickened. Angina pectoris and claudication are frequent symptoms. [2]

In Werner's syndrome (progeria), the skin appears atrophic and tight: there s marked loss of subcutaneous tissue, with ulcerations of the legs and severe coronary atherosclerosis; death by myocardial infarction is frequent at an early age.

CHANGES IN SKIN COLOR

Changes in skin color are caused by a number of variables including hemoglobin, melanin, carotene, vasoactivity, metals, and miscellaneous other phenomena.

Cyanosis

An increase in the absolute amount of desaturated (reduced) hemoglobin results in a purplish or bluish discoloration of the skin. By definition, cyanosis is divided into "central" and "peripheral" types, the latter being the more common. Conceptually, the terms refer to the level of arterial oxygen saturation and not to the anatomic source of the cyanosis. Thus, central cyanosis occurs in states that produce low arterial oxygen saturation, such as congenital heart disease with intracardiac or intrapulmonary right-to-left shunting, as well as most severe pulmonary diseases. Peripheral cyanosis occurs in states that have normal arterial oxygen saturation but reduced blood flow, such as low-output cardiac failure of any etiology, and local vasospastic phenomena. Pulmonary embolism may result in a combination of central cyanosis caused by intrapulmonary shunting and peripheral cyanosis caused by low cardiac output.

Central cyanosis is usually present on the warm areas of the skin such as the tongue, oral mucosae, and conjunctivae. Peripheral cyanosis is usually seen on the cool areas such as the nose, lips, earlobes, and fingertips. However, this distinction is not absolute because both central and peripheral cyanosis may affect any of the aforementioned areas of the body. Detection of cyanosis may be difficult, even to the experienced observer. Although the tongue is probably the area where it is most easily detected, a number of false-positive evaluations may occur. Therefore examination of the fingertips and conjunctivae, although less sensitive, may reflect the underlying condition more clearly. In the anemic patient, detection of cyanosis may be impossible because the absolute amount of reduced hemoglobin is not increased. To avoid confusion with staining of the skin, either topically or from systemic deposits of heavy metals or other chemicals, it is important to note that cyanosis fades when pressure is applied because the color is within the blood vessels. Cyanosis that is more intense in the fingers than in the toes suggests complete transposition of the great vessels, with either a preductal coarctation or complete interruption of the aortic arch, pulmonary hypertension, and a reversed shunt through a patent ductus arteriosus. If the cyanosis is slightly more on the right hand, coarctation of the aorta is more likely. Equal cyanosis of both hands suggests complete aortic interruption. Cyanosis and clubbing of the toes associated with cyanosis in the left hand and a normal right hand suggest pulmonary hypertension with a reversed shunt through a patent ductus arteriosus bringing saturated blood to the left arm and both legs.

Redness/Flushing

Redness of the skin may be caused by an increase in the amount of saturated hemoglobin, an increase in the diameter or actual number of skin capillaries, or a combination of these factors. Erythroderma or exfoliative dermatitis with intense redness may be associated with so much capillary dilatation that high-output cardiac failure occurs, especially in compromised patients (see Chap. 44). Polycythemia may produce the characteristic "ruddy" complexion, but may also cause a peculiar ruddy cyanosis. The tongue, lips, nose, earlobes, conjunctivae, and fingertips especially demonstrate this coloration, which results when increased amounts of saturated hemoglobin produce the redness and when increased amounts of desaturated hemoglobin produce cyanosis because of the inability of the body to oxygenate fully the increased absolute amounts of hemoglobin. The absence of nail clubbing may help differentiate patients with polycythemia vera from those patients with cardiopulmonary disease who develop secondary polycythemia. In addition, the hypervolemic state of polycythemia vera is associated with increased stroke volume and may lead to high-output cardiac failure, while pulmonary infarction may result from venous thrombosis and embolization caused by hyperviscosity.

Paroxysmal intense flushing of the face, neck, chest, and abdomen, often with telangiectases of the face and neck, may occur in patients with carcinoid tumors (see Chap. 170), systemic mastocytosis (see Chap. 163), pheochromocytoma, and Sipple's syndrome. Edema of the face, arms, and hands associated with redness and/or cyanosis may indicate

obstruction of the superior vena cava due to mediastinal disease.

ERYTHROMELALGIA (LABILE HYPERTHERMIA) (See also Chap. 167) Erythromelalgia is a clinical syndrome that is characterized by recurrent attacks of burning pain in the hands and/or feet together with redness, warmth, and sometimes swelling that may extend to the elbows and knees. The pulse is either normal or slightly increased. Erythromelalgia may be primary (it was recently associated with a chromosomal marker) or secondary to a wide variety of disorders such as atherosclerosis, hypertension, and polycythemia. [3] Recently, human immunodeficiency/AIDS patients were identified with the syndrome. Symptoms are hypothesized to be caused by dysfunctional vascular dynamics including arteriovenous shunting and reduced capillary perfusion with corresponding tissue hypoxemia. [4]
PALMAR ERYTHEMA Palmar erythema may occur in many healthy women, but recent onset or increased intensity of this condition raise the possibility of liver involvement (see Chap. 164). Palmar erythema may be associated with high-output cardiac failure. The erythema primarily involves the hypothenar eminence but may also affect the thenar eminence and the fingertips. Other factors, including pregnancy and hyperthyroidism, may cause this condition.
JAUNDICE (See also Chap. 164) Hyperbilirubinemia and jaundice may occur in patients in heart failure as a result of raised intrahepatic pressure due to passive congestion. Hemorrhagic pulmonary infarction with destruction of red cells and hemoglobin may also produce jaundice, especially in patients with passive congestion of the liver. Constrictive pericarditis and tricuspid valvular disease may produce jaundice secondary to cardiac cirrhosis. Under fluorescent light, jaundice may be difficult to assess.

ALTERATIONS IN SWEATING

Sweating may be prominent in a number of cardiopulmonary states such as acute myocardial infarction, cardiogenic shock, left ventricular failure, massive pulmonary emboli, and pulmonary edema. Pallor and clamminess or coldness of the extremities and exposed surfaces are also often found. When associated with hypertension, excessive sweating may suggest pheochromocytoma. There may also be additional features such as flushing, which is most prominent in those patients with Sipple's syndrome in whom prostaglandin and serotonin production by the tumor may simulate a carcinoid. Myocardial infarction may occur or cardiac failure may develop as a consequence of a metabolic cardiomyopathy. Neurofibromatosis and café au lait macules have been found in as many as 10 percent of patients, especially those with bilateral pheochromocytoma. The sodium and chloride content of sweat is increased in patients with cystic fibrosis and may lead to an increase in skin wrinkling after immersion, as when bathing. [5]

ALTERATIONS OF NAILS, HANDS, AND ARMS

Nail Clubbing

Nail clubbing and osteoarthropathy are distinct entities that may be associated with significant cardiopulmonary abnormalities (Fig. 166-1). Clinically, nail clubbing has various manifestations. Beaking or distal curvature of the nail may occur. There may be loss of the normal 15° angle between the nail and cuticle. Sponginess or “floating” of the nail when pressure is applied is also characteristic. Finally, the size of the terminal tuft may increase. This change may be quantified by measuring the depth of the finger at the base of the nail and dividing by the depth of the finger at the distal interphalangeal (DIP) joints. The ratio should normally be less than 1.0. Clubbing most commonly occurs in patients with bronchogenic carcinoma, suppurative lung disease, endocarditis, and congenital heart disease, but it may be idiopathic or familial.

FIGURE 166-1 Clubbing of fingernails.

Quincke Pulse

Flushing of the nail beds that is synchronous with the heartbeat is one sign of the aortic regurgitation called *Quincke pulsation*. In addition, the fingernail beds may be used to evaluate the microcirculation. Capillary “fill” is estimated by pressing down on the nail bed until blanching occurs. Following release, there should be immediate filling and a pink appearance. However, perfusion of the skin may not reflect perfusion of internal organs.

Hypertrophic Osteoarthropathy

Hypertrophic osteoarthropathy often has clubbing as a feature, but in addition there is associated arthralgia and/or arthritis of the fingers, wrists, knees, and ankles, as well as painful periostitis revealed as subperiosteal new bone formation on x-ray. Suffusion of the digits may be prominent, with pitting edema. Shiny skin with increased sweating and paronychial thickening are sometimes noted. Although hypertrophic osteoarthropathy is most often associated with malignant tumors of the chest, there are numerous other disorders that produce this syndrome. In addition, some cases are primary or idiopathic. Pachydermoperiostosis, a primary form, is frequently familial. Its onset is around puberty, and it has a number of cutaneous manifestations. Distinctive thickening and furrowing of the skin of the scalp, forehead, and cheeks may create leonine facies. Other features include excessive sweating, especially of the hands and feet, severe seborrhea of the scalp and face, and dermatitis of the hands and feet. Familial clubbing alone may also be found and

may represent a partial expression of this syndrome. Thyroid acropachy (Chap. 169) may mimic osteoarthropathy but is most often painless.

REFLEX SYMPATHETIC DYSTROPHY

The shoulder-hand syndrome is a painful periarthritis or adhesive capsulitis of the shoulder ("frozen shoulder"), usually on the left side, associated with erythema, sweating, shiny induration, edema, tenderness, pain, and immobility of the ipsilateral hand. Neurotrophic ulcerations of the fingers and thickening of the palmar aponeurosis with nodules and/or Dupuytren's contracture may be late sequelae. This syndrome was observed in up to 15 percent of patients with myocardial infarction in the past when bed rest was prolonged, but it is now uncommon. Other predisposing conditions include arterial embolization, cerebrovascular accidents, and protective disuse of the arms for any reason. [6]

THE HEART AND THE SKIN

Coronary Heart Disease

FAMILIAL HYPERLIPIDEMIA The risk of coronary artery disease (CAD) may increase with elevation of plasma cholesterol and triglyceride concentrations. Familial hyperlipidemias comprise a group of metabolic disorders with elevated plasma cholesterol and/or triglycerides, and some may be associated with a high incidence of CAD. Xanthomatosis may be present in patients with these disorders, and they have been associated for many years with a high incidence of CAD (see Chap. 150).

EARLOBE CREASE A number of reports relate CAD to the presence of a diagonally positioned skin crease along the earlobe. These creases may be unilateral or bilateral. It is not known whether such creases are congenital or acquired, nor is the mechanism of their formation understood. Their presence suggests an increased risk for CAD in men younger than age 60 years, based on clinical, angiographic, and postmortem studies. [7]

MALE BALDING Male pattern baldness was 40 percent more prevalent in a case-control hospital-based study of 842 men admitted with nonfatal myocardial infarction. After allowing for age and other established coronary risk factors, the relative risk of myocardial infarction for frontoparietal male pattern baldness compared with no hair loss was 1.77 (95% CI 1.27 to 2.45). [7] Another large study of 22,081 male physicians over an 11-year time frame also reached similar conclusions, and also suggested that vertex hair loss was more strongly associated with cardiovascular risk factors, such as hypertension and hypercholesterolemia. [8]

CHOLESTEROL EMBOLI (See also Chap. 167) In patients with advanced atherosclerosis of the abdominal aorta, cholesterol crystals may microembolize to the lower extremities, particularly after invasive vascular procedures or surgery. The pulses may remain normal. In addition to complaints of pain in the legs, buttocks, and low back, as well as myalgia, restless legs, or abdominal symptoms, both renal insufficiency and various skin lesions frequently develop. Livedo reticularis may affect the lower abdomen and back, buttocks, and legs, and ulcerations on the legs and feet, surrounded by an erythematous or violaceous halo and a small scab, may be present. Digital cyanosis ("blue toe") and gangrene may simulate necrotizing vasculitis (Fig. 166-2). Indurated plaques and nodules and their association with livedo reticularis and ulceration may mimic polyarteritis nodosa (see Chap. 174). These plaques and nodules are firm, violaceous, painful, and necrotic in the center. Deep skin biopsy of areas of livedo reticularis or adjacent to nodules or ulceration reveal occlusions of arterioles by multinucleated foreign-body giant cells and fibrosis surrounding biconvex, needle-shaped clefts corresponding to the cholesterol crystal microemboli. [9]

FIGURE 166-2 Cholesterol emboli: Blue toe and infarctions.

POSTBYPASS SKIN CHANGES Coronary artery bypass surgery is commonly performed using the superficial veins of the legs as donor-graft sites. A dermatitis has been reported to occur along the saphenous vein graft scars on the medial aspect of the legs. Patients have no history of venous stasis, thrombophlebitis, ankle edema, or skin disease. Examination generally reveals a reddish-brown, slightly scaling, and fissured dermatitis along the distal part of a well-healed saphenous vein graft scar. Dermatitis develops 2 to 6 months after surgery and the patient's return to full activity. The cause is unclear but may be related to the high incidence of postoperative thrombophlebitis and resultant stasis dermatitis. The dermatitis responds to topical glucocorticoids. Recurrence is usual and most patients require continued treatment. Recurrent cellulitis may develop in the healed vein graft many months after surgery. These patients present with fever and chills; erythema may extend along the entire vein graft site, accompanied by pain and tenderness. Swelling may be significant, and often the patients are initially considered to have thrombophlebitis. Although cultures are not always positive, beta-hemolytic streptococcus has been isolated in a number of cases. The presence of tinea pedis in patients with this complication has been reported and it is recommended that all patients considered for vein graft surgery be examined carefully for evidence of tinea infections of the feet. If found, patients should be treated vigorously with antifungal medication prior to surgery.

Cardiomyopathy

Cutaneous abnormalities may aid in the diagnosis, classification, and subsequent treatment of some kinds of cardiomyopathy. These disorders of the myocardium affect ventricular function and may produce cardiac failure. A useful classification divides cardiomyopathies into dilated, nondilated, and hypertrophic types. [10] It was recently stressed that each type of cardiomyopathy has a distinct differential diagnosis and that little etiologic overlap occurs. [11], [12] Thus, a specific cutaneous finding, in conjunction with the appropriate studies to determine the type of cardiomyopathy, may be

very important in making the correct diagnosis. For instance, *Naxos disease* is an autosomal recessive mutation in desmoplakin, the most abundant protein in desmosomes that are important for cell adhesion in many tissues, including skin and heart. [13] Individuals affected by this disorder have generalized striate keratoderma particularly on the palmoplantar epidermis, woolly hair and dilated left ventricular cardiomyopathy, which leads to arrhythmia, heart failure, and early sudden death. Either radionuclide ventriculography or two-dimensional echocardiography estimates ventricular volume and left ventricular ejection fraction. These measurements are used to distinguish among the three types of cardiomyopathy. Table 166-2 and Table 166-3 list the causes of cardiomyopathy according to type.

Dilated	Neoplastic*
Coronary artery disease	Melanoma*
with multiple infarcts*	Ventricular thrombosis
Alcoholic*	Polycythemia vera*
Peripartum	Mitral valve prosthesis
Valvular*	Idiopathic
Infectious acute inflammatory	Hypertrophic
myocarditis*	Genetic form (↑ autosomal
Chagas' disease*	dominant)
Sarcoid*	Acquired or secondary forms
Doxorubicin toxicity	Neurofibromatosis*
Uremia*	Lentiginosis*
Hemochromatosis*	Hyperthyroidism*
Pheochromocytoma*	Hypothyroidism*
Hypocalcemia	Noonan's syndrome
Diabetes mellitus*	Hypertension
Nutritional (↑ selenium)	Valvular or subvalvular
Idiopathic	obstruction of left ventricular
Nondilated	outlet tract
Amyloid heart disease*	Pompe's disease
Endomyocardial diseases	Friedreich's ataxia
Löffler's disease*	In infants of diabetic mothers
Pseudoxanthoma elasticum*	
Endomyocardial fibrosis	
(Davies' disease)	

*May have significant cutaneous features.

TABLE 166-3 **Infectious Causes of Acute Dilated Cardiomyopathy**

Myxoma

Atrial myxomas, the most common primary tumors of the heart, are benign hamartomatous intracardiac tumors that may produce a wide variety of clinical symptoms and signs and may simulate a number of disease states. The cardiopulmonary findings include, in order of frequency, congestive heart failure, mitral murmur, chest pain, pulmonary edema, and embolic phenomena. Additionally, valvular insufficiency, constrictive pericarditis, conduction blocks, arrhythmias, and intracardiac shunts may occur. Variable murmurs may be an important clue. Pulmonary emboli and pulmonary hypertension may also occur in addition to other systemic findings, including fever, cachexia and malaise, arthralgias, arthritis, clubbing, hypergammaglobulinemia, anemia or polycythemia, thrombocytosis or thrombocytopenia, and leukocytosis.

The cutaneous manifestations of atrial myxomas may be dramatic. In addition to biphasic digital color changes on cold exposure, various cutaneous lesions have been described that simulate collagen vascular disease or vasculitis: tender, violaceous, nonblanching, annular, and serpiginous lesions of the digital pads, as well as splinter hemorrhages presenting as a systemic vasculitis or infective endocarditis. Characteristic pruritic, erythematous papules as well as cyanosis and ecchymosis of the extremities may also occur. The diagnosis may be made by biopsy of the skin and subcutaneous tissue in an area of embolic infarct. Myxomatous emboli with large pale-staining cytoplasms and stellate nuclei may be found among occluded blood vessels.

Before the introduction of the echocardiogram in 1960, more than 80 percent of patients were undiagnosed postmortem. The diagnosis may now be made earlier and more frequently during routine echocardiography, allowing successful surgical intervention. [14] Various associations of atrial myxoma with mucocutaneous pigmented lesions, including lentigines (Fig. 166-3), nevomelanocytic nevi, and blue nevi, as well as dermal myxomatous nodules, have been described (Table 166-4). [15]

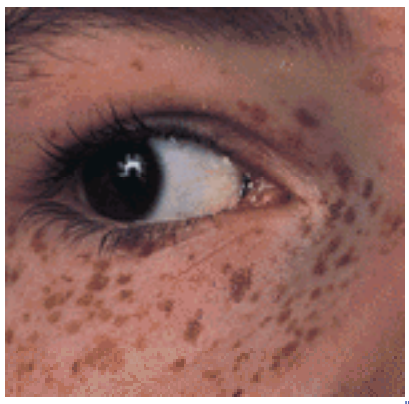

FIGURE 166-3 Lentiginous lesions in the atrial myxoma syndrome complex. This child has the LAMB syndrome (see Table 166-4).

LEOPARD syndrome	NAME syndrome
Lentiginosis	Nevi
Electrocardiographic abnormalities	Atrial myxoma
Ocular hypertelorism	Myxoid neurofibroma
Pulmonic stenosis	Ephelides
Abnormal genitalia	Danoff syndrome
Retardation	Adrenocortical micronodular dysplasia
Deafness	Lentigines
LAMB syndrome	Atrial myxoma
Lentigines	Spindle-cell tumors
Atrial myxoma	
Mucocutaneous myxomas	
Blue nevi	

TABLE 166-4 **Clinical Findings Associated with Lentigines**

LEOPARD Syndrome

Multiple lentigines syndrome, an autosomal dominant disorder, is associated with numerous abnormalities of variable clinical expression including disturbances of the heart. Each letter of the mnemonic represents a feature of the syndrome (see Table 166-4): *l*entigines, multiple; *e*lectrocardiogram conduction defects; *o*cular hypertelorism; *p*ulmonary stenosis; *a*bnormalities of genitalia; *r*etardation of growth; *d*eafness, sensorineural (see also Chap. 90). The types of cardiac involvement include electrocardiographic conduction disturbances and anatomic malformations. Axis deviation, prolonged P-R intervals, left anterior hemiblock, bundle branch block, and complete heart block have been reported.

Hypertrophic cardiomyopathy appears to be the most common anatomic abnormality. Subaortic stenosis is the most common valvular lesion. Although earlier reports suggested that pulmonary stenosis was frequent, some of the clinical and physiologic features of hypertrophic cardiomyopathy mimic pulmonary stenosis and were clarified only after catheterization or echocardiography. Because the clinical expression of the conduction disturbances and the anatomic malformation vary in onset and severity, frequent cardiac evaluation should be performed.

Subacute Bacterial Endocarditis

The cutaneous manifestations of bacterial endocarditis are important clues to the diagnosis, although less frequently than in the preantibiotic era. They include Osler's nodes, Janeway lesions, subungual splinter hemorrhages, cutaneous purpura and petechiae, and conjunctival petechiae (Roth's spots) (see also Chap. 194). Petechiae are the most common mucocutaneous manifestation of bacterial endocarditis, their incidence varying from 20 to 40 percent of patients with both acute and subacute bacterial endocarditis. Small, red or violaceous macules that do not blanch subsequently become brownish and fade. Purpuric lesions, both flat and elevated, are also associated with subacute endocarditis without evidence of platelet dysfunction and may represent a leukocytoclastic vasculitis. The petechiae may be observed on the skin, especially on the heels, shoulders, and legs, but the conjunctiva and oral mucosa must also be evaluated.

Osler's nodes and Janeway lesions may both present as erythematous or hemorrhagic macules, papules, or nodules (Fig. 166-4). However, while Osler's nodes are exquisitely painful, tender, and located distally on the digital tufts, Janeway lesions are nontender and located proximally on the palms and soles. Osler's original description, in 1885, did not specify the tenderness of these lesions, but his later report did emphasize the findings noted above. Histologically, Osler's nodes are a perivasculitis or necrotizing vasculitis without microabscess formation or other evidence of infection or emboli. Cultures have generally been negative, although more recent reports have reemphasized the possibility of septic microemboli with microabscess formation. Janeway lesions have also been described histologically as a vasculitis with microabscess formation. The cutaneous and conjunctival petechiae are histologically similar.

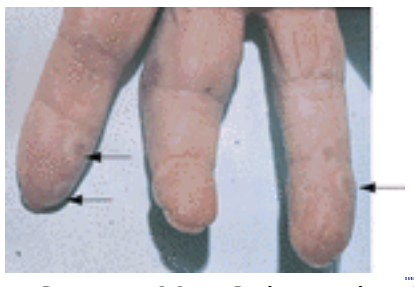

FIGURE 166-4 Osler nodes (*arrows*).

Current theories regard the pathogenesis of both Osler's nodes and Janeway lesions as immunologic or allergic due to immune complex deposition. Some reports dispute this concept, suggesting that the initial event is a septic microembolism that subsequently causes the endothelial swelling and perivasculitis seen in older lesions. Thus, organisms may be occasionally cultured initially, but later the lesions become sterile. That infected arterial catheters may precipitate clinical lesions comparable to Osler's nodes, Janeway lesions, and splinter hemorrhages, supports the concept that these lesions are infectious in etiology. Osler's nodes and Janeway lesions have been found in patients with other conditions, particularly systemic lupus erythematosus (SLE), gonococcemia, hemolytic anemia, and typhoid fever.

THE LUNGS AND THE SKIN

Yellow Nail Syndrome

Yellow nails with primary lymphedema were described in 1964. Separately, primary lymphedema and pleural effusion

were reported. The triad of yellow nails, primary lymphedema, and pleural effusion was then recognized, followed by a number of reports with partial or complete features. The characteristics of the nails include thickening, transverse ridging, diminished growth, increased curvature with a “hump,” and onycholysis. The lunulae and cuticles may be absent. The color may vary from pale yellow to green (Fig. 166-5). The nail changes are secondary to congenitally hypoplastic lymphatics, [16] leading to lymphedema, which is characteristically slowly progressive and somewhat asymmetric, with induration and hyperkeratosis extending to the thighs. Periodic lymphangitis is frequent and may contribute to the swelling.

FIGURE 166-5 Yellow nail syndrome. There is thickening, increased curvature, and yellowish discoloration of all fingernails. This patient had lymphedema of the extremities and bronchiectasis with multiple recurrent respiratory infections.

Respiratory findings include sinusitis, bronchiectasis, and pleural effusions. Symptoms vary from mild to severe, and some patients require repeated thoracentesis, treatment for pneumonia secondary to bronchiectasis, and drainage of the sinuses. Patients may have a productive or nonproductive cough, dyspnea, frequent upper respiratory infections, and pneumonia. Chest x-rays may be normal, but generally reveal evidence of fibrosis and/or effusion at the bases.

Pulmonary features and lymphedema may not occur until late in the course; therefore follow-up of patients who present with this type of nail dystrophy is recommended. Finally, a number of patients have developed lymphomas or sarcomas with metastases.

Pulmonary Arteriovenous Fistulas

Pulmonary arteriovenous fistulas are congenital abnormalities of capillary development that may not become clinically apparent until late adolescence. *Osler-Rendu-Weber* disease (hereditary hemorrhagic telangiectasia), an autosomal dominant trait, may be present in one-third to one-half of such patients. It is characterized clinically by punctate, linear, or spider-like telangiectasias of the skin, especially the upper body, oral and nasal mucous membranes, and nail beds (Fig. 166-6). The radiating arms about an elevated punctum are the most characteristic feature, especially on the lips and tongue. They are distinguished from true spider telangiectasis in that they do not pulsate.

FIGURE 166-6 Osler-Rendu-Weber disease. Note the punctate and splinter-like telangiectasia on the lips and tongue.

Recurrent epistaxis is the most frequent presenting symptom and may begin in early childhood or adolescence. Other organ systems besides the lungs may be involved, including the liver, gastrointestinal and genitourinary tracts, and central nervous system, and recurrent hemorrhage may result. Bleeding may be enhanced by an associated von Willebrand's disease.

The pulmonary findings in those patients with an arteriovenous fistula of the lungs include dyspnea, hemoptysis, cyanosis, clubbing, polycythemia, and pulmonary bruits accentuated by inspiration. Chest x-rays reveal nodular “coinlike” lesions, sometimes initially considered to be metastatic disease.

Chronic Pulmonary Diseases

Chronic obstructive pulmonary disease (COPD) is actually a group of disorders that includes chronic bronchitis, bronchiectasis, emphysema, and asthma. The incidence and mortality of COPD have increased recently and approach

that of heart disease in the United States. Smoking habits, as well as increased longevity of the population, may be partly responsible for this increase. Genetic, infectious, occupational, and environmental factors also contribute.

There are two basic types of COPD: type A, or emphysematous, and type B, or bronchial. Clinically, both may present with dyspnea, cough, wheezing, and recurrent respiratory infections. Type A patients have been termed “pink puffers” because they usually hyperventilate and maintain arterial oxygen tension. Type B patients have been termed “blue bloaters” because they frequently are hypoxic with cyanosis and associated right congestive heart failure. These patients, especially if young, should be evaluated for the possibility of cystic fibrosis.

Cystic Fibrosis

Cystic fibrosis is an autosomal recessive disorder of the exocrine glands that subsequently involves the tracheobronchial tree, pancreas, and gastrointestinal tract. The basic alteration of mucus is unknown, but viscid mucous plugs may cause fecal impaction, intussusception, and rectal prolapse in infancy. Pancreatic insufficiency may subsequently predominate, but it is the pulmonary disease that is the most significant feature. Progressive lung disease with chronic bronchitis, emphysema, and cor pulmonale from cystic fibrosis is a leading cause of death among patients with genetic disorders in the United States. The cutaneous features of this disorder result from increased amounts of electrolyte in the sweat, which leads to excessive skin wrinkling when the palms and soles are immersed in water. Although this feature is not always present, it may be a valuable clue to the disease. Parents are often aware of, but not disturbed by, the wrinkling. [5]

Larva Migrans and Pulmonary Involvement (See also Chap. 236)

Cutaneous larva migrans, or creeping eruption, may occasionally cause minimal respiratory symptoms and be associated with transient pulmonary infiltrates and a peripheral eosinophilia (Löffler's syndrome). Visceral larva migrans, or toxocariasis, may lead to granulomatous involvement of the liver, lungs, heart, muscle, brain, and eyes. Marked eosinophilia, hyperglobulinemia, pneumonitis with wheezing, recurrent bronchitis, fever, and tender hepatomegaly frequently occur. Skin lesions may present as patchy urticaria or erythematous papular eruptions.

Fat Embolism Syndrome

Petechiae, respiratory insufficiency, and cerebral dysfunction after long bone fracture are termed the *fat embolism syndrome*. Petechiae alone after fractures should suggest this syndrome. Histologically, fat globules are present within the dermal and pulmonary vessels. Additional factors such as hyperglycemia, diabetes, or elevated ß-lipoproteins may play a contributing role. The petechiae are most commonly on the neck, axillae, shoulders, chest, and conjunctivae, and they often appear before other manifestations. They begin about the second or third day after injury, appear in crops, and are almost never found on the face or posterior aspects of the body. When widespread, they tend to herald more significant cerebral and pulmonary dysfunction. In addition, cyanosis may be prominent.

The respiratory involvement may begin with dyspnea, tachypnea, or hemoptysis. Tachycardia, fever, and pulmonary edema may occur. X-rays may show patchy densities or linear streaks progressing to the bilateral opacities characteristic of the adult respiratory distress syndrome. Cerebral dysfunction includes restlessness, irritability, delirium, and coma. Additional features include jaundice, renal involvement, anemia, thrombocytopenia, and elevated sedimentation rate. [17]

SELECTED DISEASES AFFECTING THE CARDIOPULMONARY SYSTEM

Lipoid Proteinosis (Hyalinosis Cutis et Mucosae) (See also Chap. 152)

Skin changes include confluent, waxy papules, acne-like scarring, and plaques, particularly on the face. Oropharyngeal and laryngeal mucous membranes are usually affected early in the course of the disease, during infancy or childhood. The tongue enlarges and acquires a firm consistency and a smooth, glistening surface. Hoarseness due to laryngeal infiltration is often the initial finding and may be present at birth. Laryngeal and tracheal infiltration may progress to obstruction and cause respiratory insufficiency requiring tracheostomy. The trachea and main stem bronchus may be thickened and studded with wartlike hyaline projections. An increased risk of aspiration pneumonia has been reported, as has repeated upper respiratory infections. Cardiovascular involvement is rare, but conduction defects and arrhythmias have been reported.

Multicentric Reticulohistiocytosis (See also Chap. 162)

Multicentric reticulohistiocytosis is an uncommon disorder presenting with characteristic mucocutaneous lesions consisting of deeply set, firm, small papules, and a deforming arthritis in association with systemic symptoms such as fever, malaise, weight loss, and myopathy. Neurofibroma-like, soft, sessile, larger lesions have been reported. The cardiopulmonary complications include pulmonary infiltrates, pleural effusions, pericarditis, cardiomegaly, congestive heart failure, angina pectoris, myocardial infarction, and pulmonary infarction. An association of multicentric reticulohistiocytosis with malignancy has been recorded in a few reports, suggesting the need for complete evaluation of these patients. [18]

Sarcoidosis (See also Chap. 183)

Sarcoidosis is a multisystem granulomatous disease with unknown cause and widespread manifestations. Cardiac involvement consisting of myocardial or conduction system granulomata may be occult, but it may be clinically evident in about 20 percent of the patients. Ventricular arrhythmias and conduction disturbances are responsible for the palpitations, presyncope, and syncope reported. Congestive heart failure and chest pain occur less frequently and may be due to cardiomyopathy or cor pulmonale. Additionally, prolapsed mitral valves, papillary muscle dysfunction, and aneurysm formation are rarely found. The prognosis for patients with cardiac involvement is unfavorable. Sarcoidosis

affecting the pulmonary system may be suggested by lupus pernio (see Chap. 183) with involvement of the hilar nodes, bronchi, and/or alveoli resulting in obstructive and/or restrictive dysfunction. Respiratory failure is often the most difficult clinical problem, characterized by shortness of breath and hypoxemia. [19]

While there are at least two forms of sarcoidosis—acute (transient) and chronic (persistent)—no definite correlation between skin and internal involvement has been made. However, those patients who present abruptly with hilar adenopathy and nonspecific skin involvement, such as erythema nodosum (Löfgren's syndrome), appear to respond to glucocorticoid therapy and have fewer recurrences and a more favorable prognosis.

Amyloidosis (See also Chap. 148)

Cutaneous involvement occurs most often in the primary and myeloma-associated types, and therefore serves as a marker for cardiopulmonary involvement. A skin biopsy of clinically normal skin in a patient suspected of having amyloidosis might demonstrate deposition within the vessels in as much as 50 percent of patients.

Involvement of the heart may be associated with all three systemic forms of amyloidosis but appears to be clinically predominant in the primary myeloma-associated types. Senile amyloidosis may also affect the heart but is often asymptomatic. Clinical findings include dizziness, palpitations, syncope, orthostatic hypotension, and congestive heart failure. Chest x-ray may reveal cardiomegaly. Electrocardiograms may show low-voltage, abnormal Q waves, conduction defects, and arrhythmias. Echocardiography may reveal a restrictive cardiomyopathy with enlargement of the left ventricular wall and obstruction of the outflow tract. Pathologically, infiltration of the endocardium, myocardium, pericardium, valves, and coronary vessels may occur. [20] Upper and lower respiratory tract involvement also occurs in all systemic forms of amyloidosis but is clinically predominant in primary and myeloma-associated types. Macroglossia may impede respiration, especially when complicated by bleeding. The larynx and trachea may become infiltrated, causing hoarseness, cough, and respiratory stridor. Bronchial and lung parenchymal involvement may cause asthma-like symptoms, hemoptysis, and severe pulmonary disease. Chest x-rays may reveal interstitial type involvement and occasionally amyloid nodules may mimic a malignant tumor. Pulmonary function studies may reveal obstructive or restrictive dysfunction depending on the location of the amyloid deposition.

Lymphomatoid Granulomatosis (See also Chap. 158)

Lymphomatoid granulomatosis (LYG) is a rare angiocentric and angiodestructive, Epstein-Barr virus-associated B cell lymphoproliferative disorder, varying widely from an indolent process to an aggressive large cell lymphoma. The skin is the extrapulmonary organ most commonly involved. The disease also affects the lungs, heart, central nervous system, kidneys, and other organs. Pulmonary involvement may begin with transient alveolar or interstitial infiltrates and effusions on chest x-ray, which subsequently may progress to nodular, masslike densities. These lesions may cavitate and be responsible for profuse hemoptysis. Although many patients remain asymptomatic, cough, dyspnea, and chest pain may occur. Cardiac involvement is uncommon but, when present, may involve the coronary vessels with subsequent myocardial ischemia.

COLLAGEN VASCULAR DISEASES

The cardiopulmonary complications of the various collagen vascular diseases may sometimes be associated with a specific cutaneous sign or constellation of features.

Rheumatoid Arthritis (See also Chap. 179)

Extraarticular manifestations of rheumatoid arthritis, especially in the pulmonary system, appear to correlate with subcutaneous nodules and vasculitic skin lesions. In addition, laboratory evidence of high-titer rheumatoid factor, hypocomplementemia, cryoimmunoglobulinemia, and hypereosinophilia may be associated with the extraarticular manifestations including cardiopulmonary disease. These manifestations occur more commonly in men with long-standing disease, but may not necessarily correlate with arthritis activity at the time. The pulmonary disease consists of pleural effusions, localized or diffuse parenchymal infiltrates, or, rarely, lung nodules. Complaints include dyspnea, cough, pleuritic chest pain, and hemoptysis. Cardiac involvement may not be clinically apparent, although autopsy studies have revealed a high incidence of cardiac lesions related to granuloma or vasculitis.

Systemic Lupus Erythematosus (See also Chap. 171)

Cutaneous manifestations of SLE appear in more than 75 percent of patients during the course of their disease. While the extent of the cutaneous features in SLE may not correlate with the severity of visceral disease, the trend toward serologic and clinical subsets has suggested certain associations.

PLEUROPULMONARY DISEASE IN SLE Pleuritis may be present during the course of the disease in about half of patients with SLE. Chest pain may become subacute or chronic because of adhesions and may be confused with costochondritis. Pleural effusions with or without a friction rub may also occur. Parenchymal lung involvement in SLE is usually a result of secondary factors such as infections or pulmonary emboli. Primary lung involvement in SLE may be classified as (1) diffuse interstitial pneumonitis, (2) acute pneumonitis, (3) intrapulmonary hemorrhage, (4) diaphragm dysfunction with decreased lung volume (shrinking lung syndrome), (5) pulmonary hypertension with cor pulmonale, and (6) fibrosing alveolitis. [21] Respiratory difficulty may also be due to acute epiglottitis, necrotic and ulcerative laryngitis, and tracheobronchitis.
CARDIAC DISEASE IN SLE Cardiac involvement in patients with SLE is frequently subclinical. Pericarditis may be more common in patients with drug-induced syndromes or in those patients with photosensitive discoid lesions. Chest pain may be present, especially when associated with effusion. A friction rub may be heard. The ECG changes primarily are T-wave abnormalities. Myocarditis is often undiagnosed and may be associated with prolonged P-R intervals, heart

block, and arrhythmias. Since the introduction of glucocorticoid therapy, an increased incidence of atherosclerotic-related myocardial infarction has been reported. Valvular heart disease in patients with SLE, most often of the Libman-Sacks type, is frequently associated with antiphospholipid antibodies, and manifested by systolic murmurs, which may occur in almost 50 percent of all patients. These murmurs are rarely clinically significant. [22] Although diastolic murmurs may occur because of noninfectious mitral stenosis or aortic insufficiency, the onset of a new diastolic murmur should provoke a search for subacute bacterial endocarditis. The cutaneous clues of this disease, such as splinter hemorrhages, Osler's nodes, Janeway lesions, and Roth's spots, should be sought, although they may occur in SLE without infection. It appears that SLE, as well as other cutaneous vascular diseases, may be associated with complete heart block in newborn infants. In SLE, this may be because of placental transfer of maternal antibodies, especially the anti-Ro antibody. [23] The newborn infants of patients with SLE or of clinically normal but Ro-antibody–positive mothers may also have distinctive evanescent cutaneous eruptions, including prominent telangiectasia and periorbital erythema (neonatal lupus erythematosus). [24]

Dermatomyositis (See also Chap. 172)

Interstitial lung disease occurs as part of the disease process itself, and occurs in 5 to 30 percent of patients with inflammatory muscle disease. [25] The course of the lung disease is variable; other pulmonary manifestations seen in dermatomyositis include bronchiolitis obliterans, vasculitis, pneumomediastinum, subcutaneous emphysema, and spontaneous pneumothorax. Upper pharyngeal weakness can lead to chronic aspiration and resulting parenchymal changes. In addition, exertional dyspnea can occur because of weakness of the respiratory muscles. Anti-Jo-1 antibodies are associated with increased lung disease, as well as “mechanics hands.”

Symptomatic cardiac involvement is rare. Patients can have rhythm disturbances, conduction defects, left ventricular diastolic dysfunction, congestive heart failure, and, rarely, pericarditis and pulmonary hypertension. Mitral valve prolapse has been described. Myocardial fibrosis, necrosis, or carditis can be seen.

Systemic Sclerosis (See also Chap. 173)

Microvascular abnormalities are among the earliest pathologic changes seen in patients with systemic sclerosis, a finding supporting the concept of a primary vascular defect in the disease. Typically, the vascular lesions are characterized by intimal proliferation with loose connective tissue at the internal elastic membrane, medial thinning, and adventitial fibrosis. Many of the cutaneous features of this disorder are directly attributable to vascular abnormalities and occur early in the disease. They include vasospastic episodes (Raynaud's), telangiectases, and nail fold capillary changes appearing as dilated and distorted capillary loops alternating with avascular areas on wide-field capillary microscopy.

PULMONARY ABNORMALITIES Dyspnea on exertion, occurring in approximately 50 percent of patients, is usually the most common symptom. Chronic, nonproductive cough and pleuritic chest pain may also occur. Examination may reveal dry rales, especially at the bases, as well as diminished breath sounds and pleural rubs. Chest x-ray may show a diffuse reticulonodular interstitial pattern, cystic changes, calcification, pleural effusion, or scarring. Pulmonary function tests reveal diminished diffusing capacity, decreased volume, and decreased compliance characteristic of restrictive disease. [26] Abnormalities of the respiratory system may be due to processes other than parenchymal lung disease. For example, pulmonary hypertension with cor pulmonale and congestive heart failure may develop independently of parenchymal disease, and is seen fairly early in the course of limited cutaneous scleroderma [calcinosis cutis, Raynaud's phenomenon, esophageal dysfunction, sclerodactyly, and telangiectasia (CREST)]. Biopsies of the lung show the typical changes described earlier around the small pulmonary arteries and arterioles. Esophageal dysmotility may cause aspiration pneumonia and acute respiratory insufficiency, and is associated with a higher incidence of interstitial lung disease. [23] Finally, abrupt changes in respiratory function suggest the possibility of a bronchoalveolar carcinoma in association with long-standing pulmonary fibrosis.
CARDIOVASCULAR DISEASE Acute or chronic pericarditis is an important feature of the disease and, when associated with congestive heart failure, may be a marker for incipient renal failure. Pericardial effusions may be occult, and constrictive pericarditis and tamponade may occur. Transient vasospasm may involve the coronary vessels and cause myocardial ischemia with angina. Additionally, small-vessel involvement of the myocardium may lead to fibrosis (scleroderma heart). Fibrosis of the conduction system may cause arrhythmias and sudden death. Right ventricular hypertrophy because of cor pulmonale with congestive heart failure and pulmonary hypertension is observed. The presence of the CREST variant may be associated with biliary cirrhosis and may not imply diminished cardiopulmonary or renal involvement in all cases as originally described. Increased tortuosity of capillaries and areas of avascularity suggest an increased probability of cardiopulmonary and renal disease.

Relapsing Polychondritis (See also Chap. 178)

Relapsing polychondritis is characterized by inflammation and destruction of cartilage and connective tissues, including those of the cardiopulmonary system. The pathogenesis is unknown, although it appears to be an autoimmune process frequently associated with other immunologic disorders such as SLE and rheumatoid arthritis. Auricular chondritis with pain, swelling, and redness of the pinna but complete sparing of the lobes is characteristic. Respiratory tract involvement may begin with hoarseness or tenderness of the anterior trachea. Degeneration of the laryngeal, tracheal, and/or bronchial rings may lead to progressive insufficiency or to sudden collapse requiring emergency tracheostomy. Adequate ventilatory support may not be possible if advanced scarring and deformity are present. Cardiac involvement includes degeneration of the aortic ring with valvular insufficiency and aneurysmal dilatation. “Floppy” mitral valve syndrome also occurs. Pericardial and myocardial abnormalities have been reported.

ARTERIOSCLEROSIS OBLITERANS

Arteriosclerosis obliterans is characterized by muscle pain or fatigue with exercise or by rest pain, ulcers, or gangrene of the distal lower extremities as a result of stenosis or obstruction of large arteries by atheroma and thrombosis.

Epidemiology

Intermittent claudication because of arteriosclerosis obliterans affects about 1 percent of the population older than 35 years of age. It occurs predominantly in males. Most patients have superficial femoral artery disease and develop symptoms in the seventh decade, but symptoms from aortoiliac disease usually occur a decade earlier. [1]

Etiology and Pathogenesis

Arteriosclerosis is similar to vascular disease that occurs in other areas of the body. Arteriosclerosis obliterans develops at twice the frequency in patients who smoke than in nonsmokers. Approximately 50 percent of patients have hyperlipidemia. It is more common in patients with hypertension. Patients with diabetes mellitus develop the disease at an earlier age than do nondiabetics and have more severe and progressive disease. The distribution of the disease is different in diabetics than in nondiabetics in that diabetics have less aortoiliac disease and more disease of the vessels between the knees and the ankles than do nondiabetics; however, superficial femoral artery disease is similar in both populations. [1]

The cause of atheromas is unknown, but progressive buildup of cholesterol plaques narrows the vessel lumen, and, finally, occlusion may occur by thrombosis. Because the disease progresses slowly, collateral blood vessels develop to supply the extremity distal to the stenosis or obstruction. Therefore, the blood supply to the limb is usually adequate at rest, but the blood pressure distal to the lesions is decreased because of the high resistance of the collateral vessels. [1] When skin lesions develop, the blood supply to the limb is severely compromised.

Prevention

Preventive measures that may help avoid arteriosclerosis obliterans are targeted at the risk factors. [2] Tobacco smoking is contraindicated. Hypertension and diabetes mellitus should be controlled, and hyperlipoproteinemias should be treated. Evidence is accumulating that control of hypercholesterolemia will prevent progression of atherosclerotic complications. In patients with diabetic neuropathy, trauma to the limbs must be avoided and special shoes may be needed.

Clinical Manifestations

The patient complains of pain, fatigue, or a tiredness in the muscles distal to the diseased segment on walking (intermittent claudication). The distance covered before symptoms appear is quite constant for each patient, except that shorter distances can be covered when walking up inclines or carrying heavy bundles. The symptoms are usually relieved within 5 min by rest, even while standing. Patients with inadequate collateral circulation will complain of coldness, hyperesthesias, rest pain, discolored toes, or skin breakdown. Rest pain may be so severe that patients cannot sleep or sleep with the leg in a dependent position; they then may develop edema of the lower parts of the extremity.

The limbs in patients with only intermittent claudication may appear normal, although there may be hair loss, coldness, and thickened or malformed toe nails. In aortoiliac disease, there may be global atrophy of the lower limbs. Pulses will be decreased or absent distal to the diseased arterial segment, and there may be bruits over the distal vessels. In patients with severe ischemia, the skin is apt to be atrophic, dry, and shiny. In patients with rest pain, the foot is usually bright red and cold in dependency. Rest pain occurs in the foot; the muscles rarely have rest symptoms. Ulcerations most often start at the tips of the toes and are extremely painful except when a diabetic neuropathy is present. Ulcers occasionally start on the lower calves (Fig. 167-1). The ulcers have a sloughing gray or black base. The heels may show cracks in the skin. When gangrene occurs, usually one or more toes become black, dry, and mummified.

FIGURE 167-1 An ischemic ulcer in a patient with arteriosclerosis obliterans. The location on the lateral aspect of the ankle is typical. The base of the ulcer shows fibrous tissue with scant granulation tissue and the outline of tendons. The distal foot and toes are cyanotic from ischemia.

Bedside and Special Examinations

The collateral circulation to limbs affected by arteriosclerosis obliterans can be evaluated by simple tests. [1] With the patient supine, elevation of the limb at a 45-degree angle for 2 min should not produce pallor. The collateral circulation is not adequate if the toes and feet become pale. If the patient then assumes a sitting position with the legs dependent, the

times for filling of the foot veins and flushing of the feet can be measured. The veins should fill within 20 s and the feet flush immediately in a warm environment. When these times exceed 30 s, the collateral circulation is inadequate and the patient must be observed frequently for the development of rest pain, ulcers, or gangrene. Venous filling times are not of value in the presence of varicose veins. An objective test to document the disease is the measurement of ankle systolic blood pressure. The ankle systolic pressure in the supine position should be equal to or greater than the brachial artery systolic pressure. An ankle-to-arm systolic pressure index is usually calculated; values greater than 0.95 are considered normal, while those less than 0.4 are indicative of severe disease. Arteriography or magnetic resonance angiography can be used to demonstrate the location and extent of disease in the arteries but supply no hemodynamic information. They are usually used only before vascular surgery and not as a diagnostic test.

Pathology

There is a focal accumulation of lipids, mucopolysaccharides, blood and blood products, fibrous tissue, and calcium deposits in the intima of arteries. Localized areas of thickening of the intima by fibroblastic proliferation and phagocytes laden with lipid material are seen. The media is atrophic with thin strands of smooth muscle, disrupted elastic lamella, collagen tissue, and calcium deposits. Enlarging plaques encroach on the lumen despite dilation of the artery, and the plaques may ulcerate. Hemorrhages occur in the arterial wall. Thrombi may form and occlude the narrowed arterial lumen.

Diagnosis and Differential Diagnosis

The diagnosis of arteriosclerosis obliterans can usually be made by the typical history of intermittent claudication and palpation for diminished or absent pulses in the limbs. In questionable cases, ankle systolic blood pressures should be measured at rest and, if needed, after exercise. In patients with diabetes mellitus, ulcers may develop on the heel, toes, or anterior calf in the presence of normal pulses. These painless ulcers are due to repetitive trauma not noticed by the patient because of peripheral neuropathy (Fig. 167-2; see also Chap. 168). Other causes of neuropathy also lead to neurotropic ulcers. Surrounding callus formation is typical of these ulcers.

FIGURE 167-2 Two neurotropic ulcers over the metatarsal head and on the heel in a patient with diabetes mellitus and neuropathy. The ulcers are painless and deep, and surrounded by callus.

Thromboangiitis obliterans also causes intermittent claudication, ulcers, and gangrene. It occurs in a younger age group (onset of symptoms before age 45) and is often associated with superficial thrombophlebitis and vasospasm. It affects medium and smaller arteries and the upper extremities more commonly than does arteriosclerosis obliterans. Neurogenic claudication is often a difficult differential diagnosis and is due to compression or intermittent ischemia of the lower spinal cord or corda equina with exercise. Etiologic factors are prolapsed intervertebral discs, congenital stenosis, or hypertrophic bony ridging of the spinal canal. In contrast to arteriosclerosis obliterans, leg pain may occur in the erect position without exercise, neurologic signs may be present before or after exercise, and peripheral pulses are normal. Magnetic resonance imaging (MRI) or computed tomographic (CT) scan will confirm the diagnosis.

Treatment and Prognosis

For patients with intermittent claudication and an adequate collateral circulation, an exercise regime is the treatment of choice. [2] Patients are instructed to exercise to tolerable pain, rest, and then exercise again for 30 to 60 min a day in excess of their normal activity. The exercise period must be performed in one session, and any type of exercise is beneficial as long as it is in the upright position. In several studies, approximately 80 percent of patients have increased their walking distance. Patients must also quit smoking, for smokers have a greater amputation and vascular graft occlusion rate than nonsmokers. Patients should also be instructed to keep their feet warm, clean, and dry; extremes of temperature should be avoided, as ischemic tissue is more susceptible to burning and to frostbite than normal tissue. Cuts or severe bruises of the limbs or feet should be treated immediately. Vasodilators have no value in treatment. Cilostazol, a phosphodiesterase inhibitor, and propionyl-L-carnitine increase treadmill walking distance and quality of life; the latter is not available in the United States and the former has formidable side effects. [3] In some studies, pentoxifylline, an agent that has hemorheologic effects, has improved walking distance.

Surgery or endovascular intervention is usually reserved for patients with intermittent claudication that interferes with employment, ischemic symptoms at rest, or ulcers and gangrene. Sympathectomy is not of value for intermittent claudication but may allow small ulcers or areas of gangrene to heal. In patients with rest pain, ulcers, or gangrene who cannot undergo revascularization procedures, treatment is difficult. A period of rest with legs dependent may help some patients, but amputation is a frequent outcome. Parenterally administered prostacyclin or prostaglandin E_1 has had favorable reports but has not yet been adequately evaluated.

Dry gangrene of the digits or lower limbs should be allowed to demarcate by itself. Soaking or ointments are unnecessary. The edges of the gangrenous areas should be kept open if possible and observed frequently for infection. Pain medication is usually necessary for 2 to 3 months with digital gangrene. Conservatism and patience will save many

digits and extremities. Infected (wet) gangrenous areas must be débrided and appropriate antibiotics administered. Amputations may be necessary.

In most studies, 60 to 90 percent of patients with intermittent claudication as a consequence of arteriosclerosis obliterans remained stable over a period of 5 to 9 years. Patients with diabetes mellitus, however, have progressive disease, and their amputation rate is fourfold greater than for patients without diabetes.

ATHEROMATOUS EMBOLISM

Atheromatous embolism is the embolization of small pieces of atheromatous debris from arteries to the extremities or body organs. This disease has also been called “blue toe syndrome” and “trash foot syndrome.”

Epidemiology

In 100 consecutive autopsies of patients predominantly older than 50 years of age, 4 percent revealed atherosclerotic emboli. [4] In another autopsy series, only 0.79 percent of 2126 patients over 60 years of age had such emboli, but many cases may have been missed. Usually patients are males older than age 50 years.

Etiology and Pathogenesis

Instigating causes are often absent, but coughing or straining has been postulated as a factor in breaking loose the emboli. Catheterization of blood vessels is one of the most common causes of embolization. [4] Coumarin derivatives have also been blamed, but it is more likely that they aggravate the lesions and prevent healing. The emboli usually originate from the aorta or proximal blood vessels that are severely involved with atherosclerotic lesions. An aneurysm can also be the source. The vessel lining of the atherosclerotic vessels is usually irregularly ulcerated and shaggy. The clinical picture is caused by ischemia of the skin and muscle due to the emboli, although all organs of the body may be involved.

Prevention

One way of prevention is to avoid catheterization of severely atherosclerotic blood vessels.

Clinical Manifestations

Patients will present with unilateral or bilateral discolored or ulcerated painful toes. They may complain of painful and tender calf muscles and a rash on the lower calf or foot. If the entire aorta is involved, transient ischemic attacks or strokes, renal failure, hemorrhagic pancreatitis, and gastrointestinal ulcerations and bleeding may occur. In these patients, almost all organs except the lung have been shown to contain cholesterol crystals. [4]

Physical examination reveals tender, blue toes, and there may be ecchymoses of the sole and lateral aspects of the feet. In some patients, the entire extremities and trunk may show ecchymotic lesions and petechiae. Livedo reticularis and petechiae may be present on the calf and feet. Ulcers or gangrene may be present (Fig. 167-3A, Fig. 167-3B), although surrounding the ischemic areas is normally perfused tissue. The calf muscles are often tender. Occasionally there are elevated plaques of skin. The upper extremities are involved in patients with disease of the entire aorta (Fig. 167-4). Pedal and proximal pulses are usually normal, but there may be systolic bruits over the aorta or common femoral arteries. Fever may be present.

FIGURE 167-3 Multiple atheromatous emboli to the lower body and limbs in a patient with extensive atheromatous disease of the aorta. *A*. Livedoid vascular pattern with early infarcts. *B*. Within several days the initial infarction and necrosis is much more extensive.

FIGURE 167-4 Atheromatous emboli to the fingers in an 80-year-old patient with extensive atheromatous disease of the aorta. There is gangrene of the third and fourth distal fingers and ecchymotic discrete areas proximally. Radial and ulnar pulses were normal.

Laboratory and Specific Examinations

Eosinophilia is common and has been described in up to 80 percent of patients with renal atheromatous emboli. [5] Thrombocytopenia, hypocomplementemia, and anemia may occur. The sedimentation rate is often elevated. In patients with multisystem involvement, there may be elevated renal function tests, increased amylase levels, blood in the urine or stool, and anemia. Angiography demonstrates diffuse atherosclerotic involvement of the vessels proximal to the lesions.

Pathology

Skin or muscle biopsies may reveal the characteristic elongated, needle-shaped clefts of cholesterol crystals in small arterial vessels. There may be inflammatory infiltrates, intimal thickening, and perivascular fibrosis. Giant cells may also be present.

Diagnosis and Differential Diagnosis

The diagnosis of atheromatous emboli is suggested by the blue or ulcerated painful digits, livedo reticularis, petechiae, tender calf muscles, and elevated skin plaques in the presence of normal pulses. A definite diagnosis can be made by skin, muscle, or renal biopsies. Occasionally, cholesterol emboli may be visualized in the retinal arterioles. In the differential diagnosis of the blue toe syndrome, several other entities must be considered (Table 167-1). Biopsy of skin or muscle showing cholesterol crystals usually rules out other causes.

Atheromatous emboli	Vasculitis
Emboli from the heart	Polyarteritis
Connective tissue diseases	Malignancy with or without cryoglobulins or macroglobulins
Primary Raynaud's disease	Antiphospholipid and anticardiolipin antibodies
Thrombocytosis	
Polycythemia	

TABLE 167-1 **Differential Diagnosis of the Blue Toe Syndrome**

Treatment and Prognosis

Atheromatous emboli can usually be stopped by surgical bypasses or endarterectomy to remove or exclude the source, although many of these patients have contraindications to major surgery. In these cases, antithrombotic therapy such as subcutaneous heparin or low molecular weight heparin, or antiplatelet agents such as or aspirin and dipyridamole, can be tried and, if successful, therapy should be continued for at least 1 year. [4] Warfarin is usually avoided, especially if toe ulcers are present. Many patients will not respond to any therapy except surgery. The syndrome usually subsides and lesions heal following successful surgical or medical treatment. Sometimes the emboli cease spontaneously. When surgery cannot be performed and emboli continue, amputations may result. In the malignant multisystem disease, patients usually die within a year if treatment is unsuccessful.

THROMBOANGIITIS OBLITERANS

Thromboangiitis obliterans (also known as Buerger's disease) is an inflammatory occlusive disease affecting medium and small arteries and veins.

Epidemiology

The prevalence of the disease is greatest in eastern Europe, the Mediterranean area, and Asia. Males are afflicted in much greater number than females, although an increased incidence in females has occurred in recent years. Patients are usually between the ages of 20 and 40 years. For some reason, there has been a marked decline in the prevalence of the disease in the United States.

Etiology and Pathogenesis

The etiology of thromboangiitis obliterans remains unknown. [6] Almost all patients who develop this disease are smokers, and the syndrome sometimes abates with the cessation of tobacco smoking. An increased cellular sensitivity to types I and III collagen has been reported as compared to the sensitivity of normal men and patients with arteriosclerosis obliterans. During active disease serum antiendothelial cell antibody titers are very high, and impaired

endothelial-dependent vasodilation to acetylcholine has been found, even in nondiseased limbs. The pathogenesis involves the production of tissue ischemia and all its manifestations by an inflammatory reaction of medium and small arteries of the extremities and obstruction by thrombi. Veins may also be involved. Occasionally, cardiac, intestinal, and cerebral vessels are involved.

Prevention

The only preventive measure is never to smoke.

Clinical Manifestations

The most common initial complaints are claudication of the foot or lower calf, digital cyanosis or gangrene, or rest pain. Patients may present with ulcers of the toes or fingers, for although the lower extremities are affected most often, more than a third of patients have upper extremity involvement. Ulcerations or gangrenous areas are characteristically extremely painful. Vasospasm or migratory superficial thrombophlebitis may occur in 40 percent of patients. Physical examination may reveal cyanotic, ulcerated, or gangrenous, very painful digits. The dorsalis pedis, posterior tibial, and ulnar pulses are often absent. During episodes of thrombophlebitis, small indurated red, tender nodules will be found, which follow the course of superficial veins and are common on the thigh or calf. Typical changes of Raynaud's phenomenon, with well-demarcated pallor or cyanosis of the digits, may be seen on exposure to cold; one or more extremities may be involved.

Laboratory and Special Examinations

There are no specific blood studies. Arteriography is sometimes typical, showing segmental occlusions of medium and small blood vessels with normal vessel walls between diseased areas, no arteriosclerosis of proximal vessels, and corkscrew configuration of collateral vessels originating from occluded vessels.

Pathology

In the acute stage, there is a panvasculitis of arteries and veins; the diagnostic finding is arterial thrombi with foci of microabscesses and giant cells. In contrast to systemic vasculitis (see Chap. 174) and arteriosclerosis obliterans, the vessel wall and internal elastic lamina are not disrupted. [6] In the chronic stage, only fibrotic obliteration of the arteries is seen, and the diagnosis can only be surmised because arteriosclerosis is absent.

Diagnosis and Differential Diagnosis

The diagnosis should be considered in young male smokers presenting with symptoms and signs of distal extremity ischemia, migratory thrombophlebitis, and Raynaud's phenomenon. Arteriography may suggest the diagnosis, but only a biopsy of an artery or vein during the active phase of the disease that shows the characteristic pathologic picture is diagnostic. Arteriosclerosis obliterans occurs in an older age group, usually over 45 years of age, larger vessels are involved, Raynaud's phenomenon is infrequent, and the upper extremities are rarely involved. In diabetes mellitus, the arteriosclerosis may affect medium-sized vessels, but the blood sugar is normal in thromboangiitis obliterans. Raynaud's phenomenon associated with scleroderma may present with a similar picture, but systemic symptoms, proximal skin changes, and antinuclear antibodies will help in the diagnosis.

Treatment and Prognosis

There is no specific treatment. Patients must give up smoking; in some, the disease will abate. Daily infusions of iloprost, a prostaglandin analogue, relieve rest pain, heal ulcers, and prevent amputation more frequently than does aspirin. Bypass surgery is rarely possible because of the small size of the vessels affected. Vascular endothelial growth factor gene therapy may prove of value. Sympathectomy may help patients with a prominent vasospastic component. The course of the disease is marked by exacerbations and remissions, but the disease usually becomes quiescent after many years. Cessation of tobacco smoking sometimes hastens the disappearance of the disease. Amputations of digits or even extremities may be necessary, especially in patients who continue to smoke. Patients have a normal life expectancy.

ERYTHROMELALGIA (ERYTHERMALGIA)

Erythromelalgia is characterized by intense, burning pain with marked erythema of the affected region.

Epidemiology

This is a rare disorder with limited epidemiologic data available. In Norway, the incidence is estimated to be 0.25 for 100,000 population with a prevalence of 2 per 100,000. [7] Primary erythromelalgia occurs, although at all ages more in males than females. In contrast, secondary erythromelalgia has an equal sex distribution and occurs mostly after the third decade.

Etiology and Pathogenesis

The etiology of the primary disease is unknown. [7] It is postulated that the precapillary sphincters may be constricted while the arteriovenous shunts are open leading to an increased total perfusion but a deficient nutritive blood flow. The substances produced by the local hypoxia cause increased local blood flow, warmth, redness, and pain. Secondary erythromelalgia occurs in polycythemia, thrombocythemia, autoimmune disease, hypertension, and neuropathies. The blood dyscrasia syndromes are believed to be caused by platelet breakdown products because they respond to aspirin

therapy.

Genetics

The primary erythromelalgia gene has been localized to chromosome 2q. Families have been described with an autosomal dominant mode of inheritance of erythromelalgia.

Clinical Manifestations

The disorder is characterized by intense burning pain, redness, swelling, and increased skin temperature. It occurs primarily in the feet but may also involve the hands, face, and ears. It may spread to the limbs and is usually bilateral although it can be unilateral in secondary cases. The onset may be gradual or abrupt. Symptoms may be continuous or occur in flares late in the day or night. Exposure to heat, dependency of the extremity, or exercise may trigger flares while cold water immersion relieves them. Examination during attacks reveal warm, red, extremely sensitive extremities with normal pulses. Between flares, the extremities may appear normal. The constant use of ice water leads to maceration of the skin, secondary infection, nonhealing ulcers, and necrosis.

A few patients have been described who have both erythromelalgia and Raynaud's phenomenon. During the hyperemic phase of Raynaud's phenomenon, patients often complain of erythromelalgic-like symptoms. It is postulated that both syndromes have a common basis in a dysfunction of the regulation of vasomotor tone.

Pathology

The pathology of the primary disease is unknown. In the secondary syndrome caused by thrombocythemia or polycythemia, fibromuscular dysplasia, internal elastic membrane splitting, and thrombotic occlusions of arterioles are present.

Laboratory and Special Examinations

There are no confirmatory tests. Warm water immersion at 32° to 36°C (89.6° to 96.8°F) may induce attacks.

Diagnosis and Differential Diagnosis

The diagnosis must be made from the history and clinical manifestations. Skin injury is sometimes present from the constant cold-water immersion. Secondary disease must be ruled out by complete blood cell counts and platelet counts; antinuclear antibodies will help to distinguish autoimmune diseases. The main differential diagnosis is reflex sympathetic dystrophy during the early warm phase, but this is usually unilateral and there is a history of trauma. Nerve conduction studies may be necessary to rule out neuropathies.

Treatment and Prognosis

No therapy has proved beneficial in all patients. [7] Serotonin reuptake inhibitors or tricyclic agents may help. Biofeedback, hypnosis, propranolol, lorazepam, cycloheptadine, methysergide, piroxicam, pizotifen, and calcium channel antagonists are not usually beneficial. Gabapentin or capsaicin cream may reduce the pain. Intravenous prostaglandins have also been used, as has surgical or medical sympathectomies. Aspirin is often of great benefit, but only in secondary cases. The symptoms may be mild for several years or totally disabling within weeks. Many patients become unable to work or carry on daily activities. Constant immersion in ice water may lead to trophic changes of the skin and even the necessity of amputation from ulcers and infections.

VASOSPASTIC DISEASES AND DISEASE DUE TO COLD EXPOSURE (See alsoChap. 126)

Raynaud's Phenomenon

Raynaud's phenomenon is the occurrence of episodic attacks of well-demarcated blanching or cyanosis of one or more digits on exposure to cold.

Epidemiology

Primary Raynaud's phenomenon usually occurs in patients 15 to 40 years of age but may occur in children younger than 15 years of age, and in patients older than 50 years of age. [8] There is a strong 4:1 female to male predominance. Primary Raynaud's phenomenon occurs in 4.6 to 30 percent of randomized questioned populations. [9]

Etiology and Pathogenesis

The pathogenesis of primary Raynaud's phenomenon or episodic vasospastic attacks is unknown. A local fault at the digital artery level in which the blood vessels are abnormally sensitive to cold and an overactivity of the sympathetic nervous system are the two proposed theories. The local fault theory has the most scientific backing. The local fault may be at the a $_2$-adrenoceptor level, because there are increased levels of a $_2$-adrenoceptors in platelets of patients with primary Raynaud's phenomenon and they show an increased digital vasoconstrictor response to an intraarterial a $_2$-adrenoceptor but not to an a $_1$-adrenoceptor agonist. [10] Vasospastic attacks are probably due to a combination of factors, including (1) normal vasoconstriction as a result of reflex sympathetic activity and local cold; (2) low systemic and intravascular blood pressure; (3) external pressure on the digit; (4) increased sensitivity of certain receptors (a

$_2$-adrenoceptors, S $_2$-serotonergic receptors); and (5) release of vasoactive agents from platelets.

The connective tissue diseases are the most common cause of secondary Raynaud's phenomenon (Table 167-2). [8] Between 80 and 90 percent of patients with scleroderma manifest Raynaud's phenomenon and/or persistent vasospasm. It is the presenting symptom in about one-third of patients, and may be the only manifestation of the disease for years. Raynaud's phenomenon occurs in 10 to 35 percent of patients with systemic lupus erythematosus and in about 30 percent with dermatomyositis. Arteriograms in patients with connective tissue diseases show digital and sometimes ulnar or radial artery obstructions.

Connective tissue disease	Trauma
Sclerodema	Vibratory tools
Systemic lupus erythematous	Hypothenar hammer syndrome
Dermatomyositis and polymyositis	Pianists, typists
Mixed connective tissue disease	Meat cutters
Rheumatoid arthritis	Hematologic causes
Sjögren's syndrome	Cryoproteins
Obstructive arterial disease	Cold agglutinins
Arteriosclerosis obliterans	Macroglobulins
Thromboangiitis obliterans	Polycythemia
Arterial embolism	Miscellaneous
Neurogenic disorders	Hypothyroidism
Thoracic outlet syndrome	Vinyl chloride disease
Carpal tunnel syndrome	Neoplasms
Reflex sympathetic dystrophy	Vasculitis and hepatitis B antigenemia
Hemiplegia	Intraarterial injections
Poliomyelitis	
Multiple sclerosis	
Syringomyelia	
Drug	
β-Adrenergic blockers	
Ergot preparations	
Methysergide	
Bleomycin and vinblastine	
Clonidine	
Bromocriptine	
Cyclosporine	

TABLE 167-2 **Causes of Raynaud's Phenomenon**

Raynaud's phenomenon may be occupational in origin and is especially common in people who use vibratory tools to cut stones or wood. Arteriograms have shown digital, radial, ulnar, or palmar arch thromboses. Any neurologic condition that produces permanent disuse of a limb can produce a sympathetic nervous system disturbance to that limb. This is usually manifested by persistent vasospasm with coldness, paleness, or cyanosis, and even ulcerations, but Raynaud's phenomenon may occur. Nerve root pressure or nerve entrapment may produce Raynaud's phenomenon. It is often present in the carpal tunnel syndrome and may occur secondary to neurovascular compression at the thoracic outlet.

Several drugs are implicated as causing Raynaud's phenomenon. Both selective and nonselective ß-adrenoceptor blocking drugs are common causes. Ergot preparations and methysergide used in the treatment of migraine headaches also cause the phenomenon. Ergotamine is a powerful a-adrenoceptor vasoconstrictor agonist that can produce gangrene of the fingers. Methysergide, a serotonin antagonist and agonist, produces peripheral vascular symptoms or signs in about 7 percent of patients. Industrial exposure to the vinyl chloride polymerization process may produce acroosteolysis of the distal phalanges of the fingers in a small percentage of workers, and Raynaud's phenomenon may also occur. Arteriograms in these patients show digital artery obstructions. The chemotherapeutic agents bleomycin and vinblastine may also cause the phenomenon.

Patients with cryoglobulins, macroglobulins, and polycythemia can exhibit Raynaud's phenomenon, probably secondary to rheologic disturbances or actual occlusion of small vessels. Cold agglutinins may occasionally cause the syndrome due to blockage of the vessels by agglutinated erythrocytes. The most common hormonal disturbance causing Raynaud's phenomenon is hypothyroidism, and the condition usually remits with thyroid replacement.

Prevention

Moving to a warmer climate alleviates symptoms in about 50 percent of patients. Some of the secondary causes can be prevented. Measures have been instituted to decrease the vibration of tools and to shorten hours for workers to prevent traumatic vasospastic disease. Vasoconstrictor drugs must be used with care to prevent overdoses. Mechanics and meat cutters should be warned not to use the hand as a hammer.

Clinical Manifestations

Patients complain of episodic attacks of well-demarcated, white or blue digits on exposure to cold; these are also sometimes induced by emotional stimuli (Fig. 167-5). During the attacks, one or more fingers or toes may become numb and be described as “dead.” The thumbs are often spared. On rewarming, the digits may become bright red and throbbing pain may occur. When pain is a prominent symptom in the ischemic phase, a secondary cause should be suspected. Attacks may last minutes to hours. Patients may experience one or more attacks per cold season or multiple attacks throughout the year. The fingers are most commonly involved, but vasospastic attacks may occur in the toes in 40 percent of patients.

FIGURE 167-5 A vasospastic attack in a young woman with Raynaud's phenomenon. Well-demarcated blanching of the fingers on exposure to cold is present. Ulnar and radial pulses were normal. The hand is not involved. The attacks were episodic.

Examination is usually normal in patients with primary Raynaud's phenomenon, and vasospastic attacks are difficult to induce in the office. If an attack is witnessed, there is well-demarcated blanching or cyanosis of the digits extending from the tips to varying levels of the digits. The digits distal to the line of ischemia are cold, while the proximal skin is pink and warmer. The hands and feet are not involved except in some secondary etiologies. On rewarming, blanched digits may become cyanotic due to the slow blood flow and then bright red due to reactive hyperemia. The digits appear normal between attacks but may be cool and moist with excess perspiration. The radial and ulnar pulses are normal. Patients may show the nail change known as pterygium, which refers to a cuticle widened to several millimeters with a proximal thin skin fold that merges with the cuticle (see also Chap. 72). Trophic changes with tense and atrophic skin, deformity of nails, and shortening and contracture of digits (sclerodactyly) may also be present.

Gangrene is rare and only affects the tips of fingers. Patients with secondary Raynaud's phenomenon may show other manifestations of their underlying disease; persistent ischemic discoloration of digits suggests a secondary cause.

Laboratory and Special Examinations

Blood and urine studies are normal in patients with primary Raynaud's phenomenon. The effect of local cooling with an ischemic stimulus has been used as a diagnostic test for Raynaud's phenomenon. When compared to normal individuals, patients with Raynaud's phenomenon have a greater reduction in finger systolic pressure with cooling and many show a loss of pressure or digital artery closure. Nail-fold capillary microscopy might be valuable for diagnosing secondary causes of Raynaud's phenomenon, but is normal in the primary disease. In scleroderma, mixed connective tissue disease, and dermatomyositis, there may be enlarged, deformed capillary loops surrounded by avascular areas. [11] Abnormal capillary loops and a prominent subpapillary venous plexus occur in lupus erythematosus, whereas bushy capillary formations are most prominent in mixed connective tissue disease.

Pathology

Histologic examination of digital arteries has been performed in a few patients with mild primary Raynaud's phenomenon and has been normal. In patients with more severe disease, intimal hyperplasia, narrowing or total occlusion of arteries, or thrombi are present.

Diagnosis and Differential Diagnosis

The diagnosis is usually made from the history of typical episodic attacks of well-demarcated white or blue discoloration of the digits on cold exposure. Patients with sufficient symptoms to seek a physician's advice should have a complete workup to exclude secondary causes. The history will elicit symptoms of connective tissue disease, a drug etiology, symptoms of obstructive arterial diseases, and exposure to vibratory tools or continuous finger trauma. During the physical examination, the physician should pay attention to all pulses, blood pressure in both the arms, and signs of secondary causes. The thoracic outlet maneuvers should be performed, and Tinel's sign (distal tingling or pain on percussion of the median nerve at the wrist) sought. Blood analyses for anemia, polycythemia, leukopenia, sedimentation rate, serum protein electrophoresis, antinuclear antibodies, rheumatoid factor, cryoglobulins, and cold agglutinins are necessary. Proteinuria and red blood cell casts should be specifically looked for in the urinalysis. A chest film will rule out the presence of cervical ribs. The history, physical examination, and laboratory tests should all be normal before a patient is reassured that the benign, idiopathic disease is probably the diagnosis. The main differential diagnoses are patients complaining of cold digits and acrocyanosis. Many patients complain of cold, sometimes painful digits but color changes are absent. This may be one extreme of the spectrum of normal sympathetic nerve activity. In acrocyanosis, the hands and feet are involved, whereas in Raynaud's phenomenon only the digits are involved, the color change is persistent and not episodic, a pallor phase is absent, and there is no sex predilection.

Treatment and Prognosis

Most patients with primary Raynaud's phenomenon respond to reassurance that they have a benign disease, to instructions to wear loose-fitting warm clothes covering as much of the body as possible to prevent reflex sympathetic vasoconstriction, and to avoid cold especially with pressure on the digits. [8] Tobacco smoking should be discouraged because nicotine induces cutaneous vasoconstriction; smokers are more numerous among patients with primary Raynaud's phenomenon and with traumatic vasospastic disease. The underlying cause must be treated in patients with secondary Raynaud's phenomenon.

Drug therapy can be used in the more severe cases of the phenomenon but is only successful in about two-thirds of patients. [8] Several studies show that nifedipine decreases the frequency, duration, and severity of attacks in about two-thirds of patients with primary or secondary Raynaud's phenomenon. The long-acting preparations have fewer side effects and are just as beneficial. [12] Diltiazem, felodipine, and isradipine, but not verapamil, may also be beneficial. Prazosin, an a_1-adrenoceptor antagonist, produces moderate benefit. Nitrates or their ointments have their proponents,

but are usually used in combination with other agents. Parenteral prostacyclin is reportedly beneficial, but oral preparations are not available. Either biofeedback or pavlovian conditioning may provide some benefit to patients, but they require a time commitment by the patient. Upper extremity sympathectomy is not of value in primary or secondary Raynaud's phenomenon; its benefit only lasts from 6 months to 2 years. Lumbar sympathectomy does produce lasting relief for lower-extremity Raynaud's phenomenon.

In patients with primary Raynaud's phenomenon, approximately 38 percent have no change in symptoms over time, 36 percent improve, 16 percent develop more severe attacks, and in 10 percent, the syndrome disappears. Although trophic changes of the fingers may develop in many patients, the prognosis is fairly good. Unfortunately, scleroderma is difficult to diagnose, and some patients will develop manifestations of this disease many years after the onset of Raynaud's phenomenon.

LIVEDO RETICULARIS

Livedo reticularis is characterized by a reddish-blue mottling of the skin in a “fishnet” reticular pattern.

Epidemiology

All types of livedo reticularis occur most commonly in women younger than 40 years of age.

Etiology and Pathogenesis

Livedo reticularis has been called by many names including idiopathic livedo reticularis, cutis marmorata, livedo annularis, livedo racemosa, sympathetic livedo reticularis, and asphyxia reticularis. Livedo reticularis with ulceration is also known as livedo or livedoid vasculitis and atrophie blanche. A variety of names usually reflects an unknown etiology. Secondary livedo reticularis is most commonly seen accompanying vasospastic conditions such as primary and secondary Raynaud's phenomenon, acrocyanosis, and vasculitis. It is often a manifestation of an underlying disease and may be a clue to its diagnosis. It has been reported in association with connective tissue diseases, especially lupus erythematosus, obstructive arterial disease, endocrine disorders, neurogenic diseases, drug reactions, hyperviscosity states, hypertension, and lymphomas. It is an important diagnostic manifestation in atheromatous embolization. It is induced by amantadine, a drug used for Parkinson's disease and influenza. Livedo reticularis with cerebrovascular lesions has been described (Sneddon's syndrome); [13] this may be part of a syndrome with arterial and venous thromboses, spontaneous abortions, and anticardiolipin or antiphospholipid antibodies (Fig. 167-6). [14]

FIGURE 167-6 Livedo reticularis of the buttocks and thighs in a woman who had a cerebrovascular thrombosis. This is an example of Sneddon's syndrome.

Livedo reticularis with ulceration (livedoid vasculitis) may be secondary to a localized vasculitis. [15] Immunofluorescence studies have shown IgM deposits. Complement factors, fibrin, and sometimes IgA have also been found in the vessel walls, which suggests an immune complex pathogenesis. Other investigators consider that this disease may be caused by blood or tissue abnormalities that induce thromboses of arterioles. A defect in the fibrinolytic system may be present. Abnormalities of platelet aggregation or increased platelet adhesiveness have also been reported. Amantadine causes livedo reticularis and is known to release norepinephrine from central and peripheral nerves in addition to enhancing the action of norepinephrine and dopamine on several peripheral tissues. These actions with amantadine's ability to inhibit uptake of dopamine and norepinephrine in neurons could lead to arteriolar constriction.

Vasospasm or obstruction of the small perpendicular arterioles in the dermis is the probable cause of the fishnet appearance of the skin. The red to blue periphery of each web of the net is a result of deoxygenated blood in surrounding horizontally arranged venous plexuses. Elevation of the extremity therefore decreases the intensity of the color changes by emptying the veins. The reversibility of the color pattern with warming, the frequent association with vasospastic diseases of the digits, and the beneficial response to sympathetic blocking agents suggest an increased sympathetic nerve activity as the cause of benign livedo reticularis.

Clinical Manifestations

Patients with benign livedo reticularis have no complaints except for the cosmetic appearance of the cutaneous fishnet. Numbness and pain are rare, but a subjective feeling of coldness is common. Patients with secondary livedo reticularis may complain of symptoms of their underlying disease. Persistence of the fishnet pattern during warming and purpuric macular lesions or skin nodules that ulcerate are the complaints in patients with livedo reticularis with ulceration. Most patients have the painful ulcers only in winter, although a few also have them in summer. In the benign form, a fishnet pattern affects mainly the extremities and the webs are rose, violet, red, or blue. Between the webs, the skin appears pale. The colors are aggravated by exposure to cold and may disappear on warming. The examination is normal except for the skin. In livedo reticularis with ulceration (livedoid vasculitis), purpuric lesions, cutaneous papules, or ulcers may be found (Fig. 167-7A). The ulcers are usually covered with eschars and surrounded by red inflammation; they are very

tender. Approximately 50 percent of patients have edema of the legs, which often occurs before the ulcerations. Healed ulcers have a smooth ivory-white plaque of atrophic skin surrounded by hyperpigmented borders and telangiectatic blood vessels (atrophie blanche) (Fig. 167-7B). Most ulcers are found on the lower part of the legs, ankles, and dorsa of the feet. In patients with secondary livedo reticularis, other manifestations of their underlying disease may be present.

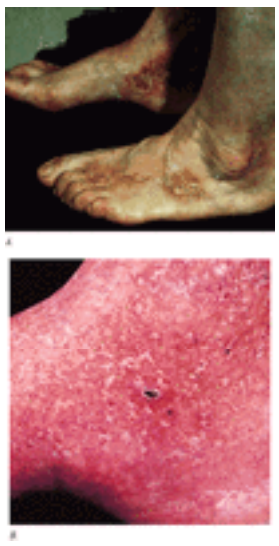

FIGURE 167-7 *A*. Recurrent irregular, extremely painful ulcers of the feet and lower legs in a 32-year-old woman with livedo reticularis with ulceration. Pigmented areas of healed ulcers are present. Ulcerations had been recurrent since age 16 years with no relation to seasons. Pedal pulses were normal. *B*. Close up of atrophie blanche with irregular porcelain-white atrophic scars, ulcerations, and crusting in a similar patient.

Laboratory and Special Examinations

In livedo reticularis with or without ulceration, no specific blood or urine tests are abnormal. [15]

Pathology

In benign livedo reticularis and that due to drug therapy, biopsies have shown nonspecific changes or increased numbers of dilated capillaries. A segmental hyalinizing vasculitis of the middle dermal vessels has been described in the ulcerative disease. [15] In Sneddon's syndrome, there is also a noninflammatory hyalinization and thickening of vessel walls and vascular occlusions, which are seen only in biopsies obtained from the center of the mesh of the fishnet pattern.

Diagnosis and Differential Diagnosis

The diagnosis is made easily from the typical fishnet pattern on the skin in the benign form. In patients with ulcers, other causes of lower extremity ulcers must be ruled out. Secondary causes must be sought before the diagnosis is considered to be benign livedo reticularis or with ulceration. It is therefore a diagnosis by exclusion of underlying diseases.

Treatment and Prognosis

The benign type of livedo reticularis needs no treatment. The skin discoloration can be covered with cosmetics or, as a last resort, sympatholytic agents can be tried for patients bothered by the social stigma.

In secondary causes, the underlying disease should be treated. Patients with anticardiolipin antibodies and thromboses should be treated with anticoagulants. In livedo reticularis with ulceration, treatment has been unsuccessful. Saline soaks and analgesic ointments are helpful. Antiplatelet agents and agents that induce fibrinolysis [16] are the most recently recommended therapies. A large variety of other therapies have all been reported to benefit some patients. Because the disease is rare, there are no large controlled studies of treatment modalities. The benign condition has an excellent prognosis. In livedo reticularis with ulceration, the painful ulcers are often recurrent and may be disabling. The lower limbs and feet become scarred; amputations have been necessary for deep ulcers and severe pain.

DISEASES OF THE VEINS

Thrombophlebitis

Thrombophlebitis or deep venous thrombosis is due to thrombotic obstruction of veins with or without an inflammatory response to the thrombus.

ETIOLOGY AND PATHOGENESIS The mechanisms of thrombosis described by Virchow includes the triad of vessel wall injury, stasis, and hypercoagulability. In the lower extremity, low venous flow and hypercoagulability are the key elements, whereas in the upper extremity, vascular damage and hemodynamic factors, such as after strenuous exercise, probably play the major role. Table 167-3 lists the most common causes. Some malignancies, such as those of the lung, pancreas, and stomach, are associated with thrombophlebitis, which may be of the migratory variety. Oral contraceptives disturb the hemostatic balance with an increase in procoagulant effects, a decrease in anticoagulant effects, and equivocal effects on fibrinolysis yielding a net prothrombotic effect. The past decade has seen discovery of genetic mutations or inherited thrombophlebitis that predispose to thrombosis. These include the common mutation in the factor V gene (factor V Leiden), providing resistance to activated protein C, and the mutation in the prothrombin gene (factor II), as well as the rarer antithrombin, protein C, and protein S deficiencies. [17] Elevated levels of several coagulation factors,

including factor VIII, factor IX, factor XI, and dysfibrinogenemia, are associated with thrombosis. Arterial and venous thrombosis may occur in patients with hyperhomocystinuria caused by genetic disorders affecting the transsulfuration or remethylation pathways of homocysteine metabolism or with antiphospholipid antibodies.

Common Factors	
Major surgery	Oral contraceptives
Fractures	Malignancies
Congestive heart failure	Venous varicosities
Acute myocardial infarction	Previous history of venous thrombosis
Stroke	Leiden factor 5 mutation
Pregnancy and postpartum	Prothrombin gene mutation (G 20210A)
Spinal cord injuries	Severe pulmonary insufficiency
Shock	Prolonged immobilization
Less-Common Factors	
Sickle cell anemia	Antithrombin III deficiency
Homocystinuria	Antiphospholipid antibodies
Protein C or S deficiency	Ulcerative colitis

TABLE 167-3 **Predisposing Factors in Deep Venous Thrombosis**

Superficial thrombophlebitis is usually a result of infections of or trauma to superficial veins from needles or catheters. A migratory variety is seen in thromboangiitis obliterans and malignancies. Mondor's disease is an inflamed subcutaneous vein from the breast to the axillary region, which has no association with underlying disease. [18] An occlusion of a vein by thrombus imposes a block to venous return, which leads to increased venous pressure and causes pain and tenderness. Prominent collateral veins appear early to bypass the obstruction and relieve the edema; recanalization may occur in several weeks. If the venous pressure is too high, arterial inflow may rarely be compromised and ischemia of the distal limb occurs. The thrombus within the vein often has a free-floating tail, which may break off to produce a pulmonary embolus. The free-floating tail is bound down to the vein wall in about 10 days. Organization of the thrombus in the vein destroys the venous valves which leads to the postphlebitic syndrome.

PREVENTION Agents evaluated to prevent the development of deep vein thrombosis include unfractionated heparin, low molecular weight heparin, and warfarin. Early ambulation has been advocated for the low risk surgical patient. Adjunctive therapy includes elastic compression stockings and intermittent pneumatic compression in selected patient populations. Unfractionated heparin (dosed at 5000 U subcutaneously every 8 to 12 h) is effective in general surgical and selected medical patients, but not in orthopedic patients. The use of low molecular weight heparin is preferred with major orthopedic surgeries, trauma, and acute spinal cord injuries.

CLINICAL MANIFESTATIONS The presenting history may be quite varied depending upon the clinical setting. Symptomatic patients may complain of pain or aching in the involved limb or have notable limb swelling. Some patients present with symptoms of pulmonary emboli without extremity symptoms. Other patients may be entirely asymptomatic at the time of diagnosis but were at high risk because of concurrent medical conditions. The clinical assessment alone is unreliable to establish or exclude the diagnosis. The clinical picture may vary from subtle signs of swelling to a tensely swollen, warm, tender limb with prominent, distended collateral veins. Swelling may first be detected by an increased turgor of the muscles or careful measurement of limb circumference and comparing it to the opposite limb. Pitting edema may occur but is not always present. A tender cord may be felt where the vein is thrombosed. With iliofemoral thrombophlebitis, the limb is swollen from the foot to the inguinal region (Fig. 167-8), tenderness is not present in the limb because the thrombus is proximal, and collateral veins may form from the thigh to the abdominal wall. The limb may be very pale (*phlegmasia alba dolens*) or may be cyanotic with cold digits if the arterial inflow is compromised (*phlegmasia coerulea dolens*). In thrombosis of calf veins, the calf and foot are swollen and warm; there is deep tenderness with or without a palpable cord. Increased resistance to dorsiflexion of the foot may be present (Homans' sign). Thrombophlebitis of a superficial vein or varicosity is evidenced by painful induration of the vein with redness and increased heat. Migratory cases have successive areas of superficial veins involved over a variable period of time. Mondor's disease is manifested by a tender cord from the breast to the axillary region; during healing, the venous cord shortens and puckers the skin. [18]

FIGURE 167-8 Acute iliofemoral deep venous thrombosis in a woman postpartum. The thigh and calf are very swollen, when compared to the opposite limb, and have a blotchy cyanotic discoloration.

LABORATORY AND SPECIAL EXAMINATIONS Contrast venography remains the gold standard for the diagnosis of venous thrombosis but has numerous clinical limitations including its invasive nature. Noninvasive modalities, most commonly venous ultrasonography and impedance plethysmography, have nearly replaced venography. Venous ultrasonography using B-mode imaging with venous compression, with or without Doppler flow assessment, is the optimum noninvasive test for the diagnosis of deep vein thrombosis. [19] Incomplete compressibility of the lower extremity veins is the principal diagnostic feature but direct visualization of the thrombus and abnormalities in Doppler flow, such as loss of spontaneous respiratory variation, may be seen. This test is most accurate for the first symptomatic proximal deep vein thrombosis and is much less reliable for asymptomatic, recurrent, or isolated calf (distal) deep vein thrombosis. Complementary tests, particularly the D-dimer assay, may be used to clarify the results of other testing. Serial examinations, particularly with venous ultrasonography, have been employed with a negative proximal evaluation to monitor for progression of distal deep vein thrombosis over 1 to 2 weeks if treatment with anticoagulation is not being employed.

PATHOLOGY The thrombus is composed of fibrin, red blood cells, and platelets. The thrombus propagates proximally and then consists predominantly of fibrin interspersed with red cells. The underlying vein wall may show minimal to marked inflammatory changes with infiltration of white blood cells and loss of endothelium. The thrombus may also undergo the same process and thereby become adherent to the vein wall. Some thrombi recanalize. The venous valves within the area of the thrombus are permanently damaged as the thrombus becomes adherent to the vein wall.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS Thrombophlebitis is difficult to diagnose clinically. The symptoms and signs are nonspecific: studies show that the clinical diagnosis is incorrect in about 50 percent of patients. [20] A definitive test by impedance plethysmography, or, preferably, by venous ultrasound, is necessary to make a diagnosis. A venogram is only necessary when these tests give indeterminate results. Although the cause of a painful or swollen extremity is

often not found, these patients have a benign prognosis if noninvasive tests are negative for deep venous thrombosis. Superficial thrombophlebitis can be diagnosed by the characteristic clinical picture, although lymphangitis and cellulitis must be considered; the former usually has red streaking up the limb and tender lymph nodes proximally, while the latter presents a more diffuse involvement of the extremity. The most common differential diagnosis of thrombophlebitis includes rupture of the plantar muscle, which produces an ecchymotic area in the dependent ankle area and sometimes a tender knot over the muscle. Ruptured synovial membrane of the knee joint can imitate thrombophlebitis; knee joint fluid, inflammation or arthritis are clues to the diagnosis, but an arthrogram may be needed.

TREATMENT AND PROGNOSIS Anticoagulation is the mainstay in the treatment of deep vein thrombosis—preventing embolism and preventing clot propagation. [21] Heparin has been given by using weight-based protocols to achieve a therapeutic level, corresponding to an activated partial thromboplastin time of 1.5 to 2.5 times control. Low molecular weight heparins are replacing unfractionated heparin because of equal or greater efficacy with a more predictable anticoagulant response and no need for monitoring. These agents are shifting the care of the routine deep vein thrombosis to the outpatient setting, which may significantly decrease cost but has raised some safety concerns. Warfarin is used as a long-term oral anticoagulant to prevent recurrence. Warfarin is dose adjusted to prolong the international normalized ratio (INR) to 2.0 to 3.0 times normal. Because of transient prothrombotic effects, heparin should be overlapped with warfarin for 5 days. The duration of therapy with warfarin is under some debate but should continue for at least 3 months. Prolonged therapy has been suggested for idiopathic deep vein thrombosis and prolonged, or even indefinite, therapy for inherited thrombophlebitis. [17] Thrombolytic agents enhance lysis of thrombi but do not reduce subsequent pulmonary embolus mortality. Early thrombolytic use may help to alleviate symptoms, and perhaps reduce late complications, and should be considered for massive iliofemoral or subclavian venous thrombosis. Ambulation is allowed when symptoms and signs subside, and elastic compressive stockings (with a tension of 30 mmHg or greater) should be worn for several months. The therapy of choice for patients who have a contraindication, hemorrhage during anticoagulation, or pulmonary emboli while adequately anticoagulated, is insertion of an inferior vena cava filter. When gangrene of the toes is impending in ileofemoral venous thrombosis, surgical removal of the thrombus often alleviates the condition, even though there is rethrombosis of the vein. Septic thrombophlebitis is treated by removal of catheters and appropriate antibiotic therapy. However, resistant cases may require removal of the affected area of the vein. Treatment of upper extremity deep venous thrombosis is controversial. Early reports of a low risk of developing a pulmonary embolus with an upper extremity deep venous thrombus have been refuted and anticoagulation is the therapy of choice if there are no contraindications. The treatment of superficial thrombophlebitis has been conservative with warm compress and limb elevation. Most cases of thrombophlebitis subside within 10 days, but many patients have persistent limb swelling, especially with iliofemoral and subclavian venous thrombosis. The postphlebitic syndrome may develop in some patients within 2 years, whereas it may not occur for 20 years in others.

Varicose Veins (see also Chap. 273

Varicose veins are dilated, distended, tortuous veins with incompetent valves.

EPIDEMIOLOGY Varicose veins are more common in women than in men and usually appear in women during the child-bearing years. They are more common in countries where the population eats a low-fiber diet than in African countries where the diet is high in fiber. [22]

ETIOLOGY AND PATHOGENESIS A hereditary influence in some patients with varicose veins is suggested by the presence of the disorder in several members of the same family and the appearance of varices during adolescence. Because varicosities, hemorrhoids, and diverticula of the colon are infrequent in countries subsisting on a high-fiber diet, constipation with its associated increased intraabdominal pressure has been incriminated for all three entities. [22] Pregnancy is a prime cause of varicose veins due to vein relaxation by the increased hormones, expansion of blood volume, and increased venous pressure, especially in the limb whose iliac vein is compressed by the enlarged uterus. Thrombophlebitis leads to the formation of varicosities by the destruction of venous valves. Arteriovenous communications also cause varices. The first abnormality inducing varicosities is a weakening of the commissures of the valves with dilation. The dilation leads to incompetence of the valves and increased venous pressure distally. The increased venous pressure creates a vicious cycle because it causes further dilation of the vein and valves. The increased venous pressure is transmitted to the capillaries, which results in leakage of fluid into the subcutaneous tissues and muscles.

PREVENTION Many varicose veins would be prevented if women wore elastic support hose during pregnancy. Chronic constipation should be avoided.

