The physiology of neuromuscular transmission could be analyzed and understood at the most simple level by using the classic model of nerve signaling to muscle through the acetylcholine receptor (AChR). The mammalian neuromuscular junction is the prototypical and most extensively studied synapse. Research has provided more detailed information on processes that, within the classic scheme, can modify neurotransmission and response to drugs. One example is the role of qualitative or quantitative changes in AChRs that modify neurotransmission and response to drugs.[1-3] In myasthenia gravis, for example, the decrease in AChRs results in decreased efficiency of neurotransmission (and therefore muscle weakness)[4] and altered sensitivity to neuromuscular relaxants.[3] Another example is the importance of nerve-related (prejunctional) changes that alter neurotransmission and response to drugs.[3,5] At still another level is evidence that muscle relaxants act in ways that are not encompassed by the classic scheme of a unitary site of action. The observation that muscle relaxants can have prejunctional effects[6] or that some nondepolarizers can also have agonist-like stimulatory actions on the receptor[7] whereas others have effects not explainable by purely postsynaptic events[8] has provided new insight into some previously unexplained observations. Although muscle relaxants are known to have effects on the presynaptic and postsynaptic receptors of the neuromuscular junction, recent evidence indicates that they can react with nicotinic and muscarinic AChRs other than those in muscle, including receptors on the carotid sinus, on the vagus to the heart, and on bronchial smooth muscle.[9-11] Although this multifaceted action-response scheme makes the physiology and pharmacology of neurotransmission more complex, these added insights also bring experimentally derived knowledge much closer to clinical observations.

Crucial to the seminal concepts that have developed relative to the neurotransmitter acetylcholine and its receptor systems has been the introduction of powerful and contemporary techniques in molecular biology, immunology, and electrophysiology, as well as more elegant techniques for observation of the neuromuscular junction in vivo.[12] These techniques have augmented the more traditional pharmacologic, protein chemical, morphologic, and cytologic approaches.[13,14] Research has elucidated the manner in which the nerve ending regulates the synthesis and release of transmitter and the release of trophic factors, both of which control muscle function, and how these processes are influenced by exogenous and endogenous substances.[14-17] Research continues into how receptors are synthesized and anchored at the end plate, the role of the nerve terminal in the maturation process, and synthesis and control of acetylcholinesterase, the enzyme that breaks down acetylcholine. Several reviews that provide detailed insight into these areas are available.[15-19]

Neuromuscular Transmission

Neuromuscular transmission occurs by a fairly simple and straightforward mechanism. The nerve synthesizes acetylcholine and stores it in small, uniformly sized packages called vesicles. Stimulation of the nerve causes these vesicles to migrate to the surface of the nerve, rupture, and discharge acetylcholine into the cleft separating nerve from muscle. AChRs in the end plate of the muscle respond by opening their channels for influx of sodium ions into the muscle to depolarize the muscle. The end-plate potential created is continued along the muscle membrane by the opening of sodium channels present throughout the muscle membrane to initiate a contraction.[17] The acetylcholine immediately detaches from the receptor and is destroyed by the enzyme acetylcholinesterase, which is also present in the cleft. Drugs, notably depolarizing relaxants or nicotine and carbachol (a synthetic analog of acetylcholine not destroyed by acetylcholinesterase), can also act on these receptors to mimic the effect of acetylcholine and cause depolarization of the end plate. These drugs are therefore called agonists of the receptor because to a greater or lesser extent, they stimulate the receptor, at least initially. Nondepolarizing muscle relaxants (NDMRs) also act on the receptors, but they prevent acetylcholine from binding to the receptor and thus prevent depolarization by agonists. Because these nondepolarizers prevent the action of agonists (e.g., acetylcholine, carbachol, succinylcholine), they are referred to as antagonists of the AChR. Other compounds, frequently called reversal agents or antagonists of neuromuscular paralysis (e.g., neostigmine, prostigmine), inhibit acetylcholinesterase and therefore impair the hydrolysis of acetylcholine. The increased accumulation of undegraded acetylcholine can compete with NDMRs effectively and thereby displace the latter from the receptor (i.e., law of mass action) and antagonize the effects of NDMRs.

Morphology

The neuromuscular junction is specialized on the nerve side and on the muscle side to transmit and receive chemical messages.[12-17] Each motor neuron runs without interruption from the ventral horn of the spinal cord or medulla to the neuromuscular junction as a large, myelinated axon (Fig. 14-1A). As it approaches the muscle, it branches repeatedly to contact many muscle cells and gather them into a functional group known as a motor unit (see Fig. 14-1B). The architecture of the nerve terminal is quite different from that of the rest of the axon. As the terminal reaches the muscle fiber, it loses its myelin, forms a spray of terminal branches against the muscle surface, and is covered by Schwann cells. This arrangement conforms to the architecture on the synaptic area of the muscle membrane (see Fig. 14-1C). The nerve is separated from the surface of the muscle by a gap of approximately 20 nm, called the junctional or synaptic cleft. The nerve and muscle are held in tight alignment by protein filaments called basal lamina that span the cleft between the nerve and end plate. The muscle surface is heavily corrugated, with deep invaginations of the junctional cleft—the primary and secondary clefts—between the folds in the muscle membrane; thus, the end plate's total surface area is very large. The depths of the folds also vary between muscle types and species. Human neuromuscular junctions, relative to muscle size, are smaller than those of the mouse, although the junctions are located on muscle fibers that are much larger. Human junctions have longer junctional foldings and deeper gutters.[12] The functional significance of these folds is unclear. The shoulders of the folds are densely populated with AChRs, about 5 million of them in each junction. AChRs are sparse in the depths between the folds. Instead, these deep areas contain sodium channels (see Fig. 14-1D).

The trophic function of the nerve is vital for the development and maintenance of adequate neuromuscular function. Before birth, each muscle cell commonly has contacts with several nerves and has several neuromuscular junctions.[17,19] At birth, all but one of the nerves retract, and a single end plate remains. Once

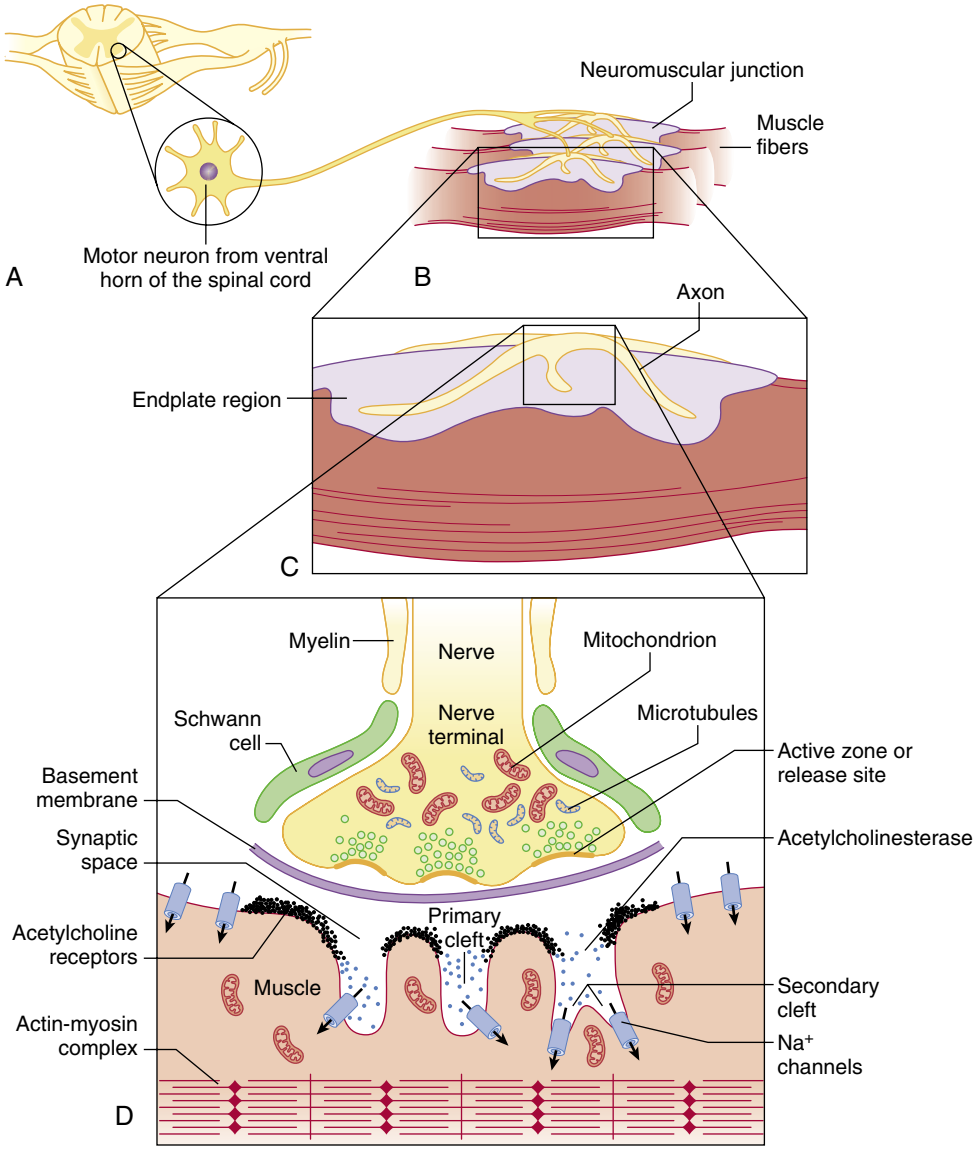

Figure 14-1 Structure of the adult neuromuscular junction showing the three cells that constitute the synapse: the motor neuron (i.e., nerve terminal), muscle fiber, and Schwann cell. **A,** The motor nerve originates in the ventral horn of the spinal cord or brainstem. **B,** As the nerve approaches its muscle fibers and before attaching itself to the surface of the muscle fiber, the nerve divides into branches that innervate many individual muscle fibers. **C,** Each muscle receives only one synapse. The motor nerve loses its myelin and further subdivides into many presynaptic boutons to terminate on the surface of the muscle fiber. **D,** The nerve terminal, covered by a Schwann cell, has vesicles clustered about the membrane thickenings, which are the active zones, toward its synaptic side and mitochondria and microtubules toward its other side. A synaptic gutter or cleft made up of a primary and many secondary clefts separates the nerve from the muscle. The muscle surface is corrugated, and dense areas on the shoulders of each fold contain acetylcholine receptors. Sodium channels are present at the bottom of the clefts and throughout the muscle membrane. The acetylcholinesterase and proteins and proteoglycans that stabilize the neuromuscular junction are present in the synaptic clefts.

formed, the nerve-muscle contact, especially the end plate, is durable. Even if the original nerve dies, the one replacing it innervates exactly the same region of the muscle. The nerve endings on fast muscles are larger and more complicated than those on slow muscles. The reason for this is unclear. These differences in the nerve endings on muscle surfaces may play a role in the difference in response of fast- and slow-twitch muscle fibers to muscle relaxants.

Because all the muscle cells in a unit are excited by a single neuron, stimulation of the nerve electrically or by an action potential originating from the ventral horn or by any agonist, including depolarizing relaxants (e.g., succinylcholine), causes all muscle cells in the motor unit to contract synchronously. Synchronous contraction of the cells in a motor unit is called *fasciculation* and often is vigorous enough to be observed through the skin. Although most adult human muscles have only one neuromuscular junction per cell, an important exception is some of the cells in extraocular muscles. The extraocular muscles are "tonic" muscles, and unlike other mammalian striated muscles, they are multiply innervated, with several neuromuscular junctions strung along the surface of each muscle cell.[20,21] Quite in contrast to other muscles, even the adult ocular muscle contains mature and immature fetal receptors (see "Postjunctional Acetylcholine Receptors") segregated into distinct synapses on different fibers.[20] The ocular muscles contract and relax slowly rather than quickly as other striated muscles do; they can maintain a steady contraction, or contracture, the strength of which is proportional to the stimulus received. Physiologically, this specialization apparently holds the eye steadily in position. These muscles are important to an anesthesiologist because depolarizing relaxants affect them differently than they do most skeletal muscles. Instead of causing a brief contraction followed by paralysis, the drugs cause a long-lasting contracture response that pulls the eye against the orbit and could contribute to an increase in intraocular fluid pressure.[22] The clinical significance of a succinylcholine-induced increase in intraocular pressure has been questioned. Although many textbooks invoke the reported extrusion of intraocular content with succinylcholine, the basis for this effect seems to be anecdotal.[23]

The perijunctional zone is the area of muscle immediately beyond the junctional area, and it is critical to function of the neuromuscular junction. The perijunctional zone contains a mixture of receptors, including a smaller density of AChRs and a high density of sodium channels (see Fig. 14-1D). The admixture enhances the capacity of the perijunctional zone to respond to the depolarization (i.e., end-plate potential) produced by AChRs and to transduce it into the wave of depolarization that travels along the muscle to initiate muscle contraction. The density of sodium channels in the perijunctional area is richer than in more distal parts of the muscle membrane.[17,24] The perijunctional zone is close enough to the nerve ending to be influenced by transmitter released from it. Moreover, special variants (i.e., isoforms) of receptors and sodium channels can appear in this area at different stages of life and in response to abnormal decreases in nerve activity (see "Biology of Prejunctional and Postjunctional Nicotinic Receptors"). Congenital abnormalities in the AChR[4,5] or in the sodium and calcium channels (i.e., mutations)[25,26] are also known. These variabilities seem to contribute to the differences in response to relaxants that are seen in patients with different pathologic conditions and ages.[1-3,27]

Quantal Theory

The contents of nerve ending are not homogeneous. As shown in Figures 14-1 and 14-2, vesicles are congregated in the portion toward the junctional surface, whereas microtubules, mitochondria, and other support structures are located toward the opposite side. The vesicles containing transmitter are ordered in repeating clusters alongside small, thickened, electron-dense patches of membrane referred to as active zones or release sites. This thickened area is a cross section of a band running across the width of the synaptic surface of the nerve ending that is believed to be the structure to which vesicles attach (active zones) before they rupture into the junctional cleft (see "Process of Exocytosis"). High-resolution scanning electron micrographs reveal small protein particles arranged alongside the active zone between vesicles. These particles are believed to be special channels—voltage-gated calcium channels—that allow calcium to enter the nerve and cause the release of vesicles.[28,29] The rapidity with which the neurotransmitter is released (200 μsec) suggests that voltage-gated calcium channels are close to the release sites. Proteomic studies suggest that at least 26 genes encode presynaptic proteins, and mutations in 12 of them cause defects in presynaptic structure that can lead to decreased acetylcholine release and muscle weakness.[30] These defects can be related to exocytosis, endocytosis, formation of active and periactive zones, vesicle transport, and neuropeptide modulation.[30]

When observing the electrophysiologic activity of a skeletal muscle, small, spontaneous depolarizing potentials at neuromuscular junctions can be seen. These potentials have only one hundredth the amplitude of the evoked end-plate potential produced when the motor nerve is stimulated. Except for amplitude, these potentials resemble the end-plate potential in the time course and manner in which they are affected by drugs. These small-amplitude potentials are called miniature end-plate potentials (MEPPs). Statistical analysis led to the conclusion that they are unitary responses; that is, there is a minimum size for the MEPP, and the sizes of all MEPPs are equal to or multiples of this minimum size. Because MEPPs are too big to be produced by a single molecule of acetylcholine, it was deduced that they are produced by uniformly sized packages, or quanta, of transmitter released from the nerve (in the absence of stimulation). The stimulus-evoked end-plate potential is the additive depolarization produced by the synchronous discharge of quanta from several hundred vesicles. The action potential that is propagated to the nerve ending allows entry of calcium into the nerve through voltage-gated calcium channels, and this causes vesicles to migrate to the active zone, fuse with the neural membrane, and discharge their acetylcholine into the junctional cleft.[28,29] Because the release sites are located immediately opposite the receptors on the postjunctional surface, little transmitter is wasted, and the response of the muscle is coupled directly with the signal from the nerve.[17,28]

Alignment of the presynaptic receptor site is achieved by adhesion molecules or specific cell-surface proteins located on both sides of the synapse that grip each other across the synaptic cleft and hold the prejunctional and postjunctional synaptic apparatuses together.[15,31-33] One such protein implicated in synapse adhesion is neurexin, which binds to neuroligins on the postsynaptic membrane. The amount of acetylcholine released by each nerve impulse is large, at least 200 quanta of about 5000 molecules each, and the number of AChRs activated by transmitter released

by a nerve impulse is also large, about 500,000 molecules. The ions (mostly Na^+ and some Ca^{2+}) that flow through the channels of activated AChRs cause maximum depolarization of the end plate, which results in an end-plate potential that is greater than the threshold for stimulation of the muscle. This system is very vigorous. The signal is carried by more molecules of transmitter than are needed, and they evoke a response that is greater than needed. At the same time, only a small fraction of the available vesicles and receptors or channels are used to send each signal. Consequently, transmission has a substantial margin of safety, and at the same time the system has substantial capacity in reserve.[34]

The Neuromuscular Junction

Formation of Neurotransmitter at Motor Nerve Endings

The axon of the motor nerve carries electrical signals from the spinal cord to muscles and has all of the biochemical apparatus needed to transform the electrical signal into a chemical one. All the ion channels, enzymes, other proteins, macromolecules, and membrane components needed by the nerve ending to synthesize, store, and release acetylcholine and other trophic factors are made in the cell body and transmitted to the nerve ending by axonal transport (Fig. 14-2).[19,31,33] The simple molecules choline and acetate are obtained from the environment of the nerve ending, the former by a special system that transports it from extracellular fluid to the cytoplasm and the latter in the form of acetyl coenzyme A from mitochondria. The enzyme choline acetyltransferase brings about the reaction of choline and acetate to form acetylcholine; the acetylcholine is stored in cytoplasm until it is transported into vesicles, which are in a better position for release.