CLINICAL MANIFESTATIONS Most patients have no symptoms but seek medical advice because of the cosmetic appearance. Some patients do complain of fatigue or aching in the calves or swelling of the ankles at the end of the day. The swelling disappears with bed rest overnight. Rarely, patients with very large varicosities will complain of lightheadedness or blurry vision on standing due to venous pooling. Varicose veins can be seen as dilated, tortuous, sacculated superficial veins (Fig. 167-9). They are often thick walled. The greater saphenous vein is most commonly involved, but varicosities may be found anywhere on the legs and feet without involvement of the saphenous veins. There may be pitting edema at the ankle area or increased turgor of the calf muscles. In patients with very large varicosities, systemic blood pressure may fall on standing. Many patients have prominent, multiple, fine cutaneous veins on the thigh which are not varicose veins; they usually appear after age 20 years in females and increase in number with aging (superficial phlebectasia or spider veins).

FIGURE 167-9 Extensive superficial varicose veins of the thigh and calf.

LABORATORY AND SPECIAL EXAMINATIONS The incompetent valves of varicose veins can be demonstrated by applying a tourniquet on the elevated extremity so that the superficial veins are empty (Fig. 167-10). On patient's assuming the erect posture, release of the tourniquet will allow rapid filling of a varicose vein if the valves are incompetent. Venography is seldom necessary but will show the dilated, tortuous veins and incompetent valves. Air plethysmography can document the degree of venous insufficiency. Duplex scanning with Doppler flow assessment can show reversal of venous flow during distal muscle compression and estimate the severity of reflux. Involvement of the superficial and deep venous system in the lower extremity can be determined using venous duplex imaging.

FIGURE 167-10 Varicose veins. Demonstration of venous reflux by the Trendelenburg test. *A*. Elevation of the leg empties the varices and a tourniquet is applied. *B*. While the patient is standing, varices remain empty until the tourniquet is removed, showing reflux from the saphenous vein. *C*. Reflux takes place via communicating veins before removal of the tourniquet, with additional reflux from the saphenous vein when the tourniquet is removed.

PATHOLOGY The pathology is variable, with some varicose veins appearing normal but dilated so that the venous valves no longer are in opposition. Others show damage, deformed valves, and fibrotic vein walls.
DIAGNOSIS The diagnosis of varicose veins rests primarily on seeing and palpating the varices. The above tourniquet test will delineate the incompetent valves.
TREATMENT AND PROGNOSIS (See also Chap. 273) Symptoms from varicose veins respond to heavy-gauge elastic stockings (30 mmHg or greater). Such stockings will prevent further enlargement of veins and edema but will not reverse the size of varicosities. Panty girdles or garters should never be worn. Ligation and stripping of veins are usually reserved for patients with very large and symptomatic varicosities. Small to medium-sized varicosities can be injected with a sclerosing solution 0.5 to 1 mL of sodium tetradecyl sulfate (Sotradecol) or concentrated saline solutions. These solutions cause an inflammation and then fibrosis of the vein. Stab avulsion has been used successfully to remove clusters of varicose veins and to interrupt perforating veins in the leg; this method usually involves small incisions. Laser therapy has been used to treat superficial and spider veins. Without adequate external support, varicose veins continue to enlarge in most, but not all, patients. New varicose veins usually appear in a 10-year period after stripping or sclerosing injections. Some patients will develop a postphlebitic syndrome.

Postphlebitic Syndrome

The postphlebitic syndrome is characterized by edema, stasis pigmentation, and ulcers of the lower extremities as a result of venous stasis.

EPIDEMIOLOGY Studies are lacking on the epidemiology, but it is more common in females than in males. Whites and blacks appear equally affected.
ETIOLOGY AND PATHOGENESIS The postphlebitic syndrome may occur soon after an episode of deep venous thrombosis or up to 20 years later. [23], [24] It is a common belief that most patients have had thrombophlebitis, although many do not give a history of the disease. It can occur in patients with superficial varicosities or incompetent deep veins; the perforating veins may also have defective valves. Valve destruction occurs with thrombophlebitis and is the main factor in causing increased venous pressure in the leg. The edema is caused by leakage of fluid from the capillaries. Stasis pigmentation is the result of red blood cells escaping into the tissues, which results in an inflammatory reaction to the deposited hemoglobin. The exact mechanism of spontaneous ulcer formation is unknown. A reasonable explanation is that there is ischemia in the area in the erect state from the high venous pressure preventing capillary blood flow. Venous blood drawn from the ulcer area is often “black” from desaturation. Marked fibrosis in the subcutaneous tissue may develop, and channels can be palpated where veins course in the fibrotic tissue.
PREVENTION Elastic stockings with suitable venous compression will prevent progression of venous insufficiency to the postphlebitic syndrome. Similarly, elastic compression may prevent recurrence of venous ulcers late in the disease.
CLINICAL MANIFESTATIONS Patients complain of swelling of the limb, discoloration of the calf and ankle area, and breakdown of skin or ulcers. Because the ulcers are often painless, patients may not see a physician for several weeks to months after the beginning of an ulcer. A history of thrombophlebitis may or may not be obtained. Some patients present with fever, chills, and redness of the involved extremity because of cellulitis. Pitting edema of the extremity is usually present, but varicose veins are not always apparent. There is brownish to dark pigmentation and often extensive scaling of the skin, especially on the medial side of the ankle and lower calf. Although cellulitis may occur, the leg may also be red, warm, and tender from an inflammatory reaction to the pigment in the dermis. Small erosions to very large, but

usually not deep, ulcers may develop (Fig. 167-11). The ulcers usually have a red base of granulation tissue. They also occur on the medial ankle or lower calf in the majority of cases. Sometimes a fluctuant area denoting an incompetent perforating vein can be palpated at the base or near an ulcer, or a varicosity can be traced draining the ulcer area. The subcutaneous tissue may be indurated, and retraction of the subcutaneous tissue of the lower third of the leg may occur with pitting edema above it. One or both legs may be involved with signs of the postphlebitic syndrome.

FIGURE 167-11 A large venous ulcer in a patient with the postphlebitic syndrome. This painless ulcer is shallow with good granulation tissue. Surrounding tissue shows typical stasis pigmentation, varicose veins, and subcutaneous tissue fibrosis and contraction.

LABORATORY AND SPECIAL EXAMINATIONS Incompetence of the superficial or deep venous system can be determined by tourniquet tests as described in the preceding section on varicose veins. Incompetent perforators can be detected by applying two tourniquets at various levels of an extremity with the veins empty (see Fig. 167-10). When the patient assumes the standing position, the segment of the superficial vein between the two tourniquets will fill when the underlying perforator has an incompetent valve. Before surgery, air plethysmography or high-resolution real-time ultrasonic imaging combined with Doppler pulsed-wave ultrasound should be performed.

PATHOLOGY In the area of postphlebitic changes there may be edema, inflammation, fibrosis, hemosiderin deposits, and tissue breakdown of the skin and subcutaneous tissues. In late cases, venous walls are thickened, and endothelial proliferation and fragmentation of the walls of venules and arterioles of the skin may be seen.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS The characteristic picture of edema, stasis pigmentation, and ulcers is diagnostic of the postphlebitic syndrome. The differential diagnosis includes lymphedema, which does not have stasis pigmentation or ulcers. Other causes of ulcers discussed below are usually painful, while venous ulcers are painless or only tender. Demonstration of superficial or deep venous valvular incompetence by plethysmography, Doppler, duplex scanning, or venography may be needed when varicosities are absent.

TREATMENT AND PROGNOSIS (See also Chap. 272) The treatment of the postphlebitic syndrome is elastic compression to prevent venous stasis. Ace bandages or elastic stockings (30 mmHg or greater) must be worn throughout the day whenever the patient is sitting or standing. It also helps to sleep with the foot of the bed elevated 18 cm so that the patient starts the day with as little tissue fluid as possible. Itching or inflammation of stasis dermatitis usually yields to the application of glucocorticoids in cream or ointment. Unna boots are a very successful treatment method for venous ulcers. Without treatment, stasis dermatitis will usually progress to venous ulceration. The course is then recurrent ulcers and episodes of cellulitis. With adequate elastic compression and sometimes surgical procedures to decrease venous pressure in the area, the course will stabilize. However, the prognosis depends on great effort and cooperation by the patient.

LYMPHEDEMA

Lymphedema is the occurrence of chronically swollen extremities as a consequence of an inadequate drainage of interstitial tissue fluid by the lymphatic vessels.

Epidemiology

The prevalence of primary lymphedema is less than 1 in 6000 [25] and it has a 1:3 male to female predominance. Secondary lymphedema is more common in countries with warm climates because of their higher prevalence of filariasis.

Etiology and Pathogenesis

Primary lymphedema is most often seen in women and appears between the ages 10 and 25 years. [26] It may be congenital, appear at puberty (praecox), or occur after age 35 years (tardum) (Table 167-4). Milroy's disease is both familial and congenital. Other lymphatic defects causing yellow finger and toe nails (yellow nail syndrome), chylous pleural effusions or ascites, malabsorption, or intrahepatic cholestasis rarely might accompany primary lymphedema. Secondary lymphedema is caused by obstruction of lymphatic flow following surgical removal or radiation fibrosis of lymph nodes, infiltration by malignancies of lymph vessels or nodes, or destruction of lymphatics by recurrent infections or filariasis. The pathogenesis is the accumulation of tissue fluid as a consequence of failure of lymphatic drainage.

Primary
Congenital
Familial (Milroy's disease)
Idiopathic
Praecox
Tardum
Variant with yellow nails and pleural effusions
Secondary
Infection
Bacterial
Filariasis
Bartonella (cat-scratch fever)
Radical lymph node excision or surgical scarring
Malignant infiltration
Fibrosis
Radiation therapy
Stasis
Localized myxedema
Panniculitis
Idiopathic or pharmacologic retroperitoneal fibrosis

TABLE 167-4 **Classification of Lymphedema**

Prevention

In some patients, recurrent episodes of cellulitis and lymphangitis occur in the involved limb. Each attack destroys more lymphatic vessels and aggravates the lymphedema. These patients should be treated with antibiotic prophylaxis, usually penicillin. The acute attacks produce a red, warm extremity with increased swelling; red streaks may be seen on the proximal extremity extending from the inflamed area, and regional lymph nodes may be enlarged and tender. Fever and leukocytosis may accompany the infection. The common offending organisms are the coagulase-positive staphylococcus and the hemolytic streptococcus. Even when organisms cannot be cultured, therapy should be directed toward these bacteria.

Genetics

A genetic abnormality (FOX C2) causing distichiasis and lymphedema affects males more than females. [27]

Clinical Manifestations

The patient often does not notice the swelling of the limb as the onset is very gradual and the edema is painless. The swelling may also disappear overnight, which leads to delay in seeking medical advice. The abdomen may swell with ascites. Intestinal lymphangiectasis may produce pale-colored stools and diarrhea. Secondary lymphedema will have symptoms of the underlying disease. There is soft, pitting edema of the distal extremity in the beginning. In the later stages, the swelling becomes indurated and nonpitting. The skin may thicken and resist wrinkling; hair follicles are prominent. A pebbled surface may develop and may lead to pseudopapillary growths and hyperkeratosis (Fig. 167-12A). This process is known as elephantiasis nostras verrucosa. Some patients proceed to develop disfigured extremities with thick folds of skin (Fig. 167-12B). Patients may present with cellulitis of the involved extremity because lymphedematous limbs are susceptible to infection.

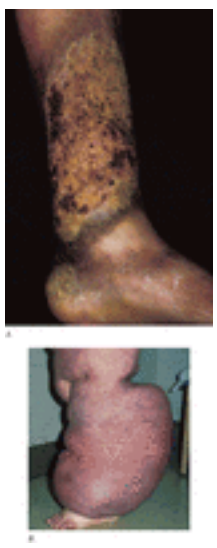

FIGURE 167-12 *A.* Lymphedema with hyperkeratosis (elephantiasis nostra verrucosa). Edema has been replaced by fibrosis, pseudopapillomatosis, hyperkeratosis, and hyperpigmentation. *B*. Lymphedema of the left leg in a 47-year-old fireman. The extreme swelling began at birth and was painless. Note the lack of stasis pigmentation or ulceration. The patient functioned normally at work and wanted no treatment.

In primary lymphedema, the lower extremities are involved most often and bilateral swelling occurs in about 50 percent of patients. In secondary lymphedema, usually only one extremity is involved. Discoloration of nails, distichiasis (a double row of eyelashes), jaundice, and signs of pleural effusion or ascites may occur rarely in patients with primary lymphedema.

Laboratory and Special Examinations

Invasive diagnostic tests are usually unnecessary. Blood and urine studies are normal in primary and most cases of secondary lymphedema. Lymphoscintigraphy with radioisotope preparations is useful in differentiating lymphedema from other causes of extremity edema. [28] Lymphangiography is usually avoided because it is painful and involves an incision with the chance of infection.

Pathology

The pathologic picture as determined by lymphangiography varies from aplasia or hypoplasia to varicosities of the lymphatic channels. [26] Primary lymphedema with distichiasis is associated with bilateral hyperplasia of the lymphatic vessels. In secondary cases, there may be neoplastic involvement of lymph nodes or fibrosis of lymph nodes and lymph vessels.

Diagnosis and Differential Diagnosis

The diagnosis of lymphedema can usually be made by physical examination; the patient has a swollen, painless limb without varicosities, stasis pigmentation, or collateral veins (Table 167-5). Invasive tests are unnecessary in most

patients. Noninvasive studies of the venous system or venography may be indicated to rule out venous disease. Lymphoscintigraphy and, rarely, lymphangiography are used to distinguish the lipomatous nodular masses of lipodystrophy. Secondary lymphedema should be considered in most patients before a diagnosis of primary lymphedema is made. A history of radiation or radium treatment, surgery of lymph nodes, or symptoms of malignancy should be ascertained. Patients from endemic areas may need blood tests or biopsies for filariasis. Males should be carefully examined for prostate cancer, which often presents with a unilateral swollen limb due to lymph node invasion. An ultrasound examination of the abdomen is usually performed, especially in females, to rule out tumors or enlarged lymph nodes. A venogram may be necessary to rule out the May-Thurner syndrome, which results in impaired venous return because of compression of the left common iliac vein by the right common iliac artery. [28] Occasionally, women present complaining of swollen legs, but no edema or other pathology can be found in the large legs. This configuration of the legs is usually familial. Clues to the absence of pathology are symmetric measurements of the ankles, calves, and thighs; small ankles in comparison to the calves and thighs; and lack of edema.

Postphlebitic syndrome	Idiopathic or cyclic edema
Edema of inactivity (old age)	Arthritis and synovitis
Hereditary "piano" legs	Panniculitis
Edema of constitutional disease	Localized myxoedema
Lipodystrophy	

TABLE 167-5 **Differential Diagnosis of Lymphedema**

Treatment and Prognosis

It is important to minimize extremity edema to prevent subcutaneous fibrosis, skin thickening, and recurrent episodes of cellulitis. Elastic garments with at least 30 mmHg pressure, but sometimes as high as 60 mmHg, must be worn from morning to bedtime. The elastic garments should have graded pressure from the distal to the proximal portion of the extremity. The patient should also sleep with the foot of the bed elevated 18 cm to promote drainage of tissue fluid overnight. A low-sodium diet and occasional, but not continuous, use of diuretics may be helpful. Administration of 5,6-benzo-alpha-pyrone (coumarin) decreases the size of the arms and legs slowly and improves symptoms in patients with primary and secondary lymphedema. [29] In patients with edema resistant to conservative measures, a sequential pneumatic compression device may be used. However, these machines must be used for at least 4 h on the extremity each night, are uncomfortable, and only move the fluid more proximally in some patients. Decongestive physical therapy may also help. In very large incapacitating limbs or for the development of lymphangiosarcoma, various surgical procedures have been performed, including removal of the subcutaneous tissue [26] or lymphovenous anastomoses. Removal of the subcutaneous tissue leaves a very scarred but more usable limb. Lymphovenous anastomosis is less successful in primary than in secondary lymphedema. Lymphatic grafts are also being used with some benefit.

Primary lymphedema usually progresses to a chronically swollen limb. Some patients with primary, and many patients with secondary, lymphedema remain stable and do not progress. Malignant degeneration of the lymphatic vessels, called lymphangiosarcoma, develops in 1 percent of cases and is more common in secondary lymphedema as a consequence of mastectomies (Stewart-Treves syndrome). In lymphedema associated with Turner's syndrome, the edema has abated in some patients.

Differential Diagnosis of Ulcers

Table 167-6 lists the common and some of the uncommon etiologies and characteristics of extremity ulcers. The most common ulcer is caused by venous stasis. Arterial ulcers due to large vessel disease are next in frequency; then the neurotropic ulcers of diabetic neuropathy. Normal pulses are usually present in the limbs except in ulcers due to large vessel arterial disease. Pain is characteristically absent to mild in venous, neurotropic, and neoplastic ulcers. An ulcer with a red granulating base is usually venous. Excess callus formation around a painless ulcer on pressure points suggests a neuropathic ulcer (see Fig. 167-2). Very painful, often serpiginous ulcers occur on the feet and legs in vasculitis, connective tissue diseases, and livedo reticularis with ulceration (see Fig. 167-7). Most secondary causes of Raynaud's phenomenon may lead to digital ulcers. Ulcers may also occur in scleroderma over subcutaneous calcification and will not usually heal until the calcium is extruded. These ulcerations usually occur on the digits, wrists, elbows, knees, or ankles.

TABLE 167-6 **Differential Diagnosis of Ulcers**

A painful ulceration may occur on the posterolateral aspect of the calf in hypertensive patients (hypertensive ulcer). [30] These lesions may start as purplish blebs and then ulcerate with a black eschar that is surrounded by purpura (Fig. 167-13). The etiology is unknown, but biopsy of surrounding tissue shows thrombosis and hyalinization of arterioles. A variety of infections may cause ulcerations, and diagnosis is usually difficult without a culture or biopsy. Ulceration of the nonischemic lesion of necrobiosis lipoidica in diabetes mellitus is uncommon. Malignancies of the skin must always be considered in indolent, nonhealing ulcers.

FIGURE 167-13 A hypertensive ulcer in a 56-year-old woman. The usual location is the lateral aspect of the calf. The base has a black eschar with surrounding ecchymotic tissue. Pain was extreme. All pulses in the extremity were normal.

REFERENCES

Diabetes mellitus (DM) is a major cause of morbidity and mortality in the United States. More than 15 million Americans have the disease, and approximately 13 percent of all health care expenditures in the United States are for DM. [1], [2] The risk of overall mortality is almost four times greater for women with DM than for those without DM. [3] Of great importance, major studies show that tight glycemic control decreases retinopathy, neuropathy, nephropathy, and coronary artery disease, which remain the major contributors to morbidity and mortality. [4], [5] Likewise, tight glycemic control may have a beneficial effect on a subset of skin-related, DM-associated disorders.

DM is characterized by a state of relative or complete insulin deficiency leading to gross defects in glucose, fat, and protein metabolism. In type 1 DM [insulin-dependent DM (IDDM)], an insufficiency of insulin occurs through a gradual, antibody-driven destruction of beta islet cells in the pancreas. In type 2 diabetes [non-insulin-dependent DM (NIDDM)], chronic hyperglycemia occurs mainly through end-organ insulin resistance followed by a progressive decrease in pancreatic insulin release associated with aging. A genetic predisposition and a strong association with obesity exist in type 2 DM. In both types of DM, abnormalities of insulin and elevated blood glucose levels lead to metabolic, vascular, neuropathic, and immunologic abnormalities. Affected organs include the cardiovascular, renal, and nervous systems, the eyes, and the skin.

Nearly all patients with DM have cutaneous manifestations. Although the mechanisms for many DM-associated skin conditions remain unknown, the pathogenesis of others is linked to hyperglycemia and insulin dysfunction, either directly, or through damage to the vascular, neurologic, or immune systems.

Hyperglycemia leads to nonenzymatic glycosylation (NEG) of various structural and regulatory proteins, including collagen. Although NEG occurs normally with aging, the process is greatly accelerated in DM. [6], [7] NEG leads to formation of nondegradable advanced glycosylation end products (AGEs) that are responsible for decreases in both acid solubility and enzymatic digestion of cutaneous collagen. Disorders such as diabetic thick skin and limited joint mobility (LJM) are thought to result directly from accumulation of AGEs. [8] Studies show that the degree of cutaneous AGEs correlates strongly with retinopathy, nephropathy, and other microvascular complications of DM. [9]

Macro- and microangiopathy contribute significantly to the cutaneous complications of DM. Microvascular abnormalities include increased “leakiness” or vessel wall permeability, decreased response of vessels to sympathetic innervation, and less ability to respond to thermal and hypoxemic stress. [10] In combination with arteriosclerosis of large vessels, these microvascular abnormalities contribute to the formation of diabetic ulcers.

In addition, a loss of cutaneous sensory innervation occurs with DM, predisposing patients to infection and injury. The loss of neuroinflammatory cell signaling plays a causal role in nonhealing lower extremity ulcers. [11] Patients with DM who lack lower extremity vibratory perception have a 15.5-fold increased probability of leg amputation. [12]

Derangements of immunoregulatory mechanisms also occur in DM. Hyperglycemia and ketoacidosis diminish chemotaxis, phagocytosis, and bactericidal ability of white blood cells. [10] Despite immune dysfunction at the cellular level, studies fail to document an increased prevalence of cutaneous infection in patients with well-controlled DM. [13], [14] Certain infections, however, such as streptococcal pyoderma, candidiasis, and the more devastating diseases of mucormycosis and necrotizing fasciitis, do appear to be associated with poorly controlled diabetes [15] (see below).

Dysregulation of lipid metabolism occurs with DM-associated insulin deficiency. The activity of lipoprotein lipase (LPL) is directly dependent on insulin, [16] making insulin central to the processing of triglyceride-rich chylomicrons and very-low-density lipoproteins (VLDLs). In insulin-deficient diabetic patients, defective lipid processing may lead to massive hypertriglyceridemia, manifesting in the skin as eruptive xanthomas. Naturally, disorders of lipid processing also play an integral role in the vasculopathies of DM.

Finally, cutaneous manifestations result from hyperinsulinemia, which occurs in early insulin-resistant type 2 DM. In this

case, the excess insulin is thought to bind and activate insulin-like growth factor-1 (IGF-1) receptors that may mediate the abnormal epidermal proliferation and resulting phenotype of acanthosis nigricans. [17]

This chapter reviews the cutaneous disorders associated with DM. They are characterized by disorders with evidence for metabolic, vascular, neurologic, or immunologic pathogenesis (induced by glucose and insulin abnormalities) and disorders associated with DM, but without a clear pathogenesis (Table 168-1 and Table 168-2). The glucagonoma syndrome is described briefly, with emphasis on cutaneous manifestations.

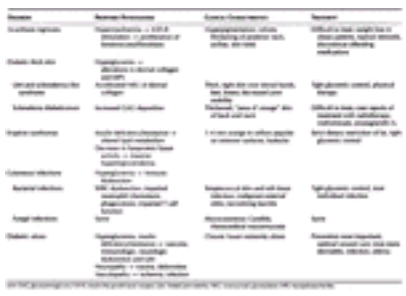

TABLE 168-1 **Cutaneous Disorder of DM with Known or Postulated Pathogenesis**

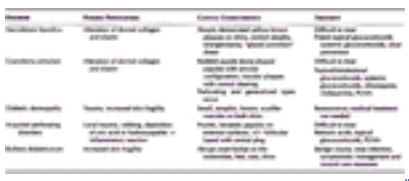

TABLE 168-2 **Cutaneous Disorders of DM without a Clear Pathogenesis**

CUTANEOUS DISORDERS OF DIABETES MELLITUS ASSOCIATED WITH METABOLIC, VASCULAR, NEUROLOGIC, OR IMMUNOLOGIC ABNORMALITIES

Acanthosis Nigricans (See Chap. 185)

Clinically, acanthosis nigricans (AN) presents as brown to gray-black papillomatous cutaneous thickening in the flexural areas including the posterolateral neck, axillae, groin, and abdominal folds. The affected skin has a dirty, velvety texture. In some cases, oral, esophageal, pharyngeal, laryngeal, conjunctival, and anogenital mucosal surfaces may be involved. In general, however, the back of the neck is the most consistently and severely affected area. [18]

Although some reports on AN suggest an association with malignancy, [19] other studies show that AN is common in the general population and most cases are associated with obesity, insulin resistance, and hyperinsulinemia. [19], [20] AN may be considered as a prognostic indicator for development of type 2 DM. [18] In a large, population-based study from Galveston, Texas, AN was present in 7.1 percent of 1412 school-age children. [20] AN occurred in 66 percent of children who weighed 200 percent of ideal body weight (IBW), and in 27 percent of children at 120 percent IBW. In this study, fasting insulin levels correlated with the presence and severity of AN.

The rate of AN varies among different ethnic groups. In the Galveston study, despite similar obesity rates, the prevalence was 0.5 percent in white, 5 percent in Hispanic, and 13 percent in African American children. [20] This finding suggests a possible genetic predisposition or increased sensitivity of the skin to hyperinsulinemia among certain populations. [18]

Advances are taking place in understanding the pathogenesis of AN. It is postulated that excess growth factor stimulation in the skin causes aberrant proliferation of keratinocytes and fibroblasts resulting in the phenotype of AN. [19] In states of insulin resistance and hyperinsulinemia, AN may result from excess insulin binding to IGF-1 receptors on keratinocytes and fibroblasts. [17], [21] Studies show, for example, that high concentrations of insulin stimulate in vitro fibroblast DNA synthesis and proliferation through IGF-1 receptors. [22] In AN associated with malignancy, evidence suggests that transforming growth factor -a released from the tumor cells may stimulate keratinocyte proliferation via epidermal growth factor (EGF) receptors. [23], [24] Support for the role of different growth factors in the pathogenesis of AN continues to accrue.

In addition to hyperinsulinemia, other associations with AN include hyperandrogenic states in females [25] and certain medications. Systemic glucocorticoids, nicotinic acid, and estrogens such as diethylstilbestrol have all been implicated. [19]

Treatment of AN is generally ineffective. Resolution may occur with weight loss (to IBW) in obese patients. [17], [19] Removal of offending medications generally results in skin clearance. [26] Although historical data have emphasized the relation between AN and malignancy, a true association is rare and does not warrant an extensive work up in the face of a negative history and physical examination. Of 12,000 patients with cancer in a 10-year study, only 2 developed AN. [27] The most important aspect of recognizing AN is that hyperinsulinemia is a known risk factor for type 2 DM, [28] and possibly coronary heart disease. [29]

Diabetic Thick Skin

Several specific syndromes are associated with localized thickening of the skin in DM. The common underlying

pathogenesis involves biochemical alterations in dermal collagen and mucopolysaccharides. Increased deposition and improper degradation of these constituents (through the formation AGEs) results in the clinical syndromes.

LIMITED JOINT MOBILITY AND SCLERODERMA-LIKE SYNDROME Diabetic LJM, or cheiroarthropathy, presents as tightness and thickening of the skin and periarticular connective tissue of the fingers, resulting in a painless loss of joint mobility. Initial involvement of the distal interphalangeal joints of the fifth digit usually progresses proximally to involve all fingers. Larger joints of the elbow, knee, and foot may be affected. The actual joint space, however, remains uninvolved, so that LJM is not a true arthropathy. This disorder is characterized by the "prayer sign" [30] (Fig. 168-1), which is an inability to approximate the palmar surfaces and interphalangeal joint spaces with the hands pressed together and fingers separated.

FIGURE 168-1 LJM in a 31-year-old male with type 1 DM. Patient is unable to approximate the palmar surfaces of the proximal and distal interphalangeal joints with palms pressed together (known as the "prayer sign"). *A.* Ulnar view: only fingertips are able to be approximated. *B.* Radial view: straining to press palms together.

Thirty to 50 percent of adult patients with type 1 DM have LJM; some authors believe this to be the earliest clinically apparent complication of diabetes in childhood and adolescence. [31] It also is common in type 2 DM. LJM is associated with increased duration of diabetes and poor glucose control. [31], [32] One longitudinal prospective study showed a 2.5-fold increase in the risk of LJM for every unit increase in the glycosylated hemoglobin (HbA1c). [32] Most importantly, LJM is directly correlated with microvascular disease. [30], [31], [33] Evidence indicates that intensive insulin therapy is important in prevention, and possibly treatment of LJM and scleroderma-like syndrome (SLS). Monnier et al. [9] showed that long-term tight glycemic control leads to decreased skin AGEs, and tight glycemic control is associated with delayed onset and severity of LJM. [32] On the basis of improvements in DM management, Infante et al. [34] reported a fourfold reduction in the frequency of LJM over the last 20 years. Treatment for LJM is difficult and should focus on tight control of blood sugar as well as physical therapy to preserve active range of motion. SLS is discussed together with LJM in patients with DM. It appears clinically as thickened waxy skin over the dorsal hands and feet, perhaps involving the forearms and thighs. The thickened skin may have a "pebbly" quality. [35] Although SLS can occur independently, most patients also have LJM. SLS is not associated with systemic sclerosis but does correlate with the duration of DM, the severity of joint contractures, and retinopathy. [33] It seems likely that the historical description of "diabetic hand syndrome" represents the same syndrome as SLS and LJM.

SCLEREDEMA DIABETICORUM (See Chap. 186) Recognized in 1970 as a syndrome, [36], [37] scleredema of diabetes [scleredema diabeticorum (SD)] presents with the insidious onset of painless, symmetric induration and thickening of the skin on the upper back and neck. Spread to the face, shoulders, and anterior torso may occur. The skin retains a nonpitting, woody, "peau d'orange" quality. Identical changes occur with postinfectious scleredema (see Chap. 186), usually associated with streptococcal pharyngitis. In scleredema associated with infection, however, the onset is often sudden, and the symptoms usually remit over time. Reported in 2.5 to 14 percent of patients with DM, SD is not uncommon. [38], [39] SD is a disease of long-standing diabetes, associated with obesity. Most patients have type 2 DM. This disorder has not been reported in children. The pathogenesis of SD is postulated to be unregulated production of extracellular matrix molecules by fibroblasts leading to thickened collagen bundles and increased deposition of glycosaminoglycans (mainly hyaluronic acid). Studies using in vitro fibroblast analysis from involved skin have variably demonstrated increased synthesis of glycosaminoglycans (GAGs) and type I collagen. [40] However, most of these reports involved nondiabetic patients with paraproteinemia and were based on small numbers of cases. Patients with SD may experience decreased sensation to pain and light touch over the affected areas and difficulties with upper extremity and neck range of motion. Extreme cases may result in full loss of range of motion. Unlike LJM and SLS, the presence of scleredema does not correlate with retinopathy, nephropathy, neuropathy, or principal vascular disease. [38] However, no large-scale prospective studies have been done. Most patients with SD become insulin dependent, are difficult to treat, and have multiple complications of DM. [40] Treatment for SD is usually unsuccessful. Case reports describe treatment with radiotherapy, low-dose methotrexate, and prostaglandin E_1. [41], [42]

Eruptive Xanthomas (See Chap. 150)

Eruptive xanthomas present clinically as 1- to 4-mm reddish-yellow papules on the buttocks and extensor surfaces of the extremities. The lesions occur in crops, and may coalesce into plaques over time (Fig. 168-2). Although eruptive xanthomas are generally asymptomatic, correct diagnosis is crucial because these lesions are often the first harbingers of untreated DM and severe hypertriglyceridemia. Histologic and biochemical studies show that lipoproteins (mainly chylomicrons) in the blood permeate cutaneous vessel walls and accumulate in macrophages in the dermis. [43] Because the triglycerides in eruptive xanthomas are mobilized more easily than the cholesterol, the initially triglyceride-rich lesions contain progressively more cholesterol as they resolve. [43] Whether this mechanism plays a role in the atherosclerosis of large arteries is unknown.

FIGURE 168-2 Eruptive xanthomas. Yellow-orange papules and plaques on the buttocks of a male patient with type 2 DM. (*Courtesy of G. Raugi, MD.*)

Most patients with hypertriglyceridemia do not have onset until adulthood. The prevailing thought is that these patients have a mild to moderate genetic defect in LPL and subsequently develop an additional acquired disorder of lipid metabolism. [44] The main acquired forms of hypertriglyceridemia result from medications (estrogens, retinoids), alcohol, and, importantly, untreated DM. In fact, DM is the most common cause of massive hypertriglyceridemia in genetically susceptible individuals. [45]

In uncontrolled DM, LPL activity decreases. [16] The degree of enzymatic dysfunction is proportionate to the amount of insulin deficiency and hyperglycemia. [16] Clearance of plasma lipoproteins depends on adequate insulin. [46] The inability to metabolize and clear triglyceride-rich chylomicrons and VLDLs can lead to plasma triglyceride levels in the thousands.

In addition to eruptive xanthomas, triglyceride levels above 4000 may cause lipemia retinalis. On funduscopic examination, lipemia retinalis appears as pale pink to white retinal arterioles and venules. The fundus may have a milky hue. Untreated, severe hypertriglyceridemia may also lead to abdominal pain, hepatosplenomegaly, pancreatitis, or dyspnea from decreased pulmonary diffusing capacity and abnormal hemoglobin oxygen affinity. [45] Treatment of hypertriglyceridemia involves strict dietary fat restrictions and control of the underlying DM. LPL activity returns to normal after treatment with long-term insulin or oral glucose-lowering agents. [16] The eruptive xanthomas respond rapidly and usually resolve completely in 6 to 8 weeks. [47]

Cutaneous Infections

Although the association between DM and cutaneous infections is not well supported, [12], [14] several infections are discussed below that occur more commonly, with greater severity, or with a greater risk for complications in patients with DM. Because dermatologists are often the only physicians to routinely examine the skin (a critical barrier to infection), they should be aware of these infections in patients with DM. Joshi et al. recently reviewed this subject. [15]

Much research has been undertaken on the pathogenesis of immune dysfunction in DM. Although some studies could not detect defects at the cellular level, [48] other studies show that leukocyte chemotaxis, adherence, and phagocytosis are impaired in patients with DM, especially during hyperglycemia and diabetic acidosis. [10], [49] Further studies show that cutaneous T cell function and response to antigen challenge are also decreased in DM. [15]

BACTERIAL INFECTIONS Patients with DM are at a higher risk for contracting certain bacterial infections, including Group A and Group B streptococcal infections, necrotizing fasciitis, and malignant otitis media. The relation between diabetes and staphylococcal infections is controversial.

Group B streptococcal infections (See Chap. 194) Group B streptococcus (*Streptococcus agalactiae*), a major cause of morbidity in neonates and pregnant women, is also a significant source of invasive bacterial infection in nonpregnant adults. Both retrospective and prospective population-based studies show DM to be a risk factor in these infections. [50], [51] In a study of 424 nonpregnant adults with invasive group B streptococcal infection, 30 percent of cases occurred in patients with DM. The most common sites of infection were skin, soft tissue, and bone (cellulitis, foot ulcers, and decubitus ulcers). [51] In young adults, the presence of DM increases the risk of group B streptococcal infection 30-fold. [51] Despite therapy, approximately 20 percent of these cases are fatal. [50], [51] In pregnancy, maternal DM (but perhaps not gestational DM alone) [52] increases the risk even more. [53]

Group A streptococcal infections In a prospective population-based surveillance of invasive group A streptococcal disease, the risk of infection was 3.7-fold greater in patients with DM. Soft tissue infections were the most common clinical presentation for all patients. [54]

Staphylococcal infections (See Chap. 194) Historically, *Staphylococcus aureus* skin infections were associated with DM. Past recommendations even suggested testing patients with recurrent furunculosis or folliculitis for DM. [55] In a review, however, Breen and Karchmer [56] concluded that current data do not permit estimation of proportional risk of staphylococcal infections in patients with DM. With respect to staphylococcal carriage rates in patients with DM, they concluded that, although study comparisons were difficult, it is likely that certain subsets of patients with DM have increased carriage rates. [56]

Malignant external otitis Invasive “malignant” otitis externa is an uncommon, life-threatening infection of the external auditory canal with potential cranial bone and intracranial involvement. *Pseudomonas aeruginosa* is usually implicated, and preceding aural irrigation with tap water may play an etiologic role. [57] This painful infection, which occurs in older patients with DM, is characterized by purulent discharge, unilateral facial swelling, hearing loss, and granulation tissue in the ear canal. [15], [58] Approximately 70 to 94 percent of patients with malignant external otitis have underlying diabetes. [10] Diagnosis is often delayed, and mortality rates are as high as 20 to 40 percent despite appropriate antibiotic therapy. [15], [58]

Necrotizing fasciitis (See Chap. 196) Ten to 60 percent of all cases of necrotizing fasciitis occurs in patients with DM. [59] Necrotizing fasciitis is a life-threatening bacterial infection of the soft tissues with spread along fascial planes. The perineum, trunk, abdomen, and upper extremities are most commonly involved. [10] Clinical presentation includes erythema, swelling, induration, necrosis, and possible bullae formation. The degree of pain and toxicity are often out of

proportion to the severity of the findings. Although most cases result from polymicrobial facultative gram-negative bacilli such as *Escherichia coli* and anaerobes such as *Bacteroides*, *Peptostreptococcus,* and clostridium species, approximately 10 percent of cases are monomicrobial, often due to streptococcal species. [15], [60] Treatment includes urgent surgical debridement and appropriate antibiotics. Mortality rates of 40 percent have been reported. [15]

FUNGAL AND YEAST INFECTIONS

Candidal infections (See Chap. 206) Most authors believe that mucocutaneous *Candida* infections occur more frequently among patients with DM, especially those with poorly controlled disease. [13], [61] Intertrigo (axillary, inguinal, web space), vulvovaginitis, balanitis, paronychia, onychomycosis, glossitis, and angular cheilitis are most common. In one study, the clinical diagnosis of candidal paronychia was made in 9.6 percent of 250 diabetic women, compared to only 3.4 percent of nondiabetic women. [62] In addition to symptomatic vaginal yeast infections, asymptomatic carriage rates are also elevated in patients with DM. [61] Postmenopausal females with recurrent vulvovaginal candidiasis should undergo screening for diabetes. Treatment for candidal infections includes topical and oral antifungals. Patients with candidal paronychia should avoid wetting of the nails and use drying agents (e.g., 15% sulfacetamide in 50% ethanol, three to four drops, four times per day, and after each time hands get wet). [10]

Dermatophyte infections (See Chap. 205) Although two studies failed to show an overall increased prevalence of dermatophyte infections in patients with DM compared to control subjects, [14], [63] Gupta et al. [64] demonstrated that the rate of toenail onychomycosis was 2.77 times greater for patients with DM as compared to controls. In addition, they found peripheral vascular disease to be a significant predictor. Probably the most important aspect of dermatophyte infection in patients with DM is aggressive diagnosis and treatment of tinea foot infections because of the potential portal of entry for subsequent bacterial infections.

Rhinocerebral mucormycosis (See Chap. 207) Rhinocerebral mucormycosis (RCM) is caused by Zygomycetes (*Mucor* and *Rhizopus* species). It often presents with headache, fever, and lethargy, in addition to nasal congestion and facial–ocular pain and swelling. Subsequent findings include unilateral proptosis, ophthalmoplegia, and palate or nasocutaneous necrosis. Seventy-five to 80 percent of all cases occur in patients with DM, [65] with diabetic ketoacidosis as the most important risk factor. [15] Ketoacidosis reportedly blunts the normal inhibitory activity of serum against *Rhizopus*. [66] Amphotericin B and surgical debridement are the treatments of choice. Mortality rates for RCM range from 15 to 34 percent. [66] In addition to RCM, *Mucor* species have also been observed complicating skin ulcers on the legs and hands of patients with DM. [10], [61]

Diabetic Ulcers

Chronic, nonhealing foot ulcers are a significant problem for patients with DM, accounting for a quarter of all days spent in the hospital by this population. [67] Lower-extremity ulcers were the proximal cause of amputation in 67 of 80 patients (84 percent) in a 1990 study by Pecoraro et al. [68] It has been estimated that 15 percent of individuals with DM will develop lower-extremity ulcers [69] and that 14 to 24 percent of patients with DM who have foot ulcers will eventually undergo amputation. [70]

The pathogenesis of diabetic ulcers is affected by many of the factors previously described in this chapter. For example, LJM and SLS (related to NEG) result in a less flexible foot with uneven distribution of pressure while walking. NEG of regulatory molecules that participate in the wound healing cascade may also contribute to the slow healing observed in patients with DM. Neuropathy (associated with uncontrolled hyperglycemia) is one of the major predictors of diabetic ulcers. [12] The loss of cutaneous sensory nerves also diminishes neuroinflammatory signaling via neuropeptides to keratinocytes, fibroblasts, endothelial cells, and inflammatory cells. [11] Blood lipid abnormalities (associated with insulin deficiency or resistance) are associated with vasculopathy, a major contributing factor in the formation of lower-extremity ulcers leading to amputation. [12] Factors affecting the immune response to infection become important when the skin barrier is breached and the healing response is adversely affected by the poor response of patients with DM to wound infection.

Ulcer prevention is the most important intervention physicians and other health care professionals can provide for diabetic patients with neuropathy. These interventions [10] are summarized as follows:

- Implement formal education, including recommendation of daily foot inspection.
- Advise careful selection of footwear that is not rigid or constricting in design and does not require a break-in period. Ill-fitting shoes and socks were the most common reasons for foot ulcers in a study of 314 diabetic patients with ulcers. [71] Issuing sports shoes to a group of patients with DM as an experimental variable resulted in a measurable reduction of calluses. [72] Calluses are a sign of excess friction and often precede foot ulcers (see Chap. 130).
- Advise patients to inspect shoes for foreign bodies before putting them on and to avoid walking barefooted, even indoors.
- Urge patients to seek early health care attention for calluses, blisters, “ingrown” toenails, dermatitis, or “athlete's foot.”
- Personally inspect the feet of patients with DM at each visit.
- Advise patients with a history of ulceration that they are at high risk for reulceration (34 percent at 1 year, 61 percent at 3 years, and 70 percent at 5 years). [73] Redouble education and prevention efforts in this group. Lifelong surveillance is required.

Treatment of diabetic ulcers requires modification of factors that have contributed to the ulceration, for example, stasis dermatitis, leg edema, and skin infection. Standard therapy for neuropathic diabetic ulcers includes debridement, pressure relief (often non–weight bearing), wet compresses, and protective dressings.

Data on treatment for diabetic ulcers were recently reviewed at an international Consensus Development Conference on Diabetic Foot Wound Care in Boston, MA. [70] The following assessment was published in *Diabetes Care*: “New technologies include growth factors, living skin equivalents, electrical stimulation, cold laser, and heat. Becaplermin

(recombinant platelet-derived growth factor) for the topical treatment of diabetic foot ulcers shows a modest benefit if used with adequate off-loading, debridement, and control of infection." For patients with significant ischemia it was concluded: "Once infection is controlled, arteriography, including visualization of the foot vessels, and subsequent vascular reconstruction can be undertaken in suitable patients with vascular insufficiency." A large multicenter, clinical trial of a bilayered living skin equivalent (Graftskin) [74] showed 56 percent healing at 12 weeks as compared with 38 percent healing for standard care. The most favorable published results for a monolayered living skin equivalent (Dermagraft) and platelet-derived growth factor (Becaplermin) show roughly comparable improvement in healing to that reported for Graftskin when each is compared to standard care or placebo. [75] These newer technologies await definitive analysis of cost effectiveness compared to standard older approaches.

Specialized ulcer care teams have published impressive results on the prevention and healing of ulcers. [76] This multidisciplinary team approach is likely to become important in the treatment of diabetic ulcers in large population centers.

DISORDERS ASSOCIATED WITH DIABETES MELLITUS BUT OF UNKNOWN PATHOGENESIS

Necrobiosis Lipoidica

Coined by Urbach in 1932 as necrobiosis lipoidica diabeticorum, this disorder was named after characteristic histologic findings and was first described in patients with DM. Because not all patients have concurrent DM, the shortened term, necrobiosis lipoidica (NL), is preferred. [77]

The classic clinical picture of NL is one to several sharply demarcated yellow-brown plaques on the anterior pretibial region (Fig. 168-3). The lesions have a violaceous, irregular border that may be raised and indurated. Initially, NL often presents as red-brown papules and nodules that may mimic sarcoid or granuloma annulare (GA). Over time, the lesions flatten, and the central yellow area becomes atrophic and develops telangiectasias, taking on the characteristic "glazed-porcelain" sheen. Aside from the shins, other sites of predilection include ankles, calves, thighs, and feet. Fifteen percent of patients develop lesions on the upper extremities and trunk that tend to be more papulonodular. Although pain and pruritus have been reported, most lesions are asymptomatic. Anesthesia of the plaques does occur. [78] Epidemiologic data show that the mean age of onset is around 30 years and that NL occurs three times more often in women than in men. [79]

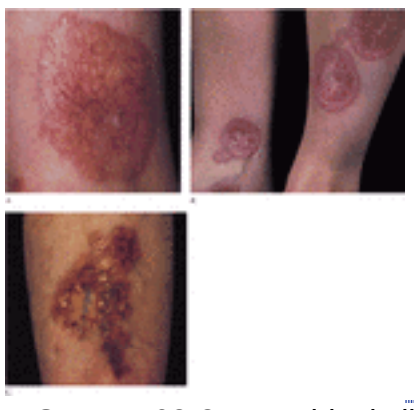

FIGURE 168-3 Necrobiosis lipoidica (NL) *A.* A single orange plaque with atrophy of the overlying epidermis and arborizing telangiectasis is seen on the lower leg of a juvenile with DM; the crust marks an area of early ulceration. *B.* Older lesions with striking central atrophy involving both the epidermis and dermis. *C.* NL of long-standing duration with sharply demarcated atrophic areas and sites of healed ulcerations.

The course of NL is often indolent, with spontaneous remission in less than 20 percent of cases. [10] Over time, the plaques of NL tend to stabilize, and formation of new lesions tapers off. However, the possibility of ulceration, a poor spontaneous remission rate, and cosmetic concerns lead patients to seek treatment. Ulceration, the most serious complication, occurs in approximately 13 to 35 percent of cases on the legs. [77], [79], [80] A few cases of squamous cell carcinoma arising in chronic ulcerative NL have been reported. [81] Multiple reports document the association of NL with GA and sarcoidosis. [82]

The most often quoted statistics concerning the association of NL with DM are from a 1966 retrospective study at the Mayo Clinic. Of 171 patients with NL, two-thirds had DM at diagnosis, and another 5 to 10 percent had glucose tolerance abnormalities. [79] In a 1999 study of 65 patients with NL, only 11 percent had DM after 15 years of follow-up. [83] Conversely, the prevalence of NL has been found to be only 0.3 to 3 percent in patients with DM. [79], [84] Although lacking full concordance, NL definitely has a strong association with DM and remains a valid marker of disease.

The pathogenesis of NL is unclear. Many etiologic mechanisms have been proposed and reviewed. [77] Evidence suggests that the degree of hyperglycemia and diabetic control does not correlate with the presence of NL. [85]

Treatment for NL is disappointing. At this time, only case reports and small, uncontrolled trials provide the basis for treatment decisions (summarized in Lowitt et al. [77]. Early application of potent topical glucocorticoids might slow progression. [77] Although some authors [79] report improvement with intralesional injection of glucocorticoids to the active border, the risk of ulceration with this treatment modality should be considered. A few case reports [80] and one series of six patients [86] showed benefit with short-term systemic glucocorticoids. Aspirin and dipyridamole have produced variable

results. [77]

Given the generally benign nature of the lesions, physicians should consider the adage “do no harm.” Focus should be on prevention of ulcers. When ulceration occurs in patients with NL, the same wound care principles apply as for all diabetic ulcers. Recently, cyclosporine resulted in ulcer closure and sustained response in two patients. [87] Surgical excision down to fascia and split-thickness skin grafting remain as the last resort for very recalcitrant NL ulcers. [88]

Granuloma Annulare (See Chap. 100)

Clinically, GA presents as erythematous to violaceous domed-shaped papules arranged in an annular configuration. They may form indurated, circular or semicircular plaques with central clearing. Localized GA, the most common form, occurs more frequently in children and young adults. Eighty-five percent of patients have fewer than 10 lesions, and sites of predilection include the dorsum of the hands, ankles, and feet. GA is a benign, self-limited disorder. Forty to 50 percent of patients report clearing within 2 years. [89] Women are affected two to three times more often than men. [89], [90] Atypical forms of GA include generalized, subcutaneous, and perforating types. Seven to 10 percent of patients have generalized GA, [90] which presents as hundreds to thousands of 1- to 2-mm flesh-colored papules that may form small annular plaques. The lesions are symmetric, and appear more commonly on the abdomen, chest, thighs, and extensor elbows. [90] Generalized GA occurs more frequently in older adults (mean age of onset is 52) [90] and has a more chronic and relapsing course. [89] Only 8 percent clear spontaneously. [90]

The association of GA with DM is widely discussed and appears to be less strong than that of NL. Although most patients with GA are in good health, without underlying systemic illness, an association with DM is supported in the literature. Dabski and Winklemann [90] reported DM in 10 percent of 1353 patients with localized GA and 21 percent of 100 patients with systemic GA. [90] An additional small retrospective case-control study showed an increased prevalence of DM among patients with GA (11 of 61, 18 percent) as compared with the prevalence in age-matched controls (10 of 120, 7.9 percent). [91]

Although controversial, many authors agree that DM is found more frequently in patients with adult onset GA, and in those with generalized or perforating GA, and that these patients tend to experience a more chronic, relapsing course of GA. [89] However, most studies to date suffer from referral bias or are small and retrospective, thus making interpretation of data difficult. To adequately address the association between GA and DM, a large, longitudinal population-based study is needed.

The pathogenesis of GA is unclear. Proposed mechanisms are discussed in Chap. 100. The mainstay of treatment remains potent topical or intralesional glucocorticoids. Because generalized GA may be pruritic and also cosmetically crippling, systemic treatments have been tried including systemic glucocorticoids, niacinamide, chloroquine, aspirin, and potassium iodide. [92] There is no clear drug of choice. Clofazimine has shown promise, [93] and treatment with PUVA resulted in complete clearance in one case [94] and in a series of five patients. [92] Taking a careful history and performing a physical examination to discern possible DM are recommended. In addition, most experts advocate checking a fasting glucose level in patients with chronic relapsing, perforated, or generalized GA. [10], [89]

Diabetic Dermopathy

Atrophic skin lesions of the lower extremity, or shin spots, were first characterized and presented as a cutaneous marker for DM by Melin in 1964. [95] Shortly after, Binkley coined the term diabetic “dermopathy” to correlate the pathologic changes with those of retinopathy, nephropathy, and neuropathy. [96] Since that time, controversy has existed as to the disorder's etiology, specificity for DM, and association with other microangiopathic complications of DM.

Diabetic dermopathy presents as small (<11 mm), atrophic, brown, scarlike macules on the pretibial areas (Fig. 168-4). The lesions are asymptomatic and clear within 1 to 2 years with light residual atrophy or hypopigmentation. [95] New lesions usually arise, giving the sense that the pigmentation and atrophy are persistent.

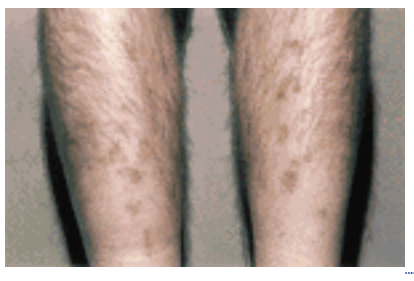

FIGURE 168-4 Diabetic dermopathy. Hyperpigmented macules are seen on the anterior lower legs.

The prevalence of shin spots in ambulatory patients with DM varies. In a recent population-based study from Sweden, diabetic dermopathy was found in 33 percent of patients with type 1 DM, and in 39 percent of patients with type 2 DM. Of the healthy control group, only 2 percent had similar lesions on their shins. [97] In other studies, the prevalence rate for individuals without DM ranges from 1.5 percent for healthy medical students, to 20 percent for a group of nondiabetic endocrine patients. [98] Diabetic dermopathy occurs more often in patients with an increased duration of DM and is more frequent in men. [98]

An association does seem to exist between diabetic dermopathy and the more serious complications of DM. In a study of

173 patients with DM, the incidence of shin spots was significantly increased in patients with retinopathy, nephropathy, and neuropathy. [99] Diabetic dermopathy does not, however, correlate with obesity or hypertension in patients with DM. [98]

It is likely that the lesions are related to antecedent trauma. Lithner [100] induced diabetic dermopathy on the legs of diabetic patients with heat and cold injury, whereas nondiabetic control subjects healed without residual change. [100] When questioned, most patients feel that the changes are caused by injury but they are often unable to detail preceding trauma, and they note that the lesions tend to be painless. No treatment is necessary for the individual atrophic tibial lesions. They are asymptomatic and are not directly associated with an increase in morbidity.

Acquired Perforating Disorders (See Chap. 57)

Acquired perforating disorders (APDs) comprise an overlapping group of disorders characterized by transepidermal elimination or “spitting” of altered dermal constituents. Clinically, lesions grouped under the heading of APDs appear as pruritic, keratotic papules mainly on the extensor surfaces of the extremities. Papules and nodules with a perforating component may also occur on the trunk and face. Many are follicular and contain a prominent central keratotic plug. The papules may be grouped, or coalesce to form verrucous plaques.

The APDs include Kyrle's disease, reactive perforating collagenosis, perforating folliculitis, and elastosis perforans serpiginosa. [101] Historical attempts have been made to delineate the disorders in this group based on differing pathogenesis, associated diseases, and hereditary versus acquired forms of APD. [101] Unlike the inherited forms of perforating collagenosis, APDs occur in adulthood and lack a predilection for sex or race. [102] Several studies in the literature suggest a causal relationship of APDs with chronic renal failure and DM with or without hemodialysis. [102] The prevalence among patients on hemodialysis is reported at 4.5 to 10 percent. [103]

The pathogenesis of the APDs is unknown. One possible factor may be deposition of “uremic substances,” such as uric acid or hydroxyapatite, that incite an inflammatory response and foreign body reaction resulting in transepidermal elimination of dermal constituents. [102] Local trauma and chronic rubbing secondary to pruritus appear to play a role. Microangiopathy and dysregulation of vitamins A or D have also been proposed. [102]

Treatment for APDs is usually unsuccessful. Retinoic acid, topical glucocorticoids, and PUVA have been found to be partially successful. [102]

Bullosis Diabeticorum

Bullosis diabeticorum (BD) is characterized by abrupt onset of bullae on the lower extremities, usually the toes, feet, and shins. Occasionally, the distal upper extremities are involved. The blisters are usually painless and not pruritic. Healing occurs within 2 to 5 weeks and rarely leaves scarring. The condition may recur as successive crops of bullae over many years. Studies of affected individuals excluded other blistering skin disorders, and revealed no abnormalities of porphyrin metabolism. [104] As of 1985, 43 cases of BD had been reported. [105]

The pathogenesis of diabetic bullae is unknown. Patients with BD do not have a history of antecedent trauma or infection. Histopathologic examination of the bullae shows an inconsistent level of separation varying from intraepidermal to subepidermal. [105] No immunopathologic features are consistently observed. One study found a decreased threshold to suction-induced blister formation in patients with DM. [106] Reduced suction blister time is also observed with increasing age in nondiabetic subjects. [105] Although a history of antecedent trauma is not elicited, this finding suggests a role of increased skin fragility in diabetic bullae. Perhaps the formation of AGEs leads to increased fragility.

The differential diagnosis of diabetic bullae includes bullous impetigo, bullous pemphigoid, pemphigus vulgaris, epidermolysis bullosa acquisita, porphyria cutanea tarda, bullous erythema multiforme (e.g., to drugs), and insect bite reaction. Biopsy should be performed and the tissue examined histologically as well as by immunofluorescence. In addition, cultures and blood work to screen for porphyrins should be considered.

BD runs a benign course, without involvement of large body surface areas. The only serious complication is that of secondary infection, which should be managed with culture and appropriate antibiotics if suspected. Otherwise, therapy is supportive. The real importance of this disorder is that of correct diagnosis because several of the blistering skin diseases have a high rate of morbidity and require potentially toxic systemic treatments. A negative workup should be documented, and the patient should be educated and reassured.

GLUCAGONOMA SYNDROME (See Chap. 164 and Chap. 184)

Glucagonoma syndrome is a rare paraneoplastic syndrome consisting of DM, an erosive rash [necrolytic migratory erythema (NME)], glossitis, weight loss, diarrhea, anemia, and hypoalbuminemia (Table 168-3). It is caused by a glucagon-secreting pancreatic tumor of the alpha islet cells. Age of onset is typically 50 to 60 years, and no gender predilection has been observed. [107] More than 15 percent of patients may not have DM. [108] Malignancy as defined by presence of metastases is reported to be 60 to 70 percent, [10] but the true malignancy rate may be as high as 100 percent. Metastases occur with most frequency in the liver, and then adjacent lymph nodes, bone, adrenals, kidney, and lung. [109]

Sign/Symptom	Frequency (or Review)
Diabetes mellitus	56–94%[107,108,110]
Cutaneous findings	
Necrolytic migratory erythema	~70–80%[108,110] most common presenting symptom
Cheilitis, angular cheilitis	~30%[107,108]
Weight loss, cachexia	56–97%[107,108,110] marker of metastasis
Gastrointestinal abnormalities	
Diarrhea	20–30%[108,109]
Constipation	5%
Neuropsychiatric disorder	16–20%[108]
Depression	
Paranoid delusions	
Insomnia	
Apnea	
Visual difficulties	
Thromboembolic disease	~23% overall[108]
Pulmonary emboli	
Deep venous thrombosis	11%[108]
Cerebrovascular artery thrombosis	
Laboratory abnormalities	
Elevated glucagon levels[a]	~100%,[110] rarely, initial level is normal
Elevated sedimentation rate	
Anemia, normocytic	55–80%[107,110]
Hypoalbuminemia	
Hypoaminoacidemia	100%[107]
Other neuroendocrine syndromes	
Zollinger-Ellison syndrome	11%[108]
MEN1[b]	5–17%[107,108]
Insulinoma

TABLE 168-3 **Signs and Symptoms of Glucagonoma Syndrome**

All patients with untreated glucagonoma eventually develop NME. [107] Sites of involvement include groin, thighs, buttock, central face, frictional areas, and distal extremities. [109], [110] Initial clinical presentation is usually erythematous macules and papules, often in the groin. [107], [109] The lesions evolve into blistering plaques resulting in a scalded appearance with erosion and crusting. Perilesional pustules may occur, and pain and intense pruritus are common. [109] The rash has a cyclical nature with concurrent lesions at different levels of healing. In addition to NME, approximately 30 percent of patients develop glossitis and angular chelitis. [108], [110]

Although there may be histologic variation in skin lesions of NME, [111] typical lesions show epidermal necrosis, edema, and separation in the upper spinous layer. Infiltrates are mainly neutrophilic. [111] The differential diagnosis of NME includes bullous and papulosquamous disorders, as well as certain nutritional deficiencies in which clinical and histologic skin findings closely resemble those of NME.

Normally, glucagon maintains glucose levels during states of metabolic stress such as fasting, exercise, and childbirth by increasing liver gluconeogenesis and glycogenolysis and inhibiting glycogen synthesis. In glucagonoma syndrome, excessive levels of glucagon promote amino acid catabolism, leading to a deficiency of the proteins needed for cellular growth and division. This chronic state of amino acid deficiency is thought to be responsible for the cellular necrosis of the epidermis in NME. Supporting data include improvement of NME with correction of hypoaminoacidemia [112] and the cutaneous resemblance to other states of nutritional deficiency.

The rarity of glucagonoma syndrome often results in delayed diagnosis, and many patients have metastatic disease at the time of workup. In the correct clinical setting, an elevated serum glucagon level is usually diagnostic. Levels generally range from 1000 to 5000 pg/mL [110] (normal, 50 to 150 pg/mL). Contrast-enhanced computed tomography is recommended for visualization of the tumor. The gold standard, however, remains selective celiac axis arteriography for localization of tumor as well as liver metastases. [109], [113] A high level of suspicion is necessary to diagnose glucagonoma syndrome, and several authors recommend obtaining glucagon levels in any patient with DM and a chronic dermatosis. [10], [107] In addition, given the association between glucagonomas and other neuroendocrine tumors, evaluation for abnormal levels of other gastrointestinal hormones should be undertaken. [107]

The mainstay of treatment is surgical resection of the primary tumor. [10], [107], [108] Most patients show significant clinical improvement even with incomplete resection of metastases. [107] Octreotide and other new longer acting somatostatin analogs have been shown to significantly reduce serum glucagon levels and improve symptoms. [107], [110] In advanced metastatic and nonresectable disease, chemotherapeutic agents such as streptozotocin, 5-fluorouracil (5-FU), and dimethyltriazenoimidazolecarboxamide (DTIC) have been used. Although good prognostic data still are lacking, the overall 5-year survival rate appears to be greater than 50 percent, and those with localized tumors have complete cure with total resection. [108], [110]

REFERENCES

A hormone is a substance produced by a cell that interacts with another cell to cause a specific biologic change or activity. Hormones are major effectors of homeostasis, and the effect of abnormalities in their balance can be widespread. Many hormones have direct effects on the skin, and disruptions in a hormonal axis can alter normal skin physiology in various ways. For instance, a disruption may not affect mature skin in the same way it affects developing skin, either in the fetus or prior to puberty. The effect may also be appropriate in one sex and undesired in the other. Hormonal axis disruption may cause distant effects that secondarily affect the skin, as is the case with hyperthyroid-induced hyperhidrosis or flushing related to vasodilatory effects of thyroid hormone. Cutaneous effects may also occur as a byproduct of immunologically related endocrine disease, an example being pretibial myxedema in Graves' disease. It must be emphasized that the skin not only is a target for hormone activity but also is a synthesizer and secretor of hormones (for example, the peripheral conversion of testosterone to dihydroxytestosterone). [1]

Hormones are regulated by feedback mechanisms specific to each hormonal axis. Their effect on the skin is contingent upon their binding to a specific receptor expressed by the target cell. The number of these receptors is the determinant of the magnitude of the response. There are two principal types of hormone receptors: cytosolic-nuclear receptors that bind steroid and steroid-like molecules, and plasma membrane-associated receptors that bind peptide hormones and other ligands. [2]

Steroids (glucocorticoids, mineralocorticoids, androgens, estrogens, and progestins) and thyroid hormone share a “steroid” mechanism of action. In general, these hormones promote keratinocyte growth and differentiation, glycosaminoglycan synthesis, and growth factor production and secretion. Steroid and steroid-like hormones penetrate the cell membrane by either passive diffusion or carrier protein-enhanced transport. Inside the cell, they bind to a hormone-binding protein that is maintained in an inactive multiprotein-bound complex of multiple heat shock proteins (hsps). Once the hormone is bound, the heat shock proteins are released and the hormone-protein complex enters the nucleus and attaches to a chromatin acceptor site. The sequence of protein production occurs with initiation of mRNA transcription with protein translation. Peptide hormones (growth hormone, thyroid-stimulating hormone, and parathyroid hormone) are bound onto cell surface receptors. This attachment initiates a conformational change in the cell membrane or hormone receptor and/or internalization of the hormone-receptor complex. To facilitate a biologic response, the receptor is coupled to an enzyme or an intermediate acceptor protein (G protein) juxtaposed between the hormone complex and the enzyme. The G protein is then coupled to adenylate cyclase or phospholipase C, which, upon binding of the hormone, become activated to initiate the intracellular response. [2]

THYROID HORMONE

Physiology of Thyroid Hormone and the Skin

Thyroid homeostasis and the regulation of appropriate concentrations of thyroid hormone are regulated by the hypothalamic-pituitary-thyroid axis. Neural stimulation by the hypothalamus produces thyrotropin-releasing hormone (TRH), which traverses the hypophyseal-hypothalamic portal system to the anterior pituitary where thyrotropin (TSH) and prolactin synthesis and secretion are initiated. TSH is released from the anterior pituitary in a circadian rhythm, with the highest levels occurring at night. After TSH binds to the thyroid follicular cells in the thyroid gland, a cyclic adenosine monophosphate second messenger system is activated, leading to the production of thyroid hormone. Approximately 90 percent of the thyroid secretion is thyroxine [3,5,3',5'-tetraiodothyronine (T4)] and 10 percent is triiodothyronine

[3,5,3'-triiodothyronine (T3)]. T4 is more prevalent, but T3 is four times as potent. [3] Most T4 is eventually converted to T3 by deiodination in peripheral tissues, primarily the liver and kidneys, although cutaneous fibroblasts and keratinocytes both harbor the conversion enzyme. [4] Both T4 and T3 are highly bound to serum proteins, including thyroxine-binding globulin (TBG), thyroxine-binding prealbumin, and albumin. [3] Negative feedback of thyroid hormone synthesis appears to be through T4 and T3 downregulation of TRH mRNA expression (and TRH secretion), direct inhibition of TSH synthesis and release, and downregulation in the thyroid follicular cell of the TRH receptor gene. [4]

The skin is a target for thyroid hormone, in particular skin fibroblasts and keratinocytes, although the mechanism of action on cutaneous receptors is unknown. Thyroid hormone stimulates proteoglycan synthesis by skin fibroblasts, regulates epidermal differentiation, and appears to be essential for hair formation and sebum production. [3] It has been suggested that T3 induces expression of epidermal turnover genes and promotes keratinocyte differentiation by activating the plasminogen activator gene. [2] Epidermal maturation is also linked to thyroid hormone by its effects on epidermal growth factor (EGF). Thyroid hormones elevate the levels of EGF in the skin and affect the binding of EGF to skin receptors to promote maturation. [2] Skin perfusion depends, in part, on the regulation of the cardiovascular system by thyroid hormones. In hyperthyroid states, there is increased cardiac output, decreased peripheral resistance, and increased venous constriction, which increases cutaneous circulation. In hypothyroid states, the converse is true, leading to pale, cool skin. [5] In almost all tissues, thyroid hormone accelerates oxygen consumption and increases the metabolic rate either through direct action or by sensitizing tissues to catecholamine stimulation. [3]

Cutaneous Manifestations of Hyperthyroidism

Hyperthyroidism may occur secondary to a stimulatory disruption in any part of the hypothalamic-pituitary-thyroid-target cell axis. A patient may have a TSH-secreting pituitary adenoma, a single toxic nodule of the thyroid gland, a toxic multinodular goiter, Graves' disease, early non-Graves' thyroiditis, excessive thyroxine intake, or, less commonly, a molar pregnancy, struma ovarii, or metastatic follicular carcinoma. The skin is warm, moist, and smooth, resembling infantile skin. The increased cutaneous circulation leads to facial flushing and palmar erythema. Generalized hyperhidrosis may occur, often more pronounced on the palms and soles. The epidermis may be thin but is not atrophic. The scalp hair may be fine, soft, or friable, and diffuse nonscarring alopecia may be present. Approximately 5 percent of patients exhibit nail changes consisting of soft, rapidly growing nails and/or Plummer's nails with concave contours and distal onycholysis. [3] Approximately 2 percent of patients have hyperpigmentation, which may resemble addisonian hyperpigmentation (palmar creases, soles, gingivae, and buccal mucosa) or may occur diffusely with a prominence on the shins and feet while sparing the mucous membranes, nipples, and genital skin (in contrast to addisonian hyperpigmentation). [6] Pruritus may occur in both hyper- and hypothyroidism, and urticaria and angioedema have been described as uncommon manifestations of hyperthyroidism. [7]

GRAVES' DISEASE Graves' disease is an autoimmune infiltration of the thyroid gland by specific T cells that stimulate B cells to produce antibodies. The antibodies stimulate TSH receptors to initiate thyroid hormone production and hyperthyroidism. [4] Classic clinical findings include those of hyperthyroidism as well as pretibial myxedema (dermopathy), ophthalmopathy, and acropachy (Fig. 169-1).

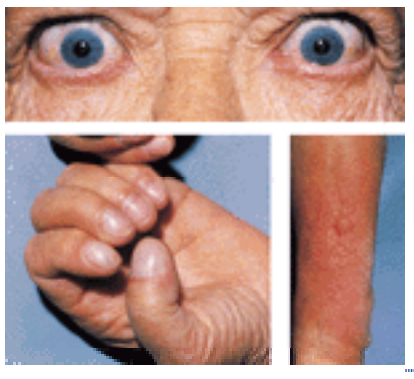

FIGURE 169-1 Graves' disease. This composite illustrates the proptosis, acropachy, and pink or skin-colored papules, plaques, and nodules of pretibial myxedema.

Pretibial myxedema is a misnomer because lesions may appear on the arms, shoulders, head, neck, or at sites of trauma or scars. It may present in 0.4 percent to 4 percent of patients with Graves' disease in the setting of a hyperthyroid, hypothyroid, or euthyroid state. It has also been reported in patients with Hashimoto's thyroiditis. The usual presentation is that of bilateral, asymmetric, raised, firm plaques or nodules of a pink to purple-brown hue (Fig. 169-2). The depth and degree of cutaneous glycosaminoglycan infiltration result in appearances ranging from a “peau d'orange” over the shins and feet to elephantiasis nostras verrucosa. Hyperhidrosis and hypertrichosis may overlie the affected areas in rare cases. Ophthalmopathy usually accompanies cutaneous findings, but even the most extreme forms of dermopathy (elephantiasic) have been reported to occur in the absence of periocular findings. [8]

FIGURE 169-2 Hyperthyroidism with pretibial myxedema. Note infiltrated plaques that also extend to the calf and are partially hyperkeratotic. There is also an isolated nodule on the dorsum of the right foot.

Thyroid acropachy is a triad consisting of digital clubbing, soft tissue swelling of the hands and feet, and periosteal new bone formation. It is the least frequent manifestation of hyperthyroidism, and fewer than 100 cases have been reported, with 95 percent of those affected developing the condition after the diagnosis and treatment of thyrotoxicosis. It can also occur in the setting of Hashimoto's thyroiditis and H¨rthle cell adenocarcinoma. Graves' disease is associated with other autoimmune disorders, including bullous diseases (pemphigus vulgaris, pemphigus foliaceus, bullous pemphigoid, and herpes gestationis), Sweet's syndrome, and vitiligo. Chronic urticaria and angioedema are linked to thyroid autoimmunity. [7] The pathogenesis of myxedematous dermopathy is unclear. Histologically, dermopathy presents as an accumulation of hyaluronic acid in the dermis and sometimes the subcutis. Marked hyperkeratosis may be present in verrucous lesions. It is postulated that a target cell in the skin, most likely the fibroblast, is stimulated to produce abnormally high amounts of glycosaminoglycans by autoantibodies directed against thyroid antigen(s). Another possibility is that T cells that react with the TSH receptor are targeted to the skin and, in the presence of antigen, secrete cytokines to stimulate production of hyaluronic acid. [9] A third theory is that Graves' dermopathy and ophthalmopathy are the product of local factors such as edema and trauma in the setting of a connective tissue inflammation, leading to a decrease in the return of lymphatic fluid and a prolonged half-life of fibroblast-stimulating cytokines, which, in turn, cause an increased deposition of glycosaminoglycans in affected tissues. [10] However, fibroblasts have not been confirmed to be the source of deposited glycosaminoglycans; other possible sources are adipocytes, keratinocytes, and endothelial cells. [3] The management of dermopathy remains problematic, as lesions do not resolve with resolution of the thyroid hormone abnormality. Surgery should be avoided. Topical and intralesional glucocorticoids have demonstrated value, and case reports exist of improvement after intravenous glucocorticoids followed by oral glucocorticoids. Newer therapies include the use of octreotide, a somatostatin analogue that appears to work by suppressing insulin-like growth factor-I activity. Intravenous immunoglobulin (IVIG) has also been used effectively and is believed to function either as an immunomodulatory agent that decreases autoantibody production or by stabilizing immune complexes. Pentoxifylline decreases production of glycosaminoglycans by fibroblasts in vitro. Adjunctive compression therapy is often valuable.

Cutaneous Manifestations of Hypothyroidism

Hypothyroidism is the result of inadequate circulating thyroid hormone, or, rarely, of peripheral resistance to hormone stimulation. Primary hypothyroidism is the most common form of hypothyroidism; it is caused by glandular failure that results from autoimmune destruction, previous therapy with ^{131}I, thyroid surgery, administration of antithyroid drugs, or infiltrative disease. Secondary hypothyroidism and tertiary hypothyroidism are caused by pituitary and hypothalamic dysfunction, respectively. Secondary hypothyroidism results from a defect in TSH release due to tumor, infarction, trauma, radiation, or surgical treatment of the pituitary gland. Secondary hypothyroidism is usually accompanied by other endocrinopathies. Tertiary hypothyroidism is caused by similar etiologies; however, primary idiopathic hypothalamic hypothyroidism has been reported and is presumably secondary to a TRH deficiency, with pituitary function being normal.

The skin is cold, dry, and pale, particularly over extensor surfaces. Hypothermia and a reduced core body temperature result from a hypometabolic state and reflex cutaneous vasoconstriction. Pallor of the skin is a result of both peripheral vasoconstriction and increased amounts of water and mucopolysaccharides in the dermis, which alter the refraction of incident light. Despite pallor elsewhere, a malar flush may occur in up to 50 percent of patients. [11] Xerosis may be the result of a multitude of factors, including diminished epidermal sterol biosynthesis, diminished sebaceous gland secretion, and hypohidrosis secondary to eccrine apparatus changes. The dryness can become so severe that it resembles an acquired ichthyosis. The palms and soles can present as an acquired keratoderma. A yellowish hue, predominantly on the palms, soles, and nasolabial folds, may be present and is due to carotenemia because of a reduced capacity of the liver to synthesize vitamin A. Hair of the scalp and body is classically dry, coarse, and brittle, and tends to fall out, resulting in a diffuse or partial alopecia. Loss of the lateral third of the eyebrows is a characteristic finding. The rate of hair and nail growth is slowed, and nails tend to be thick and brittle with longitudinal and transverse striations.

The most classic cutaneous manifestation of hypothyroidism is generalized myxedema. In contrast to the dermopathy associated with Graves' disease, myxedema of hypothyroidism will disappear in time with correction of the level of thyroid hormone. The skin typically appears doughy, swollen, dry, pale, and waxy to the touch; however, despite the edematous appearance, it is nonpitting. The face manifests a characteristic appearance with a broad nose, swollen lips, macroglossia, puffy eyelids, and a flat affect (Fig. 169-3). The eyelids may droop as the result of decreased sympathetic stimulation of the superior palpebral muscle. Wound healing is impaired, and purpura may be a consequence of diminished clotting factors and/or the loss of vascular support secondary to the dermal mucin. [3]

FIGURE 169-3 Hypothyroidism. This patient has many of the typical features of hypothyroidism: a cold, dry, pale skin; absence of hair in the lateral third of the eyebrow; and a puffiness of the face and lips due to the accumulation of water and mucopolysaccharides in the dermis. The hair is dry, coarse, and brittle. The nose is broadened; the tongue is large, smooth, red, and clumsy; and there is drooping of the eyelids. The face lacks expression and is the most pathognomonic of any of the features.

The pathogenesis of myxedema may be explained by the deposition of dermal acid mucopolysaccharides, especially hyaluronic acid and chondroitin sulfate, which are hygroscopic and accumulate water. This is presumably secondary to increased production by skin fibroblasts that in vitro accumulate hyaluronate in the absence of T3. [12] Extravascular accumulation of albumin and inadequate lymphatic drainage may also contribute to the edematous state.

There are several associations of other disorders with autoimmune-related hypothyroid states. Alopecia areata, pernicious anemia, dermatomyositis, polymyositis, myasthenia gravis, pemphigoid, dermatitis herpetiformis, and Norwegian scabies are all associated with Hashimoto's thyroiditis. There has also been reported a relationship between primary hypothyroidism and chronic mucocutaneous candidosis, which appears to be manifest as an autosomal dominant syndrome with no identifiable autoantibodies. [13]

PARATHYROID HORMONE

Physiology of Parathyroid Hormone and the Skin

Parathyroid hormone (PTH) maintains homeostasis of calcium levels in the body through various mechanisms, including the stimulation of vitamin D production, which, in turn, promotes gastrointestinal absorption of calcium, increases renal reabsorption of calcium, decreases renal reabsorption of phosphate, and mobilizes calcium from bone. The release of PTH is regulated by circulating levels of ionized calcium. Cutaneous manifestations of PTH abnormalities are primarily the result of the dysregulation of calcium.

The effects of PTH on the skin have not been fully elucidated. PTH-like protein is present in keratinocytes and is implicated in keratinocyte growth and dermal fibroblast function. PTH-like protein has also been linked to skin wound healing, squamous neoplasms, and control of the hair growth cycle. [14], [15]

Cutaneous Manifestations of Hyperparathyroidism

Skin manifestations in hyperparathyroidism are uncommon. When associated with a calcium phosphate product (serum calcium × serum phosphate) of greater than 65 to 70 mg/dL, subcutaneous calcifications can be seen, usually overlying large joints as linearly arranged firm white papules, or as infiltrating plaques. Histologically, large subcutaneous deposits of von Kossa–positive material, with a foreign-body reaction consisting of histiocytes, giant cells, and fibrosis, appear. Lesions do not contain true cutaneous ossification in contrast to the lesions of pseudohypoparathyroidism and Albright's syndrome, in which cutaneous osteocytes, true bony spicules, and haversian canals can be seen. Subcutaneous calcification can be associated with severe pruritus that improves with normalization of mineral levels or ultraviolet light. [1] Chronic urticaria has been reported with primary hyperparathyroidism, with resolution of symptoms after parathyroidectomy. [16]

An important association is that of hyperparathyroidism and potentially life-threatening calciphylaxis. Although calciphylaxis is more commonly reported in chronic renal failure with secondary hyperparathyroidism, there have been reports of occurrence with primary hyperparathyroidism in the absence of renal abnormalities. Calciphylaxis typically presents as violaceous, mottled to reticulated patches and plaques with occasional bullae. Lesions evolve into painful necrotic, indurated plaques, nodules, and ulcers with a thick, dark eschar. They are most common on the lower extremities but can also appear on the trunk. Acral gangrene that necessitates amputation may occur. Histologically, calcium deposits are present in the walls of small- to medium-sized vessels in the dermis and subcutaneous fat. Fibroblast proliferation and giant cell formation may lead to fibrosis, intimal hyperplasia, and, occasionally, thrombosis of the vessel, which, in turn, result in ischemia and necrosis of the skin. [17] The cause of calciphylaxis is not clear, although hypercoagulable states and microorganisms capable of inducing calcium salt deposition have been implicated in the pathogenesis. The prognosis is poor, with the mortality rate as high as 80 percent; death usually ensues secondary to overwhelming infection. Total or subtotal parathyroidectomy is the treatment most frequently reported to have the best results. [17]

Hyperparathyroidism in the setting of multiple endocrine neoplasia type 1 (MEN1) is associated with multiple angiofibromas (particularly on the face), collagenomas, and lipomas, which are presumably related to allelic deletion of

the *MEN1* gene. [18]

Cutaneous Manifestations of Hypoparathyroidism

Hypoparathyroidism results from a disruption in the parathyroid hormonal axis. There may be a PTH deficiency secondary to a congenital absence of the parathyroid gland (as in DiGeorge's syndrome), destruction of the parathyroid gland as a result of thyroid surgery (the most common cause), infiltration (hemochromatosis) and invasion (metastatic cancer), or resistance of target cells to normal or elevated levels of PTH. Idiopathic hypoparathyroidism also exists, often related to a multiple endocrine deficiency syndrome.

Hypoparathyroidism presents with scaly, hyperkeratotic, and puffy skin. Hair may demonstrate patchy alopecia or generalized thinning with coarse texture. Nails can become opaque and brittle with transverse ridges. [1] Impetigo herpetiformis, eczematous dermatitis, and psoriatic flares have also been reported in association with hypoparathyroidism. Normalization of the calcium level is usually accompanied by resolution of the skin abnormalities, and thus calcium is implicated in the pathogenesis of skin changes, as opposed to a deficiency of PTH directly.

Idiopathic hypoparathyroidism may present with prominent ectodermal malformations including skin abnormalities, dental changes, and chronic mucocutaneous candidiasis. Ectodermal defects, which occur in 50 percent of patients with idiopathic hypoparathyroidism, manifest as dry, scaly skin, dental abnormalities (anodontia, hypoplasia, alveolar bone changes, abnormally spaced dentition, stumpy roots, and a thickened lamina dura), and nail changes. Nails tend to be thin and brittle, may split or crumble at the free edge, and have characteristic transverse grooves. Chronic mucocutaneous candidiasis occurs in 15 percent of patients with idiopathic hypoparathyroidism and can present with nail, paronychial, vaginal, oral, and rarely laryngeal and pulmonary involvement. It can precede the diagnosis of hypoparathyroidism by years. The pathogenesis of chronic mucocutaneous candidiasis is unclear, although a deficiency in cell-mediated immunity has been implicated. Treatment of the underlying hypoparathyroidism with calcium and vitamin D does not lessen the susceptibility to chronic candidal infections. [19]

GLUCOCORTICOIDS

Physiology of Glucocorticoids and the Skin

Glucocorticoids are regulated by the hypothalamic-pituitary-adrenal axis. Corticotropin-releasing hormone (CRH), the most potent regulator of corticotropin secretion, is released from the hypothalamus, traverses the hypophyseal portal system to the pituitary, and stimulates secretion of adrenocorticotropic hormone (ACTH). ACTH is derived from a precursor molecule, pro-opiomelanocortin, which gives rise to other molecules besides ACTH, including ß-lipoprotein, ß-endorphin, and alpha-melanocyte–stimulating hormone (a-MSH). ACTH enters the systemic circulation to stimulate the adrenal cortex to secrete cortisol, which exerts negative feedback on pituitary ACTH secretion.

Glucocorticoids regulate tissue metabolism through binding to cytosolic receptors and traversing nuclear membranes to interact with DNA in the cell nucleus. In the skin, glucocorticoids cause profound effects through regulation of cell cytokine production and the inflammatory response, collagen synthesis, keratinocyte growth and differentiation, wound healing, glycosaminoglycan synthesis, and hair growth.

Glucocorticoids inhibit the inflammatory reaction in the epidermis through a variety of mechanisms. Glucocorticoids regulate cytokines involved in the inflammatory process such as interleukin (IL)-1, IL-1a, tumor necrosis factor-a (TNF-a), interferon-?, IL-2, and migration inhibitory factor. [20] The numbers of resident Langerhans cells in the epidermis are decreased with the use of topical glucocorticoids. [20] The mechanisms of these cutaneous actions remain unknown.

Glucocorticoids affect keratinocyte growth, differentiation, and wound healing. Histologic examination of skin exposed to cortisol demonstrates a noncornified epidermis, flattening of the epidermal granular layer, and a reduced size and number of keratohyalin granules. [2] It has been proposed that one reason for these changes is a glucocorticoid effect on keratinocyte growth factor (KGF). Glucocorticoids inhibit KGF mRNA production in dermal fibroblasts by reducing the rate of KGF gene transcription and by causing destabilization of KGF mRNA. [21] Glucocorticoids may also have a deleterious effect on wound healing through inhibition of the production of collagen VII, an important component of anchoring fibrils in the basement membrane zone, which is expressed in both epidermal keratinocytes and dermal fibroblasts. [22]

Glucocorticoids induce significant skin atrophy, possibly by affecting glycosaminoglycan regulation. Glucocorticoids reduce the tissue content of glycosaminoglycan, particularly hyaluronic acid, through inhibition of hyaluronan synthase in dermal fibroblasts. [23] Additionally, glucocorticoids dramatically reduce the synthesis of collagen types I and III, which constitute 70 to 80 percent and 15 percent of the total skin collagen, respectively. [24]

Glucocorticoids inhibit hair formation by blocking expression of hair-forming genes at the point of anagen initiation. [25] Despite this finding, hirsutism is a common complaint in syndromes of hypercortisolism, most commonly manifested by vellus hypertrichosis of the forehead or upper cheeks. Signs of virilization, with terminal hair growth on the face and body in women, and development of pattern thinning of scalp hair, is usually secondary to associated adrenal-derived androgen excess.

Glucocorticoids do not directly affect skin pigmentation; however, regulatory elements of the hypothalamus-pituitary-adrenal axis (ACTH, a-MSH, and beta-lipoprotein) do induce pigmentary changes. Both ACTH and a-MSH stimulate melanogenesis in the skin.

Cushing's Syndrome

Cushing's syndrome of chronic glucocorticoid excess may be induced by ACTH-dependent and independent mechanisms. In 60 to 80 percent of cases, hypercortisolism is caused by Cushing's disease, which is defined as pituitary-dependent Cushing's syndrome, and is most commonly caused by ACTH overproduction from a pituitary microadenoma. [26] Other causes include iatrogenic Cushing's syndrome (secondary to glucocorticoid therapy), ectopic ACTH production (secondary to small cell lung cancer and other malignancies), ectopic CRH, adrenal adenoma, adrenal carcinoma, and adrenal hyperplasia.

Cutaneous manifestations of Cushing's syndrome mirror the previously described biologic effect of excess glucocorticoids. The skin is atrophic, smooth, and transparent, often described as paper-thin, with decreased collagen, elastic fibers, ground substance, and epidermal thinning. Mild trauma may cause tearing, ulceration, purpura, and ecchymoses, and wound healing is poor. Underlying vasculature may be more easily visualized and may be accompanied by broad purple striae, particularly on the abdomen, arms, and thighs. [27] The striae have significant depth, breadth, and intensity of color, which differentiate them from striae common in pregnancy, obesity, and adolescence. Striae continue to be present even after the hypercortisolism is corrected. Petechiae and a purplish mottling (cutis marmorata) are common on the lower extremities, secondary to decreased vascular tone. The face may have a plethoric appearance with telangiectasias related to vascular proliferation, polycythemia, and erythrocytosis.

Glucocorticoids cause a profound redistribution of subcutaneous fat, resulting in moon facies (full, round facies); a buffalo hump; increased fat in the supraclavicular fossae, over the dorsal cervical vertebrae, and around the pelvic girdle; and a relative lack of fat deposition over the extremities (Fig. 169-4). [27] Compression fractures of the spine may result in pronounced kyphosis and decreased height. Suppression of growth hormone in children may lead to compromised adult height. [28]

FIGURE 169-4 Cushing's syndrome. Plethoric moon facies.

Suppression of immune function is evidenced by a variety of infections. Patients are particularly susceptible to cutaneous fungal infections by *Malassezia furfur* and *Trichophyton rubrum,* resulting in tinea versicolor and chronic nail, toe web, inguinal, trunk, and buttock infections. These infections may resolve with treatment of the underlying excess glucocorticoid state.

Steroid acne may occur, and is composed of monomorphic, small pustules and erythematous papules in the absence of open comedones, with a predilection for the trunk, shoulders, and arms, with the face less often affected. Acne vulgaris may become aggravated in the setting of concomitant androgen excess.

When the etiology of Cushing's syndrome is Cushing's disease or ectopic ACTH production, generalized hyperpigmentation, identical to that seen in Addison's disease, may also be present. Sex hormone disruption may also occur in Cushing's syndrome when the adrenal glands are involved in the pathogenesis. This may manifest as hirsutism, and/or male pattern baldness in females and prepubertal children, feminization in males, or acanthosis nigricans. [27]

Addison's Disease

Addison's disease is defined as primary adrenocortical insufficiency, which leads to inadequate amounts of both glucocorticoids and mineralocorticoids. In 60 to 70 percent of cases, the cause is autoimmune adrenalitis in which complement-fixing adrenocortical autoantibodies destroy adrenocortical tissue. The steroid-producing enzyme 21-hydroxylase is a target antigen. Other possible etiologies for adrenal destruction include infectious causes (tuberculosis and systemic fungal infections, including coccidioidomycosis, histoplasmosis, and cryptococcus), infiltrative causes (metastatic cancer, sarcoidosis, or amyloidosis), adrenoleukodystrophy, hemorrhage, and Waterhouse-Friderichsen syndrome. [29] Primary adrenal insufficiency may also occur as congenital adrenal hypoplasia.

The most classic clinical manifestation of Addison's disease is hyperpigmentation. Sun-exposed areas may be affected (face, neck, and arms) leading patients to attribute the appearance to a persisting suntan. Hyperpigmentation commonly occurs in flexural areas, or sites of frequent pressure, such as intertriginous folds, axillae, perineum, nipples, knuckles, knees, and elbows. Scars and preexisting nevi may be accentuated, and new nevi may appear. In patients with lighter skin types, hyperpigmentation of the palmar creases is highly indicative of Addison's disease (although it may also be seen in pernicious anemia), whereas in darker skin types, it is a normal variant (Fig. 169-5). Mucous membranes are frequently affected, and hyperpigmentation may be seen in the mouth (buccal mucosa, gums, and tongue), vagina, and

anus. Although this appearance may also exist as a normal variant in darker skin types, when it is present in multiple sites, or extensive in nature, it suggests the diagnosis of Addison's disease. The nails may be affected and manifest longitudinal pigmented bands. [27] Generalized xerosis is common and is thought to arise from excess salt on the stratum corneum and/or disrupted keratinocyte differentiation. [27] Congenital adrenal atrophy or hypoplasia occurs in 1 of 12,500 births and may manifest with hyperpigmentation ranging from generalized coal-black at birth (rarely) to gradually increasing pigmentation over the first months to years of life. [30]

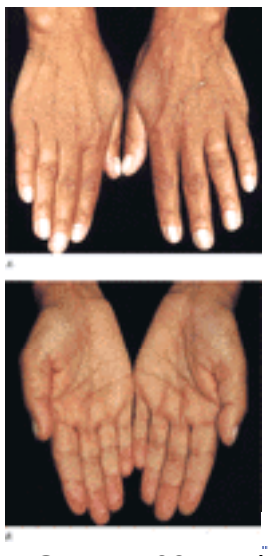

FIGURE 169-5 Addison's disease. Hyperpigmentation of the hands: (*A*) dorsa; (*B*) palmar creases.

Symptoms of adrenocortical insufficiency may not appear until 90 percent of the adrenocortical tissue is lost. In addition to hyperpigmentation, patients may present with weakness, fatigue, depression, salt craving, diarrhea, weight loss, anorexia, nausea, vomiting, hypotension, syncope, and addisonian crisis. The latter is a rapidly deteriorating clinical setting of hypotension, shock, hypoglycemia, and hyperkalemia. [29]

Hyperpigmentation in primary adrenal insufficiency results from a disruption in the negative feedback pathway of glucocorticoids and ACTH. As previously detailed, glucocorticoids suppress ACTH production in the pituitary gland. In the absence of glucocorticoids, excess proopiomelanocortin is produced, leading to increased levels of ACTH and MSH peptides. ACTH and a-MSH then stimulate melanogenesis to cause hyperpigmentation. Correction of glucocorticoid levels suppresses ACTH and MSH levels and results in a gradual disappearance of increased pigment.

In addition to loss of glucocorticoids, androgen production by the adrenal glands is disrupted in primary adrenal insufficiency. Ambisexual hair (axillary and lower pubic triangle) is lost in postpubertal females and fails to grow in prepubertal females. Glucocorticoid replacement can partially reverse this occurrence. Postpubertal males do not manifest similar findings because production of testosterone by the testes overshadows the loss of adrenally derived androgens.

Other cutaneous findings in Addison's disease include fibrosis and calcification of ear cartilage with long-standing adrenal insufficiency, vitiligo, and mucocutaneous candidiasis in association with polyendocrine autoimmune failure syndrome type I. [27] Other autoimmune disorders may occur in conjunction with Addison's disease. When present with autoimmune thyroid disease (Graves' disease for example) and/or insulin-dependent diabetes mellitus, the association is referred to as polyglandular autoimmune syndrome type II.

GONADAL HORMONES

Physiology of Sex Hormones and the Skin

Gonadal hormones in general exert a trophic effect on cutaneous cells with a predilection for hair follicles, sebaceous glands, and sexual zones. The response of gonadal hormones is regulated by cutaneous receptors, which have varying density and expression levels depending on anatomic site and gender. Gonadal hormones exert their effect similarly to glucocorticoids in that they bind to cytosolic receptors, traverse nuclear membranes, and act directly to stimulate mRNA transcription. [31] Gonadal hormone receptors are not entirely specific, and cross-reactivity may occur. For example, progesterone is able to bind to androgen receptors and exert either androgenic or antiandrogenic effects, depending on the site of action, and may downregulate estrogen receptor expression at other receptor sites. [2] Both androgens and estrogens are implicated in the regulation of hair growth, sebaceous gland function, proliferation and differentiation of epithelial cells of the epidermis and adnexa, functional activity of dermal fibroblasts and fibrocytes, wound healing, and skin immune cell activity. [31] Androgens and estrogens stimulate collagen synthesis, maturation, and turnover in the dermis; however, their effect on dermal ground substance may differ. [2] Melanocytic proliferation and melanogenesis are regulated by both androgens and estrogens, but the mechanism is unclear.

Androgens promote hair growth in the beard, axillary, and pubic regions while playing a primary role in the development of androgenetic alopecia in susceptible individuals. Androgens also promote sebaceous gland function (with increased sebum production and secretion), epithelial cell differentiation via androgen receptors in epithelial cells of hair follicle and sebaceous gland structures, and in specialized dermal papilla fibroblasts that regulate hair morphogenesis. Androgen receptors have been found in epidermal keratinocytes, melanocytes, dermal fibroblasts, and resident and circulating immune-related cells. [31] Both keratinocytes and hair follicle cells harbor 5a-reductase, the enzyme that converts circulating testosterone to the potent androgen dihydrotestosterone (DHT). DHT is primarily responsible for end-organ

effects of androgen receptor binding, including androgenetic alopecia, hirsutism, and acne. It is necessary for development of male beard growth, whereas testosterone alone may stimulate axillary and pubic hair growth. [32]

Estrogen receptors are expressed in epithelial cells of the epidermis, hair follicle, sebaceous glands, eccrine, and apocrine glands; in melanocytes; and in dermal fibroblasts. [31] Estrogens tend to inhibit hair growth and decrease sebaceous gland function. Cutaneous estrogen receptors have been found in greater number in women than in men, especially in the face and lower extremities. Estrogens may have a role in cutaneous vascularization, prevention of epidermal atrophy, dermal ground substance and collagen composition, and stratum corneum barrier function. [33]

Cutaneous Manifestations of Androgen Excess

Androgen excess may occur in various settings. Adrenal and ovarian tumors may produce androgens or androgen precursors; and congenital adrenal hyperplasia due to a deficiency in 11-hydroxylase, 21-hydroxylase, or 3ß-hydroxylase steroid dehydrogenase can result in increased androgen precursors. Polycystic ovarian syndrome in women is a major cause of virilization with increased plasma androgen levels as well as increased levels of luteinizing hormone. Exogenous glucocorticoid, testosterone, and oral contraceptives may all act at androgen receptors to provoke hirsutism or virilization. Relative androgen excess may result from altered cutaneous metabolism of circulating hormones. For example, the enzyme 5a-reductase is increased in pubic and labial skin of hirsute women, and urinary concentrations of DHT metabolites have been found in hirsute women, raising the possibility that cutaneous metabolism of androgens may be an independent risk factor in the development of virilization and hirsutism in women. [27]

The primary clinical manifestations of androgen excess are acne, hirsutism, and virilization in women, and precocious puberty in prepubertal children. Body hair growth is accelerated with coarse, heavy, thick, pigmented hair on the chest, abdomen, extremities, and bearded areas. Women may develop menstrual irregularities, clitoromegaly, increased muscle mass and loss of typical female-distributed fat over the thighs and shoulders, and androgenetic alopecia (vertex thinning with temporal hair recession). Men may manifest increased muscle mass as well as hypertrophy of the penis, with accentuation of scrotal folds. Sebaceous glands are stimulated, resulting in enlargement of facial pores, oily residue, and exacerbation or production of acne vulgaris. Hyperpigmentation may occur both in erogenous skin (genitalia, areolae, and nipples) and elsewhere. Children may develop pubic and axillary hair prematurely. Accelerated bone growth and premature epiphyseal closure with resultant relatively short stature may occur. [27]

Cutaneous Manifestations of Androgen Deficiency

Androgen deficiency may result from either inadequate production (gonadal failure, destruction, or lack of stimulation) or end-organ unresponsiveness. In the setting of inadequate testosterone production by the testes in males, with retained adrenal androgen production, ambisexual hair in the pubic region and axillae develops, but remains sparse.

In prepubertal males, a eunuchoid appearance occurs with maintenance of childhood-like fine, thin skin with small pores, the absence of sebaceous and apocrine maturation, and lack of acne vulgaris. Secondary sexual characteristics of facial, chest, and abdominal hair do not develop. The penis remains small, and the scrotum is smooth. Body habitus remains child-like, with poor muscular development and delayed closure of the epiphyses, resulting in disproportionate increased height because of the length of extremities.

Males in the postpubertal stage are less dependent on large amounts of androgens to maintain secondary sexual characteristics and, depending on the etiology and degree of androgen loss, may show little change. Although coarse hair is present on the extremities, trunk, and face, growth may be noticeably slowed. Sebaceous glands, requiring constant androgen stimulation, cease to be active, leading to decreased sebum deposition and resolution of acne vulgaris. Pallor of both genital and nongenital skin is due to both decreased pigment and reduced cutaneous blood flow. Flushing may occur in the setting of acute testicular failure and may manifest as sweating and flush of the face and neck. The administration of exogenous androgens reverses all skin changes associated with deficiency. [27]

Cutaneous Manifestations of Estrogen Excess

Estrogen excess can result from excess secretion by ovarian, testicular, or hypothalamic tumors, or more commonly, from oral contraceptive and hormonal replacement therapy in women, and pregnancy. In men, estrogen excess is manifest as gynecomastia, which may exist alone or in combination with testicular atrophy and manifestations of androgen deficiency. In prepubertal females, precocious puberty may occur with development of secondary sexual characteristics. Genitalia display maturation of the vaginal epithelium, breasts develop, axillary and pubic hair arise, and there is premature epiphyseal closure with resultant relative shortening in height. The menstrual cycle may also begin. In cases of adrenal or ovarian pathology, excess secretion of androgens may occur simultaneously, with concomitant manifestations of androgen excess (acne, hirsutism, and clitoromegaly). [27]

Exogenous estrogens from oral contraceptives or hormonal replacement can have both beneficial and undesired effects. In postmenopausal women, estrogen therapy appears to reverse epidermal atrophy and to prevent or restore cutaneous collagen with a beneficial effect on cutaneous extensibility. Estrogen therapy also increases the water-holding capacity of the stratum corneum with potential improvement in the epidermal barrier. [33] Estrogen therapy inhibits sebum production, and acne may improve with the use of estrogen dominant oral contraceptives. In pregnancy, however, acne may become exacerbated due to relative androgen excess with elevated progesterones. [27]

Undesired effects of estrogens include telangiectasias, palmar erythema, and spider angiomas, which appear with increased frequency in pregnant women and those taking synthetic estrogens. Pigmentary changes are frequent. For example, melasma may present with mottled or hyperpigmented irregularly shaped macules and patches over the forehead, cheeks, upper lip, nose, chin, and neck. Hyperpigmentation of the nipples, linea nigra, and genitalia may occur, acanthosis nigricans may develop, and preexisting nevi may darken. Because exposure to ultraviolet light may

accentuate the pigmentation, the use of broad-spectrum sunscreen is recommended. Melasma may fade completely with delivery, although it frequently recurs with subsequent pregnancies. Conversely, in patients in whom oral contraceptive use results in melasma, cessation of the drug therapy rarely results in complete disappearance of pigmentary changes. Hirsutism over the face, breasts, and extremities may develop in pregnancy and with oral contraceptive use, secondary to estrogen stimulation of hair growth. Telogen effluvium may develop after delivery or cessation of oral contraceptive medication, with a diffuse loss of scalp and body hair. [27]

Estrogens have been implicated in the enhancement of autoimmune processes. Specifically, hormone replacement therapy has been linked to increased risk of systemic lupus erythematosus, herpes gestationis, and erythema nodosum. Estrogen dermatitis has been described and is marked by cyclic perimenstrual flares with clinical manifestations that include pruritus (either localized or generalized), urticaria, vesicles, papules, and eczematous eruptions. Familial porphyria cutanea tarda (type II) may be induced by estrogen therapy in those patients with the underlying enzymatic deficiency. The mechanism is not well defined. [33]

Cutaneous Manifestations of Estrogen Deficiency

Estrogen deficiency most commonly arises as a component of menopause in women aged 49 to 51 years. Estrogen deficiency may also arise from either pituitary or gonadal failure. Vasomotor instability (hot flashes), atrophy of urogenital epithelium, and decreased breast size are the most common manifestations of estrogen deficiency. [27] Estrogen therapy reverses these changes in most women, although the benefits and risks of hormone replacement therapy must be weighed on an individual basis.

OTHER PITUITARY HORMONES

Physiology of Growth Hormone

Growth hormone (GH) secretion from the adenohypophysis of the pituitary gland is regulated by GH-releasing hormone (GHRH) and somatostatin, which exerts an inhibitory effect on GH secretion. GH is secreted in a pulsatile manner; consequently, single measurements are not reliable diagnostic indicators for abnormalities in GH levels. Once released into the systemic circulation, GH stimulates the synthesis and release of insulin growth factor-1 (IGF-1; somatomedin C) from the liver, as well as other sites.

GH receptors have been detected in human epidermis, hair follicles, eccrine glands, dermal fibroblasts, adipocytes, Schwann cells, and myocytes. [31] This finding suggests a direct effect of GH on the skin; however, IGF-1 is implicated in many of the manifestations of GH dysregulation. Specifically, IGF-1 is implicated in the dermal proliferation in acromegaly manifested by connective tissue proliferation, accumulation of intercellular matrix, and the deposition of hyaluronic acid with subsequent interstitial edema. [1]

Cutaneous Manifestations of Growth Hormone Excess

Acromegaly, the clinical state of GH hypersecretion, is the result of a GH-secreting pituitary adenoma in greater than 98 percent of cases. [34] Acromegaly may also result from disordered hypothalamic function (excess GHRH or deficient somatostatin secretion or action), GH-secreting pituitary carcinoma, ectopic GH secretion (pancreas, adrenal, breast, and ovary), or lymphocytic hypophysitis.

The most striking clinical manifestation of GH excess is coarsening of the facial features because of dermal thickening (Fig. 169-6). This dermal thickening results in accentuation of facial, neck, and scalp creases, leading to deep folds and furrows, and imparting a corrugated appearance to the surface of the scalp and neck (cutis verticis gyrata). [1] Although obvious in retrospect, the changes occur slowly, and only infrequently do patients consult their physician for this condition. [35] The hands and feet may become swollen, doughy, and blunted, with increased ring, glove, and shoe size. Heel pad thickness increases, and measurements with x-ray or ultrasound are used to follow response to therapy. [1] The lips may become large and protruding, the eyelids may thicken, macroglossia may occur, and the nose may widen with a characteristic triangular shape. The nails may thicken; the skin may darken moderately, with acanthosis nigricans being a common presenting feature; and the numbers of small fibromas and fibroepithelial polyps may increase. Patients with increased numbers of fibroepithelial polyps may also have increased numbers of adenomatous polyps of the colon and a potential for increased malignancy of the gastrointestinal tract. [35]

FIGURE 169-6 Acromegaly. Coarse facies with enlargement of the nose, chin, hands, and fingers.

GH affects sebaceous and eccrine structures, resulting in increased size and function of sebaceous glands and sweat glands in acromegaly. This condition may be accompanied by an offensive odor and oily residue in areas of sebaceous secretion with the potential for exacerbation of acne vulgaris. [1] Body hair may be coarse. Other characteristics of

acromegaly include osteoarthritis, headaches, fatigue, visual abnormalities, peripheral neuropathies, and sleep apnea. Associated gonadal hormone disruption may lead to ovulatory dysregulation, amenorrhea, and galactorrhea in women and hypogonadism with decreased libido in men. [34] Diagnosis is difficult because the clinical presentation may be confounded by plurihormonal tumors that secrete both GH and one or more anterior pituitary hormones such as prolactin. With successful treatment of the underlying abnormality and normalization of GH levels, the signs of dermal proliferation can regress within days to weeks.

Cutaneous Manifestations of Growth Hormone Deficiency and Panhypopituitarism

The destruction of the pituitary gland through any means, including postpartum hemorrhage (Sheehan's syndrome), mass effect (pituitary adenoma or craniopharyngioma), infiltration (sarcoidosis, neoplasm), and infection (tuberculosis), may create a deficiency in the hormones that the gland secretes and regulates. The simultaneous loss of multiple hormones may lead to cutaneous effects that differ from those produced by the loss of any single hormone. For instance, hypothyroidism secondary to pituitary failure results in less myxedema than elicited by primary hypothyroidism, as the other hormones required for expression of myxedema are also absent. Moreover, most endocrine glands controlled by the pituitary retain a basal level of hormonal secretion, even after pituitary destruction, resulting in less severe deficiency than that observed in primary end-organ failure. [1]

In solitary GH deficiency, skin thickness and total skin collagen are reduced and sweat secretion rates are lowered, all of which may have implications in the reduced exercise capacity of GH-deficient patients. [36] In panhypopituitarism, the skin is typically xerotic, with fine wrinkling around the eyes and mouth, imparting an aged appearance. The nails may be thin, brittle, slow growing, and opaque. Pallor may be evident as a result of anemia and decreased cutaneous blood flow. Carotenemia may be present. Melanin content is decreased resulting in increased sensitivity to sunlight.
Hypopigmentation may be generalized. Hypotrichosis may present with generalized hair thinning of the scalp, beard, and pubic regions with loss of axillary hair. Eccrine and sebaceous gland secretion may be diminished.

FLUSHING

Flushing is defined as episodes of erythema on the face, ears, and neck, and sometimes the upper chest and epigastric areas. [1] It is caused by a transient increase in cutaneous blood flow. The limited distribution of flushing can be accounted for by both greater capacitance of facial vasculature and greater visibility of blood vessels near the surface with less tissue to obscure them. [2], [3]

The mechanisms of flushing are classified according to the Burnstock-Iwayama model, which emphasizes dual control of vascular smooth muscle by nerves and circulating vasoactive agents. [4] Vasomotor innervation of cutaneous blood vessels consists of both vasodilatory and vasoconstrictor control, although active vasodilation, not release of vasoconstriction, is the mechanism that predominates in the scalp, forehead, cheek, chin, neck, and upper chest. [5] Because autonomic nerves also control eccrine sweat glands, sweating often accompanies flushing caused by autonomic vasodilation. Thus, it has been proposed that perspiration at the time of erythema, or “wet flushing,” can be distinguished from “dry flushing” caused by the direct action of vasoactive agents, in which there is no activation of eccrine sweating. [1]

Repeated episodes of flushing eventually lead to rosacea with fixed erythema, telangiectasias, and inflammatory changes. [6] The term *flushing* is sometimes misused to describe other conditions that can cause a red face, such as photosensitivity reactions, drug eruptions, lupus erythematosus, and seborrheic dermatitis. [2] However, flushing is transient, whereas these other disorders cause long-term reddening of the face. Because the differential diagnosis of flushing is broad (Table 170-1), the clinician must be aware of the possible causes of flushing and know when to investigate for internal disease.

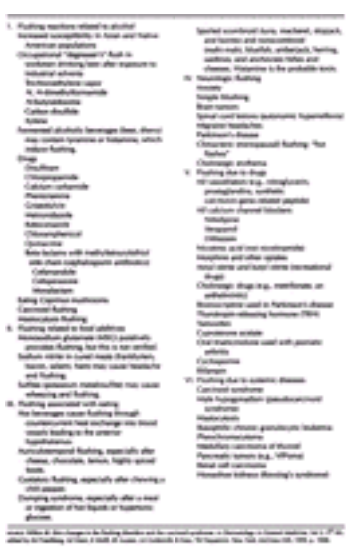

TABLE 170-1 **Differential Diagnosis of Flushing Reactions**

Clinical Evaluation

Evaluation of the patient with flushing begins with a focused medical history that should consist of four key elements: provocative and palliative factors, morphology, associated findings, and temporal characteristics. [1] Key provocative factors to consider are alcohol, foods, drugs, emotional stimuli, and exposures. When flushing is associated with a systemic disease, it is common for a variety of nonspecific agents to trigger flushing, such as exercise, hot foods, and

stress.

Different causes of flushing often result in unique clinical presentations. For example, the presence of perspiration and its temporal relationship to the flush can help determine whether the flush is neurologically based. [1] The color of the flush, which may range from bright pink to cyanotic, is a clue, as is the presence of pallor or cyanosis preceding or following the flush. The physician must ask about the specific location of the flush, whether it is patchy or confluent, and if it occurs in a single phase or in discrete phases and stages.

Associated findings include abdominal cramping, diarrhea, headache, urticaria, pruritus, hypotension, tachycardia, and bronchospasm. Associated urticaria and pruritus should focus consideration on mast cell disorders, whereas cramping, diarrhea, and bronchospasm suggest the carcinoid syndrome. The patient should be questioned about psychologic symptoms such as anxiety, depression, or a vague sense of malaise or lethargy, as psychiatric disorders are occasionally the source of flushing. The age of onset, frequency (both original and current), and temporal patterns (e.g., only on the weekends) can also provide useful information. For example, flushing present since childhood could suggest Rovsing's syndrome; this condition occurs in patients with a horseshoe kidney and is characterized by flushing, abdominal pain, and nausea, which are relieved by an anteflexed posture. [7]

As patients often are not prepared to answer detailed historical questions at the first office visit, a 2-week diary can be helpful. [1] Patients are asked to record detailed qualitative and quantitative aspects of each flushing episode. All possible precipitating agents, including foods, drugs, alcohol, activities, exposures, and emotions, should be recorded. The 2-week diary often reveals the cause(s) of flushing, which can then be appropriately eliminated.

When the 2-week diary is inconclusive, it is advisable to place the patient on a diet that eliminates foods and additives high in histamines (see Table 170-1), alcohol, and hot foods and beverages that are commonly associated with flushing. Menopausal flushing should be treated with hormone replacement therapy or low-dose clonidine. The elimination of foods and additives that affect urinary excretion of 5-hydroxyindoleacetic acid (5-HIAA) (Table 170-2) also prepares the patient for diagnostic urine collection. If the exclusion diet eliminates flushing, then each item can be restored individually until the cause is discovered. [1] If flushing continues unabated despite the exclusion diet, systemic causes must be sought.

Foods and beverages
Hot (thermal) food/beverages
Spicy food
Chocolate
Cheeses
Tomatoes
Avocados
Red plums
Walnuts
Eggplant
Ingestion of any food
Alcohol
Emotional stress
Valsalva maneuver
Straining during defecation
Vigorous coughing
Sudden, direct pressure on a large carcinoid tumor
Physical examination
Intraoperative manipulation
Spontaneous

TABLE 170-2 **Factors That Precipitate Flushing in the Carcinoid Syndrome**

Flushing Syndromes

BLUSHING Blushing, or emotional flushing, is very common, although it infrequently causes patients to seek medical attention. If severe, this type of flushing is often accompanied by sweating, indicative of its neurologic origin. Sometimes, anxiety may be the cause of blushing, and these patients respond to anxiolytics. More often, blushing is just an exaggerated physiologic response to emotion, often in predisposed individuals with fair skin and readily visible vasculature. Emotional blushing can often be effectively reduced with nadolol, a long-acting nonselective beta blocker, at a dose of 40 to 80 mg every morning. [8]

THERMAL FLUSHING Overheating, due either to endogenous causes such as exercise or to exogenous ones such as sitting in a sauna, can also cause physiologic flushing or lower the flushing threshold for other causes such as the carcinoid syndrome. The anterior hypothalamus, which is the site of the body's thermostat, reacts to an increase in blood temperature by heat-dissipating mechanisms such as flushing and eccrine sweating. [1] Simple measures, such as sucking on ice chips or applying a cold wet towel to the face and neck, often alleviates thermal flushing. Flushing from the ingestion of hot liquids occurs primarily via a countercurrent heat exchange mechanism. The increased heat of the oral cavity is transferred to the internal jugular vein. The heat then gets exchanged with blood in the contiguously running internal carotid, and from there is transmitted to the anterior hypothalamus, where it sets off the heatregulating mechanisms leading to flushing and sweating. [1]

MENOPAUSAL/CLIMACTERIC FLUSHING The most common type of physiologic flushing is menopausal, otherwise known as a “hot flash.” Approximately 75 percent of women experience flushing during the time surrounding the transition to menopause (the climacteric) or after oophorectomy. [7] Various drugs, including 4-hydroxyandrostenedione, danazol, tamoxifen, clomiphene citrate, decapeptyl, and leuprolide, can induce a “pharmacologic menopause.” Flushing episodes also can occur in women in their thirties, just before or during their menstrual periods, when estrogen levels are lowest. [1] The most common feature described is a sudden, intense sensation of uncomfortable heat. The flush typically lasts for 3 to 5 min and is often accompanied by drenching perspiration. Other associated symptoms are palpitations, throbbing sensations, headaches, and nausea. [9] Hot flashes often are provoked by hot drinks, meals, alcohol, emotional upset, or exogenous heat; but they can occur at any time, often resulting in sleep disturbances. Climacteric flushing is thought to be caused by a sudden lowering of the setting of the central thermostat. The flushing is not directly related to plasma estrogen because blood estrogen levels do not correlate with symptoms. [7] Pulsatile release of luteinizing hormone follows the flush in most women, but flushing still can occur after hypophysectomy. [9] Naloxone, a specific opiate antagonist, is an

effective treatment for menopausal flushing and suggests that opiate-mediated central mechanisms may be involved. [10] Although hormone replacement therapy is the mainstay of treatment for menopausal flushing, clonidine, starting at a dose of 0.05 mg twice daily, is an effective nonhormonal regimen. [11] Although uncommon, “hot flashes” can occur in men, most often in association with either surgery (orchiectomy or bilateral hernia repairs with subsequent vascular compromise to the testes) or drug therapy with luteinizing hormone-releasing hormone (LHRH) analogues such as leuprolide acetate (Lupron). Antiandrogens, once thought to precipitate hot flashes in men, apparently have no effect on the incidence of male flushing. The most effective treatment for male hot flashes is sex steroid replacement. However, this is not always possible, as in the case of men with prostate cancer. In one study, megestrol acetate, 20 mg bid, completely eliminated hot flashes in a majority of affected men being treated for prostate cancer. [12]

ALCOHOL FLUSHING Alcohol is a well-established cause of flushing. Sensitivity to alcohol alone is usually due to aldehyde or alcohol dehydrogenase deficiency, which is most prevalent in Asians but has also been reported in Native Americans and Eskimos (Inuits). The flush usually occurs within 20 min after drinking and is the result of elevated acetaldehyde levels. The flushing may also be associated with tachycardia, tachypnea, and decreased blood pressure. [2] Fermented alcoholic beverages, such as beer and sherry, can cause flushing independent of ethnicity because they contain vasoactive chemicals such as tyramine and histamine. [7] Alcohol-related flushing, along with dizziness, can occur in workers exposed to organic solvents such as trichloroethylene, carbon disulfide, and others (see Table 170-1). Several drugs, including disulfiram, cephalosporins, metronidazole, and chlorpropamide, are associated with flushing when combined with alcohol. Flushing within minutes of drinking alcohol is associated with carcinoid tumors, mastocytosis, medullary carcinoma of the thyroid, and lymphoid tumors. [7]

DRUG-INDUCED FLUSHING Drugs, alone or in combination with alcohol, are common causes of flushing (see Table 170-1). If severe, these reactions may require discontinuation of the offending agent. Notably, aspirin or indomethacin can be used to inhibit flushing from nicotinic acid. [13]

FOOD-ASSOCIATED FLUSHING Spicy foods are a well-known cause of flushing, and foods containing nitrites or sulfites can also cause flushing, along with headaches and wheezing in some individuals. Sour foods can cause unilateral flushing. Monosodium glutamate (MSG), which was once regarded as the cause of “Chinese restaurant syndrome,” has since been shown to be an uncommon cause of flushing. [14] Flushing associated with spoiled scombroid fish is a result of histamine intoxication and is usually accompanied by sweating, vomiting, and diarrhea. [15]

SYSTEMIC DISEASES ASSOCIATED WITH FLUSHING Several systemic diseases can cause flushing and are often included in the differential diagnosis of carcinoid syndrome. Mastocytosis is discussed in Chap. 163. Flushing is uncommon in pheochromocytoma and usually occurs only after an attack, whereas pallor is found during the attack. [2] Medullary carcinoma and various pancreatic tumors (e.g., VIPoma, insulinoma) can cause flushing. A patient was reported to have carcinoid-like flushing associated with POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, monoclonal proteinemia, and skin changes), which was accompanied by hypotension and bronchospasm. The flushing improved with steroid therapy. [16]

CARCINOID SYNDROME

Carcinoid tumors arise from neuroendocrine cells and can appear in a variety of locations such as the lungs, bronchi, stomach, small intestine, appendix, and large bowel. [17] Carcinoid tumors secrete a variety of hormones and biogenic substances and are best-known for serotonin secretion. In some patients with carcinoid tumors, the secretion of serotonin and other vasoactive substances leads to the carcinoid syndrome. The characteristic manifestations of the carcinoid syndrome are bronchoconstriction, gastric hypermotility and diarrhea, right-sided cardiac valvular disease, and flushing. [18] Up to 5 percent of new onset flushing may be due to the carcinoid syndrome. [19] Carcinoid-associated flushing episodes are often precipitated by foods, alcohol, stress, and exercise (see Table 170-2). When severe and untreated, carcinoid flushing can lead to constant facial erythema, telangiectasias, and other rosacea-like symptoms. [2]

Historical Aspects

Oberndorger first used the term *karzinoide* in 1907, and the carcinoid syndrome was first described by Thorson et al. in 1954. [18] It was initially thought that elevated levels of serotonin were its cause, but a variety of chemical mediators have been implicated. [20]

Epidemiology

Recent reports estimate the overall incidence of carcinoid tumors to be anywhere from 1 to 8.4 cases per 100,000 people. Many carcinoid tumors are indolent and may be discovered only at autopsy. Analyses of cases from 1950 through 1971 reported the appendix as the most common site for carcinoid tumors, followed by the rectum, ileum, lungs, bronchi, and stomach. [17] However, more recent data from 1973 to 1991 report pulmonary sites to be most common (32.7 percent), followed by the ileum (17.6 percent), rectum (10.1 percent), and appendix (7.6 percent). [21] Differences are likely a result of increased detection and reporting of carcinoid tumors.

Carcinoid syndrome occurs in about 5 percent of patients with carcinoid tumors. [19] When carcinoid tumors are present in the abdomen, the liver effectively detoxifies most vasoactive substances secreted by the tumor. Symptoms of the carcinoid syndrome often suggest liver metastases, a bulky abdominal tumor producing large amounts of neuroendocrine products, or extra-abdominal disease. An estimated 40 to 50 percent of patients with small bowel or proximal colonic tumors have some symptoms, likely related to the propensity for these sites to metastasize. [6] The carcinoid syndrome occurs in less than 5 percent of patients with carcinoid tumors of the lung, rectum, or appendix. [17]

Etiology and Pathogenesis

Although serotonin (5-hydroxytryptamine, 5-HT) is the likely cause of the diarrhea, it is not solely responsible for the carcinoid flush because intravenous 5-HT does not produce a true carcinoid flush and arterial concentrations do not rise

during a flush. Bradykinin has been investigated as a cause of flushing. [20] The systemic infusion of substance P reportedly causes flushing, tachycardia, and hypotension in humans, and some authors suggest that substance P may be responsible for the fibrosis that often surrounds intestinal carcinoid tumors. [6] However, the fact that there is no reported relationship between plasma levels of substance P and the degree of flushing argues against substance P as the primary mediator. [20]

Histamine is implicated in the flushing due to gastric carcinoid tumors. [22] Other substances that may be involved in the carcinoid syndrome are prostaglandins, tachykinins, neuropeptide K, and neurokinin A. Carcinoid tumors may stimulate the release of endothelium-derived relaxing factor (EDRF), thereby causing indirect vasodilation. Because various foods can precipitate attacks, it may be that intestinal hormones or food derivatives trigger carcinoid tumor secretion. [6], [20]

Genetics

The only type of carcinoid tumors with a reported genetic basis are gastric carcinoids associated with the Zollinger-Ellison syndrome, which occur almost exclusively in patients with multiple endocrine neoplasia type 1 (MEN1). This is an autosomal dominant disorder associated with the loss of *MEN1*, a possible tumor-suppressor gene, located on chromosome 11q13. This type of carcinoid is uncommon, accounting for only 5 to 10 percent of all gastric carcinoid tumors, and is very rarely associated with the carcinoid syndrome. [17]

Clinical Manifestations

DERMATOLOGIC MANIFESTATIONS Severe flushing episodes occur in approximately 75 percent of patients affected by the carcinoid syndrome. Some reports indicate that up to 90 percent of patients with carcinoid syndrome complain of flushing. [19] The location of the secreting tumor helps to determine the character of the flushing along with associated symptoms. Gastric carcinoid tumors produce histamine, causing a vivid, bright, pinkish-red and patchy (a geographic pattern) flush, with bright white patches most evident at the base of the neck. This pattern is often associated with a sensation of burning along with lacrimation, sweating, and wheezing. Bronchial carcinoid tumors often cause intensely red, occasionally purple flushing that may last several hours to days. Flushing of other body areas may occur, along with profuse lacrimation. Repeated episodes can cause facial swelling and accentuation of skin folds. The “classic” carcinoid flush, which is associated with mid-gut (small intestine to mid-colon) carcinoid tumors, is usually characterized by areas of pallor and erythema superimposed on a cyanotic background. These flushes are often of shorter duration, sometimes only a few minutes. Diarrhea, hypotension, and bronchoconstriction are common accompanying symptoms. [20], [23] A common skin finding is pellagra, which is a result of niacin deficiency. Tryptophan is a precursor for both serotonin and niacin. Consequently, when tryptophan stores are shunted toward excessive serotonin production, there is little left for generation of niacin. Pellagra includes hyperkeratosis, xerosis, diffuse scaling, gray-black pigmentation, angular cheilitis, and glossitis. The repeated severe episodes of flushing can lead to rosacea, including ocular rosacea, telangiectasias, cyanosis, and connective tissue hypertrophy leading to phymas. [2] Other skin changes reported in association with the carcinoid syndrome include yellow-brown or brown-gray patches on the forehead, back, and wrists; pruritus; pruritus with pressure-induced “orange blotches” [24]; scleroderma-like changes [25], [26]; acropachyderma and pachyperiostitis [27]; cutaneous metastatic nodules [27]; erythematous, telangiectatic, atrophic patches with central ulceration [28]; pyoderma gangrenosum [29]; erythema annulare centrifugum and white banding of the toenails [30]; blisters that heal leaving white sclerotic papules and macules surrounded by an erythematous halo [31]; and reddish, cyanotic, hyperkeratotic papules. [32]
SYSTEMIC MANIFESTATIONS Seventy to 85 percent of patients experience watery diarrhea with the carcinoid syndrome. Common respiratory manifestations include bronchospasm, wheezing, stridor, dyspnea, and cough. [33] Systemic symptoms include arthritis, psychiatric symptoms, osteoblastic bone lesions from metastases, acromegaly due to ectopic growth hormone secretion, and Cushing's syndrome from corticotropin secretion. Two-thirds of patients with the carcinoid syndrome experience carcinoid heart disease. Heart disease is the result of fibrosis, which characteristically affects the right side of the heart, especially the tricuspid and pulmonary valves. Left-sided heart disease affects less than 10 percent of patients with the carcinoid syndrome and is associated with pulmonary carcinoid tumors. Fibrosis appears in other areas as well and may lead to intestinal obstruction when it occurs around intestinal tumors. Both serotonin and substance P have been postulated to cause the fibrosis. [6], [34]

Pathology

Because carcinoid tumors are derived from neuroendocrine cells, they are characterized on pathologic examination by reactions to silver stains and to markers of neuroendocrine tissue, including neuron-specific enolase, synaptophysin, and chromogranin. Electron microscopy reveals numerous membrane-bound neurosecretory granules. [17]

Diagnosis

A search for the carcinoid syndrome should be made when flushing episodes are accompanied by systemic symptoms such as abdominal cramping, diarrhea, bronchoconstriction, tachycardia, and hypotension. A carcinoid tumor should be considered when an exclusion diet and the removal of other possible provocative factors (see “ Clinical Manifestations” above) does not yield an etiology for flushing. Furthermore, because most patients with the carcinoid syndrome have liver metastases, an enlarged liver in a patient with flushing should always warrant testing for carcinoid syndrome. A history of systemic complaints, such as weight loss and vague abdominal pain, should raise the suspicion for carcinoid syndrome in a patient with flushing.

The carcinoid syndrome is characterized by 5-HT overproduction. The diagnosis is made by testing for elevated urinary excretion of 5-HIAA, the major metabolite of serotonin (Table 170-3). Urinary excretion fluctuates, so collections should be repeated if initial findings are negative but the clinical picture is highly suggestive of carcinoid syndrome. Because many foods and drugs affect urinary excretion of 5-HIAA (Table 170-4), it is important for the patient to be on an exclusion diet at least 3 days before urine collection. The reference range of 5-HIAA excretion is usually 8 to 47 µmol/24

h, and a level of 80 µmol/24 h has a specificity of 100 percent when dietary intake is controlled. [19]

1. Perform qualitative "spot-test" for urine 5-HIAA.
2. If negative, place patient on 3-day exclusion diet (see Table 170-4).
3. Perform quantitative 24-h urine 5-HIAA measurement.
   a. Reference range: 8–47 µmol/24 h.
   b. Level of 80 µmol/24 h is 100 percent specific for carcinoid syndrome.
4. If quantitative test negative, but clinical suspicion high, repeat test.
5. If repeat test is negative, consider radiolabeled octreotide scintigraphy.

TABLE 170-3 **Carcinoid Syndrome Diagnosis**

Foods	
Avocados	Red plums
Bananas	Tomatoes
Eggplant	Walnuts
Pineapples	
Drugs	
ACTH	Mephenesin
Acetaminophen	Methamphetamine
Acetanilid	Methenamine
Bromocriptine	Methocarbamol
Caffeine	Methyldopa
Chlorpromazine	Methysergide
Fluorouracil	Monoamine oxidase inhibitors
Guaifenesin	Phenacetin
Glyceryl guaiacolate	Phenmetrazine
Heparin	Phenothiazines
Imipramine	Promethazine
Isoniazid	Reserpine
Lugol's solution	Somatostatin analogues (e.g., octreotide)
Melphalan	

TABLE 170-4 **Foods and Drugs That Affect Urinary Excretion of 5-Hydroxyindoleacetic Acid**

If liver metastases are suspected, abdominal CT with and without contrast can often be useful to identify tumors. Primary abdominal tumors are often very small and difficult to visualize before surgery. Scintigraphy with radiolabeled octreotide has been successful in localizing both primary and metastatic carcinoid tumors and is also useful in predicting response to octreotide therapy. [17] One study reported that somatostatin scintigraphy had a sensitivity of 89 percent for detecting carcinoid tumors. [35] With newer methods for detecting carcinoid tumors such as octreotide scanning, the potentially dangerous provocative method of injecting intravenous adrenaline to provoke flushing is now considered outdated and should be used only as a last resort in the appropriate clinical setting. [6]

Treatment and Prognosis

The prognosis for patients with carcinoid tumors correlates closely with the stage of the tumor at presentation. [17] Because the carcinoid syndrome usually indicates the presence of either bulky abdominal tumor or liver metastases, it usually carries a worse prognosis. Typical mean survival periods are in the range of 8 years, with long survival times ranging up to 20 years. [36]

Patients with the carcinoid syndrome should avoid alcohol, foods, and activities that are known to exacerbate their symptoms (see Table 170-2). Niacin supplementation is often needed to prevent pellagra. Clonidine is sometimes used in treatment because catecholamines are known to precipitate carcinoid attacks. [37] The combination of both H_1 and H_2 antihistamines is often effective in blocking the flush caused by gastric carcinoids. [22]

Somatostatin analogues are the gold standard in the treatment of the carcinoid syndrome, relieving both flushing and diarrhea. [38] Somatostatin binds to its receptors, found on more than 80 percent of carcinoid tumors, and inhibits the secretion of a broad range of hormones. Octreotide is a long-acting somatostatin analogue that is given as a subcutaneous injection one to three times a day. Doses necessary to relieve symptoms vary, but 450 µg per day relieves the symptoms in up to 90 percent of patients. While some authors suggest that octreotide is also effective in shrinking tumors, recent reports suggest that the role of the somatostatin analogues is in controlling symptoms, not in curing disease. There is no convincing evidence that octreotide alters survival in patients with carcinoid tumors. Octreotide is also essential in reducing operative complications of cardiovascular and respiratory instability ("carcinoid crisis") in patients with the carcinoid syndrome. [17], [38]

Surgical resection has been the only treatment shown to prolong life in patients with carcinoid tumors. [38] However, by the time of presentation, tumor burden is often bulky and surgical cure is often impossible. Hepatic artery occlusion and embolization have been tried, although the duration of response is often short. Other studies suggest that chemoembolization, or the combination of tumor ischemia and chemotherapy, may elicit a better and longer-lasting response. [39] Liver transplantation has historically played little role in the treatment of carcinoid tumors, but a recent report is encouraging. Although only performed in a small number of highly selected patients, a French study reported a 5-year survival rate of 69 percent. [40]

Other than with somatostatin analogues, medical management of carcinoid disease has been lacking. Interferon-a monotherapy decreases urinary 5-HIAA in 42 percent of patients and causes tumor regression in 15 percent. It has been used in combination with octreotide for patients who are resistant to octreotide alone. [41] The use of interferon-a is often limited by its side effects, which include fever, fatigue, anorexia, and weight loss. Chemotherapeutic regimens have been tried for intractable carcinoid disease with only moderate success. [17] Although radiation therapy has not been extensively studied, recent small studies suggest that radiolabeled somatostatin analogues may have a role in tumor shrinkage and symptomatic improvement for metastatic carcinoid tumors. [42], [43]

REFERENCES

Lupus erythematosus (LE) is the root designation for a diverse array of illnesses that are linked together by distinctive clinical findings and characteristic patterns of polyclonal B cell autoimmunity. Some patients present with life-threatening manifestations of systemic lupus erythematosus (SLE); whereas others, who are affected with what likely represents the same basic underlying disease process, express little more than discoid lupus erythematosus (DLE) skin lesions throughout their illness. Many physicians find it convenient to conceptualize LE as a clinical spectrum ranging from mildly affected patients with only localized DLE skin lesions to those at risk of dying from the systemic manifestations of LE such as nephritis, central nervous system disease, or vasculitis. The pattern of skin involvement expressed by an individual patient with LE can provide insight about the position on the spectrum where the patient's illness might best be placed.

The nomenclature and classification system originally devised by James N. Gilliam divides the cutaneous manifestations of LE into those lesions that show characteristic histologic changes of LE (LE-specific skin disease) and those that are not histopathologically distinct for LE and/or may be seen as a feature of another disease process (LE-nonspecific skin disease). The rationale behind this system of nosology and classification was recently discussed in depth. [1] The term cutaneous LE is often used synonymously with LE-specific skin disease as an umbrella designation for the three major categories of LE-specific skin disease: acute cutaneous lupus erythematosus (ACLE), subacute cutaneous lupus erythematosus (SCLE), and chronic cutaneous lupus erythematosus (CCLE). This will be the framework used in our discussion of the extraordinarily diverse set of cutaneous lesions that occur in patients with LE (Table 171-1).

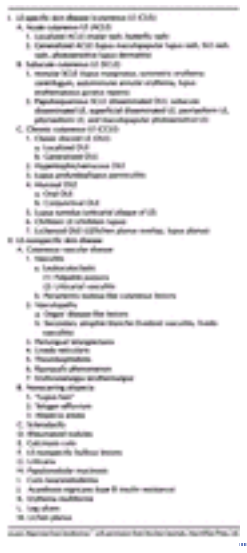

TABLE 171-1 **The Gilliam Classification of Skin Lesions Associated with LE**

The essence of LE is in its heterogeneity, and the challenge for those who treat it is to recognize clinically useful patterns within the mosaic of features that constitute this protean illness. The focus of this presentation is on the cutaneous features of this disorder, especially the LE-specific skin lesions. (The LE-nonspecific skin lesions are summarized in the last section of this chapter, “LE-nonspecific Skin Lesions.”) The systemic manifestations of LE and their management are covered in current monographs. [2] An overview of the systemic manifestations of LE can be surmised from the American College of Rheumatology's classification criteria for SLE, [3] which are presented in Table 171-2, and from the outline of the systemic manifestations of SLE presented in Table 171-3. In addition, the cutaneous manifestations of LE with comprehensive citations have been reviewed elsewhere. [2], [3], [4] and [5]

TABLE 171-2 **The 1982 Revised Criteria for Classification of Systemic Lupus Erythematosus***

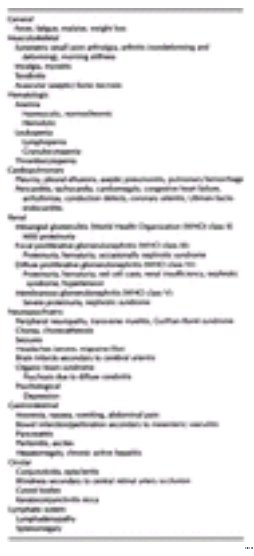

TABLE 171-3 **Overview of the Extracutaneous Manifestations of SLE**

HISTORICAL ASPECTS

Cazenave is credited for first using the term *lupus érythèmateaux,* in 1851, to refer to Biett's earlier description of DLE skin lesions. The use of this term helped to distinguish cutaneous LE from cutaneous tuberculosis (lupus vulgaris) with which it had been earlier confused. In 1875, Kaposi expanded Hebra's description of what is now recognized as SLE. Kaposi employed the “butterfly” simile, which had first been used by Hebra to describe the facial skin lesions associated with SLE. Jonathan Hutchinson, in 1880, and William Osler, at the turn of the century, emphasized the multisystem nature of LE. Until 1936, it was thought to be unusual for the systemic features of LE to be present in the absence of skin lesions. Comprehensive historic perspectives on the cutaneous manifestations of LE have been written. [2]

EPIDEMIOLOGY

The epidemiology and socioeconomic impact of LE in general, [6] and cutaneous LE specifically, [2], [7] have been reviewed. Skin disease is the second most frequent clinical manifestation of LE after joint inflammation. As many as 45 percent of patients with cutaneous LE experience some degree of vocational handicap.

Demographics

Malar, or butterfly rash (localized ACLE), has been reported in 20 to 60 percent of large cohorts of patients with LE. Limited data suggest that the maculopapular or SLE rash of generalized ACLE is present in about 35 to 60 percent of patients with SLE. ACLE, like SLE in general, is much more common in women than men (8:1). All races are affected; however, the early clinical manifestations of ACLE can be overlooked in a dark-skinned individual.

Patients presenting with SCLE lesions constitute 7 to 27 percent of LE patient populations. SCLE is primarily a disease of white females, with the mean age of onset in the fifth decade.

The most common form of CCLE, a classic DLE skin lesion, is present in 15 to 30 percent of SLE populations selected in various ways. Approximately 5 percent of patients presenting with isolated localized DLE subsequently develop SLE. It has been suggested that SLE is sevenfold more common than DLE. Although DLE can occur in infants and the elderly, it is most common in individuals between 20 and 40 years of age. DLE has a female:male ratio of 3:2 to 3:1, which is much lower than that of SLE. All races are affected, but investigations suggest that DLE might be more prevalent in blacks.

ETIOLOGY AND PATHOGENESIS

The cause(s) of and pathogenetic mechanisms responsible for LE-specific skin disease are not fully understood. The pathogenesis of LE-specific skin disease is inextricably intertwined with SLE pathogenesis. An attractive contemporary model of SLE pathogenesis describes four theoretical temporally sequential phases that are prerequisite for the clinical expression of this disease. These phases are the inheritance of susceptibility genes, induction of autoimmunity, expansion of autoimmune processes, and immunologic injury (Figure 171-1).

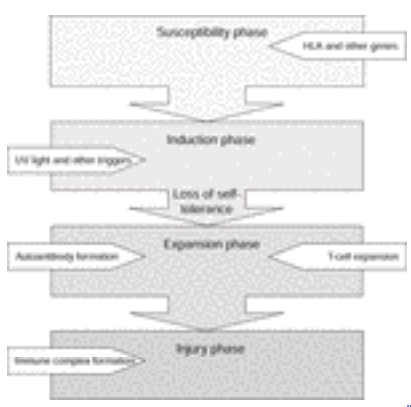

FIGURE 171-1 Model of SLE pathogenesis.

The first phase can be thought of as a susceptibility phase involving the inheritance of genes that confer predisposition to SLE. There is a ten-fold difference in heritability of SLE between dizygotic and monozygotic twins, suggesting the presence of at least four genes. The genetic association between LE-specific skin disease and serologically determined major histocompatibility (MHC) class II DR specificities is well known, and is described in detail below. Additionally, other genes have been implicated in the pathogenesis of SLE, including genes encoding complement proteins and tumor necrosis factor, genes mediating apoptosis, genes involved in cell-cell signaling processes, and genes for the clearance of immune complexes. [8]

The second phase of SLE pathogenesis or the induction phase involves the initiation of autoimmunity characterized by the appearance of autoreactive T cells that exhibit the loss of self-tolerance. Potential mechanisms include the presentation of cryptic peptides during apoptosis, aberrant expression of human leukocyte antigen (HLA)-DR molecules, failure of central thymic or peripheral tolerance mechanisms, and molecular mimicry induced by infection. UV exposure and other environmental factors play a large role in this stage (see below).

Once an autoimmune clone is established, mechanisms to perpetuate and expand this aberrant clone come into play. This third or expansion phase seems to involve progressive augmentation of the autoimmune response and has features of an antigen-driven response. Elucidation of cell-cell signaling mechanisms involving costimulatory molecules such as CD40 and CD40 L have shed valuable light on this process and also serve as potential novel therapeutic targets. [9] During the expansion phase, serologically detectable autoantibodies are produced by the population of clonally expanded B cells. Despite their abundance, autoantibodies in SLE are directed against a limited number of nuclear and cytoplasmic antigens. Three major targets are the nucleosome (anti-DNA and antihistone antibodies), the spliceosome (anti-Sm and anti-RNP antibodies) and the Ro and La molecules (anti-Ro and anti-LA).These autoantibodies often arise in grouped sets, probably because these targets are available to the immune system as intact rather than as individual particles. The aggregation of these autoantibodies and the source of the triggering autoantigens were a mystery until it was realized that most of the lupus target autoantigens are clustered in distinct structures at the surface of apoptotic cells. Once immune tolerance to the intact particles is broken down, the autoantibody response diversifies to the individual components via recognition of new epitopes within the intact complex. This phenomenon has been referred to as *epitope spreading*. [10]

The last and perhaps clinically most relevant stage that heralds the onset of clinical disease is that of immunologic injury. Much of this phase can be attributed to the action of autoantibodies and the immune complexes they form, which may cause tissue damage by means that include direct cell death, cellular activation, opsonization, and the blocking of target molecule function.

Role of Genetics in LE-specific Skin Disease

Initial associations of SLE were detected with genes of the MHC, specifically HLA alleles. While there is a strong theoretical basis that MHC alleles can act as disease susceptibility genes by shaping the T cell repertoire, it is also increasingly recognized that HLA class II alleles are more closely associated with specific autoantibody and clinical phenotypes of disease. ACLE is usually encountered in patients having overt SLE, and SLE is known to be associated with HLA-DR2 and -DR3. Several other genes outside the MHC region have been identified in the pathogenesis of SLE and LE-specific skin disease.

SCLE was initially associated with the HLA-B8, DR3 haplotype. Advances in DNA typing of HLA molecules revealed that patients with SCLE and overlapping features of Sjögren's syndrome are more likely to have the HLA-DR3, DQA1*0501, DQB1*0502 haplotype, which is more closely associated with anti-Ro antibodies. This autoantibody occurs in high frequencies in patients with SCLE. [11] Genetic deficiencies of complement components, including C2, C3, C4, and C5, as well as the C1 esterase inhibitor, are associated with both SCLE and DLE.

Significant increases of HLA-B7, -B8, -DR2, -DR3, and -DQA0102 and a significant decrease in HLA-A2 have been reported for patients with DLE. The combination of HLA- DR3, HLA-DQA0102, and HLA-B7 conferred the maximum relative risk (7.4) for DLE. DLE also occurs with increased frequency in female carriers of X-linked chronic granulomatous disease.

Interleukin (IL)-1 receptor antagonist and tumor necrosis factor-a (TNF-a) gene polymorphisms have been implicated as genetic factors in cutaneous LE. Werth and colleagues found a substantial increase in the prevalence of a promoter polymorphism of TNF-a (-308A) in patients with SCLE. Additionally, they found that there was a striking synergy between UVB and added IL-1a (a photoinduced cytokine) in the induction of transcription of the TNF-a 308A promoter. [12] This finding suggests that this polymorphism may directly contribute to the photosensitivity of patients with SCLE. An alternate explanation is that TNF-a may be a marker allele for the extended HLA-A01,B08, DRB1*0301 haplotype that is associated with a number of autoimmune conditions, including SCLE. [13]

Role of UV Light in LE-specific Skin Disease

Ultraviolet light is probably the most important environmental factor in the induction phase of LE-specific skin disease. Early studies demonstrated that cutaneous LE lesions could be provoked in the clinically normal skin of patients with both SLE and cutaneous LE by repeated delivery of high doses of UVB radiation to the same test site. More recent studies argue that UVA radiation can also induce cutaneous LE lesions.

UV light could uncover an already established autoimmune state by triggering autoantigen release from an injured keratinocyte. Conceivably, UV light could also affect localization of preexisting autoantibody-containing immune complexes by altering endothelial permeability. UV light may additionally have an early critical role in the induction phase by altering cellular DNA. Aberrant expression of HLA-DR molecules may result in the recognition of self peptides that may have escaped thymic tolerance. UVB radiation can displace autoantigens such as Ro/SS-A and related autoantigens, La/SS-B and calreticulin, from their normal locations inside epidermal keratinocytes to the cell surface. Evidence suggests that UV-induced keratinocyte apoptosis is a major mechanism responsible for this aberrant pattern of cell surface autoantigen expression. [10], [14] Cell surface expression would allow Ro/SS-A, La/SS-B, and calreticulin autoantibodies in the circulation to bind to these autoantigens that are normally sequestered from the humoral immune response inside cells. Autoantibody binding to the exposed antigens could result in tissue injury through complement-mediated lysis or antibody-dependent cell-mediated cytotoxicity. It is possible that humoral factors other than anti-Ro/SS-A might be involved in the pathogenesis of LE photosensitivity.

UV light may cause an exaggerated release of immune mediators such as IL-1, TNF-a, prostaglandin E, proteases, oxygen free radicals, and histamine in genetically predisposed individuals with LE. The aberrant expression of adhesion molecules such as intercellular adhesion molecule (ICAM)-1 could play a role in the pathogenesis of LE photosensitivity. UV light may directly affect immunoregulatory cells such as cutaneous T cells, which normally help suppress “abnormal” patterns of cutaneous inflammation. [14], [15] and [16]

Role of Tobacco Exposure

A recent large case-control study reported that smokers are at a greater risk of developing SLE than are nonsmokers and former smokers. Investigators suggest that this fact may be related to lupogenic aromatic amines, which are contained in tobacco smoke. Two abstracts from the Baltimore Lupus Cohort suggest an increased frequency of DLE in smokers, and several authors have shown that patients with LE-specific skin disease who smoke are less responsive to antimalarial treatment. [17], [18] and [19]

Role of Drugs

Numerous drugs have been implicated in inducing various features of SLE [e.g., procainamide, hydralazine, isoniazid, chlorpromazine, phenytoin (Dilantin), and, most recently, minocycline, as well as COL-3, an anticancer tetracycline derivative]. [20], [21] Classic drug-induced SLE is associated with antihistone antibodies and manifests similarly to SLE, but without cutaneous involvement. A mechanism for drug-induced LE by which the provocative agent induces T cell DNA hypomethylation inducing altered repair of DNA has been proposed. A decrease in the amount of methylation of DNA correlates with increased biological autoreactivity of lymphocytes. [22]

The skin is often spared in classic drug-induced SLE states in contrast to drug-induced SCLE, which has been convincingly associated with exposure to hydrochlorothiazide, calcium channel blockers, angiotensin-converting enzyme

inhibitors, and cinnarizine. Recently, there have been accounts of patients with terbinafine-induced SCLE, including one report documenting Ro (SS-A), La (SS-B), and antihistone antibody positivity in these patients. Other drugs reported to precipitate SCLE include piroxicam, d-penicillamine, sulfonylureas, oxprenolol, parenteral gold therapy, griseofulvin, naproxen, spironolactone (Aldactone), interferon-ß, and ranitidine. [20], [23]

Role of Viruses

There has been much speculation about the role of infectious agents, particularly viruses, in the induction of SLE and cutaneous LE. Infections of all types have long been known to exacerbate SLE. Infection by alphaviruses such as Sindbis, rubella, and cytomegalovirus appears able to induce cell surface expression of Ro/SS-A and related autoantigens in cells undergoing virus-induced apoptosis. Seroconversion to Epstein-Barr virus among patients with SLE is nearly universal. Epstein-Barr virus infection is associated with overexpression of bcl-2 and the inability of lupus T cells to suppress growth of infected/activated B cells. [24]

CLINICAL MANIFESTATIONS

Table 171-4 compares the key clinical, histopathologic, and laboratory features of patients presenting with ACLE, SCLE, and CCLE (classic DLE) skin lesions. It is important to distinguish among the subtypes of LE-specific skin disease, because the type of skin involvement in LE can reflect the underlying pattern of SLE activity. In fact, the designations acute, subacute, and chronic, in regard to cutaneous LE, refer to the pace and severity of any associated SLE and are not necessarily related to how long individual lesions have been present. For example, ACLE almost always occurs in the setting of acutely flaring SLE, whereas CCLE often occurs in the absence of SLE or in the presence of mild smoldering SLE. SCLE occupies an intermediate position in this clinical spectrum. Subclassification, although important for assigning risk, is sometimes difficult, as it is not uncommon to see more than one subtype of LE-specific skin disease in the same patient, especially in patients with SLE.

Disease Features	ACLE	SCLE	Classic DLE
Clinical features of skin lesions			
Induration	0*	0	+++
Dermal atrophy	0	0	+++
Pigment changes	+	++	+++
Follicular plugging	0	0	+++
Hyperkeratosis	+	++	+++
Histopathology			
Thickened basement membrane	0	+	+++

TABLE 171-4 **Comparison of the Major Types of LE-Specific Skin Disease**

ACLE

Although ACLE localized to the face is the usual pattern of presentation, ACLE can assume a generalized distribution. Localized ACLE has commonly been referred to as the classic butterfly rash or malar rash of SLE (Fig. 171-2). In localized ACLE, confluent symmetric erythema and edema is centered over the malar eminences and bridges over the nose (unilateral involvement with ACLE has been described). The nasolabial folds are characteristically spared. The forehead, chin, and V area of the neck can be involved, and severe facial swelling may occur. Occasionally, ACLE begins as small macules and/or papules on the face that later may become confluent and hyperkeratotic. Generalized ACLE presents as a widespread morbilliform or exanthematous eruption often focused over the extensor aspects of the arms and hands and characteristically sparing the knuckles (Fig. 171-3A). Although perivascular nail fold erythema and telangiectasia can occur (Fig. 171-3B), they are considerably more common and occur in more exaggerated forms in dermatomyositis (see Fig. 172-3). Generalized ACLE has been indiscriminately referred to as the maculopapular rash of SLE, photosensitive lupus dermatitis, and SLE rash. An extremely acute form of ACLE is rarely seen that can simulate toxic epidermal necrolysis. This form of bullous LE results from dissolution of the epidermal basal cell layer due to very intense lichenoid inflammation.

FIGURE 171-2 Localized acute cutaneous LE (ACLE). Erythematous, slightly edematous, sharply demarcated erythema is seen on the malar areas in a “butterfly” distribution.

FIGURE 171-3 Generalized ACLE. *A.* Well-demarcated patches of erythema with fine overlying scale on the dorsal aspect of the hands, fingers, and periungual areas. Note the characteristic sparing of the knuckles, which are preferentially involved in dermatomyositis. *B.* Closeup view of periungual erythema and grossly visible telangiectasia. Although these lesions can be seen in LE, they are more typical of dermatomyositis.

ACLE is typically precipitated or exacerbated by exposure to UV light. This form of cutaneous LE can be quite ephemeral, lasting only hours, days, or weeks; however, some patients experience more prolonged periods of activity. Postinflammatory pigmentary change is most prominent in patients with heavily pigmented skin. Scarring does not occur in ACLE unless the process is complicated by secondary bacterial infection. ACLE occasionally occurs in conjunction with SCLE; however, the simultaneous occurrence of ACLE and active DLE is unusual. [6] Both localized and generalized ACLE wax and wane in parallel with underlying SLE disease activity, including LE nephritis.

SCLE

A number of names have been used to describe SCLE skin lesions: symmetric erythema centrifugum; disseminated DLE; autoimmune annular erythema; subacute disseminated LE; superficial disseminated LE; psoriasiform LE; pityriasiform LE; maculopapular photosensitive LE; and lupus erythematosus gyratum repens. A disease presentation dominated by SCLE lesions marks the presence of a distinct subset of LE having characteristic clinical, serologic, and genetic features. Although a finding of circulating autoantibodies to the Ro/SS-A ribonucleoprotein particle strongly supports a diagnosis of SCLE, the presence of this autoantibody specificity is not required to make a diagnosis of SCLE.

SCLE initially presents as erythematous macules and/or papules that evolve into hyperkeratotic papulosquamous or annular/polycyclic plaques (Fig. 171-4). Whereas most patients have either annular or papulosquamous SCLE, a few develop elements of both morphologic varieties. SCLE lesions are characteristically photosensitive and occur in predominantly sun-exposed areas (i.e., upper back, shoulders, extensor aspects of the arms, V area of the neck, and, less commonly, the face). SCLE lesions typically heal without scarring but can resolve with long-lasting if not permanent vitiligo-like leukoderma and telangiectasias.

FIGURE 171-4 Subcute cutaneous LE (SCLE). *A.* Annular SCLE on the upper back of a 38-year-old woman. Note the central areas of hypopigmentation in which no dermal atrophy is present. *B.* Papulosquamous SCLE over the extensor aspect of the forearm of a 26-year-old woman.

Several variants of SCLE have been described. On occasion, SCLE lesions present initially with an appearance of erythema multiforme, and such cases can simulate the appearance of Rowell's syndrome (erythema multiforme-like lesions occurring in patients with SLE in the presence of La/SS-B autoantibodies). As a result of intense injury to epidermal basal cells, the active edge of an annular SCLE lesion occasionally undergoes a vesiculobullous change that can subsequently produce a strikingly crusted appearance. Such lesions mimic toxic epidermal necrolysis. Rarely, SCLE presents with exfoliative erythroderma or displays a curious acral distribution of annular lesions. Pityriasiform and exanthematous variants of SCLE have been reported. In one case, annular SCLE lesions were observed to evolve over time to plaques of morphea. The skin lesions of neonatal LE (transient, photosensitive, nonscarring LE-specific skin lesions in neonates who have received IgG anti-Ro/SS-A, and, occasionally, other autoantibody specificities

transplacentally) share many features with SCLE. [25]

Between 15 and 20 percent of patients with SCLE lesions may also develop ACLE or classic DLE at some point. ACLE skin lesions tend to be more transient than SCLE lesions and heal with less pigmentary change. They are also more edematous and less hyperkeratotic than SCLE lesions. ACLE more commonly affects the malar areas of the face, whereas SCLE focuses more on the neck, shoulders, upper extremities, and trunk. DLE lesions occurring in the context of SCLE are generally associated with a greater degree of hyper- and hypopigmentation, atrophic dermal scarring, follicular plugging, and adherent scale. A consistent clinical difference is that DLE lesions are characteristically indurated, whereas SCLE lesions are not; this difference reflects the greater depth of inflammation seen histopathologically in DLE lesions.

Approximately half of patients with SCLE meet the American College of Rheumatology's revised criteria for the classification of SLE. However, manifestations of severe SLE such as nephritis, central nervous system disease, and systemic vasculitis develop in only 10 to 15 percent of patients with SCLE. It has been suggested that the papulosquamous type of SCLE, leukopenia, high titer of antinuclear antibody (ANA) (>1:640), and anti–double-stranded DNA antibodies are risk factors for the development of SLE in a patient presenting with SCLE lesions.

SCLE can overlap with other autoimmune diseases including Sjögren's syndrome, rheumatoid arthritis, and Hashimoto's thyroiditis. Other disorders that have been anecdotally related to SCLE are Sweet's syndrome, porphyria cutanea tarda, gluten-sensitive enteropathy, and Crohn's disease. There has also been the suggestion that SCLE can be associated with internal malignancy (carcinoma of the breast, lung, gastrointestinal tract, uterus; Hodgkin's disease).

CCLE

Classic DLE lesions, the most common form of CCLE, begin as red-purple macules, papules, or small plaques and rapidly develop a hyperkeratotic surface. Early classic DLE lesions typically evolve into sharply demarcated, coin-shaped (i.e., discoid) erythematous plaques covered by a prominent, adherent scale that extends into the orifices of dilated hair follicles (Fig. 171-5).

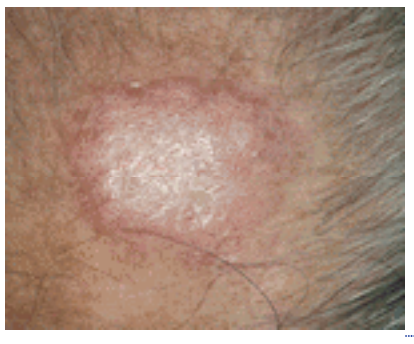

FIGURE 171-5 Classic discoid LE (DLE). Typical early erythematous plaque on the forehead demonstrating hyperkeratosis and accentuation of follicle orifices in a 60-year-old male with a 25-year history of cutaneous LE. The lesion had been present for 3 months; no dermal atrophy was present at this stage.

Early DLE lesions typically expand with erythema and hyperpigmentation at the periphery, leaving atrophic central scarring, telangiectasia, and hypopigmentation (Fig. 171-6). DLE lesions at this stage can merge to form large, confluent, disfiguring plaques. DLE in persons of certain ethnic backgrounds, such as Asian Indians, can present clinically as isolated areas of macular hyperpigmentation. Follicular involvement is a prominent feature. Keratotic plugs accumulate in dilated follicles that soon become devoid of hair. When the adherent scale is lifted from more advanced lesions, keratotic spikes similar in appearance to carpet tacks can be seen to project from the undersurface of the scale (i.e., the “carpet tack” sign).

FIGURE 171-6 Classic DLE. Sharply demarcated, round-to-ovoid, slightly indurated, erythematous plaques on the neck and face. Most plaques show a mild degree of hyperkeratosis and some show dermal atrophy. Noninflamed areas of hypopigmentation and scarring mark the sites of prior lesions that have resolved.

DLE lesions are most frequently encountered on the face, scalp, ears, V area of the neck, and extensor aspects of the

arms. Any area of the face including the eyebrows, eyelids, nose, and lips can be affected. A symmetric, hyperkeratotic, butterfly-shaped DLE plaque is occasionally found over the malar areas of the face and bridge of the nose. Such lesions should not be confused with the more transient, edematous, minimally scaling ACLE erythema reactions that occur in the same areas. DLE, like ACLE and SCLE, usually spares the nasolabial folds. When DLE lesions occur periorally, they resolve with a striking acneiform pattern of pitted scarring. DLE characteristically affects the external ear including the outer portion of the external auditory canal (Fig. 171-7A). Such lesions often present initially as dilated, hyperpigmented follicles. The scalp is involved in 60 percent of patients with DLE; irreversible, scarring alopecia resulting from such involvement has been reported in one-third of patients (Fig. 171-7B). The irreversible, scarring alopecia resulting from DLE differs from the reversible, nonscarring alopecia that patients with SLE often develop during periods of systemic disease activity. This type of hair loss, so-called “lupus hair,” may be telogen effluvium occurring as the result of flaring systemic disease.

FIGURE 171-7 Classic DLE and mucosal DLE in a 45-year-old African-American female with a 20-year history of untreated cutaneous LE. *A.* Characteristic involvement of the ear shows lesions with atrophy and postinflammatory hyperpigmentation as well as inflammatory red plaques on the scalp with postinflammatory hypopigmentation. *B.* Confluent lesions on the scalp have resulted in extensive scarring alopecia. *C.* Plaques of DLE on the palatal mucosa showing morphologic features similar to those of cutaneous lesions.

Localized DLE lesions occur only on the head or neck, whereas generalized DLE lesions occur both above and below the neck. DLE lesions below the neck most commonly occur on the extensor aspects of the arms, forearms, and hands, although they can occur at virtually any site on the body. The palms and soles can be the sites of painful, and at times disabling, erosive DLE lesions. On occasion, small DLE lesions occurring only around follicular orifices appear at the elbow and elsewhere (follicular DLE). DLE activity can localize to the nail unit. The nail can be impacted by other forms of cutaneous LE as well as SLE, producing nail fold erythema and telangiectasia, red lunulae, clubbing, paronychia, pitting, leukonychia striata, and onycholysis.

DLE lesions can be potentiated by sunlight exposure but to a lesser extent than ACLE and SCLE lesions. DLE, as well as other forms of LE skin disease activity, can be precipitated by any form of cutaneous trauma (i.e., the Koebner or isomorphic response).

The relationship between classic DLE and SLE has been the subject of much debate. [2], [5] The following summary points can be made: (1) 5 percent of patients presenting with classic DLE lesions subsequently develop unequivocal evidence of SLE; and (2) patients with generalized DLE (i.e., lesions both above and below the neck) have somewhat higher rates of immunologic abnormalities, a higher risk for progressing to SLE, and a higher risk for developing more severe manifestations of SLE than patients with localized DLE.

The following have been suggested as risk factors for the development of SLE in patients with DLE: diffuse nonscarring alopecia; generalized lymphadenopathy; periungual nail fold telangiectasia; Raynaud's phenomenon; SCLE/ACLE skin lesions; LE-nonspecific skin lesions such as vasculitis; unexplained anemia; marked leukopenia; false-positive tests for syphilis; persistently positive high-titer ANA assay; anti–single-stranded DNA antibody; hypergammaglobulinemia; an elevated erythrocyte sedimentation rate (especially >50 mm/h); positive, sun-protected, nonlesional lupus band test; and elevated levels of soluble IL-2 receptor.

Roughly one-fourth of patients with SLE develop DLE lesions at some point in the course of their disease, and such patients tend to have less severe forms of SLE. Figure 171-8 illustrates the relative risks for systemic disease activity that are associated with the clinical varieties of LE-specific skin disease.

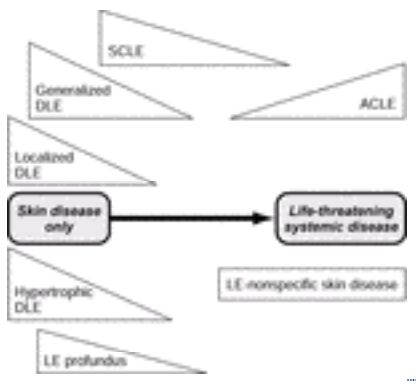

FIGURE 171-8 Relative risk for coexistence of or progression to SLE in patients presenting with various forms of LE-specific skin disease. The spectrum of LE is depicted as a disease continuum ranging from skin disease alone to life-threatening systemic disease.

Hypertrophic DLE, also referred to as hyperkeratotic or verrucous DLE, is a rare variant of CCLE in which the hyperkeratosis normally found in classic DLE lesions is greatly exaggerated. The extensor aspects of the arms, the upper back, and the face are the areas most frequently affected. Overlapping features of hypertrophic LE and lichen planus have been described under the rubric lupus planus. The entity lupus erythematosus hypertrophicus et profundus appears to represent a rare form of hypertrophic DLE affecting the face with the additional features of violaceous/dull red, indurated, rolled borders and striking central, crateriform atrophy. The name for this clinical entity is ambiguous because LE panniculitis is not characteristic of its histopathology. Patients with hypertrophic DLE probably do not have a greater risk for developing SLE than do patients with classic DLE lesions.

Patients with DLE in a linear configuration following the lines of Blaschko have been described. This rare subtype of DLE appears most frequently in children and seems to be associated with a low incidence of associated SLE. [26]

Mucosal DLE occurs in approximately 25 percent of patients with CCLE. The oral mucosa is most frequently affected; however, nasal, conjunctival, and genital mucosal surfaces can be targeted. In the mouth, the buccal mucosal surfaces are most commonly involved, with the palate (Fig. 171-7C), alveolar processes, and tongue being sites of less frequent involvement. Lesions begin as painless, erythematous patches that evolve to chronic plaques that can be confused with lichen planus. Chronic buccal mucosal plaques are sharply marginated and have irregularly scalloped, white borders with radiating white striae and telangiectasia. The surfaces of these plaques overlying the palatal mucosa often have a honeycomb appearance. Central depression often occurs in older lesions, and painful ulceration can develop. Oral mucosal DLE lesions can degenerate into squamous cell carcinoma, similar to long-standing cutaneous DLE lesions. Any degree of nodular asymmetry within a mucosal DLE lesion should be evaluated for the possibility of malignant degeneration. Chronic DLE plaques also appear on the vermilion border of the lips. At times, DLE involvement of the lips can present as a diffuse cheilitis, especially on the more sun-exposed lower lip.

The nasal, conjunctival, and anogenital mucosa can be sites of DLE lesions. Perforation of the nasal septum is more often associated with SLE than DLE. Conjunctival DLE lesions affect the lower lid more often than the upper lid. Lesions begin as focal areas of nondescript inflammation most commonly affecting the palpebral conjunctivae or the lid margin. Scarring becomes evident as lesions mature, and the permanent loss of eyelashes and ectropion can develop, producing considerable disability.

The risk for systemic disease activity in patients with LE and mucosal involvement is a function of the type of mucosal lesion present. Chronic mucosal DLE plaques are seen most commonly in patients with LE who do not have life-threatening manifestations of SLE. However, transient superficial oral or nasal mucosal ulcerations with a relatively nonspecific histopathology occur in patients with active SLE. Mucosal lesions of this type represent 1 of the 11 revised classification criteria for SLE of the American College of Rheumatology.

LESS COMMON SUBTYPES OF LE-SPECIFIC SKIN DISEASE LE profundus/LE panniculitis (Kaposi-Irgang disease) is a rare form of CCLE typified by inflammatory lesions in the lower dermis and subcutaneous tissue. Approximately 70 percent of patients with this type of CCLE also have typical DLE lesions, often overlying the panniculitis lesions. The term *LE profundus* is used to designate those patients who have both LE panniculitis and DLE lesions, whereas *LE panniculitis* refers to those having only subcutaneous involvement. Typical subcutaneous lesions present as firm nodules, 1 to 3 cm in diameter. The overlying skin often becomes attached to the subcutaneous nodules and is drawn inward to produce deep, saucerized depressions (Fig. 171-9). The head, proximal upper arms, chest, back, breasts, buttocks, and thighs are the sites frequently affected. LE panniculitis in the absence of overlying DLE may produce breast nodules that can mimic carcinoma clinically and radiologically (lupus mastitis). Confluent facial involvement can simulate the appearance of lipoatrophy. Dystrophic calcification frequently occurs in older lesions of LE profundus/LE panniculitis, and pain associated with such calcification can at times be the dominant clinical problem. Roughly 50 percent of patients with LE profundus/panniculitis have evidence of SLE. The systemic features of patients with LE panniculitis/profundus tend to be less severe, similar to those of patients with SLE who have DLE skin lesions.

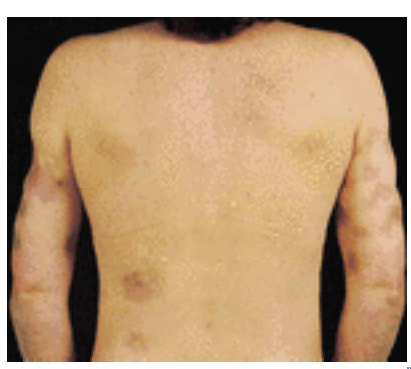

FIGURE 171-9 LE panniculitis. Lupus panniculitis has resulted in large, sunken areas of overlying skin; erythema and

atrophy of the skin are present.

Chilblain LE/perniotic LE lesions initially develop as purple-red patches, papules, and plaques on the toes, fingers, and face that are precipitated by cold, damp climates and are clinically and histologically similar to idiopathic chilblains (pernio). As they evolve, these lesions usually assume the appearance of scarred atrophic plaques with associated telangiectases. They may resemble old lesions of DLE or may mimic acral lesions of small vessel vasculitis. Histologic findings include a superficial and deep lymphocytic vascular reaction in addition to fibrin deposition in reticular dermal-based blood vessels. Patients with chilblain LE often have typical DLE lesions on the face and head. Chilblain LE appears to be associated with anti-Ro/SSA antibodies. [27] A recent study suggests that persistence of lesions beyond the cold months, a positive ANA, or presence of one of the other American College of Rheumatology criteria for SLE at the time of diagnosis of chilblain lesions helps to distinguish chilblain LE from idiopathic chilblains. [28] Approximately 20 percent of patients presenting with chilblain LE later develop SLE. Lupus erythematosus tumidus (LET; tumid LE) is a rare variant of CCLE in which the dermal findings of DLE, namely excessive mucin deposition and superficial perivascular and periadnexal inflammation, are found on histologic evaluation. The characteristic epidermal histologic changes of LE-specific skin disease are only minimally expressed, if at all. This results in succulent, edematous, urticaria-appearing plaques with little surface change (Fig. 171-10). The paucity of epidermal change often produces confusion concerning the diagnosis of LET as a form of cutaneous LE. Recently, there have been several reports of patients with this clinicopathologic presentation that have helped to alleviate some of this confusion. Ruiz and Sanchez [29] reported four patients who had firm diagnoses of classic DLE and/or SLE in addition to red-violet plaques on the upper body; histologic examination showed the dermal changes that occur in LE-specific skin disease. Kuhn et al. [30] reported a cohort of 40 patients with similar clinical and histologic features who were markedly photosensitive and who had a very high response rate to antimalarial therapy. [30] This cohort had a very low incidence of SLE, further suggesting that LET is a subset of CCLE. The authors noted that unlike classic DLE, however, LET lesions tend to resolve completely without either scarring or atrophy. [30], [31]

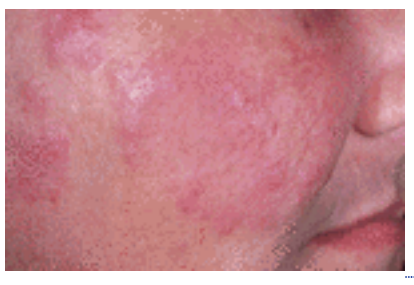

FIGURE 171-10 LE tumidus. Note succulent, indurated plaques.

Vesiculobullous Skin Change in LE

Vesiculobullous skin change in LE is a very confusing subject. [5] As with nonbullous LE skin disease, vesiculobullous skin lesions in patients with LE can be divided on the basis of histopathology into those that are LE-specific and those that are LE-nonspecific (Table 171-5). Bullae may develop in ACLE and SCLE as a manifestation of particularly aggressive liquefactive degeneration of the epidermal basal layer, resulting in basal cell dissolution and simulating the clinical and histopathologic appearance of toxic epidermal necrolysis. Vesiculobullous changes can develop at the active edge of annular SCLE lesions, and subepidermal bullous changes occasionally develop in DLE lesions.

LE-Specific Vesiculobullous LE
Acute cutaneous LE
Toxic epidermal necrolysis-like ACLE
Subacute cutaneous LE
Toxic epidermal necrolysis-like SCLE
Vesiculobullous annular SCLE
Chronic cutaneous LE
Bullous DLE
LE-Nonspecific Vesiculobullous LE
"Bullous SLE" (proposed alternative terms: dermatitis herpetiformis (DH)-like LE-nonspecific skin disease, epidermolysis bullosa acquisita (EBA)-like LE-nonspecific skin disease; LE-nonspecific vesiculobullous eruption of SLE)
Vesiculobullous skin disorders anecdotally reported to occur in LE patients but whose relationship to LE has not yet been firmly established
Bullous pemphigoid
Dermatitis herpetiformis
Pemphigus erythematosus
Porphyria cutanea tarda

TABLE 171-5 **Proposed Classification Scheme for Vesiculobullous Skin Disorders Encountered in Patients with LE**

The cutaneous entity described as bullous SLE is an example of LE-nonspecific bullous skin change. Patients who typically have or subsequently develop active SLE including nephritis occasionally develop a severe vesiculobullous eruption. Histopathologically, marked neutrophilic infiltration with papillary microabscess formation is present similar to that of dermatitis herpetiformis (DH) and the inflammatory variant of epidermolysis bullosa acquisita (EBA). However, the direct immunofluorescence findings are more typical of those of LE. Type VII collagen autoantibodies are present in some patients. Although the vague term *bullous SLE* is most often used to describe such lesions, more descriptive terms such as *DH-like cutaneous LE* or *EBA-like cutaneous LE* seem more appropriate inasmuch as other forms of bullous skin lesions can occur in patients with SLE, as noted above.

Other bullous skin diseases that have been linked anecdotally to LE include bullous pemphigoid, pemphigus erythematosus (the Senear- Usher syndrome), DH, and porphyria cutanea tarda. It is not clear whether there is a primary association between these bullous skin disorders and LE, or whether their coexistence is the result of chance alone.

LABORATORY FINDINGS

Table 171-4 summarizes the major laboratory findings associated with the varieties of LE-specific skin disease, and Table 171-6 presents the autoantibody associations of SLE. Because of the strong association between ACLE and SLE, the laboratory features of ACLE are those associated with SLE (high-titer ANA, anti–double-stranded DNA, anti-Sm, hypocomplementemia).

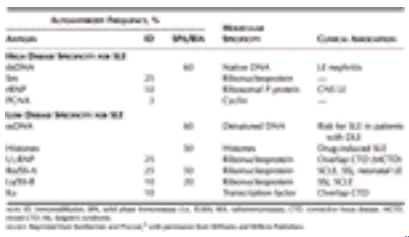

TABLE 171-6 **Autoantibodies Associated with Unselected SLE**

The laboratory markers for SCLE are the presence of anti-Ro/SS-A (70 to 90 percent) and, less commonly, anti-La/SS-B (30 to 50 percent) autoantibodies. ANA are present in 60 to 80 percent of patients with SCLE, and rheumatoid factor is present in approximately one-third. Other autoantibodies in patients with SCLE include false-positive serologic tests for syphilis [Venereal Disease Research Laboratory (VDRL) rapid plasma reagin] (7 to 33 percent), anticardiolipin (10 to 16 percent), antithyroid (18 to 44 percent), anti-Sm (10 percent), anti–double-stranded DNA (10 percent), and anti-U1 ribonucleoprotein (RNP) (10 percent). Patients with SCLE, particularly those with systemic involvement, may have a number of laboratory abnormalities including anemia, leukopenia, thrombocytopenia, elevated erythrocyte sedimentation rate, hypergammaglobulinemia, proteinuria, hematuria, urine casts, elevated serum creatine and blood urea nitrogen (BUN), and depressed complement levels (resulting from genetic deficiency or increased complement consumption).

ANA are present in low titer in 30 to 40 percent of patients with DLE; however, fewer than 5 percent have the higher ANA levels that are characteristic of patients with overt SLE (>1:320). Antibodies to single-stranded DNA are not uncommon in DLE, but antibodies to double-stranded DNA are distinctly uncommon. Precipitating antibodies to U1RNP are sometimes found in patients whose disease course is dominated by DLE lesions; however, such patients usually have only mild manifestations of SLE or overlapping connective tissue disorders such as mixed connective tissue disease. Precipitating Ro/SS-A and La/SS-B autoantibodies are rare in patients with DLE; low levels of anti-Ro/SS-A antibody detected by enzyme-linked immunoassay are more common. A small percentage of patients with DLE have low-grade anemia, biologic false-positive serologic tests for syphilis [VDRL, rapid plasma reagent (RPR)], positive rheumatoid factor tests, slight depressions in serum complement levels, modest elevations in gamma globulin, and modest leukopenia. It has been suggested that such findings are risk factors for the development of SLE. ANA are present in 70 to 75 percent of patients with LE profundus/panniculitis, but anti–double-stranded DNA antibodies are rare.

The laboratory findings associated with SLE, as well as with cutaneous LE, in both adults and newborns, have been reviewed. [5], [25], [32]

HISTOPATHOLOGY

The LE-specific skin disease histopathology is a distinctive constellation of hyperkeratosis, epidermal atrophy, vacuolar basal cell degeneration, dermal–epidermal junction basement membrane thickening, dermal edema, dermal mucin deposition, and mononuclear cell infiltration of the dermal–epidermal junction and dermis, focused in a perivascular and periappendageal distribution (Fig. 171-11). Variable degrees of these features are encountered in the different forms of LE-specific skin disease. Differences of opinion exist as to whether ACLE, SCLE, and DLE lesions can be distinguished reliably on the basis of their histopathologic appearances alone. [5], [8], [33]

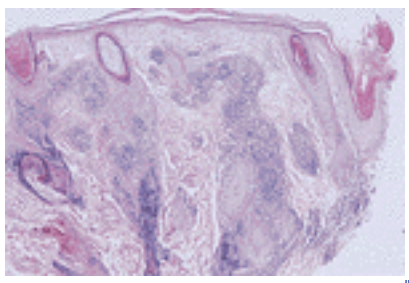

FIGURE 171-11 Histopathology of LE-specific skin disease. Histology of a DLE lesion demonstrating marked basal cell layer damage with vacuolization and irregularity of basal cell size. Mild hyperkeratosis is present.

ACLE

P>The histopathologic changes in ACLE lesions are generally less impressive than those in SCLE and DLE lesions, and are mainly those of a cell-poor interface dermatitis. The lymphohistiocytic cellular infiltrate is relatively sparse. Some authors have noted an increase in the number of neutrophils in the infiltrate. A mild degree of focal vacuolar alteration of basal keratinocytes can be seen, in addition to telangiectases and extravasation of erythrocytes. One may see individually necrotic keratinocytes, and in its most severe form, ACLE can display extensive epidermal necrosis similar to toxic epidermal necrolysis. The upper dermis usually shows pronounced mucinosis, and may be very helpful in

distinguishing ACLE from other causes of a cell-poor interface dermatitis. It is uncommon to see basement membrane zone thickening, follicular plugging, or alteration of epidermal thickness in ACLE, although epidermal atrophy is sometimes present. [33]

SCLE

SCLE also frequently presents as an interface dermatitis, with foci of vacuolar alteration of basal keratinocytes alternating with areas of lichenoid dermatitis. Pronounced epidermal atrophy is often present. SCLE is in the differential diagnosis of atrophic lichenoid dermatitis, along with atrophic lichen planus and lichenoid drug eruptions. Dermal changes include edema, prominent mucin deposition, and sparse mononuclear cell infiltration usually limited to areas around blood vessels and periadnexal structures in the upper third of the dermis. Lesser degrees of hyperkeratosis, follicular plugging, mononuclear cell infiltration of adnexal structures, and dermal melanophages might help distinguish SCLE lesions from DLE lesions. It has not been possible to differentiate papulosquamous from annular SCLE by histopathologic criteria alone. [8]

CCLE

In classic DLE lesions, epidermal changes include hyperkeratosis, variable atrophy, and interface changes similar to those described for SCLE. The epidermal basement membrane is markedly thickened. Dermal changes include a dense mononuclear cell infiltrate composed primarily of CD4 T lymphocytes and macrophages predominantly in the periappendageal and perivascular areas, melanophages, and dermal mucin deposition. The infiltrate is often quite dense and typically extends well into the deeper reticular dermis and/or subcutis, which may help to distinguish it from ACLE or SCLE. In chronic scarring DLE lesions, the dense inflammatory cell infiltrate subsides and is replaced by dermal fibroplasia. A folliculotropic variant of DLE, in which the inflammatory infiltrate is predominantly around hair follicles, has been described, as have lymphomatoid variants, in which there are extremely dense infiltrates that may contain atypical lymphoid cells. [33]

LESS COMMON SUBTYPES OF LE-SPECIFIC SKIN DISEASE The histopathology of hypertrophic DLE lesions is similar to that of classic DLE lesions except for a much greater degree of epidermal acanthosis and hyperkeratosis. At times, prominent acanthosis may simulate keratinocytic neoplastic processes such as squamous cell carcinoma. In LE panniculitis, the absence of the characteristic epidermal and dermal changes of LE can make the histologic diagnosis difficult. In LE panniculitis, subcutaneous tissue displays a lobular lymphocytic panniculitis with perivascular infiltration with lymphocytes, plasma cells, and histiocytes in the deep dermis and subcutaneous fat (including lymphoid nodule formation); vessel wall thickening and invasion by mononuclear cells (lymphocytic vasculitis); absence of polymorphonuclear leukocytes; hyaline fat necrosis; prominent fibrinoid degeneration of collagen; and mucinous degeneration and calcification in old, established lesions. Except for the differences related to the absence of hair follicles and stratum corneum in mucous membranes, the microscopic changes of mucosal DLE are highly reminiscent of those in cutaneous DLE lesions. Chilblain LE shows an interface dermatitis, with superficial and deep perivascular lymphocytic infiltration much like classic DLE. However, a lymphocytic vasculitis and fibrin within the lumina of dermal blood vessels are present in addition. [8], [33] In tumid LE, the dermal changes of DLE are present, namely a variable perivascular mononuclear infiltrate with prominent mucin between collagen bundles; but the classic epidermal changes that occur in other forms of LE-specific skin disease are not present. [29], [31] Histopathologic changes in vesiculobullous lesions of LE are noted above.

IMMUNOHISTOLOGY

Immunohistology is often helpful in confirming a diagnosis of LE-specific skin disease and has been shown to boost the sensitivity and specificity of diagnosis. [33] Because it is not uncommon to see negative immunofluorescence studies in patients with acute, subacute, and chronic LE, and false-positive studies in healthy individuals, immunohistology must be interpreted in the context of clinical and histologic findings in a given patient.

Immunoglobulins (IgG, IgA, IgM) and complement components (C3, C4, Clq, properdin, factor B, and the membrane attack complex C5b-C9) deposited in a continuous granular or linear bandlike array at the dermal–epidermal junction have been observed in the lesional and nonlesional skin of patients with LE since the early 1960s (Fig. 171-12). However, debate about terminology in this area continues to cloud the field. [5] Some restrict the use of the term lupus band test (LBT) to refer to the examination of nonlesional skin biopsies for the presence of this bandlike array of immunoreactants at the dermal–epidermal junction. Others qualify the LBT as being either “lesional” or “nonlesional.” Less confusion might exist if the terms lesional LBT or lesional lupus band and nonlesional LBT or nonlesional lupus band were uniformly adopted.

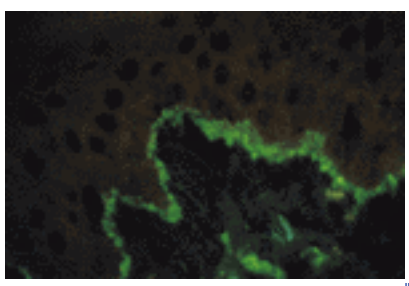

FIGURE 171-12 Immunopathology of LE-specific skin disease. Direct immunofluorescence examination of a DLE lesional skin biopsy showing a continuous band of granular fluorescence at the dermal-epidermal junction as a result of staining with fluorescein isothiocyanate-conjugated goat anti-IgG.

ACLE

The sparse data that exist suggest that 60 to 100 percent of ACLE lesions display a lesional lupus band. However, the realization that sun-damaged skin from otherwise healthy individuals can display similar immunopathology has diluted the clinical value of this finding.

SCLE

Initial studies indicated that approximately 60 percent of patients with SCLE had lesional lupus bands. A “dustlike particle” pattern of IgG deposition focused around epidermal basal keratinocytes has been suggested to be more specific for SCLE by reflecting the presence of in vivo-bound Ro/SS-A autoantibody.

CCLE

Early reports suggested that more than 90 percent of classic DLE lesions had lesional immunoreactants at the dermal–epidermal junction, often extending along the basement membrane of the hair follicle, but subsequent studies report somewhat lower rates. Lesions on the head, neck, and arms are positive more frequently (80 percent) than those on the trunk (20 percent). The lesional lupus band also appears to be a function of the age of the lesion being examined, with older lesions (>3 months) being positive more often than younger ones. Ultrastructural localization of immunoglobulin at the dermal–epidermal junction confirms that these proteins are deposited on the upper dermal collagen fibers and along the lamina densa of the epidermal basement membrane zone.

In LE profundus, immunoglobulin and complement deposits are usually found in blood vessel walls of the deep dermis and subcutis. Immunoglobulin deposits at the dermal–epidermal junction may or may not be present depending on the site biopsied, the presence or absence of accompanying SLE, and the presence or absence of overlying changes of DLE at the dermal–epidermal junction.

Nonlesional Lupus Band Test There has been much debate over the past three decades regarding the diagnostic and prognostic significance of an immunoglobulin/complement band at the dermal–epidermal junction of nonlesional skin taken from patients with LE. [5], [8] When totally sun-protected nonlesional skin (e.g., buttocks) is sampled, the diagnostic specificity for SLE appears to be very high when three or more immunoreactants are present at the dermal–epidermal junction. Prospectively ascertained follow-up data also suggest that the presence of a nonlesional LBT correlates positively with risk for developing LE nephritis. However, the nonlesional LBT has fallen out of favor as a clinical tool largely because the information gained from this invasive procedure has not been proven to be of significantly greater value than the results of more readily available serologic assays such as antibody to double-stranded DNA.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

ACLE

A number of unrelated dermatoses that can produce a red face, such as acne rosacea, dermatomyositis, seborrheic dermatitis, polymorphous light eruption, and photoallergic contact dermatitis, can be confused with localized ACLE. Routine histopathologic examination of a lesional skin biopsy is the most definitive way to make this distinction, since each of these red face look-alikes except for dermatomyositis has a pathology quite different from that of LE-specific skin disease (dermatomyositis can be distinguished from cutaneous LE by its nonfacial clinical features). Generalized ACLE can be confused with other causes of widespread exanthematous reactions such as drug hypersensitivity and viral infections.

SCLE

Papulosquamous SCLE can be simulated by the photosensitive variant of psoriasis. Annular SCLE lesions can be confused with erythema multiforme and other figurate erythemas such as erythema annulare centrifugum, erythema gyratum repens, and granuloma annulare. The photodistribution of SCLE lesions and the LE-specific histopathology are often crucial in helping the clinician differentiate SCLE from these other conditions. Seborrheic dermatitis, polymorphous light eruption, dermatophyte infections, nummular eczema, contact dermatitis, dermatomyositis, pityriasis rubra pilaris, disseminated superficial actinic porokeratosis, and cutaneous T cell lymphoma/mycosis fungoides have also been confused with SCLE. The presence of circulating Ro/SS-A autoantibodies further supports a diagnosis of SCLE.

CCLE

Although fully evolved classic DLE lesions are unlikely to be confused with other dermatoses, DLE lesions lacking all of the classic clinical findings might be confused with other disorders that produce persistent red plaques on the face such as plaque-type polymorphous light eruption; granuloma faciale; sarcoidosis; Jessner's benign lymphocytic infiltration of the skin; pseudolymphoma of Spiegler-Fendt (synonymous with Spiegler-Fendt sarcoid); lymphocytoma cutis; lymphoma cutis; angiolymphoid hyperplasia with eosinophilia; lupus vulgaris; and tertiary syphilis. The histopathologies of these conditions are quite distinct from that of DLE and would be expected to be negative for immunoglobulin and complement components at the dermal–epidermal junction on direct immunofluorescence microscopic examination. Hypertrophic DLE can be mistaken for keratoacanthoma, squamous cell carcinoma, prurigo nodularis, or hypertrophic lichen planus. The differential diagnosis of patients with lupus panniculitis includes Weber-Christian panniculitis; factitial panniculitis; meperidine (Talwin)-induced panniculitis; pancreatic panniculitis; traumatic panniculitis; morphea profundus; eosinophilic fasciitis; sarcoidosis; subcutaneous granuloma annulare; and rheumatoid nodules. Deep excisional biopsy may be required to distinguish LE panniculitis from these other disorders, particularly when classic DLE lesions are not present. With respect to the differential diagnosis, oral lichen planus presents the closest clinical appearance to that of oral

mucosal DLE.

TREATMENT

The initial management of patients with any form of cutaneous LE should include an evaluation to rule out underlying SLE disease activity at the time of diagnosis. All patients with cutaneous LE should receive instruction about protection from sunlight and artificial sources of UV radiation and should be advised to avoid the use of potentially photosensitizing drugs such as hydrochlorothiazide, tetracycline, griseofulvin, and piroxicam. With regard to specific medical therapy, local measures should be maximized and systemic agents used if significant local disease activity persists or systemic activity is superimposed.

ACLE lesions usually respond to the systemic immunosuppressive measures required to treat the underlying SLE disease activity that so frequently accompanies this form of cutaneous LE (e.g., systemic glucocorticoids, azathioprine, cyclophosphamide). Increasing evidence suggests that aminoquinoline antimalarial agents such as hydroxychloroquine can have a steroid-sparing effect on SLE, and these drugs can be of value in ACLE. The local measures discussed below can also be of value in treating ACLE. Because the lesions of SCLE and CCLE are often found in patients who have little or no evidence of underlying systemic disease activity, unlike the lesions of ACLE, nonimmunosuppressive treatment modalities are preferred for SCLE and CCLE (Table 171-7). For the most part, SCLE and CCLE lesions respond equally to such agents.

First line
Hydroxychloroquine (Plaquenil, Quineprox)
Hydroxychloroquine + quinacrine (Atabrine)
Chloroquine (Aralen) + quinacrine
Second line
Dapsone, retinoids (isotretinoin (Accutane), etretinate (Tegison), acitretin (Soriatane)), thalidomide
Third line
Clofazimine, gold
Fourth line
Systemic glucocorticoids
Oral prednisone
Pulse intravenous methylprednisolone
Azathioprine (Imuran)
Methotrexate
Cyclophosphamide (Cytoxan)
Evolving/experimental
Sulfasalazine, phenytoin (Dilantin), danazol, dehydroepiandrosterone, cytosine arabinoside (Cytarabine), cyclosporine, immunotherapy (high dose IV gamma globulin, CD4 T cell–depleting monoclonal antibody), phototherapy (UVA-I phototherapy, photopheresis)

TABLE 171-7 **Options for Systemic Therapy in Cutaneous LE**

Local Therapy

SUN PROTECTION Advise patients to avoid direct sun exposure, wear tightly woven clothing and broad-brimmed hats, and regularly use broad-spectrum, water-resistant sunscreens [SPF =15 with an efficient UVA blocking agent such as Parsol 1789 (avobenzone) or micronized titanium dioxide]. UV-blocking films should be applied to home and automobile windows, and acrylic diffusion shields should be placed over fluorescent lighting. Corrective camouflage cosmetics such as Dermablend and Covermark offer the dual benefit of being highly effective physical sunscreens as well as aesthetically pleasing cosmetic masking agents.
LOCAL GLUCOCORTICOIDS Although some prefer intermediate-strength preparations such as triamcinolone acetonide 0.1% for sensitive areas such as the face, superpotent topical class I agents, such as clobetasol propionate 0.05% or betamethasone dipropionate 0.05%, produce the greatest benefit in cutaneous LE. Twice-daily application of the superpotent preparations to lesional skin for 2 weeks followed by a 2-week rest period can minimize the risk of local complications such as steroid atrophy and telangiectasia. Ointments are more effective than creams for more hyperkeratotic lesions such as hypertrophic DLE. Occlusive therapy with glucocorticoid-impregnated tape (e.g., flurandrenolide) or glucocorticoids with plastic food wrap (e.g., Saran) can potentiate the beneficial effects of topical glucocorticoids but also carries a higher risk of local side effects. Class I or class II topical glucocorticoid solutions and gels are best for treating the scalp. Unfortunately, even the most aggressive regimen of topical glucocorticoids by itself does not provide adequate improvement for most patients with SCLE and CCLE.
INTRALESIONAL GLUCOCORTICOIDS Intralesional glucocorticoids (e.g., triamcinolone acetonide suspension, 2.5 to 5 mg/mL for the face with higher concentrations allowable in less sensitive sites) are more useful in the management of DLE than SCLE. Intralesional glucocorticoids themselves can produce cutaneous and subcutaneous atrophy (deep injections into the subcutaneous tissue enhances this risk). A 30-gauge needle is preferred because it produces only mild discomfort on penetration, especially when injected perpendicularly to the skin. The active borders of lesions should be thoroughly infiltrated. Intralesional therapy is indicated for particularly hyperkeratotic lesions or lesions that are unresponsive to topical glucocorticoids, but most patients with cutaneous LE have too many lesions to be managed exclusively by intralesional glucocorticoid injections.