Nerve Action Potential

During a nerve action potential, sodium from outside flows across the membrane, and the resulting depolarizing voltage opens calcium channels, which allows entry of calcium ions into the nerve and causes acetylcholine to be released. A nerve action potential is the normal activator that releases the transmitter acetylcholine. The number of quanta released by a stimulated nerve is greatly influenced by the concentration of ionized calcium in extracellular fluid. If calcium is not present, depolarization of the nerve, even by electrical stimulation, will not produce release of transmitter. Doubling the extracellular calcium results in a 16-fold increase in the quantal content of an end-plate potential.[35]

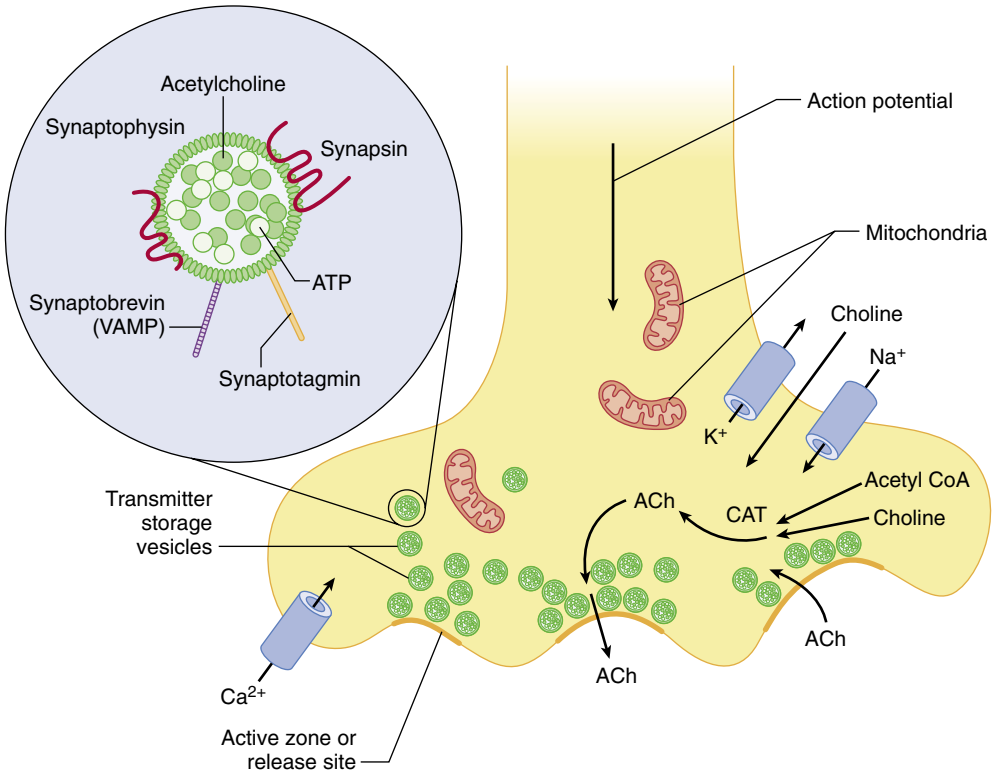

Figure 14-2 The working of a chemical synapse, the motor nerve ending, including some of the apparatus for synthesis of transmitter. The large intracellular structures are mitochondria. Acetylcholine (ACh), synthesized from choline and acetate by acetyl coenzyme A (acetyl CoA), is transported into coated vesicles, which are moved to release sites. A presynaptic action potential that triggers influx of calcium through specialized proteins (Ca^{2+} channels) causes the vesicles to fuse with the membrane and discharge transmitter. Membrane from the vesicle is retracted from the nerve membrane and recycled. Each vesicle can undergo various degrees of release of contents—from incomplete to complete. The transmitter is inactivated by diffusion, catabolism, or reuptake. The *inset* provides a magnified view of a synaptic vesicle. Quanta of ACh together with adenosine triphosphate (ATP) are stored in the vesicle and covered by vesicle membrane proteins. Synaptophysin is a glycoprotein component of the vesicle membrane. Synaptotagmin is the vesicle's calcium sensor. Phosphorylation of another membrane protein, synapsin, facilitates vesicular trafficking to the release site. Synaptobrevin (vesicle-associated membrane protein [VAMP]) is a SNARE protein involved in attaching the vesicle to the release site (see also Fig. 14-3). CAT, choline acetyltransferase.

The calcium current persists until the membrane potential is returned to normal by outward fluxes of potassium from inside the nerve cell. Along with calcium channels on the nerve terminal are potassium channels, including the voltage-gated and calcium-activated potassium channels, whose function is to limit entry of calcium into the nerve and therefore depolarization.[31,36] The calcium current can be prolonged by potassium channel blockers (e.g., 4-aminopyridine, tetraethylammonium), which slow or prevent the efflux of potassium out of the nerve. The increase in quantal content produced in this way can reach astounding proportions.[25,37] An effect of increasing calcium in the nerve ending is also seen clinically as the so-called post-tetanic potentiation, which occurs after a nerve of a patient paralyzed with an NDMR is stimulated at high, tetanic frequencies. Calcium enters the nerve with every stimulus, but because it cannot be excreted as quickly as the nerve is stimulated, it accumulates during the tetanic period. Because the nerve ending contains more than the normal amount of calcium for some time after the tetanus, a stimulus applied to the nerve during this time causes the release of more than the normal amount of acetylcholine. The abnormally large amount of acetylcholine antagonizes the relaxant and causes the characteristic increase in size of the twitch.

Calcium enters the nerve through specialized proteins called calcium channels.[15,25] Of the several types of calcium channels, two seem to be important for release of transmitter: P channels and the slower L channels. P channels, probably the type responsible for normal release of transmitter, are found only in nerve terminals.[13,38] In motor nerve endings, they are located immediately adjacent to the active zones (see Fig. 14-2). They are voltage dependent and opened and closed by changes in membrane voltage caused by the nerve action potential. In addition to calcium channels, several forms of potassium channels are present in the nerve terminal, including voltage-gated and calcium-activated potassium channels. Potassium channels limit the duration of nerve terminal depolarization and hence entry of calcium and release of transmitter.[25,31] Alterations in entry of calcium into the nerve ending can also alter release of transmitter. Eaton-Lambert myasthenic syndrome, which should not be confused with myasthenia gravis, is an acquired autoimmune disease in which antibodies are directed against voltage-gated calcium channels at nerve endings.[39] In this syndrome, decreased function of the calcium channel causes decreased release of transmitter, which results in inadequate depolarization and muscle weakness. Patients with myasthenic syndrome exhibit increased sensitivity to depolarizing and nondepolarizing relaxants.[3,4,31]

Higher than normal concentrations of bivalent inorganic cations (e.g., magnesium, cadmium, manganese) can also block entry of calcium through P channels and profoundly impair neuromuscular transmission. This is the mechanism for muscle weakness in the mother and fetus when magnesium sulfate is administered to treat preeclampsia. P channels, however, are not affected by calcium entry–blocking drugs such as verapamil, diltiazem, and nifedipine. These drugs have profound effects on the slower L channels present in the cardiovascular system. As a result, the L-type calcium channel blockers have no significant effect at therapeutic doses on the normal release of acetylcholine or on the strength of normal neuromuscular transmission. There have been a few reports, however, that calcium entry–blocking drugs may increase the block in neuromuscular transmission induced by NDMRs. The effect is small, and not all investigators have been able to observe it. The explanation may lie in the fact that nerve endings also contain L-type calcium channels.

Synaptic Vesicles and Recycling

There seem to be two pools of vesicles that release acetylcholine, a readily releasable pool and a reserve pool, sometimes called VP2 and VP1, respectively.[40,41] Vesicles in the former are a bit smaller and limited to an area very close to the nerve membrane, where they are bound to the active zones. These vesicles are the ones that ordinarily release transmitter. Electron microscopic studies have demonstrated that the majority of synaptic vesicles (VP1) are sequestered in the reserve pool and tethered to the cytoskeleton in a filamentous network composed mainly of actin, synapsin (an actin-binding protein), synaptotagmin, and spectrin.[40-42]

Release seems to occur when calcium ion enters the nerve through the P channels lined up on the sides of the active zones by SNARE proteins.[40-42] The SNARE (soluble *N*-ethylmaleimide–sensitive attachment protein receptors) proteins are involved in fusion, docking, and release of acetylcholine at the active zone. Calcium needs to move only a very short distance (i.e., a few atomic radii) to encounter a vesicle and activate the proteins in the vesicle wall involved in a process known as docking (see "Process of Exocytosis").[43] The reactivated proteins seem to react with the nerve membrane to form a pore through which the vesicle discharges its acetylcholine into the junctional cleft. Studies using fluorescent proteins have visualized how synaptic vesicles fuse with release sites and release their contents, which are then retrieved.[41] Some vesicles stay open briefly before retrieval and do not completely collapse into the surface membrane ("kiss and run"). Others stay open longer and probably do not collapse completely ("compensatory"). Still others collapse completely and are not retrieved until another stimulus is delivered ("stranded").[41]

The larger reserve (VP1) vesicles, from their position deeper from the nerve ending and firmly tethered to the cytoskeleton by many proteins, including actin, synapsin (an actin-binding protein), synaptotagamin, and spectrin,[40-42] may be moved to the readily releasable store to replace worn-out vesicles or to participate in transmission when the nerve is called on to work especially hard (e.g., when it is stimulated at very high frequencies or for a very long time). Under such strenuous circumstances, calcium may penetrate more deeply than normal into the nerve or may enter through L channels to activate calcium-dependent enzymes that break the synapsin links holding the vesicles to the cytoskeleton, thereby allowing the vesicles to be moved to the release sites. Repeated stimulation requires the nerve ending to replenish its store of vesicles filled with transmitter, a process known as *mobilization*. The term is commonly applied to the aggregate of all steps involved in maintaining the nerve ending's capacity to release transmitter—everything from the acquisition of choline and the synthesis of acetate to the movement of filled vesicles to release sites. Uptake of choline and the activity of choline acetyltransferase, the enzyme that synthesizes acetylcholine, are probably the rate-limiting steps.[13,29,38]

Process of Exocytosis

The readily releasable pool of synaptic vesicles constitutes the vesicles directly available for release. During an action potential

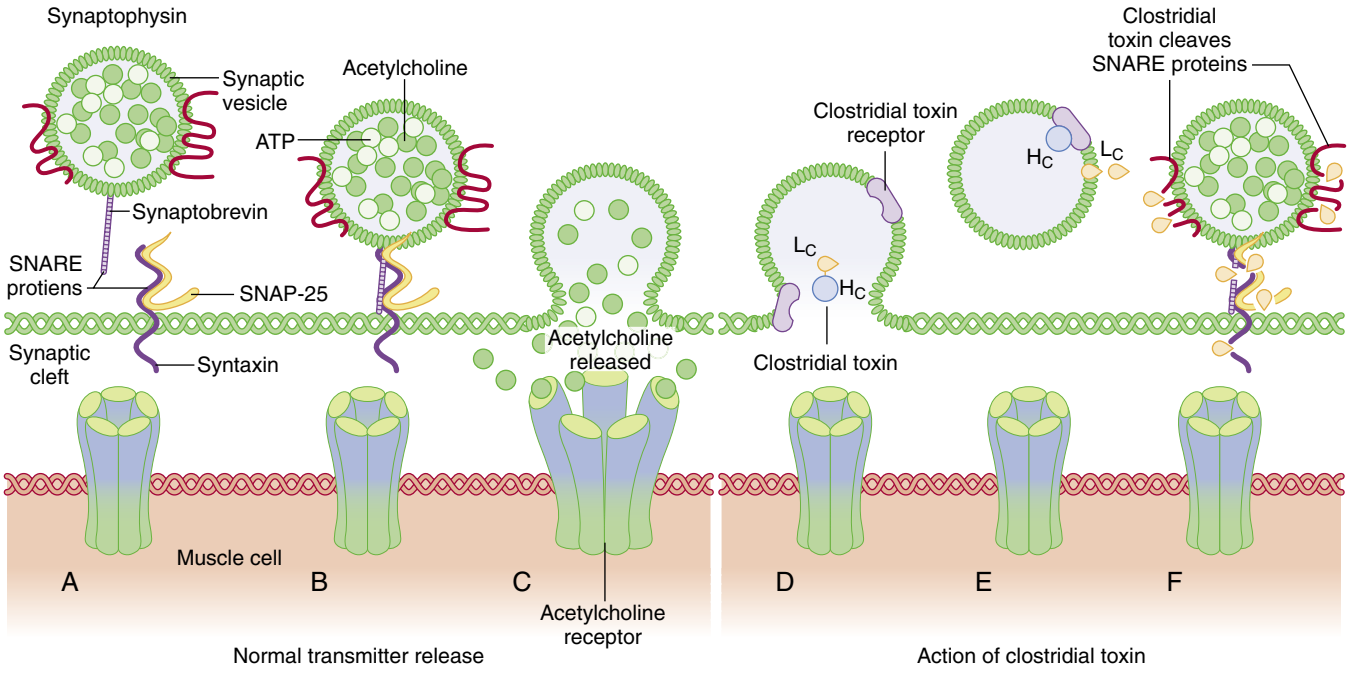

Figure 14-3 Model of protein-mediated membrane fusion and exocytosis. **A,** Release of acetylcholine from vesicles is mediated by a series of proteins collectively called SNARE proteins. Synaptotagmin is the neuronal calcium receptor that detects entry of calcium. Synaptobrevin (i.e., vesicle-associated membrane protein [VAMP]) is a filament-like protein on the vesicle. **B,** During depolarization and entry of calcium, synaptobrevin on the vesicle unfolds and forms a ternary complex with syntaxin/SNAP-25. This process is facilitated by phosphorylation of synapsin, also present on the vesicle membrane. **C,** Assembly of the ternary complex forces the vesicle in close apposition to the nerve membrane at the active zone with release of its contents, acetylcholine. The fusion is disassembled, and the vesicle is recycled. Clostridial toxins, including tetanus and botulinum, inhibit the release of acetylcholine and cause paralysis of muscles. The toxin consists of a light (L_c) and heavy (H_c) chain. **D,** The first stage in intoxication is interaction of the toxin with a thus far unidentified receptor. **E,** This is followed by internalization of the toxin within the vesicle and release of the light chain from the vesicle. The liberated L_c cleaves a variety of SNARE proteins, depending on the type of toxin released, thereby preventing assembly of the fusion complex and thus blocking release of acetylcholine.

and calcium influx, neurotransmitter is released. Studies have shed some light on the inner workings by which the vesicle releases its contents. The whole process is called *exocytosis*. The SNAREs include the synaptic-vesicle protein synaptobrevin and the plasmalemma-associated proteins syntaxin and synaptosome-associated protein of 25 kd (SNAP-25).[42] The current model of protein-mediated membrane fusion in exocytosis is as follows. Syntaxin and SNAP-25 are complexes attached to the plasma membrane. After initial contact, the synaptobrevin on the vesicle forms a ternary complex with syntaxin and SNAP-25. Synaptotagmin is the protein on the vesicular membrane that acts as a calcium sensor, localizes the synaptic vesicles to synaptic zones rich in calcium channels, and stabilizes the vesicles in the docked state.[44] Assembly of the ternary complex forces the vesicle close to the underlying nerve terminal membrane (i.e., the active zone), and the vesicle is then ready for release (Fig. 14-3). An action potential in the nerve terminal allows the entry of calcium. The close proximity of release sites, calcium channels, and synaptic vesicles and use of the calcium sensor lead to a burst of release of new transmitter synchronous with the stimulus.[42,44] The vesicle can release part or all of its contents, some of which can be recycled to form new vesicles as described previously (kiss and run, etc.).[40,41]

Botulinum toxin and tetanus neurotoxins, which selectively digest one or all of these SNARE proteins, block exocytosis of the vesicles.[45,46] The result is muscle weakness or paralysis. These toxins in effect produce a partial or complete chemical denervation. Botulinum toxin is used therapeutically to treat spasticity or spasm in several neurologic and surgical diseases and cosmetically to correct wrinkles.[47,48] Botulinum toxin consists of two protein segments known as heavy and light chains. The heavy chain interacts with lipid molecules called polysialogangliosides in the cell membrane and synaptotagmin on the vesicle to enter the vesicle. Once in the vesicle, the light chain inactivates neuromuscular transmission by breakdown and thereby inhibits the function of SNARE proteins (Fig. 14-4). Recent reports indicate an increased incidence of clostridial infections in both Canada and the United States, with *Clostridium botulinum* infection being particularly common after traumatic injuries, in drug abusers, and after musculoskeletal allografts.[49] Thus, systemic paralysis can occur after clostridial infection. Local injection for therapeutic purposes will usually result in localized paresis, although systemic effects have been reported.[50]