Systemic Therapy

ANTIMALARIALS One or a combination of the aminoquinoline antimalarials can be effective for approximately 75 percent of patients with cutaneous LE who have failed to benefit adequately from the local measures described above. [34] The risks of retinal toxicity should be discussed with the patient, and a pretreatment ophthalmologic examination should be performed. However, the risk of antimalarial retinopathy is extremely rare if recommended daily dose maximum levels of these agents are not exceeded (hydroxychloroquine, 6.5 mg/kg per day; chloroquine, 4 mg/kg per day). Patients should have follow-up ophthalmologic evaluations every 6 to 12 months while on therapy. Hydroxychloroquine sulfate (Plaquenil), 400 mg/day by mouth, should be given for the first 6 to 8 weeks of treatment to reach equilibrium blood levels. Once an adequate clinical response has been achieved, the daily dose should be decreased to a maintenance dose of 200 mg/day for at least a year to minimize chances of recurrence (some authorities recommend even longer periods of inductive treatment). If no response is seen after 8 to 12 weeks, quinacrine hydrochloride, 100 mg/day (currently available in the United States only through compounding pharmacies), can be added to the hydroxychloroquine without enhancing the risk of retinopathy (quinacrine does not cause retinopathy). If after 4 to 6 weeks adequate clinical

control has not been achieved, consideration should be given to replacing the hydroxychloroquine with chloroquine diphosphate (Aralen), 250 mg/day. In Europe, chloroquine is generally felt to be more efficacious than hydroxychloroquine in treating cutaneous LE, perhaps due to the earlier therapeutic responses that might occur as a result of the shorter time period required to reach equilibrium blood levels with chloroquine as compared to hydroxychloroquine. Hydroxychloroquine and chloroquine should not be used simultaneously because of enhanced risk for retinal toxicity. Multiple side effects other than retinal toxicity are associated with the use of antimalarials. Quinacrine is associated with a higher incidence of side effects, such as headache, gastrointestinal intolerance, hematologic toxicity, pruritus, lichenoid drug eruptions, and mucosal or cutaneous pigmentary disturbance, than is either hydroxychloroquine or chloroquine. Quinacrine commonly produces a yellow discoloration of the entire skin in fair-skinned individuals, which is completely reversible when the drug is discontinued. Quinacrine can produce significant hemolysis in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency (this adverse effect has also been reported to occur rarely with hydroxychloroquine and chloroquine). Each of the aminoquinoline antimalarials can produce bone marrow suppression including aplastic anemia, although this effect is exceedingly rare with the current dosage regimens. Toxic psychosis, grand mal seizures, neuromyopathy, and cardiac arrhythmias occurred with the use of high doses of these drugs in the past; these reactions are uncommon with the lower daily dose regimens used today. Before therapy with hydroxychloroquine and chloroquine is begun, complete blood counts, as well as liver and renal function tests, should be performed; these tests should be repeated 4 to 6 weeks after therapy has been initiated, and every 4 to 6 months thereafter. A screen for hematologic toxicity when quinacrine is used is recommended more often. To reduce the risk of acute hemolysis, some authorities advocate confirming that patients are not deficient in G6PD activity before beginning treatment with antimalarials, especially quinacrine. Patients with overt or subclinical porphyria cutanea tarda are at particularly high risk for developing acute hepatotoxicity, which often simulates an acute surgical abdomen, when treated with therapeutic doses of antimalarials for cutaneous LE. It is also recommended to check urine levels of beta-human chorionic gonadotropin initially in women with childbearing potential, although recent evidence indicates that the risk to pregnant women of currently recommended dose regimens of antimalarials is minimal.

NONIMMUNOSUPPRESSIVE OPTIONS FOR ANTIMALARIAL-REFRACTORY DISEASE Some patients with refractory cutaneous LE (SCLE more than DLE) respond to diaminodiphenylsulfone (Dapsone). [35] An initial dose of 25 mg by mouth twice daily can be increased up to 200 to 300 mg/day if necessary. Significant dose-related hemolysis and/or methemoglobinemia can result from the use of diaminodiphenylsulfone, especially in individuals deficient in G6PD activity, and therefore complete blood counts and liver function tests should be performed regularly. Isotretinoin (Accutane), 0.5 to 2 mg/kg per day, and acitretin (Soriatane), 10 to 50 mg/day, have also been used in this setting, but their efficacy is limited by their side effects (teratogenicity, mucocutaneous dryness, hyperlipidemia). In addition, breakthrough of cutaneous LE activity has been a problem with the long-term use of retinoids. Thalidomide (Thalomid) (50 to 300 mg/day) is strikingly effective for cutaneous LE that is refractory to other medications. Several studies have cited response rates between 85 percent and 100 percent, with many patients experiencing complete remission. [36] However, strict prescribing regulations, put in place in the United States, in 1998, because of severe teratogenicity, make thalidomide challenging to dispense to women of childbearing potential. Sensory neuropathy is another toxicity associated with thalidomide, and approximately 25 percent of patients with cutaneous LE develop peripheral neuropathy while taking the drug. Most cases are reversible when therapy is stopped. Excess somnolence as well as constipation and other minor side effects sometimes limit its use, although these effects usually abate with lower daily doses. Relapses after the drug is stopped are common. Other drugs reported to be of value in the treatment of refractory cutaneous LE are gold (Auranofin, Myochrysine) and clofazimine (Lamprene); however, the benefit varies from case to case and both of these agents are associated with the risk of significant side effects. Vitamin E, phenytoin (Dilantin), sulfasalazine, danazol, dehydroepiandrosterone (DHEA), and phototherapy (UVA-I phototherapy, photopheresis) have also been reported in uncontrolled trials to be of value in cutaneous LE.

SYSTEMIC GLUCOCORTICOIDS Every effort should be made to avoid the use of systemic glucocorticoids in patients with LE limited to the skin. However, in occasional patients who have especially severe and symptomatic skin disease, intravenous pulse methylprednisolone has been used. In less acute cases, moderate daily doses of oral glucocorticoids (prednisone, 20 to 40 mg/day, given as a single morning dose) can be used as supplemental therapy during the loading phase of therapy with an antimalarial agent. The dose should be reduced at the earliest possible time because of the complications of long-term glucocorticoid therapy, especially avascular (aseptic) bone necrosis, a side effect to which patients with LE are particularly susceptible. Because steroid-induced bone loss occurs most rapidly in the first 6 months of use, all patients who do not have contraindications should begin agents to prevent osteoporosis with the initiation of steroid therapy. An excellent review describing current recommendations for prevention of bone loss and other side effects of systemic glucocorticoids has been published. [37] When the disease activity is controlled, the daily dosage should be reduced by 5- to 10-mg decrements until activity flares again or until a daily dosage of 20 mg/day is achieved. The daily dose should then be lowered by 2.5-mg decrements (some physicians prefer to use 1-mg dose decrements below 10 mg/day). Alternate-day glucocorticoid therapy has not been successful in suppressing disease activity in most patients with cutaneous LE or SLE. Prednisolone rather than prednisone should be used in patients who have significant underlying liver disease, because prednisone requires hydroxylation in the liver to become biologically active. Any amount of prednisone given as a single oral dose in the morning has less adrenal-suppressing activity than the same amount given in divided doses throughout the day. However, any given amount of this drug, taken in divided doses, has a greater LE-suppressing activity than does the same amount of drug given as a single morning dose.

OTHER IMMUNOSUPPRESSIVES Azathioprine (Imuran) (1.5 to 2.0 mg/kg per day orally) can play a glucocorticoid-sparing role in the severely affected patient with cutaneous LE. Mycophenolate mofetil (CellCept) (25 to 45 mg/kg per day orally) is a purine analogue similar to azathioprine, but with more specific inhibition of the de novo pathway in lymphocytes. This characteristic may allow for more efficacy and less toxicity in treating severe, recalcitrant cutaneous LE, including refractory erosive DLE of the palms and soles. [38] Methotrexate (7.5 to 25 mg orally 1 day per week) is effective for severe refractory cutaneous LE. A double-blind, randomized, placebo-controlled trial in patients with SLE showed that moderate doses of methotrexate (15 to 20 mg weekly) effectively controlled cutaneous and articular activity and permitted a reduction in prednisone dose. [39] Several biologic therapies are being studied at present, including a monoclonal antibody to CD40 ligand and another to IL-10. [9] T cell-depleting anti-CD4 monoclonal antibody therapy has been reported to be of value in refractory cutaneous LE. Other immunosuppressives that have been used anecdotally include cytosine arabinoside (Cytarabine) and cyclosporine. Immunotherapy with high-dose IV gamma globulin has also been used.

Surgical and Cosmetic Therapy

DLE lesions can produce permanent scarring alopecia, cosmetically disturbing dermal atrophy, and pigmentary changes. Patients so affected often ask about the possibility of cosmetic correction of these changes. Surgical interventions such as hair transplantation and dermabrasion carry finite risks because cutaneous LE is characterized by a tendency for nonspecific mechanical trauma, including surgical incision or laser ablation, to exacerbate disease activity (i.e., Koebner's phenomenon/isomorphic phenomenon). Some patients tolerate scar revision techniques, including dermabrasion, if they are on maintenance systemic therapy (e.g., antimalarials). Anecdotal reports of the successful management of active cutaneous LE with argon and pulsed dye laser therapy have appeared. Resurfacing of atrophic scars with the Erbium:YAG or carbon dioxide resurfacing laser has been reported to be beneficial. [40], [41] The injection of atrophic lesions with collagen or other similar materials should be avoided.

PROGNOSIS

ACLE

Both localized and generalized forms of ACLE lesions flare and abate in parallel with underlying SLE disease activity. Therefore, the prognosis for any given patient with ACLE is dictated by the pattern of the underlying SLE. Both 5-year (80 to 95 percent) and 10-year (70 to 90 percent) survival rates for SLE have progressively improved over the past four decades as a result of earlier diagnosis made possible by more sensitive laboratory testing and improved immunosuppressive treatment regimens. Ominous prognostic signs in SLE are hypertension, nephritis, systemic vasculitis, and central nervous system disease.

SCLE

Because SCLE has been recognized as a separate disease entity for only two decades, the long-term outcome associated with SCLE lesions has yet to be determined. It is the authors' experience that most patients with SCLE have intermittent recurrences of skin disease activity over long periods of time without significant progression of systemic involvement (we are aware of only one death directly attributable to SLE in approximately 150 patients with SCLE). Other patients enjoy long-term if not permanent remissions of their skin disease activity. A few patients have experienced unremitting cutaneous disease activity.

It has also been the authors' experience that approximately 15 percent of the patients with SCLE develop active SLE, including lupus nephritis. This subgroup of patients is marked by the presence of papulosquamous SCLE, localized ACLE, high-titer ANA, leukopenia, and/or antibodies to double-stranded DNA. Long-term follow-up studies of SCLE are required to determine the true risk of severe systemic disease progression in patients presenting with SCLE skin lesions. CCLE lesions, typically classic DLE, have also arisen in patients initially presenting with SCLE.

Evidence suggests that overlap occurs between SCLE and Sjögren's syndrome. Patients with SCLE who develop Sjögren's syndrome are at risk for developing the extraglandular systemic complications associated with Sjögren's syndrome, including vasculitis, peripheral neuropathy, autoimmune thyroiditis, renal tubular acidosis, myositis, chronic hepatitis, primary biliary cirrhosis, psychosis, lymphadenopathy, splenomegaly, and B cell lymphoma.

CCLE

Most patients with untreated classic DLE lesions suffer indolent progression to large areas of cutaneous dystrophy and scarring alopecia that can be psychosocially devastating and occupationally disabling. However, with treatment, skin disease can be largely controlled. Spontaneous remission occurs occasionally, and the disease activity can recrudesce at the sites of older, inactive lesions. Rebound after discontinuation of treatment is typical, and slower taper of medications during periods of inactivity is recommended. Squamous cell carcinoma occasionally develops in chronic smoldering DLE lesions.

Death from SLE is distinctly uncommon in patients who present initially with localized DLE. As previously discussed, patients presenting with localized DLE have only a 5 percent chance of subsequently developing clinically significant SLE disease activity. Generalized DLE and persistent, low-grade laboratory abnormalities appear to be risk factors for such disease progression.

LE-NONSPECIFIC SKIN LESIONS

LE-nonspecific skin lesions are lesions that occur in clinical settings other than LE. For the most part, LE-nonspecific skin lesions are seen in the setting of SLE. A comprehensive discussion of the numerous LE-nonspecific skin lesions can be found elsewhere. [5] From 20 to 70 percent of patients with SLE develop vasculitic lesions that range from palpable purpura to urticaria-like lesions to large ulcers. Most frequently, such lesions are the result of cutaneous small vessel leukocytoclastic vasculitis. Urticarial vasculitis (and chronic urticaria) is occasionally the presenting manifestation of SLE. However, some vessel-based skin lesions in patients with LE result from thrombotic vasculopathies rather than vasculitis. Skin lesions resulting from thrombotic occlusion of cutaneous vessels (livedo reticularis with or without ulceration, acral cyanosis, cutaneous infarction, Degos'-like lesions, atrophie blanche- or “livedo vasculitis”-like lesions) often occur in the setting of antiphospholipid antibody (i.e., anticardiolipin antibodies and/or lupus anticoagulant). Approximately 10 to 15 percent of patients with SLE have nail fold erythema and/or telangiectasia; however, this finding is more frequent in patients with dermatomyositis. The incidence of Raynaud's phenomenon in patients with SLE ranges between 18 and 46 percent and often occurs in patients with LE who have features of an overlapping connective tissue disease associated with anti-U1RNP antibodies, such as mixed connective tissue disease. Erythromelalgia (erythermalgia) has been found

on rare occasion to be associated with SLE.

Several forms of nonscarring alopecia occur in patients with SLE. Patients may have a transient, diffuse, nonscarring hair loss associated with exacerbations of their systemic disease that appears to be a form of telogen effluvium. Another form of nonscarring alopecia in patients with SLE, especially at the periphery of the scalp, has been termed lupus hair or wooly hair. Alopecia areata has occasionally been detected.

Other LE-nonspecific skin lesions include sclerodactyly, rheumatoid nodules, erythema multiforme-like lesions in the context of Rowell's syndrome, cutaneous mucinosis, anetoderma, cutis laxa, lichen planus, acanthosis nigricans, and cytophagic histiocytic panniculitis.

Nail changes, including pitting, horizontal and longitudinal ridging, leukonychia, onycholysis, dyschromia, nail bed atrophy, and telangiectasia of the cuticle nail fold, have been observed in patients with SLE. Red lunulae are thought to be a marker of SLE, although they have been seen in association with other disorders as well. [42] The pathogenesis is unknown, but both vascular dilatation and nail matrix/plate composition have been implicated. Most commonly, all 10 fingernails are involved. [42]

It is important to recognize LE-nonspecific skin lesions because they may be a marker of underlying systemic disease activity. In a recent study of 66 patients with SLE, those with LE-nonspecific lesions had significantly increased disease activity when compared to those with only LE-specific lesions and to those with both kinds of lesions. [43] Additionally, patients with more than one type of either LE-nonspecific or LE-specific skin lesions had a significant increase in systemic disease symptoms. This study adds to our understanding of LE skin lesions as markers of underlying systemic disease by documenting that both the type and the number of cutaneous diagnoses are important in assigning risk and in following activity of SLE.

Classic dermatomyositis (DM) is one of the idiopathic inflammatory myopathies (IIM). The IIM are a heterogeneous group of genetically determined autoimmune disorders that predominately target the skin and/or skeletal musculature, resulting in widespread, highly symptomatic, inflammatory cutaneous disease and/or skeletal muscle weakness. Of particular interest to the dermatologist is the subgroup of patients who express the hallmark cutaneous manifestations of DM for prolonged periods without clinical evidence of muscle weakness [clinically amyopathic DM (C-ADM; syn. DM siné myositis)] (see Table 172-1 for definitions of terminology used in this chapter). In a minority of patients with IIM, other organ systems such as the lungs (e.g., interstitial lung disease), joints (arthritis), and heart (e.g., cardiomyopathy, conduction defects) can also be the target of inflammatory injury. Differences exist between adult-onset and juvenile-onset DM. For example, juvenile DM displays higher rates of the hallmark skin lesions of DM and vasculopathy/vasculitis with the resulting complication of dystrophic calcification. Thus, the IIM can be conceptualized as a spectrum of illness with subgroups of patients who share common clinical and immunologic features at distinct positions along this spectrum (Fig. 172-1).

TABLE 172-1 **Dermatomyositis-Related Terminology Used in This Chapter***

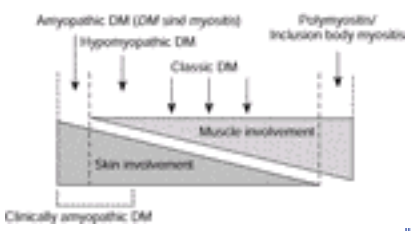

FIGURE 172-1 Graphic representation of the relationships between the cutaneous and muscular manifestations of the idiopathic inflammatory dermatomyopathies, including the nosologic entities within this spectrum of illness.

The diagnostic criteria for DM under the current consensus IIM classification system have not allowed for the inclusion of cutaneous-only or cutaneous-predominantly subsets of DM such as amyopathic DM and hypomyopathic DM (i.e., C-ADM) (Table 172-2). A more inclusive disease category designation, “idiopathic inflammatory dermatomyopathies” (IIDM), has been proposed as an alternative to the “IIM” designation since it allows for the inclusion of these cutaneous subsets of DM [1] (Table 172-3). For further discussion, the reader is referred to multiple comprehensive reviews of all aspects of DM, [1], [2], [3], [4], [5], [6], [7], [8], [9], [10], [11], [12], [13] and [14] including a historical perspective emphasizing the cutaneous

manifestations of DM. [2]

Clinical subgroups
1. Polymyositis
2. Dermatomyositis
3. Polymyositis or dermatomyositis associated with malignancy
4. Childhood dermatomyositis
5. Polymyositis or dermatomyositis with an associated connective tissue disorder
Diagnostic criteria
1. Typical skin rash
2. Symmetric proximal muscle weakness with or without dysphagia or respiratory muscle involvement
3. Abnormal muscle biopsy specimen
4. Elevation of skeletal muscle-derived enzymes
5. Abnormal electromyogram
Confidence limits for diagnosis of dermatomyositis
1. Definite dermatomyositis—rash and three of the four other diagnostic criteria
2. Probable dermatomyositis—rash and two of the four other diagnostic criteria
3. Possible dermatomyositis—rash and one of the four other diagnostic criteria

*While recent population-based European studies have clearly confirmed that adult-onset classic DM is associated with a significant risk for internal malignancy, if such a relationship exists for PM, it is much weaker.

TABLE 172-3 **Comprehensive Classification of Idiopathic Inflammatory Dermatomyopathies**

EPIDEMIOLOGY

Classic DM

Cutaneous involvement occurs in 30 to 40 percent of adults and in 95 percent of children with DM and polymyositis (PM). By definition, skin disease is absent in patients with PM and present in 100 percent of patients with classic DM and C-ADM. Skin disease commonly precedes muscle disease in classic DM by weeks to months.

The incidence of classic DM/PM between 1963 and 1982 was estimated to be 5.5 cases per million. The incidence probably is higher, inasmuch as this study was based on hospital-based diagnoses only and did not include cases of ADM. Black women during their childbearing years were affected most frequently, and DM might be underdiagnosed in blacks because of the more subtle coloration of inflammatory changes in their skin. Recent reports from Singapore, Hong-Kong, and Taiwan indicate that individuals of those ethnic backgrounds with DM are more likely to be male than female (females are affected twice as often as males in white populations). DM-associated interstitial lung disease appears to occur more commonly in Japanese patients than in other ethnic groups.

Classic DM can occur from infancy to adult life, most frequently presenting in the fifth and sixth decades (PM is extremely rare in children). Cutaneous ulceration occurring as a result of infarctive vasculopathy and calcification is more common in the childhood form of the disease. Familial concordance occurs rarely, and concordant disease expression has been reported in identical twins.

Environmental factors have been implicated as disease triggers. Seasonality, suggesting the possibility of an infectious etiology, has been noted in both childhood-onset and adult-onset DM/PM. DM- and PM-like syndromes have been reported in patients with Coxsackie virus, parvovirus B19, Epstein-Barr virus (EBV), AIDS, and human T cell leukemia virus type I infection. Other environmental factors that have been implicated include silicone breast implants and bovine collagen implants (however, the links to silicone implants and bovine collagen implants have not been established). In addition, drugs such as hydroxyurea, penicillamine, statin-type cholesterol-lowering agents, niflumic acid/diclofenac, phenytoin, tryptophan, and practolol can induce skin changes that mimic both classic DM and C-ADM. [1], [15]

Clinically Amyopathic DM

The incidence/prevalence of C-ADM in the United States is unknown, but it is assumed to be extremely low. However, most incidence data relating to classic DM have been collected from hospitalized patient populations fulfilling the Bohan and Peter diagnostic criteria, thereby excluding patients with C-ADM. Information related to the incidence of C-ADM in the United States derives predominately from the outpatient practices of academic dermatologists; in these settings, C-ADM is estimated to occur with approximately 10 percent the incidence of classic DM. In Europe, a similar incidence has been observed, [16] whereas in Asia, C-ADM appears to be relatively more common. A retrospective analysis of 28 patients with DM at the National Skin Center in Singapore between 1996 and 1998 revealed that 13 (46 percent) had C-ADM. [17] In another cohort of 143 Taiwanese patients with DM/PM treated in a veterans hospital system, C-ADM was

the second most commonly encountered subgroup (14 percent) after classic adult-onset DM (64 percent). C-ADM was somewhat more common than juvenile DM/PM (13 percent) and PM (10 percent) in this study. [18] Very little information currently exists about the incidence of juvenile C-ADM. In a retrospective analysis of all children with DM seen at an academic medical center in Pennsylvania between 1968 and 1998, 2 of 16 (12 percent) were categorized as having C-ADM. [19]

C-ADM appears to have an even stronger female preponderance than classic DM in the United States. In Asian patients, C-ADM appears to be more common in males. [18] One of the authors (RDS) has observed a familial constellation of ADM in a father and his only children—two adult daughters. Indirect evidence suggests that C-ADM has human leukocyte antigen (HLA) associations similar to those found in patients with classic DM (i.e., HLA-DQA1). [20]

Certain drugs can induce the cutaneous and/or systemic manifestations of DM/PM. [1], [15] Chronic hydroxyurea therapy for chronic myelogenous leukemia can produce a DM-like cutaneous eruption that is clinically and histopathologically similar to idiopathic DM-specific skin disease. [21] However, muscle weakness and other systemic symptoms are absent. Painful leg ulcers are often seen in association, as are xerosis and cutaneous atrophy. This symptom complex usually occurs only after the patient has been treated with hydroxyurea for long periods (2 to 10 years).

ETIOLOGY AND PATHOGENESIS

The inflammatory nature of the muscle and skin manifestations coupled with the characteristic humoral autoimmune abnormalities have led to the hypothesis that DM/PM results from a genetically determined, aberrant autoimmune response to environmental agents. Figure 172-2 presents a summary overview of current thought in this area. Like other systemic autoimmune diseases involving autoantibody production such as systemic lupus erythematosus (SLE), DM is thought to evolve through multiple sequential phases: the susceptibility phase, the induction phase, the expansion phase, and the injury phase.

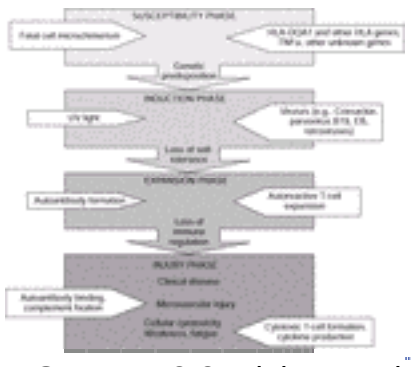

FIGURE 172-2 Etiology and pathogenesis of DM: current concepts. See text for discussion.

The susceptibility phase of DM is thought to result largely from a genetic predisposition. DM is one of the human autoimmune diseases that is linked to the 8.1 ancestral haplotype (HLA-A1, -C7, -B8, -C4AQ0, -C4B1, -DR3, -DQ2). [22] PM and DM have been specifically associated with HLA-B8, -DR3, and -DRw52, especially in white patients. This association is likely a result of linkage disequilibrium with HLA-DQA1*0501. The production of antisynthetase antibodies such as Jo-1 is strongly linked to HLA-DR3, and even more strongly linked to its supertypic specificity HLA-DRw52. A single nucleotide polymorphism in the tumor necrosis factor (TNF)-a promoter (TNF-a308A), which is also a component of the 8.1 ancestral haplotype, has been associated with disease chronicity, calcinosis, and high levels of TNF-a in a cohort of white patients with juvenile-onset classic DM. [23] In addition, there was a single case report of adult-onset DM in a young Japanese woman who was shown to be genetically deficient in the fifth component of complement. [24]

The cutaneous manifestations of DM are precipitated or exacerbated by natural and artificial sources of ultraviolet light. Approximately 50 percent of patients with DM experience photosensitivity. The action spectrum appears to include both ultraviolet B (UVB) and ultraviolet A (UVA). TNF-a308A promoter polymorphism has been linked to the photosensitive lupus erythematosus (LE)-specific skin disease subset, subacute cutaneous LE. [25] In these studies, epidermal keratinocytes containing this TNF-a allele produced exaggerated levels of TNF-a in the presence of interleukin (IL)-1a after exposure to ultraviolet B radiation. These observations raise the possibility that TNF-a–inhibiting therapy such as thalidomide or monoclonal antibodies (infliximab, etanercept) might be of value in selected patients with photosensitive DM as well as subacute cutaneous LE.

Environmental stimuli, including infection and ultraviolet irradiation, could represent inductive factors in DM leading to loss of self tolerance. Various types of infections have been circumstantially implicated as causative factors in DM. These include RNA viruses such as coxsackievirus, echovirus, and human retroviruses [i.e., human T cell leukemia/lymphoma virus type I (HTLV-1) and HIV]. Nonviral pathogens such as *Toxoplasma gondii* have also been implicated. However, repeated attempts to confirm persistent myotropic infection by viruses or other pathogens have not been successful.

The expansion phase of DM is marked by autoantibody production signaling loss of normal immune regulation. DM is associated with the production of a number of different autoantibody specificities (Table 172-4). Whether these autoantibodies are truly pathogenetic or represent only a by-product of muscle injury is unknown. It was recently suggested that C-ADM might be associated with a specific autoantibody profile (antibodies to 155 kDa and Se antigens). [26] It is assumed that autoantibodies and autoreactive T cells play a major role in the tissue-injury phase of DM. Cell-mediated immunity against muscle autoantigens is thought to be predominately responsible for the muscle injury that occurs in PM, whereas humoral autoimmune mechanisms have been implicated in the pathogenesis of muscle and skin injury in DM. Further evidence was presented recently supporting the concept that cell-mediated myocytotoxicity plays a

role in the pathogenesis of myositis. Both myocytotoxic CD3+ T cell clones and non–HLA-restricted myocytotoxic cells of other lineages have been identified in the peripheral blood of patients with inflammatory myopathies. [27] Little has been done experimentally to date to probe for cytotoxic epidermal or dermal cell injury in patients having DM skin disease activity.

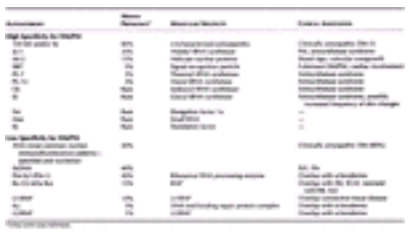

TABLE 172-4 **Autoantibodies in the Idiopathic Inflammatory Dermatomyopathies**

There is not always good agreement between the degree of muscle weakness or fatigue experienced by patients with classic DM and the degree of inflammation noted on muscle biopsy and elevation of serum muscle enzymes. This observation has led to the idea that inflammatory cytokines might be capable of mediating metabolic disturbances within muscle that can exacerbate muscle weakness and fatigue. [28] As with other rheumatic diseases such as systemic sclerosis, maternal microchimerism has been observed in children with juvenile classic DM. [29] The pathogenetic significance of the presence of alloreactive maternal lymphoid cells in the circulation, muscle, and skin of patients with juvenile DM is unknown. The overproduction of primary cytokines such as TNF-a after exposure to environmental stimuli such as UV irradiation could play a role in the induction of DM cutaneous inflammation.

The pathogenesis of cutaneous inflammation in C-ADM and classic DM requires study. The preliminary observation that patients with C-ADM might preferentially produce a pair of autoantibodies (155 kDa, Se) [26] could yield a new experimental approach to addressing this issue. It is not yet known whether these two autoantigens might be aberrantly expressed in the skin of patients with C-ADM endogenously or as a result of environmental stimuli (e.g., ultraviolet light), thereby targeting cutaneous tissue for autoantibody-mediated inflammatory injury.

The immunopathology of cutaneous DM includes a variable degree of immunoglobulin and complement deposition at the dermal–epidermal junction and within the dermal microvasculature. The predominate infiltrating cell types in cutaneous DM are activated macrophages and CD4 T cells, arguing for a cell-mediated pattern of immune injury.

The dermal microvasculature is more prominently altered in cutaneous DM than in cutaneous LE. It has been suggested that humoral factors could produce microvascular injury by triggering local activation of complement with deposition of C5–9, perhaps through endothelial-specific autoantibodies. Class II histocompatibility antigen expression by dermal endothelial cells is decreased in DM skin lesions, and this cell type appears to display an activation phenotype with respect to adhesion molecule expression [intercellular adhesion molecule-1 (ICAM-1), vascular cell adhesion molecule-1 (VCAM-1), and E-selectin].

Dermal mucin is a prominent finding in biopsies of DM skin lesions. It has been suggested that this might be caused by the increased production of glycosaminoglycans by dermal fibroblasts as a result of immunologic stimulation. Evidence suggesting that mononuclear cells from patients with DM can be cytotoxic for cultured dermal fibroblasts exists. Serum factors in patients with LE can stimulate the production of glycosaminoglycans by dermal fibroblasts. Recent work indicates that factor XIIIa+ dermal perivascular dendritic cells may be the source of abnormal mucin production in conditions such as the reticular erythematous mucinosis syndrome. [30] It is tempting to extrapolate these observations to autoimmune conditions that involve abnormal dermal mucin accumulation such as cutaneous LE and DM.

CLINICAL MANIFESTATIONS

Cutaneous Features

HALLMARK SKIN LESIONS Table 172-5 presents the hallmark cutaneous manifestations of DM and amyopathic DM (to date, no recognizable differences in the cutaneous manifestations of classic DM and amyopathic DM have been reported). Some of these lesions, such as Gottron's sign of DM (Fig. 172-3) and Gottron's papules (Fig. 172-3 and Fig. 172-4), are pathognomic of this disease, whereas others are highly characteristic, such as periorbital, confluent, macular, violaceous (heliotrope) erythema/edema, and grossly visible periungual telangiectasia/dystrophic cuticles. The primary skin change of DM is a highly characteristic, often pruritic, symmetric, confluent, macular violaceous erythema variably affecting the skin overlying the extensor aspect of the fingers, hands, forearms, arms, deltoid areas, posterior shoulders, and neck (the shawl sign), the V area of the anterior neck and upper chest, the central aspect of the face, periorbital areas, the forehead, and the scalp (Fig. 172-5 and Fig. 172-6). The lateral aspects of the hips and thighs (holster sign) are also frequently involved. [31] Lesions such as poikiloderma atrophicans vasculare (poikilodermatomyositis) (Fig. 172-7) and calcinosis cutis are often present in patients with DM but may also appear in patients with cutaneous T cell lymphoma (poikiloderma atrophicans vasculare) and scleroderma (calcinosis cutis).

Pathognomonic

1. Gottron's papules
   Papules having a violaceous hue overlying the dorsal-lateral aspect of interphalangeal and/or metacarpophalangeal joints. When fully formed, these papules become slightly depressed at the center, which can assume a white, atrophic appearance. Associated telangiectasia can be present.
2. Gottron's sign of DM
   Symmetric confluent macular violaceous erythema with or without edema overlying the dorsal aspect of the interphalangeal/metacarpophalangeal joints, olecranon processes, patellae, and medial malleoli.

Characteristic

1. Periorbital confluent macular violaceous (heliotrope) erythema with or without associated edema of the eyelids and periorbital tissue.
2. Grossly visible periungual telangiectasia with or without dystrophic cuticles and cuticular hemorrhage.
3. Symmetric confluent macular violaceous erythema overlying the dorsal aspect of the hands and fingers (where it can track along the extensor tendons), extensor aspects of the arms and forearms, deltoids, posterior shoulders and neck (shawl sign), V area of anterior neck and upper chest (V sign), central aspect of the face and forehead, and scalp.
4. Mechanic's hand lesion—bilaterally symmetric confluent hyperkeratosis having the appearance of that produced by manual labor distributed along the ulnar aspect of the thumb and radial aspect of the fingers; also prominent on the index and middle fingers with occasional extension to the palmar surfaces.

Compatible with dermatomyositis

1. Poikilodermatomyositis
   Circumscribed violaceous erythema with associated telangiectasia, hypopigmentation, hyperpigmentation, and superficial atrophy most commonly found over the posterior shoulders, back, buttocks, and V area of the anterior neck and chest. Often asymmetric.
2. Calcinosis cutis

TABLE 172-5 **Classic Cutaneous Manifestations of Dermatomyositis**

FIGURE 172-3 Hand of a 30-year-old female with a 15-year history of amyopathic DM. Note the confluent macular violaceous erythema, most pronounced over the metacarpophalangeal/interphalangeal joints, extending in a linear array over the extensor tendons overlying the hand and fingers. These changes, referred to as Gottron's sign, are a hallmark cutaneous feature of DM. Early Gottron's papules, an extension of Gottron's sign, can be seen over the distal interphalangeal joints along with periungual erythema and dystrophic cuticles. In DM, the violaceous erythema is centered over the metacarpophalangeal/interphalangeal joints, whereas in LE, these areas are relatively spared.

FIGURE 172-4 Fingers of an elderly female with classic DM. Note the fully formed Gottron's papules over the distal interphalangeal joints, a hallmark cutaneous feature of DM. Prominent, grossly visible nail fold telangiectasias are also present, along with dystrophic cuticles. The combination of Gottron's papules and nail fold changes such as these is pathognomic for DM. Such changes are seen to an equal degree in classic DM and amyopathic DM.

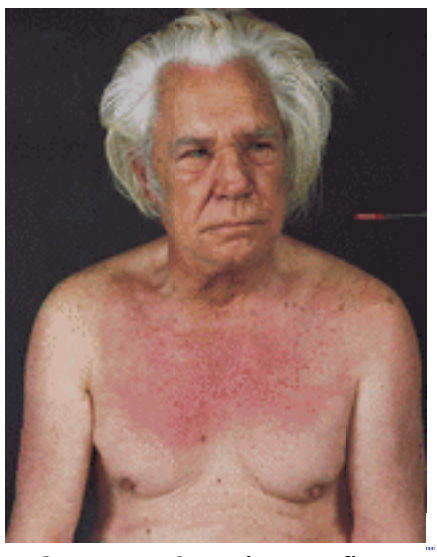

FIGURE 172-5 The confluent, macular, violaceous erythema of the V area of the upper chest and neck (V sign), when persistent over time, can evolve to poikilodermatous skin changes. Less evident in this photograph are periorbital edema and confluent, macular, violaceous (heliotrope) erythema of the upper eyelids. Note the absence of involvement of the malar areas, which are often involved in LE.

FIGURE 172-6 Periorbital confluent, macular, violaceous (heliotrope) erythema most prominent on the upper eyelids.

Like Gottron's papules and Gottron's sign, this is a hallmark cutaneous feature of DM.

FIGURE 172-7 An asymmetric plaque of poikiloderma atrophicans vasculare on the flank of a 55-year-old male with classic DM.

Several other types of skin lesions have been suggested to be characteristic of DM/PM; however, there is not yet enough published experience to determine their true disease specificity or prevalence. The mechanic's hand lesion consists of a nonpruritic, hyperkeratotic eruption accompanied by scaling, fissuring, and hyperpigmentation, giving the false appearance of the callused hands of a laborer. These changes are bilaterally symmetric and distributed along the ulnar aspect of the thumb and radial aspect of the fingers; they are prominent on the index and middle fingers with occasional extension to the palmar surfaces. It was originally suggested that there was a strong association between this skin lesion and the presence of active myositis and antisynthetase antibodies such as Jo-1. However, subsequent observations suggest that this skin change occurs in classic DM without elements of the antisynthetase syndrome, as well as in C-ADM. Table 172-6 presents the characteristic anatomic distribution of the hallmark cutaneous manifestations of DM. There is very little published information on the prevalence of involvement in these different anatomic locations. In some series reported by dermatologists, Gottron's papules have been more commonly seen than periorbital heliotrope erythema, which, by many outside of dermatology, is felt to be the hallmark cutaneous manifestation of DM.

Anatomic Location	Lesions
Scalp	Confluent, macular, violaceous erythema (CMVE) nonscarring diffuse alopecia
Face	
Periorbital region	CMVE (usually most intense on the upper eyelids), edema
Malar eminences	CMVE sparing the nasolabial fold
Forehead, chin	CMVE
Neck and shoulders	
Anterior	CMVE evolving to poikiloderma
Posterior	CMVE (shawl sign)
Upper extremities	
Arms, forearms	CMVE on the extensor aspects
Elbows	CMVE usually most intense in this location (Gottron's sign of CDM)
Hands, fingers	
Dorsal aspect	CMVE usually most intense over the extensor tendons and metacarpophalangeal/interphalangeal joints (Gottron's sign), Gottron's papules overlying the dorsal lateral aspect of the metacarpophalangeal/interphalangeal joints, relative sparing of the dorsal aspects of the phalanges, periungual nailfold telangiectasia (often greatly visible), cuticular microvascular hemorrhage, dystrophic/haggard cuticles
Palmar aspect	Mechanic's hand lesion, mucinous plaques centered over the flexural creases
Trunk	CMVE evolving to large areas of poikiloderma (poikiloderma atrophicans vasculare) commonly seen over the flanks and lower back
Lower extremities	
Thighs	CMVE (holster sign)
Knees	CMVE (Gottron's sign)
Lower legs, feet	CMVE often focal centered over the medial malleoli, Gottron's sign overlying the medial malleoli

TABLE 172-6 **Anatomic Distribution of Hallmark Cutaneous Manifestations of Dermatomyositis**

The violaceous hue of the cutaneous inflammation is a striking clinical finding that usually is evident from the outset of disease activity. This hue helps to distinguish cutaneous DM from cutaneous LE, in which it is a late finding when present. It has been suggested that edema associated with the DM skin disease indirectly produces the violaceous hue by displacing the hyperemic cutaneous vasculature more deeply into the dermis. It could also result from the deoxygenation of blood flow through an abnormal dermal microvascular bed. A striking clinical feature that helps to distinguish cutaneous DM from cutaneous LE is pruritus, which can be so severe in DM as to be disabling, even in the absence of systemic involvement. A number of other skin changes can be encountered in patients with DM. Hyperkeratosis may follow the onset of the confluent, macular, violaceous erythema; however, the scale in DM skin lesions is usually less prominent than that in subacute cutaneous LE and discoid LE. Secondary skin changes in DM skin lesions include excoriation with secondary infection and ulceration. Subepidermal vesicles and/or bullae occasionally occur in areas of particularly intense cutaneous inflammation. Postinflammatory pigmentary changes, both hyperpigmentation and hypopigmentation, occur. Older lesions may have white lacy markings somewhat similar to those of Wickham's striae in lichen planus. Other similarities between cutaneous DM and lichen planus include the characteristic violaceous hue. Mucinous infiltration, a common histologic finding in the dermis of DM skin lesions, can be clinically prominent, producing an infiltrated, glistening appearance. Superficial erosions and ulcers can subsequently develop over the face and eyelids, as well as in other areas affected by intense and protracted inflammation. Deep, irregular retiform ulcers can also develop in areas of poikiloderma in both adults and children. Clinical experience suggests that the activity of DM/PM can be precipitated or exacerbated by emotional and physical stress, although there is scant published evidence. Strenuous physical exertion can be detrimental to patients suffering from active myositis. Cutaneous calcification is more common in children than in adults with DM. The higher rate of vasculopathy/vasculitis that occurs in juvenile DM is thought to be a forerunner of dystrophic calcification. Approximately 25 percent of children with juvenile-onset classic DM have dystrophic calcification at the time of diagnosis, and 40 to 50 percent develop calcinosis sometime during the course of their illness. Some patients die from septic complications of ulcerating dystrophic calcification long after complete resolution of their myositis disease activity. In adults, calcification often presents as firm dermal and/or subcutaneous papules or nodules that are often most prominent around the elbows and hands. Large subcutaneous tumoral deposits can also occur over the trunk; such lesions can be filled with a liquid suspension of calcium crystals (i.e., “milk of calcium”). Four types of calcification have been described in children with DM: (1) a superficial pattern consisting of small, firm nodules and plaques in the skin; (2) periarticular subcutaneous nodules (calcinosis circumscripta); (3) deposition along fascial planes in muscles (calcinosis universalis) (Fig. 172-8); and (4) a severe “exoskeleton” pattern of deposition in the subcutaneous tissue. Calcinosis cutis or calcium deposition in muscles and tendons is more common in the late phases of the disease in children. The TNF-a308A promoter polymorphism might represent a risk factor for developing calcinosis. [23]

FIGURE 172-8 Calcinosis universalis. Calcification of subcutaneous tissue and pectoralis fascia in a child with DM.

Magnetic resonance imaging (MRI) may identify edema/ inflammation in skin, subcutaneous tissue, and fascia resulting from vasculopathy/vasculitis in patients with classic juvenile DM. [32] In approximately 80 percent of the 26 children studied, MRI abnormalities indicating skin, subcutaneous, and/or fascial edema were observed. Clinical skin disease activity scores correlated positively with MRI skin edema scores. Five children developed soft tissue calcification in areas previously found to be edematous by MRI after 4- to 9-month follow-up intervals. These observations suggest that the assessment of soft tissue by MRI could be of value in predicting risk for developing calcification and in monitoring treatment to prevent or minimize it. Dystrophic calcification appears to be quite uncommon in both adult- and juvenile-onset C-ADM. Little relationship was found between MRI indices of edema/inflammation in the superficial (skin and subcutaneous tissue) and deep (fascial and muscle) tissue compartments of patients with juvenile-onset classic DM. [32] DM can develop as a component of an overlap connective tissue disorder. Most common are overlaps with SLE and systemic sclerosis. Raynaud's phenomenon, sclerodactyly, sclerosis of the skin, and the characteristic hyperpigmentation can all be present in the latter setting. The term *sclerodermatomyositis* describes patients who present with DM and who develop striking features of scleroderma 6 months to 3 years later. In addition, myositis occurs in approximately 5 percent of anti-Ro/SS-A autoantibody-positive patients (most of whom have Sjögren's syndrome). The cutaneous manifestations of DM are usually not found in this setting. The highly pruritic scaling scalp involvement in patients with adult-onset classic DM and C-ADM that can be associated with nonscarring alopecia was also recently demonstrated to occur in approximately 25 percent of patients with juvenile-onset DM. [19]

UNCOMMON CUTANEOUS ASSOCIATIONS A number of rare cutaneous associations have been reported in patients with DM, including acquired ichthyosis; erythroderma; facial swelling without erythema; follicular hyperkeratosis; hypertrichosis; lichen planus; linear IgA bullous dermatosis; malakoplakia; malignant erythema (suffusion); mucous membrane lesions; nasal septal perforation; panniculitis; cutaneous mucinosis; glucocorticoid-induced acanthosis nigricans; urticaria/urticarial vasculitis; cutaneous vasculitis; vulvar and scrotal involvement; zebra-like stripes (i.e., centripetal flagellate erythema); malignant atrophic papulosis; and anasarca (reviewed in Ref. [5]). Recently, attention has been refocused on another unusual cutaneous finding of DM: pityriasis rubra pilaris (PRP)-like lesions (i.e., type Wong DM). [33] This variant usually presents as perifollicular keratosis over the extensor aspects of the upper extremities in adult-onset classic DM. [34] It can simulate the appearance of florid keratosis pilaris, and some such patients have had atopic dermatitis as well as DM. However, more widespread patterns of involvement that better simulate PRP have been described, although such patients have not had other classic features of PRP such as desquamative palmar plantar hyperkeratosis. Acquired lipodystrophy has been increasingly recognized in patients with juvenile classic DM. One report of 20 patients indicated that 25 percent had evidence of lipodystrophy, while 50 percent demonstrated hypertriglyceridemia and insulin resistance. [35] In another preliminary report, lipodystrophy was associated with calcinosis. [36] Gingival telangiectasia is an oral mucosal manifestation of juvenile-onset classic DM. [37] However, these mucosal changes are not specific for DM, occurring also in patients with LE and systemic sclerosis. Mucinous plaques centered over the flexural creases of the palms and fingers have also been seen in the context of DM/PM. [5], [38]

Systemic Features

Table 172-7 outlines the systemic manifestations and associations of classic DM/PM. Most of the extramuscular systemic features associated with classic DM have not been reported in amyopathic DM except for interstitial pneumonitis.

Musculoskeletal
Myositis with proximal weakness
Muscle atrophy and contracture*
Muscular calcification*
Cardiac
Cardiomyopathy
Conduction defects
Respiratory
Dysphonia
Diffuse interstitial pneumonitis/fibrosis
Aspiration pneumonia
Respiratory failure from muscle weakness
Gastrointestinal
Proximal dysphagia
Large bowel infarction/perforation secondary to vasculopathy*
Ophthalmologic
Retinopathy*
Internal malignancy†

*Usually limited to juvenile dermatomyositis.
†Not significantly increased in juvenile dermatomyositis.

TABLE 172-7 **Systemic Manifestations/Associations of Dermatomyositis/Polymyositis**

MUSCLE DISEASE Muscle involvement typically presents as symmetric weakness of the proximal muscles of the extremities. Lower extremity weakness manifesting as difficulty with routine activities of daily living, such as rising from a chair or bathtub and climbing stairs, is often the initial clinical finding. Weakness of the upper extremities soon follows, often manifest by difficulty in raising the arms above the head to perform routine activities such as combing the hair. Pain or tenderness in the affected muscle groups commonly occurs. Some patients experience a fulminant course, resulting in disabling weakness within a few weeks. Confirmation that proximal muscle weakness is caused by the inflammatory myositis of DM/PM can be difficult because so many other clinical disorders produce proximal muscle weakness (Table 172-8). The diagnosis can be supported by demonstration of characteristic serum muscle enzyme elevations, as well as identification of diagnostic electromyographic (EMG), muscle imaging, and muscle biopsy changes. It is possible that some patients with amyopathic DM suffer from low-grade, subclinical muscle disease (hypomyopathic DM). However, no

symptoms of muscular weakness develop in some patients who express the hallmark cutaneous manifestations of DM for 10 to 20 years.

Infectious myopathies
HIV-1, HTLV-I, coxsackievirus, echovirus, influenza, adenovirus, hepatitis B, Epstein-Barr virus
Other myopathies
Inclusion-body myositis, rheumatic disease vasculitis, muscular dystrophies, metabolic myopathies
Neurologic disorders
Myasthenia gravis, amyotrophic lateral sclerosis, Guillain-Barré syndrome
Endocrine disorders
Hypothyroidism and hyperthyroidism, Cushing's syndrome, diabetic neuropathy, hypokalemia
Drug-induced myopathies
Alcohol, antimalarials (vacuolar myopathy), colchicine, glucocorticoids, cyclosporine, street drugs (cocaine, heroin), lipid-lowering agents (lovastatin, simvastatin, gemfibrozil, clofibrate, niacin), D-penicillamine, zidovudine, isotretinoin/etretinate

SOURCE: Adapted from Evans and Sontheimer,[7] with permission of the publisher, Williams & Wilkins.

TABLE 172-8 **Conditions That Can Simulate the Proximal Muscle Weakness of Dermatomyositis/Polymyositis**

Inclusion-body myositis is a pathologically distinctive type of steroid-resistant myositis that more commonly affects the distal muscle groups of men in an asymmetric pattern. Cutaneous involvement is not seen with this disorder or with classic PM. Myositic inflammation can be highly focal. A number of noninvasive techniques are currently being examined for their ability to localize affected muscle groups. MRI is the method of choice for diagnostic imaging of muscle abnormalities in patients with myositis. [39] The possibility that MRI-guided needle biopsy could obviate the need for the more costly and invasive open muscle biopsy is being explored. In addition, MRI and ^{31}P magnetic resonance spectroscopy (MRS) are also useful in assessing the status of muscle disease activity during treatment with systemic glucocorticoids and other immunosuppressive drugs. These procedures are expensive and cannot be used in some individuals with metallic implants. Less costly approaches to monitoring muscle disease activity, such as power Doppler and gray-scale ultrasonography, are being examined. [40] Functional metabolic changes in muscles identified by MRS have been especially evident on exercise in some patients with amyopathic DM (such patients would better be classified as having “hypomyopathic DM”). Artificial neural networks have been proposed as an effective way to analyze the multichannel functional data that result from ^{31}P MRS examination. [41] A central issue in this area is whether the subtle muscular abnormalities that can be identified with these sensitive imaging systems have clear prognostic value. A retrospective analysis of all patients with DM seen at the Mayo Clinic between 1976 and 1994 revealed that 32 (4 percent) of 746 patients conformed to the definition of C-ADM [42]; 27 had amyopathic DM and 5 had hypomyopathic DM. Follow-up information was available on 16 of the patients with amyopathic DM. Ten had no muscle weakness after 2 to 10 years, 4 had no weakness at 1 year, and 2 developed weakness within 5 years after diagnosis. None of the three patients with hypomyopathic DM who were followed showed evidence of muscle weakness 8 to 17 years after diagnosis. Thus, of these 19 patients with C-ADM, only 2 developed clinical evidence of myositis after prolonged periods of time. The presence of subclinical muscle abnormalities at the time of diagnosis of amyopathic DM does not necessarily portend the subsequent development of clinically significant muscle disease. While fatigue and/or myalgia without objective evidence of muscle inflammation have been described in a number of C-ADM case descriptions, a single case report of documented fibromyalgia occurring in amyopathic DM has now appeared. [43] The symptoms of fatigue, muscle pain, and muscle tenderness associated with fibromyalgia could falsely imply the development of myositis in a patient with C-ADM. There continues to be debate concerning the risk for patients with juvenile-onset C-ADM of ultimately developing clinically significant myositis. Some groups see a relatively low risk, [44] while others see a relatively high risk. [45] To fulfill the definition of C-ADM, clinical evidence of muscle weakness should not be present. Muscle strength testing is graded on a scale of 1 to 5: 0 = no muscle action; 1 = trace contraction; 2 = visible contraction but unable to overcome gravity; 3 = fair contraction but can overcome gravity; 4 = contraction able to offer some resistance; 5 = evaluator cannot overcome contracted muscle. The examination should focus on the proximal muscle groups that control the neck, shoulders, and hips. Manual muscle testing is reproducible; variables such as pain, contractures, voluntary effort, and motivation may influence the ability of an individual to exert maximal muscle effort.

PULMONARY DISEASE Among the most feared nonmuscular systemic manifestations (Table 172-7) is pulmonary disease. Lung function can be compromised in a number of ways in patients with classic DM: a restrictive lung defect because of respiratory muscle weakness; aspiration pneumonia secondary to gastrointestinal reflux and impaired esophageal muscle function; opportunistic infections; or a pattern of interstitial pneumonitis related to the underlying autoimmune disease process. In addition, systemic drugs used to treat DM such as methotrexate can produce pulmonary complications (i.e., hypersensitivity pneumonitis). Interstitial pneumonitis resulting from both classic DM and C-ADM was recently reviewed. [46], [47] Between 5 and 40 percent of patients with classic DM develop interstitial lung disease (chest CT scan can identify earlier lung involvement than routine chest x-ray). This complication presents clinically with symptoms of nonproductive cough and exertional dyspnea that are accompanied by bibasilar fine crackling rales. Pulmonary function tests show a restrictive pattern with reduced diffusion capacity. Several clinical patterns of interstitial lung disease have been described: bronchiolitis obliterans organizing pneumonia; diffuse alveolar damage; desquamative interstitial pneumonia; nonspecific interstitial pneumonia; and respiratory bronchiolitis interstitial lung disease. Interstitial lung disease can present clinically as an acute/subacute type or a chronic type. In the acute or subacute type, patients present with severe, rapidly progressive dyspnea and progressive hypoxemia within a month from onset of lung involvement. Such a patient is often treatment-resistant and at risk for death. In the chronic type, patients present with a much slower pace of progressive dyspnea. Interstitial lung disease can also be identified by chest x-ray and/or pulmonary function tests in the complete absence of symptoms. It has been suggested that interstitial lung disease associated with the myositis-specific autoantibodies (antisynthetases) can occasionally occur in the absence of skin and muscle disease. [48] In some individuals, interstitial lung disease presents before the clinical appearance of myositis. Patients with classic DM who have the antisynthetase syndrome (Jo-1, PL-7, PL-12 or other synthetase autoantibodies; arthritis; Raynaud's phenomenon) have increased risk of developing interstitial lung disease. The antisynthetase syndrome and interstitial pneumonitis occur also in children with classic DM. Interstitial pneumonitis and air leakage were recently observed in one child with classic juvenile DM. [49] Interstitial pneumonitis and pulmonary fibrosis can complicate both C-ADM and classic DM. [50] In many cases, interstitial pneumonitis has occurred in patients with C-ADM in the absence of antisynthetase autoantibodies such as Jo-1, which are considered to be markers for interstitial lung disease risk in patients with classic DM. The prevalence of interstitial pneumonitis in C-ADM may approach 5 to 10 percent. A disproportionately high percentage of patients with C-ADM and interstitial lung disease has been reported from Japan, perhaps related to the fact that interstitial pneumonitis appears to be an especially common complication of classic DM in the Japanese. In addition, the acute/subacute pattern of disease presentation with rapidly progressive dyspnea,

progressive hypoxemia, treatment-resistance, and fatal outcome has been observed in a disturbingly high percentage of patients with C-ADM who develop pulmonary disease.

ARTHRITIS Arthritis occurs in 20 to 65 percent of patients with juvenile-onset classic DM. [51] Typically, this is a nonerosive arthritis involving knees, wrists, elbows, and fingers. It is seen early in the course of the disease. For some patients, arthritis can be a major symptomatic problem. Arthritis also occurs in some patients with juvenile-onset C-ADM. In one recent study, 3 of 5 patients with juvenile C-ADM (60 percent) followed over an average period of 4.9 years were reported to have arthritis, whereas 49 of 80 children with classic DM had arthritis. [51]

INTERNAL MALIGNANCY Population-based studies document that patients with DM have a higher than expected risk for malignancy. [52], [53], [54], [55] and [56] Relative risks for malignancy range from 2.4 in males with DM to 3.4 in females with DM. The risk for malignancies was negligible in patients with PM. During the 5-year period after the diagnosis of DM, the risk of a woman developing ovarian cancer in these studies was 16.7-fold higher than the risk for women without DM. In a more recent study, the standardized incidence ratio for malignancy in patients with DM was 6.5. In the first year following diagnosis, the relative risk for malignancy in patients with DM was 26.0. Females with DM in this study had a 32-fold higher risk of developing ovarian carcinoma. This study also found that PM was not associated with an increased risk of cancer and that the treatment of DM with cytotoxic drugs did not increase the risk of malignancy. Because of the risk of ovarian cancer in females with DM, it has been suggested that all women with DM (classic DM and amyopathic DM) undergo an initial and repeat comprehensive gynecologic examination at 6- to 12-month intervals at least for the first 2 years after the diagnosis. Cancer antigen-125 (CA-125) serum level determinations and transvaginal ultrasonography are also recommended for females with DM and intact ovaries. Tumors other than ovarian carcinoma have been reported with DM, including melanoma, mycosis fungoides, and Kaposi's sarcoma. Carcinomas are more frequent than sarcomas, and lymphoproliferative malignancies are uncommon. Except for ovarian cancer in women, no preponderance of specific types of cancer are seen in whites with DM/PM. Oriental males most frequently develop nasopharyngeal carcinoma. [52], [53] The diagnosis of cancer is most often made by history, review of systems, physical examination, and routine laboratory/radiologic testing. Debate exists about the routine use of surveillance imaging techniques, such as chest or abdominal computed tomography and/or MRI, in this setting. Age appears to be a factor in malignancy risk; there is not a significant risk of occult malignancy in children with juvenile-onset DM, whereas individuals 50 years of age or older at the time of onset of DM appear to have an increased risk of malignancy. The leading cause of death in patients with DM/PM who have malignancy is metastatic spread of the malignancy rather than complications directly related to the myositis. In patients with malignancy, the myositis and cutaneous manifestations are less responsive to systemic glucocorticoid therapy. In a few well-documented cases, definitive therapy for the malignancy resulted in resolution of the DM, and a recurrence of the cancer was associated with the reappearance of the DM. Increasing age, skin disease extent and severity (i.e., blistering, ulceration), and creatine kinase levels appear to enhance the risk of malignancy in patients with classic DM. It has been suggested that other systemic manifestations of DM, such as interstitial lung disease, are negatively correlated with risk for internal malignancy. [18] All routine age- and sex-directed malignancy surveillance guidelines should be followed. Repeat malignancy surveillance measures need to be carried out regularly (every 6 to 12 months) for the first 2 years after the diagnosis of DM. After 2 years, the risk of malignancy appears to fall back to that of the age- and sex-matched population in general. However, many physicians carefully observe such patients for the first 5 years after diagnosis. There is a broad consensus that serum tumor markers (e.g., CEA, CA-125, CA 15–3, MUC-1, TPS) are not sufficiently sensitive or specific enough for malignancy screening purposes in the general population. However, in a patient population (i.e., classic DM) having a higher incidence of a disease (i.e., malignancy), Bayes' theorem would argue that the usefulness of tumor markers should increase. [57] Thus, tumor markers such as those indicated above might be of greater value in monitoring for malignancy in patients with classic DM, especially if a trend of changing values is noted in multiple assays obtained sequentially over time in the same patient. [57] There have been no reports examining the role that screening for mutations in familial and sporadic cancer-associated genes such as BRCA-1/2 might have in stratifying the risk of malignancy in women with classic DM. There are no population-based data concerning the risk of internal malignancy in patients with C-ADM. In a recent systematic review of the world literature, approximately 300 published cases of C-ADM were identified, [58] and only 10 percent of these cases were associated with internal malignancy. Population-based studies will be required to resolve the apparent risk of malignancy in C-ADM. Until then it is recommended that the same approach to occult malignancy surveillance be used with patients with C-ADM as is used with patients with classic DM.

Relationship Between Cutaneous and Systemic Manifestations

There is little correlation between skin and muscle disease activity in DM. Patients who have skin and muscle disease at the outset of their illness and have all evidence of their disease activity suppressed by systemic immunosuppressive therapy can have DM skin disease activity return unaccompanied by muscle disease activity once their treatment has been discontinued.

Attempts have been made to correlate the periungual microvascular changes in patients with adult and juvenile DM by nail fold capillaroscopy (i.e., dilatation, tortuosity, budding or arborization, and avascularity) with the systemic manifestations of this disease process, including myositis. In our experience the periungual nail fold capillary changes in patients with C-ADM are qualitatively similar and as prominent as those in patients with classic DM. Similar changes can be seen in patients with systemic sclerosis and, to a lesser degree, in those with systemic LE and mixed connective tissue disease.

LABORATORY FINDINGS

Classic DM

MUSCLE ENZYMES An elevation in the level of serum creatine kinase (CK) is the most sensitive and specific laboratory indicator of muscle disease activity in DM/PM. Ninety percent of patients with classic DM/PM have elevated levels of CK at some point. The elevated CK activity is predominately caused by the CK-MM isoenzyme; however, elevations caused by the CK-MB isoenzyme are also seen. Elevated levels of CK can be associated with some of the disorders listed in Table 172-8 (e.g., other myopathies, hypothyroidism, and drug ingestions), as well as with strenuous physical exertion

and needle trauma (intramuscular injection, EMG needle insertion). Enzymatic detection of CK activity can at times be inhibited by serum factors. Levels of CK may become elevated before the development of weakness and can normalize several weeks before the return of normal strength during treatment. Patients with DM/PM who present with normal CK levels may have a worse prognosis with respect to pulmonary disease and associated malignancy. Levels of CK are usually normal in patients suffering from glucocorticoid-induced myopathy. Serum aldolase is a somewhat less sensitive indicator than CK for active myositis in DM/PM. However, aldolase levels are occasionally elevated in the presence of a normal CK level, especially in juvenile DM. Levels of transaminases (AST, ALT) and lactic dehydrogenase can also be elevated in active myositis, but these values are less useful clinically because of their low degree of specificity. Elevations of transaminase levels during treatment with methotrexate may reflect the activity of myositis, as well as drug-induced hepatotoxicity. Urinary creatine excretion can also be used to monitor the status of myositis. However, the specificity is low in that urinary creatine excretion can also be elevated in steroid myopathy. Serum myoglobin levels can also be elevated in DM/PM.

AUTOANTIBODIES Elevated antinuclear antibody (ANA) levels with human tumor cell substrates are found in 60 to 80 percent of patients with classic DM. Autoantibodies of known molecular specificity in DM are now categorized into two groups: myositis-specific autoantibodies and myositis-associated autoantibodies. [59], [60] Myositis-specific autoantibodies include the antisynthetases (Jo-1, PL-7, PL-12, OJ), Mi-2, and SRP. PM/Scl, Ro/SS-A (Ro52, Ro60), and U1RNP represent the major myositis-associated autoantibodies. Table 172-4 lists the molecular specificities and clinical correlations of these autoantibodies. The fact that none of the myositis-specific autoantibodies occurs with a prevalence greater than 1 in 5 of patients with DM makes routine clinical testing for these autoantibodies of little clinical use. Among the most frequently encountered myositis-specific autoantibodies are those that target the various aminoacyl transfer RNA synthetases. Of these “antisynthetase” autoantibodies, autoantibodies to Jo-1 (histidyl transfer RNA synthetase) are the most common, being found in 20 percent of patients with classic DM/PM overall and 30 to 40 percent of adult patients with PM. Fever, interstitial lung disease, polyarthritis, Raynaud's phenomenon, and incomplete response to therapy occur more often in patients who produce these antibodies (the “antisynthetase syndrome”), as does the mechanic's hand skin lesion. Patients who produce Jo-1 antibodies less frequently display the classic cutaneous manifestations of DM. Signal-recognition particle (SRP) antibodies occur in 5 percent of patients with PM and are more common in those who exhibit acute-onset, severe, treatment-resistant forms of classic DM/PM with cardiac involvement. Such patients rarely have any type of skin involvement. Autoantibodies to Mi-2, a nuclear protein complex, are seen almost exclusively in patients with classic DM. Mi-2 antibody is found in 5 to 10 percent of patients with classic DM/PM overall, and in 15 to 20 percent of patients with classic DM. This autoantibody is associated with more treatment-responsive forms of classic DM, as well as with the shawl sign and prominent cuticular changes. The clinical correlations of the myositis-specific autoantibodies found in adults also occur in children with classic DM/PM. DM/PM autoantibodies that currently have less clinical significance are also listed in Table 172-4.

OTHER LABORATORY ABNORMALITIES The erythrocyte sedimentation rate is elevated in about half of patients with classic DM/PM, but it does not closely correlate with disease activity. Rheumatoid factor is elevated in 20 percent of cases, more often in patients with overlap disease. Other serum factors such as neopterin and factor VIII-related antigen (von Willebrand factor) and CD19+ B cells [23] have been reported to correlate with disease activity in children with classic DM. Elevated levels of other markers of vascular activation including soluble forms of VCAM-1 and E-selectin have also been reported to occur in the circulation of patients with classic DM. KL-6 is a human MUC-1 class mucin that is preferentially expressed on type II pneumocytes. KL-6 has been proposed to be a sensitive serum marker for the presence of interstitial pneumonia in the setting of classic DM (reviewed in Ref. [61]).

ELECTROMYOGRAPHY The EMG changes of myositis include a myopathic pattern of the motor unit action potential, a myopathic recruitment pattern, increased insertional activity, and increased spontaneous activity. EMG changes of myositis can be erratically distributed. The paraspinous muscles can be abnormal by EMG when the limb girdle musculature is normal. As many as 10 percent of patients with biopsy-documented myositis have a normal EMG.

Clinically Amyopathic DM

By definition, the levels of CK and other muscle enzymes are normal in amyopathic DM. Most of the reported patients with C-ADM are ANA-positive. However, such patients do not appear to produce myositis-specific or myositis-associated antibodies. Preliminary studies have indicated that a unique pair of new autoantibody specificities (155 kDa and Se) might serve as serologic markers for this subset of patients with DM. [26], [62] When the results of immunoblot and immunoprecipitation studies employing HeLa cell extracts were combined, 16 of 18 (89 percent) white adult patients with C-ADM showed autoantibodies to the 155-kDa autoantigen and/or the Se autoantigen. The molecular identities of these autoantigens have not yet been revealed, but neither appears to be associated with RNA. If these preliminary results can be confirmed, they could provide a useful clinical tool for confirming a diagnosis of C-ADM. As in classic DM, serum levels of KL-6 are also suggested to be correlated with the activity of interstitial pneumonia in patients with C-ADM. [63]

HISTOPATHOLOGY

Skin

The earliest histologic appearance of cutaneous DM is similar to normal skin except for PAS-positive thickening of the basement membrane, a smudgy, homogeneous appearance of the papillary dermis, and increased dermal mucin and edema. No lymphocytic infiltrate is seen at this stage, and vacuolar alteration of basal keratinocytes, pigment incontinence, and colloid body formation are variably present. Biopsy specimens from more advanced lupus-like skin lesions (i.e., scaling violaceous erythema) have changes similar to or indistinguishable from those of LE. These changes include hyperkeratosis, epidermal atrophy, and effacement of the rete ridges. An interface dermatitis with vacuolar degeneration of the basal keratinocytes and a sparse, superficial, patchy, or bandlike perivascular lymphocytic infiltration can also be seen, along with thickening of the basement membrane and pigment incontinence. The dermis is often pale as a result of the accumulation of edema and mucin. In poikiloderma, these same features are encountered except that ectatic dermal vessels are present. Hyperkeratosis, acanthosis, undulating papillomatosis, vacuolar alteration of basal keratinocytes, thickened basement membrane, variable lymphocytic exocytosis, and increased mucin deposition in the epidermis are seen in Gottron's papules. The cutaneous histologic changes of amyopathic DM are reportedly indistinguishable from those of classic cutaneous DM. Lipomembranous (membranocystic) changes previously thought to

be specific for panniculitis have been noted in the histopathology of punched-out ulcers of DM. No differences in the histopathology or immunopathology of the cutaneous manifestations of classic and amyopathic DM have been observed.

Muscle

Muscle fiber degeneration/regeneration, perifascicular atrophy, and capillary injury are frequently present in the muscle biopsies of patients with DM/PM. A perivascular infiltrate of T lymphocytes and histiocytes and occasionally B lymphocytes, plasma cells, and eosinophils is also seen. Biopsies from patients with DM often show CD4 T cells and B cells in the perivascular areas, whereas CD8 T cells preferentially associate with damaged muscle fibers in patients with PM. The capillary density in muscle specimens from patients with DM is decreased. Inflammation may be absent in up to 25 percent of biopsy specimens from patients with otherwise typical muscle disease by clinical, electromyographic, or biochemical criteria.

An occlusive vasculopathy is a striking aspect of the pathology of childhood DM/PM. Phlebitis and arteritis leading to intimal hyperplasia, fibrinous occlusion of vessels, and infarction of the involved tissues can be seen. The muscles, gastrointestinal tract, and nerves are particularly affected. This vasculopathy in muscles is noninflammatory and occurs predominately in the capillaries. There is a spectrum of endothelial changes from swelling to obliteration to necrosis.

IMMUNOHISTOLOGY

Skin

Bandlike granular deposits of immunoglobulin and complement along the dermal–epidermal junction, subepidermal cytoid bodies, dermal connective tissue staining, and epidermal cytoplasmic staining have been described in DM skin lesions. Lesional dermal–epidermal junction immunoglobulin and complement bands reportedly occur in 5 to 86 percent of patients, depending on the site of biopsy, with the nail fold being a high-prevalence area. However, similar findings can be observed in actinically exposed skin of otherwise normal individuals. It has been suggested that components of the complement membrane attack complex (C5–9) are more often present in the dermal microvessels than at the dermal–epidermal junction in cutaneous DM lesions, whereas the opposite occurs in cutaneous LE lesions. However, there is no general agreement in this area.

The dermal infiltrate of cutaneous DM lesions contains predominately macrophages and CD4 T lymphocytes, some of which demonstrate an activation phenotype. Focal HLA-DR antigen expression has been noted on lesional keratinocytes while being reduced on dermal endothelial cells.

Muscle

Immunoglobulin and complement deposition occur in affected muscle tissue, albeit inconsistently and unrelated to disease activity. The presence of the complement membrane attack complex in muscle capillaries suggests that local activation of complement with resulting endothelial cell toxicity could be related to the microvascular abnormalities of this disorder.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

In the earlier stages, cutaneous DM might be confused with contact dermatitis, seborrheic dermatitis, lichen planus, psoriasis, polymorphic light eruption, and atopic dermatitis. In the later stages, when the more typical cutaneous manifestations of DM have evolved, the greatest challenge can be to distinguish the skin involvement of DM from that of LE (Table 172-9). Periorbital heliotrope erythema and edema can occasionally be seen in SLE, but Gottron's papules are never seen as a cutaneous manifestation of LE. The pattern of involvement over the hands also differs; in LE the skin over the dorsal interphalangeal and metacarpophalangeal joints is spared, and the skin between these joints is preferentially involved. The exact opposite is true for DM; the skin overlying the dorsal interphalangeal and metacarpophalangeal joints is usually affected first (Fig. 172-3). However, when extensive, the linear streaking of violaceous erythema along the track of the extensor tendons of the hands and fingers can sometimes obscure this point of differential diagnosis.

TABLE 172-9 **Comparative Features of Skin Involvement in Dermatomyositis and Lupus Erythematosus**

As previously noted, certain drugs can produce an eruption with clinical similarities to cutaneous DM. Multicentric reticulohistiocytosis has been reported to masquerade as DM. However, the “string of pearls” papules that occur in the periungual areas in multicentric reticulohistiocytosis can be clearly distinguished from the periungual inflammatory changes of DM by clinical and pathologic examination. Many conditions other than DM/PM can be associated with proximal muscle weakness. [64] Table 172-8 outlines these disorders.

TREATMENT

While systematically ascertained information exists about the treatment of the muscle manifestations of DM, virtually no such information exists that is related specifically to treatment of the cutaneous manifestations of this disease.

Local

Patients with either classic or amyopathic DM should avoid excessive sun exposure and use substantive broad-spectrum sunscreens. An in-depth discussion of practical and theoretical photoprotection and local therapy for autoimmune connective tissue skin disease such as DM was recently presented elsewhere. [65] Topical glucocorticoids (classes I and II) can dampen cutaneous inflammation and pruritus, and such agents can be used safely for prolonged periods of time when administered cyclically (2 weeks of daily treatment followed by 2 weeks off treatment). However, these agents alone usually cannot fully suppress DM skin disease activity. Daily use of a medicated shampoo followed by application of a topical glucocorticoid solution, gel, spray, or foam to the affected areas can provide relief for the scalp pruritus. Xerosis is often present, especially in the elderly, and effective moisturization regimens can be of value in managing the pruritus often experienced by patients with DM. Topical antipruritic agents such as combinations of menthol/phenol/camphor, pramoxine, and doxepin can provide short-term relief.

Systemic

When possible, nonsteroidal systemic therapy should be maximized. Doxepin, a tricyclic antidepressant, is a potent H_1- and H_2-blocking antihistamine. When given at bedtime in doses of 10 to 50 mg, it can ameliorate pruritus and excoriation. Conventional or nonsedating antihistamines can be used during the day. Hydroxychloroquine sulfate (6 mg/kg per day given as two divided doses) has been used to treat DM skin disease. Some patients respond better to a combination of hydroxychloroquine and quinacrine, 100 mg/day, or to chloroquine (4 mg/kg per day) and quinacrine (100 mg/day). However, the authors' experience has been that even with combination therapy, only a minority of DM patients respond fully. Precautions should be taken to minimize the risk of retinal toxicity with hydroxychloroquine or chloroquine and hematologic toxicity with quinacrine. If extrapolation from the experience gained from patients with cutaneous LE is valid, patients with DM who smoke cigarettes might be less responsive to antimalarial therapy than those patients who do not smoke. It should be remembered that on rare occasion antimalarials can contribute to muscular weakness by causing a vacuolar myopathy. Dapsone has recently been suggested to be of value for the cutaneous manifestations of DM.

Systemic glucocorticoids remain the traditional first-line therapy for classic DM. Early intervention with systemic glucocorticoids is associated with a better overall prognosis. In adults, prednisone (prednisolone for those with decreased liver function) is given orally in divided doses of 1 to 1.5 mg/kg per day, while children are given 1 to 2 mg/kg per day. Significant improvement of muscle strength, normalization of muscle enzyme levels, and improvement in cutaneous inflammation are the end points of therapy. Most patients require 1 to 3 months of full-dose treatment with prednisone. With improvement, the dose can be consolidated from a divided dose to a single daily dose given in the morning to reduce the risk of adrenal suppression and other glucocorticoid side effects. The glucocorticoid dose can then be progressively decreased. Treatment should be continued for 12 to 24 consecutive months to minimize the chance for recurrence. Attention should be paid to managing the side effects of long-term systemic glucocorticoids. In acutely ill patients, intravenous pulse therapy with methylprednisolone can be used; this approach has become increasingly popular in the management of juvenile DM. Alternate-day glucocorticoids usually do not provide adequate relief during active phases of the disease. The cutaneous lesions of DM can be refractory to high-dose, long-term glucocorticoids in some patients. Other patients have recrudescent disease activity only in their skin after complete suppression of their muscle disease with systemic glucocorticoid therapy.

Systemic glucocorticoids have also been used for the disabling skin disease activity in patients with amyopathic DM. However, it remains to be determined whether early aggressive immunosuppressive treatment of C-ADM might prevent the development of clinically significant myositis later.

Approximately 25 percent of patients with classic DM/PM do not respond adequately to systemic glucocorticoids within the first 2 months of treatment. Azathioprine (1 to 2 mg/kg per day), cyclophosphamide (1 to 2 mg/kg per day), methotrexate (10 to 50 mg/week), chlorambucil (2 to 6 mg/day), cyclosporine (3 to 5 mg/kg per day), and mycophenolate (1 to 1.5 g/day) have been used in this setting for patients who cannot tolerate the side effects of high-dose glucocorticoids. Extracorporeal photochemotherapy has been explored as an adjunctive therapy.

Oral methotrexate (10 to 25 mg) given once weekly has also been successful in the treatment of patients with classic DM and some patients primarily affected by the cutaneous manifestations of DM. Higher doses can be given subcutaneously or intravenously; the intramuscular route may spuriously elevate muscle enzyme levels. Cyclosporine and cyclophosphamide have each been reported to be of benefit in severe complications of interstitial lung disease in patients with C-ADM, especially when started before frank respiratory failure has developed. [66], [67] In children, oral cyclophosphamide (2 to 4 mg/kg per day) has traditionally been used in cases that could not be satisfactorily managed by systemic glucocorticoids. High-dose intravenous gamma globulin therapy has been used in both children and adults in this setting, with the advantage of low toxicity. A controlled clinical trial has indicated that plasmapheresis and leukapheresis have little additional value in the management of DM/PM.

Based on experimental evidence indicating a role for TNF-a in the pathogenesis of the classic DM muscle inflammation, anti–TNF-a therapy was recently used on an anecdotal basis for both the muscular and cutaneous manifestations of DM. A small number of cases of severe, treatment-resistant DM have been successfully treated with etanercept (Enbrel) or infliximab (Remicade), and thalidomide has been used in several centers. More systematic study is needed to define the value of such treatment. Such therapy would have to be used with caution concerning the possibility of its uncovering other patterns of systemic autoimmunity (e.g., SLE).

Because enzymatic indicators of muscle inflammation tend to normalize quite quickly after systemic therapy is begun, other surrogate markers of DM systemic disease activity are used by some to guide therapy. Such markers include the vWF:Ag, CD19+ B cells, and neopterin (reviewed in Ref. [23]). Serum levels of KL-6 have also been suggested to reflect DM interstitial lung disease activity.

Treatment of dystrophic calcification in DM is challenging. Aluminum hydroxide antacids and diltiazem are currently used for this problem with less-than-ideal results. Other agents that can be tried include probenecid (250 mg/day), potassium para-amino benzoic acid (15 to 25 g/day), warfarin (1 mg/day), EDTA, and colchicine (1.2 to 1.8 mg/day). The bisphosphonates, such as alendronate, might be of value. [68] The surgical removal of symptomatic cutaneous or subcutaneous calcium deposits can be considered as a last resort.

Passive range-of-motion exercise should be provided early in the disease course to prevent disabling joint contractures, especially in children. After disease activity is suppressed medically, an active exercise program can facilitate the return of normal strength.

Surveillance for the detection of occult malignancy was discussed earlier. In addition, changes in the clinical status of the respiratory, cardiovascular, and gastrointestinal systems should be evaluated carefully for the possibility of systemic disease activity in these target organs.

Current approaches to the treatment of adults and children with C-ADM are based on anecdotal observations of individual cases or a relatively small case series.

One approach has been to treat patients with C-ADM aggressively from the outset with systemic glucocorticoids in the hope that progression to systemic involvement might be delayed or prevented. [69] This approach is supported by studies of patients with both juvenile- and adult-onset classic DM that indicate that early systemic immunosuppressive treatment can lessen long-term disability from muscle dysfunction and complications such as calcification. However, in the large majority of published reports, a more conservative treatment approach has been taken. This approach is validated by reports of patients with C-ADM going 10 to 20 years and longer without any sign of disease activity other than in the skin. [1], [42], [43], [70]

Until it is confirmed that adult patients with C-ADM do not have an increased risk of internal malignancy, they should be evaluated for this potential complication in a manner similar to patients with classic DM. Because internal malignancy has not been reported in juvenile C-ADM, it can be assumed that, as in children with classic DM, routine evaluation for internal malignancy is not indicated.

PROGNOSIS

Classic DM

Reports of mortality rates vary from 25 to 80 percent, depending on the case mix and the medical era in which the cases were collected. In the past two decades, the mortality rate has decreased considerably because of the more aggressive use of glucocorticoids and other immunosuppressives and better supportive medical care. The 5- and 8-year survival rates for 76 patients with DM/PM studied in the 1980s were 80 and 73 percent, respectively. A more recent examination of prognosis in 77 consecutive patients with DM/PM having a minimum of 18 months follow-up revealed a 22 percent mortality rate resulting predominately from malignancy and lung disease. [71] As was previously observed, a better prognosis was seen in individuals who received early systemic treatment for their disease. The early and aggressive use of glucocorticoids has reduced the mortality rate in children to less than 10 percent. The most common causes of death in DM/PM are malignancy, infection, and cardiac and pulmonary disease.

Antisynthetase antibodies and TNF-a308A allele may represent risk factors for disease chronicity and severity in juvenile-onset classic DM. [23] African American children with DM tend to have more aggressive disease than do white or Hispanic children. Calcinosis remains a primary cause of both disease morbidity and mortality in patients with juvenile classic DM.

Some adults with classic DM respond quickly to treatment with systemic glucocorticoids and enjoy treatment-free intervals of various durations after these drugs have been tapered. Most such patients eventually experience a recurrence of disease activity. Others do not respond fully to systemic glucocorticoids or to other immunosuppressive agents and have a long-term, unremitting course. Some patients have a fulminant course with early death. Factors suggested to be associated with a poor prognosis include older age at onset, fulminant disease onset, dysphagia, interstitial lung disease, cardiac involvement, associated malignancy, glucocorticoid resistance, and delay in treatment.

Certain types of skin lesions have also been said to correlate with a poor outcome. Ulcers arising over violaceous indurated plaques on the trunk with or without indurated papules were reported to be more frequent in adults with DM who developed a malignancy. Necrotic/ulcerative skin disease has been noted to be a bad prognostic feature. The mechanic's hand lesion has been suggested to be associated with an increased risk for interstitial lung disease.

Prognosis in both adults and children with classic DM/PM is associated with the types of autoantibodies produced. Antisynthetase autoantibodies (Jo-1, PL-7, PL-12) have been correlated with incomplete response to therapy and interstitial lung disease. Signal-recognition particle antibodies have been found in patients with more acute onset, severe, and treatment-resistant forms of disease with frequent cardiac involvement. Autoantibodies to Mi-2 are associated with more treatment-responsive forms of DM.

Clinically Amyopathic DM

There are insufficient long-term follow-up data available to assess prognosis in adults or children with amyopathic DM. All six patients in one cohort, who initially presented with only skin disease and who were treated conservatively, ultimately developed muscle disease. [72] In another cohort, none of the five adults with amyopathic DM treated aggressively with high-dose systemic glucocorticoids developed clinical evidence of myositis. [69] While fatal malignancies have been reported to occur in patients with amyopathic DM, the statistical significance of such an association has not yet been determined. Based on the reports to date, there appears to be a low frequency of systemic organ involvement in patients with amyopathic DM. However, the potentially fatal complication of interstitial lung disease has been reported in approximately 40 patients presenting with C-ADM. [50]

One study has suggested that patients with juvenile DM who have only cutaneous manifestations are usually not treated aggressively and may frequently develop pathologic calcifications. [45] This report is contrary to other studies of C-ADM, in both children [44] and adults, [16], [42] that have indicated that this mode of presentation is usually not associated with a high rate of subsequent dystrophic calcification. One study indicating that both rheumatologists and dermatologists tend to be conservative in treating patients with C-ADM [44] also reports that a high percentage of patients with juvenile-onset C-ADM enjoy spontaneous remission without systemic immunosuppressive treatment.

REFERENCES

Scleroderma is a chronic disease of unknown etiology that affects the microvasculature and loose connective tissue. It is characterized clinically by fibrous deposition and obliteration of vessels in the skin, lungs, gastrointestinal tract, kidneys, and heart. [1] Scleroderma literally means “hard skin” and was first reported by William and Robert Watson in 1754. The diffuse thickening and induration of the skin in the systemic form of scleroderma, systemic sclerosis (systemic scleroderma, SSc) is accompanied by fibrosis and vascular obliteration of internal organs. Its course is often progressive and fatal. The localized form has a more restricted pattern of involvement and does not affect internal organs.

CLASSIFICATION

Several clinical forms of localized scleroderma are now recognized, including morphea, generalized morphea, guttate morphea (which may be a variant of lichen sclerosus et atrophicus, LSA), nodular (keloidal) morphea, subcutaneous morphea (morphea profunda), and linear scleroderma. Localized scleroderma is not a life-threatening disease but can cause disfigurement. The most common type is morphea, in which the lesions are usually single or few in number. In the generalized form of morphea, symmetric and bilateral lesions occur. The absence of Raynaud's phenomenon, acrosclerosis, and organ involvement differentiates generalized morphea from SSc. In linear scleroderma the lesions are arranged in a bandlike linear distribution and may involve the deeper layers of the skin and underlying structures. Deformities, such as hemiatrophy, may be associated with linear scleroderma.

Systemic scleroderma is divided into two distinct subsets: limited SSc (lSSc) and diffuse SSc (dSSc). [2] Several other minor scleroderma subtypes are also recognized (Table 173-1). Sixty percent of patients with SSc are in the lSSc group, which includes individuals with the CREST syndrome, so-called for its features of *c*alcinosis cutis, *R*aynaud's phenomenon, *e*sophageal dysfunction, *s*clerodactyly, and *t*elangiectasia. Patients with lSSc typically are women who are older than patients with dSSc and have a long history (10 to 15 years) of Raynaud's phenomenon; skin involvement limited to the digits or hands, face, feet, and forearms; nail fold capillary dilatation; and early onset of facial and digital telangiectasias. Anticentromere antibodies (ACA) have been identified in 50 to 96 percent of patients with CREST syndrome, but in only 12 to 25 percent of patients with dSSc. Scl-70 autoantibodies are more frequently associated with dSSc (approximately 30 percent). Systemic involvement (notably pulmonary hypertension) may not appear for years (often decades), and many patients outlive their disease and die of other causes. Miners, users of vibrating machines, and those exposed to chemicals or plastics may develop a seronegative form of lSSc.

“Presclerodermа”
Raynaud's phenomenon plus nail fold capillary changes
Disease-specific circulating antinuclear autoantibodies (antitopoisomerase-I, anticentromere (ACA), or nucleolar)
Digital ischemic changes
Diffuse cutaneous SSc (dSSc)
Onset of skin changes (puffy or hidebound) within 1 year of onset of Raynaud's phenomenon
Truncal and acral skin involvement
Tendon friction rubs
Early and significant interstitial lung disease, oliguric renal failure
Diffuse gastrointestinal disease
Myocardial involvement
Nail fold capillary dilatation and drop out
Antitopoisomerase-I (Scl-70) antibodies (30% of patients)
Limited cutaneous SSc (lSSc)
Raynaud's phenomenon for years (occasionally decades)
Skin involvement limited to hands, face, feet, and forearms (acral)
A significant (10–15%) late incidence of pulmonary hypertension, with or without interstitial lung disease, skin calcification, telangiectasia, and gastrointestinal involvement
High prevalence of ACA (70–80%)
Dilated nail fold capillary loops, usually without capillary dropout
Scleroderma sine scleroderma
Raynaud's phenomenon
No skin involvement
Presentation with pulmonary fibrosis, scleroderma, renal crisis, cardiac or gastrointestinal disease
Antibodies may be present (Scl-70, ACA, nucleolar)

TABLE 173-1 **Classification of Systemic Scleroderma Subsets**

The typical patient with dSSc is well until the abrupt onset of swelling (nonpitting) of the hands and feet associated with Raynaud's phenomenon and hidebound changes in the skin, often sparing only the back and buttocks. Polyarticular symmetric synovitis, tenosynovitis, and tendon friction rubs are often present. Nail fold capillary dilatation and destruction

are common, and there is early onset of internal organ involvement. In some patients, skin involvement progresses rapidly initially and then subsides slowly over years. [1] Some patients with dSSc do not develop extensive or severe internal organ involvement. These patients form a subset whose disease is termed *chronic dSSc*. The subsets of SSc are classified in detail in Table 173-1.

EPIDEMIOLOGY

Localized scleroderma is relatively uncommon. Women are affected 2.6 times more often than men. The disease appears more commonly in whites than in blacks, and 75 percent of patients with morphea present between the ages of 20 and 50. In linear scleroderma, the age of onset is earlier, with a significant number occurring in the first two decades of life.

SSc is four times more common in women than in men. Results from two large US studies spanning the period between 1950 and 1979 indicate incidence rates from 10 to 12 per million and prevalence rates between 105 and 138 per million. [3] Certain populations are more likely to develop scleroderma. Black women have higher prevalence rates of scleroderma than do black men and whites. A 50-fold higher prevalence of scleroderma has been reported in Choctaw Native Americans residing in Oklahoma than in the general population. [4] Diffuse disease occurs more commonly in the black than in the white population, and the age of onset is younger than the age of onset of limited disease. SSc may occur at any age, but the age of onset generally lies between 30 and 50 years.

The classification of SSc into the lSSc and dSSc subsets is important prognostically. It is estimated that the survival rates for 1, 6, and 12 years for patients with dSSc are 80 percent, 30 percent, and 15 percent, respectively, whereas for those patients with lSSc, the corresponding survival rates are 98 percent, 80 percent, and 50 percent, respectively. [2] Older patients have a significantly decreased survival rate. Women have a significantly better survival rate than men, and the mortality from scleroderma for black women is significantly greater, because of their predilection for diffuse disease, than for white women. In a study of 177 patients, [5] the 10-year survival rate was 71 percent in patients with sclerodactyly alone, 58 percent in patients with skin stiffness proximal to the metacarpophalangeal joint but sparing the trunk, and only 21 percent in those with diffuse skin stiffness including the trunk.

Familial transmission of scleroderma is rare. In an Australian study of 710 patients with scleroderma and their families, the frequency of familial scleroderma was 1.4%. [6] The relative risk of developing scleroderma in patients with a positive family history is high, approximately 11-fold. [5] Also noted in this study is the increased prevalence of lupus and other collagen vascular diseases in those same families. The modifiers that favor scleroderma over other diseases are unknown. Human leukocyte antigen (HLA) types correlate more with the expression of specific autoantibody subsets than with scleroderma itself and may play a role in modifying disease.

Scleroderma-like Disorders

Scleroderma-like disorders have been reported in association with numerous environmental toxins and drugs. These agents include solvents (vinyl chloride, benzene, toluene, epoxy resins), drugs (bleomycin, carbidopa, pentazocine, cocaine, docetaxel, metaphenylenediamine), and miscellaneous substances (silica, rapeseed oil, L-tryptophan).

SSc was reported to occur in underground coal and gold miners. In male patients with silicosis who are older than 40 years of age, the likelihood of developing SSc is approximately 190 times greater than in males not exposed to silica, and 50 times greater than in males without silicosis but exposed to silica dust. [7] Most epidemiologic studies have failed to show a significant association between silicone gel implants and other silicone products and the development of scleroderma. [8]

An unusual form of scleroderma characterized by Raynaud's phenomenon, morphea-like skin changes, capillary abnormalities of the nail fold (similar to those in SSc), osteolysis of the distal phalanges, and hepatic and pulmonary fibrosis may occur in workers exposed to polyvinyl chloride. Bleomycin also produces pulmonary fibrosis, Raynaud's phenomenon, and cutaneous changes indistinguishable from those of SSc. [9] The development of these changes appears to be dose dependent and is reversible upon discontinuation of the drug.

Collectively, chemical exposures account for a small fraction of scleroderma cases. Large epidemiologic studies have not yet revealed a significant role for toxins and drugs in scleroderma.

Scleroderma-like skin changes may also be associated with scleromyxedema, porphyria cutanea tarda, and graft-versus-host disease (GVHD). Similar skin changes, primarily in the legs, have been described in the carcinoid syndrome, but these entities, although related, are clearly separable from scleroderma per se.

CLINICAL MANIFESTATIONS

Localized Scleroderma

Localized morphea is characterized by circumscribed sclerotic plaques with ivory-colored centers and, if the disease is in an active state, violaceous borders (Fig. 173-1). The lesion often begins as a reddened or lilac-colored area that may show some nonpitting edema. The center gradually becomes white or yellowed. There may be a diminished sweat response and an absence of hair in the lesion. The plaques, whether slightly elevated or depressed, are indurated but not bound to the deeper structures. Most commonly, the lesions are single or few in number, but they may be multiple, ranging in size from 1 to 30 cm. Uncommonly, localized morphea may occur after radiation therapy at the site of treatment. Its development is not related to dosage or to the severity of the acute reaction. Whether it results from the well-recognized fibroblastic response to irradiation is unknown.

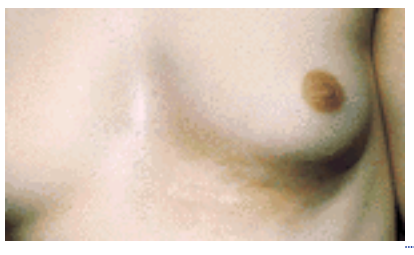

FIGURE 173-1 Morphea. There is an indurated, poorly defined plaque under the left breast. The lesion is multicolored with a central, yellow, “carnauba-wax” area surrounded by a lilac border.

Generalized morphea is a severe form of the local disease. Involvement of the skin is widespread, with multiple indurated plaques and hyperpigmentation. The plaques may be larger than the lesions of localized morphea, but in early stages they are often indistinguishable. They involve the upper trunk, abdomen, buttocks, and legs. Generalized morphea is not associated with systemic disease.

Guttate morphea may be a variant of localized morphea or of LSA. The coexistence of these two disorders in patients has been reported, with the same lesion frequently showing histologic evidence of both diseases. [10] Guttate morphea is characterized by multiple small chalk-white lesions that lack the firm character of morphea, involving primarily the neck and upper trunk.

Nodular (keloidal) morphea is a rare variant characterized by the presence of nodular lesions resembling keloids. The coexistence of typical lesions of localized morphea may aid in the diagnosis.

Subcutaneous morphea (morphea profunda) is characterized by deep, bound-down, sclerotic plaques. Because inflammation is in the subcutaneous fat and fascia, the typical color changes that occur in the skin of localized morphea are absent.

A morphea-like reaction to phytonadione injections has also been described, which involves the proximal limbs and buttocks, a pattern akin to a “gunbelt-and-holster.” [9]

Atrophoderma of Pierini and Pasini is an uncommon superficial form of localized morphea in which several oval, hyperpigmented, atrophic plaques develop on the trunk. The unusual feature is the absence of sclerosis. The well-defined lesions have a slightly depressed center; the defined border has been described as having a cliff-drop appearance. Whether this disorder is an end stage of morphea is unclear.

Linear scleroderma is a form of the disease that occurs as a linear band, usually with a single unilateral lesion. The lower extremities are most often involved, followed in frequency of occurrence by the upper extremities, frontal areas of the head, and anterior thorax. If the upper and lower extremities are involved, the lesions are on the same side. Calcinosis within a linear lesion occurs rarely. Frontal or frontoparietal linear scleroderma, called *coup de sabre,* is characterized by atrophy and a furrow in the skin (Fig. 173-2). The depression may be extensive, causing facial hemiatrophy, sometimes with atrophy of the tongue on the same side. Linear frontal lesions and active morphea plaques may coexist on the same side of the face. An important distinction between linear scleroderma and morphea is that linear scleroderma involves not only superficial but also deeper layers of the skin, with fixation to underlying structures. Because linear scleroderma occurs most often during the first two decades of life, it may cause severe deformities, such as hemiatrophy of an extremity or a side of the face, or contractures. Linear scleroderma may also be associated with anomalies of the vertebral column, the most common being spina bifida occulta.

FIGURE 173-2 *Coup de sabre.* Linear, atrophic depression involving the forehead.

Melorheostosis is an unusual linear, dense, cortical hyperostosis that occurs rarely. It usually affects an involved limb but occasionally is widespread.

The *tick-borne spirochete Borrelia burgdorferi,* the etiologic agent of Lyme disease, is thought to play a role in morphea and LSA. [11] Polymerase chain reaction (PCR) has been used to show the presence of *B. burgdorferi* in some cases of morphea reported from Europe and Japan. However, no cases have been linked to *Borrelia* infection in the United States. Furthermore, *Borrelia* infection responds readily to treatment with penicillin or ceftriaxone, whereas morphea is chronic and refractory to treatment. [9] Thus, cases related to *Borrelia* infection may represent a variant of morphea.

The *Parry-Romberg syndrome* (facial hemiatrophy) is characterized by unilateral hyperpigmentation, usually along trigeminal nerve distributions, followed by atrophy of the dermis, subcutaneous fat, and muscle, and sometimes the underlying bone. [9] The skin is less bound down than that seen in *coup de sabre,* but the atrophy is usually deeper. A scleroderma-like hemiatrophy of the face that spreads to the homolateral or contralateral side of the body may be a

variant of the Parry-Romberg syndrome. A patient with progressive facial hemiatrophy and serum positive antinuclear antibodies (ANA), rheumatoid factor, and elevated gamma globulin levels has been reported. [12]

ANA, elevated immunoglobulin levels, and rheumatoid factor have been reported in all forms of localized scleroderma particularly in linear scleroderma. Eosinophilia may occur in localized scleroderma. In one such study, [13] eosinophilia (> 400 cells/µL) was most common in generalized morphea and linear scleroderma and correlated with active disease. The prognosis is good; the disease often becomes inactive in 3 to 5 years. Slight atrophy, often with hyperpigmentation, may be the only persisting sequela of either form of morphea. However, disability from muscle atrophy may be a sequela of severe morphea.

Systemic Sclerosis

The clinical manifestations of SSc depend on the sites involved. The initial complaints are usually related either to Raynaud's phenomenon or to chronic, usually nonpitting, edema of the hands and fingers. As many as one-third of patients first have pain and stiffness of the fingers and knees. In some patients, the first manifestation is active, often migratory, polyarthritis. In others, severe erosive digital osteoarthritis (related to the CREST syndrome, particularly in females) occurs first. Flexion contractures and sclerodactyly are present; on x-ray, digital tuft resorption, subcutaneous calcification, joint space narrowing, and focal erosions of the periarticular bone are seen. Usually, skin changes precede visceral involvement by several years, but occasionally this order is reversed.

The disease then extends to involve the upper extremities (Fig. 173-3), trunk, face, and, finally, the lower extremities, which may sometimes be spared. In the early stages, the painless, slightly pitting edema often lasts several months before tightening of the skin occurs. Isolated periorbital edema may occur in the early edematous phase in patients with few other manifestations of SSc. Often the skin feels indurated and stiff; as it progresses to the atrophic state, it becomes tense, smooth, hardened, and, eventually, firmly bound to the underlying structures (Fig. 173-4). The skin of the face becomes masklike and expressionless, with loss of the normal facial lines and then thinning of the lips and constriction of the opening of the mouth (microstomia). Radial furrowing around the mouth is seen (Fig. 173-5). Uncommonly, the mucous membranes are involved, with painful induration of the gums and tongue. A prominent feature is tightening of the skin over the nose, giving it a small, sharp appearance. The neck sign, ridging and tightening of the skin of the neck on extending the head, is common. Matlike telangiectases may develop (Fig. 173-5), especially about the face and upper trunk. There may be thinning or complete loss of hair and anhidrosis in the affected areas. Generalized hyperpigmentation, similar to that of Addison's disease but with no evidence of adrenal insufficiency or elevated plasma levels of melanocyte-stimulating hormone ß, can occur and may antedate the sclerosis. Focal hyper- or hypopigmentation may represent a postinflammatory response in the areas of sclerosis.

FIGURE 173-3 Scleroderma. The connective tissue changes in the face result in loss of the normal facial lines producing a masklike appearence, a thinning of the lips, and a perioral furrowing (rhagades). The hands exhibit a sclerodactylia with tapering of the fingers and a waxy, shiny, atrophic skin. There are flexion contractures and ulceration of the skin overlying the bony prominences on the right hand.

FIGURE 173-4 Scleroderma. Skin is atrophic, appears tense and smooth, and has become firmly bound to the underlying structures.

FIGURE 173-5 Radial furrowing around the mouth and matlike telangiectases are prominent on the cheeks in a patient with scleroderma.

Sclerodactyly causes the fingers to become tapered, with marked skin atrophy. As in systemic lupus erythematous and dermatomyositis, periungual telangiectasia occurs. In as much as 75 percent of patients with SSc, enlarged, dilated nail fold capillaries forming “giant” or sausage-shaped loops can be seen by capillary microscopy of nail folds (done with an ophthalmoscope), and this examination can be useful in confirming the diagnosis. [14] The pattern in scleroderma can be distinguished from the changes in systemic lupus erythematosus but not from those in dermatomyositis. Capillary microscopy may be of prognostic value in Raynaud's disease, because, if nail fold capillary changes are present, the patient is more likely to develop SSc later. Another common problem is recurrent painful ulceration of the fingertips (Fig. 173-6). Slow-healing ulcers over the knuckles may also occur. These may heal with stellate scarring, become chronic, or, rarely, become gangrenous. Flexion contractures of the stiff fingers trouble many patients. Resorption of bone may cause dissolution of terminal phalanges, and cutaneous calcification develops in some cases, especially around fingertips and bony prominences but also in any area involved with scleroderma. These calcifications may ulcerate, extrude calcified material, and reepithelialize very slowly.

FIGURE 173-6 Ulceration of the fingertips in a patient with Raynaud's phenomenon and scleroderma.

Dental x-rays of patient with SSc often show widening of the periodontal membrane and loss of the lamina dura. Bone absorption at the angle of the mandible may occur, perhaps secondary to tightness of facial skin and atrophy of the underlying muscles.

Systemic involvement manifests itself in many ways. Esophageal dysfunction is the most common internal manifestation, occurring in more than 90 percent of patients. Dysphagia is a result of diminished peristalsis, especially in the distal two-thirds of the esophagus, and is easily seen on radiologic or manometric study. Heartburn from reflex esophagitis because of a loss of tone in the lower esophageal sphincter occurs commonly, but hemorrhage is rare. Dysphagia may occur long before skin involvement, thereby giving rise to the idea of systemic sclerosis sine scleroderma. Abnormal esophageal motility has also been reported in Raynaud's phenomenon, dermatomyositis, and lupus erythematosus. In SSc, the small intestine may be involved, producing symptoms of constipation, diarrhea, bloating, and sometimes malabsorption. Common findings on x-ray include delayed transit with prolonged retention of barium and distension of the small bowel, all secondary to atonia.

Another important feature of SSc is pulmonary involvement with fibrosis. Patients complain of exertional dyspnea, and small airway disease is an early sensitive indicator of pulmonary involvement that often precedes measurable impairment of gas diffusion. Alveolitis, which can be detected by bronchoalveolar lavage, occurs frequently in SSc and results in progressive reduction in pulmonary function over time. Early treatment with prednisone and cyclophosphamide may produce significant clinical improvement. Early pulmonary involvement, functionally characterized by a lowered diffusing capacity of the alveolocapillary membrane, correlates with morphologic changes of the nail fold capillaries. [15] Cardiac involvement in SSc may cause conduction defects, heart failure, or pericarditis; the latter is often associated with pericardial effusion and sometimes with tamponade. The overall prevalence of myocardial fibrosis in SSc is approximately 50 to 70 percent. Myocardial fibrosis is associated with microvascular coronary vasospasm, which is linked to a myocardial Raynaud's phenomenon.

Renal involvement occurs in about 45 percent of patients with SSc. Some patients have slowly progressive uremia, but for most, the renal failure is abrupt and associated with a malignant form of hypertension. Although there has been some suggestion that the acute renal failure and hypertension were induced by glucocorticoids, these findings have occurred in patients who had never received glucocorticoids.

CREST SYNDROME

A clinical variant of scleroderma is the CREST syndrome. The telangiectasias are most evident on the skin of the face (see Fig. 173-5), upper trunk, and hands, but also occur on the lips and oral mucosa and throughout the entire gastrointestinal tract. Gastrointestinal bleeding from the lesions is uncommon. The CREST syndrome is a more slowly progressive form of scleroderma; it develops later in life than dSSc and so has a more favorable prognosis. It is not entirely a benign syndrome, because the esophageal dysfunction is identical to that of the more severe forms of the disease, and occasionally pulmonary hypertension and biliary cirrhosis occur.

MIXED CONNECTIVE TISSUE DISEASE

Patients with combined features of scleroderma, lupus erythematosus, and myositis have been grouped under the heading of mixed connective tissue disease. The patients have high titers of antibody to a ribonucleoprotein, the extractable nuclear antigen. Patients with SSc do not have this antibody.

EOSINOPHILIC FASCIITIS AND EOSINOPHILIA-MYALGIA SYNDROME

Other syndromes that cause scleroderma-like skin changes, such as eosinophilic fasciitis (Shulman's syndrome) and the eosinophilia-myalgia syndrome, are discussed in Chap. 96.

TOXIC OIL SYNDROME

The toxic oil syndrome occurred in epidemic form in Spain in 1981, and affected approximately 25,000 people. [7], [16] It resulted from the consumption of denatured rapeseed oil sold as olive oil for cooking. Ingestion of the denatured rapeseed oil caused approximately 600 deaths and left 300 individuals disabled by a chronic multisystem disease. This syndrome has the features of a toxic allergic reaction, with an acute phase associated with a morbilliform-type eruption, pruritus, fever, interstitial pneumonitis, myalgia, and liver function abnormalities. Serum IgE levels were elevated in 37 to 50 percent of the cases. Approximately 5 percent of those affected presented with seizures and encephalopathy. Several months after onset, a chronic phase began that was characterized by severe neuromuscular abnormalities, generalized edema, scleroderma-like skin lesions, joint contractures, Sjögren-like syndrome, and pulmonary hypertension. The histopathology of the skin lesions is similar to that described in the eosinophilia-myalgia syndrome (see Chap. 96). In both processes, the primary injury is vascular, with evidence of perivascular inflammation, intimal proliferation, reduplication of the basal lamina, endothelial damage, and luminal obliteration. Immunofluorescence with antiprocollagen and antifibronectin antibodies and electron microscopy confirmed the vascular damage.

The exact cause of the syndrome remains obscure, but it appears that the ingestion of aniline-degraded, reprocessed rapeseed oil led to a chronic autoimmune disease. An oil of comparable chemical composition to case-related oils has been produced, and an in vitro toxicologic assay with mouse neuroblastoma and rat liver epithelial cells has been developed. [17] Extracts from aniline-treated rapeseed oil and several high-performance liquid chromatography fractions were toxic to these cells when compared to appropriate controls. It appears that at least some of the puzzling aspects of this syndrome may be solved.

CUTANEOUS HISTOPATHOLOGY

The features of morphea or SSc in histologic sections of a skin biopsy depend on the stage of the disease and the biopsy site (Fig. 173-7 and Fig. 173-8). In morphea, specimens from the peripheral violaceous border show many inflammatory cells among collagen bundles of the lower two-thirds of the reticular dermis, the fibrous trabeculae of the subcutaneous tissue. Usually lymphocytes and histocytes predominate, but there may be large numbers of plasma cells, and occasionally there are mast cells. Formation of typical lymphoid follicles with germinal centers may be seen. Mononuclear cell infiltrates are much less common in SSc than in localized scleroderma, and are often less prominent.

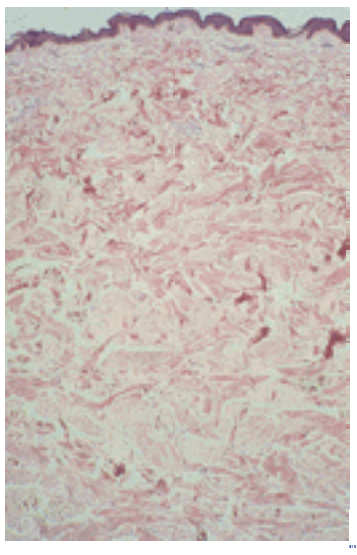

FIGURE 173-7 Scleroderma. The changes of generalized scleroderma and localized scleroderma (morphea) overlap; the former, however, is dominated by dense, acellular sclerosis, and the latter shows varying degrees of inflammation with some extension into the subcutis. Fig. 173-7 shows the pathologic changes of scleroderma, and Fig. 173-8 shows the pathologic changes of morphea. In this photomicrograph one sees broad collagen bundles that tend to parallel each other, diminished interbundle spaces, and few cells of any kind.

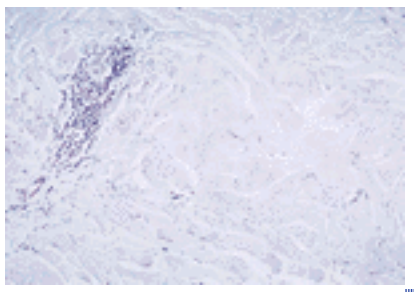

FIGURE 173-8 Morphea. The connective tissue changes in morphea seem to extend from the lower reticular dermis outward and are usually indistinguishable from the changes of generalized scleroderma. Biopsies taken from the margins of morphea lesions, however, frequently show extensive inflammation; such inflammation may be patchy, as one sees here, or it may involve the reticular dermis rather diffusely, presenting some difficulty in histologic diagnosis.

Associated with the inflammatory infiltrate are collagen changes that first occur in the lower third of the dermis and in the fibrous trabeculae of the subcutaneous tissues. Later in the disease, the changes extend to the upper portion of the dermis and consist of a markedly increased eosinophilia of collagen, broadening of collagen bundles, and decreased space between collagen bundles. Biopsies from the central region of well-developed lesions of morphea may show only collagen changes and no inflammation. In these later stages of morphea the pathology is similar to that of SSc. The collagen bundle pattern is altered so that most bundles appear to parallel the dermal-epidermal junction. The inflammatory stage is followed by the replacement of the subcutaneous tissue by hyalinized connective tissue. On electron microscopy, the fibrous trabeculae of the subcutaneous tissue are increased in thickness by deposition of immature collagen fibrils smaller in diameter than normal, suggesting increased collagen synthesis.

In morphea profunda, the lesions are associated with a subcutaneous, dense, mononuclear cell infiltrate with abundant plasma cells. There is extensive sclerosis and hyalinization of the connective tissue and occasional involvement of the underlying fascia. Lymphoid aggregates with germinal center formation have been described in some of the solitary lesions.

The pathology of SSc is similar to that of morphea. The lower two-thirds of the dermis and the subcutaneous fibrous trabeculae are sclerosed. Panniculitis may also be a prominent feature in the early stages. Subcutaneous fat is replaced by hyalinized connective tissue, and this process is particularly evident around eccrine sweat glands. The collagen bundles appear pale, homogeneous, and swollen, but the collagen bundle swelling, increased numbers of eosinophils, and inflammation are not as prominent as in morphea. In the late stages of SSc, secondary changes, such as absence of pilosebaceous units, eccrine ducts, and glands, and effacement of the rete ridges of the epidermis may be evident. Electron microscopy has revealed randomly arranged “immature” collagen fibrils, from 10 to 40 nm in diameter, in contrast to mature collagen fibrils, from 70 to 80 nm in diameter. Whether the immature fibrils represent newly synthesized collagen remains speculative.

Vessels of all sizes may be involved in SSc, and vascular involvement is an important, although inconsistent, feature. In the early stages, there may be only dilatation of capillaries and lymphatics. Then intimal proliferation and complete occlusion of the vessel can occur. These changes also appear in muscle capillaries.

Occlusive vascular changes are not found in morphea, but the precise implications of the difference are unclear; possibly they are related to the spontaneous involution of morphea. In morphea, skeletal muscle fibers underlying affected skin may be structurally damaged in the absence of histologic changes in muscle capillaries.

PATHOGENESIS

The primary defect in scleroderma is still unknown. Exposures to environmental toxins and perhaps infections such as *Borrelia* account for only a small subset of scleroderma patients. The majority of patients have no identifiable trigger. [1]

Three pathologies have been identified in scleroderma: endothelial damage, immunologic and inflammatory activation, and dysregulated extracellular matrix production. The basic pathogenic mechanisms are believed to be similar in localized and systemic disease.

A number of experimental models, including UCD-200 and UCD-206 avian models, [18] suggest that endothelial damage is an early event in the pathogenesis of scleroderma. The first identifiable histologic changes in scleroderma include endothelial cell swelling and contraction of intercellular junctions, which correlate clinically with the early edematous lesions seen in this disorder. [19] Biochemical changes in the endothelium are found in both early lesional and nonlesional scleroderma skin, and include decreased stores of von Willebrand factor, factor VIII, and Weibel-Palade bodies. These changes are accompanied by decreased adenosine uptake and membrane blebbing, which collectively indicate endothelial damage and activation. Endothelial damage leads to the release of proinflammatory cytokines such as tumor necrosis factor alpha (TNF-a), interleukin-1 (IL-1a, -1ß), IL-6, IL-8, and others that shift the endothelium from an anticoagulant, vasodilatory resting state to a proinflammatory, procoagulant, vasoconstrictive-activated phenotype. [4], [20], [21] Release of prostaglandins, nitric oxide, and endothelin-1 affect vascular beds, both locally and systemically, perhaps contributing to the micro- and macrovascular dysfunction in scleroderma. Platelet aggregation and activation occur as a result of endothelial activation and lead to the release of platelet-derived growth factor (PDGF), a potent mitogen for fibroblasts and smooth muscle cells. These signals are also thought to contribute to intimal thickening of vessel walls.

The mechanism of endothelial damage is unclear. Cytotoxic autoantibodies have been implicated as one mechanism. [22] Pooled IgG immunoglobulin from scleroderma patients recognizes a common cytomegaloviral (CMV) protein and cross-reacts with an endothelial adhesion molecule. These antibodies are present in 93 percent of patients with scleroderma, as compared to 0 percent of age/sex-matched controls, 5 percent of patients with rheumatoid arthritis, and 12 percent of patients with systemic lupus erythematosus. Importantly, these antibodies in vitro can trigger endothelial

apoptosis. The molecular mimicry in these studies between a CMV antigen and an endothelial cell surface protein is intriguing, but it is as of yet unknown whether inhibition of these autoantibodies can affect progression or inhibit scleroderma. Furthermore, the role of autoantibodies (Table 173-2) against topoisomerase I (IgG1), centromeres (IgG1, IgG3), RNA polymerase I/III, and U3 ribonucleoprotein in the pathogenesis of scleroderma is also unknown. [23] These antibodies do not cause apoptosis, and immunofluorescence studies on lesional skin do not show antibody deposition.

TABLE 173-2 **Autoantibodies in Scleroderma**

The role of the immune response in the initiation of scleroderma is unclear as many of the early changes are not specific to scleroderma. The late response involves CD4-positive T helper cells, plasma cells, and histiocytes, and is believed to lead to tissue fibrosis. The T helper 2 (T_H2) subset, which is important in chronic graft-versus-host disease (cGVHD), may contribute during fibrotic stages of scleroderma. Sera from patients with SSc show elevated levels of IL-4, IL-10, and IL-13, indicative of a T_H2 response. [24] Interferon (IFN)-?, a cytokine produced by T_H1 cells, has been reported to be unchanged in patients with SSc, despite other reports demonstrating elevated IL-12 levels. Whether T_H1 and T_H2 subsets predominate at different stages of the disease and how they might participate have not been clarified. The production of a number of other cytokines has been reported in patients with scleroderma, including IL-2, soluble IL-2 receptors, TNF, PDGF, and ß-thromboglobulin. [25], [26] IL-2, which is critical for T cell activation and proliferation, is found in abundance in patients with scleroderma. IL-2 also plays a role in natural killer cell activation, which may also contribute to endothelial damage. Intimately linked to tissue remodeling and the chronic immune response are mast cells, which produce many cytokines, vasoactive peptides, and lipid mediators (prostaglandins, platelet-activating factors, and leukotrienes). Mast cells are a rich source of histamine and heparin, the latter of which is important in fibroblast growth factor (FGF) signaling. [27] Several investigators have shown that histamine levels are elevated in patients with SSc and, in experimental models, can play a role in sclerosis. Fibrosis is also seen in cGVHD, porphyria cutanea tarda, and a number of experimental models of scleroderma, [28] but often differs clinically in terms of organ involvement or tissue-specific patterns. These patterns may reflect vascular bed-specific differences or chemokine dysregulation.

IL-4 and transforming growth factor-ß (TGF-ß) [29] are two important mediators of tissue fibrosis, and both are elevated in scleroderma. The role of TGF-ß is complex because of its leiomorphic effects on immune regulation and tissue remodeling. Production of TGF-ß $_2$ by perivascular lymphocytes, monocytes, and endothelial cells directly activates transcription of collagen in adjacent fibroblasts. [6], [30] TGF-ß can be secreted in a latent form that is bound by latent TGF-ß binding proteins; this latent form cannot bind to TGF-ß receptors until it is activated by proteases, glycosidases, and other posttranslational modifications. TGF-ß leads to the activation of SMAD transcription factors, which may serve as novel targets for the pharmacologic intervention of tissue fibrosis. [31]

IL-4 plays a role in collagen upregulation and is countered by the activities of IFN-?. [29] In an autosomal dominant murine model of scleroderma known as the tight-skin mouse (tsk), in which many features of SSc, including pronounced dermal fibrosis, overproduction of collagen I, II, VI, and production of antitopoisomerase I antibodies are present, IL-4R or STAT6 deficiency rescues the sclerotic phenotype. [5] In addition, mice deficient in IFN-? develop vascular intimal thickening and increased collagen production. [32] The mutations in the tsk mouse lead to genomic duplications and rearrangements in the fibrillin gene. Overexpression of this mutant fibrillin gene leads to localized and diffuse sclerosis. [33] Fibrillin dysfunction has also been proposed in populations with genetic susceptibility to scleroderma. Linkage analysis of the Choctaw Native American population has mapped the susceptibility locus within a 2 cM interval on chromosome 15q, proximal to the fibrillin gene. Polymorphisms in the fibrillin gene have also been identified in this population. These mutations have been hypothesized to alter TGF-ß and latent TGF-ß–binding protein (LTBP) stability, processing, or extracellular matrix signaling properties. [34] In the tsk mice, however, an inflammatory infiltrate is often absent, and lymphocyte deficiency does not abrogate the sclerotic phenotype. [35] These mice do not develop the exact pattern of internal organ involvement present in human scleroderma. The tsk mouse model suggests that fibrosis and vascular disease can exist as distinct pathologies and that the key features of scleroderma, fibrosis, and Scl-70 autoantibody production are tightly linked events. The exact role of fibrillin dysfunction in scleroderma, however, still remains unclear.

cGVHD frequently has been compared to SSc (although renal involvement is rare in cGVHD). [36] The sclerodermatous cGVHD displays progressive skin and internal organ fibrosis as well as production of autoantibodies such as the Scl-70 antibody. A noniatrogenic form of GVHD, termed fetal microchimerism, was recently described. Fetal microchimerism refers to the seeding of maternal tissue by fetal cells during pregnancy. Surprisingly, allogeneic cells, which are presumably of fetal origin, can be found in the blood and skin of women as many as 27 years postpartum, as detected by the presence of male-specific Y chromosome markers. Microchimerism is a common finding in scleroderma. With the polymerase chain reaction, male DNA was detected in the skin of 11 of 19 women with scleroderma, but not in 68 unaffected women. [37] Also, allogeneic DNA has been detected in women with no previous history of pregnancy, and in men, presumably due to maternal intrauterine mixing. It is also possible that HLA associations allow syngenic fetal tissue to persist and to interact with the maternal T cells. Additional studies are required to demonstrate a functional relationship between fetal microchimerism and the pathology of scleroderma. However, it is tempting to speculate that microchimerism could provide an explanation for the female predominance and the onset of scleroderma around the childbearing age.

COURSE

In patients with morphea or linear scleroderma, the disease may last from a few months to many years. In the 50 percent of patients in whom lesions disappear or soften, areas of hypo- or depigmentation are left. *Coup de sabre* lesions may remain unchanged or become more extensive.

Limited SSc rarely progresses to dSSc. In dSSc, visceral involvement develops in most patients if they are followed for sufficient duration. The overall 5-year mortality rate in dSSc is 40 to 50 percent. The main causes of death are pulmonary fibrosis and renal hypertensive crisis in dSSc and isolated pulmonary hypertension in lSSc. [38] Clinical parameters associated with poor prognosis include proximal sclerosis, trunk skin involvement, presence of anti–Scl-70 autoantibody, pulmonary and/or heart involvement, and advanced age at time of diagnosis (45 or older). [39], [40] ACA are predictive for lSSc including CREST (sensitivity 60 percent, specificity 98 percent); Scl-70 are predictive for dSSc (sensitivity 38 percent, specificity 100 percent). Findings of ACA and Scl-70 are positively associated with the development of telangiectasias and tight skin, respectively. [41] Scl-70 and HLA-DR3/DR52a are associated with increased risk of pulmonary fibrosis, a major cause of morbidity and mortality in SSc. [42] Antibodies to RNA-polymerases seem to correlate with severe renal and lung disease. [43] Laboratory methods to track disease activity include measurement of soluble IL-2 receptor levels and von Willebrand factor (vWF) levels, which correlate with clinical disease activity and vascular damage, respectively.

MANAGEMENT

The treatment of localized scleroderma (morphea) remains unsatisfactory, but because the disease is generally self-limited, most cases require little or no treatment. When treatment is attempted, it usually involves application of high- to ultrahigh-potency topical glucocorticoids to the lesions, which may be augmented by intralesional injections of glucocorticoids. Antimalarials, phenytoin, colchicine, and systemic glucocorticoids are used in generalized morphea, but provide little proven benefit. In one study of 11 patients with severe localized scleroderma treated with D-penicillamine, 6 improved after 3 to 6 months of therapy, with skin softening, resumption of growth in affected limbs, and absence of new lesions. The mean length of treatment was 21 months (range, 15 to 53) at a daily dose of 2.0 to 5.0 mg/kg. Careful monitoring for renal and hematologic toxicity is essential. [44] The use of high dose UVA 1 (340 to 450 nm) produced marked clinical improvement of treated lesions in patients with morphea. [45] Relapse did not occur once therapy was discontinued, but a longer period of observation will be required to determine whether the results of treatment are long lasting.

Organ-specific aspects of SSc, particularly renal, lung, and gastrointestinal involvement should be treated to ameliorate morbidity and potential mortality. Prior to the introduction of angiotensin-converting enzyme (ACE) inhibitors by Lopez-Ovejero and colleagues, renal crisis was the leading cause of mortality in patients with scleroderma. [46]

Blood pressure monitoring should be routinely performed, particularly in light of reports of normotensive renal crisis. Captopril markedly improves survival and, in some patients, may permit discontinuation of dialysis. Inflammatory lung disease, which has a “ground glass” appearance on high-resolution CT scan, responds to cyclophosphamide and prednisolone. [47], [48] Continuous epoprostenol therapy may be helpful in the treatment of pulmonary hypertension associated with scleroderma. [49]

The peripheral vasospasm in lSSc occasionally improves with oral vasodilators such as diltiazem. [50] Angiotensin receptor blockers have also been introduced as possible remedies in Raynaud's phenomenon, although their role in the treatment of renal crisis is still unclear. [51] Intravenous prostacyclin infusion or radical microarteriolysis is advocated for critically ischemic digits. [52] In patients with calcinosis in both CREST and dSSc, there is some suggestion that calcium channel blockers may alleviate the calcinosis. [53] Reflux esophagitis with spasm responds to omeprazole and cisapride. Bacterial overgrowth, identifiable by a positive hydrogen breath test, can be treated with courses of broad-spectrum antibiotics. Octreotide (30 to 100 µg/day subcutaneously) stimulates intestinal motility in patients with dSSc and reduces abdominal symptoms, small-bowel dysfunction, intestinal pseudoobstruction, and bacterial overgrowth. [54]

Physical therapy is paramount in minimizing the loss of function in sclerotic digits and limbs. The cessation of smoking provides a significant decrease in morbidity in those patients with documented Raynaud's phenomenon.

Of the many agents tried in the therapy of SSc, most have been found wanting. Global immunosuppression with such agents as azathioprine, chlorambucil, methotrexate, cyclophosphamide, and minocycline has had variable success. Plasmapheresis [55] and extracorporeal photopheresis [56] have demonstrated equivocal results.

Cyclophosphamide improves survival and may be useful in the treatment of SSc lung fibrosis, [57] but long-standing fibrosis does not appear to be affected significantly by global immunosuppression. Systemic glucocorticoids may be of some benefit early in the disease, or for specific inflammatory lesions (e.g., myositis, alveolitis, myocarditis), but do not alter the overall disease course. Chlorambucil, 5-fluorouracil, and ketotifen (a mast cell stabilizer) are ineffective. In some studies, cyclosporine has resulted in a 40 percent decrease in mean skin thickness scores over 1 year. Pulmonary diffusing capacity remains unchanged. However, the use of cyclosporine is limited at higher doses by hypertension and renal insufficiency, which may be attributable to either the drug or SSc and may confound clinical assessment of efficacy. [58]

D-Penicillamine, which interferes with intermolecular cross-linking of collagen, has been used with some success in the treatment of early aggressive dSSc, decreasing body surface area involvement from 65 to 16 percent. [59] It is administered orally at a dosage of 250 mg/day on an empty stomach, and the dosage is increased every 2 to 3 months to a maximum of 750 to 1500 mg/day. In patients with a disease duration of less than 3 years, significant reductions in skin thickness and joint contractures are apparent after 18 to 30 months of therapy. Patients have improved survival, due in part to a lower incidence of renal disease. However, long-term use is limited by side effects that include hematologic abnormalities as well as autoimmune syndromes such as pemphigus, nephrotic syndrome, lupus/polymyositis-like syndrome,

Goodpasture syndrome, and myasthenia gravis. Relaxin, a hormone produced during pregnancy, has antifibrotic activities and is under investigation for the treatment of scleroderma. [60]

One early trial series of 18 patients with rapidly progressive SSc, treated with an 18-week course of IFN-?, showed a decrease in the mean skin thickness score from a baseline of 25.9 to 19.1, and a decrease of the mean area scores from 33.1 to 19.6. Ten patients had more than a 25 percent decrease in the area score, five patients had more than a 70 percent decrease in the area score, and three had not experienced disease recurrence 6 to 17 months after cessation of IFN-?. [61] Other novel immunomodulatory agents are currently being evaluated, including anti-TNF blockade, intravenous immunoglobulins, [62] immune tolerance induction to type I collagen, [63] and autologous bone marrow transplantation. Chapter 174

Brian Mandell Gary Hoffman

Systemic Necrotizing Arteritis

GENERAL PRINCIPLES OF DIAGNOSIS
SPECIFIC VASCULITIC SYNDROMES
Small Vessel Vasculitis
Wegener's Granulomatosis
Churg-Strauss Syndrome (Allergic Angiitis and Granulomatosis)
Polyarteritis Nodosa and Microscopic Polyangiitis
Kawasaki Disease
Large Vessel Arteritis (Takayasu's Arteritis and Temporal Arteritis)
GENERAL COMMENTS ON THE TREATMENT OF PATIENTS WITH SYSTEMIC ARTERITIS

REFERENCES

Blood vessels may be affected by a number of diverse processes, including Raynaud's vasospasm, coagulopathies, myointimal proliferation with occlusion (e.g., scleroderma), embolic occlusion, congenital or acquired dysplasias (e.g., Marfan's syndrome, fibromuscular dysplasia), and atherosclerosis. This chapter focuses on the primary inflammatory disorders that are grouped together as the systemic vasculitides. The small vessel vasculitides, Wegener's granulomatosis, Churg-Strauss syndrome, polyarteritis nodosa, microscopic polyangiitis, Kawasaki disease, Takayasu's arteritis, and giant cell arteritis of the elderly are presented in specific detail. Diseases characterized by primary isolated cutaneous vasculitis, the necrotizing capillaritis/venulitis syndromes, are discussed in greater detail in Chap. 175.

The inflammatory process per se is often associated with laboratory and clinical abnormalities; but these, however prominent, tend to be nonspecific (e.g., elevated erythrocyte sedimentation rate, anemia, fatigue, fevers) and do not substantially aid in distinguishing vasculitis from other inflammatory, infectious, or proliferative diseases. Blood vessels have limited ways of responding to injury: increased permeability may lead to edema and purpura, attenuation of the vessel wall may lead to aneurysm formation or hemorrhage, and intimal proliferation or thrombosis may cause stenosis or occlusion with tissue ischemia or infarction. The definitive diagnosis of a primary vasculitis remains dependent upon histopathologic documentation of vasculitis in conjunction with the appropriate clinical picture and the exclusion of diseases that can cause secondary vascular inflammation such as infection (e.g., meningococcemia, rickettsial diseases, and endocarditis). The principal clinical clue to diagnosis of a specific vasculitic disorder is the pattern of organ involvement. Identification of qualitative pathologic changes in affected organs (pattern of necrosis, presence of granulomas, eosinophilic infiltration) further delineates the differential diagnosis. The primary determinants of prognosis and selection of therapy include whether critical organs are involved, the severity of involvement, and the rate of disease progression. The toxic nature of the therapies for severe systemic vasculitis emphasizes the need for an accurate diagnosis. The nonspecific diagnosis of “vasculitis” should not be the final diagnosis; this concept should be avoided in favor of a more specific final diagnosis whenever possible.

Cutaneous involvement in systemic vasculitis may lead to consultation with a dermatologist. However, it is the symptomatic or asymptomatic involvement of other organ systems that is generally more ominous. Cutaneous involvement may precede visceral organ involvement. Conversely, not all cases of cutaneous vasculitis are part of a systemic process.

GENERAL PRINCIPLES OF DIAGNOSIS

The differential diagnosis of the systemic vasculitides often includes distinct or coexistent coagulopathy, occult malignancy, or infection; particularly deep-seated abscess, viral hepatitis, or bacterial endocarditis. Thus, an approach directed towards ruling in a specific form of vasculitis should be pursued, in addition to ruling out defined alternatives.

Cutaneous involvement can occur in any of the primary systemic vasculitic syndromes. However, the cutaneous features are virtually never sufficient to provide a complete diagnosis. Histopathology and immunofluorescent evaluation of skin biopsies may be invaluable in supporting the diagnosis of systemic inflammatory diseases such as Henoch-Schönlein purpura (HSP), sarcoidosis, Sweet's syndrome, or systemic lupus erythematosus (SLE); in diagnosing proliferative disorders (T cell lymphomas, leukemia cutis, Kaposi's sarcoma) and emboli from atherosclerosis or atrial myxomas; and, occasionally, in diagnosing specific infections (syphilis, cytomegalovirus, fungemia). Angiographic and selected serologic studies may provide support for certain diagnoses but are not by themselves pathognomonic for any specific form of vasculitis. In general, the diagnosis of a specific form of systemic arteritis will come from a careful documentation of the pattern of organ involvement and histopathology. Serologic tests, such as those for antineutrophil cytoplasmic autoantibodies (ANCA) or antinuclear antibodies (ANA), in the presence of clinically isolated cutaneous vasculitis, do not confirm the diagnosis of Wegener's granulomatosis or SLE.

Several classification schemes have been proposed in attempts to organize the systemic vasculitic disorders into a consistent paradigm. [1], [2] and [3] Such schemes are useful in providing a diagnostic framework to distinguish clinical disorders with distinct differences in prognosis and response to treatment. Although no scheme is perfect or universally accepted, classification systems such as the one shown in Fig. 174-1 provide useful constructs for communication.

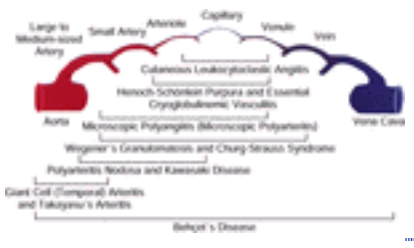

FIGURE 174-1 A classification scheme for the vasculitides. (*Adapted from Jennette et al.,* [2] *with permission.*)

The most widely used diagnostic classification systems are based on the caliber of affected blood vessels, the pattern of organ involvement, and the presence or absence of granulomas and/or eosinophilic infiltration. Some authors propose a prime diagnostic role for the presence or absence of specific serum ANCAs, particularly antibodies to PR3 and myeloperoxidase. We believe that the role of these tests at present is to support a rationally developed clinical diagnosis, not to define one. In patients who do not fit neatly into a well-defined diagnostic category, these serologic tests should not supplant an attempt to obtain a tissue diagnosis, if the latter is feasible. In patients who present with symptoms and findings shared by several diseases, such as cutaneous venulitis, targeted serologic testing for potential etiologies may be valuable. Examples include studies for hepatitis B or C infection, HIV, and cryoglobulinemia. The value of indiscriminate testing for ANAs, rheumatoid factor, and angiotensin-converting enzyme to look for the presence of possible systemic autoimmune disease is arguable, at best. These studies should be used primarily as aids in supporting a tenable clinical diagnosis.

The evaluation of the patient with a vasculitic syndrome begins with a detailed patient history and directed physical examination to seek or document specific organ involvement. Special attention should be paid to finding evidence of inflammation in the eyes, ears, nose, paranasal sinuses, mouth, trachea, joints, intestine, or peripheral nerves. The presence of adenopathy, periungual capillary abnormalities, cardiac abnormalities, asymmetric peripheral pulses, or abdominal and subclavian bruits provides other diagnostic clues. It is reasonable to include a few basic laboratory tests in the initial evaluation; more specialized studies should be obtained only after a focused differential diagnosis is generated. Initial studies should include a complete blood count with differential, measurement of serum creatinine and transaminase levels, and a dipstick and microscopic urinalysis. Ideally, the urinalysis should be performed immediately by a physician on a fresh sample; urine that has been allowed to sit for several hours before analysis will not permit identification of cellular casts that may rapidly degenerate ex vivo. Red blood cell casts are highly suggestive of the presence of glomerulonephritis. A clinical axiom is that the primary vasculitides are almost never associated with leukopenia or thrombocytopenia. The presence of these laboratory findings should suggest alternative diagnoses such as SLE, vasculitis associated with malignancy, disseminated intravascular coagulation, infection, or drug-induced cytopenias. Table 174-1 lists some of the disorders that may mimic or be associated with a vasculitis.

Infections	Carcinoma (disseminated: renal cell, colon, lung)*
Endocarditis*	Lymphoma*
Histoplasmosis	Hairy-cell leukemia*
Syphilis*	Myelogenous leukemia/myelofibroplasia*
Borrelia burgdorferi (Lyme disease)	Drug reactions, toxicities, and abuse
Viral	Phencyclidine
Hepatitis (A,B,C)*	Cocaine
HIV*	Amphetamines*
CMV*	Warfarin
Pneumonia (Legionella, Streptococcus pneumoniae)	Ergotamine
Mycobacteria	Others
Parasites	Amyloidosis
Trichinella	Cryoglobulinemia*
Toxoplasma	Sarcoidosis*
Plasmodium (malaria)	Anti-glomerular basement membrane disease
Strongyloides	Multiple sclerosis
Noninfectious processes	Familial Mediterranean fever
Sickle-cell anemia	Heavy metal poisoning
Disseminated intravascular coagulation	Hepatic porphyrias
Antiphospholipid antibody syndrome	Systemic lupus erythematosus*
Thromboangiitis obliterans	Hypereosinophilic syndrome
Protein C or S deficiency	Hypercoagulable syndrome
Warfarin-induced skin necrosis	Still's disease
Thrombotic thrombocytopenic purpura	Occult cirrhosis
Neoplastic diseases	Rheumatoid arthritis*
Atrial myxoma	Fabry's disease

TABLE 174-1 **Selected Conditions That May Mimic or Be Associated with* Systemic Arteritis**

SPECIFIC VASCULITIC SYNDROMES

Small Vessel Vasculitis

The most common form of vasculitis exclusively affects capillaries and venules, [4], [5] almost invariably involves the skin, and is extensively discussed in Chap. 175. It is frequently, although not always, associated with immune complex deposition. It can occur in these circumstances: (1) as an isolated primary cutaneous disorder; (2) secondary to drug allergy, bacterial endocarditis, viral infections (such as hepatitis B or C, [6] parvovirus B19, cytomegalovirus, or Epstein-Barr virus), or disseminated neisserial and rickettsial infection; (3) as part of defined systemic autoimmune disorders (e.g., Sjögren's syndrome, SLE, dermatomyositis, rheumatoid arthritis); or (4) in association with hematologic, [7], [8] lymphoid, [9], [10] and solid organ [11] malignancies. Primary small vessel vasculitis may be limited to the skin, [12] or may be associated with visceral involvement including pulmonary hemorrhage, [13] intestinal ischemia or hemorrhage, [14] and glomerulonephritis.

Visceral involvement may or may not be part of the syndrome of HSP, which occurs in adults as well as children and is usually associated with vascular and renal deposition of IgA-containing immune complexes. Common manifestations include purpura and/or urticaria, abdominal pain, gastrointestinal bleeding or intussusception, arthralgias, arthritis or periarthritis, and glomerulonephritis. Visceral symptoms may precede the skin lesions, leading to diagnostic confusion. Delayed skin involvement may be misinterpreted to be a drug reaction. Purpura tends to occur in crops of lesions of similar age. Small vessel vasculitis/purpura is generally more pronounced in gravity-dependent areas. One exception is vasculitis as a consequence of cryoglobulinemia, especially in association with lymphoma. Cutaneous vasculitis may be associated with such striking edema that nephrotic syndrome is suggested. A punch biopsy is useful in excluding infiltrative causes of nonvasculitic purpura. Immunofluorescent staining for IgA can support the diagnosis of HSP in the appropriate clinical setting.

In managing patients with cutaneous vasculitis, it must be established that the vasculitis is not caused by a process that may not benefit from, or that may be aggravated by, immunosuppressive therapy. Examples include infections such as disseminated gonorrhea, bacterial endocarditis, and viral-related vasculitides. Furthermore, the finding of small vessel vasculitis in the skin does not exclude concurrent medium or larger vessel arteritis. For example, purpura may occur in Wegener's granulomatosis (WG), [15] Churg-Strauss syndrome (CSS), polyarteritis, Behçet's disease, and Cogan's syndrome.

Therapy for isolated cutaneous vasculitis is directed at the underlying process, if one can be identified. Documented infections should be treated. Suspected offending antigens such as drugs should be withdrawn. If no precipitants are apparent, low-risk therapy can be attempted with nonsteroidal anti-inflammatory drugs, colchicine, pentoxifylline, dapsone, or short-term, low-dose glucocorticoids. However, if visceral involvement with organ dysfunction is present, a more aggressive approach is usually required. In the latter case, higher dose glucocorticoids are generally effective. In the setting of severe visceral involvement, methotrexate, azathioprine, cyclophosphamide, or other immunosuppressive agents may be required. When treating disease that is not organ- or life-threatening, close attention must be paid to the risk-versus-benefit ratio of selected therapies.

Urticarial vasculitis [16] represents a peculiar subset of small vessel vasculitis. The clinical presentation is that of typical wheals or serpentine papules, sometimes with surrounding or geographically separate angioedema. Individual lesions are slower to resolve than typical urticaria and often last for several days. There is frequently a burning, dysesthetic quality to the discomfort from the lesions. They often heal with skin discoloration, hyperpigmentation, or an ecchymotic area. Most cases are idiopathic, although they may be associated with an underlying autoimmune disorder such as SLE or Sjögren's syndrome, [17] IgM paraproteinemia (Schnitzler's syndrome [18], viral infections (hepatitis, acute Epstein-Barr), and HSP. Joint and, less commonly, abdominal pain may occur. There may be an association with ocular inflammatory disease and obstructive pulmonary disease. A form of urticarial vasculitis with neutrophil infiltration and destruction of the postcapillary venules has been described [19] in association with hypocomplementemia. The lesions are generally responsive to moderate doses of daily glucocorticoids. However, this approach is fraught with long-term toxicity. Anecdotal reports have noted improvement with colchicine, dapsone, nonsteroidal agents, and the antimalarials. [16]

Wegener's Granulomatosis

WG is a relatively uncommon, potentially lethal disease characterized by necrotizing granulomatous inflammation and vasculitis of small- and medium-sized vessels. Multiple organs are often involved, with a predilection for the upper and lower respiratory tracts, the eye, and the kidney. [20], [21] and [22] Males and females of all ages can be affected. Upper airway disease tends to be particularly striking but is often initially attributed for months or even years to “sinus disease” until other manifestations of WG are recognized. In addition to pansinusitis, WG can cause septal perforations and saddle nose deformities. Ear involvement is common, particularly otitis media. Auricular destruction, similar to that in polychondritis, has rarely been reported and may represent an overlap syndrome. [23] Occult involvement of the inner ear and nose must be sought. Sinus disease is often destructive and may be recalcitrant to therapy because of superinfection of the necrotic tissue by *Staphylococcus aureus*. [22] Laryngotracheal involvement may result in subglottic stenosis. [20] Orbital pseudotumors and nasolacrimal duct stenosis occur frequently in WG. Orbital pseudotumors may cause proptosis with intractable pain and loss of vision; these inflammatory and fibrous masses may be refractory to anti-inflammatory, immunosuppressive, and even radiation therapy. Isolated uveitis and retinal disease are less common.

Lower respiratory tract involvement is part of the WG diagnostic triad (upper and lower respiratory tract and glomerulonephritis). However, it may not be clinically evident at the outset of disease or even at the time of diagnosis. Pulmonary involvement may be dramatic with diffuse alveolar hemorrhage. More commonly, patients present with mild or no symptoms, and chest radiographs or computed tomography scans are necessary to demonstrate the infiltrates or nodules. Nodules may undergo necrosis, leading to cavity formation. Pleural involvement occurs, but bronchospasm is not characteristic of WG. It is frequently necessary to rule out infectious causes of the pulmonary infiltrates, and bronchoscopy is useful in this regard. However, tissue obtained from transbronchial biopsy is usually quantitatively insufficient to make the pathologic diagnosis of WG. Open-lung biopsy generally provides the optimal opportunity to demonstrate the typical pathologic findings of WG (Fig. 174-2 and Fig. 174-3) and to exclude malignancies and atypical infections. Biopsy of alternative tissues may not have the same likelihood of revealing the specific diagnosis. Nasal tissue, although readily available, has a far lower likelihood of yielding the correct diagnosis [24] than does lung tissue obtained by thoracoscopy-guided or open biopsy. Renal biopsy may reveal focal and segmental glomerulonephritis with variable proliferative changes, in the absence of significant immune-complex deposition. Although supportive of the diagnosis of WG, these are not specific histopathologic findings. Open-lung biopsies contain areas of necrosis (frequently in a “geographic” pattern), giant cell granulomas in the parenchymal tissue, and vasculitis. Not all histopathologic components may be present in the same section. Because these findings may also occur in chronic mycobacterial or fungal infections, special stains and cultures are essential.

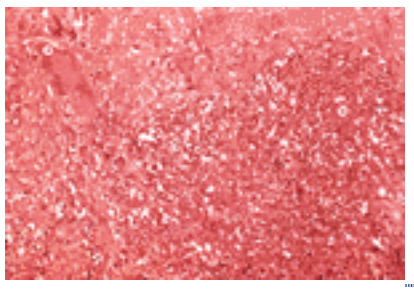

FIGURE 174-2 Lung histopathology from a patient with Wegener's granulomatosis demonstrating necrosis, giant cells, and mixed cellular inflammation.

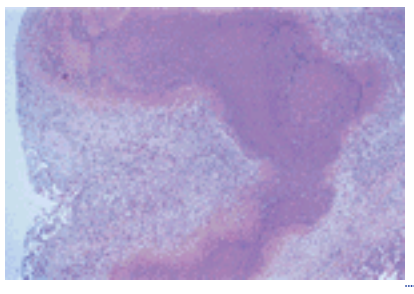

FIGURE 174-3 “Geographic necrosis” in a low-power view of an open lung biopsy specimen from a patient with Wegener's granulomatosis.

Glomerulonephritis is a common cause of morbidity and mortality in WG. Its presence or absence defines the generalized versus limited forms of the disease. When present, its expression may be relatively indolent or, more frequently, aggressive. It may be clinically and pathologically indistinguishable from idiopathic, rapidly progressive, crescentic glomerulonephritis. The evolution from subclinical to dialysis-dependent renal disease may take place over several weeks. [20], [25] Glomerulonephritis may be present at the outset or initial recognition of the disease or may develop only after the patient has been ill with an apparently limited form of the disease for long periods of time. [20], [21] and [22], [25] Frequent microscopic urinalyses in the initial and follow-up evaluation of patients with WG are important. Occasional 24-h urine collections to establish a more accurate estimate of the glomerular filtration rate than the serum creatinine measurement alone can provide may be valuable, especially in elderly or debilitated patients.

Musculoskeletal involvement occurs in more than half of patients with WG. Most note only arthralgias or myalgias, but some may experience true polyarthritis or migratory or fixed inflammatory mono- or oligoarthritis. [20], [26] Rheumatoid factor, which is frequently present in patients with WG, may cause some diagnostic confusion with rheumatoid arthritis when joint symptoms are significant. The joint disease of WG, however, only rarely produces bone erosions. [27] Neurologic signs and symptoms occur in fewer than 50 percent of patients, peripheral neuropathy in fewer than 20 percent, and involvement of the central nervous system in fewer than 10 percent. [20], [28] Oculomotor involvement may occur as a result of the presence of retroorbital mass impingement. Gastrointestinal ulcerations and ischemic syndromes can occur, [29] as can cardiac ischemia, conduction disease, and pericarditis. [20], [30]

Cutaneous involvement has been reported in up to 50 percent of patients with WG. [21] The author has seen several patients who experienced acute or indolent deep inflammatory skin masses as the initial manifestation of their disease. Reported manifestations include palpable purpura, [15], [31] pyoderma-like ulcerations, [31], [32] gingival hyperplasia, [33] inflammatory papules, small ulcers, panniculitis, and subcutaneous nodules. [21], [31], [33], [34] The activity of the skin disease generally parallels systemic disease activity. No skin histopathology is pathognomonic for WG. Leukocytoclastic angiitis is most apparent in the presence of purpura or inflammatory papules but is clearly not sufficient to make the diagnosis of WG. Granulomatous vasculitis [34] may be seen, occasionally in the presence of soft tissue necrosis or panniculitis, which may suggest the diagnosis of WG. Skin biopsies are not usually sufficient to confirm the diagnosis. Cutaneous granulomatous vasculitis, similar to that in patients with WG, has been described in patients with isolated skin involvement, Crohn's disease, sarcoidosis, or lymphoproliferative disorders. [5] Oral and nasal ulcerations are common. Several patients with orbital WG and a treatment-responsive yellow discoloration of the eyelids have been described. [35]

The diagnosis of WG should be considered in patients with otherwise unexplained inflammation of the upper or lower respiratory tract or eye or with glomerulonephritis. Suspicion of WG should be increased when multiple organ involvement is present, the upper airway disease is destructive, or pulmonary nodules (especially with cavities) are demonstrated by radiography. Any combination of organ involvement is conceivably possible, but most patients exhibit upper airway involvement at the time of diagnosis. [20] If the entire clinical picture is compatible with WG, and alternative diagnoses have been appropriately ruled out, the finding of a cytoplasmic pattern of antineutrophil cytoplasmic autoantibody (C-ANCA) with anti-PR3 specificity in the patient's serum is sufficient to make the diagnosis and initiate therapy. However, if there are any atypical features or special concerns about the initiation of immunosuppressive therapy, or if the patient does not respond appropriately to therapy, tissue documentation of the diagnosis is mandatory. Because WG generally requires glucocorticoid plus cytotoxic drug therapy, it should be distinguished from other inflammatory disorders, including other vasculitic syndromes, that may be effectively treated with a less toxic approach. ANCA positivity in the absence of a typical pattern of clinical WG is inadequate to make the diagnosis.

Treatment of systemic WG virtually always requires dual-drug immunosuppressive therapy. Glucocorticoids may induce symptomatic improvement in the upper airway, lungs, skin, and musculoskeletal system but only rarely produce remission. Glucocorticoids alone essentially never control aggressive renal disease. Even if improvement follows single-drug treatment with glucocorticoids, tapering usually results in a flare in the disease. Consequently, serious disease, particularly renal disease, is treated initially with glucocorticoids and daily cyclophosphamide, with subsequent tapering of the steroids. There are some strong relative contraindications to the use of cyclophosphamide, including bladder outlet obstruction and leukopenia. In patients with milder or limited WG, weekly methotrexate (0.20 to 0.30 mg/kg, adjusted for renal function) with folic acid or leucovorin may be substituted for the cyclophosphamide. [21], [36] Patients treated with either regimen must be continuously monitored for flares in disease or side effects of therapy. Side effects include cytopenias; hepatic or pulmonary toxicity from methotrexate; and pulmonary toxicity, cystitis, bladder cancer, or pancytopenia from cyclophosphamide. Some authors have suggested using trimethoprim-sulfamethoxazole as adjunctive therapy for treatment of the WG and/or for prevention of bacterial infections that may promote upper airway disease flares, but this approach remains controversial. [37] Three times weekly therapy with trimethoprim-sulfamethoxazole is of use, however, to protect patients against *Pneumocystis carinii* pneumonia (PCP) while they are receiving high doses of glucocorticoids or a cytotoxic agent. Patients who cannot tolerate sulfur antibiotics should receive prophylaxis against PCP with inhaled monthly pentamidine therapy. Local nasal and sinus care and

otolaryngoscopic evaluations are a routine part of the therapy of patients with WG and upper airway disease.

Churg-Strauss Syndrome (Allergic Angiitis and Granulomatosis)

CSS, like WG, affects small- to medium-sized arteries and veins. Clinically, CSS and WG have similar patterns of organ involvement and pathology, especially in regard to upper and lower airway disease and glomerulonephritis. CSS differs most strikingly from WG by its usual occurrence in patients with a history of atopy, asthma, or allergic rhinitis, which is often ongoing. In the prevasculitic atopy phase, as well as during the systemic phase of the illness, eosinophilia is characteristic and often of striking degree (>1000 eosinophils/µL). When eosinophilia is present in WG, it is usually more modest (500 eosinophils/µL). Systemic features of CSS include some combination of pulmonary infiltrates, cardiomyopathy, coronary arteritis, pericarditis, polyneuropathy (symmetric or mononeuritis multiplex), ischemic bowel disease, eosinophilic gastroenteritis, ocular inflammation, nasal perforations, glomerulonephritis, and cutaneous nodules and/or purpura.

The pulmonary infiltrates of CSS are usually transient and patchy, [38] and may be associated with alveolar hemorrhage. Pulmonary nodules are uncommon; when present, they rarely cavitate. [39] Pleural effusions are common and often contain abundant eosinophils. Clinical distinction of CSS from hypersensitivity pneumonitis, allergic aspergillosis, and pulmonary lymphoma is at times difficult. Cardiac disease can be severe and is a leading cause of death in these patients. It often does not manifest itself until late in the course of the illness. Valvular heart disease is not as striking or as common as in the hypereosinophilic syndrome. Neurologic involvement occurs in approximately 60 percent of patients, may be severe, and is generally attributable to arteritis of the vasa nervorum. Purpura is the most common cutaneous feature. Urticaria and polymorphous erythematous eruptions also occur. [40] Cutaneous nodules appear in approximately one-third of patients, primarily on the extensor surfaces of the arms and scalp. [41], [42] and [43] The nodules may be tender and occasionally may infarct. Gastrointestinal involvement is due to ischemic vasculitis and/or eosinophilic gastroenteritis, which can cause pain, cramping, and diarrhea.

Histopathologic examination of involved skin, nerve, lung, heart, and gastrointestinal tract typically reveals a vascular or extravascular granulomatous inflammation, with a prominent eosinophilic infiltrate and vasculitis. Vasculitis in a given tissue section may be granulomatous or nongranulomatous. Granulomas can be found in tissue at areas separate from the demonstrable vasculitis. Eosinophilic infiltrates are more striking than those in WG. Eosinophils, granulomas, and giant cells are not found in abundance in classic polyarteritis nodosa (PAN). It has been suggested that the initial small vessel vasculitis in the skin evolves into a pattern of inflammation with granulomas that coalesce into the palpable nodules. [44] However, the pathology of these nodules, by itself, is insufficient to make a diagnosis of CSS because similar pathology can be seen in lymphoma and sarcoidosis. [43], [45] Glomerulonephritis is not as common as in WG but, when present, is usually focal and segmental, occasionally with crescents. [46] The glomerulonephritis of CSS is often milder than that of WG or microscopic polyangiitis.

CSS generally responds to treatment with glucocorticoids. Some patients can be tapered from steroids. However, the presence of bronchial asthma and sinus disease may require ongoing therapy, even if the vasculitic component of the disease has remitted. Patients with severe or refractory visceral organ involvement are treated with additional agents, such as cyclophosphamide, [47], [48] methotrexate, or azathioprine.

Polyarteritis Nodosa and Microscopic Polyangiitis

Attempts to neatly separate these two forms of necrotizing small- and medium-sized vessel arteritis have not been universally accepted. [2], [48], [49] An international consensus conference proposed that the diagnosis of these disorders be based on the absence of granulomatous inflammation in both and the lack of involvement of arterioles, capillaries, venules, and glomerular capillaries in classic PAN. Microscopic polyangiitis (MPA) involves vessels ranging in size from capillaries and venules to medium-sized arteries (see Fig. 174-1). Glomerulonephritis, especially rapidly progressive glomerulonephritis, and alveolar hemorrhage are particularly common in MPA and absent in classic PAN. Antibody to myeloperoxidase, a type of perinuclear-staining antineutrophil cytoplasmic autoantibody (p-ANCA), is detected in sera from 60 percent of patients with MPA. It may well be that some cases of classic PAN do involve the smaller vessels, and until it can be demonstrated that the two syndromes have distinct pathophysiologies, attempts to clearly distinguish MPA from PAN will remain imperfect. Hepatitis B and C infections are associated with a classic PAN-like syndrome [48] as well as with MPA-like disease.

Given the diagnostic nuances and disagreements, it is not surprising that a clear-cut distinction between the two syndromes cannot be provided in terms of prognosis or response to therapy. Most importantly, because the distinction between these two syndromes is still being defined, it is difficult to interpret the clinical descriptions in the older studies of PAN, which included patients with both classic PAN and MPA. This accounts for some of the wide variation in the reported frequency of pulmonary [50] or glomerular involvement in PAN.

Constitutional symptoms, such as fever, asthenia, and myalgias, are often present in both PAN and MPA. Elevated acute-phase reactants, thrombocytosis, leukocytosis, and the anemia of inflammatory disease are common, although not uniformly present. MPA is typically manifest by crescentic necrotizing, segmental glomerulonephritis and/or alveolar hemorrhage in conjunction with small and medium-sized vessel vasculitis in other organ systems.

Antiglomerular basement membrane antibodies are generally absent. Alveolar hemorrhage may manifest as dyspnea, pulmonary infiltrates, and anemia. Hemoptysis may not be present. Peripheral neuropathy with symmetric mixed motor and sensory components, or mononeuritis multiplex pattern is common. Upper airway and ocular inflammation may occur [51] and may occasionally make the distinction from WG difficult. Purpura and/or splinter hemorrhages are commonly found in MPA. [51], [52]

Classic PAN may present with hypertension and/or renal insufficiency with a bland urine sediment or hematuria on microscopic analysis. Renal ischemia may result from inflammation, stenosis, or occlusion of preglomerular muscular arteries. Peripheral neuropathy, testicular pain, epididymitis, ischemic myalgias, and livedo reticularis occur. Both PAN and MPA may cause cardiac or gastrointestinal tract ischemia. PAN is associated with the development of microaneurysms, 1 to 5 mm in size, in the mesenteric, hepatic, or renal arteries in perhaps 40 percent of patients. Microaneurysms can also occur in patients with MPA, WG, CSS, Behçet's disease, SLE, and other disorders affecting medium-sized vessels (see Fig. 174-1), including endocarditis.

When PAN or MPA is recognized clinically, it is imperative to be certain that it is not associated with infection with hepatitis B or C. The presence of hepatitis B or C infection does not seem to alter the presentation of the PAN or MPA syndrome dramatically, although membranous glomerulonephritis, liver failure, and thrombocytopenia are more likely to occur with viral hepatitis infection. Infection with parvovirus B19 and HIV should also be excluded.

The diagnosis of these disorders should ideally be based on histopathology and clinical pattern of disease. In the patient with a urine sediment analysis suggestive of glomerulonephritis or with neuropathy, a renal biopsy or biopsy of a clinically involved nerve may provide the diagnosis of necrotizing medium vessel arteritis. The presence of serum p-ANCA with antimyeloperoxidase specificity further supports the clinical diagnosis but is not specific for this disease. p-ANCA positivity is also found in patients with drug-induced vasculitis. The renal biopsy tissue in MPA, as in WG, is negative for immune complexes by immunofluorescent staining and electron microscopy (so-called pauci-immune glomerulonephritis). Lung biopsy in the setting of pulmonary infiltrates or hemorrhage reveals capillaritis, but yields less specific pathology than in WG. Biopsy is useful to rule out alternative pulmonary diagnoses. The diagnosis of classic PAN is more difficult in the setting of dominant, but nonspecific, constitutional symptoms and the absence of easily accessible disease-affected tissue such as nerve. Biopsy of clinically uninvolved tissue (e.g., asymptomatic muscle or testes) is not usually fruitful. Several diagnostic algorithms have been proposed. [4], [53], [54] If biopsy is not indicated due to the absence of accessible involved tissue, complete abdominal angiography should be considered to evaluate the medium-sized vessels. The sensitivity and specificity of this procedure is not well defined, especially in the absence of abdominal complaints. Angiography is generally avoided, whenever possible, in the setting of progressive or significant renal insufficiency. Magnetic resonance angiography may not be sufficiently sensitive to detect microaneurysms.

Treatment of both PAN and MPA is somewhat empirical, although work by Guillevin et al. [55] has provided valuable information. Glucocorticoids in high doses remain the initial mainstay of therapy for both PAN and MPA. Glucocorticoids alone may be sufficient therapy for patients who do not have critical organ involvement, defined as renal insufficiency, gastrointestinal ischemia, cardiomyopathy, dense peripheral neuropathy, and central nervous system involvement. Those with critical organ involvement have increased risk of morbidity or mortality and are usually treated with glucocorticoids and an additional immunosuppressive agent such as cyclophosphamide. Although the use of initial combination therapy in this setting is the common practice, its efficacy has not been formally studied.

When active hepatitis B or C infection is present, a relatively short course of glucocorticoids should be considered, based on disease severity, in conjunction with antiviral therapy and perhaps apheresis. [55] Controlled studies have not been conducted to assess objectively the value of adding apheresis to the combination of antiviral and glucocorticoid therapy. In subsets of patients with cryoglobulinemia, particularly in the presence of nonhealing skin ulcers, apheresis may be of value.

Kawasaki Disease

Kawasaki disease (KD) was first described in 1967 as mucocutaneous lymph node syndrome. [56], [57] The presence of characteristic clinical features [58] has permitted the establishment of diagnostic criteria (Table 174-2). KD typically affects infants and young children with dominant cutaneous manifestations. The vascular component of the disease may involve vessels ranging in size from venules to the aorta. The inflammation is primarily in the larger coronary arteries, which results in aneurysm formation in approximately 25 percent of untreated patients. It has been postulated, but not proved, that there is an infectious trigger for KD. No specific diagnostic tests exist. However, the immediate and delayed life-threatening cardiac complications of the disease, coupled with its unique therapy (intravenous gamma globulin, IVIG), mandate prompt clinical diagnosis.

Persistent fever (>5 days)
Plus 4 of the following 5 conditions:
Bilateral conjunctivitis (nonpurulent)
Oral mucosal involvement (erythematous pharynx, red or fissured lips, strawberry tongue)
Soft tissue abnormalities of hands and feet (edema/erythema, desquamation)
Rash (polymorphous but nonvesicular)
Cervical adenopathy

TABLE 174-2 **Diagnostic Criteria for Kawasaki Disease**

Fever is usually high and spiking and may persist for 1 to 2 weeks if untreated, but rapid defervescence is usually achieved with the initiation of appropriate therapy. Conjunctivitis, usually nonexudative, often appears concurrent with the fever. Uveitis occurs less frequently. Aseptic (lymphocytic) meningitis may contribute to the photophobia as well as to headache and prominent irritability. Oral involvement includes erythema, dryness and fissuring of the lips, nonexudative pharyngitis, and tongue erythema with very prominent papillae (Fig. 174-4 and Fig. 174-5). Mucosal ulcerations do not characteristically occur.

FIGURE 174-4 Kawasaki disease: lip and facial involvement. (*Courtesy of B. Singsen, MD.*)

FIGURE 174-5 Kawasaki disease: strawberry tongue. (*Courtesy of B. Singsen, MD.*)

Distal limb swelling often begins several days after the fever. The hands and feet may have associated erythema and tenderness that is not limited to the joints. Desquamation (Fig. 174-6), often in sheets, may begin days to a few weeks after the onset of the fever. When desquamation occurs early in KD, it may appear concurrently with a truncal rash and with eye and lip changes and may mimic a drug reaction or Stevens-Johnson syndrome. The rash is usually diffuse and polymorphous (Fig. 174-7), with urticarial, morbilliform, annular, or plaque components; but it is not vesicular. It is generally less evanescent and more readily apparent than the rash of Still's disease (systemic pattern juvenile rheumatoid arthritis). However, it may not be present at the time of initial presentation or concurrent with the febrile component of the illness. Distal vasculitis has been described, and digital necrosis may occur. [59]

FIGURE 174-6 Kawasaki disease: distal extremity desquamation. (*Courtesy of B. Singsen, MD.*)

FIGURE 174-7 Kawasaki disease: rash on trunk. (*Courtesy of B. Singsen, MD.*)

Adenopathy, which is present in 75 percent of patients, is generally most apparent in the cervical region and ranges from mild to extensive. [60] Other, less common (noncardiac) aspects of the disease include abdominal cramping and diarrhea, hydrops of the gall bladder, synovitis of large and small joints, hepatitis, pulmonary infiltrates, otitis media, thrombocytopenia with evidence of disseminated intravascular coagulation, and urethritis.

The severe morbidity and mortality rates (3 percent) for KD are overwhelmingly associated with the development of inflammatory coronary artery aneurysms, most of which are asymptomatic at the time of formation. Many aneurysms can

be detected by echocardiography. Cardiac involvement occurs in at least 20 percent of unsuccessfully treated patients. Thrombosis occurs in some of the aneurysms, resulting in direct or embolic coronary occlusion syndromes, including sudden death. Clinical coronary events often do not occur until weeks or years after the onset of febrile illness. The focus of initial prompt therapy is on the prevention of aneurysm formation and coronary thrombosis. A baseline echocardiogram should be obtained at the time of the acute illness and repeated 2 and 6 weeks later. If abnormalities are identified, additional studies are warranted. [61] Early recognition of the disease and treatment with IVIG and aspirin have significantly decreased the frequency of aneurysm formation and thrombotic coronary events.

Histopathology of the conjunctiva or skin is not specific, revealing edema and vessel dilatation with a mixed mononuclear infiltrate of predominantly CD4-positive cells and macrophages. [62], [63] Lymph node pathology demonstrates variable necrosis and occasional areas of vasculitis.

Treatment should be initiated with IVIG (2 g/kg as a single dose) and aspirin (80 to 100 mg/kg per day, given every 6 h) as soon as the disease is suspected. [64] It has been suggested that the early administration of IVIG therapy is most effective at preventing aneurysm formation. Aspirin is more effective than glucocorticoids in preventing aneurysms, and glucocorticoid therapy is usually unnecessary. Fever, conjunctivitis, and rash tend to respond within several days to aspirin and IVIG. Patients who do not respond to aspirin and IVIG therapy may benefit from high-dose glucocorticoid therapy. [65]

Large Vessel Arteritis (Takayasu's Arteritis and Temporal Arteritis)

Takayasu's arteritis (TA) and temporal (giant cell) arteritis (GCA) are the most common inflammatory diseases of the aorta and its major branches. Similar vascular targeting may occur in Behçet's disease, Cogan's syndrome, and sarcoidosis. Their associated extravascular features readily distinguish these diseases. GCA generally affects individuals older than 50 years. It is associated in some patients with polymyalgia rheumatica, a syndrome characterized by proximal muscle pain that is more severe at night and in the early morning. There may be a subjective sense of weakness, without true weakness on examination or elevation of serum muscle enzyme levels. GCA is variably associated with fever, headache, masticatory muscle claudication, peripheral vascular disease, inflammatory aortic aneurysms, and retinal ischemic syndromes. Cutaneous manifestations include rare cases of scalp or tongue ischemia and necrosis and, in a minority of cases, cyanosis or pallor due to distal extremity ischemia arising from proximal large vessel occlusive disease. Symptoms and signs in the extremities may be clinically indistinguishable from those occurring in atherosclerotic obliterative disease.

GCA is generally diagnosed by biopsy of the superficial temporal artery. The pathology of GCA usually includes chronic mononuclear cell infiltrates and giant cells. There are isolated reports of GCA overlap syndromes also involving medium-sized vessels of the viscera, but generally this disease is not associated with small (capillary, venule) blood vessel inflammation. [4], [66]

Takayasu's arteritis (pulseless disease) is also a chronic inflammatory disease affecting the aorta and its major branches. Although it is usually recognized in younger (<40 years) predominantly female patients of reproductive age, it can also occur in children and older patients of either sex. TA is more commonly associated with aortic and aortic branch vessel stenoses and aneurysms than GCA. It is uncertain whether TA and GCA are distinct disorders or the same disorder, with modified expression in different age groups. TA is associated with erythema nodosum and, rarely, pyoderma-like lesions more frequently than is GCA. [67], [68] and [69] The presenting clinical syndrome may include prolonged flu-like illness, with a polymyalgia rheumatica pattern of muscle pain. Other patients present only with evidence of limb, cerebral, or cardiac ischemia. Renal ischemia can elicit high renin hypertension. The characteristic features of the disease reflect the ischemia produced by the inflammatory stenoses of the aorta and its major branches. Predominant sites of involvement are the aortic arch vessels, particularly the subclavian artery. Arm claudication is common. Bruits are frequently detectable. Superficial artery pain and tenderness (e.g., carotidynia) may be found on examination but are not diagnostic of TA. Severe central hypertension due to renal artery stenosis may not be recognized because of coexistent arm artery stenosis; thus, four extremity blood pressures must be evaluated initially and monitored on a frequent basis. Stroke is not uncommon and is often related to hypertension. It is extremely difficult to assess the activity of TA; the presence or absence of constitutional features or of elevated acute-phase reactants are poor measures of disease activity. This impression is supported by histopathologic studies of vessel tissue obtained at the time of reconstructive surgery. [67], [70], [71] More than 40 percent of specimens from patients thought to be in remission revealed active inflammation.

Diagnosis is usually made by arteriographic demonstration of stenotic and obstructive lesions. Aneurysms are less commonly observed. The entire arch as well as abdominal aorta and renal vessels should be evaluated; central arterial pressure should be obtained at the time of angiography and compared with simultaneously obtained arm and leg arterial pressures. The role for vascular magnetic resonance imaging in the evaluation and follow-up of these patients is under investigation. Pathologic documentation is more difficult to obtain in TA, but the histopathology is similar to that described above in GCA.

Sarcoidosis may involve the large arteries and occasionally may mimic the vascular disease of TA. [4] A full physical examination and chest radiograph are requisite components of the evaluation of any patient with suspected systemic vasculitic syndrome, and careful examination may reveal subtle findings, such as lacrimal enlargement, to suggest the diagnosis of sarcoidosis. Atherosclerotic disease often presents a more difficult diagnostic distinction in patients with obliterative arterial disease, and certainly can coexist with a primary form of large vessel arteritis. Livedo reticularis (Fig. 174-8) may be present in patients with peripheral vascular disease of various etiologies.

FIGURE 174-8 Livedo reticularis.

The initial therapy of both TA and GCA is with glucocorticoids. GCA is generally quite responsive, although the most appropriate initial dose remains controversial. Different authors have advocated different initial daily doses, ranging from a total of 20 mg to 1 mg/kg body weight, with tapering of the glucocorticoids over 8 to 12 months. The measurement of acute-phase reactants provides an imperfect index of disease activity and an imperfect guide to glucocorticoid tapering. If significant glucocorticoid-induced side effects occur, or if patients relapse during tapering, a second-line agent such as methotrexate is usually (empirically) added to the glucocorticoid regimen. TA appears to respond less consistently to initial glucocorticoid therapy than GCA, but this observation has not been carefully studied. Some authors have advocated the earlier use of methotrexate therapy in TA to reduce the toxicity risks of long-term glucocorticoid therapy. [72] Vascular reconstructive surgery or angioplasty is an adjunctive therapeutic option for some patients. [73]

GENERAL COMMENTS ON THE TREATMENT OF PATIENTS WITH SYSTEMIC ARTERITIS

The systemic vasculitides are potentially life-threatening and often require potent anti-inflammatory and immunosuppressive therapy. Diagnoses should be made with as much certainty as possible. However, questions regarding alternative diagnoses or coexistent diseases may linger. Hence, even after therapy is initiated, physicians need to maintain a high degree of vigilance to detect unrelated medical problems and/or complications of therapy. After the initiation of potent immunosuppressive therapy, there is increased susceptibility to opportunistic infection. The greatest risks occur in patients with marked neutropenia or lymphopenia. Physicians must be particularly wary about attributing new problems to a flare in the underlying disease without considering the possibility of a new or recrudescent infection. Varicella-zoster may present with fever and pain before the appearance of the tell-tale vesicles. Infections from *P. carinii* and cytomegalovirus, systemic fungal infections, and the reactivation of mycobacterial disease occur more frequently than in the normal host. Significant immunosuppression from glucocorticoids and the other medications is frequently associated with mucosal candidiasis, less commonly with molluscum contagiosum, and rarely with Kaposi's sarcoma. Methotrexate may cause a flulike illness after each dose. Methotrexate, azathioprine, and cyclophosphamide may cause leukopenia and, less often, other cytopenias. Glucocorticoids can cause a significant amount of facial and truncal acne, which, especially in younger patients, must be addressed to encourage compliance with therapy. Cutaneous complications, including allergic purpura, can also result from adjunctive medications for hypertension, epilepsy, or arthritis. Reactions to thrombolysis or angiographic studies may include urticaria as well as the cholesterol embolization syndrome in patients with atherosclerosis. Drug-induced pneumonitis has been reported with the use of immunosuppressive agents, especially methotrexate and cyclophosphamide. Azathioprine hypersensitivity reactions can include high spiking fevers, vasculitis, and polymorphous cutaneous eruptions.

Necrotizing angiitis or *vasculitis* comprises a diverse group of disorders that combine segmental inflammation with necrosis of the blood vessels. The vascular damage may result from immunologic and/or inflammatory mechanisms. Clinical syndromes are based on criteria that include the gross appearance and the histologic alterations of the vascular lesions, the caliber of the affected blood vessels, the frequency of involvement of specific organs, and laboratory abnormalities. Necrotizing vasculitis may be a primary disease, may develop as a feature of a systemic disorder, or may be idiopathic.

Necrotizing vasculitis in the skin involves predominantly venules and is known as *cutaneous necrotizing venulitis* (CNV) and *leukocytoclastic vasculitis.* The occurrence of CNV in association with systemic involvement of the small blood vessels has been termed *hypersensitivity angiitis* or *vasculitis, systemic polyangiitis,* and *microscopic polyangiitis.* CNV may occur in association with an underlying chronic disease, may be precipitated by infections or drugs, or may develop for unknown reasons (Table 175-1). Although IgA-mediated small-vessel necrotizing vasculitis has been proposed as a nosologic entity, at the present time an immunopathobiologic classification of CNV is not possible. Systemic forms of necrotizing vasculitis that affect larger blood vessels are considered in Chap. 174.

Associated chronic disorders
Rheumatoid arthritis
Sjögren's syndrome
Systemic lupus erythematosus
Hypergammaglobulinemic purpura
Paraneoplastic vasculitis
Cryoglobulinemia
Ulcerative colitis
Cystic fibrosis
Antineutrophil cytoplasmic or antiphospholipid antibody syndromes
Precipitating events
Bacterial, viral, and mycobacterial infections
Therapeutic and diagnostic agents
Idiopathic disorders
Henoch-Schönlein syndrome
Acute hemorrhagic edema of childhood
Urticarial vasculitis and variants
Erythema elevatum diutinum
Nodular vasculitis
Livedoid vasculitis
Genetic complement deficiencies
Eosinophilic vasculitis
Idiopathic

TABLE 175-1 **Cutaneous Necrotizing Venulitis**

HISTORICAL ASPECTS

Various syndromes of necrotizing vasculitis were described in the nineteenth century, including necrotizing vasculitis of small blood vessels, which were described by Schönlein in 1837 and by Henoch in 1847. In 1952, Zeek differentiated systemic hypersensitivity angiitis that involved small blood vessels from polyarteritis nodosa. In various countries, different diagnostic terms were used to describe necrotizing vasculitis of the small blood vessels in the skin, which were perceived to be arterioles in the 1960s, but were shown to be venules in the 1970s by multiple investigators. CNV and leukocytoclastic vasculitis are the terms in current use.

EPIDEMIOLOGY

The age of patients has a limited influence on CNV. The associated chronic disorder usually determines the age of the affected individual. In children, CNV is most commonly described as the Henoch-Schönlein syndrome or acute hemorrhagic edema of childhood. Antineutrophil cytoplasmic antibody (ANCA)-associated vasculitides are most common in patients older than 50 years.

ETIOLOGY AND PATHOGENESIS

Experimental studies in animal models and observations in humans implicate immune complexes as a major pathobiologic mechanism in the production of CNV. Data obtained in animal models suggest that the localization in venules is related to vasoactive amines and subsequent vasopermeability alterations. Additional factors that are operative in the localization of immune complexes include endothelial-cell surface receptors and the defective clearance

of immune complexes by the reticuloendothelial system.

The most frequently postulated mechanisms in the production of CNV are the local deposition of circulating immune complexes formed during antigen excess or the formation of immune complexes in situ in the skin. Immune complexes may activate the complement system and lead to the generation of C5a anaphylatoxin, which attracts neutrophils. In turn, the neutrophils release lysosomal enzymes that damage tissue. The neutrophil superoxide-generating system may produce reactive oxygen products, which also cause tissue injury. The generation of the chemoattractant leukotriene (LT) B_4 from infiltrating neutrophils enhances the influx of neutrophils. An infiltrate composed predominantly of neutrophils in the lesional skin of patients with CNV is consistent with tissue damage induced by immune complexes that activate the complement system. In the Henoch-Schönlein syndrome, the fragmentation of neutrophils was attributed to apoptosis on the basis of the detection of inducible nitric oxide synthase and nitrotyrosine in the infiltrates and the detection of interleukin (IL)-8 on vascular endothelial cells. [1]

In patients with CNV, circulating immune complexes have been demonstrated in serum as mixed-type cryoglobulins and indirectly by assays that detect C1q precipitins, materials that bind to complement receptors on human lymphocytoid (Raji) cells, materials that bind to monoclonal rheumatoid factor, and substances that function in the antibody-dependent cellular cytotoxicity inhibition assay. The presence of immune complexes is inferred from the occurrence of serum hypocomplementemia with activation of the classic activating pathway and by the detection of increased plasma levels of C4a and C3a anaphylatoxins.

Immune complexes have been detected in lesional tissues by ultrastructural observation as electron-dense subendothelial deposits; and the membrane-attack complex, C5b-9, of the complement system has been detected on the surface of endothelial cells and infiltrating neutrophils. Decay-accelerating factor, a regulatory complement protein that prevents the assembly of the membrane-attack complex, is not present on the surface of endothelial cells of the upper dermal microvasculature. Tissue immune complexes also have been detected by direct immunofluorescence techniques as deposited immunoglobulins and complement proteins. In time-course studies of the evolution of cutaneous vascular lesions, immune reactants have been identified in lesions less than 24 h old. Antigens have been identified in only a few instances as bacterial, viral, mycobacterial, or rickettsial proteins by direct immunofluorescence techniques or by the polymerase chain reaction (PCR).

A role for lymphocytes, mononuclear cells, and Langerhans cells in the production of CNV is suggested by a perivenular infiltrate in skin lesions that is rich in lymphocytes with large and hyperchromatic nuclei, and by a prominence of mononuclear cells in the vascular skin lesions of patients with CNV and Sjögren's syndrome. The lymphocytes express CD3, CD4, CD1a, CD36, intercellular adhesion molecule (ICAM)-1, and lymphocyte function–associated antigen (LFA)-1. Lymphocytes may be activated by immune complexes, by cellular immune mechanisms, or by primary activation in autoimmune disease to produce lymphokines. Endothelial cells also can present antigens to and activate T lymphocytes. Activated macrophages secrete chemokines and lysosomal enzymes. Gamma/delta T cells have been detected in CNV with a neutrophil-rich pattern and with a documented infectious etiology. [2] In these specimens, a 72-kDa heat shock protein was expressed by endothelial cells and antigen-presenting cells.

The participation of mast cells in CNV is suggested by hypogranulated mast cells with shed extracellular granules, by a decreased number of mast cells in biopsy specimens of skin lesions, and by the development of vascular lesions after the intracutaneous injection of histamine in patients with active episodes of CNV. Mast cells can be activated directly by immune complexes through Fc?RIII or by complement fragments acting through their specific receptors. Through the production of histamine, prostaglandin (PG) D_2, and cysteinyl leukotrienes, the mast cell could alter venular permeability; interendothelial cell gaps have been noted in venules in patients with CNV. Eosinophils and neutrophils could be recruited by mast cell–derived chemotactic factors. The neutral proteases and acid hydrolases of mast cells may facilitate tissue damage, and the release of tumor necrosis factor (TNF)-a may increase expression of E-selectin on endothelial cells, thereby facilitating neutrophil recruitment.

Evidence for the role of the mast cell is provided by time-course analyses of the sequential histopathologic changes in individuals with physical urticaria. In a patient with circulating immune complexes and hypocomplementemia, in whom cold and trauma elicited CNV, initial mast cell degranulation was followed by the infiltration by neutrophils with an influx of eosinophils and basophils, the deposition of fibrin, and venular endothelial-cell necrosis. A postulated sequence of events would be the activation of the mast cell by physical stimuli, the release of vasoactive mediators, the deposition of circulating immune complexes with activation of the complement system, the influx of neutrophils, and the development of CNV. Another example of the time course of necrotizing vasculitis in human skin has been provided in an individual with exercise-induced vasculitis. [3] At 3 h, the number of mast cells decreased and the eosinophil was the next cell to appear around the venules with the deposition of eosinophil peroxidase. TNF-a levels were elevated, and E-selectin was expressed on endothelial cells. Subsequently, an influx of neutrophils appeared with the deposition of neutrophil elastase and the development of CNV.

Early in the course of necrotizing vasculitis, endothelial cells show increased expression of ICAM-1 and E-selectin without the expression of vascular cell adhesion molecule (VCAM)-1 in response to TNF-a. Because E-selectin is an adhesion molecule for neutrophils and for skin-homing, memory T lymphocytes, the increase in E-selectin is consistent with the appearance of an infiltrate of neutrophils that express CD11b within the first 24 h. [4]

In skin biopsy specimens from patients with idiopathic cutaneous vasculitis, hypersensitivity vasculitis, urticarial vasculitis, and Henoch-Schönlein syndrome, E-selectin was detected on endothelial cells of lesions less than 48 h old and was associated with an infiltrate of neutrophils expressing CD11b. The endothelial cells expressed human leukocyte antigen (HLA)-DR and very-late activating antigen (VLA)-1 but not P-selectin, and the perivascular cells demonstrated VCAM-1 and HLA-DR. Diminished cutaneous fibrinolytic activity with reduced release of plasminogen activator from venular endothelial cells occurs in patients with CNV; the subsequent reduction in fibrinolytic activity leads to fibrin deposition. Increased levels of plasma thrombomodulin, tissue-type plasminogen activator, and plasminogen activator

inhibitor-1 were detected in patients with Henoch-Schönlein syndrome. [5], [6]

Cutaneous nerve fibers can release neuropeptides, such as substance P, neurokinin A, and calcitonin gene-related peptide (CGRP), that cause vasodilation. Substance P activates mast cells and macrophages and increases fibrinolytic activity mediated by plasminogen activator. CGRP induces expression of E-selectin on endothelial cells and is chemotactic for T lymphocytes.

Eosinophils are minor infiltrating cells in CNV except in eosinophilic vasculitis. Eosinophils could produce LTC_4 and platelet-activating factor (PAF), which increase vascular permeability. Eosinophil granule proteins are toxic to endothelial cells and cause the release of chemical mediators from mast cells.

Associations have been recognized between small-vessel necrotizing vasculitis and ANCAs, which have specificity for proteins of the cytoplasmic granules of neutrophils and the lysosomes of monocytes. Two forms are recognized: cytoplasmic (C-ANCAs) and perinuclear (p-ANCAs). In patients with necrotizing vasculitis, most C-ANCAs are specific for proteinase 3 and most p-ANCAs are specific for myeloperoxidase. Antiendothelial cell antibodies have been detected in the sera of patients with systemic vasculitis, rheumatoid arthritis with vasculitis, microscopic polyangiitis, and Sneddon's syndrome.

An increased prevalence of the HLA haplotype HLA-A11, Bw35 in patients with CNV and associated connective tissue disorders suggests that genetic factors may be operative.

CLINICAL MANIFESTATIONS

The skin lesions of CNV are polymorphous; however, erythematous papules that do not blanch when the skin is pressed, which are known as *palpable purpura,* are the signature lesions (Fig. 175-1A). Macules, papules, urticaria/angioedema, pustules, vesicles, ulcers, necrosis, and livedo reticularis may be present. Occasionally, there is subcutaneous edema below the area of the dermal lesions.

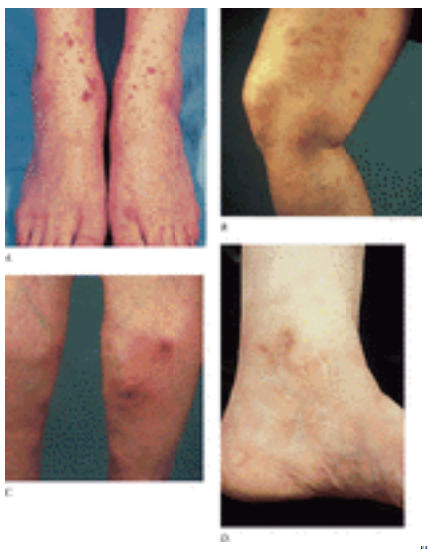

FIGURE 175-1 *A*. Palpable purpura over the feet and ankles of a patient with Henoch-Schönlein syndrome. *B*. Idiopathic urticarial vasculitis over the leg. *C*. Nodular vasculitis over the lower legs. Note ulcers. *D*. Atrophie blanche over the medial malleolus with atrophic areas, telangiectases, punctate ulcers, and hyperpigmentation.

The vascular eruption most often appears on the lower extremities or over dependent areas, such as the back and gluteal regions. The lesions may occur anywhere on the skin but are uncommon on the face, palms, soles, and mucous membranes. The clinical lesions are episodic and may recur over weeks to years. Palpable purpura persists for 1 to 4 weeks and resolves at times with transient hyperpigmentation and/or atrophic scars. Lesional symptoms include pruritus or burning and, less commonly, pain.

An episode of cutaneous vascular lesions may be attended by fever, malaise, arthralgias, or myalgias irrespective of a defined underlying or associated disease. Systemic involvement of the small blood vessels most commonly occurs in the synovia, gastrointestinal tract, voluntary muscles, peripheral nerves, and kidneys.

Associated Chronic Disorders

CNV is associated with connective-tissue diseases, notably rheumatoid arthritis, Sjögren's syndrome, systemic lupus erythematous (SLE), and hypergammaglobulinemic purpura. It rarely occurs in mixed connective-tissue disease, relapsing polychondritis, and scleroderma. In patients with rheumatoid arthritis and CNV, the development of vascular lesions is related to the severity of the disease, which is generally but not always seropositive. Subcutaneous nodules, as well as cutaneous ulcers, may be present. Patients with rheumatoid arthritis often have involvement of larger vessels with associated peripheral neuropathy, nail fold infarcts, and digital gangrene.

In patients with SLE, the vasculitis is associated with exacerbations of the underlying disease. Vasculitis, however, is rare in patients with subacute cutaneous lupus erythematosus. Approximately 5 percent of women with necrotizing vasculitis without connective-tissue disease have anti-Ro antibodies, and their infants may be born with neonatal lupus erythematosus. [7]

In patients with Sjögren's syndrome, the vascular lesions are located predominantly on the lower extremities and appear

after exercise. Both hyperpigmentation and cutaneous ulcers are common features. Hypergammaglobulinemic purpura occurs in older women and may be associated with Sjögren's syndrome, SLE, or a lymphoproliferative disorder. Dermatomyositis in children, but not in adults, may be associated with vasculitis of the gastrointestinal tract.

Paraneoplastic vasculitis is used to describe CNV with associated malignant conditions, including Hodgkin's disease, lymphosarcoma, adult T cell leukemia, mycosis fungoides, myelofibrosis, acute and chronic myelogenous forms of leukemia, IgA myeloma, diffuse large-cell leukemia, hairy-cell leukemia, squamous-cell bronchiogenic carcinoma, prostatic carcinoma, renal carcinoma, and colon carcinoma. However, the association between CNV and neoplasia is rare. It is not necessary to evaluate all patients with CNV for associated malignant conditions.

Cryoglobulins, especially mixed types II and III, may be found in patients with idiopathic CNV and in patients with CNV associated with connective-tissue diseases, lymphoproliferative disorders, and hepatitis A, B, and C virus infections, although hepatitis C virus is the most common infection. [8] CNV occurs in patients with cystic fibrosis, inflammatory bowel diseases of the colon, and Behçet's disease. [9]

Both ANCAs and antiphospholipid antibodies are associated with various forms of necrotizing vasculitis. ANCAs are present in patients with microscopic polyangiitis and cutaneous vasculitis with hepatitis C virus infection. The most common cutaneous feature in patients with ANCAs is palpable purpura. Microscopic polyangiitis is associated with small-vessel systemic vasculitis that involves the cutaneous venules and arterioles, kidneys with necrotizing and crescentic glomerulonephritis, and p-ANCAs. A male patient has experienced microscopic polyangiitis restricted to the skin and ANCAs for 20 years without progression to systemic vascular disease. [10]

Antiphospholipid antibodies, either anticardiolipin antibodies and/or lupus anticoagulant, occur in patients with autoimmune and connective-tissue diseases and as an idiopathic disorder. Livedo reticularis is the most frequently recognized cutaneous finding. [11] Antiphospholipid antibodies of the IgA class were detected in 6 of 10 patients with idiopathic cutaneous necrotizing vasculitis, and antiphospholipid antibodies have been detected in some individuals with livedoid vasculitis. [12] A female patient with antiphospholipid antibodies and cutaneous nodules that demonstrated vasculitis and thrombosis on biopsy has been reported.

Precipitating Infections and Drugs

Infections and drugs precipitate episodes of CNV. The most commonly recognized infectious agents are group A hemolytic streptococci, *Staphylococcus aureus, Mycobacterium leprae,* and hepatitis B and C viruses. Transient episodes of urticaria may occur early in the course of hepatitis B virus infection and represent immune complex–induced vasculitis; episodes of palpable purpura may occur in patients with chronic active hepatitis. Cutaneous vasculitis was identified in patients with hepatitis A and C infections. [13] Cutaneous vasculitis has been recognized in a limited number of individuals with HIV infection; the skin lesions consisted of palpable purpura, at times with a follicular localization, and cutaneous ulcers.