Acetylcholinesterase

The acetylcholine released from the nerve diffuses across the junctional cleft and reacts with specialized receptor proteins in the end plate to initiate muscle contraction. Transmitter molecules that do not react immediately with a receptor or those released after binding to the receptor are destroyed almost instantly by acetylcholinesterase in the junctional cleft. Acetyl-

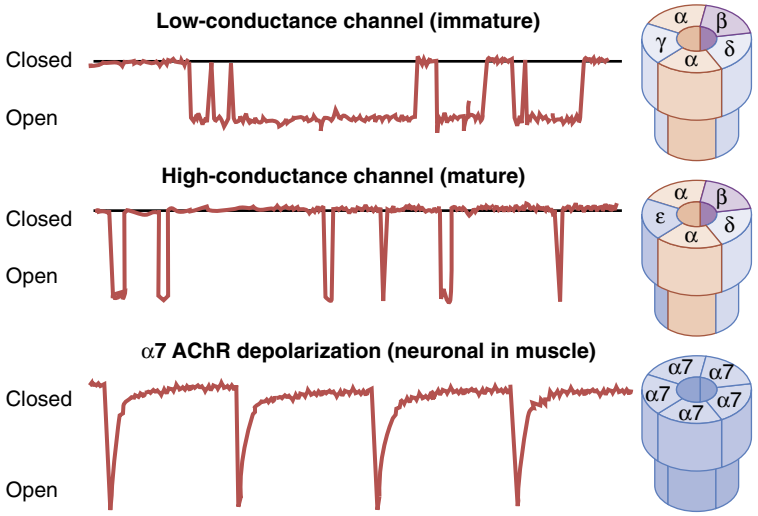

Figure 14-4 Sketch of acetylcholine receptor (AChR) channels (*right*) and tracings of cell-patch records of receptor channel openings (*left*). The mature, or junctional, receptor consists of two α-subunits and one each of β-, δ-, and ε-subunits. The immature, extrajunctional or fetal, form consists of two α- and one each of β, δ, and γ-subunits. The latter is thus called the γ-subunit receptor. Recently, a neuronal receptor consisting of five α7-subunits has been described in muscle. All the subunits are arranged around the central cation channel. The immature isoform containing the γ-subunit has long open times and low-amplitude channel currents. The mature isoform containing the ε-subunit has shorter open times and high-amplitude channel currents during depolarization. Substitution of the ε-subunit for the γ-subunit gives rise to the fast-gated, high-conductance channel type. As expected, application of acetylcholine to the α7 AchR also results in a fast, rapidly decaying inward current. All these depolarizing events are insensitive to treatment with atropine but sensitive to treatment with α-bungarotoxin or muscle relaxants, which block the flow of current.

cholinesterase at the junction is the asymmetric or A12-form protein made in the muscle, under the end plate. Acetylcholinesterase (enzyme classification 3.1.1.7) is a type B carboxylesterase enzyme. There is a smaller concentration of it in the extrajunctional area. The enzyme is secreted from the muscle but remains attached to it by thin stalks of collagen fastened to the basement membrane.[13,17] Most of the molecules of acetylcholine released from the nerve initially pass between the enzymes to reach the postjunctional receptors, but as they are released from the receptors, they invariably encounter acetylcholinesterase and are destroyed. Under normal circumstances, a molecule of acetylcholine reacts with only one receptor before it is hydrolyzed. Acetylcholine is a potent messenger, but its actions are very short lived because it is destroyed in less than 1 millisecond after it is released.

Some congenital and acquired diseases are caused by altered activity of acetylcholinesterase. Congenital absence of the secreted enzyme (in knock-out mice) leads to impaired maintenance of the motor neuronal system and organization of nerve terminal branches.[51] Many syndromes caused by congenital abnormalities in cholinesterase function have been described and result in neuromuscular disorders whose symptoms and signs usually resemble those of myasthenia gravis or myasthenic syndromes.[52,53] Denervation decreases acetylcholinesterase at the junctional and extrajunctional areas.[31] Other acquired diseases involving cholinesterases are related to chronic inhibition of acetylcholinesterase by organophosphate pesticides or nerve gas (e.g., sarin) or to chronic pyridostigmine therapy given as prophylaxis against nerve gas poisoning.[54,55] Symptoms ranging from chronic fatigue to muscle weakness have been attributed to chronic cholinesterase inhibition, thus underscoring the importance of acetylcholinesterase in normal and abnormal neuromuscular function.

Postjunctional Acetylcholine Receptors

The similarity of AChRs among many species and the abundance of AChRs from *Torpedo* electric fish have greatly facilitated research in this area. The availability of messenger RNA from humans and other species and DNA has allowed study of the receptor in artificial systems such as oocytes from frogs and in mammalian cells that do not express the receptor, such as COS or fibroblast cells. It is also possible to mutate receptors by molecular techniques so that they simulate pathologic states and then study receptor function in these artificial systems. By using these and related techniques, much has been learned about the synthesis, composition, and biologic function and the mechanisms that underlie physiologic and pharmacologic responses in AChRs.[56-59] Three isoforms of postjunctional nicotinic AChRs exist, a junctional or mature receptor, an extrajunctional or immature (fetal) receptor, and the most recently described neuronal α7 receptor (see "Biology of Prejunctional and Postjunctional Nicotinic Receptors").[1-3] The differences between receptor subtypes, however, can be neglected in a general discussion of the role of receptors in neuromuscular transmission.

AChRs are synthesized in muscle cells and are anchored to the end-plate membrane by a special 43-kd protein known as rapsyn. This cytoplasmic protein is associated with the AChR in a 1:1 ratio.[31] The receptors, formed of five subunit proteins, are arranged like the staves of a barrel into a cylindrical receptor with a central pore for ion channeling. The key features are sketched in Figure 14-4. The receptor protein has a molecular mass of about 250,000 daltons. Each receptor has five subunits. The mature receptor consists of α, β, δ, and ε and the fetal (immature, extrajunctional) receptor, α, β, δ, and γ; there are two subunits of α and one of each of the others. The neuronal α7 AChR consists of

five α7-subunits.[2] Each of all receptor subunits consists of approximately 400 to 500 amino acids. The receptor-protein complex passes entirely through the membrane and protrudes beyond the extracellular surface of the membrane and into the cytoplasm. The binding site for acetylcholine is on each of the α-subunits, and these are the sites of competition between receptor agonists and antagonists. Agonists and antagonists are attracted to the binding site, and either may occupy the site, which is located near cysteine residues (unique to the α-chain) at amino acid positions 192-193 of the α-subunit.[60] Radiolabeled α-bungarotoxin from the cobra, used to quantitate the receptor, binds to heptapeptide region 189-199 of the α-subunit.[61] Motor neuron–derived neuregulin-1β (NRβ-1), originally described as acetylcholine receptor–inducing activity (ARIA), induces AChR gene transcription in subsynaptic myonuclei by activating ErbB receptors.[62]

Synthesis and Stabilization of Postjunctional Receptors

Muscle tissue is formed from the mesoderm and initially appears as myoblasts. Myoblasts fuse to produce myotubes, which therefore have multiple nuclei. As the myotubes mature, the sarcomere, which is the contractile element of the muscle consisting of actin and myosin, develops.[63] The protein β-integrin seems to be essential for myoblast fusion and sarcomere assembly.[63] Shortly afterward, motor nerve axons grow into the developing muscle, and these axons bring in nerve-derived signals (i.e., growth factors), including agrin and neuregulins (NRβ-1 and NRβ-2), which are key to maturation of myotubes to muscle.[62] Agrin is a protein from the nerve that stimulates postsynaptic differentiation by activating muscle-specific kinase (MuSK), a tyrosine kinase expressed selectively in muscle. With signaling from agrin, the AChRs, which have been scattered throughout the muscle membrane, cluster at the area immediately beneath the nerve. Agrin together with other growth factors (neuregulins, etc.) also induce the clustering of other critical muscle-derived proteins, including MuSK, rapsyn, and ErbB proteins, all of which are necessary for maturation and stabilization of AChRs at the junction (Fig. 14-5). In addition to effects on postsynaptic differentiation, agrin and MuSK display effects on presynaptic differentiation as well. Agrin and MuSK induce retrograde signals that instruct axons to undergo neuron outgrowth and terminal differentiation.[19] Current understanding of presynaptic development of the neuromuscular junction, however, is much less advanced than understanding of postsynaptic development. Just before and shortly after birth, the immature, γ-subunit–containing AChRs are converted to the mature, ε-subunit–containing receptors. Although the mechanism of this change is unclear, a neuregulin, NRβ-1, also called ARIA, that binds to one of the ErbB receptors seems to play a role.[44,62-65]

Basic Electrophysiology of Neurotransmission

Progress in electrophysiologic techniques has moved at an equal pace with advances in molecular approaches for studying prejunctional and postjunctional receptors. Patch-clamping is a technique in which a glass micropipette is used to probe the membrane surface until a single functional receptor is encompassed. The tip of the pipette is pressed into the lipid of the membrane, and the electronic apparatus is arranged to keep the membrane potential clamped (i.e., fixed) and measure the current that flows through the channel of the receptor. The solution in the pipette can contain acetylcholine, muscle relaxant, another drug, or a mixture of drugs. By application of these drugs to the receptor through the micropipette, electrical changes can be monitored.

Figure 14-5 illustrates the results of the classic depolarizing action of acetylcholine on end-plate receptors. Normally, the pore of the channel is closed by approximation of the cylinders (i.e., subunits). When an agonist occupies both α-subunit sites, the protein molecule undergoes a conformational change in which a channel is formed in the center through which ions can flow along a concentration gradient. When the channel is open, sodium and calcium flow from the outside of the cell to the inside and

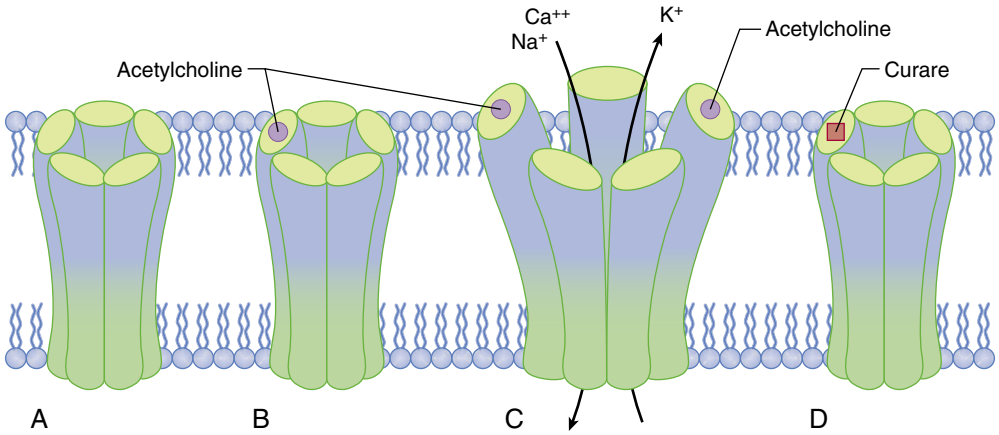

Figure 14-5 Actions of acetylcholine or curare on end-plate receptors. **A,** The ion channel is inactive and does not open in the absence of acetylcholine. **B,** Even binding of one acetylcholine molecule (*filled circle*) to one of two binding sites does not open the channel. **C,** When acetylcholine binds to the recognition sites of both α-subunits simultaneously (*filled circles*), a conformation change is triggered that opens the channel and allows ions to flow across the membrane. **D,** Action of antagonists such as curare (*filled square*). Acetylcholine is in competition with tubocurarine for the receptor's recognition site but may also react with acetylcholinesterase. Tubocurarine is a prototypical nondepolarizing muscle relaxant. Inhibiting the enzyme increases the lifetime of acetylcholine and the probability that it will react with a receptor. When one of the two binding (recognition) sites is occupied by curare, the receptor will not open, even if the other binding site is occupied by acetylcholine.

potassium flows from the inside to the outside. The channel in the tube is large enough to accommodate many cations and electrically neutral molecules, but it excludes anions (e.g., chloride). The current carried by the ions depolarizes the adjacent membrane. The net current is depolarizing and creates the end-plate potential that stimulates the muscle to contract. In this instance, downward-going (i.e., depolarizing) current can be recorded by the electrophysiologic technique described previously (see Fig. 14-4).

The pulse stops when the channel closes and one or both agonist molecules detach from the receptor. The current that passes through each open channel is minuscule, only a few picoamperes (about 10^4 ions/msec). However, each burst of acetylcholine from the nerve normally opens about 500,000 channels simultaneously, and the total current is more than adequate to produce depolarization of the end plate and contraction of muscle. Opening of a channel causes conversion of chemical signals from a nerve to flow of current to end-plate potentials, thereby leading to muscle contraction. We are used to thinking of the end-plate potential as a graded event that may be reduced in magnitude or extended in time by drugs, but in reality, the end-plate potential is the summation of many all-or-nothing events occurring simultaneously at myriad ion channels. It is these tiny events that are affected by drugs.

Receptors that do not have two molecules of agonist bound remain closed. Both α-subunits must be occupied simultaneously by agonist; if only one of them is occupied, the channel remains closed (see Fig. 14-5). This is the basis for prevention of depolarization by antagonists. NDMRs typified by tubocurarine act by binding to either or both α-subunits and thus preventing acetylcholine from binding and opening the channel. This interaction between agonists and antagonists is competitive, and the outcome—transmission or block—depends on the relative concentrations and binding characteristics of the drugs involved (see "Drug Effects on Postjunctional Receptors").

Individual channels are also capable of a wide variety of conformations.[66-68] They may open or stay closed and thereby affect total current flow across the membrane, but they can do more. They may open for a longer or shorter time than normal, open or close more gradually than usual, open briefly and repeatedly (i.e., chatter), or pass fewer or more ions per opening than they usually do. Their function is also influenced by drugs, changes in fluidity of the membrane, temperature, electrolyte balance in the milieu, and other physical and chemical factors.[68] Receptor channels are dynamic structures that are capable of a wide variety of interactions with drugs and of entering a wide variety of current-passing states. All these influences on channel activity are ultimately reflected in the strength or weakness of neuromuscular transmission and the contraction of a muscle.

Drug Effects on Postjunctional Receptors

Classic Actions of Nondepolarizing Muscle Relaxants

Neurotransmission occurs when acetylcholine released by the nerve action potential binds to AChRs. All NDMRs impair or block neurotransmission by competitively preventing the binding of acetylcholine to its receptor. The final outcome (i.e., block or transmission) depends on the relative concentrations of the chemicals and their comparative affinities for the receptor. Figure 14-5 shows a system exposed to acetylcholine and tubocurarine. One receptor has attracted two acetylcholine molecules and opened its channel, where current will flow to depolarize that segment of membrane. Another has attracted one tubocurarine molecule; its channel will not open, and no current will flow, even if one acetylcholine molecule binds to the other site. The third receptor has acetylcholine on one α-subunit and nothing on the other. What will happen depends on which of the molecules binds. If acetylcholine binds, the channel will open and the membrane will be depolarized; if tubocurarine binds, the channel will stay closed and the membrane will not be depolarized. At other times, one or two tubocurarine molecules may attach to the receptor, in which case the receptor is not available to agonists; no current flow is recorded. In the presence of moderate concentrations of tubocurarine, the amount of current flowing through the entire end plate at any instant is reduced from normal, which results in a smaller end-plate potential and, if carried far enough, a block in neurotransmission or production of neuromuscular paralysis.

Normally, acetylcholinesterase destroys acetylcholine and removes it from competition for a receptor, so tubocurarine has a better chance of inhibiting transmission. If, however, an inhibitor of acetylcholinesterase such as neostigmine is added, the cholinesterase cannot destroy acetylcholine. The concentration of agonist in the cleft remains high, and this high concentration shifts the competition between acetylcholine and tubocurarine in favor of the former, thereby improving the chance of two acetylcholine molecules binding to a receptor even though tubocurarine is still in the environment. Cholinesterase inhibitors overcome the neuromuscular paralysis produced by NDMRs by this mechanism. The channel opens only when acetylcholine attaches to both recognition sites. A single molecule of antagonist, however, is adequate to prevent depolarization of that receptor. This modifies the competition by biasing it strongly in favor of the antagonist. Mathematically, if the concentration of tubocurarine is doubled, the concentration of acetylcholine must be increased fourfold if acetylcholine is to remain competitive. Paralysis produced by high concentrations of antagonist is more difficult to reverse than that produced by low concentrations. After large doses of NDMRs, cholinesterase inhibitors may be ineffective until the concentration of relaxant in the perijunctional area decreases to a lower level by redistribution or elimination of the drug.