Erythema nodosum leprosum, which appears as cutaneous nodular lesions in lepromatous leprosy, is a form of necrotizing vasculitis involving capillaries, venules, arterioles, small-to- medium-sized arteries, and veins. The vascular lesions occur spontaneously or are precipitated by the administration of chemotherapeutic agents. They may be accompanied by fever, malaise, arthralgias, lymphadenopathy, and polyneuritis.

Necrotizing vasculitis caused by the direct invasion of the blood vessel wall occurs in *Neisseria meningitidis* bacteremia, in Rocky Mountain spotted fever, and in infections localized at the site of a catheter.

Palpable purpura is one of the less common forms of drug reactions. The most commonly incriminated therapeutic agents are penicillin, sulfonamides, thiazides, allopurinol, hydantoins, and nonsteroidal anti-inflammatory agents. Propylthiouracil [14] and hydralazine may cause vasculitis in association with ANCAs. Cutaneous vasculitis has occurred after the administration of streptokinase, radiocontrast media, monoclonal antibodies, granulocyte colony-stimulating factor, staphylococcal protein A column immunoadsorption therapy, drug additives, and etanercept. [15]

Idiopathic Disorders

HENOCH-SCHÖNLEIN SYNDROME The most widely recognized subgroup of idiopathic CNV is the *Henoch-Schönlein syndrome,* formerly known as anaphylactoid purpura. It occurs predominantly in children, with a peak incidence at 5 years of age, but it may occur in adults. [16] A history of a recent upper respiratory tract infection, especially streptococcal, is obtained in up to 75 percent of individuals; however, Henoch-Schönlein syndrome has been associated with other infections. Sites of involvement include the skin, synovia, gastrointestinal tract, and kidneys. Long-term morbidity from progressive renal disease occurs in 5 percent of patients. The spread of purpura to the upper parts of the trunk is a predictive factor for renal involvement. [16]

ACUTE HEMORRHAGIC EDEMA OF CHILDHOOD This uncommon disorder, which often goes unrecognized or has been confused with Henoch-Schönlein syndrome, affects infants and children younger than 2 years of age, but it has been reported in one adult. The lesions appear as painful, edematous petechiae and ecchymoses that affect the head and distal portions of the extremities. Facial edema may be the initial sign. The skin lesions may be associated with a target-like appearance and may develop bullae and necrosis. Infection, drugs, or immunization may be triggering factors. Acute hemorrhagic edema of childhood is distinguished from Henoch-Schönlein syndrome by its occurrence in children aged 4 months to 2 years, lack of systemic features, and resolution within 1 to 3 weeks without sequelae.

URTICARIAL VASCULITIS Episodes of recurrent and chronic urticaria and angioedema may be a clinical manifestation of CNV. [17], [18] Known as *urticarial vasculitis,* this edematous form of necrotizing venulitis occurs in patients with serum sickness, connective-tissue disorders, an IgM $_{K}$ M component, infections, and physical urticarias; after the administration of potassium iodide and nonsteroidal anti-inflammatory agents; and as an idiopathic disorder. Single case reports exist of

patients with urticarial vasculitis and colon carcinoma, IgA myeloma, polycythemia vera, [19] Muckle-Wells syndrome, and Cogan's syndrome. Infections include hepatitis B and C viruses and infectious mononucleosis. The term *hypocomplementemic urticarial vasculitis syndrome* has been used to describe patients with more severe systemic manifestations and an autoantibody to Clq. The skin lesions appear as erythematous, occasionally indurated, wheals that may contain foci of purpura (Fig. 175-1B). Other skin manifestations include angioedema, macular erythema, livedo reticularis, nodules, and bullae. Although the individual urticarial lesions may last for fewer than 24 h, they often persist for up to 3 to 5 days. The lesions are pruritic or possess a burning or painful quality; they usually resolve without residua, although some individuals may develop contusions or hyperpigmentation. The episodes of urticaria are chronic, range in duration from months to years, and vary in frequency. Approximately 70 percent of affected individuals are women. The prevalence of this disorder remains unknown. General features include fever, malaise, and myalgia; the lymph nodes, liver, and spleen may be enlarged (Table 175-2).

General features
Fever
Malaise
Myalgia
Specific organ involvement
Lymphadenopathy
Hepatosplenomegaly
Synovia (arthralgia, arthritis)
Kidneys (glomerulitis, glomerulonephritis)
Gastrointestinal tract (nausea, vomiting, pain, diarrhea)
Respiratory tract (laryngeal edema, shortness of breath, chronic obstructive pulmonary disease, and, less commonly, interstitial pulmonary disease)
Eyes (conjunctivitis, episcleritis, iridocyclitis, uveitis)
Central nervous system (headache, benign intracranial hypertension)

TABLE 175-2 **Extracutaneous Manifestations of Urticarial Vasculitis**

Episodic arthralgias are a major clinical manifestation and affect the elbows, wrists, fingers, knees, ankles, and toes. Arthritis with necrotizing venulitis apparent in biopsy specimens of the synovial tissue occasionally develops. Urticarial vasculitis is associated with Jaccoud's syndrome. [20] Renal involvement occurs as a diffuse glomerulitis or glomerulonephritis; however, progression to severe impairment of renal function is rare. Gastrointestinal tract manifestations include nausea, vomiting, diarrhea, and pain. Laryngeal edema may occur. Chronic obstructive pulmonary manifestations and less frequently interstitial lung disease may develop. Conjunctivitis, episcleritis, iridocyclitis, and uveitis develop in some individuals. Rarely, cardiac valvular involvement may occur. [21] There is one report of an individual becoming blind. Headaches and pseudotumor cerebri (benign intracranial hypertension) reflect central nervous system involvement. The natural history of urticarial vasculitis is unknown, although individuals have been described with historical episodes of cutaneous lesions for up to 25 years. In one series of patients followed for 1 year, 40 percent experienced complete resolution of skin lesions; in another series of individuals followed for as long as 14 years, resolution occurred in only one patient. Sjögren's syndrome and SLE have developed. Deaths have been reported from pulmonary disease, sepsis, and myocardial infarction. The prevalence of urticarial vasculitis in individuals with chronic idiopathic urticaria is unknown, although series have reported rates ranging from 1 percent to 50 percent. Most of these data have been reported from tertiary referral centers, and the prevalence is most likely less than 1 percent. Necrotizing vasculitis of cutaneous venules has been described in isolated instances of dermographism, cold urticaria, delayed pressure urticaria, solar urticaria, and exercise-induced urticaria. [3] However, the prevalence of necrotizing vasculitis in patients with physical urticaria is unknown, and the importance of this histologic finding for prognosis and therapy remains to be elucidated. Individuals with these physical urticarias have provided experimental models for time-course studies of the evolution of necrotizing vasculitis in human skin. *Schnitzler's syndrome* consists of episodes of urticarial vasculitis that occur in association with a monoclonal IgM $_K$ M component. Associated features include fever, lymphadenopathy, hepatosplenomegaly, bone pain with osteosclerosis, and a sensorimotor neuropathy. Evolution into a lymphoplasmacytic malignant condition has been reported in 15 percent of patients. [22]

ERYTHEMA ELEVATUM DIUTINUM *Erythema elevatum diutinum* (see Chap. 95) occurs as symmetric, persistent, red-purple or red-brown plaques that are predominantly disposed over the joints of extensor surfaces and over the gluteal area. Arthralgia of the associated joints may be a feature. Other systemic manifestations are lacking. A history of recurrent streptococcal infections is frequently obtained. This condition may be associated with IgA monoclonal gammopathy, multiple myeloma, B cell lymphoma, [23] myelodysplasia, celiac disease, relapsing polychondritis, and HIV infection. [24], [25]

NODULAR VASCULITIS *Nodular vasculitis* (Fig. 175-1C) appears as tender, red, subcutaneous nodules over the lower extremities, especially the calves, without systemic manifestations. At times, lesions may be develop on the thighs, buttocks, trunk, and arms, and ulcerated nodules are present. Recurrent episodes are common. It is more common in women and has a peak incidence in individuals between 30 and 40 years of age. *Erythema induratum* is a form of nodular vasculitis, that has been associated with *Mycobacterium tuberculosis* infection, as demonstrated by polymerase chain reaction (PCR) amplification for *M. tuberculosis* DNA in skin biopsy specimens. [26] Various sizes of blood vessels including venules are affected. [27]

LIVEDOID VASCULITIS *Livedoid vasculitis* (Fig. 175-1D), known also as livedoid vasculopathy, livedo vasculitis, segmental hyalinizing vasculitis, and atrophie blanche, occurs as recurrent, painful ulcers of the lower extremities in association with a persistent livedo reticularis (*livedo racemosa*) that often is deep purple in color. Healing results in sclerotic pale areas surrounded by telangiectases that are designated atrophie blanche. Many patients have arteriosclerosis or stasis of the lower extremities, and mononeuritis multiplex has been identified in a single patient. [28] Livedoid vasculitis is more common in women, may occur in patients with SLE who develop central nervous system features, and has been reported in two patients with protein C deficiency. [29] Atrophie blanche, however, probably represents the end stage of a variety of forms of vascular damage in the skin. Elevation of fibrinopeptide A levels may occur in blood. Pathogenesis has focused on a hypercoagulable state with fibrin thrombi in the lumens of the superficial blood vessels. Some consider this condition a thrombogenic vasculopathy rather than a small-vessel vasculitis. Antiphospholipid antibodies have been detected in a few individuals. [12] *Sneddon's syndrome* [30], [31] is a condition in which livedo reticularis and livedoid vasculitis are associated with ischemic cerebrovascular lesions, hypotension, and extracerebral arterial and venous thromboses. Antiendothelial cell antibodies were detected in the serum in 35 percent of individuals; antiphospholipid antibodies, anti–ß $_2$-glycoprotein antibodies, and antiprothrombin antibodies [32] were detected in some patients.

GENETIC COMPLEMENT DEFICIENCIES Genetic C2 deficiency has been recognized in association with CNV in three children, and a C4 deficiency was present in one child with CNV. Deficiencies of C4A and C4B isotypes were found in

some children and adults with Henoch-Schönlein syndrome. A partial C4B deficiency with C4 A1, A3, B1, and a null allele B*QO was reported in a 51-year-old woman with CNV. [33]

EOSINOPHILIC VASCULITIS Eosinophilic vasculitis has been described as an idiopathic syndrome in individuals with recurrent, pruritic, and purpuric papular skin lesions, urticarial plaques, and angioedema. Skin biopsy specimens showed an infiltrate composed of eosinophils expressing CD40 [34] and VCAM-1 on endothelial cells of involved vessels. Eosinophilic vasculitis also has been described in some individuals with a hypereosinophilic syndrome, [34] and in others with connective-tissue disorders. [35], [36]

IDIOPATHIC Individuals with CNV who do not meet the criteria for recognized syndromes are classified as idiopathic.

LABORATORY FINDINGS

The laboratory evaluation of patients with CNV depends on information obtained from the history and physical examination (Table 175-3). An elevated erythrocyte sedimentation rate is the most consistent abnormal laboratory finding. The platelet count is usually normal. Other abnormalities reflect either a coexistent chronic disorder or the involvement of additional organ systems. Occasionally, leukocytosis, anemia, thrombocytosis, an abnormal urine sediment, circulating immune complexes, rheumatoid factor, and antinuclear antibodies have been reported in idiopathic disease.

Erythrocyte sedimentation rate
White blood cell count with differential analysis
Platelet count
Urinalysis
24-Hour urine protein and creatinine clearance
Blood chemistry profile
Serum protein electrophoresis
Hepatitis B antigens and hepatitis A and C antibodies
Cryoglobulins
CH50
Antinuclear antibody
Rheumatoid factor
Antineutrophil cytoplasmic antibodies
Antiphospholipid antibodies
Circulating immune complexes
Skin biopsy

TABLE 175-3 **Laboratory Evaluation of Cutaneous Necrotizing Venulitis**

Serum complement levels are usually normal. Hypocomplementemia may develop in patients with concomitant connective tissue diseases or cryoglobulinemia and reflects the associated disease or the composition of the cryoglobulin. Hypocomplementemia also occurs in some individuals with idiopathic CNV and in 40 percent of individuals with urticarial vasculitis.

In some patients with the hypocomplementemic urticarial vasculitis syndrome, a low-molecular-weight 7s C1q precipitin, identified as an IgG autoantibody against the collagen-like region of C1q, was detected. The antigen-antibody interaction involves the $F(ab')_2$ fragment of IgG. Autoantibodies to vascular endothelial cells were detected in patients with the hypocomplementic urticarial vasculitis syndrome, in patients with SLE and urticarial vasculitis, and in patients with urticarial vasculitis alone. [37] In a single patient with Schnitzler's syndrome, autoantibodies against dermal microvascular endothelial cells, mast cells, and the FceRIa receptor were detected. [38] In Henoch-Schönlein syndrome, serum IgA_1 levels are elevated. In patients with CNV, various types of circulating immune complexes and IgA ANCAs [39] have been described. IgG autoantibodies against IgE also have been identified in four of eight patients with urticarial vasculitis.

PATHOLOGY

In skin biopsy specimens of palpable purpura and urticarial vasculitis stained with hematoxylin and eosin (H&E) (Fig. 175-2A), the histologic criteria requisite for the diagnosis of CNV include necrosis of the blood vessels with the deposition of fibrinoid material and dermal cellular infiltrates that consist of neutrophils with nuclear debris, mononuclear cells, and extravasated erythrocytes. The dermal inflammatory infiltrates vary in intensity and are usually perivenular in location but at times are dispersed widely. The fibrinoid material consists of fibrin, necrotic endothelial cells, and deposited immunoreactants.

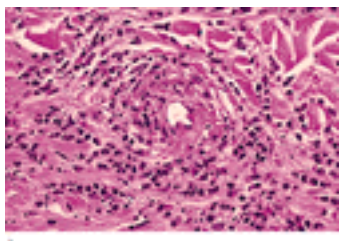

FIGURE 175-2 *A*. Perivenular infiltrate of neutrophils with fibrin deposition. H&E stain, ×50 in the original magnification. *B*. Endothelial cell necrosis of venule with perivenular fibrin and neutrophils. 1-µm section, Giemsa stain, ×1000 in the original magnification.

Studies with 1-µm-thick sections (Fig. 175-2B) show two distinct cellular patterns in CNV: one rich in neutrophils and the other in lymphocytes. Neither pattern appears to be the result of evolution of the tissue changes associated with the dynamic nature of the cellular infiltrate. Although the infiltrate of neutrophils regresses with the persistence of an infiltrate of mononuclear cells, repeat biopsy specimens in some patients consistently demonstrated an infiltrate of mononuclear cells. In a time-course study over 6 days of the evolution of experimentally induced CNV in a patient with physical urticarias, the number of infiltrating neutrophils decreased without a concomitant increase in lymphocytes, although the number of monocyte-macrophages was increased at 48 and 72 h. Other features in both cell patterns of CNV include hypogranulated mast cells, macrophages containing debris, and the perivenular and interstitial deposition of fibrin. Venular alterations in both cell patterns consist of endothelial cell swelling, activation of nuclei, wrinkling of nuclear membranes, necrosis (Fig. 175-2B), and basement membrane reduplication and thickening. The arterioles are not affected. Some patients with connective-tissue disorders and cutaneous vasculitis have an infiltrate of inflammatory cells composed of eosinophils with deposited major basic protein and decreased numbers of mast cells. [35]

By direct immunofluorescence techniques, fibrin deposition in venules is routinely identified in biopsy specimens, whereas the deposition of immunoglobulins and complement proteins varies widely. IgG is the most commonly deposited immunoglobulin, although IgM and IgA also have been detected. IgA is deposited about blood vessels in the skin, intestines, and kidneys in the Henoch-Schönlein syndrome and has become an immunopathologic marker of this condition. In the skin in Henoch-Schönlein syndrome, IgA_1 is the dominant subclass deposited. [40] C3 is the only complement protein that has been sought with frequency.

Biopsy specimens of the acute lesions of erythema elevation diutinum exhibit necrotizing venulitis with neutrophil infiltration, dermal expression of CR3 and LFA-1, and increased numbers of mast cells; [41] specimens of the chronic lesions exhibit fibrosis and an infiltrate containing macrophages. [42]

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Thrombocytopenia may result in purpura; however, these lesions are flat. Other causes of nonpalpable cutaneous purpura include local trauma to the skin of aged individuals with vascular fragility, chronic sun exposure, and endogenous or iatrogenic hypercorticism. Erythema elevatum diutinum may resemble Kaposi's sarcoma. Scurvy may appear as hemorrhagic, follicular papules over the lower extremities. Various infectious agents may be associated with hemorrhagic skin lesions that arise from disseminated intravascular coagulation or septic emboli. The cutaneous manifestations of disseminated intravascular coagulation, known as *purpura fulminans,* appear as extensive areas of purpura with a slate-gray color. These lesions occur in patients with acute meningococcemia; skin biopsy specimens show thrombosis but not necrotizing venulitis. Septic emboli occur as finite numbers of hemorrhagic pustules, papules, and vesicles distributed over acral areas. Rarely, echo and coxsackie virus infections may cause purpuric papules. Rocky Mountain spotted fever typically begins as purpuric papules over the ankles and wrists that spread to include the trunk. Cholesterol embolization includes purpura, livedo reticularis, ulcers, and nodules.

The progressive pigmentary purpuric dermatoses (purpura simplex) (see Chap. 176), which include a number of disorders, appear as macular, petechial, pigmented, or lichenoid lesions.

The differential diagnosis of cutaneous nodules includes erythema nodosum, panniculitis, superficial forms of thrombophlebitis, fat necrosis associated with pancreatic disease, and systemic vasculitides, such as polyarteritis nodosa, Wegener's granulomatosis, and Churg-Strauss syndrome.

TREATMENT

Therapeutic approaches may be divided into removal of the antigen, treatment of an underlying disease, and treatment of CNV. Treatment of necrotizing vasculitis consists of prevention of the deposition of immune complexes, suppression of the inflammatory response, modulation of underlying immunopathologic mechanisms, and local therapy. When the eruption is associated with a precipitating event, withdrawal of the medication or treatment of the infection results in resolution of the cutaneous lesions. If a coexistent chronic disease is present, treatment of the underlying disease may be associated with improvement in the cutaneous vascular lesions. In many cases, CNV is a self-limited condition, and double-blind, placebo-controlled, prospective trials of therapeutic agents are usually lacking.

The treatment of CNV can be divided into two phases (Table 175-4), each of which depends on an analysis of the cutaneous disability as well as the toxicity and side effects of the therapeutic agents. H_1 antihistamines are used in patients with palpable purpura to alleviate lesional symptoms and perhaps to reduce tissue deposition of circulating immune complexes. Nonsteroidal anti-inflammatory agents are combined with the H_1 antihistamine. Depending on the therapeutic response, colchicine or hydroxychloroquine sulfate can be added to or substituted for these agents. However, colchicine was shown to have no significant therapeutic effect in a prospective, randomized, controlled trial. If there is no benefit, dapsone can be used. If there still is no therapeutic response, a major decision must be made because the medications to be considered in the second phase (systemic glucocorticoids, azathioprine, methotrexate, cyclophosphamide, plasmapheresis, cyclosporine, [43] and intravenous immunoglobulin [44]) are associated with more serious side effects. Although all of these agents have been reported to benefit some patients, controlled clinical trials are not available. The administration of interferon-a is associated with clearing of cutaneous vasculitis in patients with hepatitis C virus infection.

Phase one
H_1 antihistamines
Nonsteroidal anti-inflammatory agents
Colchicine
Hydroxychloroquine sulfate
Dapsone
Phase two
Systemic glucocorticoids
Azathioprine
Cyclophosphamide
Intravenous gamma globulin
Cyclosporine
Plasmapheresis

TABLE 175-4 **Algorithm for Treatment of Cutaneous Necrotizing Venulitis**

The treatment of urticarial vasculitis is similar to that of palpable purpura. Additional case reports exist on the treatment of patients with intramuscular gold therapy, cyclophosphamide-dexamethasone pulse therapy, [45] mycophenolate mofetil, [46] and psoralen plus ultraviolet A (PUVA) photochemotherapy. [47]

In patients with erythema elevatum diutinum, dapsone is the drug of choice. Plasma exchange plus chlorambucil was a successful treatment for one individual with erythema elevatum diutinum and a monoclonal IgA paraprotein. [48] The treatment of nodular vasculitis consists of empiric trials of a variety of therapeutic agents that include a saturated solution of potassium iodide, nonsteroidal anti-inflammatory drugs, colchicine, and systemic glucocorticoids. Thalidomide is the treatment of choice for erythema nodosum leprosum.

In the treatment of livedoid vasculitis, support stockings are useful. Empiric trials of aspirin and dipyridamole, colchicine, dapsone, danazol, [49] low-dose heparin, systemic glucocorticoids, nicotinic acid, low-molecular-weight dextran, phenformin and ethylestrenol, nifedipine, and pentoxifylline are used. Infusions of prostacyclin, prostaglandin E_1, and intravenous immunoglobulin [50] have been used successfully in one patient each.

REFERENCES

The pigmented purpuric eruptions are a group of dermatoses characterized by petechiae, pigmentation, and occasionally telangiectasia in the absence of associated venous insufficiency or hematologic disorders (see Table 176-1). Synonyms include *persistent pigmented purpuric dermatitis, purpura simplex,* and *purpura pigmentosa chronica*. They are found most commonly on the lower extremities; however, the lesions may involve the upper body and rarely become generalized. There are reports of palm, sole, and oral mucosal involvement. Although most common in men, they also occur in women and children. These benign, generally asymptomatic eruptions tend to be chronic with remissions and flares. They share common histopathologic features including perivascular lymphocytic inflammation, erythrocyte extravasation, and hemosiderin deposition.

TABLE 176-1 **Pigmented Purpuric Eruptions**

Despite the similarity in histopathology, the clinical variation among these processes led to the subclassification of pigmented dermatoses into eponymic groups. Although there is some clinical variation between the groups, there is also frequent overlap, which may make differentiation difficult. These subgroups are more of historical interest than clinical usefulness. It is especially important to distinguish the pigmented purpuric eruptions from the types of purpura associated with systemic disease.

PROGRESSIVE PIGMENTARY DERMATOSIS (SCHAMBERG'S DISEASE)

Schamberg first described a macular pigmented eruption on the legs of a 15-year-old boy in 1901. The patient had irregularly shaped reddish-brown patches with “pinhead sized reddish puncta, closely resembling grains of cayenne pepper.” [1]

Although the first case was described in a teenager, the average age of onset of Schamberg's disease is in the fifth decade. The lesions tend to develop insidiously on either or both lower legs. Lesions can involve the trunk or the upper extremities (Fig. 176-1 and Fig. 176-2). Schamberg's disease is generally asymptomatic and persistent. Remissions and flares can occur indefinitely.

FIGURE 176-1 Schamberg's disease.

FIGURE 176-2 “Cayenne pepper” appearance of Schamberg's disease. (*Courtesy of S. Mallory, MD.*)

PURPURA ANNULARIS TELANGIECTODES (MAJOCCHI'S PURPURA)

The original case described by Majocchi, in 1896, was a 21-year-old man with annular patches of follicular and punctate reddish-brown macules, with telangiectasias and purpura on the lower extremities. [2] The annular pattern is the distinctive characteristic of this subtype (Fig. 176-3). The individual lesions may have central hypopigmentation and slight atrophy, with peripheral telangiectasias. Linear and irregularly shaped patterns may also occur. The lesions most often present symmetrically on the lower extremities; however, the upper extremities and trunk may be involved. The lesions are asymptomatic and usually last several months with relapses and remissions. This subtype occurs more commonly in young adult females.

FIGURE 176-3 Purpura annularis telangiectodes (Majocchi's purpura).

PIGMENTED PURPURIC LICHENOID DERMATOSIS (GOUGEROT AND BLUM)

In 1925, Gougerot and Blum reported a pigmented eruption on the lower extremity of a 41-year-old male. [3] They described the lesions as orange-red, individual and grouped, papules. The distinguishing feature of this subtype is the primary lesion, a reddish-brown polygonal or round lichenoid papule, sometimes with telangiectasia (Fig. 176-4). Individual papules frequently coalesce into plaques with or without overlying scale. The term *lichenoid* describes the clinical appearance rather than a histologic feature. The color and morphology of the lesions can be mistaken clinically for Kaposi's sarcoma (Fig. 176-4). Like the other subtypes, this eruption is found on the lower extremities and occasionally the arms. It occurs in males more often than females, and has a chronic course.

FIGURE 176-4 Lichenoid dermatosis of Gougerot and Blum. (*Courtesy of S. Mallory, MD.*)

ECZEMATID-LIKE PURPURA OF DOUCAS AND KAPETANAKIS

Doucas and Kapetanakis reported a group of patients with an asymptomatic seasonal eruption occurring in the spring-summer. [4] Its distinguishing quality was the mild scale overlying the typical patches and pinpoint erythematous macules. These spread rapidly over a period of 15 to 30 days, involving the legs and, occasionally, the upper body. This eruption fades without treatment over several months to years.

ITCHING PURPURA (DISSEMINATED PRURIGINOUS ANGIODERMATITIS)

The acute onset and widespread involvement of orange-brown to purpuric macules with severe pruritus distinguishes this eruption (Fig. 176-5). It usually appears first on the lower extremities and may become generalized (Fig. 176-5). This disorder has a chronic course, but there can be spontaneous remissions. Middle-aged men are most commonly affected.

FIGURE 176-5 Disseminated pruriginous angiodermatitis (itching purpura). (*Courtesy of S. Mallory, MD.*)

LICHEN AUREUS (LICHEN PURPURICUS)

Marten first coined the term “lichen purpuricus” in 1958, [5] and Calnan later termed the same eruption “lichen aureus.” [6] In this condition, lichen refers to both the clinical and histopathologic descriptions. There is a bandlike dermal inflammatory infiltrate that accompanies the typical pathology of the pigmented purpuras. Clinically, there are circumscribed areas of confluent gold to copper-orange to purple macules or papules (Fig. 176-6). Although these lesions may be intensely pruritic they are typically asymptomatic. They are most commonly unilateral and localized on the lower extremities, but they can affect the forearms and trunk. This disorder has a predilection for young adults with a peak incidence in the second and third decades. The lesions tend to be chronic, remaining stable or progressing slowly. Spontaneous resolution rarely occurs in adults, but in children the eruption may be self-limited.

FIGURE 176-6 Lichen aureus. (*Courtesy of S. Mallory, MD.*)

UNILATERAL LINEAR CAPILLARITIS

Riordan et al. reported a linear and pseudodermatomal distribution of pigmented purpura in four young males (average age 22 years). [7] The four patients all had a macular, pigmented unilateral eruption involving the foot, leg, or buttock. Clinically, the lesions most closely represented lichen aureus; however, the pathology did not show a lichenoid infiltrate. Furthermore, all four cases resolved spontaneously in approximately 2 years, unlike the typically chronic course of lichen aureus. There are also reported cases of segmental or zosteriform lichen aureus. [8] A similar segmental pattern was described in a 48-year-old woman involving the right lower extremity and lower trunk. The clinical description of this case was that of “numerous punctate purpuric and ‘cayenne pepper’ spots most suggestive of Schamberg's disease.” [9]

GRANULOMATOUS PIGMENTED PURPURA

Saito and Matsuoka reported a granulomatous variant of pigmented purpuric dermatosis in 1996, [10] and Wong reported two additional cases. [11] The mean age of onset was 59 years; all patients were of Asian descent and all lesions occurred only on the dorsum of the feet. Histopathologic examination showed a dense mononuclear cell infiltrate with granulomas in the papillary dermis, thickened capillaries, and hemosiderin deposits. The duration of the lesions ranged from 2 months to 20 years.

HISTOPATHOLOGY

The pigmented purpuric dermatoses share similar histopathology. In early lesions, a lymphocytic perivascular infiltrate is found in the papillary dermis with extravasated erythrocytes (Fig. 176-7). The epidermis may show spongiosis or parakeratosis, especially in the pigmented purpuric lichenoid dermatitis of Gougerot-Blum and in the eczematid-like purpura of Doucas and Kapetanakis. In older lesions, there is less inflammation and extravasated red blood cells may no

longer be present. Hemosiderin is deposited primarily in macrophages. In lichen aureus, the mononuclear infiltrate in the upper dermis is distributed in a bandlike fashion with a Grenz zone.

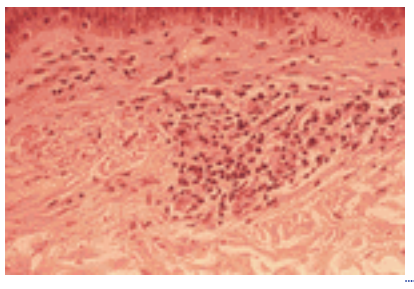

FIGURE 176-7 Pigmented purpuric dermatosis showing superficial perivascular lymphocytes and extravasated erythrocytes.

PATHOGENESIS

There are three different views to the pathogenesis of these processes. The first is a disturbance or weakness of the cutaneous blood vessels leading to capillary fragility and erythrocyte extravasation. However, this does not account for the inflammatory infiltrate common to these disorders. The second mechanism is humoral immunity. This suggested pathogenesis is supported by direct immunofluorescent studies showing vascular deposition of C3, C1q, IgM, or IgA. However, several cases have not shown these deposits. The third proposed mechanism is cellular immunity. The infiltrate in pigmented purpuric dermatoses consists of lymphocytes, macrophages, and Langerhans cells. This inflammatory infiltrate leads to vascular fragility and subsequent leakage of erythrocytes. Aiba and Tagami [12] used immunohistologic studies in eight cases of Schamberg's disease to demonstrate that the dermal infiltrate was predominantly composed of helper-inducer T cells and OKT6-reactive cells, whereas the epidermis showed intercellular staining with human leukocyte antigen (HLA)-DR antibody and OKT6 antibody. Based on this study, they concluded that a cellular immune reaction, specifically the Langerhans cell, likely plays an important role in the pathogenesis.

The mechanism behind drug-induced or other secondary causes may be immune-mediated, but this is unproven. Gravity and increased venous pressure may account for the lesions localizing to the lower extremities.

DIAGNOSTIC STUDIES

Diagnosis is generally made clinically and supported by histopathologic examination. No consistent laboratory abnormalities have been identified. The clinical measurement of capillary fragility by application of a sphygmomanometer (Hess test) does not appear to be reliable because some reports show an increased capillary fragility in pigmented purpuric eruptions, and others were negative. Because secondary causes may be reversible, review of the patient's medical history, medications, and potential contact allergens is advised. Skin biopsy to rule out vasculitis is especially helpful if the lesions are papular.

DIFFERENTIAL DIAGNOSIS

Table 176-2 shows the differential diagnosis.

Secondary Causes
Drug-induced[1–11]
Thiamine
Carbutamide
Carbromal
Meprobamate
Carbamazepine
Clipizide
Nitroglycerin
Chlordiazepoxide
Furosemide
Trichlomethiazide
Topical fluorouracil
Acetaminophen
Medroxyprogesterone acetate
Contact dermatitis[14–19]
Disperse dyes
Paraphenylenediamine
Black rubber
Cobalt
Benzoyl peroxide
Epoxy resin
Methylmethacrylate
EMLA
Venous stasis/hemangiodermatitis
Step aerobics
Rheumatoid arthritis
Diabetes mellitus
Benign hypergammaglobulinemic purpura (of Waldenstrom)/ dysproteinemic purpura
Hodgkin's disease
Polycythemia
Purpuric mycosis fungoides[1,17]
Vasculitis/Palpable purpura
Hypersensitivity vasculitis/necrotizing venulitis
Henoch-Schönlein purpura
Vascular Tumors
Angioma serpiginosum
Kaposi's sarcoma (especially versus Gougerot-Blum)

TABLE 176-2 **Differential Diagnosis of Pigmented Purpuric Dermatosis**

MANAGEMENT

Treatment is often ineffective. Discontinuation of the causative drug or contact allergen can lead to complete resolution; however, residual pigmentation may persist for years. Oral bioflavonoid (rutoside 50 mg bid) and ascorbic acid (500 mg bid) given to three patients with chronic pigmented purpura in an open trial led to clearance in all three patients within 4 weeks. [23] Corticosteroids have been reported to be effective, in particular triamcinolone spray or potent topical (fluorinated) steroids. Systemic corticosteroids may also be effective, but are not indicated due to the benign nature of the disorder. With both topical and systemic steroids, recurrence of the lesions is the rule if discontinued. Cyclosporin and griseofulvin are other systemic agents with reported success. [24], [25] PUVA has induced resolution of lesions in some

cases. The PUVA-induced immunosuppression of cell-mediated response is the proposed mechanism. [26]

CRYOGLOBULINEMIA

Cryoglobulins are circulating immunoglobulins complexed with other immunoglobulins or proteins that reversibly precipitate in the cold. The symptoms of type I cryoglobulinemia are caused by vascular occlusion resulting from protein precipitation; mixed cryoglobulinemia (type II or III) is an immune complex disease. Cryoglobulins may be associated with a wide spectrum of infections, connective tissue diseases, and malignancies. “Essential” mixed cryoglobulinemia describes those cases in which no underlying disease association is found; before the recognition of the association of hepatitis C virus (HCV) infection with mixed cryoglobulinemia, this classification accounted for a large percentage of cryoglobulinemia cases.

Historical Aspects

The existence of cryoproteinemia as a clinical entity was first noted by Wintrobe and Buell in 1933. [1] The immunoglobulin composition of these cryoproteins was recognized by Waldenstrom in 1943. [2] The first large-scale examination of pathologic sera for cryoglobulins found them in 11 percent of the sera examined. [3] A recent series detected cryoglobulins in 6 percent of hospital patients screened in a single center in Spain. [4] Cryoglobulins have also been detected in the sera of less than 3 percent of “healthy” blood donors. [5]

Etiology and Pathogenesis

Cryoglobulinemia is classified in three distinct groups, types I, II, and III, initially described by Brouet et al. [6] based on immunoglobulin type (Table 177-1). Type I cryoglobulins consist of a single monoclonal immunoglobulin, typically an IgG or an IgM. Patients with type I cryoglobulinemia usually have an underlying hematologic malignancy, such as multiple myeloma or a B cell lymphoma. These patients may present with an occlusive vasculopathy, without any specific clinical manifestations. [7] Mixed, type II, and type III cryoglobulins consist of rheumatoid factors, usually IgM (the antibody) complexed with IgG (the antigen), and thus constitute immune complexes. Type II cryoglobulins are single monoclonal immunoglobulins, usually IgM, that coprecipitate with polyclonal IgG. Type III cryoglobulins are polyclonal immunoglobulins that form cryoprecipitates with polyclonal IgG or a nonimmunoglobulin serum component. Patients with mixed cryoglobulinemia may present with a vasculitis or an associated glomerulonephritis. [7]

Single (single-component) cryoglobulins (type I)
IgG
IgM
IgA
Immunoglobulin light chain
Complexed to other proteins
Mixed cryoglobulins
IgM rheumatoid factors
Monoclonal (type II)
Polyclonal (type III)

*The monoclonal components in types I and II cryoglobulinemias are most frequently light molecules, and it has been estimated that approximately 10% of all Waldenström's macroglobulins are cryoprecipitable. Immunoglobulin M type I cryoglobulins are approximately 1.5 times more prevalent than IgG type I cryoglobulins. Thus, significant skewing exists among type I cryoglobulins in the light isotype, especially given that, overall, IgM accounts for only about 15% of gammopathies. This proportion reflects closely the contribution of the light isotype to the total vascular body pool of immunoglobulins. This skewing toward IgM is even more striking among type II cryoglobulins, which are almost invariably IgMκ molecules using the 16/8 subgroup and selective V-region heavy- and light-chain genes.

Isolation and Typing Techniques

Gorevic described the isolation and characterization of cryoglobulins in detail. [8] In brief, cryoproteins are isolated from blood that is collected and kept at 37°C (98.6°F). Serum obtained by centrifugation of the blood at 37°C (98.6°F) is incubated at 4°C (39.2°F) for several days and observed for the presence of a cryoprecipitate. Initial screening includes the determination that the precipitate is capable of resolubilization when the serum is rewarmed. [7] Once formed, the cryoprecipitate is isolated and resuspended in saline at 37°C (98.6°F), and the protein components are characterized by immunofixation. [5] For types I and II disease, further analysis to identify a monoclonal gammopathy may be carried out

(see below). [7] Most type I cryoprecipitates are evident within 24 h, whereas mixed type III cryoglobulins may require several days of cold incubation for precipitation. Therefore, it is important to hold serum for approximately 1 week before final determination is made of the presence of a cryoprecipitate. Cryoglobulins may become associated with serum lipids and remain suspended during centrifugation, thereby obscuring the formation of a visible precipitate. [9] Conversely, in patients undergoing heparin therapy, an insoluble cryoprecipitate may form with other serum proteins, specifically fibronectin. [10]

Once a cryoprecipitate is identified in patients with type I and type II disease, additional serum studies may aid in their further assessment. [7] Although not always present, serum protein electrophoresis may reveal the presence of a monoclonal spike, suggesting a gammopathy consistent with type I or II cryoglobulins. The likelihood of detecting a cryoglobulin by this method can be increased by both collecting the sample and running the electrophoresis at 37°C (98.6°F) (37°C serum electrophoresis). An identified monoclonal spike can be characterized by serum immunofixation, which involves electrophoretic serum protein separation in an agarose gel, followed by incubation with antisera specific to immunoglobulin classes and light-chain types; this method is highly sensitive for immunotyping a monoclonal gammopathy. [11] Quantitative immunoglobulin determination may aid in further identification of cryoglobulin-associated diseases (i.e., lymphoproliferative diseases).

The concentration of cryoglobulins may be expressed as a percentage of the volume of the total collected serum (cryocrit), or, alternatively, as the concentration of protein in the dissolved cryoprecipitate (expressed in milligrams per milliliter). Type I cryoglobulins are typically present in concentrations greater than 5 mg/mL. In contrast, type III cryoglobulins are usually present in lesser amounts, that is, “cryocrits” <1 percent. Symptom severity does not necessarily reflect cryoprotein concentration in the serum or the temperature at which cryoprecipitation takes place. [12] Isolated cryoglobulin precipitates are typed by immunofixation, immunoblotting, two-dimensional gel electrophoresis, and capillary zone electrophoresis. [7] Immunofixation methods are the most sensitive and most widely used.

Cryoglobulin Characteristics

TYPE I MONOCLONAL CRYOGLOBULINS Type I cryoglobulins are monoclonal immunoglobulins, typically IgM or IgG, although IgA and Bence Jones proteins have been identified. In a review of 86 patients with cryoglobulinemia, Brouet et al. [6] reported that 25 percent of patients had only monoclonal cryoglobulins with a predominance of IgM immunoglobulin. In a larger cohort study, 34 percent of patients with cryoglobulins had type I disease; IgG? and IgM? were equally represented. [4] The large molecular size of IgM monoclonal cryoglobulins may predispose these immunoglobulins to precipitation; in fact, it has been postulated that, in some instances, cryoprecipitation may be an extension of normal immunoglobulin solubility. [13] In certain monoclonal IgG cryoprecipitates, earlier work suggested that the cryoprecipitate determinant resided in the variable region of the immunoglobulin, since the activity could be retained in the F(ab')2 fragment. [8] Some idiotypic relatedness may exist among monoclonal IgG cryoglobulins; the report of cross-reactivity among 5 of 15 IgG cryoglobulins suggested similar variable region structures and, possibly, antigenic specificities. [14] Preferential V-region gene expression has been documented in HCV-associated mixed cryoglobulinemia (see below). [15] Complement components are not routinely found as components of type I cryoprecipitates.
MIXED CRYOGLOBULINS Type II cryoglobulins consist of two immunoglobulin components, one of which is monoclonal. The most common composition is that of a monoclonal IgM rheumatoid factor complexed with a polyclonal IgG. Some evidence suggests that there is an increased prevalence of kappa light chains in the monoclonal IgM and that the monoclonal IgM has restricted specificity for IgG. Although the serum concentration of a type II cryoglobulin is often very high, a typical monoclonal spike is not always apparent on immunoelectrophoresis. IgG monoclonal rheumatoid factors are identified in a small percentage of patients with type II cryoglobulinemia, and IgA monoclonal rheumatoid factors are rare. “Essential” mixed cryoglobulinemia describes the presence of cryoglobulins and the concomitant manifestation of symptoms without an identifiable connective tissue, neoplastic, or infectious process. Levo et al. [16] recognized the high frequency of liver involvement in these patients and identified hepatitis B surface antigen, hepatitis B surface antibody, or Dane particles associated with their sera or cryoprecipitates. Later investigations demonstrated a significant association of essential mixed cryoglobulinemia with HCV infection. In chronic HCV infection, both types II and III cryoglobulins have been found. [17], [18] The prevalence of HCV antibody and/or RNA in serum samples of patients with the diagnosis of essential mixed cryoglobulinemia ranged from 44 to 96 percent of patients studied, as documented by recombinant immunoblot assay or polymerase chain reaction, respectively. [18] Type II cryoglobulins are the most commonly isolated precipitates, because of their frequent association with chronic HCV infection. [7] Recognition of HCV disease manifestations and improved detection methods have contributed to this increased incidence. Patients with type I cryoglobulinemia may be seropositive for HCV at a much lower incidence [14], [19]; by definition, however, the cryoprecipitate does not contain the virus/antibody. It is imperative that patients with mixed cryoglobulinemia, without previously identified associated disease, be evaluated for HCV infection. Type III cryoglobulins usually occur in low concentration and consist of polyclonal immunoglobulin complexes or polyclonal immunoglobulin-nonimmunoglobulin cryoprecipitates. These cryoglobulins are found in association with diseases that may involve the formation of immune complexes. IgM-IgG cryoglobulins are most frequent. [6] The finding of complement system components in these cryoprecipitates, in particular C1q, [20] provides evidence for the immune complex nature of this phenomenon. Indeed, these cryoglobulins may activate complement in vitro, and patients with type III cryoglobulinemia often have decreased serum complement levels. Both autologous and exogenous antigens have been found associated with polyclonal immunoglobulins in this disease.

Pathophysiology

Type I cryoglobulins demonstrate a self-association of monoclonal immunoglobulins at temperatures ranging from 0° to 30°C (32° to 86°F) or more. Monoclonal cryoglobulins are present in substantial amounts, often ranging from 1 to 30 mg/mL. [6] They may precipitate as a gel, a flocculent precipitate, or, in some instances, as crystals. The specific physical forces involved in causing precipitates of type I cryoglobulins appear to include temperature-induced conformational changes, deficient carbohydrate side chains, and nucleation reactions. [8] In some instances, type I cryoglobulins, even

when present in large amounts, may not result in signs or symptoms of disease. Clinical manifestations of type I disease usually consist of occlusive peripheral vascular phenomena such as Raynaud's phenomenon, cutaneous ulcers, or gangrene. Renal disease and peripheral neuropathy are much less common (see " Clinical Features " below).

Type II and III cryoglobulins are typically present in relatively small amounts. These monoclonal (type II) or polyclonal (type III) rheumatoid factor-IgG complexes usually occur with a concomitant disease process such as connective tissue disease, infection, hepatic disease, or lymphoproliferative disease. The exception is the occurrence of mixed cryoglobulins in "essential" mixed cryoglobulinemia, where an underlying disease process cannot be identified. Analysis of types II and III cryoglobulins often reveals the presence of complement in addition to immunoglobulins.

Early work on the complement system in cryoglobulinemia revealed decreased "functional complement activity" (CH50), C1, C4, and C2. [21] A number of clinical studies have since identified patients with mixed cryoglobulinemia with depressed levels of C3, along with decreased levels of CH50, C2, and C4. [22] In a large cohort study, [4] 71 percent of patients with cryoglobulinemia had low CH50 levels, 50 percent had low C4 levels, and 25 percent had low C3 levels. In this study, patients with HCV-associated cryoglobulins had a higher frequency of hypocomplementemia than did patients without HCV. Cold-dependent activation of complement may itself affect CH50 levels in HCV-positive patients. [23]

The immunoglobulins in the serum cryoprecipitate of patients with mixed cryoglobulinemia have been identified, along with complement, in involved renal vessels; the histologically normal vasculature may evidence immunoglobulin deposition without complement. Immunofluorescence studies of the skin of patients with cryoglobulinemia revealed immune reactants and complement in the small vessel walls of 50 percent of the patients studied, but not in the uninvolved skin. [22] Studies such as these have been cited as evidence for the pathogenic role of immune complex deposition in cryoglobulinemia. Investigations evaluating the localization of HCV antigen in small vessels of the skin of patients with HCV and mixed cryoglobulinemia found evidence of HCV antigen in 6 of 15 skin biopsy specimens studied by immunohistochemistry, with immunoglobulin deposition similar to the HCV antigen deposition. [24] HCV antigen deposition was detected in both lesional and, in some cases, nonlesional, apparently normal tissue.

Clinical Manifestations (Table 177-2)

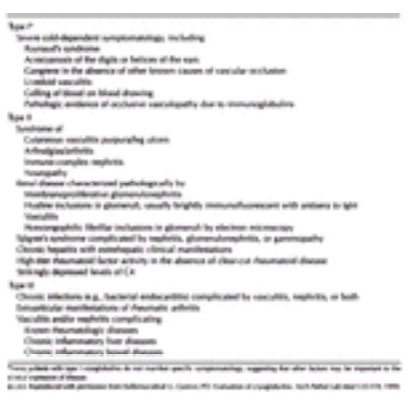

TABLE 177-2 **Clinical and Laboratory Findings in Patients with Cryoglobulinemia**

The organ systems usually affected in cryoglobulinemia are the skin, kidneys, liver, and musculoskeletal and nervous systems. In general, type I cryoglobulins are typically associated with acrocyanosis, retinal hemorrhage, Raynaud's phenomenon, and arterial thrombosis. [8] Types II and III cryoglobulins are associated with arthritis or arthralgias and vascular purpura. [8] Renal and neurologic symptoms may be found in patients with types II and III cryoglobulins. [6] In an early series of 40 patients with mixed cryoglobulins, [20] 100 percent had recurrent palpable purpura, 73 percent had polyarthralgias, and 55 percent had renal disease. A later prospective study of 115 patients with mixed cryoglobulinemia found that 45 percent had underlying identifiable diseases, or "nonessential" cryoglobulinemia. Of the remaining patients ("essential" mixed cryoglobulinemia), approximately one-half had anti-HCV antibodies, associated with cutaneous and systemic signs and symptoms of greater severity than those patients who were HCV antibody negative. Cutaneous disease included Raynaud's phenomenon, purpura, livedo, distal ulcerations, and "gangrenous" changes (see below). This cohort also had higher serum alanine aminotransferase levels, higher cryoglobulin levels, and lower complement (CH50, C4) levels.

CUTANEOUS FEATURES Purpura is a cutaneous hallmark of cryoglobulinemia. It is usually located distally, most typically on the lower extremities. Showers of these lesions may occur spontaneously, may be provoked by cold exposure, and may be induced by long periods of standing or sitting. [6] Noninflammatory purpura, with histologic evidence of an amorphous eosinophilic precipitate within the vasculature, is characteristically seen in type I cryoglobulinemia. [25] Leukocytoclastic vasculitis, presenting clinically as palpable purpura, is the characteristic hallmark of the mixed cryoglobulinemias (Fig. 177-1). The lesions are intermittent in nature (typically lasting 3 to 10 days) and are usually nonpruritic. [22] In comparative studies, the incidence of palpable purpura was found to be higher in patients with mixed cryoglobulinemia who are HCV antibody positive. [26] In a large cohort of HCV-positive patients, cutaneous manifestations were found in 17 percent and included lower extremity purpura, Raynaud's phenomenon, cutaneous vasculitis, psoriasis, porphyria cutanea tarda, and lichen planus. [17] Ulcerations (type II), livedo reticularis (type I), acrocyanosis, and gangrene (type I) [4], [22] have been described. Before the classification system of cryoglobulinemia introduced by Brouet, urticaria, urticarial vasculitis, and cold urticaria were also described. [27], [28]

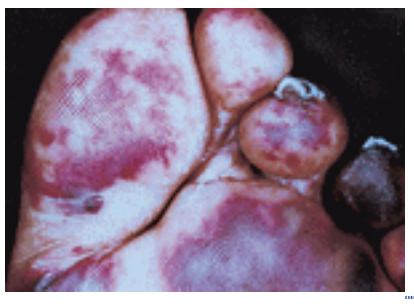

FIGURE 177-1 Leukocytoclastic vasculitis in a patient with mixed cryoglobulinemia manifested as palpable purpura. The patient also had tuberculosis, positive antinuclear antibodies, and hepatitis.

RENAL DISEASE Early reports indicated that 30 to 60 percent of patients with essential mixed cryoglobulinemia have, or will develop, renal disease. [8] Later studies demonstrate a slightly lower frequency. [29] Pathologic evaluation reveals predominantly a membranoproliferative glomerulonephritis. A specific membranoproliferative "cryoglobulinemic glomerulonephritis" has been recognized in association with HCV-induced type II cryoglobulinemia with characteristic renal findings. [30] The initial clinical presentation of membranoproliferative glomerulonephritis may include diastolic hypertension, edema, or frank renal failure. [4] Urinalysis may show proteinuria, hematuria, pyuria, and red cell casts. [22] Immunofluorescence analysis of renal tissue is characteristically positive and reflects the immunoglobulin and/or complement components identified in the isolated cryoglobulin.

OTHER Neurologic symptoms occur in a smaller percentage of patients and typically consist of a peripheral sensorimotor polyneuropathy, which may present as paresthesia or foot drop. [22] Central nervous system involvement is less common. [4] Articular manifestations, more common in types II and III cryoglobulinemias, rarely present as distinct arthritis, [9] but rather as arthralgias. [31] As serologic studies for hepatitis B and C may be positive, hepatic signs may include hepatomegaly and splenomegaly, and liver function test abnormalities. Other manifestations of vascular occlusive phenomena or immune complex disease may arise in the eye and gastrointestinal system.

Associated Diseases (Table 177-3)

Type I
Multiple myeloma
Waldenström's macroglobulinemia
Other lymphoproliferative diseases with monoclonal components
Type II
Chronic HCV infection
Sjögren's syndrome
Waldenström's macroglobulinemia
Chronic lymphocytic leukemia
Non-Hodgkin's lymphoma
Autoimmune diseases
Cold agglutinin disease
Type III*
Chronic infections
Viral (EBV, CMV, HIV, hepatitis viruses)
Bacterial (SBE, leprosy, spirochetal)
Fungal, parasitic
Autoimmune diseases
Systemic lupus erythematosus
Rheumatoid arthritis
Inflammatory bowel diseases
Biliary cirrhosis

*CMV = cytomegalovirus; EBV = Epstein-Barr virus; HIV = human immunodeficiency virus; SBE = subacute bacterial endocarditis.

TABLE 177-3 **Disease Associations**

Lymphoproliferative, autoimmune disorders, and infectious etiologies are the most frequently associated diseases. HIV infection may be present, usually coexistent with HCV. [4] Lymphoproliferative diseases such as macroglobulinemia and lymphomas are associated with types I and II cryoglobulins and autoimmune disorders, and hepatitis C is associated with types II and III (see above). Autoimmune disorders most typically include rheumatoid arthritis, systemic lupus erythematosus, and Sjögren's syndrome. In the large cohort study reported by Trejo et al., [4] autoimmune diseases were associated with 15 percent of patients with type I and with 26 percent of patients with mixed cryoglobulinemia.

Treatment

Treatment of cryoglobulinemia is based on the severity of disease presentation. Mild cutaneous symptoms may not require therapeutic intervention. Dermatologic and articular manifestations may be improved by nonsteroidal anti-inflammatory agents. More severe visceral involvement, particularly renal disease, may require glucocorticoid therapy in conjunction with cytotoxic agents. Melphalan, chlorambucil, or cyclophosphamide may benefit some patients. [8] Plasmapheresis has been used to treat patients with rapidly progressive disease refractory to conventional therapy, but a postpheresis rebound in disease activity may occur. Plasma exchange is usually instituted together with immunosuppressive or cytotoxic agents in an attempt at better disease control as well as avoidance of rebound. Patients with HCV-associated cryoglobulinemia have been treated successfully with interferon (IFN)-a. [32]

CRYOFIBRINOGENEMIA

Cryofibrinogens are cryoproteins in plasma that has been anticoagulated with oxalate, citrate, or EDTA which reversibly precipitate when the plasma is cooled to 4°C (39.2°F); cryoglobulins precipitate in both cooled serum and plasma. [6] This phenomenon was first described by Korst and Kratochvil in 1955, as referenced by Sankarasubbaiyan et al. [33] Cryoprecipitates are composed of fibrinogen, fibrin, fibrin split products with albumin, fibronectin (cold-insoluble globulin), factor VIII, immunoglobulins (rare in patients with isolated disease), and other plasma proteins. [5] Cryoprecipitates may, in fact, be composed of normal plasma proteins on freeze-thawing of plasma. [8] Heparin may produce false-positive

precipitates (heparin-precipitable fraction) through the formation of heparin-fibronectin cryoprecipitable complexes, the formation of which may be further enhanced by the presence of fibrinogen. [8]

Cryofibrinogenemias are classified as primary, without known etiology or disease association, or secondary. Many earlier investigators found evidence of cryofibrinogens in a small percentage of “normal” subjects. In fact, screening of normal “healthy” blood donors in one study revealed cryofibrinogens in 7 percent of these controls. [5] Secondary cryofibrinogenemia may occur in patients with connective tissue disease, infections, malignancies, and thromboembolic disorders, [33] and is more frequently found in patients with associated cryoglobulinemia. [5] Diabetes, hyperglycemia, chronic lung disease, hypothyroidism, and acute myocardial infarction have been described as disease associations, as has pregnancy and the use of oral contraceptive agents. [34], [35], [36] and [37] In one study of patients with associated cryoglobulinemia, [5] immunoglobulins were a predominant constituent of the cryofibrinogen precipitate, and, not surprisingly, of the same class as that characterizing the cryoglobulinemia. Similarly, fibronectin was found in the cryoglobulin cryoprecipitate.

Inhibition of fibrinolysis has been postulated in the pathogenesis of cryofibrinogenemia, a hypothesis that is based on the findings of increases in a $_1$-antitrypsin and a $_2$-macroglobulinemia in some patients. [35] These proteins are inhibitors of the major plasma fibrinolytic agent, plasmin. Plasma levels of cryofibrinogens may range from 0.05 g/L to >1 g/L. [5] In patients with isolated cryofibrinogenemia, and in those with coexisting cryoglobulinemia, plasma fibrinogen levels may be elevated. [5]

Similar to patients with cryoglobulinemia, patients with cryofibrinogenemia typically present with cutaneous disease. In primary disease, cold-induced, painful skin ulcerations may be present. [5] A thrombotic vasculopathy has been described, [38] as well as, histologically, eosinophilic thrombi of small intradermal vessels. [5] Cryofibrinogenemia may clinically simulate calciphylaxis and may similarly present in patients with end-stage renal disease. [33] Other findings in cryofibrinogenemia include purpura, ecchymosis, and arterial and venous thrombosis. [5], [35] In essential isolated cryofibrinogenemia associated with painful lower extremity ulcerations, the efficacy of fibrinolytic therapy, including stanozolol, has been described. [39] The treatment of secondary cryofibrinogenemia is that of the underlying disease or associated condition.

Relapsing Polychondritis

HISTORICAL ASPECTS
ETIOLOGY AND PATHOGENESIS
CLINICAL MANIFESTATIONS
LABORATORY FINDINGS
PATHOLOGY
DIAGNOSIS
TREATMENT
COURSE AND PROGNOSIS

REFERENCES

Relapsing polychondritis is a rare disease manifested by recurring episodes of inflammation in cartilaginous tissues throughout the body.

HISTORICAL ASPECTS

The disease was first described by Jaksch-Wartenhorst in 1921, and given the name polychondropathia in 1923. [1] In 1960, Pearson et al. [2] suggested the name relapsing polychondritis to emphasize its episodic nature, which leads to degeneration and replacement of cartilaginous structures by fibrous tissue. In 1976, McAdam et al. reviewed 159 reported cases of relapsing polychondritis, including 23 patients whom they had seen over the 15-year period of 1960 to 1975. [3] They also empirically defined diagnostic criteria that included the most common clinical features. In 2001, Frances et al. reported a broad array of dermatologic manifestations in 200 patients with relapsing polychondritis followed at a single medical center. [4]

ETIOLOGY AND PATHOGENESIS

Considerable evidence suggests that relapsing polychondritis is an autoimmune disease mediated by immunity to type II collagen. In humans, type II collagen is restricted to cartilage and constitutes more than 50 percent of the proteins of cartilage. Foidart et al. [5] detected antibodies to type II collagen in the sera of 6 of 23 patients with relapsing polychondritis. All patients in whom antibodies were detected had active disease. Subsequently, Terato et al., [6] using an enzyme-linked immunosorbent assay (ELISA), found antibodies to type II collagen in the sera of 50 percent of patients with relapsing polychondritis, but in only 15 percent of patients with rheumatoid arthritis and 4 percent of normal individuals. More recently, Bradley et al. [7] showed that human leukocyte antigen (HLA)-DQ6/8 double-transgenic mice develop a relapsing polychondritis-like disease after immunization with type II collagen.

The demonstration of antibodies to type II collagen in sera of patients with relapsing polychondritis raises the question of whether these antibodies are functionally active in vivo or whether they simply represent an epiphenomenon secondary to injury to cartilage and consequent exposure to the relevant antigens. That the antibodies are directed mainly against native rather than denatured collagen would favor the former possibility. [5] Also, the epitope specificity of the antibodies is different in patients with rheumatoid arthritis and those with relapsing polychondritis. [6] The clinical manifestations may then be influenced by this specificity. Although relapsing polychondritis is not usually detected in neonates born of mothers with the disease, [8] the observation that relapsing polychondritis may be transferred from an afflicted mother to her newborn child and that the child may then recover completely from the disease [9] suggests an important role for antibodies in the pathogenesis of relapsing polychondritis. Finally, the finding in vivo of deposits of immunoglobulin and complement in inflamed cartilage in two patients with relapsing polychondritis [10] supports the likelihood that immunity to type II collagen plays a role in the pathogenesis of relapsing polychondritis. Further evidence that immunologic mechanisms play a role in the pathogenesis of relapsing polychondritis comes from immunogenetic studies demonstrating a significant association between relapsing polychondritis and HLA-DR4. [11]

Because relapsing polychondritis affects cartilage that primarily resides outside diarthrodial joints, usually the nose, outer ears, and trachea, Hansson et al. [12] developed an animal model that is induced by immunization with cartilage matrix protein (matrilin-1). Rats immunized with this noncollagenous protein, which is expressed mainly in tracheal cartilage, developed a disease very similar to relapsing polychondritis. A humoral and cellular response to matrilin-1 has been identified in an individual with relapsing polychondritis. [13]

CLINICAL MANIFESTATIONS

The most frequent presenting manifestations are auricular chondritis and arthritis. [3], [14] The chondritis is characterized by the sudden onset of redness, warmth, swelling, and tenderness limited to the cartilaginous portion of the external ears. Often only one ear is involved initially, and the ear lobe is typically uninvolved. The acute inflammation usually subsides spontaneously in 1 to 2 weeks. It is characterized by recurrences that appear after highly variable periods—from weeks to months. Eventually 85 to 90 percent of patients with relapsing polychondritis develop auricular chondritis. [3], [14] Nasal chondritis follows the same pattern as the auricular chondritis and eventually occurs in 54 to 70 percent of patients. The recurrent episodes of chondritis usually result in the destruction of normal cartilaginous structures and their fibrotic replacement. Clinically, this process results in floppy or cauliflower ears and nasal deformities (Fig. 178-1 and Fig.

178-2).

FIGURE 178-1 Relapsing polychondritis. Cartilaginous portion of ear is deformed and fibrotic.

FIGURE 178-2 Relapsing polychondritis. “Cauliflower” ear and nasal deformity.

Arthritis, which may involve only one or many small or large joints, is the second most frequent presenting sign and is eventually manifested in 52 to 80 percent of patients. At its onset, the arthritis is often migratory and is frequently associated with effusions, but it may be monoarticular and difficult to distinguish from gouty or infectious arthritis.

Other organ system involvement includes the eyes, where the inflammation may involve almost every part of the eye and adnexal structures, [3], [15] manifesting as conjunctivitis, episcleritis, keratitis, and iritis (Fig. 178-3); the respiratory tract, where symptoms may include hoarseness, aphonia, and dyspnea; the inner ear, where symptoms may include nausea, vomiting, tinnitus, and deafness as a result of audiovestibular damage; and, less frequently, the cardiovascular system, where the most frequent abnormalities are aortic regurgitation and aortic aneurysm. [16] Aortic valve replacement may become necessary. [17] A significant percent (30 to 71 percent) of patients have an associated rheumatic or autoimmune disease, and a significant percent of patients also have leukocytoclastic vasculitis. [3], [4], [14], [18], [19] Myelodysplastic syndromes are also associated with relapsing polychondritis. [4], [20], [21] and [22]

FIGURE 178-3 Relapsing polychondritis. Acute episcleritis.

LABORATORY FINDINGS

The only laboratory finding that is consistently abnormal is an elevated erythrocyte sedimentation rate. The white blood count is elevated and/or the hemoglobin or hematocrit is decreased in more than half of patients. [3] Indirect immunofluorescence and ELISA studies have detected circulating antibodies to type II collagen in one-third to one-half of patients. [5], [6]

PATHOLOGY

Relapsing polychondritis is characterized by a loss of the normal basophilia of cartilage with a perichondrial inflammatory infiltrate. The earliest of the inflammatory cells are thought by some to be neutrophils and by others to be mononuclear cells. The end stage of the disease is characterized by the fibrotic replacement of cartilage.

DIAGNOSIS

McAdam et al. [3] suggested that the diagnosis of relapsing polychondritis can be made when three of the following criteria are present along with histologic confirmation of the chondritis:

1. Bilateral auricular chondritis
2. Nonerosive seronegative inflammatory polyarthritis
3. Nasal chondritis
4. Ocular inflammation
5. Respiratory chondritis
6. Audiovestibular damage

Ordinarily, relapsing polychondritis presents little problem in diagnosis. However, there are patients who have only

auricular and nasal chondritis and none of the other manifestations of relapsing polychondritis. If the histology shows perichondrial inflammation and the loss of the normal cartilaginous basophilia, and if other conditions are excluded, a diagnosis of relapsing polychondritis should be made.

Concurrent rheumatologic diseases may, at times, obscure the diagnosis of relapsing polychondritis. Cellulitis of the ear or nose may be confused on rare occasion with relapsing polychondritis; however, sparing of the ear lobe favors the diagnosis of relapsing polychondritis.

TREATMENT

Because of the highly variable course of relapsing polychondritis, individualized therapy is the key to optimum management. Systemic glucocorticoids are helpful in controlling the acute inflammation. Seventy-five percent of the patients in McAdam's series required chronic glucocorticoid therapy; the average dose of prednisone was 25 mg/day. [3] Immunosuppressive therapy, including cyclosporine, may also be efficacious in severe progressive disease, [3], [23] and methotrexate has been helpful as a steroid-sparing agent. [24] Dapsone has also been reported to be an effective treatment [25]; however, my experience and that of others [14] with dapsone in relapsing polychondritis has been disappointing. Although dapsone may be effective in some patients with diffuse anterior scleritis, it does not control the destructive scleral inflammation. [26] The frequent spontaneous remissions that occur during the acute episodes have made evaluation of most treatments difficult. The more chronic manifestations of relapsing polychondritis can be managed with indomethacin in some patients.

COURSE AND PROGNOSIS

The course of relapsing polychondritis is unpredictable. The acute chondritis in most patients lasts for 1 to 4 weeks, but in a few patients, it may be more prolonged. Some patients have a relatively mild course with few episodes of chondritis. Other patients may have multiple episodes of chondritis. The degree of tissue destruction and fibrosis is difficult to predict early in the course of the disease. The presence of peripheral arthritis is said to be associated with widespread disease and a poorer prognosis. [27] About one-third of the patients die as a result of relapsing polychondritis. The most frequent causes of death are airway collapse or obstruction (for which self-expandable tracheobronchial stents should be considered), cardiovascular complications including systemic vasculitis and ruptured aneurysms, and infections (probably secondary to glucocorticoid-induced immunosuppression). [3], [14], [16], [28], [29]

REFERENCES

This chapter discusses common rheumatologic diseases that ordinarily have prominent musculoskeletal presentations. All these conditions have extraskeletal manifestations that may be cutaneous in nature.

RHEUMATOID ARTHRITIS

Rheumatoid arthritis (RA) is a systemic inflammatory autoimmune disease that is characterized by a chronic, symmetric polyarthritis and significant extraarticular manifestations, which include rheumatoid nodules, vasculitis, and internal organ involvement. The disease process may be progressive and may destroy joint function, with a resultant decline in functional status and premature death. Permanent remission is extremely unusual.

Epidemiology

Approximately 1 percent of the adult population in most parts of the world is affected with RA. [1] Approximately 70 percent of patients follow a chronic disease course with exacerbations and remissions; 25 percent have intermittent disease with brief attacks of inflammation followed by remissions; and approximately 5 percent have an aggressive, malignant form with multiple extraarticular manifestations. [2] Onset of this disease is usually in the third to fifth decades. Incidence increases with increasing age until the seventh decade. RA is two to three times more common in females than in males. [1] This ratio is smaller in older populations.

Etiology and Pathogenesis

The exact cause of RA is unknown. The initial onset of joint symptoms may be induced by a variety of factors. The immunogenetic background of the patient may then determine whether the inflammation regresses or progresses. Monozygotic and dizygotic twins studies suggest both genetic and environmental factors. [3] An association between extraarticular disease and human leukocyte antigen (HLA)-DR1 and DR4 genes has been noted in some populations. [4] Some authors believe that HLA determines disease severity but not susceptibility.

Mechanical stress on joints (and at sites of subcutaneous nodules) may initiate an inflammatory response that lacks balance between a rapid response to trauma and the need to protect self from damage. Seropositive RA (positive rheumatoid factor) supports a major role of immune complexes in this disease process. Seronegative RA (negative rheumatoid factor) may still represent a disease process involving immune complexes, but also suggests other immune mechanisms. Immune complexes may interact with specific cell surface receptors on synovial macrophages, leading to the production of reactive oxygen species and other inflammatory cytokines, such as tumor necrosis factor-a (TNF-a). [3] Joints have unique anatomic and physiologic qualities that render them targets for immune and inflammatory attack. Cartilage is subject to repetitive mechanical stress, retains antigens and proinflammatory cytokines, and has a limited capacity for regeneration. Once proteolytic enzymes cause erosions, narrowing of the joint space, and mechanical instability, rheumatoid inflammation may become self-sustaining.

Clinical Features

RA often begins with general constitutional symptoms such as fatigue, anorexia, vague musculoskeletal complaints, and generalized weakness. It may be weeks or months before the characteristic synovitis presents. It is in these early stages that definite diagnosis is most difficult, despite a thorough patient evaluation. However, early diagnosis and treatment are important because most of joint damage is thought to occur in the first 2 years of the disease process. [5] The American College of Rheumatology has set guidelines for the diagnosis of RA (Table 179-1). [6] For a patient to be diagnosed with

definite RA, four of the seven criteria must be present. The first four criteria listed must be present for at least 6 weeks. Extraarticular manifestations may help to delineate the disease process early and may signify a more serious disease process requiring the initiation of aggressive therapy. [7]

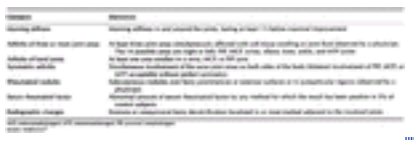

TABLE 179-1 **1987 American College of Rheumatology Revised Criteria for the Classification of Rheumatoid Arthritis (Modified)**

ARTICULAR MANIFESTATIONS The articular manifestations of RA relate to an inflammatory synovitis that can affect the synovial lining of joints, tendons, and bursae. Synovial inflammation usually results in warmth but not erythema of the affected area. There is significant pain in association with stretching of the joint capsule. Hand and foot involvement forms the basis of the disease in most patients. Although the initial manifestations in the hand may be asymmetric, the clinical course subsequently takes on a very symmetric diffuse pattern. There is characteristic involvement of the proximal interphalangeal (PIP) and metacarpophalangeal (MCP) joints with sparing of the distal interphalangeal (DIP) joints. The developing pattern of joint involvement is very suggestive of the diagnosis. Chronic inflammation may result in irreversible structural damage of the joint, including cartilage destruction and bony erosion. Late structural deformities may result from soft tissue contractures or from bony ankylosis. Characteristic deformities include radial deviation of the hand with ulnar deviation of the digits, the “swan neck” deformity from hyperextension of the PIP joint and compensatory flexion of the DIP joint, and the boutonnière deformity from flexion contracture of the PIP joint and extension of the DIP joint. Similar structural deformities occur in the feet. All can be debilitating. Involvement of the thoracic and lumbar spine in RA is exceptional. Although the shoulder joint is often affected, it is soft tissue structures, which include the rotator cuff tendons and muscles and the subacromial bursa, that are usually involved in the patient's symptomatology.

DERMATOLOGIC MANIFESTATIONS Extraarticular manifestations occur in more aggressive or extensive forms of RA. [7] The commonly encountered dermatologic findings include rheumatoid nodules and rheumatoid vasculitis. The characteristic rheumatoid nodule occurs in a small percent of patients with RA (Fig. 179-1A). Rheumatoid factor is inevitably found within nodules that occur during active phases of the disease process and form subcutaneously, in bursae, and along tendon sheaths. The usual location is over pressure points such as the olecranons, the extensor surface of the forearms, and the Achilles tendons; but they have been described in almost every location, including viscera. The main findings histopathologically (Fig. 179-1B) are palisaded granulomas in the deep dermis or subcutaneous tissues with fibrinoid degeneration of collagen, a multitude of neutrophils and neutrophilic dust, with surrounding fibrosis and proliferation of vessels. [8] The main differential diagnoses histopathologically include subcutaneous granuloma annulare, necrobiosis lipoidica, foreign body or infectious granulomatous reaction, and epithelioid sarcoid. [8]

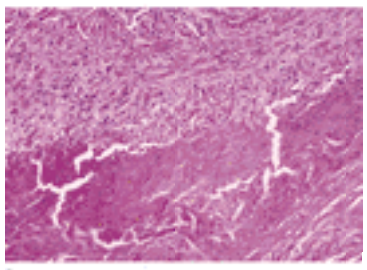

FIGURE 179-1 Rheumatoid nodules. *A.* Severely affected joints of a patient with rheumatoid arthritis with overlying rheumatoid nodules. *B.* Histopathologically, the nodule is a palisaded granuloma in the deep reticular dermis surrounding degenerated collagen.

Rheumatoid vasculitis typically affects small to medium-sized vessels with associated peripheral neuropathy (quite often motor), digital gangrene, nail fold infarcts, and palpable purpura. [9] Some patients may have nail fold telangiectasias, with minute digital ulcerations or petechiae and digital pulp papules (Bywaters' lesions) (Fig. 179-2). These papules are considered a manifestation of mild rheumatoid vasculitis because they typically occur without systemic signs of vasculitis. Histopathologic examination of skin biopsy specimens usually shows leukocytoclastic vasculitis with neutrophilic infiltration of the vessel wall, fibrinoid necrosis, and hemorrhage without palisaded granulomatous reaction. [8]

FIGURE 179-2 Bywaters' lesions. Note the purpuric papule on the finger.

Cutaneous small vessel vasculitis usually involves postcapillary venules of the skin, but the same fibrinoid process may occur in arterioles and in larger vessels of the viscera, heart, and central nervous system. The spectrum of clinical

lesions reported in rheumatoid vasculitis is wide and varies with the size and location of the vessels involved and with the extent of the disease. Fortunately, systemic vasculitis is an uncommon manifestation that usually occurs in patients with long-standing disease. Its presence, especially at the onset of the disease process, portends a poor outcome. [10] Patients with evidence of vasculitis affecting the skin should be followed closely for other organ involvement. Rheumatoid vasculitis can present as lower-extremity ulcers. However, pyoderma gangrenosum should be suspected if deep liquefying ulcers with a characteristic purple, undermined border occur in patients with RA. The ulcers may occur at any site but are most common on the abdomen and lower extremities. Leg ulcers may appear in patients with Felty's syndrome, a combination of chronic RA, hypersplenism, and leukopenia (Fig. 179-3).

FIGURE 179-3 Felty's syndrome. A refractory ulcer on the foot of a patient with rheumatoid arthritis and hypersplenism.

Rheumatoid neutrophilic dermatosis is a very rare cutaneous manifestation in patients with severe RA. First described by Ackerman in 1978, these lesions are usually chronic, erythematous, and urticaria-like plaques and papules that are sharply marginated (Fig. 179-4A). Histopathologically, these lesions have a dense infiltrate of neutrophils without leukocytoclasis, in the setting of a mixed infiltrate and often papillary edema (Fig 179-4B). [8] It may be difficult to differentiate rheumatoid neutrophilic dermatosis from acute febrile neutrophilic dermatosis (Sweet's syndrome).

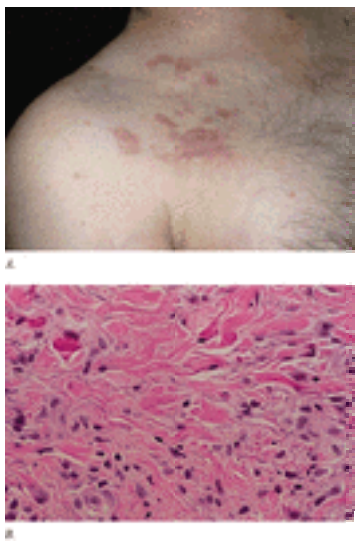

FIGURE 179-4 Rheumatoid neutrophilic dermatosis. *A.* Lesions present as erythematous urticaria-like papules and plaques in a patient with rheumatoid arthritis. *B.* Histopathologically, a mixed dermal infiltrate is predominated by neutrophils without leukocytoclasis. There is often papillary edema.

Lesions that resemble necrobiosis lipoidica diabeticorum have been called superficial ulcerating rheumatoid necrobiosis. These lesions are usually symmetric, on the lower extremities, and occur as multiple, yellow-red, well-circumscribed ulcers that do not become confluent. Telangiectasias as well as local atrophy may occur. The lesions are often confused with venostasis ulcers. Subclinical vasculitis is thought to initiate the palisading granuloma process when the RA is in an acute phase. A papular eruption with clinical and pathologic features of both granuloma annulare and leukocytoclastic vasculitis has been described. These lesions begin superficially and occur in crops, quite often during a flare of arthritis and, occasionally, in association with pyoderma gangrenosum. Other vasculitis syndromes such as erythema elevatum diutinum and livedo vasculitis (segmental hyalinizing vasculitis) have also been described in patients with RA. [7] Skin manifestations such as palmar erythema, erythromelalgia, autoimmune bullous diseases such as epidermolysis bullosa acquisita, yellow nail syndrome, erythema multiforme, erythema nodosum, and urticaria also have been reported in patients with RA and may be associated with the disease process. [7]

NONDERMATOLOGIC EXTRAARTICULAR MANIFESTATIONS In addition to systemic vasculitis, which can affect numerous organ systems, there are multiple nondermatologic extraarticular manifestations of RA. Table 179-2 lists the more common ones.

Type	Manifestations
Ocular	Keratoconjunctivitis sicca, scleritis, episcleritis, scleromalacia
Renal	Amyloidosis and vasculitis
Hematologic	Anemia, thrombocytosis, lymphadenopathy, Felty's syndrome
Neurologic	Entrapment neuropathy, cervical myelopathy, mononeuritis multiplex (vasculitis), peripheral neuropathy
Lung	Pleural effusions, pulmonary fibrosis, bronchiolitis obliterans, rheumatoid nodules, vasculitis
Cardiac	Pericarditis, premature atherosclerosis, vasculitis, nodules, aortic root dilatation

TABLE 179-2 **Nondermatologic Extraarticular Manifestations of Rheumatoid Arthritis**

Laboratory Findings

There is no specific histologic, radiographic, or laboratory test that conclusively permits the diagnosis of RA. Rheumatoid factor, an autoantibody that reacts with the Fc portion of IgG, is found in the serum of 85 percent of patients with RA. Rheumatoid factor should not be used as a definitive screening tool, because it can be found in other disease processes (sarcoidosis, liver diseases, pulmonary fibrotic processes, and cryoglobulinemia). It is also found in approximately 5 percent of the normal population. [9] A false-positive rheumatoid factor can be caused by many factors, including chronic

bacterial infections such as infective endocarditis, tuberculosis, and Lyme disease, as well as by viral diseases such as rubella and infectious mononucleosis.

Treatment

Because the exact cause of RA is unknown, treatment has been directed against various components of the chronic inflammatory process rather than at a specific cause. No single therapy is the treatment of choice. Many drugs, frequently in combination, are used to treat the disease. Because most of the joint damage occurs within the first 2 years, more rapid institution of drugs to attempt to modify the clinical course of disease activity is now suggested. [5] The decision about which drug to use and when to use it is somewhat individualized and determined by the clinical involvement, onset of loss of functional status, and concerns about the safety profile in a given patient.

Analgesics and anti-inflammatories such as salicylates and nonsteroidal anti-inflammatory drugs (NSAIDs) help symptomatically but do not alter the underlying disease course. Selective cyclooxygenase-2 (COX-2) inhibitor NSAIDs, such as celecoxib and rofecoxib, have a reduced incidence of nephrotoxicity and gastrointestinal side effects and are better tolerated. These NSAIDs block the COX-2 isoenzyme, which is upregulated during inflammation, but spare the COX-1 isoenzyme necessary for the regulation of normal cellular processes in the kidney collecting tubules, stomach, endothelial cells, smooth muscles, and platelets. These types of treatments have been considered “first line” in pyramidal treatment protocols in the past. They are still important treatments, often used first in these patients. However, more is now known about the importance of aggressive therapy to alter the disease course in the early years and to prevent permanent joint damage. Therefore, disease-modifying antirheumatic drugs (DMARDs), previously considered “second line,” are now used early in the disease process. Systemic glucocorticoids are potent anti-inflammatory agents but have a serious side effect profile when used over long periods of time. They are not a good option alone for chronic processes, such as RA, but can be used in a low dose with other DMARDs.

DMARDs decrease inflammation (confirmed by a reduction in acute phase reactants), reduce or prevent joint damage, and modify the disease process. [2] The use of DMARDs is recommended early in the disease course, when joint damage is thought to occur. Multiple medications fall into this category (Table 179-3). They may be used alone or in combination, but their use may be limited by loss of efficacy or drug toxicity. Like chemotherapy regimens, combinations of medicines at lower doses may afford a better side effect profile.

Methotrexate
Hydroxychloroquine
Gold salts
Sulfasalazine
Azathioprine
Cyclosporine
Cyclophosphamide
Leflunomide
D-Penicillamine

TABLE 179-3 **Disease-Modifying Antirheumatic Drugs (DMARDs)**

Many of the anti-inflammatory medications reviewed above work through modification of inflammatory cells or their cytokine mediators. Newer additions to the antirheumatic armamentarium are considered biologic response modifiers, and many act directly on those cytokines. The best known and now commercially available members of this category are the anti-TNF-a agents. TNF-a is a proinflammatory agent released by macrophages and T cells contributing to the synovitis and joint destruction.

There are multiple anti–TNF-a compounds, including two that have been approved by the Federal Drug Administration (FDA) in the United States for the treatment of RA: etanercept and infliximab. Etanercept (Enbrel) is a recombinant human TNF dimeric receptor fusion protein consisting of the ligand-binding portion of the human 75-kDa TNF receptor linked to the Fc portion of human IgG1. This treatment is given as a subcutaneous injection twice per week. Infliximab (Remicade) is a chimeric (mouse/human) IgG1 monoclonal antibody to TNF-a. It is given intravenously every 6 to 8 weeks. Both etanercept and infliximab block the interaction between TNF-a and its receptors, rendering it biologically inactive. Both significantly decrease the synovitis and retard the progression of cartilage destruction. [5] Other anti–TNF-a therapies are currently undergoing clinical trials.

Biologic response modifiers are very expensive treatment options. Some authors recommend that TNF-a blocking agents be reserved for patients who do not respond to an adequate trial of one or more DMARDs, including methotrexate. [5] Because TNF-a blocking agents modify the immune response, they may predispose patients to infections, such as tuberculosis, and possibly malignancies. Patients with current or recent serious infections or those predisposed to serious infections (patients with poorly controlled diabetes), as well as those with recent malignancies, may be poor candidates for this therapy. [5] Other biologic agents, such as anti-interleukin (IL)-6 and anti–IL-1 are being studied.

The dermatologist and rheumatologist must work together in the treatment of patients with cutaneous manifestations of RA, which present during phases of intense disease activity. Patients need their underlying rheumatic disease treated aggressively, but proven treatments for these associated dermatologic processes, such as pyoderma gangrenosum, cryoglobulins, vasculitis, and others, should not be forgotten. These specific treatment regimens are beyond the scope of this chapter.

RHEUMATIC FEVER

Rheumatic fever is a delayed sequel to group A ß-hemolytic streptococcal infection of the pharynx. It is an inflammatory disease that can affect the heart, joints, central nervous system, skin, and subcutaneous tissues. There is no specific diagnostic test; rather it is a clinical diagnosis. It is preventable by identification and treatment of streptococcal

tonsillopharyngitis.

Epidemiology

Acute rheumatic fever most commonly occurs in children ages 5 to 15 years after clinically severe tonsillopharyngeal infections. [11] However, it can occur in patients of all ages, even in those with asymptomatic streptococcal infections. Rheumatic fever remains a major health problem in developing countries, likely reflecting inadequate preventive medical care, crowded living conditions, and endemic strains of group A ß-hemolytic streptococcus. The incidence has declined significantly in industrialized nations over the last half century as a result of improved living conditions and the widespread use of penicillin to treat acute streptococcal infections. However, sporadic outbreaks still occur, commonly in crowded inner-city communities, but occasionally in more affluent areas. This disease should not be considered a problem of the past.

Pathogenesis

The exact mechanism by which rheumatic fever results from an infection with group A streptococcal bacteria is unclear. Theories for pathogenesis include direct infection of extrapharyngeal tissues by the bacteria, toxic effects of streptococcal products on host tissues, a serum sickness type reaction, and an autoimmune phenomenon caused by “antigenic mimicry” between antigens on certain bacterial strains and host proteins. [12] Not all strains of group A ß-hemolytic streptococci are rheumatogenic precursors. Specifically, those causing extrapharyngeal infections such as pyodermas and soft tissue infections do not result in rheumatic fever. There are more than 90 known streptococcal M-protein types, and only a limited number have a known association with rheumatic fever. [12] This finding may reflect a common antigenic domain on these M proteins that bears similarity to certain host proteins such as the glycoproteins of heart valves. There likely is a genetic predisposition, as some individuals exposed to endemic strains have not acquired rheumatic fever.

Clinical Features

Acute rheumatic fever can affect many different organ systems. The clinical picture depends upon the specific system involvement in an individual. The diagnostic criteria now known as the Jones Criteria, updated in 1992, [13] emphasize five characteristic clinical features as major manifestations: polyarthritis, carditis, chorea, subcutaneous nodules, and erythema marginatum. Additional nonspecific signs of systemic inflammation are considered minor criteria and include arthralgia, fever, elevated acute phase reactants, and a prolonged PR interval by echocardiogram. The presence of these manifestations in the setting of an antecedent group A streptococcal infection indicates a high probability of acute rheumatic fever.

Rheumatic carditis is the only manifestation that has the potential to cause long-term morbidity and mortality. It usually involves the endocardium, myocardium, and pericardium and almost always is associated with a murmur of valvulitis. [11] Carditis, if present, usually presents in the first 3 weeks of the illness. Diagnosis rests on the presence of new organic cardiac murmurs, cardiomegaly, pericarditis, and or congestive heart failure. [12]

Migratory polyarthritis, the most frequent manifestation, can affect any joint, but most often involves the large joints. It responds well to salicylate therapy, and therefore its presence may be masked by use of anti-inflammatory agents early in the disease course. [12] The diagnosis of chorea is based entirely on clinical signs, which include fleeting local muscular weakness, emotional lability, personality changes, and erratic, jerky, purposeless movements. Chorea does not occur in adult men.

DERMATOLOGIC MANIFESTATIONS The dermatologic manifestations are characteristic but rare. The subcutaneous nodules are small, painless, and localized over bony prominences and in tendon sheaths; they may be seen in the back of the scalp and over the vertebral spine. They last for a week or two and then disappear spontaneously. Erythema marginatum is most apparent in fair-skinned individuals. It begins as an erythematous macule or papule that extends outward while the skin in the center returns to normal. The eruption has a serpiginous pink border and is not usually indurated; it blanches on pressure and changes its shape to the clinician's observation. It is unusual on the face and on the lower extremities and is often hidden by the clothing. Patients are often unaware of its presence. Histopathologically, there is a superficial perivascular infiltrate of lymphocytes and sparse interstitial infiltrate of neutrophils. [8]

Treatment

The eradication of group A streptococcus from the throat of affected individuals is the primary method to prevent acute rheumatic fever. Penicillin is the antimicrobial of choice for treatment of group A streptococcus infection. It has proven efficacy, is inexpensive, and can be administered orally or intramuscularly. For individuals allergic to penicillin, oral cephalosporins or macrolide antibiotics can be substituted. Those affected with acute rheumatic fever should be treated for the primary infection but also are at increased risk of subsequent episodes. Therefore, antibiotic prophylaxis is recommended, especially in endemic areas. Sulfonamides are not effective in the treatment of acute infections but can be used as a preventive antibiotic in addition to those listed above. [14]

The acute inflammatory process, especially the carditis, should be treated with anti-inflammatory agents and rest. Salicylates are adequate for the treatment of mild carditis; more severe cases, however, may require more potent anti-inflammatory agents. Approximately 80 percent of patients who fulfill the criteria for this disorder recover spontaneously. Vaccination against rheumatic fever is not yet available.

GOUT

Gout is a clinical syndrome caused by a group of heterogeneous disorders characterized by deposition of monosodium urate crystals in synovial fluid and other tissues. Clinical manifestations include attacks of acute or chronic joint or periarticular inflammation (gouty arthritis); accumulation of tophi (tophaceous gout); renal impairment (gouty nephropathy); and uric acid calculi in the urogenital tract. The classic presentation is that of an acute lower extremity peripheral joint inflammatory synovitis. The most commonly affected sites are the first metatarsophalangeal joint and the ankle. Diagnosis can be made by demonstration under a polarized microscope of birefringent crystals in synovial fluid or other tissue.

Epidemiology

Gout is a disease that primarily affects middle-aged to elderly men. It rarely occurs in men before late adolescence or in women before menopause. Elderly patients are more likely to have a chronic indolent course. Affected women are more likely to have associated renal insufficiency and a history of diuretic use. [15] Gouty attacks in children are so uncommon that this diagnosis should prompt an evaluation for a malignant or genetic cause.

Pathogenesis

The relationship between hyperuricemia and gout is not well understood. Hyperuricemia is a risk factor for gout, but acute gouty arthritis can occur in patients with normal serum uric acid levels. Moreover, patients with elevated serum uric acid levels may never have gouty arthritis. The typical clinical presentation is in patients with elevated serum uric acid concentrations.

Uric acid is the end product of purine catabolism. Humans lack the enzyme uricase, which breaks down uric acid into a more water-soluble product. When the plasma monosodium urate level exceeds its limit of solubility, it is more likely to precipitate in tissues. Hyperuricemia results from either overproduction or underexcretion of uric acid. Most affected patients are underexcreters. Uric acid renal clearance sufficient to balance production is usually achieved with plasma concentrations below the limit of solubility of monosodium urate in plasma.

Table 179-4 presents a classification of hyperuricemia. Probably less than 10 percent of patients with hyperuricemia or gout excrete excessive quantities of uric acid in a 24-h urine collection. It is usually in this group that identifiable and inherited derangements in mechanisms regulating protein nucleotide synthesis, specifically a deficiency of hypoxanthine-guanine phosphoribosyltransferase (HGPRT), either partial or complete, can be found. In these instances, family history or early presentation may be a clue. The Lesch-Nyhan syndrome, well described but very infrequent, is an extremely severe form of HGPRT deficiency associated with mental retardation, gout, and self-mutilation.

Overproduction of uric acid
Primary hyperuricemia
Idiopathic
Hypoxanthine-guanine phosphoribosyltransferase deficiency
Phosphoribosylpyrophosphate synthetase superactivity
Secondary hyperuricemia
Excessive dietary purine intake
Increased nucleotide turnover (e.g., myeloproliferative and lymphoproliferative disorders, hemolytic diseases, psoriasis)
Diminished excretion of uric acid
Primary hyperuricemia
Idiopathic
Secondary hyperuricemia
Diminished renal function
Inhibition of tubular urate secretion by competitive anions (e.g., keto- and lactic acidosis)
Enhanced tubular urate reabsorption
Dehydration, diuretics
Miscellaneous
Hypertension
Hyperparathyroidism
Certain drugs (e.g., cyclosporine, pyrazinamide, ethambutol, low-dose salicylates)
Lead nephropathy

TABLE 179-4 **Classification of Hyperuricemia**

Uric acid underexcretion occurs in 90 percent of patients with primary yperuricemia. The kidney appears normal and no specific mechanism has been identified at the glomerulus, in the proximal tubule, or in the collecting ducts. Many pharmacologic agents affect tubular function including diuretics, cyclosporine at a low dose, and salicylates (which are frequently used for antiplatelet effect).

The presence of monosodium urate crystals in synovial fluid or other tissues incites an inflammatory response. The initial leukocytes involved may be mononuclear cells releasing IL-1. However, polymorphonuclear leukocytes later ingest the crystal and release multiple inflammatory mediators, initiating further inflammation and tissue damage.

Clinical Manifestations

Patients with gout often follow four clinical stages: asymptomatic hyperuricemia, acute gouty arthritis, intercritical gout (between gouty attacks), and tophaceous gout. [16] Often the patient has asymptomatic hyperuricemia for years. This condition does not necessitate any specific management unless there is a strong family history of gout, uric acid levels are exceedingly high, or there is a history of renal calculi.

Acute gouty arthritis usually occurs in the lower extremities. The most common site of initial involvement is the metatarsophalangeal joint (podagra). The first episode of acute gout usually has a dramatic presentation with a warm, red, tender joint. This may be confused with a sprain, a septic joint, or cellulitis, especially if cytokine-mediated constitutional symptoms such as fever are present. Other differential diagnoses include other forms of arthritis (psoriatic, Reiter's, osteoarthritis, or RA) and pseudogout (chondrocalcinosis). [16]

Intercritical gout describes the interval that occurs between attacks of gout. Initially, these periods are asymptomatic.

Repeat attacks often occur within 6 months to 2 years but become more frequent and severe if left untreated. Chronic tophaceous gout describes the presence of urate crystals in soft tissues. They are usually noted some time after the onset, often up to 10 years after the initial episode of gout. These tophi can occur anywhere, including extracutaneous sites such as cardiac valve leaflets, but the most common sites are overlying joints and tendons. They may also be found on the helix of the ear, overlying nasal cartilage, and on the eyelids and cornea (Fig. 179-5A). They may be confused with rheumatoid nodules, and aspiration or biopsy may prove useful. Subcutaneous tophi present as tender pink nodules or swellings. They may drain clear to white chalky fluid. If left untreated, they can ulcerate and erode into underlying structures. [16] Histopathologic examination shows granulomatous inflammation surrounding radially arranged needle-like spaces (Fig. 179-5B) Differential diagnoses should include rheumatoid nodules, xanthomas, and calcinosis cutis. [16]

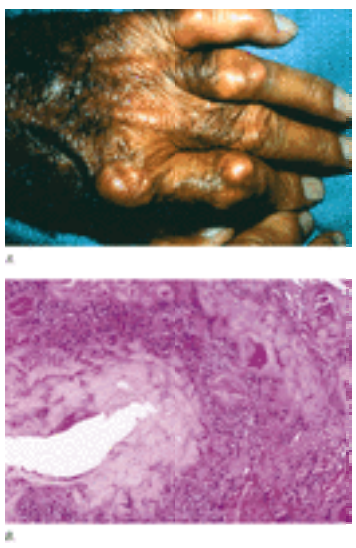

FIGURE 179-5 Gouty tophi. *A.* These tender nodules, often overlying joints and tendons, may drain chalky white material. *B.* On histopathologic examination after formalin fixation, there is granulomatous inflammation surrounding radially arranged needle-like spaces.

Laboratory Presentation/Pathology

Laboratory analysis may reveal elevated uric acid levels, but this finding is not necessary for the diagnosis. Leukocytosis and elevated sedimentation rate are often seen during acute arthritic attacks. The diagnosis depends on the demonstration by polarized microscopy of urate crystals, negatively birefringent needle-shaped crystals, in synovial fluid or tophi. Histopathologic examination of a gouty tophus reveals granulomatous inflammation surrounding yellow-brown urate crystals or needle-like spaces in a radial arrangement, representing crystals dissolved during processing (Fig. 179-5). [8]

Treatment

The goal of therapy in acute gouty attacks is analgesia and reduction in inflammation. The drugs of choice probably still are short-acting NSAIDs such as ibuprofen or indomethacin, which afford relief within hours. These drugs are often used for approximately 1 week and are discontinued when the episode has resolved. The newer COX-2 inhibitors celecoxib and rofecoxib are good alternatives. Because of the age and other characteristics of patients with gout, contraindications to the use of these agents often exist, namely, history of peptic ulceration, renal insufficiency, or a condition requiring anticoagulation. Colchicine remains an alternative to NSAIDs but has a high incidence of gastrointestinal toxicity. Systemic glucocorticoids tapered over 7 to 10 days, intralesional or intraarticular glucocorticoids, and adrenocorticotropic hormone (ACTH) are other options.

Conservative management may help to prevent future attacks and avoid the necessity for prophylaxis. Patients should avoid drugs that decrease the excretion of uric acid such as thiazide or loop diuretics, aspirin, pyrazinamide, or niacin. They should maintain adequate hydration, lose weight, control hypertension and hyperlipidemia, and make diet adjustments. Most people will not tolerate a strict purine-restricted diet. However, limiting cholesterol, fat, meat (especially organoid meat), and alcohol (especially beer) can make a difference. Conservative modification is occasionally adequate without drug therapy.

Lifelong therapy for a patient should be prescribed only when the diagnosis is absolutely established. The usual reasons for such therapy include the following: recurrent acute attacks (particularly if they occur within a short time interval); chronic tophaceous gout; renal calculi; extremely high values of serum uric acid; high serum uric acid levels in the setting of a known familial history of gout (for example, where there is a known deficiency of one of the relevant enzymes previously described); and prophylaxis for patients receiving acute courses of chemotherapy. The protracted use of small doses of colchicine, to a dose of 0.6 mg twice daily, is safe. This regimen is prophylactic against recurrent acute attacks without necessarily creating a need to address the issue of hyperuricemia.

The goal of urate-lowering drugs is to maintain the serum urate level consistently at less than 6 mg/dL. Because 90 percent of patients with gout and hyperuricemia are underexcreters of uric acid, which can be confirmed by a 24-h urine test, uricosurics are an ideal therapy. This treatment should be reserved for patients who are younger than 60 years of age, with normal renal function and, preferably documented, underexcretion of uric acid. Uricosurics include probenecid and sulfinpyrazone. The major risks associated with these medicines include hypersensitivity reactions and increased risk of uric acid nephrolithiasis (avoided by alkalinizing the urine).

The xanthine oxidase inhibitor allopurinol decreases production of uric acid. This drug is indicated for patients with nephrolithiasis, renal impairment, those who failed to respond to uricosuric agents, patients with myeloproliferative

disorders on chemotherapy, and many with hyperuricemia due to enzyme abnormalities. Dosages should be adjusted for the elderly and those with renal failure. Side effects of allopurinol include dyspepsia, headache, diarrhea, a pruritic papular eruption, thrombocytopenia, and hepatic function abnormalities. The syndrome of allopurinol hypersensitivity is well described and has a significant mortality rate. It usually occurs in elderly patients with some renal dysfunction, often with poorly defined gout. Characteristic clinical toxic features include fever, urticaria, leukocytosis, eosinophilia, interstitial nephritis, acute renal failure, granulomatous hepatitis, and toxic epidermal necrolysis.

REFERENCES

Sjögren's syndrome (SS) is an autoimmune disease characterized by dryness of the mucous membranes of the eyes, nose, mouth, and vagina. Salivary, lacrimal, and sweat glands are infiltrated by T lymphocytes leading to xerostomia, keratoconjunctivitis sicca, and xerosis. SS may occur alone (primary SS) or in association with other connective tissue diseases and rheumatoid arthritis (secondary SS). Primary SS is a heterogeneous, insidious in onset, and progressive disease with a poorly understood pathogenesis. Some patients have only mucous membrane dryness. Others, especially those with anti-Ro (SS-A) and anti-La (SS-B) antibodies, frequently have extraglandular manifestations including vasculitis and arthritis (Table 180-1 and Table 180-2). The early recognition of SS patients with cutaneous vasculitis identifies individuals at risk for the development of a chronic relapsing disease, as well as peripheral and central nervous system involvement. In the authors' experience, the European Diagnostic criteria for SS (Table 180-3) are still the most reliable. [1]

Arthritis

TABLE 180-2 **Association of Clinical and Laboratory Features in Anti-Ro(SS-A) Antibody-Positive Sjögren's Syndrome**

Criteria	Definition
1. Ocular symptoms: Positive response to any of these questions	Daily dry eyes for more than 3 months Recurrent sensations of sand or gravel in the eyes Tear substitutes employed ≥3 times per day
2. Oral symptoms: Positive response to any of these questions	Daily dry mouth for ≥3 months Recurrent or persistently swollen salivary glands in an adult Frequent drinking of liquids to swallow food
3. Ocular signs: Objective evidence of dryness in one of these tests	Schirmer's test ≤5 mm in 5 min Rose Bengal score ≥4 according to van Bijsterveld scoring system
4. Histopathology	A focus score ≥1 in a minor salivary gland (a focus defined as an aggregate of at least 50 mononuclear cells around an intralobular duct; the focus score is defined by the number of foci in 4 mm^2 of glandular tissue)
5. Salivary gland involvement: One of following test positive	Salivary scintigraphy Parotid sialography Unstimulated salivary flow (≤1.5 mL/15 min)
6. Autoantibodies: One of these antibodies present	Antibodies to La (SS-B) and/or Ro (SS-A) Antinuclear antibodies Rheumatoid factor

Sjögren's syndrome present if 4/6 criteria positive (93 percent sensitivity, 93 percent specificity).

TABLE 180-3 **European Community Criteria for Diagnosis of Sjögren's Syndrome**

HISTORY

Hadden first delineated SS in 1888. In 1892, Mikulicz described a patient with bilateral enlargement of the parotid glands. On biopsy, the glands demonstrated focal lymphocytic infiltrates. In 1933, Henrik Sjögren described the triad of keratoconjunctivitis sicca, xerostomia, and arthritis. In 1953, Castleman and Morgan reported that the pathologic features of Mikulicz disease and SS were identical.

In the early 1960s, Anderson et al. found two precipitin antibodies (detected by gel double-diffusion) in the sera of patients with SS. These were termed SjD and SjT antibodies. In 1963, Rowell et al. described erythema multiforme-like lesions in anti-SjT–positive patients with systemic lupus erythematosus (SLE) [this is the first description of subacute cutaneous lupus erythematosus (SCLE)-like lesions associated with anti-Ro (SS-A) and anti-La (SS-B) antibodies (see below)]. In 1969, Clark et al. described anti-Ro antibodies, and in 1974, Mattioli and Reichlin described anti-La antibodies in patients with SLE. In 1975, Alspaugh and Tan described two precipitin antibody systems (anti-SS-A and anti-SS-B) in patients with SS. Subsequently, an interlaboratory collaboration established the identity of anti-Ro with anti–SS-A and of anti-La with anti–SS-B.

EPIDEMIOLOGY

In North America, SS appears to occur with approximately the same frequency as rheumatoid arthritis. However, the true incidence of this disease remains largely unknown. [2] In Greece and the United Kingdom, a frequency of SS in elderly patients ranging from 3 to 5 percent has been reported. The disease most commonly occurs in women (9:1 female:male ratio). Males with SS generally have a more benign disease with fewer extraglandular manifestations and lower frequencies of anti-Ro and anti-La autoantibodies. Although SS usually occurs in the fourth and fifth decades of life, it has been described in children (albeit uncommonly). [3], [4] Elderly individuals have an increased frequency of both SS and anti-Ro antibodies. In one US study, approximately 12 percent of 103 patients >70 years of age had definite or probable SS; and of these patients with SS, 7 possessed anti-Ro antibodies.

IMMUNOGENETIC STUDIES

The pathogenesis of the syndrome remains largely unknown. In recent years, immunogenetic, autoantibody, and viral studies have provided important information possibly related to the pathogenesis of SS. Immunogenetic studies have described a variety of autoimmune diseases in relatives of SS patients, as well as various autoantibodies. Table 180-4 presents the autoimmune diseases found in 98 primary and secondary SS probands. [5] Furthermore, first-degree relatives of patients with SS demonstrate an increased frequency of antinuclear and anti-Ro antibodies.

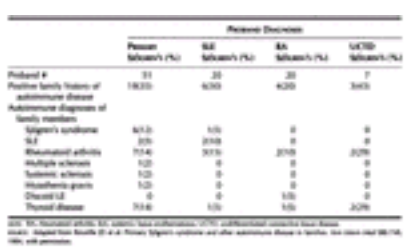

TABLE 180-4 **Autoimmune Diseases in Family Members of Probands with Primary or Secondary Sjögren's Syndrome**

Two antibody response patterns have been noted: (1) anti-Ro and anti-La and (2) anti-Ro without anti-La. The combination of anti-Ro and anti-La occurs more frequently in patients with primary SS than in patients with SLE. This coupled antibody response is associated with the serologically defined human leukocyte antigen (HLA)-B8, -DR3, -DQw2, -DRw52 haplotype (Table 180-5). The second antibody response, anti-Ro without anti-La antibodies, is detected primarily in patients with SLE and is associated with the HLA-DR2, DQwl haplotype. Heterozygosity (HLA-DQw1/DQw2) is associated with the highest anti-Ro antibody titers. Nucleotide sequence analysis of the DQA1 and DQB1 chain alleles reveals that 100 percent of anti-Ro antibody-positive patients with SS or SLE possess a glutamine residue at position 34 of the outermost domain of the DQA1 chain and/or a leucine at position 26 of the outermost domain of the DQB1 chain. Theoretically, these data indicate that the glutamine and leucine residues, located in the floor of the antigen-binding cleft of the HLA-DQA1/DQB1 heterodimer, may be important in binding the antigenic peptide(s) responsible for the anti-Ro and anti-La antibody responses. [6] A single-nucleotide polymorphism (SNP) in intron 3 was found to be strongly associated with the presence of anti-Ro 52-kDa autoantibodies in primary SS. [7] These studies also indicate that the HLA associations in SS are not disease specific; rather, they are associated with the anti-Ro antibody responses (see Table 180-5).

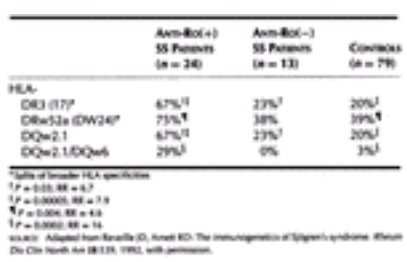

TABLE 180-5 **HLA-DR and DQ Specificities in Anti-Ro(+) and Anti-Ro(–) White Patients with Primary Sjögren's Syndrome**

ANTIBODY STUDIES

By gel double-diffusion, 40 to 45 percent of patients with primary SS possess anti-Ro antibodies, and approximately 20 percent demonstrate anti-La antibodies. However, more sensitive assays, such as hemagglutination and enzyme-linked immunosorbent assay (ELISA) techniques, show the presence of anti-Ro and anti-La antibodies in as many as 95 percent and 70 percent of these patients, respectively. [8] Anti-La antibodies are uncommonly found in the absence of anti-Ro antibodies. Thus, the frequency of anti-Ro and anti-La antibodies in patients with SS depends, at least in part, on the study techniques employed (see Table 180-2).

Immunoblotting studies have demonstrated that the anti-Ro antibody in patients with SS recognizes predominantly a 52-kDa protein. In contradistinction, the anti-Ro antibody in patients with SLE predominantly recognizes a 60-kDa protein. Mothers of infants with neonatal lupus possess anti-Ro antibodies that predominantly recognize the 52-kDa protein. [9] The 52-kDa and 60-kDa nuclear and cytoplasmic proteins are associated with small RNAs known as hY1, hY3, hY4, and hY5 RNAs. Molecular cloning studies of the Ro autoantigens have determined that the 52-kDa and the 60-kDa proteins are different, with little, if any, sequence homology. The 60-kDa protein has an RNA binding domain as well as a zinc finger motif. The RNA binding domain presumably binds with the hY RNAs, whereas the putative zinc finger motif of the 60-kDa protein may interact with the 52-kDa protein. The 52-kDa Ro protein contains a zinc finger as well as leucine zipper domains; consequently, it has been proposed that the 52-kDa Ro protein may be involved in the regulation of gene expression.

Anti-La antibodies are directed against an RNA binding protein that transiently binds all RNA polymerase III transcripts, as well as precursors of tRNA and 5sRNA.

Studies indicate that cells undergoing ultraviolet-induced apoptosis express a species of the Ro and La autoantigens on the cell surface membranes. Furthermore, keratinocytes cultured in the presence of 17ß-estradiol express these antigens on the keratinocyte cell surface. These studies suggest possible immune-mediated cellular injury mechanisms involving anti-Ro and anti-La autoantibodies. However, epitope mapping of the Ro and La peptides has thus far failed to establish a definite relationship of one or several epitopes with clinical disease expression (LE or SS).

Recently, a new subset of autoantibodies to proteins other than Ro and La was found in the sera of SS patients. Some of these antigens are proteins located in salivary and lacrimal ducts and acini, and include alpha fodrin, a membrane skeleton protein associated with ion channels and pumps, and muscarinic 3 receptor (M3R). There is a lack of definitive evidence for a primary pathogenic role of these recently described antibodies in SS. However, unique granzyme B and caspase 3 cleavage fragments of fodrin are also recognized by SS T cells, thus linking the humoral and cellular reactions in this disease. [10], [11], [12] and [13]

VIRAL STUDIES

A possible viral pathogenesis of SS is an area of active study. The salivary gland, the main site of mucous membrane involvement in SS, contains a number of viruses in their latent state. At present, all herpesviruses are possible candidates, but the strongest candidate is the Epstein-Barr virus (EBV). Biopsies of salivary glands from patients with SS contain increased Epstein-Barr viral DNA. This finding, however, is not specific for SS and has been detected n organ transplant patients receiving immune suppressive medication who have no evidence of SS.

Furthermore, experimental studies show that fodrin can be cleaved by EBV and these products induce a T cell-mediated reaction in SS. [14] Studies of the human acquired immunodeficiency syndrome (AIDS) have detected diffuse infiltrative lymphocytosis syndrome (DILS), a syndrome associated with HIV-1 infection (most commonly, AIDS) that may present with sicca features. [15] Clinically, most patients with DILS have bilateral parotid gland enlargement and xerostomia. Xerophthalmia and keratoconjunctivitis sicca occur less frequently. Although these clinical features are reminiscent of SS, there are many immunologic differences between SS and DILS. For example, in DILS, CD8 T cells predominate in the lymphocytic tissue infiltrate and peripheral lymphocytosis. In contradistinction, the inflammatory infiltrate in SS is predominantly CD4 positive. In addition, the frequency of autoantibody formation is much higher in SS, and the HLA associations in SS are markedly different from those found in DILS.

Recent studies show that several hepatitis C-infected patients have lymphohistiocytic infiltrates of the salivary and lacrimal glands. Although some of these patients complain of sicca syndrome, only a few will develop a full-blown clinical, histologic, or serologic syndrome. [16], [17]

CLINICAL MANIFESTATIONS

Mucous membrane dryness (eyes, mouth, vagina) is universally present in patients with SS. However, dryness of only one or two mucous membranes may predominate, and the disease may be heralded for several years by dryness involving only one mucous membrane.

Xerostomia

Xerostomia is caused by a chronic progressive destruction of the major and minor salivary glands by the lymphocytic inflammatory infiltrate. Dryness of the mouth is insidious in onset and progressively worsens. As a consequence, patients may have difficulty swallowing and may be unable to carry on a conversation without the frequent ingestion of fluids. Physical examination during the early phase of SS may fail to uncover dryness in the oral cavity. However, with

progression of the disease, an absence of the infralingual salivary pool becomes evident, and the patient may fail to produce any saliva or the saliva may be cloudy and stringy.

Several complications of xerostomia occur. Oral candidiasis is frequent, especially in those patients who wear dentures, and approximately one-third of patients with SS develop this complication. The oral candidiasis may manifest itself as perlèche or intraoral erythematous/whitish plaques. Patients with SS also have an increased frequency of dental caries, especially along the gingival margin. These caries are difficult to repair, making tooth restoration problematic. Consequently, many patients with SS have partial plates or are completely edentulous.

The major salivary glands are enlarged in approximately 20 percent of patients. Enlargement is generally transient and unilateral but on occasion is bilateral and, uncommonly, permanent. Both the parotid and submandibular glands are affected. Blockage of the salivary gland ducts by mucoid salivary secretion is responsible for the transient enlargement. Secondary infection is uncommon.

The diagnosis of the oral component of SS is difficult. Various drugs including sedatives, antipsychotics, antidepressants, antihistamines, anticholinergics, and diuretics may produce dryness. Also to be considered in the differential diagnosis are viral infections such as HIV. Radiation therapy to the neck, graft-versus-host disease, sarcoidosis, and amyloidosis may induce oral dryness. Furthermore, neoplasms, cirrhosis, and gonadal hypofunction may be associated with salivary gland enlargement.

PATHOLOGY OF SALIVARY GLANDS Although it is possible to investigate salivary gland function with sialometry and sialography, the most common technique is a lip biopsy to examine the minor salivary gland pathology. The lower lip is injected with a local anesthetic, and a 1-inch vertical incision is made (Fig. 180-1). The vermilion border is identified at all times and avoided. After the incision, five minor salivary glands are identified and excised with straight scissors. The incision is then closed with two or three absorbable sutures.

FIGURE 180-1 Lip biopsy technique exposing minor salivary glands (see text for description).

Both parenchymal and sialographic abnormalities detected by magnetic resonance imaging (MRI) and MR sialography are associated with the presence of Ro/SSA antibodies but not with age of the patient, disease duration, salivary flow rate, or the presence of hypergammaglobulinemia or extraglandular manifestations. [18] The classic pathology associated with SS is a patchy inflammatory infiltrate composed of mononuclear cells involving both the ductal and acinar tissue (Fig. 180-2). Most classifications are based on the detection of aggregates of 50 or more mononuclear cells. [19] Although the lip biopsy is proposed to be the “gold standard” for the diagnosis of SS, several caveats are important. Initially, the inflammatory infiltrate is patchy and may involve only one of several glands. In addition, large areas of an individual gland may be totally uninvolved; thus, sampling error is problematic. In addition, with long-standing SS, fatty metamorphosis and fibrosis of minor salivary glands occur, producing total destruction. No allowance for this end-stage SS is accommodated by the present minor salivary gland SS diagnostic criteria.

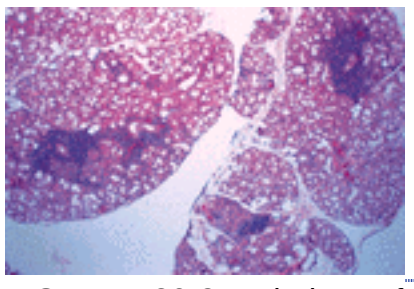

FIGURE 180-2 Pathology of SS in a minor salivary gland biopsy. Note patchy aggregates of lymphocytes involving glandular and ductal regions of the gland. Also note that large areas of gland are free of disease.

Polyclonal lymphohistiocytic infiltrates composed mostly of B cells and CD4-positive T lymphocytes are typical. B cell-attracting chemokines such as BCA1 (CXCL13) and SDF-1 (CXCL12) are abnormally and ectopically expressed in the germinal center-like structures in SS. [20] BAFF (BLyS, TALL-1, THANK, zTNF4) is a member of the tumor necrosis factor (TNF) superfamily that specifically regulates B lymphocyte proliferation and survival. In human and animal models with SS, upregulation of BAFF in blood and salivary gland occurs. [21] High levels of B7 costimulatory molecules and antiapoptotic molecules, such as Bcl-2 and Bcl-x, have a direct correlation with B cell oligoclonality and higher risk for the development of B cell lymphoma in SS. High levels of costimulatory molecules such as CD40 and CD40 ligand (CD154) and Fas-FasL (Fas ligand) may also be involved in apoptotic mechanisms in ductal acinar disease, as well as in the germinal-like structures and B cell lymphoma in SS. [22], [23], [24] and [25] Muscarinic 3 receptors are upregulated in the salivary and lacrimal acini of patients with primary SS. This phenomenon may explain the role of antimuscarinic drugs in the treatment of these patients. [26] The role of Aquaporin-5, an important protein involved in the water transport in salivary

and lacrimal glands, in the pathogenesis of SS still remains to be elucidated. [27], [28]

Xerophthalmia

The first symptoms of ocular dryness include a foreign-body sensation secondary to repeated blinking and rubbing of the eyes, which produces minor corneal abrasions. The minor corneal abrasions may produce photophobia. With severe dryness, a deep aching sensation may occur.

Ocular SS is commonly manifested by conjunctival injection. SS is one of the few conditions that may cause symmetric enlargement of the lacrimal or salivary glands (Table 180-6). However, rapid enlargement of the lacrimal or salivary glands, especially in an asymmetric fashion, should prompt studies to exclude a superimposed B cell lymphoma.

Sjögren's syndrome
Sarcoidosis
DILS
Lymphoma

NOTE: DILS, diffuse infiltrative lymphocytosis syndrome

TABLE 180-6 **Disorders Associated with Symmetric Enlargement of Lacrimal and/or Salivary Glands**

Filiform defects along the inferior portion of the cornea adjacent to the conjunctiva may occur and are detected by the rose bengal dye test. Patients with advanced SS may display a marked decrease in the aqueous component and an increased viscosity of their tears. Some can pull long strings of mucin from their eyes. Testing for ocular SS includes the Schirmer's test. The inferior eyelid is anesthetized, and a Whatman paper wick is folded over the lower eyelid. The migration of fluid along the wick is measured during a 5-min time period. Values of 5 mm or less are highly suggestive of SS.

In addition to these tests, lysosome, lactoferrin, and $ß_2$-macroglobulin assays have been used to evaluate ocular SS. These tests are more investigational and have not achieved widespread clinical acceptance.

Vaginal Dryness

Vaginal dryness in patients with SS is much more common than realized. It is not a symptom freely volunteered by the patient and generally must be elicited by direct questioning. Dyspareunia may be the initial manifestation of SS, antedating the development of other mucous membrane involvement by years. Yeast and bacterial vaginal infections are common.

Xeroderma

Table 180-7 lists the cutaneous manifestations of SS. Xerosis is a common complaint. Pruritus frequently accompanies the xerosis. [29] Patients with SS also complain of dryness of the hair and loss of luster as well as of severe dryness of the external ear canal with impaction of dried cerumen.

Xerosis
Palpable and nonpalpable purpura
Urticaria-like vasculitic lesions
Erythema multiforme-like, erythema perstans, erythema nodosum lesions
Cutaneous lymphoma
Nodular amyloidosis
Sweet's syndrome
Annular erythematous lesion (donut lesion) described in Japanese patients

TABLE 180-7 **Cutaneous Manifestations of Sjögren's Syndrome**

The pathogenesis of the xerosis is unknown. A lymphohistiocytic infiltrate of eccrine sweat glands has been reported. A decreased sweating response to pilocarpine has been observed in some patients with SS. It should be emphasized, however, that the major lubrication of the skin is provided by sebaceous glands. Whether or not the lymphohistiocytic infiltrate detected in the salivary glands and in other organs in SS also involves the sebaceous glands is not known.

Inflammatory Dermatoses

In addition to xerosis, approximately 20 percent of patients with SS have Raynaud's phenomenon. Furthermore, patients with SS uncommonly demonstrate erythematous nodules on the lower extremities. These lesions are not specific, and they may represent lesions of erythema nodosum, medium-sized vasculitis, or cutaneous extravascular necrotizing granulomas.

Neutrophilic dermatosis, such as Sweet's syndrome and pyoderma gangrenosum, has been detected in patients with SS. Cutaneous lymphomas and nodular amyloidosis have also been reported.

Japanese investigators report an erythematous, elevated, plaque-like lesion with central clearing resembling a “doughnut” in patients with SS. [30] Large quantities of mucin, a hydroscopic substance, are present in these erythematous, indurated, plaque-like lesions, which appear to fall into the clinicopathologic spectrum of lupus tumidus.

Vasculitis

The most important cutaneous feature associated with SS is vasculitis. Although medium-sized (polyarteritis nodosa-like) vessel vasculitis has been observed in patients with SS, the principal vasculitis is the one affecting small blood vessels. The most common morphologic lesions of this vasculitis are palpable and nonpalpable purpura and urticaria-like lesions (Fig. 180-3; Table 180-7 and Table 180-8). [31] The nonpalpable purpuric lesions usually mimic the presentation of Schamberg pigmented purpura disease (capillaritis). These lesions also are clinically, immunopathologically, and serologically indistinguishable from the lesions of Waldenström benign hypergammaglobulinemic purpura. Approximately 25 to 30 percent of patients with Waldenström benign hypergammaglobulinemic purpura have been reported to have clear evidence of SS. However, it is believed that most, if not all, of patients with Waldenström benign hypergammaglobulinemic purpura have SS, SLE, or overlap syndromes in the setting of anti-Ro antibodies and/or cryoglobulinemia type 2 or 3. Some of the SS patients who have both palpable and nonpalpable purpuric lesions may also have cryoglobulinemia type 2 or 3. The presence of the cryoglobulinemia syndrome in the setting of SS should prompt the exclusion of a superimposed B cell lymphoma.

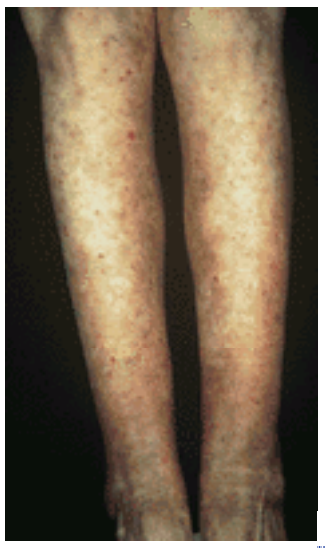

FIGURE 180-3 Palpable purpuric lesions of the lower extremities. Note, in addition to new lesions, the widespread deposition of hemosiderin (brownish patches), which is evidence of previous vasculitic lesions.

A. Small blood vessel vasculitis
1. Purpuric lesions
  a) Lymphocyte predominant vasculitis
    - Rare
    - Nonpalpable > palpable purpura
    - Clinically and histologically: mimic Schamberg's disease
    - DIF: negative
    - Associated with the so-called benign hypergammaglobulinemic purpura of Waldeström and cryoglobulinemia types 2 and 3
  b) Neutrophil predominant vasculitis
    - Common
    - Palpable > nonpalpable purpura
    - Associated with cryoglobulinemia types 2 and 3 and CTD, SS, hypersensitivity vasculitis
    - DIF very useful for cryoglobulinemia (strong IgM and C3) and to exclude IgA vasculitis
2. Urticaria-like lesions
  a) Hypocomplementemic urticarial vasculitis
    - Syndrome: arthritis, renal, ocular, etc.
    - Very-low complement levels
    - Abundant PMN and leukocytoclasia
    - Typical DIF finding: granular IgG along the BMZ and in vessels
  b) Normocomplementemic urticarial vasculitis
    - Bland histology
    - DIF inconsistent
    - Subset of hypersensitivity vasculitis (CLA)
B. Medium-sized vasculitis
    - Rare in SS
    - Occurs in severe cases of SS
    - PAN-like presentation (nodules, ulceration, livedo reticularis, digital infarcts)
    - Higher incidence of mononeuritis multiplex

NOTE: BMZ, basement membrane zone; CLA, cutaneous leukocytoclastic angiitis; CTD, connective-tissue disease; DIF, direct immunofluorescence; PAN, polyarteritis nodosa.

TABLE 180-8 **Cutaneous Vasculitis in Patients with Sjögren's Syndrome**

The second most common type of vasculitic lesion in patients with SS is hypocomplementemic urticarial vasculitis, although the normocomplementemic variant also occurs in these patients.

In both types of vasculitis—lymphocytic and neutrophilic—the architecture of the blood vessel is disrupted by the inflammatory cells.

Most of the nonpalpable purpura lesions, especially those that mimic pigment purpura belong to the lymphocytic vasculitis histology group. By contrast, most of the palpable purpura and all of the urticarial vasculitis fall into the leukocytoclastic vasculitis group. [32], [33]

Anti-La and/or anti-Ro antibodies, rheumatoid factor, antinuclear antibodies, cryoglobulins, hypocomplementemia, and hypergammaglobulinemia are significantly increased in patients with SS with neutrophilic inflammatory vascular disease (Table 180-2 and Table 180-9). The mononuclear inflammatory vascular process in patients with SS generally fails to demonstrate these serologic associations.

Pathology	ANA%	Glob%	RF%	Anti-Ro%	Anti-La%
Leukocytoclastic angiitis (%), n = 27	21(78)	14(52)	18(67)	20(74)	12(44)
Mononuclear vasculopathy (%), n = 18	7(39)	2(11)	3(17)	2(11)	2(11)
P-value	0.02	0.01	0.002	0.00006	0.036

NOTE: ANA, antinuclear antibody; Glob, hypergammaglobulinemia; RF, rheumatoid factor.

TABLE 180-9 **Serologic Correlation with Histopathologic Type of Vascular Disease in Sjögren's Syndrome**

Nervous System Involvement

The inflammatory vascular disease in patients with SS recurs over time. In general, small blood vessels (postcapillary venules and arterioles) may be involved with peripheral and central nervous system (CNS) disease (Table 180-10). Spinal fluid studies, evoked sensory response testing, MRI, and autopsy studies have all documented the presence of peripheral and CNS disease in SS. The autopsy and MRI data suggest diffuse small cerebral vasculitis.

	Number (%) of SS Patients with Nervous System Disease		
Pathology (n)	Central Alone	Peripheral Alone	Both
Leukocytoclastic angiitis (17)	3(18)	6(35)	8(47)
Mononuclear vasculopathy (16)	2(12)	3(18)	11(70)
Total (33)	5(15)	9(28)	19(58)

SOURCE: Adapted from Molina R et al: Peripheral inflammatory vascular disease in Sjögren's syndrome: Association with nervous system complications. Arthritis Rheum 28:1241, 1985, with permission.

TABLE 180-10 **Central and Peripheral Nervous System Disease in Patients with Sjögren's Syndrome with Peripheral Vascular Disease**

Table 180-11 lists the peripheral and CNS manifestations that occur in patients with SS. Originally, the presence of CNS disease associated with SS was controversial. Spanish investigators have confirmed the presence of a multiple sclerosis-like CNS disease process in association with SS, and a Finnish group confirmed the presence of CNS disease in their SS population. [34] These latter investigators describe a higher frequency of CNS complications in patients with SS than that previously reported from the United States. An increased incidence of psychiatric disorders in patients with SS has been reported.

Brain
Cognitive dysfunction
Alzheimer-like disease
Multiple sclerosis-like disease
Aseptic meningitis
Focal neurologic disease
Intranuclear ophthalmoplegia
Spinal cord
Transverse myelopathy
Neurogenic bladder
Rectal incontinence
Peripheral nervous system
Trigeminal neuropathy
Sensory neuronopathy
Sensorineural hearing defect

TABLE 180-11 **Some of the Neurologic Features Associated with Sjögren's Syndrome**

B Cell Lymphomas

Patients with SS frequently have B cell proliferation characterized by hypergammaglobulinemia. Monoclonal light chains and heavy chains have been detected in patients with SS with very sensitive immunofixation techniques. Patients with SS are also at increased risk for developing B cell lymphomas. [35] In some cases, the lymphomas involve the salivary glands, especially the parotids; in other cases, they involve the skin. Anti-Ro antibody-positive patients with SS appear to be at greater risk to develop B cell proliferative responses (Table 180-2).

Eighty-five percent of SS patients with non-Hodgkin's follicular B cell lymphomas have a characteristic chromosome translocation involving the JH segment of the immunoglobulin heavy chain (14q32.3) and the antiapoptotic Bcl-2 gene (18q 21.3). Almost all of the lymphomas in SS are classified as marginal cell lymphomas.

It is thought that these patients are at a higher risk for developing extranodal B cell lymphomas and thus they should be followed closely. EBV and other viruses do not seem to be implicated in the development of lymphoma in patients with SS. In patients with primary SS, 1 in 5 deaths is attributable to lymphoma. The presence of palpable purpura and low C4 levels at the first visit adequately distinguishes high-risk patients (type I primary SS) from patients with an uncomplicated disease course [type II (low-risk) primary SS]. [36]

RELATIONSHIP OF ANTI-RO-POSITIVE SS WITH SLE

A close association exists between the phenotypic expression of SS and SLE, occurring in HLA-DR3, anti-Ro–positive female patients. Figure 180-4 depicts this interrelationship. A large number of these female patients with anti-Ro and SLE have an exquisite photosensitivity. Many of these patients relate experiencing sun burning through window glass. [37], [38]

FIGURE 180-4 Schematic representation of the interrelationship between the various clinical presentations of HLA-DR3, anti-Ro (SS-A) antibody-positive female patients (see text for discussion).

Asymptomatic anti-Ro antibody-positive patients may alternatively develop dryness of their mucous membranes and demonstrate a phenotypic expression of SS. With time, both the anti-Ro antibody-positive patients with SS and the anti-Ro antibody-positive patients with SLE may develop variable features of both SS and SLE. These patients with SS/SLE have a high frequency of cutaneous disease including subacute cutaneous lupus lesions and cutaneous vasculitis. [39] CNS manifestations and pulmonary interstitial disease are prominent features. Renal disease occurs less frequently.

The factors that determine the phenotypic expression of these anti-Ro antibody-positive, HLA-DR3–positive female patients are unknown. Certainly, ultraviolet light precipitates and exacerbates the cutaneous lupus disease process in anti-Ro antibody-positive patients with SLE. However, clinical experience indicates that those HLA-DR3–positive, anti-Ro antibody-positive female patients with the SS phenotype are not photosensitive.

Despite the phenotypic differences, all of these HLA-DR3, anti-Ro antibody-positive females with asymptomatic SS, SLE, or SS/SLE are at risk during their childbearing years to give birth to children with the neonatal LE syndrome. [40] These women may have a dynamic disease process associated with a great deal of morbidity and cutaneous features of vasculitis or SCLE lesions extending over a 30- to 40-year period.

TREATMENT

Oral Manifestations

The treatment of xerostomia is difficult. [41] Methylcellulose saliva substitutes are generally poor, with low patient acceptance. The frequent ingestion of water or other sugarless fluids is generally the most acceptable form of therapy. Chewing sugarless gum helps massage the minor and major salivary glands, resulting in increased fluid production.

Muscarinic M3 agonists, such as oral pilocarpine (Salagen) and its analogue cevimeline (Evoxac), increase tear and saliva flow. [42] These drugs may also effectively stimulate saliva production, and both have been approved by the FDA for the treatment of dry mouth of SS, as well as radiation-associated dry mouth. Prompt treatment of oral candidiasis, prophylactic fluoride treatment, and frequent routine dental examinations are recommended. Blockade of TNF-a with infliximab is safe and effective and improves the global assessment (e.g., sicca symptoms, as well as more objective measurements such as sedimentation rate, salivary flow rate, and the Schirmer's test in SS patients.) [43]

Ocular Manifestations

Ocular SS is treated successfully with artificial tears. Many preservative-free artificial tear preparations are now commercially available. Lubricant ointments, applied at night, are also of value. According to patients, the use of a humidifier in the bedroom to increase ambient humidity helps with both the ocular and the oral symptomatology. Patients also have indicated that using underwater goggles that contain water-soaked soft cotton at night is an effective means of relieving ocular dryness. Occlusion of the nasal lacrimal duct is a common therapeutic approach to preserve moisture in the eye. A temporary punctal occlusion is first tried; if successful, a permanent ductal occlusion after local anesthesia can be achieved with either an argon laser or electrocautery. Recent studies have shown the effectiveness of cyclosporine eyedrops in sicca syndrome. [44]

Vaginal Manifestations

Vaginal dryness is a problem. Vaginal moisturizers (e.g., Replens) are commercially available, but in the authors' experience, they are of limited value. The application of Vaseline after bathing has some benefit. The frequent use of vaginal suppositories at night is helpful in combating *Candida* infections.

Cutaneous Manifestations

Xeroderma can be treated with moisturizing topical preparations. After bathing, patients pat their skin dry, leaving a residue of moisture on the skin. A liberal amount of moisturizer is applied to predetermined areas of xerosis, trapping moisture between the moisturizer and the skin.

As a general measure to combat mucous membrane dryness and xeroderma, the ambient humidity should be increased in the patient's living area by placing a humidifier on the heating system or, as noted above, using a humidifier in the bedroom.

Systemic Manifestations

Patients with primary SS frequently complain of myalgias and arthralgias; hydroxychloroquine has been used with some success in the treatment of these symptoms. [45] A retrospective study with hydroxychloroquine for at least a 2-year period of time demonstrated an approximate 50 percent improvement in ocular symptoms of pain and dryness, as well as an

improvement in the rose bengal dye staining. The Schirmer's test improved by 2 mm or more for 5 min in approximately 50 percent of patients. The salivary flow rate increased in at least 82 percent of patients, and the physician global assessment indicated an improvement in more than 62 percent of the patients. Hydroxychloroquine at doses less than 6.5 mg/kg per day is extremely safe even during pregnancy. Smoking, through inhibition of cytochrome microsomal proteins, may reduce the effectiveness of hydroxychloroquine. [46]

The presence of cutaneous vasculitis should prompt a search for evidence of systemic involvement in which rheumatologists and/or neurologists participate. Cerebral involvement or peripheral nervous system involvement detected by MRI or positron emission tomography (PET) may warrant the need for long-term suppression of the vascular insult. The risk/benefit ratio of high-dose steroids, pulse glucocorticoids, and immunosuppressive agents such as azathioprine, mycophenolate mofetil, and cyclophosphamide should be considered in patients with severe disease.

Sympathectomy
Severe Vasospasm

REFERENCES

Raynaud's phenomenon is the occurrence of episodic attacks of digital ischemia provoked by exposure to cold or emotional stress. The condition was originally described by the French physician Maurice Raynaud in 1862 [1]; and the term *Raynaud's phenomenon* was suggested by Hutchinson, who recognized that digital vasospasm occurred with multiple different disorders. [2] The classic episode of Raynaud's phenomenon is characterized by a triphasic color change of pallor, cyanosis, and hyperemia of the fingers. Although patients are often totally asymptomatic throughout an attack, symptoms of numbness, tingling, or pain during the attack or with recovery are not infrequent. Raynaud's phenomenon is generally divided into primary (idiopathic) and secondary forms on the basis of whether an underlying cause or disease associated with peripheral vasospasm can be identified.

EPIDEMIOLOGY

Studies of the epidemiology of Raynaud's phenomenon are challenging because of underreporting (most patients with primary Raynaud's never seek medical attention) and biases of studies done by investigators interested in the secondary forms of the disorder. Surveys indicate that Raynaud's phenomenon affects up to 10 percent of the general population. [3], [4] Primary Raynaud's phenomenon is estimated to be approximately twice as common as secondary Raynaud's phenomenon. [5] Symptoms most often develop in the teenage years, although onset after the age of 40 is not infrequent. Most series show a female predominance of the disorder (female:male = 4:1). Increases in the frequency and severity of attacks during menses suggest that female sex hormones are most likely involved in the pathogenesis. [6] Differences in seasonal skin temperatures, marital status, alcohol use, age, and smoking between women and men have also been suggested to contribute to the sex differences. [7], [8] Familial aggregation has been identified in a number of studies and suggests the contribution of genetic factors. [9] Other associations reported in epidemiologic studies include living in a cold climate, occupation, cardiovascular disease, low body-mass index, and use of vibratory tools.

PATHOPHYSIOLOGY

The pathophysiology of the vasospasm is complex and only partially understood. Studies show significant reductions of peripheral blood flow throughout all phases of central body cooling and rewarming, suggesting impairments of central thermoregulatory control mechanisms. [10] The principal mechanisms thought to contribute to the development of Raynaud's phenomenon include a local defect of a digital blood vessel, causing abnormal vascular reactivity or reduced blood flow; an enhanced localized production of vasoconstrictors or reduced production of vasodilators; hyperreactivity of the sympathetic nervous system; and abnormal properties of the blood that compromise distal perfusion.

The results of gross histologic examinations of digital arteries in patients with primary Raynaud's phenomenon are normal. Structural abnormalities of the digital microvasculature are frequently seen in patients with secondary forms of Raynaud's phenomenon, particularly in the connective tissue diseases. Studies show a range of pathology including intimal hyperplasia, narrowing or total occlusion of arteries, or thrombi. In most patients with systemic sclerosis, there exists evidence of activation and damage of the endothelium, fibrinolysis, and platelet activation. [11] Microcirculatory flow studies with laser Doppler in patients with scleroderma have shown marked reductions in blood flow and hand temperature during an attack, with prominent abnormalities during rewarming—findings that suggest a failure of the arteriovenous anastomoses to open. [12]

Peripheral vascular resistance is primarily controlled by the interaction between a $_1$- and a $_2$-adrenergic receptors. In vivo studies indicate that a $_2$-adrenergic receptors are more important than a $_1$-adrenergic receptors during reflex sympathetic vasoconstriction, [13] and that a $_2$-adrenergic receptors predominantly affect arteriovenous anastomoses in the fingers. Skin blood flow is especially sensitive to a $_2$-adrenergic receptor antagonism. Studies of brachial artery infusions of a $_1$- and a $_2$-adrenergic receptor antagonists in patients with primary Raynaud's phenomenon show that activation of a $_1$-adrenergic receptors is necessary for the production of the vasospastic attacks. [14] Infusion studies with bradykinin and substance P demonstrate differences between unaffected individuals and patients with primary Raynaud's phenomenon;

these findings suggest a defect in distal signaling mechanisms. [15] The presence of increased levels of a $_2$-adrenergic receptors on platelets of patients with Raynaud's phenomenon raises the possibility of a generalized increased density or sensitivity of the receptor on vascular endothelium.

Neurotransmitters are important in the control of vascular tone, although the contribution of abnormalities in neurotransmitter functions in Raynaud's phenomenon is unclear. Increased levels of endothelin-1, a potent vasoconstrictor peptide present in the digital cutaneous microvasculature, appear not to be involved in pathogenesis. [16] The level of calcitonin-related peptide, a powerful vasodilator in digital cutaneous nerves, is reduced in patients with Raynaud's phenomenon. [17] A deficit of calcitonin-related peptide is hypothesized to result in a functional deficit of vasodilation by nitric oxide synthetase. Serotonin is also incriminated as an important mediator in the induction of ischemic attacks of Raynaud's phenomenon. Patients have an increased sensitivity to intraarterial infusions of serotonin, and an S2-serotonergic antagonist relieves, but does not prevent the induction of attacks.

The evidence of direct central sympathetic nervous system hyperactivity is strongest in vibration-induced injury, in which the use of a vibration tool in one hand produces vasospasm in the other hand. [18] Similarly, vasospasm can be inhibited by proximal nerve blockade in patients with vibration-induced injury. In general, most studies of the sympathetic nervous system in patients with primary or other secondary forms of Raynaud's phenomenon have failed to detect evidence of sympathetic hyperactivity. The results of microelectrode studies of skin sympathetic nervous activity during cold pressor tests are normal, and plasma levels of catecholamines are not increased in the venous drainage of the hands of patients with Raynaud's phenomenon.

Consistent abnormalities in plasma fibrinogen, cold agglutinins, platelets, or cryoglobulins have not been demonstrated in primary Raynaud's phenomenon, but are important in certain secondary cases, particularly scleroderma. Levels of von Willebrand factor and soluble thrombomodulin, thromboxane B $_2$ and ß-thromboglobulin, and tissue plasminogen activator inhibitor-1 are increased in patients with scleroderma, when compared to levels in patients with primary Raynaud's phenomenon. [11]

Genetic studies with microsatellite markers of extended families affected with primary Raynaud's phenomenon have identified several potential candidate genes. [19]

CLASSIFICATION

The classification of Raynaud's phenomenon involves the separation into primary (idiopathic) and secondary forms based on whether an underlying cause or disease association can be identified.

Primary Raynaud's Phenomenon

Primary Raynaud's phenomenon is a disorder in which known causes of attacks of peripheral vasospasm cannot be found. Criteria for the diagnosis of primary Raynaud's phenomenon have been developed by Allen and Brown [20] and LeRoy and Medsger [21] (Table 181-1). Patients with primary Raynaud's phenomenon are typically otherwise totally asymptomatic, with the possible exception of an increase in migraine headaches and variant angina pectoris.

1. Vasospastic attacks precipitated by exposure to cold or emotional stimuli
2. Bilateral involvement of extremities
3. Normal vascular examination with symmetric peripheral pulses and normal nail fold capillary microscopy
4. Absence of gangrene or, if present, limited to the skin of the fingertips
5. No evidence of an underlying disease, drug, or occupational exposure that could be reponsible for vasospastic attacks
6. Negative antinuclear antibody test
7. Normal erythrocyte sedimentation rate
8. History of symptoms for at least 2 years
Combined criteria of Allen and Brown[20] and Le Roy and Medsger.[21]

TABLE 181-1 **Criteria for Primary Raynaud's Phenomenon**

Several studies have examined the long-term outcome of patients with primary Raynaud's phenomenon. [5], [22] Progression to a secondary form of Raynaud's phenomenon, most commonly a connective tissue disease such as scleroderma, occurs in approximately 15 percent of patients during the first decade after onset. Variables predictive of a transition to a secondary form include nail fold capillary abnormalities, hand swelling, positive Allen's test, and antinuclear antibodies.

Secondary Raynaud's Phenomenon

CONNECTIVE TISSUE DISEASES The connective tissue diseases are the most common cause of secondary Raynaud's phenomenon (Table 181-2). Among patients with scleroderma, 80 to 90 percent manifest Raynaud's phenomenon and/or persistent vasospasm. It is the presenting symptom in about one-third of patients and may be the only manifestation of the disease for years. Raynaud's phenomenon occurs in about one-third of patients with systemic lupus erythematosus, idiopathic inflammatory myopathies, and systemic vasculitis. Although patients with rheumatoid arthritis often complain of cold hands with mottled red and white areas, true Raynaud's phenomenon appears to be no more common in persons with rheumatoid arthritis than in the general population. Arteriograms of patients with connective tissue diseases usually show digital and sometimes ulnar or radial artery obstructions.

Connective tissue disease	Clonidine
Scleroderma	Bromocriptine
Systemic lupus erythematosus	Cyclosporine
Dermatomyositis and polymyositis	Amphetamines
Undifferentiated connective tissue disease	Fluoxetine
Systemic vasculitis	Interferon-α
Sjögren's syndrome	Occupational/environmental exposure
Eosinophilic fasciitis	Vibration injury (turbojacks, pneumatic hammer operators)
Obstructive arterial disease	
Atherosclerosis	Posttraumatic injury (hypothenar hammer syndrome, crush pressure)
Thromboangiitis obliterans (Buerger's disease)	Vinyl chloride disease
Thromboembolism	Cold injury
Thoracic outlet syndrome	Hyperviscosity disorders
Neurologic disorders	Cryopathies
Carpal tunnel syndrome	Cold agglutinins
Reflex sympathetic dystrophy	Macroglobulins
Hemiplegia	Polycythemia
Poliomyelitis	Thrombocytosis
Multiple sclerosis	Miscellaneous
Syringomyelia	Hypothyroidism
Drugs and toxins	Infections (bacterial endocarditis, Lyme disease, viral hepatitis)
β-Adrenergic blockers	Hemoglobinopathies
Ergotamines	Primary pulmonary hypertension
Oral contraceptives	Arteriovenous fistula
Methysergide	Intraarterial injections
Bleomycin and vinblastine	

TABLE 181-2 **Secondary Raynaud's Phenomenon**

OCCUPATIONAL Raynaud's phenomenon may be occupational in origin. It is especially common in individuals who use vibratory tools (e.g., air hammers, chain saws, rivets) and in those whose occupation requires prolonged exposure of the extremities to cold temperatures (e.g., butchers, ice cream workers, fish packers). Prevalence rates correlate with the vibration level of the tool and the duration of exposure; they can be as high as 90 percent in high-risk occupations such as logging or mining. [23] Other working conditions associated with the development of Raynaud's phenomenon include occupations requiring the use of plastic gloves, continuous repetitive movements of an extremity, and work breaks in an unheated environment. Arteriograms in patients with occupation-induced Raynaud's phenomenon often reveal digital, radial, ulnar, or palmar arch thromboses.

NEUROLOGIC DISORDERS Any neurologic condition that produces permanent disuse of a limb can be associated with sympathetic nervous system disturbances to that limb. Patients often develop persistent vasospasm with coldness, paleness or cyanosis, and even ulcerations of the limb, and Raynaud's phenomenon may occur. Thermoregulatory abnormalities may be a prominent feature of reflex sympathetic dystrophy syndrome. [24] Nerve root pressure or nerve entrapment may produce Raynaud's phenomenon. It is often present in patients with carpal tunnel syndrome and typically involves the first, index, and middle fingers, digits innervated by the median nerve. Tapping the median nerve at the wrist (Tinel's sign) or wrist flexion for 60 s (Phalen's sign) may produce shooting pain in the distribution of the median nerve. Demonstration of a prolonged conduction time in the median nerve is the definitive diagnostic test. In addition, Raynaud's phenomenon may occur as a result of neurovascular compression at the thoracic outlet. The compression may be caused by cervical ribs; abnormalities of the scalenus anticus muscle; bony abnormalities of the cervical vertebrae, clavicle, or first rib; or shoulder compression syndromes (the costoclavicular or hyperabduction syndrome). To confirm the diagnosis, assumption of postures to exaggerate the abnormality—such as the Adson test, in which the patient holds a deep breath, extends the neck, and then turns toward the side being examined—must reproduce the symptoms or produce a pale hand from which the radial pulse disappears. Loss of the pulse is not diagnostic, nor are nerve conduction studies.

DRUGS AND TOXINS Drugs and toxins can produce Raynaud's phenomenon. Propranolol, one of the most widely used ß-adrenergic blockers for cardiovascular diseases and migraine headaches, is probably the most frequent offender. Ergot preparations and methysergide used to treat migraine headaches may also cause the phenomenon. Intraarterial use of many medications and recreational drugs can result in toxicity to endothelial cells with irreversible structural damage to the microvasculature of the extremities and be responsible for severe Raynaud's phenomenon. Industrial exposure to vinyl chloride polymerization processes may produce Raynaud's phenomenon, as well as acroosteolysis of the distal phalanges of the fingers; arteriograms show digital artery obstructions. [25] The chemotherapeutic agents bleomycin and vinblastine also may cause the phenomenon. [26]

HYPERVISCOSITY Patients with cold-precipitable plasma proteins, macroglobulins, cold agglutinins, and polycythemia can exhibit Raynaud's phenomenon as a result of flow disturbances or actual occlusion of small vessels. These episodes are usually associated with monoclonal gammopathies, particularly macroglobulinemia, or polyclonal gammopathies, as with rheumatoid arthritis. Cryoglobulins are most commonly present in patients with multiple myeloma, but they also occur in patients with rheumatic diseases, chronic infections, leukemia, and lymphoma, and as an idiopathic condition.

MISCELLANEOUS The most common endocrine disturbance associated with Raynaud's phenomenon is hypothyroidism; symptoms usually remit with thyroid hormone replacement. Raynaud's phenomenon may be a feature of various infectious disorders, including subacute bacterial endocarditis, Lyme disease, and viral hepatitis, presumably a reflection of systemic vasculitis. Peripheral vasospasm may also occur in association with malignant tumors, including pheochromocytoma, carcinoid, and ovarian carcinoma.

DIFFERENTIAL DIAGNOSIS

The main differential diagnoses are cold digits, chilblain (pernio), livedo reticularis, and acrocyanosis (see Chap. 126). Many patients complain of cold, sometimes painful digits without color changes. This condition likely represents one extreme of the spectrum of normal sympathetic nervous system activity. Chilblain is an inflammatory condition of the skin of the extremities induced by cold. Patients develop a bluish-red discoloration and edema, typically involving the lower limb and associated with warmth, erythema, and burning. In severe cases, hemorrhagic lesions, bullae, or ulcers may develop, and secondary infections may supervene. The lesions last from 7 to 10 days, often leaving a residual pigmentation of the skin. Livedo reticularis is a bluish discoloration of the skin of the extremities with a characteristic lacy, irregular appearance. The bluish discoloration becomes more intense on exposure to cold and may disappear in a warm environment. Most patients are entirely asymptomatic, although livedo reticularis may be a feature of the antiphospholipid syndrome, in which patients are at increased risk for venous and arterial thromboses, thrombocytopenia, and pregnancy losses. In acrocyanosis, the hands, and less commonly the feet, develop a persistent bluish discoloration. The blue color is intensified by exposure to cold and is converted into a purplish or red color by warming; a pallor phase is absent. The skin is cold, and the palms are often wet and clammy from sweat. Trophic changes or ulcerations are rarely observed.

HISTORY AND PHYSICAL EXAMINATION

The history is important to elicit a clear description of the attacks, which is necessary to establish the diagnosis of Raynaud's phenomenon and to screen for evidence of signs and symptoms suggestive of a secondary cause. Patients complain of episodic attacks of well-demarcated, white or blue digits induced by exposure to cold and sometimes by emotional stimuli (Fig. 181-1). Often only a portion of the digit is affected, and the thumbs are typically spared. A classic tricolor change (white to blue to red) described in most textbooks is rarely volunteered by patients; most describe only

blanching of the digits accompanied by numbness. During the attacks, one or more fingers or toes may be numb and be described as “dead.” On rewarming, the digits may become bright red, and throbbing pain may occur. When pain is a prominent symptom in the ischemic phase, a secondary cause should be suspected. Attacks last minutes to hours. The fingers and toes are most commonly involved; however, the attacks may involve the nose, earlobes, or nipples. A systemic form of Raynaud's phenomenon with vasospasm of major organ systems such as the heart, lungs, kidneys, esophagus, gastrointestinal tract, and cerebral circulation has been documented in patients with connective tissue disorders, and may be an important contributory factor to pathology. There is no evidence, however, to suggest that there is a systemic vasospastic component in patients with primary Raynaud's phenomenon.

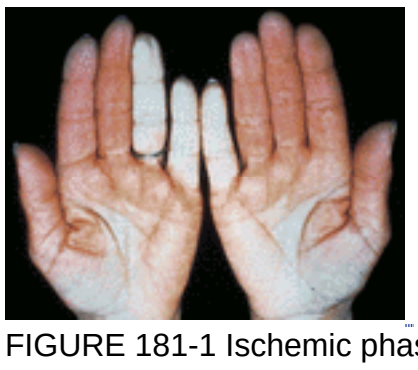

FIGURE 181-1 Ischemic phase of attack of Raynaud's phenomenon with marked pallor of the ring and little fingers of the left hand and little finger of the right hand.

A careful review of systems is important to screen for symptoms of connective tissue disease (arthralgias, arthritis, dysphagia, heartburn, rash, photosensitivity, skin changes, muscle weakness, shortness of breath, or sicca), a drug-related etiology, symptoms of obstructive arterial diseases (intermittent claudication), and exposure to vibratory tools or continuous finger trauma. In patients with primary Raynaud's phenomenon, a review of systems is entirely unrevealing with the exception of occasional complaints of migraine headaches or variant angina pectoris.

Attacks of Raynaud's phenomenon, presumably stress-induced, are commonly witnessed during the course of the history or physical examination. There is well-demarcated blanching or cyanosis of the digits extending from the tip to various levels of the digit. The digits distal to the line of ischemia are cold, while the proximal skin is pink and warmer. On rewarming, blanched digits may become cyanotic, because of the slow blood flow, and then bright red, because of reactive hyperemia. Persistent ischemic discoloration of digits suggests a secondary cause.

The digits should be carefully examined for trophic or ischemic changes, which are signs of prolonged or severe attacks of Raynaud's phenomenon. The skin may become atrophic, thin, and tight (sclerodactyly), with loss of hair over the dorsal surfaces. The nails may become brittle and deformed. Ulcerations, which can be extremely painful, particularly at night, may develop on the finger pads or around the nail bed. The ulcers heal slowly, leave characteristic small, pitted scars (Fig. 181-2), and may become infected. Gangrene of the distal aspects of the digit is rare.

FIGURE 181-2 Loss of pulp of the pad of the digit with pitting scars and ulcerations from chronic, severe Raynaud's phenomenon.

In general, the physical examination is unrevealing in patients with primary Raynaud's phenomenon. Patients with secondary Raynaud's phenomenon should have features of their underlying disease. The physical examination should pay attention to all pulses, and blood pressure should be obtained in both arms. Allen's test is useful to assess arterial and capillary function of the hands; abnormalities imply structural disease of the microcirculation and raise the suspicion of a secondary form of Raynaud's phenomenon. The radial and ulnar arteries are simultaneously compressed by the examiner's thumbs while the patient opens and closes the fist to induce blanching of the palm. Selective arterial filling is judged by the rate of color return as pressure is sequentially released from the radial and ulnar arteries. Vascular obstruction from the thoracic outlet syndrome should be assessed by the Adson maneuver, which tests for diminution in the radial pulse with exaggerated movements of the neck and shoulder. A careful neurologic examination should be performed to detect evidence of sympathetic hyperactivity, abnormal reflexes, muscular weakness or atrophy, or compression of the median nerve within the carpal tunnel. Skin changes, such as telangiectases, changes in skin texture, rashes, or purpura, provide valuable clues to the presence of a connective tissue or hyperviscosity disorder.

LABORATORY AND SPECIAL INVESTIGATIONS

Although differences in the vascular response to cooling have been reported between patients with primary and secondary Raynaud's phenomenon, [10] there is no need to attempt to induce an attack as by immersing the patient's hand in ice water. In all patients, a complete blood count, erythrocyte sedimentation rate, urinalysis, and antinuclear antibody test should be obtained. Additional laboratory studies should be directed by findings elicited by the history and physical examination. In patients with abnormal antinuclear antibody levels, tests for antibodies to specific nuclear antigens, such as topoisomerase or centromere antigens or the Smith (Sm) antigen, are helpful to detect early scleroderma or systemic

lupus erythematosus. A routine chest radiograph should be obtained to look for a cervical rib or evidence of interstitial lung disease.

Nail fold capillary microscopy is a useful procedure to distinguish primary from secondary Raynaud's phenomenon and should be done as part of the routine evaluation of all patients. [27] Although mild capillary abnormalities may be observed in patients with primary Raynaud's phenomenon, patients with connective tissue diseases may have enlarged, deformed capillary loops surrounded by avascular areas (Fig. 181-3). [28] Serial studies reveal progressive decreases in the total number of nail fold capillary loops in secondary, but not primary, forms of Raynaud's phenomenon. [29] The patency of small arteries can be assessed by Doppler techniques. Digital subtraction arteriography should be reserved for selected patients with prolonged, severe ischemia for whom arterial reconstruction is a consideration.

FIGURE 181-3 Nail fold capillary microscopy, in a patient with scleroderma, showing capillary drop out with enlarged, dilated, tortuous capillary loops.

TREATMENT

The management of Raynaud's phenomenon is guided by the frequency and severity of attacks and the complications from ischemia (Table 181-3). Secondary forms of Raynaud's phenomenon require treatment directed at the underlying medical disorder, discontinuation of drugs implicated in causing the vasospasm, or occupational modifications.

Infrequent or mild attacks	Preventive measures Cessation of smoking
Frequent or severe attacks	Calcium channel blockers (nifedipine, diltiazem) Antiadrenergic drugs (prazosin, reserpine) Topical nitroglycerin
Acute, severe ischemia	Intravenous prostaglandin E_1 or prostacyclin Digital sympathectomy Microvascular surgery
Digital ulcers	Antiseptic soaks, antibiotic ointments, occlusive dressing Calcium channel blockers (maximal doses) Intravenous prostaglandin E_1 or prostacyclin
Gangrenous, infected ulcers	Analgesics Antibiotics Surgical debridement Amputation

TABLE 181-3 **Management of Raynaud's Phenomenon**

General Measures

Mild Raynaud's phenomenon is generally easy to control with lifestyle changes to minimize exposure to the cold; dressing warmly with loose-fitting, layered clothing; and keeping the thermostat a few degrees higher than normal. Limiting time spent outdoors in winter, wearing insulated gloves, and using hand or foot warmers are usually helpful. Patients should be taught to recognize and terminate attacks promptly by returning to a warmer environment and applying local heat to the hands (e.g., by placing their hands in warm water or by using a hair dryer). Patients should be strongly encouraged to stop smoking and to avoid secondhand smoke, because nicotine induces cutaneous vasoconstriction. Stress modification and social support are valuable aspects of treatment to minimize vasoconstriction induced by hyperactivity of the sympathetic nervous system. Counseling, training in relaxation, or medications may be helpful. Some patients benefit from conditioning programs such as biofeedback training.

Dietary therapy with fish-oil supplements containing the omega-3 fatty acids (eicosapentaenoic acid and docosahexaenoic acid) has been studied in patients with Raynaud's phenomenon. [30] These fatty acids serve as alternate substrates for cyclooxygenase and 5-lipoxygenase pathways to produce vasodilation, inhibit platelet aggregation, and alter red cell deformability. The study showed that digital systolic pressures and digital artery flow improved in patients with primary but not secondary Raynaud's phenomenon.

Drug Therapy

Various drugs have been used to treat Raynaud's phenomenon, including vasodilators, platelet inhibitors, serotonin antagonists, and fibrinolytics. Drug therapy is usually reserved for patients with prolonged or frequent attacks that fail to respond to conservative measures. In general, improvements with drug therapy are more pronounced in patients with primary Raynaud's phenomenon, presumably as a consequence of fixed, structural damage in patients with secondary forms.

The calcium channel blockers are by far the most widely used and effective drugs for treating Raynaud's phenomenon. [31] Vasodilating properties vary among different agents. Nifedipine (10 to 20 mg tid or qid) reduces the severity and frequency of attacks; the long-acting preparation of nifedipine is better tolerated but may be less effective. Diltiazem (60 mg tid or qid) may be substituted if nifedipine is ineffective or not well tolerated. Side effects of calcium channel blockers

include fluid retention, light-headedness, and heartburn; these may limit therapy.

Both reserpine (0.1 to 0.5 mg daily) and guanethidine (10 to 40 mg daily) increase capillary blood flow during cold exposure and have the advantage of once-a-day administration. Painful ulcerations or gangrene respond to intraarterial reserpine (0.5 to 1.0 mg). Prazosin (1 to 5 mg tid), an a_1-adrenergic receptor agonist, produces a moderate benefit. Other sympatholytic drugs, including methyldopa, phenoxybenzamine, and tolazoline, have been recommended. The effect of ketanserin, a selective antagonist of the S2-serotonergic receptor, was not significantly different from that of placebo in primary Raynaud's phenomenon. [32] In a pilot study, the selective serotonin reuptake inhibitor fluoxetine reduced the frequency and severity of Raynaud's attacks. [33] Additional drug therapies reported to be beneficial in the treatment of Raynaud's phenomenon include low molecular weight heparin, [34] prazosin, [35] the angiotensin-II receptor antagonist losartan, [36] and stanozolol. [37]

Topical nitroglycerin paste (2%) and a sustained-release transdermal glyceryl patch are helpful in selected patients. [38] In a small study, topical minoxidil, a potent vasodilator, did not increase blood flow in patients with primary Raynaud's phenomenon. [39]

Prostaglandin E_1 (PGE_1) and prostacyclin (PGI_2), administered intravenously, have beneficial effects in patients with Raynaud's phenomenon [40]; however, the vasodilatory effects are not sustained and long-term therapy is required. [41] Oral prostaglandins are currently available only as investigational agents, although preliminary results from studies of a PGI_2 analogue (beraprost) and misoprostol, an analogue of PGE_1, have been disappointing.

Digital Ulcers

Digital ulcers from Raynaud's phenomenon can be extremely painful and typically take weeks or months to heal completely. Pain control is an important part of therapy, because pain can lead to additional vasospasm and more ischemia. On occasion, narcotic pain medications may be necessary to control symptoms. The finger should be soaked in a tepid antiseptic solution (e.g., half-strength hydrogen peroxide) twice daily to soften or loosen the crust or eschar. After drying, an antibiotic ointment is applied to the ulcer, and the digit is covered with an occlusive dressing. Maximum drug therapy with a calcium channel blocker should be used throughout treatment. Infection is a common complication of digital ulcers and is typically manifest by increasing pain, erythema, swelling, or purulent drainage. Cultures usually demonstrate *Staphylococcus* species, and treatment with dicloxacillin or cephalosporins is usually effective.

Sympathectomy

Sympathectomy may be a consideration for the management of patients with refractory, disabling attacks or with an acutely ischemic digit that is unresponsive to other measures. A positive vasodilator response to a stellate ganglion block or epidural infusion should be documented before a permanent procedure is done. Lumbar sympathectomy has an important role in the management of severe Raynaud's phenomenon of the feet, and selective digital sympathectomy may be used to relieve pain and heal digital ulcers in patients with ischemic digits. [42] The long-term effects of sympathectomy are poor, with up to two-thirds of patients reporting no benefit at the end of 1 year. Newer procedures for thoracic sympathectomy, including percutaneous radio frequency [43] and thoracoscopic procedures, [44] have been advocated as technically easier to perform, with fewer complications and more promising long-term results.

Severe Vasospasm

Severe vasospasm with prolonged ischemia (dead-white finger) poses a threat of gangrene and amputation; it is considered a medical emergency. The patient should be hospitalized and the affected extremity put to rest. Nifedipine (10 to 20 mg tid) should be started immediately, as well as PGE_1 (6 to 10 ng/kg per min) or prostacyclin (0.5 to 2 ng/kg), given by continuous intravenous infusion for several hours over 3 consecutive days. Intraarterial phentolamine or tolazoline may reverse acute vasospasm, but monitoring of vital signs is essential, and these drugs need to be used with great caution. A digital (or stellate ganglion) block with lidocaine hydrochloride or bupivacaine hydrochloride (without epinephrine) relieves pain and produces a chemical sympathectomy that may reverse vasoconstriction. Sympathectomy (thoracic, lumbar, or digital) should be considered in patients who have a positive response. Arterial reconstruction should be reserved for patients with angiographically documented occlusive vascular disease. [45]

Reiter's syndrome and the closely related disorder of reactive arthritis are genetically determined and often protracted adaptive immune responses focused on the skin and joints, which usually develop several weeks after infection of the gut or urinary tract with certain microorganisms. Reiter's syndrome has been conceptualized as an autoimmune response, initiated by an infectious agent, that persists in a sterilized joint, but some new developments suggest that this could be an oversimplification. Fully developed Reiter's syndrome is recognized by a set of clinical manifestations that are usually highly distinctive: mouth ulcers; conjunctivitis; balanitis; keratoderma blennorrhagicum; onychodystrophy; acute oligoarthritis, primarily involving the knee and ankle; enthesopathy (inflammation of the tendon and ligament insertions), especially of the Achilles tendon; dactylitis; and urethritis or cervicitis. Because there is no specific diagnostic test, diagnosis is sometimes complicated by a *forme fruste* expression of the features of the illness or by a protracted evolution of the full illness. The term *reactive arthritis* is typically applied to situations where infection elicits only arthritis. In addition, some authors use the designation *complete reactive arthritis* as synonymous with Reiter's syndrome and *incomplete reactive arthritis* to refer to the syndrome when it is limited to the joints. This latter usage is not followed in this chapter.

Reiter's syndrome and reactive arthritis are members of a family of diseases termed the *seronegative spondyloarthritides* that have in common varying degrees of arthrocutaneous and sometimes ocular manifestations (Table 182-1). They exhibit familial clustering, susceptibility associated with the presence of certain major histocompatibility gene complex (MHC) class I alleles, such as human leukocyte antigen (HLA)-B27, and are frequently precipitated by infection with certain microorganisms. The presence of enthesopathy is a diagnostic hallmark in each of these entities. Nail involvement is often prominent. Psoriatic arthritis (see Chap. 43) is a member of the spondyloarthritis group and exhibits many parallels to Reiter's syndrome. The mechanism of disease in the spondyloarthritides appears to involve an as yet imprecisely characterized cellular immune response centered on the CD8 T cell. Behçet's syndrome and Whipple's disease are sometimes included among the spondyloarthritides. Reiter's syndrome is clearly distinguished from rheumatoid arthritis by the absence of rheumatoid factor, the presence of enthesopathy, and its occurrence with undiminished, and often enhanced, intensity in the setting of the frank immunosuppression of advanced HIV infection.

Disease	HLA Markers of Susceptibility	Mucocutaneous Involvement
Reiter's syndrome	HLA-B27, HLA-B7	Marked
Reactive arthritis	HLA-B27, HLA-B7	No
Psoriatic arthritis	HLA-Cw6, HLA-B13, HLA-B27, HLA-B57	Marked
Ankylosing spondylitis	HLA-B27	No
Enteric arthritis (ulcerative colitis, Crohn's disease)	HLA-B27 (axial disease)	Occasional
Behçet's syndrome?	HLA-B51	Marked

TABLE 182-1 **The Spondyloarthritides**

HISTORICAL ASPECTS

The earliest mentions of the characteristic triad of arthritis, conjunctivitis, and urethritis after enteric or venereal infections were in 1776, by Stoll, and in 1818, by Brodie. The differentiation of this triad from the similar findings in gonococcal infection was difficult. Indeed, the term *keratoderma blennorrhagicum* was introduced at the end of the nineteenth century to refer to a supposed complication of gonococcal infection. Reiter's syndrome was independently described by Reiter and by Feissinger and Leroy in the setting of epidemics of dysentery in the appalling sanitary conditions of the Balkan and Western fronts in World War I. During World War II, the distinctive epidemiology of Reiter's syndrome again was documented in a study of more than 150,000 Finns who developed shigellosis, of whom Reiter's syndrome was found in

344, and of 602 similarly infected sailors on the cruiser USS Little Rock, of whom Reiter's syndrome developed in 9. The understanding of the importance of ligament and tendon insertional inflammation, or enthesopathy, as a general manifestation of Reiter's syndrome was advanced by the work of Ball. [1]

The fundamental observation in 1973, by Brewerton et al., [2] that susceptibility to Reiter's syndrome was strongly associated with the MHC class I specificity HLA-B27, ushered in the intense period of current interest in this disease, and made Reiter's syndrome the first instance of a human immune response to a bacterial infection that was genetically regulated by allelic forms of MHC molecules. The role of HLA-B27 in Reiter's syndrome was confirmed by returning to the survivors of the two epidemiologic studies and identifying this HLA specificity in approximately 80 percent of those with Reiter's syndrome who were available for study, while the expected low frequency of HLA-B27 was found in the unaffected controls. The importance of CD8, and not CD4, T cells was provided by an experiment of nature in which it was recognized that Reiter's syndrome occurs with increased severity and prevalence in persons with advanced AIDS. This finding introduced the idea that Reiter's disease is a CD8 T cell-driven disease process. [3], [4]

EPIDEMIOLOGY AND GENETIC FACTORS

There are two epidemiologically distinct forms of Reiter's syndrome: the venereal or endemic form, which follows a sexually transmitted route and is initiated by nonspecific urethritis, and the epidemic or postdysenteric form, which follows enteric infection. The sex ratio is approximately equal in the postdysenteric form but is greatly male-biased in the clinically equivalent form that follows urethritis, perhaps because nonspecific urethritis is more common among men. Reiter's syndrome develops in from 1 to 3 percent of individuals with nonspecific urethritis. [5] Because epidemic enteric infections are relatively uncommon in the United States and Canada, Reiter's syndrome in North America is largely a disease of men (85 to 88 percent of cases).

As would be anticipated in a disorder with an infectious etiology, characteristic modes of transmission, a genetic susceptibility associated with an allele that has a complex distribution, and no specific diagnostic test to identify atypical clinical presentations, it is difficult to arrive at a reliable estimate of the prevalence or incidence of Reiter's syndrome. In the rural midwestern United States, the annual age-adjusted incidence [6] is reported to be 3.5 per 100,000. It is considered to be the most common cause of arthritis in young men. The most frequent age of onset is in the early twenties, but Reiter's syndrome has been recognized from childhood into the sixth decade. [7] Children are reported to develop reactive arthritis after enteric infection at a lower rate than adults; this finding suggests differences in immune responsiveness between children and adults. [8] In the pediatric age group, Reiter's syndrome typically develops after enteric infections, including cryptosporidial enteritis and *Salmonella enteritidis* infection. [9], [10]

The occurrence of Reiter's syndrome parallels the population frequency of HLA-B27, being found largely in circumpolar Asians and whites. Reactive arthritis is far more cosmopolitan in distribution. Indeed, it is one of the major rheumatic diseases to develop in Africans infected with HIV, emphasizing the global problem of this disease. [11] In addition to HLA-B27, other incompletely defined genes appear to be involved. In some families with HLA-B27, there is a strong familial aggregation of Reiter's syndrome without ankylosing spondylitis, whereas in other families the opposite is the case. [12], [13] Both disorders are found in approximately 10 percent of relatives of the proband. A similar divergence between Reiter's syndrome and ankylosing spondylitis is evident among certain groups of American Indians and Inupiat Eskimos in whom HLA-B27 is prevalent. For example, the Haida and Pima have a high frequency of ankylosing spondylitis, and the Navaho and Inupiat have a high frequency of Reiter's syndrome but not ankylosing spondylitis.

ETIOLOGY AND PATHOGENESIS

Infectious Etiology

The postdysenteric form of Reiter's syndrome is initiated by infections with a specific set of gram-negative enteric organisms that are designated as arthritogenic and largely share the property of persisting in macrophage endosomes. These include *Salmonella enteritidis, S. typhimurium,* and *S. heidelberg; Shigella flexneri* types 1b and 2a, and *S. dysenteriae* but not *S. sonnei; Yersinia enterocolitica* and *Y. pseudotuberculosis; Campylobacter fetus;* and *Clostridium difficile*. Among the *Salmonella* and *Shigella* infections that result in Reiter's syndrome there is a reported connection between the ability to induce Reiter's syndrome and the presence of a distinctive plasmid. [14] In contrast, the infectious etiology of the endemic or venereal form of Reiter's syndrome has been more difficult to define. *Chlamydia trachomatis* is implicated as a possible agent. This agent can be cultured from more than one-third of men with nonspecific urethritis, regardless of whether or not they develop Reiter's syndrome, and elementary bodies of the organism have been observed in the synovial membrane. [14] Identification of the chlamydial ribosomal RNA operon by polymerase chain reaction (PCR) analyses is proving to be a more efficient means of identification of infection by this organism. The identification is enhanced if synovial tissue obtained with needle biopsy is used, as opposed to only synovial fluid. [15]

Because the clinical response of Reiter's syndrome follows the apparent inciting infection by 1 to 4 weeks, the causative pathogen can only sometimes be identified with systematic application of current microbiologic diagnostic methods. In one report, [16] a pathogen was identified in only 56 percent of all patients by using enzyme immunoassay and Widal's agglutination test for detection of *Yersinia;* stool culture and enzyme immunoassay for the detection of *Salmonella* and *Campylobacter jejuni;* stool culture for infections with *Shigella* or *Yersinia;* and culture of the urogenital tract and microimmunofluorescence and immunoperoxidase assay for infections with *C. trachomatis*. One of the enteric bacteria was identified in 52 percent of the patients with enteric reactive arthritis. *C. trachomatis* was identified in 63 percent of those with antecedent urethritis. [16]

The frequency of antigen-specific T cells and their cytokine secretion pattern on stimulation with bacteria-derived recombinant proteins are being studied. The T cell proliferative response to microbial antigens by the lymphocytes of the joint fluid is much greater than that of blood lymphocytes among those who develop Reiter's syndrome. [17], [18] Application

of the tetramer technology showed that a B27/chlamydial peptide identified through the process described above specifically stained CD8+ T cells in patients with *Chlamydia*-induced arthritis. [19] The frequency of antigen-specific T cells to *Chlamydia*- and *Yersinia*-derived antigens in reactive arthritis joint fluid is between 1:200 and 1:50. Both the chlamydial heat shock protein 60 (hsp60) and major outer membrane protein (MOMP) are dominant T cell antigens in *Chlamydia*-induced reactive arthritis. [20]

There is increasing evidence by PCR for the presence of *Yersinia, Salmonella,* and, especially, *Chlamydia* in the tissue or, less efficiently, in the joint fluids of affected persons. [14], [15], [21], [22], [23], [24] and [25] However, many patients with arthritis have bacterial DNA in the joint, and in some cases, DNA from more than a single species is present, raising the question of the significance of the observation for the pathogenesis of Reiter's disease. [24]

Genetic Factors

Cross-sectional studies demonstrate a close association between HLA-B27 and Reiter's syndrome, usually in the range of 50 to 70 percent. HLA-B27 was found in 80 percent of 906 patients and in 9 percent of 13,477 ethnically matched controls [26] (relative risk = 37). In general, the intensity of the association between Reiter's syndrome and HLA-B27 is appreciably less than that between the same specificity and ankylosing spondylitis, where it approaches 95 percent. The 20 percent or more of HLA-B27–negative patients with Reiter's syndrome have one of a group of HLA class I specificities termed HLA-B27 cross-reacting antigens, [7], [27] including HLA-B7, HLA-Bw22, HLA-Bw40, and HLA-Bw42. They share structural similarities with HLA-B27. When Reiter's syndrome occurs in individuals infected with HIV, the same genetic predisposition is found that is primarily defined by the presence of HLA-B27. The relative risk of an HLA-B27–positive person in an epidemic setting developing Reiter's syndrome is calculated to be as high as 20, but in other epidemics, such as that among the Finns, the risk is as much as an order of magnitude lower. [28] The chromosomal region around the HLA-B and HLA-C loci contains several additional polymorphic genes including MICA, HLA-17, and BAT1, which could also be relevant. [29], [30]

Immunologic Mechanisms

The central immune recognition event in Reiter's syndrome appears to involve the response of a CD8 lineage T cell to a peptide presented by a class I molecule. This observation is based on three main lines of evidence: (1) Reiter's syndrome occurs with undiminished intensity in those with advanced AIDS and loss of CD4 T cell function; (2) the response does not involve classic autoantibodies that reflect the action of CD4 T cell help occurring in diseases such as systemic lupus erythematosus and rheumatoid arthritis; and (3) susceptibility is determined by the presence of certain class I alleles that act as immune response genes. The nature of the antigen and the specificity of the T cell receptor remain unknown. But it is this CD8 T cell response that initiates the inflammation and alteration of the pattern of gene expression in target tissues through the release of cytokines and other inflammatory mediators by the responding lymphocytes.

How HLA-B27 influences the CD8 T cell immune response remains unknown. Three quite dissimilar mechanisms are proposed. The first autoimmune mimicry model postulates that the HLA-B27 molecule binds one or more particular peptides encoded by the arthritogenic microorganisms. This initiates an immune response against the microorganism involving CD8 T cells. These activated T cells then encounter normal cells of the skin, joint, and entheses that express HLA-B27 molecules containing tissue-specific self peptides closely resembling the peptide encoded by the microorganism. The immune system now attacks the normal cells. This loss of tolerance most likely arises through an induced response to minor antigenic determinants on self molecules for which tolerance does not exist (clonal ignorance) and which are usually not seen as antigenic. The resulting pathogenic immune response against normal tissue-specific self peptides, occurring at the CD8 T cell level, is autoimmune in character, now driven by a self peptide available in unlimited quantities. Interestingly, *Y. enterocolitica* can infect dendritic cells in vitro, inducing rapid maturation reflected by upregulated CD83 and CD86, but greatly reduced MHC class II expression and loss of immunostimulatory capacity in a mixed leukocyte reaction. [31] This could inappropriately activate the T cell by deviation of the immune response towards cross presentation of peptides by a class I route.

A second model invokes CD8 T cell activation to self-reactivity through innate immune receptors that sense stereotyped injury, stress, and danger signals. This may occur in CD8 T cells that have differentiated to memory/effector status through prior clonal activation and thereby express additional receptors, such as activating NK receptors that recognize molecules expressed by stressed or injured cells. Engagement of these receptors then signals through pathways that intersect those induced by the T cell receptor, thus effectively lowering the threshold for CD8 T cell triggering by self-peptides.

A third, less likely possibility involves nonantigen-specific stimulation of T lymphocytes by superantigens contained in the infecting bacteria. [32] By binding to particular portions of the T cell receptor, the superantigen triggers the T cell to activation. Now it recognizes a self peptide presented by a HLA-B27 molecule in an extension of the events in the first model.

Three experimental models are particularly relevant to the pathogenesis of Reiter's syndrome. Adjuvant arthritis in rats, resulting from the administration of inactivated *Mycobacterium tuberculosis,* is a strain-specific response characterized by tendinitis, keratoderma blennorrhagicum, urethritis, and ophthalmitis that resembles Reiter's syndrome. [33] Similarly, the 57-kDa heat shock protein of *Chlamydia* induces experimental eye inflammation that mimics the inflammation in Reiter's syndrome. [34] The expression of the HLA-B27 molecule in mice at levels from five to ten times those of the mouse MHC molecules resulted in phenotypically normal animals that had enhanced susceptibility to *Yersinia* infection. [35] Taken together with the previous information, this finding reinforces the paradigm that Reiter's syndrome is a specific immunologic reaction to a microorganism antigen presented by MHC molecules to T cells.

Although clear differences exist between Reiter's syndrome and psoriasis/psoriatic arthritis at multiple levels, certain

elements in the pathogenesis of these two entities appear to be quite similar, if not identical. T cells of the CD8 lineage and immune recognition events involving class I MHC molecules appear centrally involved in both illnesses. A diagram of the role of the CD8 T cell applicable to the pathogenesis of Reiter's syndrome is found in Chap. 43.

PATHOLOGY

Skin

Histologically, the appearance of established keratoderma blennorrhagicum is indistinguishable from that of pustular psoriasis, and is characterized by hyperkeratosis and parakeratosis, elongation and hypertrophy of the rete pegs, general epidermal hyperplasia, and extensive neutrophilic infiltration with formation of microabscesses and spongiform pustules. The initial lesion is a vesicular, pustular, or erythematous macule. Balanitis in circumcised individuals has a similar histologic appearance, whereas the moist lesion in uncircumcised males is otherwise similar to the initial lesion but is not keratinized. Mouth ulcers are similarly unkeratinized.

P>Differentiation from psoriasis may be helped by the presence of a greatly thickened horny layer in Reiter's syndrome.

Musculoskeletal System

The characteristic lesions of the entheses have not been studied in detail; the lesions do, however, contain lymphocytes and proliferating fibroblasts. The appearance of the synovium is typical of any nonspecific chronic synovitis with an extensive T cell infiltrate, but with rather more marked vascular involvement and fibroblast proliferation. Edema, vascular congestion, increased surface fibrin, lining cell proliferation, and infiltration with neutrophils are found. Occlusion by platelet and fibrin thrombi, simulating that caused by endotoxins, is common. [14]

Systemic

Sixty-seven percent of patients with Reiter's syndrome are reported to have either acute ileocolitis or evidence of Crohn's disease on biopsy, with most having no gastrointestinal symptoms. Five percent of patients have granulomatous lesions at the aortic root and annulus that may cause abnormalities in conduction, including complete heart block and frank atonic regurgitation. Secondary amyloidosis with AA protein deposition is a rare complication that is usually found after a long course of illness.

CLINICAL MANIFESTATIONS

Natural History

The temporal evolution of Reiter's syndrome often provides the clue to diagnosis. The enteric or genitourinary infection that initiates Reiter's syndrome is followed by a latent period of 1 week to 1 month, during which the initial symptoms attributable to the infection subside. Then the features of Reiter's syndrome appear, heralded by urethritis and conjunctivitis; these manifestations are followed within several days by the often abrupt and diagnostically characteristic onset of severe arthritis. The mucocutaneous involvement occurs independently, sometimes coinciding with or preceding the phase of urethritis and conjunctivitis and sometimes developing after the onset of arthritis. During the acute phase of Reiter's syndrome, constitutional symptoms and signs are prominent, including fever, fatigue, and malaise, and sometimes profound weight loss.

Reiter's disease and reactive arthritis are generally considered to be self-limited. In most individuals, the illness responds to therapy, with one or two recrudescences occurring over a 2- to 6-month period. In a still incompletely defined subset of perhaps 20 percent of patients, the disease persists. In this setting, the process occasionally assumes more features of psoriatic arthritis and psoriasis. The chronic cutaneous and joint phase of this illness can be a particularly vexing problem.

Skin Disease

Circinate balanitis is the most common cutaneous finding, reported in approximately 36 percent of patients with Reiter's syndrome. [36] The lesion is initially vesicular with little or no surrounding erythema. Irregular moist superficial ulcers form in the uncircumcised male and may coalesce to give a circinate distribution (Fig. 182-1). These ulcers may occasionally become secondarily infected. In the circumcised male, the lesions evolve to form hard crusts and plaques. Painless mucosal ulcers of varying size on the tongue, palate, buccal mucosa, and lips are found in 17 percent of cases; they are usually transient and cause little or no morbidity.

FIGURE 182-1 Reiter's syndrome, balanitis circinata. Illustrated in this patient is circinate balanitis with moist, well-demarcated erosions with a slightly raised border.

The initial lesions of keratoderma blennorrhagicum are small vesicles or erythematous macules that may coalesce and are usually surrounded by an erythematous base. The vesicle wall becomes progressively thickened, forming a small papule, nodule, or even a horny excrescence. The appearance of the lesions varies from a scaling plaquelike process that resembles pustular psoriasis to combinations of crusting, exudation, and erosion associated with erythema. Lesions of keratoderma blennorrhagicum are found in approximately 15 percent of patients. Keratoderma blennorrhagicum is most commonly found on the soles, toes, and palms, where the lesions are often densely scattered. More isolated lesions occur on the glans penis, scrotum, trunk, limbs, and scalp. In severe cases, notably those associated with HIV infection, the keratoderma blennorrhagicum may be distributed over the entire body, with an intensification on the digits in a pattern that resembles the lesions of pustular psoriasis and in the groin in the pattern of inverse psoriasis or sebopsoriasis. The soles may exhibit unusually marked keratotic changes (Fig. 182-2). The keratoderma blennorrhagicum lesions may last for weeks to months, disappear, and then recur. [37] In patients with HIV infection, the initial Reiter's syndrome may gradually assume the chronic features of pustular psoriatic arthritis.

FIGURE 182-2 Severe keratoderma blennorrhagicum with marked dyskeratotic change in an HIV-positive person. The margins of the dyskeratotic process are intensely inflamed.

Joint Disease

The foot, ankle, and knee are the principal sites of musculoskeletal involvement. Joint disease includes both enthesopathy, mainly of the plantar fascia and Achilles tendon, and arthritis of the subtalar, ankle, and knee joints. The arthritis is generally abrupt in onset and may be florid, particularly in the knee joint where massive effusion may lead to rupture of a popliteal Baker's cyst and the syndrome of pseudothrombophlebitis. The joint inflammation occasionally subsides almost immediately; more commonly, it remains as a subacute, chronic, or recurrent problem. The small or large joints of the upper limbs may be involved, but usually only in association with predominant arthritis of the large joints of the legs. In the instances of Reiter's syndrome associated with HIV infection, the course of the joint disease is sometimes slowly cumulative, and ultimately results in an extensive polyarthritis with erosions and marked periarticular osteoporosis (Fig. 182-3) involving the small and large joints of the arms and legs in a pattern more similar to that of psoriatic arthritis.

FIGURE 182-3 Juxtaarticular osteoporosis in an HIV-positive person who presented with typical Reiter's syndrome, but who exhibited a cumulative pattern of joint involvement indistinguishable from that of psoriatic arthritis. The involvement

of the small joints in the hands is also more typical of psoriatic arthritis.

Inflammation at the sites of insertion of ligaments and tendons is a striking feature of Reiter's syndrome. In addition to the plantar fasciitis and Achilles and posterior tibial tendinitis, the enthesopathy results in chest wall and inflammatory lower back pain, tenderness over ischial tuberosities and iliac crests, and dactylitis, or sausage digits. While in most patients the inflammatory back pain is directly attributable to enthesopathy, where it characteristically includes stiffness and pain after periods of rest, such as in the early morning, and improves with exercise, approximately one-quarter of patients with chronic Reiter's syndrome develop chronic sacroiliitis or a characteristic asymmetric spondylosis that limits back mobility. [38]

Nail Disease

Involvement of the nail may begin as erythema of the nail fold or, more insidiously, as subungual hyperkeratosis, a diagnostic finding in psoriasis and Reiter's syndrome that distinguishes these entities from rheumatoid arthritis. The nail becomes thickened, yellowed, and brittle. Frank onycholysis with shedding of the nail often occurs. The acral portion of the digit may be hyperkeratotic with erythema and scaling, and may exhibit the appearance of pseudoparonychia. The tendency to extensive acral disease is pronounced in HIV-associated cases. In some cases of HIV-associated Reiter's syndrome, yellowing of the nails is the first manifestation of the syndrome. Pitting of the nails, characteristic of psoriasis, is not seen in Reiter's syndrome.

Other Manifestations

Urethritis and prostatitis are frequently associated. They may present only as sterile pyuria in the first voided specimen, or range up to moderately severe dysuria with frank mucopurulent discharge. The dominant ocular lesion in Reiter's syndrome is conjunctivitis of varying intensity that usually resolves quickly. A smaller proportion of patients also exhibits uveitis, initially manifest as acute anterior iritis, which may progress to chronic iridocyclitis and visual impairment. The uveitis resembles that of ankylosing spondylitis in that it is acute in onset, frequently unilateral, and spares the choroid and retina. [39] Uveitis is a potentially serious problem that must be carefully evaluated and treated.

The cardiac symptoms in Reiter's syndrome include palpitations, pericardial type chest pain, and, relatively rarely, symptoms of aortic valve incompetence. Findings in 5 percent of the patients include first-, second-, and third-degree heart block; ST-segment and T- and Q-wave changes on electrocardiography; pericardial rubs; and various degrees of aortic and, occasionally, mitral valve incompetence from granulomatous involvement at the aortic root. [40], [41] Atrioventricular conduction disturbances may appear early in the course. Relatively rare manifestations include peripheral neuropathy and other neurologic findings, pleuritic and pulmonary parenchymal inflammation, erythema nodosum, and amyloidosis.

LABORATORY FINDINGS

High levels of cytokines associated with the inflammation of Reiter's syndrome are reflected by the elevation in acute-phase reactants, a variably elevated erythrocyte sedimentation rate, hypochromic or normochromic anemia, and mild hypoalbuminemia. Elevated antibody titers to specific enteric pathogenic agents often help with differential diagnosis. Rheumatoid factor and classic autoantibodies are absent. Urine and stool cultures are helpful in perhaps as many as half of the cases, with the persistence of *Salmonella* carriage particularly important to determine. The demonstration of persistent components of microorganisms in tissue biopsies by molecular biologic methods is still an experimental technique, but one that holds considerable promise. [15], [42] Testing for HIV should be considered because HIV infection is also a sexually acquired disease.

Much has been written about whether or not to perform HLA typing for diagnostic reasons or to guide therapy. [43] In a classic but mild case, where Reiter's syndrome is an obvious clinical diagnosis, the test seems unnecessary. However, because HLA-B27 is associated with more severe and protracted disease (including the occurrence of uveitis, carditis, and sacroiliitis), [44], [45] testing may be useful in difficult cases for diagnostic or prognostic reasons.

The joint fluid cell count is elevated, occasionally to more than 50,000 neutrophils per µL, a level that, in conjunction with the intense inflammation, might otherwise suggest a septic joint and is designated pseudosepsis. Occasionally, “Reiter's cells” are observed, which are macrophages that have ingested a neutrophilic leukocyte. Total joint fluid protein levels are elevated in proportion to the degree of inflammation; and because there is little or no intraarticular consumption of complement, the joint fluid complement component levels are about two-thirds of their levels in serum when normalized on a per gram of serum protein basis. Glucose levels are normal, and standard bacteriologic cultures are uniformly negative; these two important points differentiate the intense inflammation of Reiter's syndrome from that of septic arthritis.

RADIOGRAPHIC FEATURES

Initially, only signs of an effusion are present. Periarticular osteoporosis can develop after several weeks of inflammation; in some instances, where the arthritis becomes chronic, erosions and loss of the cartilaginous joint space are seen. Enthesopathy is characterized by a combination of erosions about tendon and ligament insertions, bone lucency, and new bone formation, often in the form of spurs extending into the tendon or fascia. Widespread periosteal new bone formation can be found, especially on the bones of the pelvis and feet. Enthesopathy and periosteal new bone formation is not a feature of rheumatoid arthritis. Sacroiliitis is typical in appearance but may be only asymmetric, distinguishing it from the uniformly bilateral form in ankylosing spondylitis. Similarly, the frank spondyloarthritis, when present, is often asymmetric, without the uniformity in extension from the lower lumbar vertebrae that occurs in psoriatic arthritis. [38]

Indeed, neck involvement is common in Reiter's syndrome.

DIAGNOSIS

The diagnosis of Reiter's syndrome can be simple or exceedingly challenging. In the absence of the distinctive mucocutaneous findings, a careful differential diagnosis must be made among entities such as other spondyloarthritides (including especially ankylosing spondylitis and psoriatic arthritis), infectious arthritis (notably that caused by the gonococcus or Lyme disease), the crystal-induced arthritides (primarily gout), and other rheumatic diseases such as rheumatoid arthritis, Behçet's syndrome, and rheumatic fever. The history of a sexual contact or risk factors leading to the acquisition of HIV infections may be concealed, or an episode of dysentery may be disregarded unless the patient is specifically questioned. Similarly, many of the features of the illness may be mild so that mouth ulcers, if noticed at all, are passed off as cold sores and transient dysuria is dismissed.

Although gonococcal arthritis and Reiter's syndrome may superficially resemble one another in that urethritis, skin rash, oligoarthritis, and tenosynovitis occur in both, the character and natural history of the two illnesses are usually readily distinguishable. Gonococcal arthritis is more common in women, and upper limb joint involvement predominates. The arthritis is not florid and is usually preceded by insidiously developing migratory arthralgia. Enthesopathy, keratoderma blennorrhagicum, balanitis, and back pain are absent. Culture may be helpful but can be negative. Be aware that both entities can coexist.

In any florid arthritis, the fluid should be studied for the presence of microorganisms by culture and staining and examined for urate or phosphate crystals by polarized light microscopy. Rheumatic fever remains a rare but strong simulator of Reiter's syndrome. Behçet's syndrome is another rare entity in North America, but the combination of mucocutaneous lesions and arthritic disease in this syndrome can cause diagnostic difficulties. Neurologic findings and the pustulonecrotic pathergic lesions at injury sites, as well as extensive, painful genital and oral ulcers, suggest the diagnosis of Behçet's syndrome.