Classic Actions of Depolarizing Muscle Relaxants

Depolarizing relaxants, at least initially, simulate the effect of acetylcholine and can therefore be considered agonists despite the fact that they block neurotransmission after initial stimulation. Structurally, succinylcholine is two molecules of acetylcholine bound together. It is thus not surprising that it can mimic the effects of acetylcholine. Succinylcholine or decamethonium can bind to the receptor, open the channel, pass current, and depolarize the end plate. These agonists, similar to acetylcholine, attach only briefly; each opening of a channel is of very short duration, 1 millisecond or less. The response to acetylcholine, however, is over in milliseconds because of its rapid degradation by acetyl-

cholinesterase, and the end plate resets to its resting state long before another nerve impulse arrives. In contrast, the depolarizing relaxants characteristically have a biphasic action on muscle—an initial contraction, followed by relaxation lasting minutes to hours. Because they are not susceptible to hydrolysis by acetylcholinesterase, the depolarizing relaxants are not eliminated from the junctional cleft until after they are eliminated from plasma. The time required to clear the drug from the body is the principal determinant of how long the drug effect lasts. Whole-body clearance of the relaxant is very slow in comparison to acetylcholine, even when plasma cholinesterase is normal. Because relaxant molecules are not cleared from the cleft quickly, they react repeatedly with receptors, attaching to one almost immediately after separating from another, thereby repeatedly depolarizing the end plate and opening channels.

The quick shift from excitation of muscle contraction to blockade of transmission by depolarizing relaxants occurs because the end plate is continuously depolarized. This comes about as a result of juxtaposition of the edge of the end plate with the muscle membrane—a different kind of ion channel, the sodium channel, that does not respond to chemicals but opens when exposed to a transmembrane voltage change. The sodium channel is also a cylindrical transmembrane protein through which sodium ions can flow. Two parts of its structure act as gates that allow or stop the flow of sodium ions.[69] Both gates must be open if sodium is to flow through the channel; closing of either cuts off the flow. Because these two gates act sequentially, a sodium channel has three functional conformational states and can move progressively from one state to another (Fig. 14-6).

When the sodium channel is in its resting state, the lower gate (i.e., the time-dependent or inactivation gate) is open, but the upper gate (i.e., the voltage-dependent gate) is closed, and sodium ions cannot pass. When the molecule is subjected to a sudden change in voltage by depolarization of the adjacent membrane, the top gate opens, and because the bottom (time-dependent) gate is still open, sodium flows through the channel. The voltage-dependent gate stays open as long as the molecule is experiencing a depolarizing influence from the membrane around it; it will not close until the depolarization disappears. However, shortly after the voltage-dependent gate opens, the bottom gate closes and again cuts off the flow of ions. It cannot open again until the voltage-dependent gate closes. When depolarization of the end plate stops, the voltage-dependent gate closes, the time-dependent gate opens, and the sodium channel returns to its resting state. This whole process is short lived when depolarization occurs with acetylcholine. The initial response of a depolarizing muscle relaxant resembles that of acetylcholine, but because the relaxant is not hydrolyzed rapidly, depolarization of the end plate is not brief.

Depolarization of the end plate by the depolarizing relaxant initially causes the voltage gate in adjacent sodium channels to open, thereby producing a wave of depolarization that sweeps along the muscle and generates a muscle contraction. Shortly after the voltage-dependent gate opens, the time-dependent inactivation gate closes. Because the relaxant is not removed from the cleft, the end plate continues to be depolarized. Because the sodium channels immediately adjacent to the end plate are influenced by depolarization of the end plate, their voltage-dependent gates stay open and their inactivation gates stay closed. Since sodium cannot flow through a channel that has a closed inactivation gate, the perijunctional muscle membrane does not depolarize. When the flow of ions through sodium channels in the perijunctional zone stops because of closure of the inactivation gates, the channels downstream (beyond the perijunctional zone) are freed of depolarizing influence. In effect, the perijunctional zone becomes a buffer that shields the rest of the muscle from events at the end plate. Consequently, the muscle membrane is separated into three zones: the end plate, which is depolarized by succinylcholine; the perijunctional muscle membrane, in which the sodium channels are frozen in an inactivated state; and the rest of the muscle membrane, in which the sodium channels are in the resting state. Because a burst of acetylcholine from the nerve cannot overcome the inactivated sodium channels in the perijunctional zone, neuromuscular transmission is blocked. This phenomenon is also called *accommodation*. During accommodation, when the synapse is inexcitable through the nerve (transmitter), direct electrical stimulation of muscle causes muscle contraction because the sodium channels beyond the junctional area are in the resting excitable state.

The extraocular muscles contain tonic muscle, which is multiply innervated and chemically excitable along most of its surface.[20,21] Despite its innervation, the ocular muscles express both mature and fetal receptors.[20] Accommodation does not occur, and these muscles can undergo a sustained contracture in the presence of succinylcholine. The tension thus developed forces the eye against the orbit and accounts for part of the increase in intraocular pressure produced by depolarizing relaxants. There is also evidence that the extraocular muscles contain a special type of receptor that does not become desensitized (discussed later) during the continued presence of acetylcholine or other agonists.[21] Whether it is the immature γ-subunit AChR or the α7 AChR that plays a role in this resistance to desensitization in the ocular muscles is unknown.

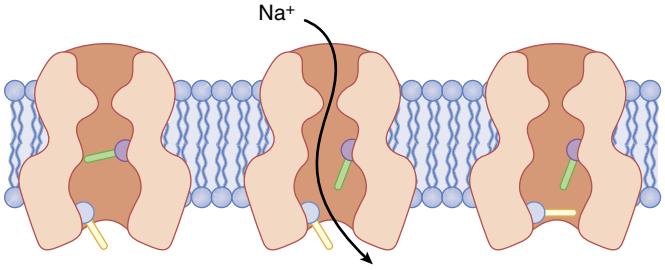

Figure 14-6 Sketch of a sodium channel. The *bars* represent parts of the molecule that act as gates. The *upper bar* is voltage dependent; the *lower bar* is time dependent. The left side of the drawing represents the resting state. Once activated by a change in voltage, the molecule and its gates progress as illustrated (left to right). See text for details.

Nonclassic and Noncompetitive Actions of Neuromuscular Drugs

Several drugs can interfere with the receptor, directly or through its lipid environment, and change transmission. These drugs react with the neuromuscular receptor to change its function and impair transmission but do not act through the acetylcholine binding site. These reactions cause drug-induced changes in the dynamics of the receptor, and instead of opening and closing sharply, the modified channels are sluggish. They open more slowly and stay open longer, or they close slowly and in several

steps, or both. These effects on channels cause corresponding changes in the flow of ions and distortions of the end-plate potential. The clinical effect depends on the molecular events. For example, procaine, ketamine, inhaled anesthetics, or other drugs that dissolve in the membrane lipid may change the opening or closing characteristics of the channel.[70,71] If the channel is prevented from opening, transmission is weakened. If, however, the channel is prevented from or slowed in closing, transmission may be enhanced. These drugs do not fit the classic model, and the impaired neuromuscular function is not antagonized by increasing perijunctional acetylcholine concentrations with cholinesterase inhibitors. Such drugs can be involved in two clinically important reactions: receptor desensitization and channel blockade. The former occurs in the receptor molecule, whereas the latter occurs in the ion channel.

Desensitization Block

The AChR, as a result of its flexibility and the fluidity of the lipid around it, is capable of existing in a number of conformational states.[68-73] Because the resting receptor is free of agonist, its channel is closed. The second state exists when two molecules of agonist are bound to the α-subunit of the receptor and the receptor has undergone the conformation change that opens the channel and allows ions to flow. These reactions are the bases of normal neuromuscular transmission. Some receptors that bind to agonists, however, do not undergo the conformational change to open the channel. Receptors in these states are called desensitized (i.e., they are not sensitive to the channel-opening actions of agonists). They bind agonists with exceptional avidity, but the binding does not result in opening of the channel. The mechanisms by which desensitization occurs are not known. The receptor macromolecule, 1000 times larger by weight than most drugs or gases, provides many places at which the smaller molecules may act. The interface between lipid and receptor protein provides additional potential sites of reaction. Several different conformations of the protein are known, and because acetylcholine cannot cause the ion channel to open in any of them, they all are included in the functional term *desensitization*. Some evidence suggests that desensitization is accompanied by phosphorylation of a tyrosine unit in the receptor protein.[74,75]

Although agonists (e.g., succinylcholine) induce desensitization, the receptors are in a constant state of transition between resting and desensitized states, regardless of whether agonists are present. Agonists do promote transition to a desensitized state or, because they bind very tightly to desensitized receptors, trap a receptor in a desensitized state. Antagonists also bind tightly to desensitized receptors and can trap molecules in these states. This action of antagonists is not competitive with that of acetylcholine; it may be augmented by acetylcholine if the latter promotes the change to a desensitized state. Desensitization can lead to significant misinterpretation of data. Superficially, the preparation seems to be normal, but its responsiveness to agonists or antagonists is altered. One variety occurs very rapidly, within a few milliseconds after application of an agonist. This may explain the increased sensitivity to nondepolarizers after prior administration of succinylcholine. There is also a phenomenon caused by prolonged administration of depolarizing relaxants that is known as *phase II block* (see "Phase II Block"). It is frequently referred to as a desensitization block but should not be because desensitization of receptors is only one of many phenomena that contribute to the process.

Many other drugs used by anesthetists also promote the shift of receptors from a normal state to a desensitized state.[70-73] These drugs, some of which are listed in Box 14-1, can weaken neuromuscular transmission by reducing the margin of safety that normally exists at the neuromuscular junction, or they can cause an apparent increase in the capacity of nondepolarizing agents to block transmission. These actions are independent of the classic effects based on competitive inhibition of acetylcholine. The presence of desensitized receptors means that fewer receptor channels than usual are available to carry transmembrane current. The production of desensitized receptors decreases the efficacy of neuromuscular transmission. If many receptors are desensitized, insufficient normal ones are left to depolarize the

Box 14-1 Drugs That Can Cause or Promote Desensitization of Nicotinic Cholinergic Receptors

- Volatile anesthetics
  - Halothane
  - Sevoflurane
  - Isoflurane
- Antibiotics
  - Polymyxin B
- Cocaine
- Alcohols
  - Ethanol
  - Butanol
  - Propanol
  - Octanol
- Barbiturates
  - Thiopental
  - Pentobarbital
- Agonists
  - Acetylcholine
  - Decamethonium
  - Carbachol
  - Succinylcholine
- Acetylcholinesterase inhibitors
  - Neostigmine
  - Pyridostigmine
  - Difluorophosphate
  - Edrophonium
- Local anesthetics
  - Dibucaine
  - Lidocaine
  - Prilocaine
  - Etidocaine
- Phenothiazines
  - Chlorpromazine
  - Trifluoperazine
  - Prochlorperazine
- Phencyclidine
- Calcium channel blockers
  - Verapamil

motor end plate, and neuromuscular transmission will not occur. Even if only some receptors are desensitized, neuromuscular transmission will be impaired, and the system will be more susceptible to block by conventional antagonists such as tubocurarine or pancuronium.

Channel Block

Local anesthetics and calcium entry blockers prevent the flow of sodium or calcium through their respective channels, thus explaining the term *channel-blocking drugs*. Similarly, block of the flow of ions can occur at the AChR with concentrations of drugs used clinically and may contribute to some of the phenomena and drug interactions seen at the receptor. Two major types, closed-channel and open-channel block, can occur.[76,77] In a closed-channel block, certain drugs can occupy the mouth of the channel and prevent ions from passing through the channel to depolarize the end plate. The process can take place even when the channel is not open. In an open-channel block, a drug molecule enters a channel that has been opened by reaction with acetylcholine but does not necessarily penetrate all the way through. Open-channel blockade is a use-dependent block, which means that molecules can enter the channel only when it is open. In open- and closed-channel blocks, the normal flow of ions through the receptor is impaired, thereby resulting in prevention of depolarization of the end plate and a weaker or blocked neuromuscular transmission. However, because the action is not at the acetylcholine recognition site, it is not a competitive antagonism of acetylcholine and is not relieved by anticholinesterases that increase concentrations of acetylcholine. Increasing the concentration of acetylcholine may cause the channels to open more often and consequently become more susceptible to blockade by use-dependent compounds. There is evidence that neostigmine and related cholinesterase inhibitors can act as channel-blocking drugs.[76]

Channel block is believed to play a role in some of the antibiotic, cocaine, quinidine, piperocaine, tricyclic antidepressant, naltrexone, naloxone, and histrionicotoxin-induced alterations in neuromuscular function. Muscle relaxants, in contrast, can bind to the acetylcholine recognition site of the receptor and occupy the channel. Pancuronium preferentially binds to the recognition site. Gallamine seems to act equally at the two sites. Tubocurarine is in between; at low doses, those that produce minimal blockage of transmission clinically, the drug is essentially a pure antagonist at the recognition site; at larger doses, it also enters and blocks channels. Decamethonium and succinylcholine, as agonists, can open channels and, as slender molecules, also enter and block them. Decamethonium and some other long, thin molecules can penetrate all the way through the open channel and enter the cytoplasm of muscle cells. Whether prolonged administration of NDMRs, as in the intensive care situation, can result in entry of the relaxant, occupation of the channel, and entry of drug into the cytosol is unknown. This effect may partially explain the muscle weakness associated with relaxant therapy in the intensive care unit.

Phase II Block

A phase II block is a complex phenomenon that occurs slowly at junctions continuously exposed to depolarizing agents. The junction is depolarized by the initial application of a depolarizing relaxant, but then the membrane potential gradually recovers toward normal, even though the junction is still exposed to drug. Neuromuscular transmission usually remains blocked throughout the exposure. Several factors are involved. The repeated opening of channels allows a continuous efflux of potassium and influx of sodium, and the resulting abnormal electrolyte balance distorts the function of the junctional membrane. Calcium entering the muscle through the opened channels can cause disruption of receptors and the sub–end-plate elements themselves. The activity of the sodium-potassium adenosine triphosphatase pump in the membrane increases with increasing intracellular sodium and, by pumping sodium out of the cell and potassium into it, works to restore the ionic balance and membrane potential toward normal. As long as the depolarizing drug is present, the receptor channels remain open and ion flux through them remains high.[78]

Factors influencing the development of a phase II block include the duration of exposure to the drug, the particular drug used and its concentration, and even the type of muscle (i.e., fast or slow twitch). Interactions with anesthetics and other agents also affect the process. All of these drugs may also have prejunctional effects on the rate and amount of transmitter released and mobilized. With so many variables involved in the interference with neuromuscular transmission, a phase II block is a complex and ever-changing phenomenon. The reversal response of a phase II block produced by a depolarizing muscle relaxant to administration of cholinesterase inhibitors is difficult to predict. It is therefore best that reversal by cholinesterase inhibitors not be attempted, although the response to tetanus or train-of-four stimulation resembles that produced by nondepolarizers.

Biology of Prejunctional and Postjunctional Nicotinic Acetylcholine Receptors

Postjunctional Conventional Acetylcholine Receptors in Muscle versus Neuronal Acetylcholine Receptors in Muscle

Currently, three variants of postjunctional AChRs have been identified. The AChR isoform present in the innervated, adult neuromuscular junction is referred to as the adult, mature, or junctional receptor. Another AChR isoform is expressed when there is decreased activity in muscle, as seen in the fetus before innervation or after chemically or physically induced immobilization; after lower or upper motor neuron injury, burns, or sepsis; or after other events that cause increased muscle protein catabolism, including sepsis or generalized inflammation.[1-3] To contrast with the mature or junctional receptors, the other isoform is referred to as the immature, extrajunctional, or fetal form of AChR. Some evidence suggests that the immature isoform is not seen in the muscle protein catabolism and wasting that occur with malnutrition.[79] Differences in the protein structure of the two isoforms cause significant qualitative variations in the responses of individual patients to relaxants and seem to be responsible for some of the anomalous results observed when administering relaxants to particular individuals. These qualita-

tive differences in isoforms can also cause variations in function of the muscle.[52,53]

In addition to their structural compositions, the two isoforms have other characteristics that are different.[1-3,31] At the molecular level, both types of receptors consists of five subunits (see Fig. 14-4). The mature junctional receptor is a pentamer of two α-subunits and one each of the β-, δ-, and ε-subunits. The immature receptor consists of two α-subunits and one each of the β-, δ-, and γ-subunits; that is, in the immature receptor the γ-subunit is present instead of the ε-subunit. The γ- and ε-subunits differ from each other very little in amino acid homology, but the differences are great enough to affect the physiology and pharmacology of the receptor and its ion channel. Although the names junctional and extrajunctional imply that each is located in the junctional and extrajunctional areas, this is not strictly correct. Junctional receptors are always confined to the end plate (perijunctional) region of the muscle membrane. The immature, or extrajunctional, receptor may be expressed anywhere in the muscle membrane. Despite the name extrajunctional, they are not excluded from the end plate. During development and in certain pathologic states, junctional and extrajunctional receptors can coexist in the perijunctional area of the muscle membrane (Fig. 14-7).