The complications of the effusive inflammatory arthritis include ruptured popliteal cysts and thrombophlebitis. The rupture of popliteal cysts with the syndrome of pseudothrombophlebitis should be differentiated from true thrombophlebitis, which can also be found in this setting because of pressure on the popliteal vein by the joint effusion and the contiguous inflammation.

The special problems of the radiologic diagnosis of juvenile-onset Reiter's syndrome with its disproportional degree of enthesitis and its distinction from the other spondyloarthritides and from forms of juvenile chronic arthritis have been reviewed. [46]

TREATMENT

Therapy of Reiter's syndrome varies from relatively straightforward in mild disease to difficult when the illness is sustained or severe. The uveitis, and the more uncommon visceral manifestations, especially those of the heart, while less overt to the patients than skin or joint disease, may require intensive drug therapy to prevent serious complications or disability.

Antibiotic therapy to eliminate persistent inciting microorganisms remains controversial. [23] The traditional view has been to not treat, although newer data about microbial persistence in the synovial tissues, especially that of *Chlamydia* described above, may support a role for antibiotics. There are conflicting double-blind studies. In a carefully performed 3-month trial with doxytetracycline, no beneficial effect was found on pain or functional status. [47] In contrast, ciprofloxacin used for 3 months to treat patients with *Yersinia*-triggered reactive arthritis resulted in faster remission, greater relief of arthritis, and much greater elimination of the microorganism from gut-associated lymphoid tissue. [48] Clearly, any suggestion that an individual had an impaired immune system with the question of enhanced microbial persistence, such as in HIV infection, would indicate antibiotic use where a specific inciting organism was documented. This is especially so because the inflammatory response of Reiter's syndrome may transactivate the virus, leading to an increase in viral load and a consequent increased viral cytopathogenic effect. For this reason, HIV-positive individuals with Reiter's syndrome should have a program of monitoring viral load and initiation of effective antiviral agents. Moreover, assiduous control of the HIV component of the disease is warranted, as emphasized by a case report describing striking improvement in Reiter's disease concomitant with introduction of highly active retroviral therapy. [49]

All patients with Reiter's syndrome must be informed about the sometimes difficult nature of the illness and its variable outcome. The management of the acute mucocutaneous lesions of uncomplicated Reiter's syndrome is usually limited to symptomatic or topical therapy. The severe, extensive, and chronic cutaneous reactions that are more common in the form of Reiter's syndrome associated with HIV infection present a much more difficult challenge. Moderate success has been obtained by treating these lesions in the same manner as pustular psoriasis. UVB irradiation, coal tar, and etretinate administration, combined with very judicious use of topical glucocorticoids, are the mainstay of therapy. When HIV infection is excluded, extremely severe skin lesions can be treated with immunosuppressive agents including methotrexate, PUVA therapy, or cyclosporine.

Whereas conjunctivitis is a common short-lived occurrence and can be adequately managed by nonspecific local therapy, the development, actual or suspected, of uveitis is a threatening complication. Eye pain, ciliary flush, and other symptoms of early iritis should prompt immediate referral to an ophthalmologist. Cardiac conduction disturbances and aortic or mitral valve involvement mandate immediate medical evaluation and systemic glucocorticoid therapy.

Arthritis and enthesopathy are the symptoms that necessitate treatment in most patients. In general, the anti-inflammatory agents have a high benefit-to-risk ratio, and the decision to use them is usually not complex. In contrast, the use of immunomodulatory/immunosuppressive agents is associated with considerably greater risks.

Nonsteroidal anti-inflammatory drug (NSAID) therapy is the first line of treatment. Sulfasalazine is reported to be effective but slow acting in the therapy of Reiter's syndrome that is unresponsive to NSAIDs, and side effects may occur. [50] Agents such as methotrexate or azathioprine remain choices for intractable, severe disease. Cyclosporine is also reported to be effective. [51] Methotrexate or other immunosuppressive agents should be used with particularly great caution, if at all, in those individuals with concurrent HIV infection. [3], [52]

COURSE AND PROGNOSIS

Reiter's syndrome does not always have a rapid, favorable outcome. Sixty-three percent of patients with Reiter's syndrome in a rural midwest setting had a prolonged or relapsing course, especially of the arthritis manifestations. [6] Less often, persistent dermal lesions, such as balanitis, can be extremely troublesome. A few patients with chronic disease progress into other forms of spondyloarthritis. The HIV-associated forms of Reiter's syndrome usually illustrate the worst features of this illness with a tendency to develop chronic arthritis and skin disease indistinguishable from pustular psoriasis.

Boeck's sarcoid is a systemic granulomatous disorder of unknown etiology with a predilection for involvement of lung, liver, lymph nodes, skin, and eyes. Other organs are less frequently affected.

HISTORICAL ASPECTS

In 1889, Besnier described a man with diffuse red swelling of the nose and fingers which he called lupus pernio, emphasizing that the disorder was an entity distinct from lupus erythematosus. In 1892, Tenneson reported another case in which a biopsy disclosed “excessive predominance of epithelioid cells and a great rarity of giant cells….” In 1898, Hutchinson reported another example of this disease in a 65-year-old woman who had dusky red plaques on the cheeks, arms, and nose. In 1899, Boeck observed a man with similar lesions on the scalp, face, and extremities, but accompanied by enlarged epitrochlear and femoral lymph nodes. He biopsied the lesions and found epithelioid granulomas with giant cells, which he interpreted as a “new growth” that developed in the perivascular lymph space. He coined the term “multiple benign sarkoid of the skin” to indicate that the lesions were of connective tissue origin. But by 1905, Boeck thought the disease was a bacillary infectious disease because he found acid-fast bacilli in the nasal mucosa in one patient. He preferred his new term “benign miliary lupoid,” but “sarkoid” had become entrenched. In 1904, Kriebrich correlated the cystic bone lesions of the fingers with lupus pernio. In 1906, Darier and Roussy described the subcutaneous form of the disease. In 1916, Boeck recognized that Besnier's lupus pernio was the same disorder he had described as “benign miliary lupoid.” Schaumann, in 1914, wrote a prize essay proposing that all the manifestations of sarcoidosis that had been reported represented the same disease. He did not publish this information until he had collected more data. In 1934, he published all his evidence and called the entity “lymphogranulomatosis benigna,” which he believed was related to tuberculosis. In 1946, Löfgren published his classic paper on the association between hilar adenopathy, erythema nodosum, and sarcoidosis. Boeck and Schaumann were the only clinicians to develop the concept of sarcoidosis as a systemic disease.

EPIDEMIOLOGY

Sarcoidosis occurs worldwide and is slightly more frequent in women than in men (ratios as high as 1.5). [1] Prevalence ranges from 10 to 40 per 100,000 in the United States and in Europe. It occurs most often between the ages of 20 and 40, but can occur in children and in the elderly. In two London clinics, sarcoidosis was 10 to 16 times more frequent, severe, and extensive in black West Indian, African, Indian, and Pakistani patients than in native whites. [2] In the United States, blacks are affected 3 to 4 times more often than whites. Sarcoidosis occurs 200 times more frequently in Irish women living in London and more frequently than expected in Puerto Rican female immigrants in New York City. The variation of prevalence in geographical locations and populations suggests that there are ethnic susceptibility factors as well as environmental factors underlying sarcoidosis.

ETIOLOGY AND PATHOGENESIS

The pathogenesis of sarcoidosis is beginning to be unraveled. In active sarcoidosis, T cells of the CD4+ helper/inducer phenotype (T_H1) are increased in affected lungs, and by implication in other affected organs as well, and show evidence of activation: expression of interleukin (IL)-2 receptors and secretion of IL-2. The alveolar macrophages are also activated: they spontaneously release IL-1, interferon ?, tumor necrosis factor (TNF)-a and IL-6, [3], [4] and demonstrate an enhanced capacity to present antigen. [4] In contrast, there is a peripheral T cell lymphopenia and absence of activated T cells in the circulation in active disease. [5] There is a sequestration of activated T cells and macrophages at sites of granulomatous inflammation. CD4+ T cells are diffusely distributed throughout the granuloma, while CD8+ suppressor cells form a mantle of sparse T cells around the granuloma. The increased numbers of CD4+ T cells within the granuloma are believed to have arisen in part through recruitment from the periphery, which explains the lymphopenia, and, in part, by proliferation in situ. In chronic berylliosis, the alveolitis is believed to be produced by a similar mechanism, except that the antigen, beryllium, is known. Berylliosis is a good model for sarcoid. [6]

Although anergy to tuberculin, mumps, *Candida,* and trichophytin antigens is present in two-thirds of patients, it can be overcome by strong antigenic challenge. The anergy is relative and not absolute as in Hodgkin's disease. In vitro, the peripheral T lymphocytes are defective in their cytotoxic and proliferative responses to antigens and mitogens. This

deficit can be partly explained by an abnormal suppression of these responses by prostaglandin-producing monocytes. Removal of the monocytes corrects the deficit in mitogen-stimulating proliferation and colony formation. [7] Despite the depression of T cell function, there is overactivity of B cells, as manifested by elevated serum levels of immunoglobulins, which can be found in up to 80 percent of patients with active sarcoidosis. However, there is no correlation of immunoglobulin elevation with the degree of disease activity or depression of delayed hypersensitivity.

Experimental data strongly support the concept that sarcoidosis is an antigen-driven disorder in which the helper/inducer T cell arm of the immune system reacts in an exaggerated fashion to as yet undetermined self- or exogenous antigen(s). The preferential use of the Vß8 regions suggests that a superantigen of microbial origin has to be specifically considered. [8]

For many years attention has focused on tuberculosis as the major cause of sarcoidosis because of the similar histopathology of the two entities and the increased incidence of tuberculosis in some patients with sarcoidosis. Scadding [9] described English patients in whom tuberculosis preceded the development of sarcoidosis. In one instance, sarcoidosis developed after the successful treatment of pulmonary tuberculosis, but disappeared when the tuberculosis became active again. He also described five cases of sarcoidosis that evolved into tuberculosis. [9] In three of the five patients, the typical cutaneous and pulmonary radiographic findings of sarcoidosis disappeared when the transition to active tuberculosis occurred.

James [10] pointed out that wherever tuberculosis is rampant, sarcoid is rarely seen, but as tuberculosis is brought under control, sarcoid becomes more frequent. This phenomenon has been observed among the Bantus in South Africa and the population in Uruguay. Some of the Bantu patients with sarcoid were found in leprosaria, just as many English patients had been discovered in sanitaria.

By using molecular biologic methods, contemporary investigators have demonstrated that DNA from *Mycobacterium tuberculosis* and unidentified nontuberculous mycobacterial DNA can be found in tissue sections of sarcoid lesions and bronchial washings from patients with sarcoid, strongly supporting the concept that tuberculosis may be a factor in some cases. [11] Mankiewicz et al. presented a role for atypical mycobacteria 35 years ago. [12]

CLINICAL MANIFESTATIONS

Skin lesions occur in 10 to 100 percent of cases, depending upon whether an internist or dermatologist is the observer. [13] Cutaneous lesions are found two to eight times more often in women than in men. In four representative series composed of adults, cutaneous lesions, histologically specific for sarcoid, occurred in 16 to 36 percent. [13] The prevalence of skin lesions in children is the same. In children, the disease occurs most commonly in the 8- to 15-year-old age group. Approximately 30 cases have been reported involving patients younger than 4 to 6 years old. The clinical features in the latter group are different from those seen in older children (Table 183-1).

Feature	Younger Than 4 Years (%)	Older Than 4 Years (%)
Rash	80	40
Eye disorders	60	45
Arthritis	55	5
Bone lesions	50	20
Adenopathy	40	45
Fever	35	24
Weight Loss	32	18
Lung involvement	22	70

*Adapted from Hetherington.[14]

TABLE 183-1 **Comparative Features of Sarcoidosis in Children***

The skin markers of sarcoid can be categorized as specific and nonspecific. The gross appearance of the specific eruption encompasses papules, nodules, plaques, subcutaneous tumors, and scaly erythematous and atrophic flat lesions. Although the lesions do not have a pathognomonic morphology, they do exhibit highly characteristic features that should strongly suggest the presence of the disease. Sarcoidosis can be diagnosed almost with certainty by histologic examination of specific lesions, thereby eliminating the need to biopsy lymph nodes, liver, muscle, or bronchial mucosa solely for diagnostic purposes.

Specific Lesions

The lesions of sarcoidosis are usually red or purple (Fig. 183-1), but they can also have a reddish-brown or yellowish-brown hue (Fig. 183-2). If the erythema is pressed out with a glass slide (diascopy), one can sometimes see tiny yellow-brown nodules produced by the granulomas; these nodules are similar to those seen in lupus vulgaris, the common form of cutaneous tuberculosis (see Chap. 200). Sarcoid lesions characteristically have a waxy translucent appearance and are almost never pruritic or painful.

FIGURE 183-1 Lesions of sarcoidosis are usually red or purple. Characteristically they are on the upper and lower lids, but they also occur in other regions of the face.

FIGURE 183-2 Lesions of sarcoidosis can also be reddish-brown or have a yellowish-brown hue. Often they occur in scars as shown here. A traumatic dermabrasion had occurred at the site 10 years before sarcoidosis developed.

Papules of sarcoidosis can arise anywhere on the body, affecting previously “normal” skin, but also occasionally occurring in surgical or posttraumatic scars and tattoos. Even scars many years old suddenly may become affected by the granulomatous reaction. Lesions are found most often around the eyes and in the nasolabial folds (see Fig. 183-1). These small elevated lesions are usually flat-topped, translucent, red or brown, and from 2 to 5 mm in diameter. Initially, papular lesions might be confused with flat warts or acne vulgaris, but on careful inspection, one can detect their characteristic translucence and color. The term *maculopapular* has been used to describe these small papules.

Papules can form a ring simulating granuloma annulare (see Chap. 100). However, the color and translucent quality of the lesions in sarcoid distinguish them from those of granuloma annulare; the borders of the latter are made up of opaque skin-colored papules. Annular lesions of sarcoid begin as papules that slowly expand peripherally and usually leave an atrophic and sometimes scaly center. In granuloma annulare, the center is neither scaly nor atrophic. Annular lesions also can be produced by plaques that undergo central atrophy. If the annular lesions have a yellow-brown color, it may be difficult to distinguish them clinically, but not histologically, from necrobiosis lipoidica (see Chap. 168). Annular lesions seem to be more common in American blacks than in other groups.

In one patient, the small papules of sarcoid mimicked lichen nitidus (see Chap. 50).

Nodules show a predilection for the extremities and trunk (Fig. 183-3), but they have also been observed on the vermillion border of the lips, on the finger pulps and palms, and on the lateral margins of the foot. Translucency is not characteristic of nodules, but the red and purple colors are. The nodules arise in the deep dermis and subcutaneous layer, with calcification a rare development. Although deep nodules of sarcoidosis are often called Darier-Roussy sarcoid, the eponym is not correct. Darier-Roussy sarcoid is a term used by dermatologists to describe several nonspecific inflammatory disorders that involve the subcutaneous fat. Uncommonly, the papules and nodules may have a verrucous surface.

FIGURE 183-3 Violaceous deep dermal and subcutaneous nodules of sarcoidosis. Nodular lesions often occur on the extremities.

Plaques of sarcoidosis are almost always violaceous and translucent and may be widespread (Fig. 183-4). Large telangiectatic vessels can be present on the surface, and some authors call these plaques *angiolupoid lesions*. However, when such extensive plaque formation arises on the ear lobes, nose, fingers, and toes, the term *lupus pernio* has been used (Fig. 183-5).

FIGURE 183-4 Reddish-violaceous plaques, some of which are annular, affecting the posterior trunk.

FIGURE 183-5 Red-purple plaque of sarcoidosis on the nose and cheek, which is called lupus pernio.

Sometimes, sarcoid mimics cutaneous T cell lymphoma (CTCL) (see Chap. 157)—the plaques become tumor-like, simulating an early leonine facies, or they can be multiple, with superficially eroded surfaces and exhibiting the "pasted-on" appearance typical of CTCL patches and plaques.

Lupus pernio of the fingers and toes produces bulbous and sausage-shaped digits and is almost always associated with lytic lesions in the underlying phalanges (Fig. 183-6). This is also a feature of sarcoidosis in infants and toddlers under 4 to 6 years of age. When the tip of the nose is involved by lupus pernio, the nasal bones may show osteoporosis and lytic lesions. The nasal mucosa may also be affected, producing purulent catarrh and obstructive symptoms. Bone involvement is present in 10 to 20 percent of patients. Although the bones most frequently involved are those of the hands and feet, occasionally the long bones, vertebrae, ribs, skull and facial bones, show identical lytic lesions. However, radiographic examination of the hands and feet of patients with sarcoid is worthwhile only if they have lupus pernio or chronic skin lesions elsewhere. Bone involvement may also portend a poorer prognosis in adults. The mortality rate of such patients was 21 percent in James' series, four times greater than the overall rate. [15] However, bony lesions, which are also a characteristic feature of sarcoid in children younger than 4 to 6 years of age, do not appear to be associated with a poor prognosis.

FIGURE 183-6 Erythema and swelling of digits associated with underlying osseous lesion (lupus pernio). (*From Braverman,* [13] *with permission.*)

Nail deformities can arise when lupus pernio develops close to the posterior nail fold (see Fig. 183-6). Often, the underlying bone will have lytic lesions. The nail plate may become thickened with an irregular surface. Sometimes there is distal crumbling of the nail plate.

Sarcoidal lesions can also take the form of red, violaceous, yellowish-brown, or reddish-brown scaly macules or patches (Fig. 183-7). The scale varies from thin and scant to heavy and thick. These types of lesions tend to develop cutaneous atrophy. When the scalp is affected, alopecia frequently results, mimicking lupus erythematosus and pseudopelade. When the face is affected, the “discoid” lesions of cutaneous lupus erythematosus are simulated (Fig. 183-8). On the trunk and extremities the picture of psoriasis or CTCL can be simulated, and on the palms, the appearance of secondary syphilis is mimicked. Psoriasiform lesions are considered to be characteristic of sarcoid in American blacks.

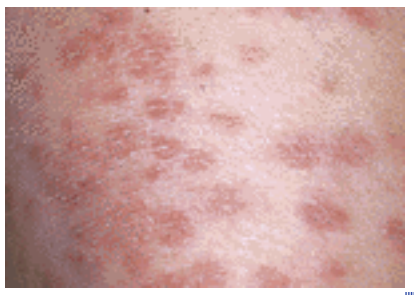

FIGURE 183-7 Violaceous minimally scaly macules characteristic of sarcoidosis.

FIGURE 183-8 A discoid lesion of sarcoidosis on the forehead and scalp with scaling, crusting, and atrophy simulating a discoid lesion of chronic cutaneous lupus erythematosus.

Well-demarcated, generalized, scaly, reddish-brown patches are rare manifestations that appear and remit intermittently over the course of years. In the acute phase, small superficial pustules arise within the patches. In the chronic phase, pustules are absent. The palms may be involved. When this reddish-brown scaling eruption covers extensive portions of the legs, buttocks, and trunk, the term “erythrodermic” sarcoidosis has been applied. In three persons, generalized skin involvement developed, simulating exfoliative dermatitis. Extensive involvement also may simulate poikiloderma vasculare atrophicans.

Ulceration may be a complication of lupus pernio on the nose and ears. Rarely, cutaneous plaques and deep cutaneous and subcutaneous nodules may ulcerate. Other uncommon manifestations include generalized perifollicular papules and pustules as the specific cutaneous markers of sarcoidosis. An ichthyosis-like picture has also been produced by the cutaneous granulomas. Only the ichthyotic areas show the histopathology of sarcoidosis.

Hypopigmentation is an uncommon manifestation. It may develop over papules and nodules or it may exist as patches that feel normal or slightly indurated. In the latter instance, papules and nodules usually arise later within or adjacent to the hypopigmented macules. Biopsies have shown sarcoid granulomas in the macules, papules, and nodules. All reported cases have been black patients. The hypopigmentation appears to be related to decreased melanization of the overlying epidermal cells. The melanocyte count is normal, and there is no evidence of postinflammatory hypopigmentation.

Occasionally, the oral mucosa and palpebral conjunctivae are involved with granulomas. Violaceous plaques can

develop on the hard palate and gingivae.

Nonspecific Lesions

Erythema nodosum (see Chap. 109) is a nonspecific sign of sarcoidosis that occurs most frequently in women 20 to 35 years old. Erythema nodosum with hilar adenopathy, arthralgia, fever, and chills is frequently the initial manifestation of sarcoidosis. When erythema nodosum occurs in sarcoid, the latter usually behaves as a benign self-limited disorder. As a general rule, progressive disease is associated with the presence of specific lesions, and not with erythema nodosum. However, exceptions do occur. The author has recorded five patients in whom sarcoidosis began with erythema nodosum and progressive sarcoidosis involving lung and liver developed a few months later. The prospective study of Veien et al. reported similar observations. [16] Several large series from different countries, compiled from 1960 to 1974, indicate that sarcoidosis is the cause of erythema nodosum in 37 percent of the cases (range, 11 to 74 percent). [17] The prevalence of erythema nodosum in sarcoidosis ranges from 4 to 35 percent (average, 17 percent). In the author's experience, sarcoid has accounted for 16 percent of the cases of erythema nodosum and erythema nodosum has occurred in 10 percent of patients with sarcoidosis.

Sarcoid in children 8 to 15 years of age is indistinguishable from that seen in adults. However, sarcoid in children younger than 4 to 6 years of age behaves differently. [14] Sarcoid can appear in infants as early as 4 months. These infants and toddlers have more joint involvement and rashes, less pulmonary disease, and eye problems only slightly more frequently than occurs in older children (see Table 183-1). The skin rashes have been described as eczematous and papular. Erythema nodosum may occur as multiple lesions and involve the soles, as well as more typical locations. The joints show a symmetric boggy synovitis without much pain or limitation of motion. Generally, the radiologic findings are negative. Although joint involvement usually does not lead to disability or contractures, sometimes they do occur. The fingers may be affected with a fusiform swelling, in which case one often finds lytic lesions and osteoporosis in the underlying bones, as in adults. In these children, multisystem involvement develops over periods of weeks to more than a year.

Eye involvement takes the form of phlyctenular keratoconjunctivitis, uveitis, miliary retinitis, and optic retinitis. Marked visual impairment has occurred in a few children.

Systemic Associations

In 20 to 40 percent of patients, sarcoidosis has an abrupt onset over weeks with fever, fatigue, weight loss, and anorexia. [18], [19] In 40 to 70 percent of patients, there may be an insidious development over months. The main organs affected are the lung (~90 percent), lymph nodes (~75 to 90 percent), and the eye (anterior and posterior uveitis, conjunctival nodules, lacrimal gland and duct involvement; ~25 percent). Less frequent associations are nasal mucosal involvement (~20 percent) and bone marrow lesions (~15 to 40 percent), usually without any functional consequences. Liver is often affected, but only in approximately 20 to 30 percent of patients are there any biochemical or functional sequelae, and renal involvement with hypercalcuria with or without hypercalcemia is uncommon. Hypercalcuria is caused by enhanced calcium absorption from the gut that is related to an abnormally high level of circulating 1,25-dihydroxyvitamin D produced by mononuclear phagocytes in the granulomas. The nervous system, musculoskeletal, heart, endocrine and reproductive systems, exocrine glands, and gastrointestinal tract are affected less often. Sarcoid also produces the Heerfordt-Waldenström syndrome, which is characterized by fever, parotid gland enlargement, anterior uveitis, and facial nerve palsy, and Mikulicz's syndrome in which the parotid, submandibular, sublingual, and lacrimal glands are affected.

LABORATORY FINDINGS

Common abnormalities often include lymphocytopenia, mild eosinophilia, increased erythrocyte sedimentation rate, hyperglobulinemia, and elevated serum levels of angiotensin-converting enzyme (ACE). Fifty to 60 percent of patients with active sarcoidosis have elevated serum levels of ACE, whose main source is the granulomas. [20] The serum level may reflect the magnitude of the body mass of granulomas. However, 10 percent of the elevated serum levels of ACE are false positives and serum levels do not reliably correlate with disease activity or progression. They are useful additional tests to support the diagnosis of sarcoidosis when other clinical features suggest that diagnosis.

The Kveim-Siltzbach test has been positive in 54 to 92 percent (average, 78 percent) of patients with sarcoid. [21] This skin test, in which an extract of splenic tissue from an affected patient is injected into the skin of a sarcoid suspect, is particularly useful when histologic confirmation of sarcoidosis is lacking or equivocal. It is also useful in the differential diagnosis of diffuse pulmonary mottling, uveitis, or erythema nodosum. The combination of the Kveim-Siltzbach test and determination of ACE levels should be especially helpful in such circumstances.

The chest x-ray in patients with sarcoidosis will almost always be abnormal with one of three patterns: bilateral hilar and mediastinal adenopathy with or without parenchymal involvement and diffuse parenchymal involvement without hilar adenopathy.

PATHOLOGY

The granulomatous reaction is composed of naked tubercles—collections of epithelioid cells with a thin rim of lymphocytes (Fig. 183-9). Giant cells are often present, necrosis is rare, and sometimes, the collar of lymphocytes is absent. The lungs, liver, lymph nodes, spleen, eyes, joints, muscles, exocrine glands, and nervous system are frequently affected by an identical granulomatous response.

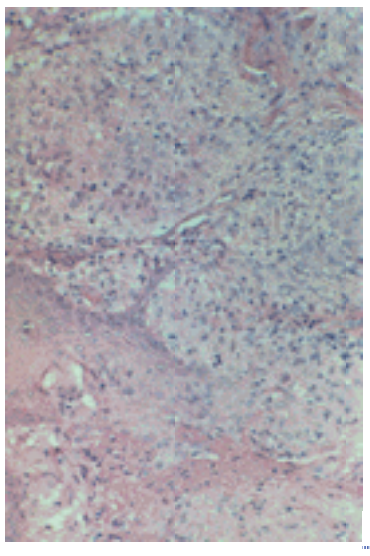

FIGURE 183-9 Histopathology of cutaneous sarcoidosis is characterized by naked tubercles, which are composed of epithelioid cells with a rim of lymphocytes, simulating tuberculosis. Although caseation necrosis is not observed, some foci of fibrinoid necrosis may be present in sarcoid infiltration, as shown here.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Diagnosis cannot be made without demonstrating the noncaseating epithelioid granulomas in the affected tissue (see Fig. 183-9). This finding then has to be correlated with the history, physical examination, and laboratory findings to establish the diagnosis of sarcoidosis. The granulomas by themselves are insufficient to establish a diagnosis. It is worthwhile to perform a biopsy of any lesion, no matter how trivial, in a patient suspected of having sarcoidosis. The author has seen two patients in whom granulomas typical of sarcoid developed at sites of an earlier folliculitis. Clinically, the lesions looked like small scars. A biopsy of these banal marks established the diagnosis of sarcoidosis in these two patients, both of whom also had radiographic findings characteristic of pulmonary sarcoidosis.

The differential diagnosis of the specific papules and nodules found in sarcoid includes cutaneous amyloidosis, lichen planus, flat warts, syringoma, trichoepithelioma, lupus erythematosus, lymphocytoma cutis, CTCL, and xanthoma. The plaques resemble those seen in lupus erythematosus, lymphoma, CTCL, and photosensitivity reactions. In addition, the deep nodules could be confused with those of malignant lymphoma. However, all of these entities can be distinguished easily from one another and from sarcoidosis by histologic examination.

Granulomatous inflammation is a characteristic response to a number of mycotic and bacterial agents and minerals. The histology of granulomas ranges from the pure epithelioid cell granuloma without inflammation or necrosis to tubercles composed of multiple cell types accompanied by necrosis. The discovery of naked tubercles is presumptive evidence of sarcoidosis, but the diagnosis cannot be made unequivocally, nor should it be made unless correlated with the clinical findings. Sometimes tuberculosis, histoplasmosis, brucellosis, syphilis, leprosy, atypical mycobacterial infection, and toxoplasmosis produce similar granulomas, but usually these diseases are associated with inflammatory granulomas exhibiting necrosis. All granulomas should be examined with polarizing lenses to detect foreign bodies and, after selective staining, to uncover microorganisms.

The differential diagnosis of cutaneous sarcoidosis also includes granulomas produced by zirconium, beryllium, silica, and other foreign bodies. In some persons, deodorants and topical poison ivy remedies containing zirconium can produce a sarcoidal eruption by delayed hypersensitivity. Systemic involvement is not known to be a feature in these cases. Cutaneous zirconium granulomas are clinically and histologically indistinguishable from those of sarcoidosis.

COURSE AND PROGNOSIS

Whether or not cutaneous sarcoidosis indicates a poor prognosis is controversial; the limited data available through 1981 had suggested that involvement of the skin had no influence on the course of the disease. Since then, a prospective study of 188 Danish patients by Veien et al. [16] clearly established that skin involvement had no effect on the course of the disease and that the number of specific cutaneous lesions bore no relation to the extent of visceral involvement. In this study, 50 patients had only skin lesions. The spectrum of these lesions was identical to that seen in 88 patients with severe pulmonary disease. Other series have reached the same conclusions. [22], [23]

When systemic disease was associated with skin lesions, there was a correlation between acute disease (<2 years' duration) and the type of skin lesion. [16] Erythema nodosum and papular lesions (<10 mm) were usually present. With chronic disease (>2 years' duration), plaques, annular configurations, scar involvement, and unusual lesions were present.

There are good data concerning the outcome of the various types of skin lesions in sarcoidosis. [16] Erythema nodosum always disappears without scarring. James [23] observed that the associated hilar adenopathy cleared within 1 year, although others reported that in their patients erythema nodosum and hilar adenopathy cleared less quickly and less often. [13] Veien et al. [16] followed 79 patients until their skin lesions had clinically healed. They used diascopy, rather than biopsy, to determine whether granuloma formation was still present. An unspecified number of these patients also were receiving some form of therapy for their sarcoidosis. Of 79 patients, the skin lesions in 15 were healed in less than 2 years; in 5, the skin lesions healed in 2 to 5 years; in 49, the skin lesions healed in 6 to 9 years; and in 10, the skin lesions healed after more than 10 years. These data support the concept that skin involvement in sarcoid eventually burns itself out, as do most cases of sarcoidosis, and that the role of treatment in this disease is suppression of activity until spontaneous remissions develop. The papules and nodules of sarcoidosis disappeared without or with minimal scarring, but the plaques—angiolupoid and lupus pernio—which were usually persistent, especially in patients older than

30 years of age, formed unsightly telangiectatic scars when they did heal.

THERAPY

The therapy of choice for sarcoidosis with significant systemic involvement is corticosteroids, 1 mg/kg per day, in divided doses. This regimen almost always clears the skin of cutaneous lesions. The steroids are tapered slowly, using the degree of systemic activity as a guide for tapering and eventual discontinuation of the drug. Often, however, the skin lesions will return when the steroids have been discontinued or lowered. When there is no significant visceral involvement to justify systemic steroids, the options for therapy of the skin lesions are limited. There are anecdotal reports of success with chloroquine and hydroxychloroquine in small numbers of cases, but controlled studies need to be performed. Topical and intralesional corticosteroids are sometimes of benefit. Methotrexate, in low doses of 7.5 to 15.0 mg once weekly, shows promise of being successful in eradicating or minimizing the cutaneous, ocular, and pulmonary lesions. [24] Minocycline [25] and thalidomide [26] are two other promising agents for cutaneous sarcoidosis, but controlled studies are required for them as well.

Cutaneous Manifestations of Internal Malignant Disease: Cutaneous Paraneoplastic Syndromes

COLOR CHANGES SECONDARY TO THE DEPOSITION OF SUBSTANCES IN THE SKIN
- Icterus
- Melanosis
- Hemochromatosis
- Xanthomas
- Systemic Amyloidosis

VASCULAR AND BLOOD ABNORMALITIES
- Flushing
- Palmar Erythema
- Telangiectasia
- Purpura
- Vasculitis
- Cutaneous Ischemia
- Thrombophlebitis

BULLOUS DISORDERS
- Bullous Pemphigoid
- Cicatricial Pemphigoid
- Pemphigus
- Dermatitis Herpetiformis
- Herpes Gestationis
- Erythema Multiforme
- Epidermolysis Bullosa Acquisita
- Linear IgA Dermatosis

INFECTIONS AND INFESTATIONS
- Herpes Zoster
- Herpes Simplex
- Other Infections and Infestations

DISORDERS OF KERATINIZATION
- Acanthosis Nigricans
- Acquired Ichthyosis
- Palmar Hyperkeratosis
- Tripe Palm
- Erythroderma
- Paraneoplastic Acrokeratosis of Bazex

COLLAGEN-VASCULAR DISEASE
- Dermatomyositis
- Lupus Erythematosus
- Scleroderma

SKIN TUMORS AND INTERNAL MALIGNANT DISEASE
- Muir-Torre Syndrome
- Gardner Syndrome
- Cowden's Disease
- Mucosal Neuroma Syndrome
- Neurofibromatosis

HORMONE-RELATED CONDITIONS

OTHER DISORDERS ASSOCIATED WITH PRIMARY SKIN CANCERS
- Basal Cell Nevus Syndrome
- Arsenical Manifestations

OTHER DISORDERS ASSOCIATED WITH INTERNAL MALIGNANT DISEASE
- Pruritus
- Erythema Gyratum Repens
- Subcutaneous Fat Necrosis
- Sweet Syndrome
- Hypertrichosis Lanuginosa Acquisita
- Necrolytic Migratory Erythema
- Clubbing
- Peutz-Jeghers Syndrome
- Tuberous Sclerosis
- Multiple Eruptive Seborrheic Keratoses
- Porphyria Cutanea Tarda

DIRECT TUMOR INVOLVEMENT IN THE SKIN
- Solid Tumors
- Lymphoma-Leukemia
- Paget's Disease

REFERENCES

Changes in the skin can be a marker for an internal malignant neoplasm. The specific relationship of the cancer with the marker can be variable. For instance, hypertrichosis lanuginosa acquisita can be a marker for many different malignant neoplasms, whereas necrolytic migratory erythema is quite specific for a glucagon-producing tumor of the pancreas.

An attempt has been made to group these manifestations in a useful manner (Table 184-1). Where possible, these groupings have been made by the major clinical manifestation. Unfortunately, our lack of knowledge does not allow us to classify these diseases by a pathophysiologic approach in all cases. Indeed, there is a very large group in which the biochemical relationship to the neoplasia is not understood.

I. Lesions secondary to the deposition of substances in the skin	VI. Collagen-vascular disease
A. Icterus	A. Dermatomyositis
B. Melanosis	B. Lupus erythematosus

E. Erythroderma	
F. Paraneoplastic acrokeratosis of Bazex	

TABLE 184-1 **Cutaneous Manifestations of Internal Malignant Disease**

There must be a proven association of the cutaneous eruption with a tumor. This is not difficult when the supposed manifestation is very rare and the tumor is also very uncommon. It becomes a major problem, however, when the manifestation is very common, such as the seborrheic keratoses in the sign of Leser-Trélat, and the presumed association is with a wide spectrum of commonly occurring neoplasms. In this situation, the literature becomes replete with anecdotal reports, which may or may not be an indication of whether there is a true association with the malignant neoplasm.

Some cutaneous manifestations of cancer are paraneoplastic syndromes, i.e., dermatoses (often unique), secondary to the cancer. There is an evolving consensus of what constitutes a true paraneoplastic syndrome. [1] There are two essential criteria: (1) the dermatosis must develop only after the development of the malignant tumor, and (2) both the dermatosis and the malignant tumor follow a parallel course, in that complete removal of the cancer results in clearing of the dermatosis and recurrence of the cancer causes relapse of the dermatosis (certainly relapse of the dermatosis cannot occur in the absence of the cancer).

COLOR CHANGES SECONDARY TO THE DEPOSITION OF SUBSTANCES IN THE SKIN

Icterus (See Chap. 164)

Icterus as a manifestation of internal malignancy is generally a late sign and usually is secondary to obstruction of the bile duct or gross intrahepatic obstruction. Extrahepatic obstruction can be secondary to malignant disease of the gallbladder, pancreas, bile duct, or adjacent bowel.

Melanosis (See Chap. 90 and Chap. 93)

Melanosis is a condition caused by the abnormal deposition of melanin pigments in tissue. It is manifested externally by a diffuse gray-brown pigmentation of the skin (Fig. 184-1), but the pigment can be deposited in most of the organs of the body. A mild darkening of the skin may be seen with adrenal insufficiency, with ACTH-producing tumors such as primary tumors of the pituitary gland, or with other malignant tumors metastatic to the pituitary gland. [2]

FIGURE 184-1 Slate-gray dermal pigmentation with metastatic melanoma and melanogenuria. *A*. Diffuse blue argyria-like hypermelanosis. This patient died 1 month after this photograph was taken, illustrating that this striking argyria-like blue pigmentation is a terminal complication. *B*. Dark urine from a patient with melanogenuria compared with normal urine.

Diffuse melanosis also can be secondary to malignant melanoma (see also Chap. 93). Usually occurring late in the disease course, melanosis can, however, be the presenting sign. The pigment of the skin has been attributed to the

presence of melanin granules in both the circulation and tissue macrophage [3] or to the presence of single-cell metastases from the primary melanoma. [4] Diffuse micrometastases also can appear in the nail matrix, leading to pigment streaks in the nail plate. Circulating tumor cells also have been found in some patients with melanosis. [4] Melanuria is frequently associated with melanosis of the skin. Urine from patients who have melanuria is usually not black when voided but gradually darkens to a deep brown and later a black color when exposed to the air for several hours as the intermediary metabolites of tyrosine are oxidized spontaneously to melanin. (Fig. 184-1). Highly increased amounts of 5-S-cysteinyldopa have been reported in the urine of such patients. [5]

Hemochromatosis (See Chap. 164)

Hemochromatosis is an iron-storage disorder resulting predominantly from increased iron absorption from the gut. Patients develop a diffuse gray-brown pigmentation of the skin. There is deposition of iron in the form of hemosiderin in many tissues. A third of untreated patients with hemochromatosis will develop hepatocellular carcinoma.

Xanthomas (See Chap. 150)

The predominant type of xanthoma associated with internal malignant disease is the plane xanthoma. The most common association of diffuse plane xanthoma is with multiple myeloma. Xanthomas, as well as atypical eruptive histiocytosis with lipid deposition, also have been associated with myelocytic leukemia, myelomonocytic leukemia, leukemic lymphocytic reticuloendotheliosis, diffuse histiocytic lymphoma, and cutaneous T cell lymphoma. [6], [7] Juvenile xanthogranuloma can be associated with juvenile chronic myeloid leukemia. [8]

Patients with xanthomas associated with cancer may be normolipidemic, [9] or they may, more commonly, have a hyperlipoproteinemia. Type 2A hyperlipoproteinemia has been described in association with IgG L type myeloma, as has type 4 or type 5 hyperlipoproteinemia. Type 3 (broad beta) and prebeta hyperlipoproteinemia have been described in association with IgA myeloma.

Purpura may be a feature of diffuse plane xanthomas associated with malignant disease. Pinch purpura has been noted in a normolipidemic patient with myeloma. Hemorrhagic bullae have been associated with xanthoma disseminatum and IgG K type multiple myeloma. [10]

Systemic Amyloidosis (See Chap. 148)

Systemic amyloidosis of both the primary type and that associated with multiple myeloma commonly have skin lesions. It is important to differentiate skin lesions of systemic amyloidosis from the far more commonly seen purely cutaneous variants of amyloidosis. All patients with skin lesions of systemic amyloidosis should be investigated thoroughly for multiple myeloma.

Familial cutaneous lichenoid amyloidosis has been reported in a large kindred in association with multiple endocrine neoplasia (MEN) type 2A. [11]

VASCULAR AND BLOOD ABNORMALITIES

Flushing (See Chap. 170)

Acquired pronounced flushing, usually of the central face and upper trunk, often with wheezing and abdominal pain, may be a manifestation of carcinoid syndrome, caused by carcinoid tumors. [12] Palpitations, syncope, and hypotension are features of benign idiopathic flushing. [13] Diarrnea can occur in both.

Vasoactive substances also can be released in patients with extensive localized or systemic mastocytosis (see Chap. 163) and in patients with pheochromocytoma. Unilateral flushing and sweating (harlequin syndrome) have been associated with a contralateral lung cancer invading the spine in a patient with Pancoast's syndrome and with Horner's syndrome. [14]

Palmar Erythema (See Chap. 164)

Palmar erythema can be associated with advanced liver failure. Such liver failure may be secondary to either a primary or a metastatic tumor in the liver.

Telangiectasia

Localized, grouped telangiectatic vessels on the anterior chest wall may be a marker for breast cancer. There is often a clinically palpable, indurated, warm, subcutaneous plaque immediately beneath the telangiectatic area. Telangiectatic vessels also may be the first evidence of skin metastases of many cancers.

Generalized telangiectasia can be a presenting factor of malignant angioendotheliomatosis (see Chap. 157), and progressive telangiectases have been associated with carcinoid tumors (see Chap. 170).

Telangiectasia also may be a manifestation of a genodermatosis, such as ataxia-telangiectasia (see Chap. 191), Bloom's disease, and xeroderma pigmentosum and its variant, De Sanctis-Cacchione syndrome (see Chap. 155), which in turn can be associated with systemic malignant disease.

Telangiectasia also can be a marker for the collagen-vascular group of diseases, including progressive systemic sclerosis, which can be associated with an increased cancer risk (see Chap. 172 and Chap. 173).

Purpura

Lymphoma is the most common cause of idiopathic thrombocytopenic purpura (ITP) associated with malignant disease. Purpura related to cancer can occur from a wide variety of mechanisms: thrombocytopenia, consumption coagulopathy, hyper- or dysglobulinemia, vascular fragility, and vasculitis.

Disseminated intravascular coagulation (DIC) as a cause of purpura in malignant disease is associated most commonly with acute leukemia. Purpura also can be associated with the hyperglobulinemia seen in multiple myeloma or lymphoma. When purpura is secondary to the presence of cryoglobulins, lesions often are found in acral areas and may be associated with Raynaud's phenomenon.

It is important not to forget that vasculitis or a bacterial septicemia can present as a palpable purpuric eruption in patients with cancer.

Vasculitis (See Chap. 175)

Leukocytoclastic vasculitis, such as can be seen in Henoch-Schönlein purpura, very rarely can be associated with malignant neoplasms, such as squamous cell carcinoma of the bronchus, renal carcinoma, and leukemia and lymphoma. A periarteritis nodosa–like syndrome also has been reported in association with leukemia and multiple myeloma.

Cutaneous Ischemia

Peripheral ischemia has been associated with many malignant neoplasms, including carcinoma of the pancreas, stomach, small bowel, ovary, and kidney, as well as lymphoma and leukemia. [15] It is frequently manifested by evidence of digital ischemia, either as Raynaud's phenomenon or frank gangrene. There may be associated splinter hemorrhages of the nail bed, suggestive of an underlying vasculitic process. The etiology, though, is rarely apparent.

The peripheral cutaneous ischemia of polycythemia rubra vera appears to be secondary to the increased viscosity of the peripheral circulation associated with this disease. [16] Similarly, some patients with leukemia can develop leukostasis secondary to very high white blood cell concentrations.

The ischemia seen in cryoglobulinemia associated with multiple myeloma or with lymphoma appears also to be secondary to increased blood viscosity.

Thrombophlebitis (See Chap. 167)

Isolated vein thrombophlebitis is uncommonly associated with internal malignant disease. Multiple-lesion “migratory” superficial thrombophlebitis is seen much more often in association with cancer, and when this syndrome is present, the patient should be examined carefully for occult malignant disease. The association of peripheral thrombophlebitis (phlebothrombosis) with gastric carcinoma was noted by Trousseau in the nineteenth century. Migratory superficial thrombophlebitis as a marker for cancer has been confirmed, and the association has been extended to include tumors of the pancreas, prostate, lung, liver, bowel, gallbladder, and ovary, as well as lymphoma and leukemia. The migratory nature of the thrombophlebitis probably relates to a generalized hypercoagulable state.

Mondor's disease is thrombophlebitis of the anterior chest wall presenting as a tender or nontender cord. While usually benign and secondary to local trauma, it may be associated with primary or recurrent breast cancer.

Patients with deep venous thrombosis who are younger than 50 years of age appear to have a very significant risk of occult cancer (relative risk 19.0) [17] and thus should have an appropriately thorough examination and laboratory investigation. Those at greatest risk for cancer had a low hemoglobin and an eosinophilia.

BULLOUS DISORDERS

Bullous Pemphigoid (See Chap. 61)

There is probably no significantly increased risk of a malignant tumor in patients with bullous pemphigoid, other than that associated with the age of the patient. [18] However, a Japanese cohort of patients with bullous pemphigoid had a 5.8 percent prevalence of neoplasia versus 0.61 percent of controls. [19] Also, there have been anecdotal reports showing that some patients with bullous pemphigoid clear when the concomitant tumor is treated, indicating a possible causal relationship in some patients.

Cicatricial Pemphigoid (See Chap. 62)

Antiepiligrin cicatricial pemphigoid would appear to have an increased risk of solid tumors, estimated as a relative risk of 6.8 (3.3–12.5). [20]

Pemphigus (See Chap. 59 and Chap. 60)

Pemphigus vulgaris can be associated with Hodgkin's disease, in which case the two diseases can run a parallel course.

[21] The relationship of solid tumors to pemphigus vulgaris is less well defined, although in one series 5 percent of pemphigus vulgaris patients had cancer, a higher rate than in controls. [19] Pemphigus vulgaris has been reported in association with many solid tumors, but other than for lung cancer, [19] these associations have been in small series or isolated case reports. There is a well-defined association of pemphigus vulgaris with thymoma, with or without clinical myasthenia gravis. [22], [23] and [24])

Paraneoplastic pemphigus [25] is clinically, histopathologically, and immunopathologically a distinct form of pemphigus with features of erythema multiforme, pemphigus-like blisters, and intractable stomatitis [26] (see Chap. 60). Described in association with lymphoma, chronic lymphocytic leukemia, Castleman's disease, thymoma, sarcoma, and Waldenstrom's macroglobulinemia, it has a very poor prognosis.

Dermatitis Herpetiformis (See Chap. 67)

Dermatitis herpetiformis is occasionally associated with intestinal lymphoma. The relative risk of non-Hodgkin's lymphoma associated with dermatitis herpetiformis is 5.4 (2.2 to 11.1) in males, less in females. [27] The lymphoma, when it occurs, is usually a diffuse histiocytic lymphoma. [28] There is no indication that there are a greater than expected number of patients with dermatitis herpetiformis developing tumors other than intestinal lymphoma. [29]

Herpes Gestationis (See Chap. 64)

Herpes gestationis has been described in association with a hydatidiform mole [30] and germ cell tumor. [31]

Erythema Multiforme (See Chap. 58)

Erythema multiforme does not appear to be a specific marker for any internal neoplasm. It appears to occur more frequently in patients with acute leukemia, but whether this relates to the leukemia or to its treatment has not been well defined. It also can occur in cancer patients secondary to drug or radiation therapy, and it has been suggested to be particularly common in patients on phenytoin and receiving radiation therapy for intracranial tumors. [32]

Epidermolysis Bullosa Acquisita (See Chap. 66)

Epidermolysis bullosa acquisita is a very rare disorder that has been described rarely in association with carcinoma of the bronchus and with amyloidosis and multiple myeloma. [33] Most cases of epidermolysis bullosa acquisita are not associated with cancer.

Linear IgA Dermatosis (See Chap. 63)

Linear IgA dermatosis has been reported in association with lymphoma, chronic lymphocytic leukemia, myeloma, carcinoma of the bladder and esophagus, and hydatidiform mole. [34], [35]

INFECTIONS AND INFESTATIONS

Herpes Zoster (See Chap. 215)

Only a small percentage of patients with localized herpes zoster have concurrent malignant disease, and investigation for malignant disease in otherwise healthy patients is not indicated. Patients with leukemia or lymphoma do have an increased risk of herpes zoster, but the herpes zoster usually occurs late in the course of their disease. The incidence of herpes zoster in patients with lymphoma is approximately 10 percent, possibly even higher in patients with Hodgkin's disease. [36]

Localized herpes zoster also can occur in association with solid tumors such as breast cancer. In the case of breast cancer, the dermatomal distribution of the herpes zoster may indicate involvement of the nerve root area with metastatic tumor. The site of the primary tumor correlates with the site of herpes zoster in patients with breast cancer, cancer of the respiratory tract, and gynecologic cancer. Segmental herpes zoster also can occur after radiation therapy, presumably secondary to nerve damage with subsequent viral activation.

Disseminated herpes zoster is commonly associated with underlying malignant disease. Any patient with disseminated herpes zoster that is otherwise unexplained should be examined carefully for evidence of cancer. The most commonly associated malignant diseases are lymphoma and leukemia. [37]

The development of herpes zoster in a previously treated lymphoma patient can be evidence of the recurrence of a lymphoma. This sign is of particular value in patients who develop the herpes zoster more than 6 months after clinical remission. [36]

Herpes Simplex (See Chap. 214)

Typical localized herpes simplex is rarely a marker for cancer. Extensive, often chronic, local herpes simplex with massive ulceration and destruction of tissue (Fig. 184-2), generalized cutaneous herpes simplex, and disseminated systemic herpes simplex are indeed associated with malignant disease, which is often far advanced. Lymphoma and leukemia are most often the associated cancers, but any advanced malignant tumor can produce the compromised host immune response associated with these conditions.

FIGURE 184-2 Woman with advanced non-Hodgkin's lymphoma and chronic ulcerative herpes simplex involving lips, cheek, and nose.

Other Infections and Infestations

Other infections of the skin as a marker for the presence of internal malignancy are very uncommon, and when they are associated with malignancy, they are usually associated with very advanced disease. Bacterial, fungal, yeast, and severe scabetic conditions are most common in profoundly immune-compromised patients.

DISORDERS OF KERATINIZATION

Acanthosis Nigricans (See Chap. 185)

Malignant acanthosis nigricans is usually of sudden onset and is rapidly progressive, but it is otherwise clinically indistinguishable from benign acanthosis nigricans. Diffuse keratoderma involving the palms, soles, and flexor surfaces of the fingers and toes may be more common in malignant acanthosis nigricans than in the benign form.

Malignant acanthosis nigricans is usually secondary to an adenocarcinoma. The adenocarcinoma is usually intraabdominal (70 to 90 percent) and gastric (55 to 61 percent). [38]

Acquired Ichthyosis (See Chap. 51)

The sudden onset of ichthyosis in an adult may indicate an occult malignant tumor, most often lymphoma. The ichthyosis is a true hyperkeratosis and can be differentiated clinically and histologically from simple dry skin (xerosis). Erythema is often present in the ichthyotic fissures. Although the ichthyosis usually occurs as a late manifestation of a lymphoma, it may precede the diagnosis by several years.

Palmar Hyperkeratosis

There are two groups of patients with palmar hyperkeratosis and associated malignant tumors: those patients with diffuse palmar hyperkeratosis and those with punctate palmar hyperkeratosis. In 1958, diffuse hyperkeratosis, or tylosis, was reported by Howel-Evans [39] to be associated in two families with an almost certain development of esophageal carcinoma by age 65. The tylosis in these patients can be separated clinically from the benign form of tylosis, which occurs at an earlier age (early childhood), has sharply delimited edges, and is of uniform thickness. In addition to the Howel-Evans families, there would appear to be a greater than expected incidence of esophageal carcinoma in other families with a pedigree of tylosis. [40]

A large kindred has been described with palmoplantar keratoderma in association with breast or ovarian carcinoma or both. [41] The clinical lesions cover the entire surface of the palms and soles and show a yellowish uniform hyperkeratosis surrounded by a red border. Histologically, the lesions show features of epidermolytic hyperkeratosis. (see Chap. 52).

The second type of palmar hyperkeratosis that may be associated with neoplasia consists of discreet hyperkeratotic papules on the palms. These patients have been reported to have a greater than expected risk of cancer of the breast and uterus, among other tumors. [42] While some kindreds have been described, arsenic, known to be associated with punctate palmar hyperkeratosis and an increased risk of cancer, may be responsible for other cases. However, other authors question the existence of the relationship of punctate palmar hyperkeratosis and internal cancer. It appears that the association, if present, is not very strong.

Palmar hyperkeratosis is also seen in paraneoplastic acrokeratosis of Bazex (see below).

Tripe Palm

Tripe palm is a rugose thickening of the palms that is strongly associated with internal cancer. [43] The honeycombed and corrugated thickening of the palms may be associated with periungual tenderness. Normal dermatoglyphic ridges are accentuated. The most common cancers associated with tripe palms are carcinomas of the stomach and lung. [44] There may be an associated acanthosis nigricans (see Chap. 185).

Erythroderma

Erythroderma, a diffuse erythema of the skin surface usually associated with induration and scaling, is not uncommonly associated with malignancy, most commonly hematologic, in particular leukemia and lymphoma, especially cutaneous T cell lymphoma, where there is direct infiltration of the skin by the malignant cells (see Chap. 44 and Chap. 157). Among solid tumors, erythroderma has been associated with carcinoma of the lung, liver, prostate, thyroid, colon, pancreas, and

stomach. The erythroderma associated with solid tumors usually occurs at a relatively late stage of the disease, is of unknown etiology, and may resolve after resection of the tumor.

Paraneoplastic Acrokeratosis of Bazex

Paraneoplastic acrokeratosis of Bazex is a symmetric dermatosis that most commonly affects the hands, feet, ears, and nose with an erythematous psoriasiform eruption. The eruption is of a bluer hue than in psoriasis. [45] Later changes involve the malar skin, elbows, and knees, with still later changes often involving the central trunk, where bullae may be seen. Acanthosis nigricans may be an associated finding. In acrokeratosis of Bazex, the nails are involved early and severely. There is subungual hyperkeratosis, as well as a flaky white surface to the nail. The nails may be shed. The distal digits show an erythematous scaling eruption, often fissured and often with suppuration. [46] Biopsy of the skin lesions of one patient showed diffuse deposition of IgA, IgM, and IgG along the basement membrane. [47] Nails appeared to have an abnormal amino acid composition. [48]

Bazex syndrome is almost always associated with cancer and is seen overwhelmingly in males. [49] It is usually associated with neoplasia of the upper respiratory system, which includes the pharynx, esophagus, tongue, and lungs, although rarely other solid tumors have been reported in association. Lung tumors have included carcinoid. The eruption predates evidence of the cancer in 67 percent of patients, [49] with the cancer often not being diagnosed until the later stages of the syndrome. Bazex syndrome has been reported to respond to etretinate, even though the primary lesion was left untreated. This syndrome should not be confused with follicular atrophoderma associated with basal cell carcinoma, hypotrichosis, and localized or generalized hypohidrosis, also described by Bazex. [50]

COLLAGEN-VASCULAR DISEASE

Dermatomyositis (See Chap. 172)

Dermatomyositis can be a marker for internal neoplasia, and the development of the dermatomyositis can predate the diagnosis of the cancer. The most common cancers are ovarian, lung, pancreatic, stomach, colorectal, and lymphoma. [51] While dermatomyositis in an adult is strongly associated with concurrent cancer, polymyositis alone is much less strongly associated. [51], [52] The cancers are usually identifiable by history and physical examination. It would appear that adults with dermatomyositis should be examined thoroughly for evidence of an associated malignant tumor. In children, dermatomyositis is not statistically linked to malignancy.

The clinical manifestations of dermatomyositis appear to be the same with and without a malignant tumor, although Basset-Sequin et al. [53] noted that cutaneous necrosis and an elevated erythrocyte sedimentation rate appeared to be markers for those with cancer and a reduced survival.

Lupus Erythematosus (See Chap. 171)

Systemic lupus erythematosus (SLE) is only rarely associated with malignant neoplasia, most often with lymphoma or thymoma.

Scleroderma (See Chap. 173)

Systemic scleroderma is not commonly associated with internal malignancy. In 727 cases of systemic scleroderma, only 2.6 percent had an internal malignant lesion. [54] The only tumor that has been found to be consistently associated with scleroderma is carcinoma of the lung. [55] Almost all patients with associated lung tumors have very advanced systemic scleroderma. The association is most likely one of a lung tumor developing secondary to the chronic pulmonary fibrosis.

SKIN TUMORS AND INTERNAL MALIGNANT DISEASE

Muir-Torre Syndrome

First described by Muir and colleagues in 1967 and by Torre in 1968, the essential features of the Muir-Torre syndrome are sebaceous tumors of the skin (Fig. 184-3), with or without keratoacanthomas, in association with often more than one visceral neoplasm. [56], [57] The sebaceous tumors are usually on the face or trunk and are frequently multiple, and whereas most are sebaceous adenomas, they can include sebaceous hyperplasia, sebaceous epithelioma, and sebaceous carcinoma. Often the same patient will have the complete histologic spectrum of sebaceous tumors. Some skin lesions have histologic features of both keratoacanthoma and sebaceous proliferation. [58]

FIGURE 184-3 Muir-Torre syndrome showing typical sebaceous adenomas in association with colonic polyposis and carcinoma in situ. (*Courtesy of T. Christensen, MD, and R. Wilkinson, MD.*)

The visceral neoplasms are often multiple and include a wide variety of tissues. Colon cancers are particularly common and may be associated with colonic polyposis. [56], [57], [58], [59] and [60]) Other neoplasms include additional tumors of the gastrointestinal tract and tumors of the larynx, endometrium, and rarely, lymphoma. Patients with Muir-Torre syndrome appear to have a reasonably good survival, despite the profusion of neoplasms. It has been suggested that a solitary benign sebaceous gland tumor of the eyelid is a good marker for the Muir-Torre syndrome and that its presence warrants review for systemic cancer.

The Muir-Torre syndrome is inherited as an autosomal dominant trait. There is an association of the Muir-Torre syndrome with cancer family syndrome, [61] and markers have been identified in chromosome 2P, a site linked to Lynch II cancer family syndrome. [62]

Long-term treatment with isotretinoin appears to be useful in some patients, [63] and immunosuppression apparently exacerbates the cutaneous manifestations. [64]

Gardner Syndrome

The essential features of Gardner syndrome are intestinal polyposis (usually colonic), with a high rate of malignant transformation; epidermoid cysts, particularly of the face, scalp, and trunk; osteomatosis of the maxilla, mandible, and cranial bones; and fibromas, desmoids, and other fibrous tumors of the skin and subcutaneous tissue. [65] Histologically, the epidermoid cysts may show areas of pilomatrixoma or a hybrid cyst with epidermal keratinization and inner root sheath keratinization. The desmoids often occur in wounds and can be deeply invasive, requiring chemotherapy or radical surgery. At times, erroneously called sebaceous cysts, the epithelioid cysts of Gardner syndrome often precede the development of bowel cancer.

There is a virtual certainty of malignant transformation of the gastrointestinal tract polyps. Some of the polyps are almost always visible by proctoscope examination, but they can be found up to the stomach. [66] There is an association of hepatoblastoma, a rare neoplasm of infants and children, with Gardner syndrome, and there may be some overlap of the features of Gardner syndrome and nevoid basal cell carcinoma syndrome. Gardner syndrome is inherited as an autosomal dominant condition.

Cowden's Disease

Cowden's disease, or multiple hamartoma syndrome, was first described in 1963 by Lloyd and Dennis and was named after the propositus. [67] Inherited as an autosomal dominant trait, the distinctive cutaneous lesions are multiple tricholemmomas (Fig. 184-4A). These lesions are grouped around the mouth, nose, and ears and clinically resemble warts. Some patients also show closely set papules with a cobblestone pattern that have a fibromatous histology and also occur on the oral mucosa (see Fig. 184-4B). Small keratotic lesions resembling plane warts occur on the acral skin. Patients may have an adenoid facies and high arched palate. Other cutaneous lesions can include lipomas, hemangiomas, neuromas, vitiligo, café-au-lait lesions, and acromelanosis. Angioid streaks may be present in the retina.

FIGURE 184-4 *A.* Cowden disease with papular lesions on the forehead that histologically proved to be tricholemmomas. *B*. Oral mucosa of same patient with multiple fibropapillomas. (*Courtesy of Peter Fritsch, MD.*)

Patients with Cowden's disease have a greatly increased risk of breast and thyroid carcinoma and thyroid adenoma. The breast changes seen in women range from fibrocystic disease to adenocarcinoma and can occur at a young age. Prophylactic mastectomy may be indicated. Gastrointestinal tract polyposis is common. [69] There also may be an increased risk of gastrointestinal malignancy. Female reproductive tract hamartomas and benign tumors are common. Squamous carcinoma of the tongue and basal cell carcinoma of the perianal skin have been reported.

Mucosal Neuroma Syndrome

Mucosal neuroma syndrome is probably a variant of multiple endocrine neoplasia type 2 (MEN 2 or 2A, Sipple's syndrome). Also designated MEN 3 or MEN 2B, the typical features include oral, nasal, upper gastrointestinal tract, and conjunctival neuromas associated with medullary thyroid carcinoma (MTC) and pheochromocytoma. The neuromas are typically soft to firm intradermal nodules. Corneal nerves may be highly visible. [70] The appearance of the neuromas usually precedes the development of cancer, but MTC can appear in early childhood. The major cause of death in patients with MEN 3 is MTC, since metastases are common. The pheochromocytomas are often bilateral. Unlike MEN 2, parathyroid hyperplasia is rare.

In addition to the mucosal neuromas, other abnormalities can include “blubbery” lips, a marfanoid habitus, lax joints, kyphoscoliosis, lentigines, cafe-au-lait lesions, medullated corneal nerve fibers, diverticulosis, and megacolon. [71] Localized intense itching may be a feature in some patients.

Neurofibromatosis (See Chap. 190)

Von Recklinghausen neurofibromatosis has many associated malignant tumors. Malignant schwannoma is the most common, occurring in one series in 29 percent of patients. [72] These patients were usually over the age of 30. Other tumors include fibrosarcoma, rhabdomyosarcoma, nephroblastoma (Wilms' tumor), and acute and chronic myelogenous leukemia. There is an increased incidence of ocular melanoma, with anecdotal reports of cutaneous melanoma. Benign neural tumors, peripheral and intracranial, are common.

HORMONE-RELATED CONDITIONS (See Chap. 169)

Malignant tumors may release hormones into the circulation, and such hormones can produce skin manifestations. The manifestation of such hormone excess is not specific to the tumor and can occur secondarily from an excess of that hormone from any cause.

Hirsutism may be a manifestation of an increase in circulating androgens. When cancer-related, such androgen excess is seen most typically with testicular or ovarian tumors. Hypertrichosis lanuginosa acquisita, from nonandrogen causes, can occur secondary to internal malignant disease (see below).

Gynecomastia in the male can be produced by an excess of estrogens. Such estrogens may be produced by a tumor of the testis. Lung tumors also can produce gynecomastia.

Cushing syndrome is generally secondary to excessive ACTH production. Tumors from widely diverse sites can produce excessive ACTH, most commonly lung and pancreas.

OTHER DISORDERS ASSOCIATED WITH PRIMARY SKIN CANCERS

Basal Cell Nevus Syndrome (See Chap. 82)

Basal cell nevus syndrome, or Gorlin-Goltz syndrome, is a syndrome consisting of multiple basal cell carcinomas, jaw cysts, skin pitting, skeletal abnormalities, and a tendency to malignant disease. The most common malignant tumor is medulloblastoma. These tumors can occur in patients without any cutaneous basal cell carcinomas but with a family history of basal cell nevus syndrome. Other tumors include astrocytomas, meningiomas, and craniopharygiomas. Basal cell nevus syndrome is the result of a defective patched gene. [73]

Arsenical Manifestations

Chronic arsenic toxicity can be manifested by arsenical melanosis, plantar and palmar keratoses (Fig. 184-5), and Bowen disease. There also would appear to be an increased risk of internal neoplasia. Malignancies have included tumors of the urogenital region, mouth, esophagus, and lung. The increased cancer risk was estimated originally to be nine times the expected incidence, with approximately one-third of patients with Bowen disease developing an internal malignancy 6 to 10 years after their initial diagnosis. [74] There is now evidence that the risk may be very much lower in patients where Bowen disease alone was the marker of risk. [75] Arsenical keratoses on the palms (see Fig. 184-5) and soles, a more specific finding, do correlate with an apparent increase in internal malignancy.

FIGURE 184-5 Punctate palmar keratoderma in a patient with previous arsenic exposure.

OTHER DISORDERS ASSOCIATED WITH INTERNAL MALIGNANT DISEASE

Pruritus

Pruritus, often accompanied by excoriations, can be a nonspecific marker of internal malignant disease. Although often associated with xerosis, the pruritus of malignant disease can occur in apparently normal skin. It can be continuous or paroxysmal. It is usually generalized.

When it occurs with malignant diseases, pruritus is most commonly associated with lymphoma and leukemia. [76] The pruritus of Hodgkin's disease often will start on the legs, is usually continuous, and may be associated with a burning feeling. Pruritus is one of the most common cutaneous manifestations of leukemia, probably exceeded only by purpura. Although the pruritus of both leukemia and lymphoma can precede the diagnosis, it is usually a sign of late disease. Its severity tends to parallel the course of the disease, with severe pruritus heralding a poor prognosis.

Pruritus associated with bathing is a marker for polycythemia rubra vera and is present in one-half of patients. [77] This itch can be severe and paroxysmal. Patients with polycythemia rubra vera also can have chronic continuous pruritus unrelated to bathing.

Severe pruritus can be a feature of Fanconi's anemia and myeloma. Pruritus associated with solid neoplasms is most commonly associated with pancreatic and stomach tumors [78] but also may be associated with most other solid tumors. Renal and liver involvement with primary or metastatic cancer also can produce pruritus secondary to the accumulation in the skin of pruritogenic metabolites.

Erythema Gyratum Repens

Erythema gyratum repens is a cutaneous eruption consisting of concentric raised erythematous bands moving in waves over the body surface in a “wood grain” pattern. [79] The erythematous bands may be flat or raised. They are frequently surmounted by a fine marginal desquamation and may move at a speed of approximately 1 cm/day. Almost all cases of erythema gyratum repens, which is extremely rare, are associated with internal malignancy. Although first described with carcinoma of the breast, [74] erythema gyratum repens also has been found in association with tumors of the lung, [80] bladder, prostate, cervix, stomach, and esophagus and with multiple myeloma. Removal of the malignant tumor usually results in complete resolution of erythema gyratum repens within 6 weeks.

Subcutaneous Fat Necrosis (See Chap. 109)

Subcutaneous fat necrosis, sometimes associated with fever, eosinophilia, and arthralgia, is a cutaneous marker for acinar cell carcinoma of the pancreas. Identical lesions also can occur with pancreatitis [81] and pancreatic pseudocyst.

Sweet Syndrome (See Chap. 94)

Clinical lesions range from generalized crimson, aggminate papules, to large red to purple-red plaques, to lesions that are truly bullous in nature, and to lesions that are indistinguishable from pyoderma gangrenosum (Fig. 184-6.) There is often fever, and there may be blood neutrophilia. The skin lesions usually erupt suddenly. Malignancy-associated Sweet syndrome is seen most commonly with acute myelocytic leukemia but also may be associated with other leukemias, myelodysplastic syndrome, multiple myeloma, and lymphoma [82], [83] (see Table 94-3). Much less commonly it is seen with solid tumors such as embryonal carcinoma of the testes, ovarian carcinoma, gastric carcinoma, and adenocarcinoma of the breast, prostate, and rectum. [84]

FIGURE 184-6 Skin lesions of malignancy-associated Sweet syndrome present either (*A*) as classic “Sweet” lesions with pseudovesiculation (see Chap. 94) or (*B*) as truly bullous lesions or (*C*) as lesions resembling early pyoderma gangrenosum.

Hypertrichosis Lanuginosa Acquisita

Hypertrichosis lanuginosa acquisita (HLA) is an acquired excessive growth of lanugo (vellus) hairs. Soft downy hairs initially cover the face and ears, but eventually all hair-bearing skin may be involved (Fig. 184-7). Associated abnormalities include a glossitis that is often painful. The tongue is studded with red papules. [85] Fully expressed HLA is usually secondary to malignant tumors, but excessive lanugo hair growth also can be caused by drugs such as exogenous steroids, phenytoin, diazoxide, streptomycin, penicillamine, cyclosporine, and minoxidil or by conditions such as anorexia nervosa.

FIGURE 184-7 Hypertrichosis lanuginosa acquisita in a 19-year-old woman with pancreatic carcinoma.

HLA secondary to malignancy is usually abrupt in its onset and is rapidly progressive. Associated tumors reported include tumors of the colon (including carcinoid tumors), rectum, bladder, lung, pancreas, gallbladder, uterus, and breast and lymphoma. [85], [86]

Necrolytic Migratory Erythema

Necrolytic migratory erythema, also called glucagonoma syndrome, is a marker for an a $_2$-glucagon–producing islet cell tumor of the pancreas. [87] It is manifested by erythema, vesicles, pustules, bullae, and erosions, which typically involve the face, the intertriginous areas (in particular the groin), and the perigenital region (Fig. 184-8). Less commonly, it also involves the shins, ankles, feet and fingertips. The vesicles are often very superficial and tend to become confluent. Patients also can have brownish red papules scattered over much of the skin surface. Associated abnormalities include a glossitis, stomatitis, dystrophic nails, alopecia, weight loss, anemia, and diabetes. Resection of the tumor clears the eruption, sometimes within 48 h.

FIGURE 184-8 The glucagonoma syndrome, necrolytic migratory erythema. Flaccid and papulovesicular lesions (*A*) with erosions, crusting, and fissures around the orifices and (*B*) appearing as geographic, circinate “necrolytic migratory

erythema” in the groin.

The dermatosis also has occurred in patients, who have hepatitic cirrhosis and hyperglucagonemia, pancreatitis, celiac sprue, or zinc deficiency [88], [89] but no malignancy.

Clubbing

Clubbing describes soft tissue enlargement of the tips of the fingers and toes. More typically associated with chronic lung disease, it also can be associated with neoplasms of the chest, usually bronchogenic carcinoma. Five to ten percent of patients with bronchogenic carcinoma develop clubbing. [90] Mesothelioma also can produce similar changes. Clubbing also can be produced by other solid tumors metastatic to the thorax, and it has been reported in Hodgkin's disease of the lung. Clubbing also can be seen with diffuse intestinal lymphoma. Some patients with clubbing secondary to pulmonary disease can develop thickening and yellowing of the nails, the yellow nail syndrome (see Chap. 72).

Clubbing accompanied by subperiosteal new bone formation is called *hypertrophic osteoarthropathy,* and accompanied by acromegalic features, it is called *pachydermoperiostosis*. Patients with these latter two conditions can have diffusely painful bones. Pachydermoperiostosis is usually idiopathic but can be secondary to lung cancer.

Peutz-Jeghers Syndrome (See Chap. 90 and Chap. 164)

Hutchinson in 1900 first described the association of cutaneous and mucosal hyperpigmentation with gastrointestinal tract polyposis and carcinoma. [91] The pigmentary changes involve both the skin and mucous membrane. The cutaneous hyperpigmented macules are usually present at birth or in early infancy and frequently fade at puberty. They are typically grouped around the mouth, eyes, and nostrils, with macules less commonly located on the fingers, palms, toes, periumbilical skin, or diffusely over the skin surface. Muscosal pigmented lesions are similar but persist for life. Buccal mucosal pigmented papillomas also have been described.

The most common malignancy associated with the Peutz-Jeghers syndrome is duodenal carcinoma. These malignant tumors are frequently associated with hamartomatous polyps. A patient with Peutz-Jeghers syndrome carries an overall lifetime relative risk for developing an upper gastrointestinal tract malignancy of up to 18. [91] Granulosa theca cell tumors may be present in as many as 20 percent of females with the Peutz-Jeghers syndrome and may be associated with precocious puberty. Peutz-Jeghers syndrome is inherited as an autosomal dominant condition.

Tuberous Sclerosis (See Chap. 189)

Tuberous sclerosis can be associated with tumors within many organ systems. Most of these are hamartomatous, and some can become malignant. However, malignant transformation in tuberous sclerosis is uncommon, occurring in probably no more than 5 percent of patients.

Multiple Eruptive Seborrheic Keratoses

Multiple eruptive seborrheic keratoses (MESKs), also known as the *sign of Leser-Trélat*, have been mentioned in association with multiple internal malignancies. [92] MESKs also have been described in association with hyperkeratosis of the palms and soles associated with malignant disease and with acanthosis nigricans.

Although anecctotal reports abound, evidence to support the presumed relationship of seborrheic keratoses to malignant disease is meager. [92] Most of the associated cancers are common, and seborrheic keratoses are extremely common. Proving an uncommon causal relationship between a common cancer and a common skin sign is difficult. Anecctotal reports are many.

Porphyria Cutanea Tarda (See Chap. 149)

Porphyria cutanea tarda has been associated with the development of malignant tumors, predominantly of the liver. The relative risk of hepatocellular carcinoma in patients with porphyria has been estimated at 61, [93] a truly significant association. The porphyria cutanea tarda can predate or antedate the apparent development of the primary liver tumor.

H3>DIRECT TUMOR INVOLVEMENT IN THE SKIN

Solid Tumors

Direct involvement of the skin by metastatic spread from a distant primary tumor is perhaps the most unquestioned sign of internal malignancy. In a large review by Lookingbill et al., [94] skin involvement was the first sign of cancer in 0.8 percent of systemic cancer patients. Of this group, approximately equal numbers had direct extension to the skin, local metastases, or distant skin metastases. Direct extension was most common in patients with breast and oral cancer. Local metastases were most common in patients with breast cancer or pelvic cancer. Distant metastases were from many tumor types and sites.

Generally, such a metastatic lesion is rapidly growing erythematous cutaneous or subcutaneous mass. Most commonly breast cancer lesions metastasize to the anterior chest wall. They can show up as small nodules ranging from 1- to 2-mm lesions to large masses of tumor (Fig. 184-9C). The tiny nodules can be erythematous or frankly hemorrhagic. The hemorrhage can be present within the nodules or in the field surrounding the nodules. Metastatic breast cancer also can present as an erysipelas-like eruption known as *carcinoma erysipelatodes* (see Fig. 184-9A, *B*). Usually asymptomatic,

this type of breast cancer can be painful. Another clinical variant is the leather-like skin change of sclerosing metastatic breast cancer known as *carcinoma en cuirasse,* which may later present as nodules and ulceration (Fig. 184-10). Carcinoma en cuirasse can be progressive for many years, even decades, in the absence of any apparent systemic involvement.

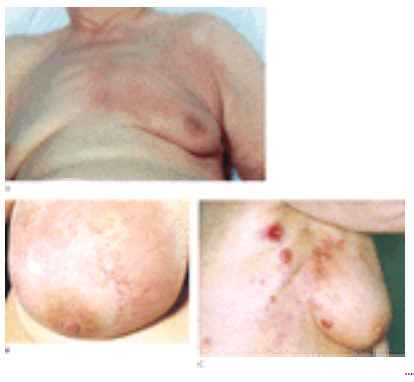

FIGURE 184-9 Involvement of skin by metastatic breast cancer. *A*. Carcinoma erysipelatodes. Intralymphatic spread of mammary carcinoma that manifests as erysipelas-like erythema. *B*. In this close-up of another patient, the erysipelas-like quality of the erythema is even more evident. In addition, there are small, bright-red lenticular metastases. *C*. Metastatic breast cancer also can present as nodules. These may ulcerate and can be very painful.

FIGURE 184-10 Carcinoma en cuirasse involving both breasts and thoracic wall.

Metastases from malignant melanoma are usually pigmented (see Chap. 93). Often there is a bluish tint to the lesion, even if it is deep in the skin. However, even if the primary tumor was pigmented, the metastases can be amelanotic. The reverse is also true.

Other tumors that commonly metastasize to skin include tumors of the lung, stomach, kidney, and ovary. The scalp is quite commonly involved by metastases from lung, kidney, and breast tumors. Alopecia may result.

The face and neck may be involved by metastases from oropharyngeal carcinomas.

Metastases to the skin can appear many years after extirpation of the primary tumor. Progression, as in the case of carcinoma en cuirasse, can be very slow and may indeed not appreciably shorten life expectancy. Generally, though, cutaneous metastases herald a poor prognosis because evidence of systemic spread to other sites is usually quickly apparent. Metastases from renal and thyroid carcinoma may be pulsatile and may have a bruit.

Lymphoma-Leukemia (See Chap. 157 and Chap. 158)

Involvement of the skin with lymphoma cells is quite common, particularly in the case of a T cell lymphoma. T cell leukemias frequently have skin involvement, and this involvement may manifest itself as a diffuse erythroderma, as is seen in Sézary syndrome.

B cell lymphomas also can involve the skin, with Hodgkin's disease being the most common. B cell lymphoma involvement of the skin is usually manifested by the development of one or more papules or nodules that may be ulcerated and form arcuate lesions (see Chap. 158). Alopecia also can be caused by lymphoma. Alopecia mucinosa is involvement of the hair follicles by lymphoma, with associated mucin deposition.

Aside from the erythroderma seen in T cell leukemia, other lymphocytic, myeloid, and myelomonocytic leukemias can have cutaneous manifestations. The most common of these are the infiltrations of the skin produced by monocytic or myelomonocytic leukemia, which can produce a leonine facies in addition to other infiltrative plaques. Involvement of the skin can be a presenting feature in myelomonocytic leukemia, although it generally occurs late in the course of the disease.

When assessing a solitary nodule that is histologically lymphoma but in the absence of any definable systemic disease, it is important to consider benign cutaneous lymphoid infiltrates in the differential diagnosis (see Chap. 159).

Paget's Disease (See Chap. 87)

Paget's disease of the nipple is an erythematous scaling eruption indicating ductal carcinoma of the underlying breast. Extramamamry Paget's disease, which can occur in the anogenital skin, similarly may be associated with an underlying adenocarcinoma. The underlying carcinoma may be of aporcine or eccrine sweat gland origin, or can be from the rectum

or urethra.

REFERENCES

Acanthosis nigricans is a cutaneous marker, most commonly of insulin resistance and less frequently of malignancy. It is recognized clinically by hyperpigmented, hyperkeratotic, verrucous plaques that bestow a velvety texture on involved skin. Typically symmetric in distribution, it usually involves intertriginous areas [1] and occasionally mucocutaneous areas. [2]

HISTORICAL ASPECTS

The term *acanthosis nigricans* was originally proposed by Unna, although the first cases were described by Pollitzer and by Janovsky in 1891. Curth classified acanthosis nigricans into malignant, benign, syndromic acanthosis nigricans or pseudoacanthosis nigricans. [2] A key advance toward understanding pathogenesis was made in 1976 by Kahn et al., [3] who described two syndromes of insulin resistance. Type A syndrome, seen in women with acanthosis nigricans, masculinization, and hyperandrogenism, is characterized by defective insulin receptors, whereas type B syndrome, seen in women with acanthosis nigricans and autoimmune diseases, is associated with circulating anti-insulin receptor autoantibodies. The concept of acanthosis nigricans as a marker of malignancy is valid, but most cases are related to insulin resistance. [4], [5] and [6]

EPIDEMIOLOGY

The prevalence of acanthosis nigricans in selected subpopulations has been studied. Stuart et al. [5] identified it in 7 percent of public school children, a prevalence that rose to 28 percent among those judged to be obese based on ideal body weight. A higher frequency was noted in African Americans (13 percent) than in Hispanics (6 percent) and whites (0.5 percent). [5] In a separate study, an even higher prevalence was seen in Native American children (32 percent). [7] Hud et al. [6] observed acanthosis nigricans in 74 percent of adult patients treated for obesity, with African Americans having the highest frequency among ethnic groups. In a study of Mexican Americans with and without diabetes mellitus, the respective prevalences were 41 percent and 31 percent. [8]

Malignancy-associated acanthosis nigricans is rare. It was present in 1 of 35 patients with intrathoracic or intraabdominal malignancies, [9] and in 2 of 12,000 cancer patients. Although reported in all age groups, it is more common in individuals 40 years of age and older of either gender. [2], [9], [10]

ETIOLOGY AND PATHOGENESIS

Although the precise etiology of acanthosis nigricans remains unclear, there is evidence of a role for insulin. [11], [12] and [13]) At normal levels, insulin binds preferentially to classic receptors, transducing effects on glucose metabolism. In contrast, at higher levels, insulin binds with greater affinity to insulin-like growth factor (IGF) receptors, promoting effects on cell proliferation. [4], [14] Insulin can reach the skin and affect fibroblasts and keratinocytes, both shown to express classic insulin and IGF receptors. [15] Tissue resistance to insulin leads to hyperinsulinemia, which favors binding to IGF receptors that may stimulate proliferation of keratinocytes and dermal fibroblasts in a manner that may produce acanthosis nigricans. [14], [15]

Hyperinsulinemia may also trigger ovarian hyperandrogenism, which commonly coexists with acanthosis nigricans in women with severe insulin resistance (e.g., type A syndrome of insulin resistance and polycystic ovarian syndrome). [14] The prevalence of the skin eruption in hyperandrogenic women was reported to be 5 to 29 percent. [11], [12] An etiologic role for androgens was suggested by improvement of acanthosis nigricans in two hyperandrogenic women treated with antiandrogen medications. [16] On the other hand, antiandrogen treatments do reverse hirsutism, with no effect on the acanthosis nigricans or insulin resistance. [17], [18]

The pathogenesis of malignancy-associated acanthosis nigricans is even less clear. A humoral factor produced by the tumor is likely, given cases in which the skin disorder improved or resolved following treatment of the malignancy.

Elevated levels of transforming growth factor (TGF)-a in urine and of epidermal growth factor (EGF) receptors in lesional skin were noted in a patient with acanthosis nigricans, acrochordons, the sign of Leser-Trélat, and melanoma. The enhanced expression of this cytokine and its receptor normalized after removal of the melanoma, and the acanthosis nigricans, acrochordons, and seborrheic keratoses improved postoperatively. [19] A separate case, with gastric cancer was also shown to express TGF-a and EGF receptors. [20]

CLINICAL MANIFESTATIONS

The clinical hallmark of acanthosis nigricans is development of gray-brown, velvety plaques that may start as a dirty appearance. The hyperpigmentation is later accompanied by hypertrophy, increased skin markings, and papillomatosis. The most commonly involved locations are the axillae, neck (Fig. 185-1 and Fig. 185-2), external genitalia, groin, face, inner thighs, antecubital and popliteal fossae, umbilicus, and perianal area. [1] Acrochordons may develop, superimposed on the acanthosis nigricans (Fig. 185-1) or on other locations. Tylosis (palmoplantar hyperkeratosis) and acanthosis palmaris or pachydermatoglyphy (exaggeration of fingerprints) may also occur, especially in malignancy-associated acanthosis nigricans. Exuberant forms of the latter are called tripe palms because of similarity to the rugose appearance of bovine foregut (Fig. 185-3). Mucocutaneous surfaces may be affected and the eruption can be generalized, particularly in malignancy-associated cases. Mucosal involvement may consist of thickening and papillomatosis with minimal hyperpigmentation (Fig. 185-4). [2]

ASSOCIATED CONDITIONS

Acanthosis nigricans is classified best based on the underlying problem or cause (Table 185-1).

Insulin resistance-related
Leprechaunism (Donohue syndrome)
Lipodystrophies
Obesity
Polycystic ovarian disease (Stein-Leventhal syndrome)
Pseudoacromegaly
Rabson-Mendenhall syndrome
Rud syndrome
Type A syndrome (HAIR-AN syndrome)
Type B syndrome
Type 2 diabetes mellitus
Malignancy-related (see Table 185-2)
Drug-induced
Idiopathic
Familial
Nonfamilial
Other
Syndromic (see Table 185-3)
Acral acanthotic anomaly
Nevoid form

HAIR-AN = hyperandrogenism, insulin resistance, and acanthosis nigricans

TABLE 185-1 **Classification of Acanthosis Nigricans Based on the Most Common Associations**

Insulin Resistance

Acanthosis nigricans is a common feature of several insulin-resistant states. Insulin resistance is defined as hyperinsulinemia inappropriate for the concurrent plasma glucose level. [2], [10], [21], [22] Obesity (previously categorized as pseudoacanthosis nigricans) is the most commonly associated condition. [23] There is a positive correlation between development of acanthosis nigricans and the severity of obesity. [5], [6] Not only do skin changes often parallel the development of obesity, but they typically regress following weight reduction. Obesity is intrinsically associated with hyperinsulinemia, insulin resistance, impaired glucose tolerance, and type 2 diabetes mellitus, as well as with dyslipidemia, hypertension, and hyperandrogenemia. [24] Genetic studies suggest that acanthosis nigricans, fasting plasma insulin level, and type 2 diabetes are under strong pleiotropic influences. [25] A study of African Americans showed fasting plasma insulin level to correlate with severity of acanthosis nigricans. [26]

Mutations of the insulin receptor gene or postreceptor defects have been implicated in other insulin-resistant states, such as leprechaunism, Lawrence-Seip syndrome (congenital lipodystrophy), pseudoacromegaly, Rabson-Mendenhall syndrome, and the type A syndrome. [4], [27], [28], [29] and [30]

Malignancy

Malignancy-associated acanthosis nigricans tends to be extensive and involves mucosal surfaces (Fig. 185-5). Other independent markers of malignancy, such as the sign of Leser-Trélat, tylosis, and florid cutaneous papillomatosis, may accompany acanthosis nigricans, suggesting common pathomechanisms. The overwhelming majority of associated malignancies are intraabdominal adenocarcinomas, most commonly gastric in origin (45 to 61 percent). Acanthosis nigricans may precede, occur simultaneously with, or develop after the clinical onset of the malignancy. [10], [31] Recent studies indicate that in many cases acanthosis nigricans was noted prior to detection of malignancy. Most tumors are inoperable or highly aggressive at the time of detection. Regression of acanthosis nigricans following tumor treatment and its redevelopment with tumor recurrence or metastasis have been reported. [2] Table 185-2 lists other associated malignancies. [2], [10], [32], [33] and [34]

Adenocarcinomas	Lung carcinomas
Gastric	Bronchoalveolar
Other	Squamous cell
Endocrinologic malignancies	Small cell
Carcinoid	Lymphomas (including cutaneous T cell lymphoma)
Pheochromocytoma	Other
Pinealoma	Wilms' tumor
Testicular	Cervical carcinoma
Thyroid	Urinary bladder carcinoma
Melanoma	
Sarcomas	

TABLE 185-2 **Malignancies Reported in Association with Acanthosis Nigricans**

FIGURE 185-5 *A.* Malignant acanthosis nigricans with pigmented, velvety, papillomatous lesions in both axillae and the neck and papillomatous, verrucous lesions on the vermilion border of the lips. *B.* Acanthosis nigricans in the groin and scrotal area. (*Courtesy of Fritz Gschnait, MD.*)

Drugs

Acanthosis nigricans is associated with systemic administration of somatotrophin, [35] testosterone, nicotinic acid, diethylstilbestrol, oral contraceptives, triazinate, and corticosteroids, and with topical application of fusidic acid. Acanthosis nigricans developing at sites of subcutaneous insulin injections has also been described. [2]

Idiopathic

True idiopathic acanthosis nigricans requires exclusion of an underlying cause (insulin resistance, obesity, endocrinopathy, malignancy, or drug). Familial cases of idiopathic acanthosis nigricans have been reported, with onset at birth or in early childhood. [10], [36] These cases appear to be inherited as an autosomal dominant trait with variable penetrance. [10], [36] Because obesity is commonly familial, it may be difficult to differentiate obesity-related familial acanthosis nigricans from the idiopathic familial form. Distinguishing features of the former are reversibility of the skin changes with weight reduction and onset at any age. [23]

Other

Numerous syndromes have been reported in association with acanthosis nigricans (Table 185-3). [2], [10], [21], [37], [38] Insulin resistance is a unifying component of many syndromes. Acral acanthotic anomaly is a variant that appears as velvety hyperkeratosis of the back of the hands and feet, often seen in dark-skinned individuals. [2] Finally, an idiopathic, unilateral (nevoid) form of acanthosis nigricans has been described. [2], [39]

Acromegaly	Laurence-Moon-Bardet-Biedl syndrome
Addison disease	Laurence-Seip syndrome (congenital lipodistrophy)*
Alström syndrome*	Lipoatrophic diabetes*
Ataxia-telangiectasia	Lipoid hepatitis
Baller syndrome	Lupus erythematosus
Beare-Stevenson syndrome	MORBAN syndrome (mental retardation, overgrowth, osteofaciale facies, and acanthosis nigricans)
Benign encephalopathy	Phenylketonuria
Bloom syndrome	Pituitary hypogonadism
Cappuccino syndrome	Pituitary tumors
Chondrodystrophy with dwarfism	Prader-Willi syndrome
Costello syndrome	Pseudoacromegaly*
Crouzon syndrome	Pyramidal tract degeneration
Cushing's syndrome	Rabson-Mendenhall syndrome*
Dermatomyositis	Ruvalcaba syndrome*
Diabetes insipidus	Schwachman
Donohue syndrome (leprechaunism)*	Stein-Leventhal syndrome (polycystic ovarian disease)*
Down syndrome	Small gonads
Edwards syndrome*	Type A syndrome of insulin resistance*
Gigantism	Type B syndrome of insulin resistance*
HAIR-AN syndrome (hyperandrogenism, insulin resistance, and acanthosis nigricans)*	Werner syndrome
Hashimoto thyroiditis	Wilson disease (hepatolenticular degeneration)
Hepatic cirrhosis	
Hirschsprung syndrome

TABLE 185-3 **Syndromes Associated with Acanthosis Nigricans**

HISTOPATHOLOGY

The histology of acanthosis nigricans is consistent regardless of clinical associations. Characteristic features include hyperkeratosis and slight acanthosis undulating with dermal papillomatosis (Fig. 185-6). The clinical brown color is likely a result of hyperkeratosis (rather than of hypermelanosis, which is usually minimal to nil). Thus, the term acanthosis nigricans has little histologic justification. [10], [40], [41] Mucous membrane involvement may display focal parakeratosis, greater acanthosis, and epithelial papillary hyperplasia. [40]

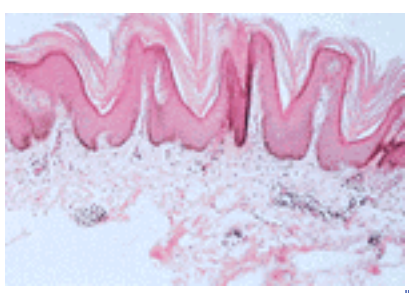

FIGURE 185-6 Histology of acanthosis nigricans demonstrating hyperkeratosis and slight acanthosis alternating with dermal papillomatosis.

DIFFERENTIAL DIAGNOSIS

The distinctive clinical appearance and distribution renders the diagnosis readily apparent. Occasionally, however, acanthosis nigricans may simulate a hyperpigmented nevus (Becker, epidermal, or melanocytic), reticulate pigmented flexural anomaly (Dowling-Degos disease), or confluent and reticulated papillomatosis (Gougerot and Carteaud). [2], [41] Mycosis fungoides can mimic acanthosis nigricans. [42] Oral acanthosis nigricans may be confused with Cowden disease, dyskeratosis congenita, hereditary benign intraepithelial dyskeratosis, lipoid proteinosis, pachyonychia congenita, pyostomatitis vegetans, and Wegener granulomatosis. [2]

LABORATORY TESTS

The underlying cause may be suggested by historical information and physical examination findings. A malignancy is important to exclude especially in nonobese patients with a history of sudden onset, severe involvement, or in cases in which there is no readily discernible cause. In these cases, diagnostic tests should be performed to screen for malignancy with particular attention paid to the possibility of an intraabdominal malignancy.

The presence of acanthosis nigricans should prompt consideration of insulin resistance. A simple screen is to test, in parallel, for fasting plasma levels of glucose and insulin. Although many insulin-resistant people may not demonstrate fasting hyperinsulinemia or have acanthosis nigricans, [43] an inappropriately elevated plasma level of insulin for the corresponding glucose level in a patient with acanthosis nigricans is evidence of insulin resistance as the cause. A fasting glucose/insulin ratio of <4.5 is used to screen for insulin resistance in adult women with polycystic ovary syndrome, [44] and <7 is considered abnormal in prepubertal girls with premature adrenarche. [45] Women with hyperandrogenism (irregular menses, acne, and hirsutism) should undergo endocrine evaluation. Patients with rheumatic diseases should be tested for the presence of anti-insulin receptor autoantibodies.

TREATMENT

Whenever possible, the underlying cause should be identified and treated. Obese patients can reverse the skin changes with weight loss. Patients with the type A syndrome have been treated with ovarian wedge resection with or without cyclical norethindrone and mestranol, [16], [46], [47] oral contraceptives, [16] /SUP>ketoconazole, [48] or cyproterone acetate. [49] Infusion of IGF in some type A patients improved the acanthosis nigricans and hyperinsulinemia, but aggravated the hyperandrogenism. [50], [51] The insulin-sensitizing agents, troglitazone (withdrawn by the Food and Drug Administration) and metformin, have been used to treat hyperandrogenemic, insulin-resistant women, but their effects on acanthosis nigricans have not been studied. [18] In a case of lipodystrophic diabetes mellitus, the acanthosis nigricans improved with dietary fish oil supplementation. [2] Management of the type B syndrome should focus on the underlying autoimmune disease.

Malignancy-associated acanthosis nigricans may regress following effective treatment of the underlying cancer. [31] In one case, treatment with cyproheptadine led to improvement of acanthosis nigricans despite progression of the metastatic disease. [52] Topical calcipotriol, salicylic acid, urea, podophyllin, systemic and topical retinoids have been used with varying success. [2], [53], [54] Continuous-wave carbon dioxide laser therapy was performed in one patient. [54]