Quite in contrast to the conventional muscle AChRs consisting of α1, β1, δ, and ε/γ subunits described earlier, receptors formed of α7 AChR subunits have recently been found in skeletal muscle during development and denervation.[80,81] Preliminary evidence (Martyn JAJ, abstract ASA 2007) suggests increased protein expression (by Western blotting) of α7 AChRs in muscle after burn injury and immobilization. These α7 AChRs are homomeric (i.e., formed of the same subunits) channels arranged as pentameres (see Fig. 14-4). Ligand (drug) binding pockets are thought to be formed at negative and positive faces of the α7-subunit assembly interphases. As expected, the endogenous agonist acetylcholine binds to α7 AChRs, and each of the five subunits has the potential to bind acetylcholine or succinylcholine molecules.[82,83] Other agonists, including nicotine and choline, and antagonists, including muscle relaxants, pancuronium, cobra toxin, and α-bungarotoxin, also bind to the α7 AChR.[81-83]

The α7 AChRs in muscle display unusual functional and pharmacologic characteristics when compared with conventional muscle (α1, β1, δ, ε/γ) AChRs or neuronal α7 AChRs in the brain. Choline, a precursor and metabolite of acetylcholine (and succinylcholine), is an extremely weak agonist of conventional muscle AChRs but is a full agonist of muscle α7 AChRs; that is, concentrations of choline that do not open conventional AChR channels will open α7 AChR channels.[81] Furthermore, no desensitization of the α7 AChR occurs even during the continued presence of choline,[81] thus allowing a greater chance for potassium to efflux from within the cell (approximately 145 mEq/L in the cell) to the extracellular space, including plasma (approximately 4.5 mEq/L), down its concentration gradient. The chemical α-conotoxin GI specifically inhibits the conventional (mature and immature) AChRs in muscle but does not inhibit α7 AChRs. Muscle α7 AChRs are different from neuronal (autonomic ganglia and brain) α7 AChRs in that the former are not strongly inhibited by methyllycaconitine, a selective antagonist of neuronal α7 AChRs. The α7 AChRs expressed in neuronal tissue are also readily desensitized with choline,[83] a feature that contrasts with muscle α7 AChRs, which do not desensitize with choline.[81] The α7 AChR in muscle also has lower affinity for its antagonists, including pancuronium

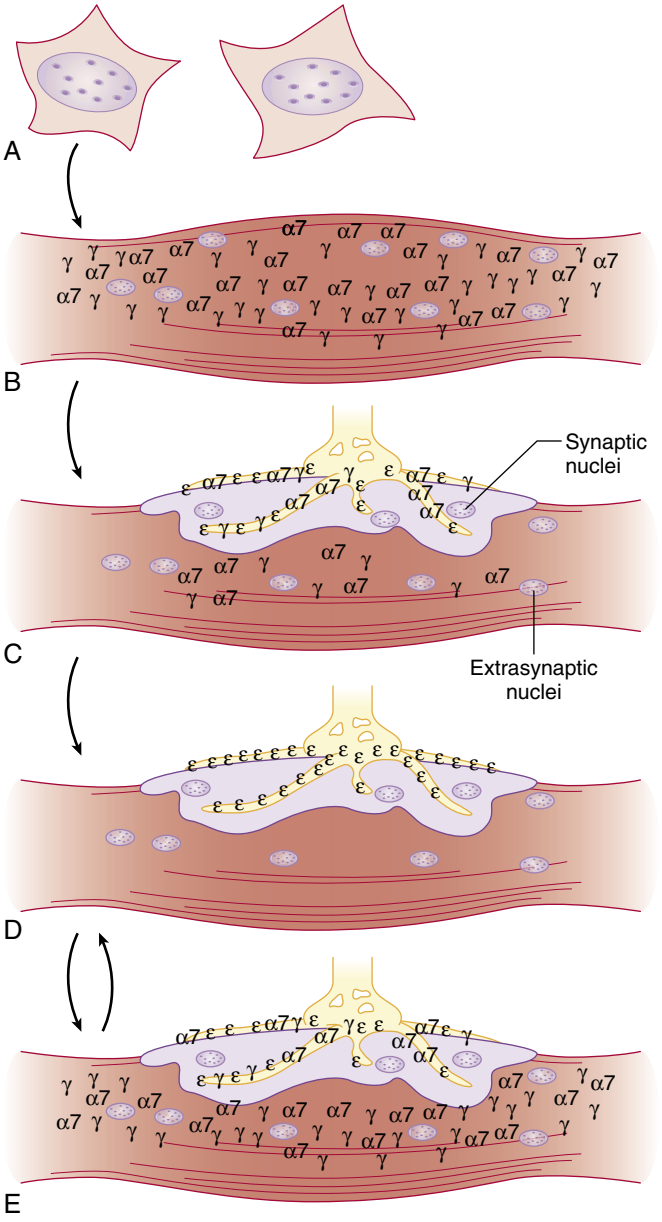

Figure 14-7 Distribution of acetylcholine receptors in developing adult, mature, denervated muscle or in immobilized or inflammation-induced catabolic muscle. **A** and **B,** In the early fetal stage, mononucleated myoblasts, derived from the mesoderm, fuse with each other to form multinucleated myotubes. The γ-subunit–containing immature acetylcholine receptors and the neuronal α7 acetylcholine receptors are scattered throughout the muscle membrane before innervation. **C,** As the nerve makes contact with muscle, clustering of the receptors occurs at the synapse and is associated with some loss of extrasynaptic receptors. **D,** Maturation of the junction is said to occur when ε-subunit–containing receptors replace the γ-subunit– and α7-containing acetylcholine receptors at the neuromuscular junction. Even mature muscle is multinucleated, but it is devoid of extrasynaptic acetylcholine receptors. **E,** Denervation and some other pathologic states, even without anatomic denervation (e.g., burns, immobilization, chronic muscle relaxant therapy, stroke, sepsis), lead to re-expression of the γ-subunit– and α7-containing acetylcholine receptors at the junctional and extrajunctional areas. The latter changes are potentially reversible if muscle immobilization/catabolism/inflammation is restored to normal.

and α-bungarotoxin; higher concentrations of these drugs are therefore required to block agonist-induced depolarization in α7 AChRs than in conventional muscle AChRs (α1, β1, δ, ε/γ).[81] In the conventional AChRs, binding of even one of the α1-subunits by an antagonist results in inactivation of that receptor because acetylcholine needs both α1-subunits of the AChR for its activation. In the α7 AChR, however, even when three subunits are bound by an antagonist (e.g., muscle relaxant), two other subunits are still available for binding to agonist and causing depolarization. This feature may account for the resistance of α7 AChRs, as opposed to conventional AChRs, to the blocking effects of drugs such as pancuronium.[2]

The clinical pharmacology of the muscle α7 AChR has not been studied yet, but its basic pharmacology provides some insight into succinylcholine-related hyperkalemia. Chemical or physical denervation of muscle results in not only upregulation and qualitative (ε-subunit → γ-subunit) changes in AChRs but also upregulation of α7 AChRs in muscle. Succinylcholine, a synthetic analog of acetylcholine that consists of two molecules of acetylcholine joined together, is capable of depolarizing not only conventional AChRs but also α7 AChRs in muscle.[83] In addition, the metabolite of succinylcholine, choline, can depolarize α7 AChRs with little desensitization. The depolarizing effects of succinylcholine and choline on the upregulated α7 AChRs can result in continued leakage of intracellular potassium and flooding of extracellular fluid, including plasma, thereby leading to hyperkalemia.

Maintenance of Mature Neuromuscular Junctions

Quite unlike other cells, muscle cells are unusual in that they have many, usually hundreds, of nuclei per cell. Each of these nuclei has the genes to make both types of receptors. Multiple factors, including electrical activity, growth factor signaling (e.g., insulin, agrin, neuregulins), and the presence or absence of innervation, control expression of the three types of receptor isoforms.[19,31] This is most clearly seen in the developing embryo as the neuromuscular junction is formed. Before they are innervated, the muscle cells of a fetus synthesize only immature and α7 AChRs—hence the term fetal isoform for the former receptor. Synthesis is directed by nearly all the nuclei in the cell, and the receptors are expressed throughout the membrane of the muscle cell (see Fig. 14-7). As the fetus develops and the muscles become innervated, muscle cells begin to synthesize the mature isoform of receptors, which are inserted exclusively into the developing (future) end-plate area. The nerve releases several growth factors that influence the synthetic apparatus of the nearby nuclei. First, nerve-supplied factors induce the subsynaptic nuclei to increase synthesis of AChRs. Next, the nerve-induced electrical activity results in repression of receptors in the extrajunctional area. Nerve-derived growth factors, including agrin and ARIA/neuregulin, cause the receptors to cluster in the subsynaptic area and prompt expression of the mature isoform (Fig. 14-8).[62-65] In conditions associated with insulin resistance, there seems to be a proliferation of AChRs beyond the junctional area. Conditions in which insulin resistance (i.e., decreased growth factor signaling) has been observed include immobilization, burns, and denervation.[84-86] In such conditions, there is associated upregulation of AChRs and

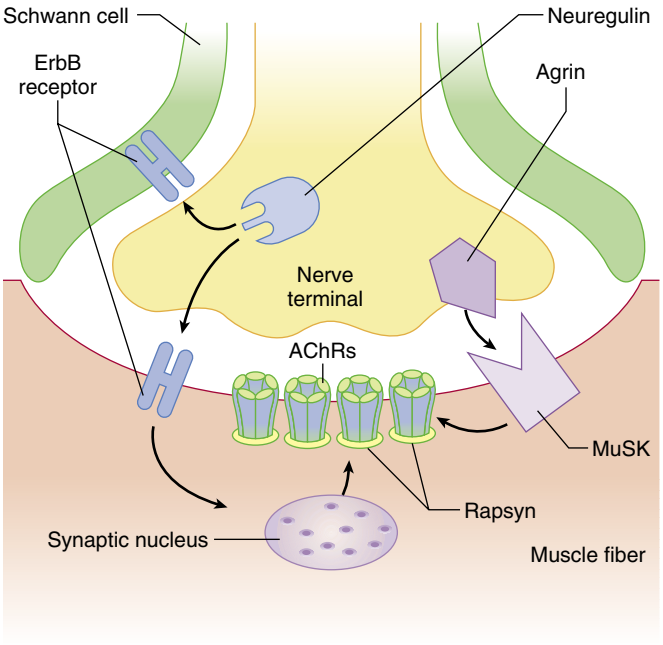

Figure 14-8 Diagram of agrin- and ARIA (acetylcholine receptor–inducing activity)/neuregulin-dependent events during maturation of the neuromuscular junction. After establishment of a nerve on the muscle, growth factors, including agrin and neuregulins, are released. Neuregulin signaling is essential for Schwann cell survival, and Schwann cells are essential for axonal maintenance. Agrin interacting with its receptor MuSK (muscle-specific kinase) enhances the clustering of synaptic proteins, including acetylcholine receptors (AChRs), rapsyn, and ErbB receptors. ARIA/neuregulin is the best candidate for involvement in the conversion of γ-subunit–containing immature receptor to ε-subunit–containing mature (innervated) receptor, which is synapse specific and therefore not inserted in the extrajunctional area.

expression of the immature and α7 AChR isoforms.[1-3] Therefore, agrin and neuregulin signaling may be important for suppression of α7 AChRs.

Before innervation, AChRs are present throughout the muscle membrane. After innervation, AChRs become more and more concentrated at the postsynaptic membrane and are virtually absent in the extrasynaptic area at birth. The innervation process progresses somewhat slowly during fetal life and matures during infancy and early childhood.[15,27,33] With time, the immature receptors diminish in concentration and disappear from the peripheral part of the muscle. In active, adult, normal innervated muscle, just the nuclei under and very near the end plate direct the synthesis of receptor; only the genes for expressing mature receptors are active. Nuclei beyond the junctional area are not active, and therefore no receptors are expressed anywhere in the muscle cells beyond the perijunctional area. Conversion of all of the γ-subunit– to ε-subunit–containing AChRs in the perijunctional area continues to take place after birth. In the rodent, it takes about 2 weeks.[15] In humans, this process takes longer. The timeframe for disappearance of α7 AChRs in the fetus or newborn is also unknown.

At birth, the postsynaptic membrane itself is also not as specialized; the newborn junction has simplified synaptic folds, a widened synaptic space, and reduced numbers of AChRs. Morphologically, the postsynaptic membrane of the newborn and that from a patient with myasthenia gravis are not too different. In

patients with myasthenia gravis, receptor numbers are usually decreased because of autoantibodies directed against the AChR.[4] It is not surprising, therefore, that neurotransmission is not as efficient in the newborn and patients with myasthenia gravis. A child is usually about 2 years old before nerve-muscle contacts are mature.[27]

Proteins implicated in linking of mature receptors to the cytoskeleton include utrophin, α- and β-dystroglycan, and rapsyn. Several lines of evidence indicate that clustering, expression, and stabilization of mature receptors are triggered by at least two growth factors: agrin, neuregulin/ARIA, and possibly calcitonin gene–related peptide.[62-65] Neuregulin and agrin are also released from muscle, but muscle-derived agrin does not seem to be as important in clustering and maturation of the receptor. ARIA is made in the nerve and seems to play a role in maturation of vesicular arrangement and conversion of the γ-to-ε switch.[65] All of these growth factors interact with distinct membrane and cytosolic receptor proteins to cause phosphorylation and activation of nuclear (gene) transcriptional systems. Agrin signals through MuSK and neuregulins through ErbB receptors (see Fig. 14-8). These receptors control qualitative and quantitative changes at the junction. Once begun, the process is very stable, and nuclei in the junctional area continue to express mature receptors.

Re-expression of Immature (Fetal) γ-Subunit and α7-Subunit AChRs in Adult Life

The extrajunctional immature receptors can reappear soon after upper and lower motor denervation and in certain pathologic states (e.g., burns, immobilization, chronic muscle relaxant therapy, loss of electrical activity). Stimulation of a denervated muscle with an external electrical stimulus can prevent the appearance of immature receptors. It has been suggested that the calcium that enters the muscle during activity is important in the suppression process.[16,17] In the pathologic states previously enumerated, if the process is severe and prolonged, extrajunctional receptors are inserted all over the surface of the muscle, including the perijunctional area (see Fig. 14-7). The junctional nuclei also continue to make mature receptors. The end plates consist of mature and immature receptors. The synthesis of immature receptors is initiated within hours of inactivity, but it takes several days for the whole muscle membrane to be fully covered with receptors. This upregulation of receptors has implications for the use of depolarizing and nondepolarizing relaxants. The changes in α7 AChRs seem to parallel the expression of immature receptors, although this has not been well studied.

The changes in subunit composition (γ versus ε) in the receptor confer certain changes in electrophysiologic (functional), pharmacologic, and metabolic characteristics.[1,33] Mature receptors are metabolically stable, with a half-life approximating 2 weeks, whereas immature receptors have a metabolic half-life of less than 24 hours. Immature receptors have a smaller single-channel conductance and a 2- to 10-fold longer mean channel open time than mature receptors do (see Fig. 14-4). The changes in subunit composition may also alter the sensitivity or affinity, or both, of the receptor for specific ligands. Depolarizing or agonist drugs such as succinylcholine and acetylcholine depolarize immature receptors more easily, thereby resulting in cation fluxes; doses one tenth to one hundredth of those needed for mature receptors can effect depolarization.[2] The potency of nondepolarizers is also reduced, as demonstrated by the resistance to nondepolarizers documented in patients with burns, denervation, and immobilization.[1,3] This resistance may be related to decreased affinity of the immature and α7 AChRs to NDMRs and to the upregulation of receptors in the perijunctional area. Data suggest that some NDMRs may also cause a partial agonist response in immature receptors, thus explaining the decreased potency.[7] The altered sensitivities for cholinergic ligands may also result from changes in composition of the lipid membrane surrounding the receptor that is known to occur in some pathologic states.[68]

The altered sensitivity to muscle relaxants may occur in just certain parts of the body or certain muscles if only some muscles are affected by the diminution in nerve activity (e.g., after a stroke). Sensitivity to relaxants can begin to change between 24 and 72 hours after an injury or hospitalization. The most serious side effect with the use of succinylcholine in the presence of upregulated AChRs in one or more muscles is hyperkalemia.[1-3] In these subjects, the receptors can be scattered over a large surface of the muscle. The AChR channels opened by the agonist (succinylcholine) allow potassium to escape from the muscle and enter the blood. If a large part of the muscle surface consists of upregulated (immature) receptor channels, each of which stays open for a longer time, the amount of potassium that moves from muscle to blood can be considerable. The resulting hyperkalemia can cause dangerous disturbances in cardiac rhythm, including ventricular fibrillation. Moreover, it is difficult to prevent the hyperkalemia by prior administration of NDMRs because the extrajunctional receptors are not very sensitive to blockade by NDMRs in the usual doses.[1] Larger than normal doses of NDMRs may attenuate the increase in blood potassium but cannot completely prevent it. However, hyperkalemia and cardiac arrest can occur after the administration of succinylcholine, even in the absence of denervation states. This is seen in certain congenital muscle dystrophies in which the muscle membrane is prone to damage by the potassium released into the circulation by succinylcholine.[87]

Prejunctional Acetylcholine Receptors

AChRs exist in a variety of forms apart from that seen in muscle.[6,88] These receptors are expressed in peripheral neurons, autonomic and sensory ganglia, and the central nervous system. There is also direct and indirect evidence of their existence in lymphocytes, fibroblasts, chondrocytes, macrophages, and granulocytes.[14] Diverse genes encode the heterogeneous AChRs, and the ion channel is formed of multiple subunits (multimers). Seventeen AChR genes have been cloned from vertebrates. They include various combinations of α-subunits (α1 through α10) and β-subunits (β1 through β4) and one each of γ-, δ-, and ε-subunits. The γ-, δ-, and ε-subunits are found only in muscle.

Prejunctional or nerve terminal–associated cholinergic receptors have been demonstrated pharmacologically and by molecular biologic techniques, but their form and functions are not as completely understood as those in the postjunctional area. Many drugs with an abundance of potential targets for drug action can affect the capacity of the nerve terminal to carry out its functions. The trophic function to maintain nerve-muscle contact involves release and replenishment of acetylcholine together with trophic factors that require signaling through many

receptors, of which the prejunctional nicotinic AChR is just one. Succinylcholine produces fasciculations that can be prevented by NDMRs. Because a fasciculation is, by definition, the simultaneous contraction of the multitude of muscle cells in a single motor unit and because only the nerve can synchronize all the muscles in its motor unit, it became apparent that succinylcholine must also act on nerve endings also. Because NDMRs prevent fasciculation, it was concluded that they acted on the same prejunctional receptor. Since then it has been shown many times that very small doses of cholinergic agonists (e.g., succinylcholine) and antagonists (e.g., NDMRs) affect nicotinic receptors on the nerve ending, the former by depolarizing the ending and sometimes inducing repetitive firing of the nerve and the latter by preventing the action of agonists.[6]

Another clue to differences between prejunctional and postjunctional AChRs was the finding that prejunctional AChRs can bind β-bungarotoxin only, whereas postjunctional receptors can also bind to α-bungarotoxin. Additional clues were found in the many demonstrations of quantitative differences in the reaction of prejunctional and postjunctional nicotinic receptors to cholinergic agonists and antagonists.[82,88] For instance, it was known that tubocurarine binds very poorly to the recognition sites of ganglionic nicotinic cholinoceptors and is not a competitive antagonist of acetylcholine at this site. Decamethonium is a selective inhibitor of the muscle receptor, and hexamethonium is a selective inhibitor of nicotinic receptors in the autonomic ganglia.[89,90] Instead, D-tubocurarine and hexamethonium can block the opened channels of these receptors and owe their ability to block ganglionic transmission to this property. The functional characteristics of prejunctional receptor channels may also be different. For example, the depolarization of motor nerve endings initiated by administration of acetylcholine can be prevented by tetrodotoxin, a specific blocker of sodium flux with no effect on the end plate.

Specific information on the molecular organization of neuronal nicotinic receptors on the motor neuron terminal is still lacking. Some of the subunit composition is similar, but other subunits do not resemble those of the postjunctional receptor. Of the 16 different nicotinic AChR gene products identified, only 12 (α2 to α10 and β2 to β4) are thought to contribute nicotinic receptors expressed on neurons. Most strikingly, nervous tissue does not contain genes for γ-, δ-, or ε-receptor subunits; it contains genes only for the α- and β-subunits. The α- and β-subunit genes in nerve and muscle are not exactly the same; they are variants. Muscle contains the genes for each of the α1 and α7 subunits. In contrast, nervous tissue does not contain α1 subunit gene but instead contains a number of related genes designated α2 through α10. To emphasize the distinction between neural and muscle nicotinic receptors, the former are sometimes designated Nn and the latter Nm. With so many different subunits available, there are many possible combinations, and it is not known which combinations are found in motor nerves. Their physiologic roles have also not been completely characterized. Expression of neuronal nicotinic AChRs in in vitro systems has confirmed that muscle relaxants and their metabolites can bind to some of these neuronal AChRs.[89,90]

The nicotinic receptor on the junctional surface of the nerve senses transmitter in the cleft and, by means of a positive-feedback system, causes the release of more transmitter. In other parts of the nervous system, this positive feedback is complemented by a negative-feedback system that senses when the concentration of transmitter in the synaptic cleft has increased appropriately and shuts down the release system. It is believed that tetanic fade and train-of-four fade during neuromuscular blockade with NDMRs arise from presynaptic cholinergic autoreceptors at the motor nerved ending.[58,59] The neuronal AChR subtype on the nerve terminal that causes fade has been identified as α3β2.[90-93] Quite in contrast, succinylcholine does not inhibit the presynaptic α3β2 autoreceptor at clinically relevant concentrations.[59,93] This may be reason for the typical lack of fade during succinylcholine-induced neuromuscular block. Succinylcholine, however, does not interact with α3β4 AChR found in autonomic ganglia.[59] It has also been shown that NDMRs reduce the hypoxic ventilatory response in partially paralyzed humans,[94] and the mechanism behind the depression might be related to inhibition of nicotine receptors on the carotid body.[9] The motor nerve terminal is also known to bear several other receptors, such as opioid, adrenergic, dopamine, purine, and adenosine receptors, as well as receptors for endogenous hormones, neuropeptides, and a variety of proteins. The physiologic roles of these receptors and the effects of anesthetics on them are unknown.

Antagonism of Neuromuscular Blockade

Mechanism of Antagonism

The NDMRs block neuromuscular transmission predominantly by competitive antagonism of acetylcholine at the postjunctional receptor. The most straightforward way to overcome their effects is to increase the competitive position of acetylcholine. Two factors are important, the first of which is the concentration of acetylcholine. Increasing the number of molecules of acetylcholine in the junctional cleft changes the agonist-to-antagonist ratio and increases the probability that agonist molecules will occupy recognition sites of the receptor. It also increases the probability that an unoccupied receptor will become occupied. Normally, only about 500,000 of the 5 million available receptors are activated by a single nerve impulse, and a large number of receptors are in "reserve" and could be occupied by an agonist. The second factor important to the competitive position of acetylcholine is the length of time that acetylcholine is in the cleft. Acetylcholine must wait for the antagonist to dissociate spontaneously before it can compete for the freed site. NDMRs bind to the receptor for slightly less than 1 millisecond, which is longer than the normal lifetime of acetylcholine. The destruction of acetylcholine normally takes place so quickly that most of it is destroyed before any significant number of antagonist molecules have dissociated from the receptor. Prolonging the time during which acetylcholine is in the junction allows time for the available acetylcholine to bind to receptor when the antagonist dissociates from the receptors.

Classes of Drugs Used

Three classes of drugs, potassium channel–blocking drugs, acetylcholinesterase inhibitors, and γ-cyclodextrin derivatives, can be used clinically to reverse nondepolarizer-induced

paralysis.[95,96] The best known of the potassium-blocking drugs is 4-aminopyridine. Its actions are predominantly prejunctional; it impedes efflux of potassium from the nerve ending. Because efflux of potassium is the event that normally ends the action potential of the nerve ending, this action prolongs depolarization of the nerve. Because the flux of calcium into the nerve continues for as long as the depolarization lasts, drugs of this class indirectly increase the flux of calcium into the nerve ending. The nerve releases more acetylcholine and for a longer time than usual, conditions that are effective in antagonizing NDMRs. Because they act prejunctionally, these drugs can antagonize a block produced by certain antibiotics that act on the nerve ending, notably the polymyxins. Although 4-aminopyridine and drugs like it can be used clinically, their use is severely restricted because they are not specific. They affect the release of transmitters by all nerve endings, including motor nerves, autonomic nerves, and central nervous system components. Their use is accompanied by a variety of undesirable effects, and in practice they are used only in special circumstances. A most serious side effect of potassium channel blockers is seizures.

The more commonly used antagonists of neuromuscular block (e.g., neostigmine, pyridostigmine, edrophonium) inhibit acetylcholinesterase by mechanisms that are similar but not identical.[95] Neostigmine and pyridostigmine are attracted by an electrostatic interaction between the positively charged nitrogen in the molecules and the negatively charged catalytic site of the enzyme. This produces a carbamylated enzyme that is not capable of further action (i.e., the catalytic site is blocked and the enzyme is inhibited). Edrophonium has neither an ester nor a carbamate group, but it is attracted and bound to the catalytic site of the enzyme by the electrostatic attraction between the positively charged nitrogen in the drug and the negatively charged acetylcholinesterase site of the enzyme. Edrophonium also seems to have prejunctional effects that enhance release of acetylcholine from the nerve terminal. This effect is therefore useful when deep neuromuscular block needs reversal. Of the three commonly used anticholinesterases, edrophonium shows far greater selectivity than acetylcholinesterase and butyrylcholinesterase, the serum esterase that hydrolyzes succinylcholine and mivacurium. It greatly favors the former enzyme and therefore seems to be the most desirable agent to reverse mivacurium. However, if the patient has normal serum esterase, pharmacokinetic factors are the principal determinants of the duration of block, and the activity of serum esterase or the lack of it plays only a minor role in recovery. There is little reason to prefer one or another reversal drug on these grounds. Anticholinesterases are administered for prolonged periods for the treatment of myasthenia gravis[4] and as prophylaxis in cases of nerve gas poisoning.[54,55] Ironically, prolonged administration of cholinesterase inhibitors can also lead to a myasthenia-like state with muscle weakness.[97]

Cholinesterase inhibitors act preferentially at the neuromuscular junction but also act at other synapses that use the same transmitter, including muscarinic receptors. An atropine-like drug should be administered with the cholinesterase inhibitor to counter the effects of the acetylcholine that accumulates in the muscarinic synapses of the gut, bronchi, and cardiovascular system. The three anticholinesterase inhibitors do not affect synapses in the central nervous system because all are quaternary ammonium ions that do not easily penetrate the blood-brain barrier. A quaternary ammonium derivative of atropine such as glycopyrrolate, which does not diffuse through the blood-brain barrier, is frequently used to limit the anticholinergic effects to the periphery. Other cholinesterase inhibitors, notably physostigmine and tacrine, are not quaternary ammonium compounds and they have profound effects on the central nervous system. They may be antagonized by atropine but not by its quaternary ammonium analog derivatives. Unlike the other cholinesterase inhibitors, physostigmine and tacrine are also potent inhibitors of the enzyme phosphodiesterase, which plays an important role in the regulation of transmitter release at many synapses in the central nervous system. This action may be related to the reported efficacy of these two drugs in the treatment of Alzheimer's dementia.

Cholinesterase inhibitors also have actions at the postjunctional membrane independent of their effects on the enzyme. Several of these compounds contain methyl groups on a positively charged nitrogen, and they can act as agonists on receptor channels by initiating flow of ions and enhancing neuromuscular transmission. Neostigmine, physostigmine, and certain organophosphates can increase the frequency of MEPPs and the quantal content of end-plate potentials, but the importance of the increased release of transmitter to reversal of neuromuscular blockade is not clear. Continuous exposure to carbamate- or organophosphate-containing inhibitors causes degeneration of prejunctional and postjunctional structures, apparently because these structures accumulate toxic amounts of calcium.[54,55] Calcium channel blockers such as verapamil prevent the neural actions of these drugs. All the drugs of this class also act in or on receptors to influence the kinetics of the open-close cycle and block the ion channel.[76,77] The clinical significance of the drugs on reversal of NDMRs is not known.

A new approach to reversing residual neuromuscular blockade is by direct binding of the relaxant by means of chemical interaction. Antidote drugs that work by binding other drugs include protamine, citrate anticoagulation, lead or copper chelators, and RNA molecules recombinantly engineered to bind drugs. Cyclodextrins (i.e., small, cyclic polysaccharides) are one such compound synthesized from starch by bacteria as early as 1891. The γ-cyclodextrin derivative ORG25969 (sugammadex) binds steroidal relaxants with very high affinity, which results in inactive muscle relaxants. The kidney then removes these complexes. Sugammadex has the potential to dramatically change clinical patterns of use of neuromuscular blocking drugs and their antagonists (i.e., neostigmine).[96]

15 Respiratory Physiology

Key Points

1. Removal of CO_2 is determined by alveolar ventilation, not by total, minute ventilation.
2. Dead space ventilation can be dramatically increased in patients with chronic obstructive pulmonary disease and pulmonary embolism to more than 80% to 90% of minute ventilation in the extreme case.
3. Breathing at low lung volume increases airway resistance and promotes closure of airways.
4. Hypoxemia can be caused by alveolar hypoventilation, diffusion impairment, ventilation-perfusion mismatch, and right-to-left shunt.
5. Almost all anesthetics reduce muscle tone, which in turn lowers functional residual capacity (FRC) to close to awake residual volume.
6. Lowered FRC during anesthesia together with ventilation with a high O_2 concentration causes atelectasis.
7. Preoxygenation before and during induction of anesthesia is a major cause of atelectasis.
8. General anesthesia causes ventilation-perfusion mismatch (airway closure) and shunt (atelectasis).
9. Hypoxic pulmonary vasoconstriction is blunted by most anesthetics, thereby enhancing any ventilation-perfusion mismatch.
10. Respiratory work is increased during anesthesia, a consequence of reduced respiratory compliance (reduced lung volume available for ventilation?) and increased airway resistance (lowered FRC and subsequent decrease in airway dimensions?).

Respiratory Function in Waking Subjects

The major task of the lung is to oxygenate the blood and eliminate carbon dioxide from it. This is accomplished by exchanging gas between alveoli and pulmonary capillary blood. Air is brought down to the alveoli by cyclic breathing, and oxygen in the inspired gas diffuses through the alveolar epithelial wall, the interstitial tissue, and the capillary endothelial wall, as well as through the plasma, and finally reaches the hemoglobin inside red blood cells. Carbon dioxide diffuses in the opposite direction, from the blood cells and plasma to the alveolar gas phase, and is expired. To establish gas exchange in the human lung, there must be ventilation of the alveoli, diffusion through the alveolar-capillary membranes, and circulation or perfusion of the pulmonary capillary bed.

The lung is regularly affected by anesthesia and mechanical ventilation. This occurs even in healthy volunteers or patients with no cardiopulmonary disease, and sometimes the dysfunction can be severe enough to cause life-threatening hypoxemia. In patients with preexisting lung disease, gas exchange will be further compromised in comparison to the awake state. Knowledge of the functional impairment that will ensue during anesthesia and mechanical ventilation will make possible ventilatory support that should, in the large majority of patients, prevent any disastrous impairment in gas exchange.

Ventilation

Dead Space and Alveolar Ventilation

Fresh air is brought into the lungs by cyclic breathing. A normal tidal breath at rest in an adult subject is approximately 0.5 to 0.6 L, and the respiratory frequency is around 16 breaths/min, with a range of 12 to 22 breaths/min. Metabolic demand and pulmonary function will determine the magnitude and rate, provided that the respiratory center in the brainstem is intact and functioning. This results in ventilation of approximately 7 to 8 L/min.[1]

All that is inspired does not reach the alveoli. Approximately 100 to 150 mL will be confined in the airways and does not participate in gas exchange. This "dead space" is approximately

30% of tidal volume; that is, the V_{DS}/V_T ratio is 0.3 (see Fig. 15-1 for different forms of dead space).[2] The remaining part of ventilation reaches the alveoli and respiratory bronchioles (with some alveoli tapered on the airway wall). Thus, "alveolar ventilation" is around 5 L/min, similar to cardiac output, which is also 5 L/min. The overall alveolar ventilation-perfusion ratio accordingly is 1.

There are several causes of increased minute ventilation, such as physical exercise, reduced inspired oxygen concentration (or rather, partial pressure of O_2), increased dead space ventilation, and metabolic acidosis.

Increased Dead Space Ventilation

If dead space is increased, ventilation must be raised to account for the "losses" and to maintain P_{ACO_2} at a normal level. Dead space is increased when ventilation is performed through a mouthpiece and a valve or through a facemask. This "apparatus dead space" is something between 25 and a few hundred mL, as compared with the 100 to 150 mL that the natural airways make up ("anatomic dead space").[3] Bronchiectasis increases anatomic dead space, but it adds only little to the total figure. A much larger increase can be caused by ventilation of alveoli that are not perfused, such as a pulmonary embolus stopping blood flow in a lung unit ("alveolar dead space") (Fig. 15-1). A worst case is plugging of the right or left main pulmonary artery, thereby leaving one lung essentially unperfused. In this case, the dead space fraction is doubled from the normal 0.3 to 0.6 or so.[4] Patients suffering from recurrent emboli, or pulmonary embolism, often have high V_{DS}/V_T ratios that can exceed 0.7 to 0.8, which means that to maintain an ordinary alveolar ventilation of 5 L/min, minute ventilation must be raised from 7 to 8 to 20 L/min. Patients with recurrent emboli also frequently complain of dyspnea, even in the absence of severe hypoxemia. The increased ventilatory demand may be the reason. Other patients who suffer from increased dead space are those with obstructive lung disease, including asthma, chronic bronchitis, and emphysema. Their major difficulty is that some regions are poorly ventilated because of airway obstruction, so these regions are underventilated in relation to their perfusion, commonly called a ventilation-perfusion mismatch ("$\dot{V}_A/\dot{Q}$" mismatch signified by low $\dot{V}_A/\dot{Q}$ ratios).[5] This forces inspired air to other regions, which may be ventilated in excess of their perfusion. Such opposite $\dot{V}_A/\dot{Q}$ mismatch (signified by high $\dot{V}_A/\dot{Q}$ ratios) has the same effect on gas exchange as an increase in dead space does and is also measured as dead space (see Fig. 15-1). Indeed, patients with advanced chronic bronchitis may have as high a $\dot{V}_A/\dot{Q}$ ratio as 0.8 to 0.9. Such patients would have to ventilate some 30 to 50 L/min to maintain normal P_{ACO_2}, a difficult task to perform even for a short period with healthy lungs. It should therefore come as no surprise that P_{ACO_2} is increasing as a result of alveolar "hypoventilation." This has led us to say, erroneously, that bronchitic patients are hypoventilating when in fact they are hyperventilating! Some help to these patients comes from the fact that CO_2 can be excreted by half the "normal" alveolar ventilation if P_{ACO_2} is doubled, as can be inferred from the alveolar gas equation (Box 15-1).

Because all subjects, even those with healthy lungs, do have some $\dot{V}_A/\dot{Q}$ mismatch, the sum of the anatomic and alveolar dead space, whether attributable to emboli or uneven ventilation and perfusion, is called "physiologic dead space."

Hyperventilation and Exercise

It is possible to voluntarily increase minute ventilation to a maximum that is almost 20-fold higher than resting ventilation, to above 100 L/min in women and above 150 L/min in men, but only for a brief period of half a minute or so.[1] In addition, hyperventilation without a simultaneous increase in metabolic demand

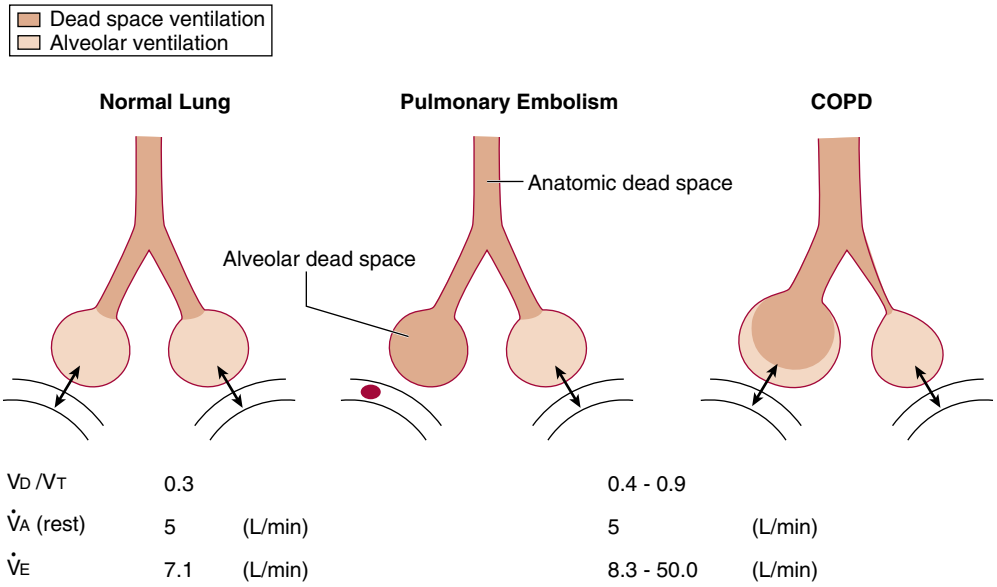

Figure 15-1 Dead space and alveolar ventilation in normal and diseased lungs. Note that both cessation of blood flow and excessive alveolar ventilation relative to perfusion cause an increase in dead space as measured by the conventional CO_2 elimination technique. See also the marked increase in minute ventilation that is required to maintain alveolar ventilation when dead space is increased. COPD, chronic obstructive pulmonary disease; $\dot{V}_A$, alveolar ventilation; V_D/V_T, dead space–to–tidal volume ratio; $\dot{V}_E$, minute ventilation (sum of dead space and alveolar ventilation). *(Courtesy of the editor of the BMJ series Respiratory Measurement.)*

Box 15-1 Alveolar Gas Equations

Alveolar Oxygen Tension (P_{AO_2})

$$P_{AO_2} = P_{IO_2} - \frac{P_{ACO_2}}{R} + \left[P_{ACO_2} \times F_{IO_2} \times \frac{1-R}{R} \right]$$

where P_{IO_2} is inspired oxygen tension, P_{ACO_2} is alveolar CO_2 tension (assumed to equal arterial P_{CO_2}), *R* is the respiratory exchange ratio (normally in the range of 0.8 to 1.0), and F_{IO_2} is the inspired oxygen fraction.

The term within brackets compensates for the larger O_2 uptake than CO_2 elimination over the alveolar capillary membranes.

A simplified equation can be written without the compensation term:

$$P_{AO_2} = P_{IO_2} - \frac{P_{ACO_2}}{R}.$$

Alveolar Ventilation

Alveolar ventilation ($\dot{V}_A$) can be expressed as

$$\dot{V}_A = f \times (V_T - V_{DS})$$

where f is breaths/min, V_T is tidal volume, and V_{DS} is physiologic dead space.

Alveolar ventilation can also be derived from

$$\dot{V}_{CO_2} = c \cdot \dot{V}_A \cdot F_{ACO_2}$$

where $\dot{V}_{CO_2}$ is CO_2 elimination, *c* is a conversion constant, and F_{ACO_2} is the alveolar CO_2 concentration.

If $\dot{V}_A$ is expressed in L/min, $\dot{V}_{CO_2}$ in mL/min, and F_{ACO_2} is replaced by P_{ACO_2} in mm Hg, $c = 0.863$. By rearranging,

$$\dot{V}_A = \frac{\dot{V}_{CO_2} \cdot 0.863}{P_{ACO_2}}.$$

will lower P_{aCO_2} and affect consciousness. In respiratory tests of ventilatory capacity it is therefore necessary to perform the test during rebreathing of expired gas or add CO_2 to the respiratory gas so that P_{aCO_2} is maintained at a normal or nearly normal level. The increase in ventilation is brought about by an increase in V_T to approximately two thirds of vital capacity (VC) (see later), or 2.5 to 4 L, and an increase in frequency to 40 breaths/min or greater. However, during maximum physical exercise, minute ventilation increases less, to around two thirds of maximum capacity, which means an increase to 65 to 100 L/min in normally fit women and men. In athletes, ventilation may exceed 150 L/min.

Lung Volumes

Functional Residual Capacity

There is a certain amount of air in the lungs after an ordinary expiration. This volume is called functional residual capacity (FRC) (Fig. 15-2). It amounts to approximately 3 to 4 L and is dependent on sex, age, height, and weight. FRC goes up with height and age and down with weight and is smaller in women than in men.[1,6] The balance of the inward force of the lung and the outward force of the chest wall determines the volume. The inward force of the lung, or "elastic recoil," consists of the elastic fibers of the lung tissue, as well as the contractile forces of airway smooth muscles and the surface tension of alveoli. The outward force of the chest wall is exerted by the ribs, joints, and muscles. It can be asked why any gas volume persists in the lung after expiration. There are two good reasons, at the least. One is that if alveoli collapse during expiration, much more effort would have to be spent to reopen them again than during a normal breath with no collapse because less resistance is encountered when expanding an alveolar wall in an open lung with a liquid-gas interphase unit than expanding a collapsed alveolus with a liquid-liquid interphase. The other reason is that the inspired air mixes with the remaining gas in the lung, thereby leveling off the variation in O_2 and CO_2 concentrations that occur during the respiratory cycle. With just little air in the lung, the gas variations in alveoli would be much greater, and they would cause a similarly varying P_{aO_2} and P_{aCO_2} in blood. This can indeed be observed in patients with reduced lung volumes (see later).

With increased ventilation, as during exercise, V_T is raised by increasing both inspiration and expiration so that FRC is lowered by approximately 0.5 L. However, in the presence of airway obstruction, as in asthma, for example, expiration is slowed down so that the end-expiratory level is elevated instead of being lowered.[7] This is called air trapping and is a means of reducing the resistance to gas flow in the narrowed airways (Fig. 15-2). However, it has to be paid for because the increased level of breathing increases the elastic work of breathing.

FRC increases with age because of loss of elastic lung tissue, which lessens the contractile force of the lung and moves the balancing point between the outward force of the chest wall and the inward force of the lung to higher lung volume. In patients with chronic obstructive pulmonary disease (COPD), FRC increases faster over the years than in normal subjects because of an effect of chronic air trapping and more severe loss of elastic tissue (in particular in emphysema).[1]

FRC is reduced in lung diseases characterized by fibrosis of the lung, such as idiopathic fibrosis, pneumoconiosis, and different forms of granulomatosis and vasculitis.[7] In extreme cases, the reduction can be down to 1.5 to 2 L (see Fig. 15-2). Obviously, pulmonectomy (e.g., for treatment of lung cancer) will also reduce FRC. However, the remaining lung will expand and fill in some of the space left after resection of lung tissue, sometimes called "compensatory emphysema."

Total Lung Capacity and Subdivisions

The gas volume in the lung after a maximum inspiration is called *total lung capacity* (TLC). It is typically 6 to 8 L.[1] TLC can be increased in patients with COPD either by overexpansion or "hyperinflation" of essentially normal alveoli or by destruction of the alveolar wall with loss of elastic tissue, as in emphysema (see Fig. 15-2).[7] In extreme cases, TLC can be increased by 50%, or up to 11 to 12 L. In restrictive disorders, TLC is reduced in proportion to the severity of the fibrotic process and may be as low as 3 to 4 L (see Fig. 15-2).[7]

Even after a maximum expiratory effort, some air is left in the lung and no region normally collapses. This persisting gas volume is called *residual volume* (RV) and amounts to 2 to 2.5 L.

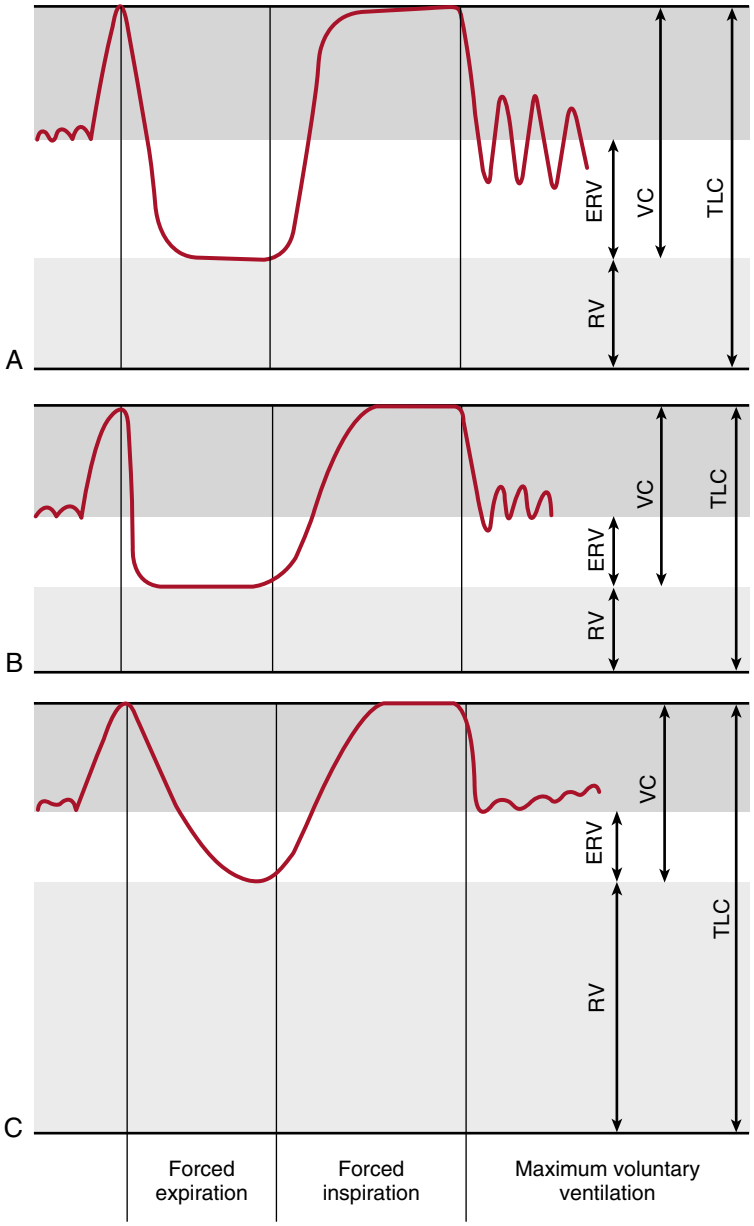

Figure 15-2 Ventilation and lung volumes in a healthy subject with normal lungs (**A**), a patient with restrictive lung disease (**B**), and a patient with chronic obstructive lung disease (**C**). Note the decrease in vital capacity (VC) and the increased expiratory flow (steeper than the normal slope of the forced expiratory curve) in the patient with lung fibrosis. Note also the increased residual volume (RV), reduction in VC, and the slow forced expiration in the obstructive, emphysematous patient. The latter patient demonstrates air trapping during hyperventilation. ERV, expiratory reserve volume; TLC, total lung capacity. *(Courtesy of the editor of the BMJ series: Respiratory Measurement.)*

The reason that expiration stops before all gas has been evacuated seems to be twofold. First, distal airways 2 mm or less in diameter close before alveoli collapse.[8] This trapping of gas will thus prevent the alveoli from being squeezed to emptiness. Second, the chest wall, rib cage, and diaphragm cannot be distorted to the point that all gas in the lung will be expelled. The advantage of not allowing lung tissue to collapse was presented earlier (see Fig. 15-2).

The maximum volume that can be inspired and expired is called *vital capacity*. VC is thus the difference between TLC and RV and is around 4 to 6 L. It is reduced in restrictive lung diseases, frequently before a decrease in RV. What may not be equally clear is that VC is also reduced in obstructive lung disease. This is an effect of the chronic "air trapping" that increases RV, mainly at the expense of VC.[7] However, as said earlier, TLC may also increase, but not in proportion to the rise in RV. The net effect can be a TLC of 12 L made up of an RV of 11 L and a VC as small as 1 L, in an extreme example of emphysema.

Respiratory Mechanics

Understanding the mechanics of the respiratory system serves at least two purposes. One, it gives a clue to what governs the distribution of inspired air, and second, recording of the mechanics can be used as a diagnostic and prognostic tool in lung disease. Here, we will begin with an analysis of the elastic and resistive forces that have to be overcome during breathing and how these forces are affected by pulmonary disorders. We will then continue to analyze the influence of respiratory mechanics on the distribution of inspired air.

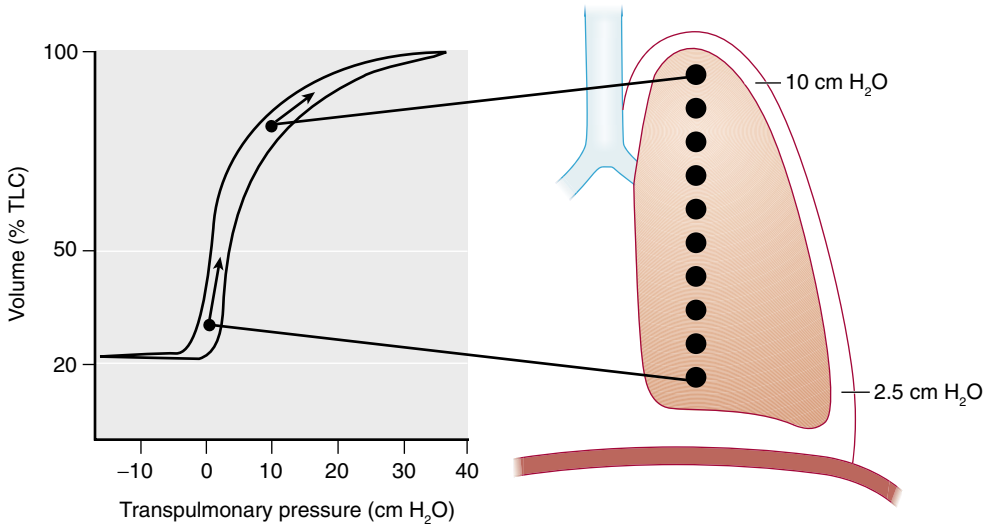

Figure 15-3 Pressure-volume relationships of the lung. Note the curved relationship, which is typical of an elastic structure. Note also the lower (more subatmospheric) pleural pressure in the upper regions. Regional transpulmonary pressure (mouth minus pleural pressure) is thus higher for apical lung units than for basal ones in an upright subject. This results in different positions of the upper and lower lung regions on the pressure-volume curve. The consequence will be that the lower lung regions expand more for a given increase in transpulmonary pressure than the upper units do. Thus, ventilation goes preferably to the lower lung regions.

Compliance of the Respiratory System

The lung recoils like an elastic rubber balloon. Thus, a certain pressure is required to keep it inflated. The pressure needed to keep the lung inflated at a certain volume is pleural minus alveolar pressure, or "transpulmonary pressure" (Ptp). It will be seen that more and more pressure is required for a given increment in volume the more the lung is inflated (Fig. 15-3).[9] Such a curved pressure-volume relationship is typical of elastic structures, and a similar curved force-length relationship will also be seen for a rubber band.

The elastic behavior of the lung is often analyzed in terms of compliance, which is the inverse of elastance. Thus, compliance is expressed as change in lung volume divided by the change in pressure required to cause the increment in volume (or the decrease in pressure that is accompanying a decrement in volume). Normal lung compliance is around 0.2 to 0.3 L/cm H_2O (2 to 3 L/kPa).[9] It varies with lung volume, as can be seen in Figure 15-3, and decreases with an increase in lung volume. Thus, compliance is critically dependent on the lung volume at which it is measured. This should be remembered if one does repeated recordings to monitor the progress of a disease. In addition, if a lung is resected or part of it, the measured compliance is reduced despite the fact that the remaining lung tissue is unaltered.

In fibrotic lung disease, compliance is reduced and the pressure-volume curve is flatter and shifted to the right, as shown in Figure 15-4 (obviously, the direction of a change in the pressure-volume curve depends on which axis is denoted pressure and which is volume; the figure shows the standard drawing).[9] Although the curve is sensitive to changes in the elastic properties of the lung, it is not good at discriminating between different diseases. Thus, idiopathic fibrosis, alveolar proteinosis, a granulomatosis-like sarcoidosis, and interstitial and alveolar edema will all reduce compliance and cause a flattening and right shift of the pressure-volume curve.

Loss of elastic lung tissue, as in emphysema, causes a steeper curve that is shifted to the left (see Fig. 15-4).[9] Similar changes are not seen in chronic bronchitis or asthma. Thus, recording of the pressure-volume curve can help in establishing the diagnosis of emphysema, which cannot easily be done with a conventional chest radiograph. The overaeration that can be seen on conventional chest radiographs does not enable a distinction between obstructive lung disease with and without loss of elastic tissue. High-resolution computed tomography (CT), however, enables visualization of the delicate lung structure and can be used for differential diagnosis.[10]

The chest wall itself also exerts an elastic impedance to breathing that goes undetected during spontaneous breathing

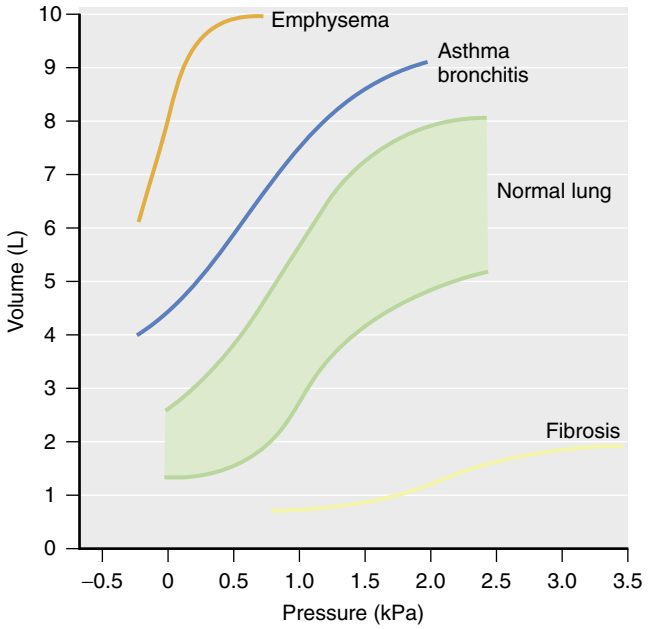

Figure 15-4 Examples of pressure-volume curves of the lung in health and lung disease. Note the much flatter slope of the curve in fibrotic lung disease, which reflects a considerable increase in pressure variation and respiratory work. Also, note the parallel shift in the pressure-volume curve of an asthmatic and bronchitic patient, which shows that compliance need not change in these diseases, although lung volume may have increased. Finally, note the steep slope of the curve of an emphysematous patient. This indicates loss of elastic tissue and might even suggest reduced respiratory work. However, such patients, as well as asthmatic and bronchitic patients, have increased airway resistance, which causes elevated respiratory work. *(Courtesy of the editor of the BMJ series: Respiratory Measurement.)*

because the chest wall is part of the pump itself. Chest wall mechanics can be measured in trained volunteers, but it requires tricky respiratory maneuvers with complete relaxation of the respiratory muscles.[11] During artificial ventilation and muscle relaxation, on the other hand, compliance of the chest wall can be measured because the respiratory muscles are allowed to rest and the rib cage and diaphragm exert elastic impedance only when the lungs are inflated and the chest wall is expanded. The change in lung volume divided by the change in pleural pressure will then give chest wall compliance. It can be seen that compliance of the chest wall is approximately the same magnitude as compliance of the lungs, around 0.2 L/cm H_2O. It may go down in obesity and in conditions associated with general edema, as well as in disorders affecting the joints, such as ankylosing spondylitis.[11]

Resistance of the Respiratory System

Pressure is required to overcome the resistance to gas flow through the airways during respiration. In addition, sliding of different components of lung tissue and the chest wall during inspiration and expiration exerts resistance.[12] This resistance is calculated as forcing pressure divided by gas flow. Flow can be measured at the airway opening, the mouth or nose, and is assumed to apply to the calculation of all three types of resistance (in airways, lung tissue, and the chest wall). The forcing pressure for airway resistance is mouth (or nose) pressure minus alveolar pressure, whereas the other driving pressures will be part of the changes in transpulmonary and pleural pressure.

Gas flow can be turbulent, with a disorderly pattern signified by vortices, or laminar, with a streamlined unidirectional flow pattern. Turbulent flow is proportional to the square of the pressure, and laminar flow, which is less pressure demanding, is linearly related to the pressure. Flow is turbulent in larger airways and at bifurcations and irregularities of the bronchi. It is laminar in the smaller airways. Thus, most of the energy, or pressure, involved in creating flow of gas is expended on overcoming resistance in the larger airways.[12] Only about 20% of the measured airway resistance, in a normal subject, is located in the small bronchi. A doubling of "peripheral" or "small" airway resistance may be difficult to detect by standard recording techniques. The difficulty in detecting changes in small airways, approximately 2 mm wide or less, has coined the expression "the lung's silent zone."

Airflow resistance is normally around 1 cm H_2O/L/sec. With obstructive lung disease it is increased to about 5 cm H_2O/L/sec in mild to moderate asthma and bronchitis and greater than 10 in more severe cases.[13] It is worth noticing that breathing through a size 8 endotracheal tube causes a resistance of 5 cm H_2O/L/sec at a flow of 1 L/sec and that a size 7 tube increases resistance to 8 cm H_2O/L/sec (i.e., comparable to moderate asthma).[14]

Airflow resistance can be higher during expiration than during inspiration, in particular during forced breathing and in patients with obstructive lung disease because the expiratory muscle effort will act not only on alveoli, to empty them, but also on airways, to make them smaller.[12] The inspiratory effort, on the other hand, helps dilate airways within the thorax by lowering pleural pressure, which acts on the outside of the airway wall. Finally, airways that are not in the thoracic cavity, specifically the pharynx, larynx, and trachea, are subject to lower pressure inside than outside their wall during inspiration because they are surrounded by atmospheric pressure, whereas luminal pressure is below atmospheric (otherwise no air would be sucked into that point of the airway tree).[12] These physiologic consequences can also be used to separate an increase in extrathoracic resistance from an increased resistance in other airways. If resistance is increased during inspiration, it is probably caused by narrowing of extrathoracic airways (e.g., sucking of a paralytic vocal chord into the lumen). Retraction of the upper airways and resultant strenuous breathing can also be seen in a neonate with respiratory distress (see Chapter 84).

Resistance of lung tissue and the chest wall has been studied to a lesser extent. Lung tissue resistance amounts to around 1 cm H_2O/L/sec in the normal case and can be increased threefold to fourfold in chronic lung disease.[15] Even less has been studied regarding chest wall resistance. However, it seems as though the sum of lung tissue and chest wall resistance is increased, and markedly so, in acute respiratory failure demanding mechanical ventilation.[16]

Respiratory resistance, in particular airway resistance, is dependent on lung volume. When it comes to airways, it can be understood that during inspiration, airways as well as alveoli are expanded and resistance in the airways will decrease. During expiration, the airways get narrower and resistance will accordingly increase. This is shown in Figure 15-5. Airway resistance may be around 1 cm H_2O/L/sec at the FRC level and is reduced further, although to a small extent, when breathing at higher lung volumes. In contrast, expiration down from FRC rapidly increases resistance, which may be 5 to 8 cm H_2O/L/sec when approaching RV. Indeed, a resistance-versus-lung volume plot as shown in Figure 15-5 approaches infinity at the end of a maximal expiration. This must be realized when taking airway resistance measurements at different lung volumes. One example is when resistance is compared between the waking state and during anesthesia. In the latter situation, FRC is reduced, as will be discussed later.

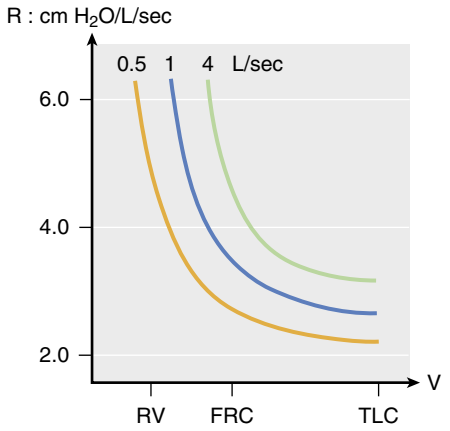

Figure 15-5 Schematic drawing of resistance against lung volume at different flow rates. Note that resistance increases with decreasing lung volume and more so below functional residual capacity (FRC) than at higher lung volume. Note also that resistance increases with an increase in flow rate. Note that at low lung volume, resistance is as high as can be seen in moderate to severe asthma (6 to 8 cm H_2O/L/sec). RV, residual volume; TLC, total lung capacity.

Inertia or Acceleration of Gas and Tissue

There is finally one additional component of the total impedance to breathing, and that is inertance, or the pressure required to accelerate air and tissue during inspiration and expiration. This component, however, is minor and can hardly be measured under normal breathing, regardless of whether the lungs are healthy. During very rapid breathing, such as during high-frequency oscillation in intensive care or the yogi exercise of rapid shallow breathing of around four breaths/sec, acceleration becomes more important and can contribute 5% to 10% of the total impedance to breathing.[17]

Gas Distribution

Distribution of Inspired Gas: Effect of Compliance, Resistance, and Airway Closure

The air that is inspired will not be evenly distributed in the lung. During quiet breathing, most gas goes to the lower, dependent regions—the basal, diaphragmatic areas in the upright or sitting position and the dorsal units in the supine position.[18] This also means that the lower part of the left lung will receive most of the air if the subject is in the left lateral position and that the right lung will be preferentially ventilated in the right position. The reason for this seemingly gravitational orientation of something as light as gas is the combined effect of the curved pressure-volume relationship of the lung tissue and the increasing pleural pressure down the lung. This topic will be discussed at some length in the next paragraph.

First, the curved pressure-volume curve, typical of an elastic tissue as stated earlier, means that with increasing lung volume, more and more pressure is required to inflate the lung with a given increment in volume (there may be a linear pressure-volume relationship for some distance). Second, the increasing pleural pressure, at constant alveolar pressure all over the lung, causes transpulmonary pressure to decrease from the top to the bottom of the lung. In the upright position, the apical lung regions are exposed to higher transpulmonary pressure than the dependent, basal ones are. Thus, the upper and lower lung regions are positioned at different levels of the pressure-volume curve (see Fig. 15-3). During inspiration, pleural pressure is lowered, which causes the lower lung regions to inflate more than the upper ones with a similar change in transpulmonary pressure (it is assumed that pleural pressure changes uniformly in the pleural space).[18] Thus, in a healthy subject, ventilation goes preferentially to the basal regions, as can be inferred from Figure 15-3 (the larger arrow in the lower, basal part of the lung indicates more ventilation than in the upper, apical regions with the subject in the upright position; Fig. 15-6). The pleural pressure gradient is oriented in a vertical, gravitational direction, which is why the distribution of ventilation changes with body position.

What causes the pleural pressure gradient? The major factor is the weight of the lung itself, with less lung tissue exerting pressure at a level higher up in the thoracic cavity than at a lower lung level. This pressure is exerted in all directions, including the pleural space. The specific density of an air-filled and perfused lung is on average approximately 0.3, and this causes the pleural pressure to increase by 0.3 cm H_2O/cm vertical distance. If the lung is heavier, as when it is suffering from edema, the pleural pressure gradient will increase, as does the vertical difference in alveolar size. If weight is reduced or eliminated, as in zero gravity or microgravity, there should be no vertical pleural pressure gradient, and lung expansion as well as gas distribution should be more even. During short parabolic flights causing very low gravity, inspiration and expiration of gases with different characteristics showed reduced inhomogeneity of the distribution of ventilation.[19] However, some inhomogeneity persisted, thus indicating that nongravitational factors also contribute to the distribution of ventilation. Such factors may be uneven convectional and diffusional flow in small lung units and may be related to differences in the anatomic structure of the airways (and parenchyma?).[20]

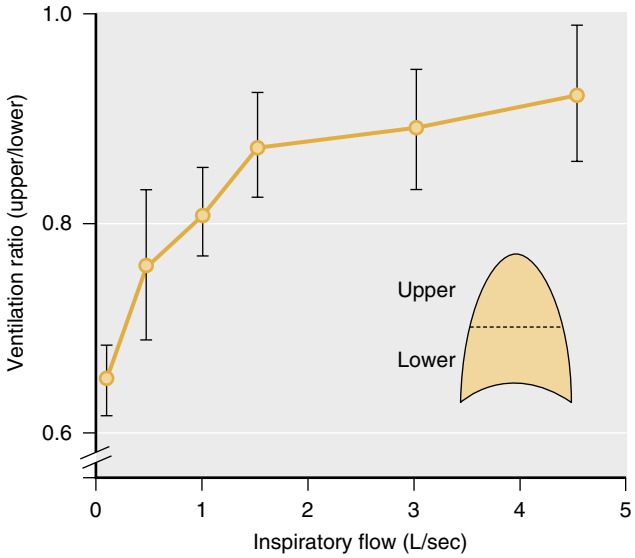

Figure 15-6 Ratio of ventilation to the upper and lower lung regions with a change in inspiratory flow. Note that the distribution of ventilation goes to the lower lung regions at a low flow rate. However, this is replaced by a more even distribution with increasing flow, as, for example, during exercise. This ensures more efficient use of lung tissue and the alveolar-capillary membranes for gas transfer (provided that pulmonary blood flow shows a similar distribution pattern). *(Redrawn from data in Bake B, Wood L, Murphy B, et al: Effect of inspiratory flow-rate on regional distribution of inspired gas. J Appl Physiol 37:8-17, 1974.)*

The vertical pleural pressure gradient may be smaller in the prone position than when supine.[21] This may be due to the weight of the heart, which is compressing the dependent parts of the lung in the supine position and permitting the nondependent regions to expand. In the prone position, the heart is resting on the sternum with less effect on the shape of the lung. The only force that can distort the lung is the weight of the lung itself. Moreover, as discussed earlier, differences in airway anatomy may contribute to differences in the distribution of ventilation when supine and prone. A more even distribution of inspired gas in the prone position has also been demonstrated by isotope technique.[22,23]

Thus far we have dealt with the distribution of inspired gas during, from a technical and purist point of view, static conditions (which, however, would not result in any gas flow). The distribution will be essentially the same during quiet breathing, up to a flow rate of 0.5 L/sec or so. However, with an increasing flow rate, regional differences in airway resistance (and in lung tissue and possibly to some extent chest wall resistance; they will be disregarded here) will play an increasing role in determining gas distribution. Because lung tissue, both alveoli and airways, is more expanded in the upper than in the lower regions, resistance to gas flow is less in the upper part of the lung. This results in a change

in the distribution pattern, with more gas going to the upper units.[24] At a flow of 0.3 L/sec, two thirds of ventilation went to the lower half of the lung as assessed by isotope technique, and when inspiratory flow was increased to 4 to 5 L/sec, distribution between the upper and lower half of the lung was even (see Fig. 15-6). This is advantageous for optimizing gas transfer in the lung, as for example during exercise, because the alveolar-capillary surface area will be more efficiently used. Perfusion distribution may be evenly distributed. Perfusion does adjust in the same way as ventilation, which will be discussed later in this section.

Airways become narrower during expiration, as can be inferred from the previous discussion. If the expiration is deep enough, airways in dependent regions will eventually close. The volume above RV at which airways begin to close during expiration is called *closing volume* (CV), and the sum of RV and CV is called *closing capacity* (CC).[25] Airway closure is a normal physiologic phenomenon and is the effect of increasing pleural pressure during expiration. When pleural pressure becomes "positive" (or rather, above atmospheric), it will exceed the pressure inside the airway, which is just or nearly atmospheric at a low flow rate. The higher pressure outside than inside will compress the airway and may close it. Because pleural pressure is higher in dependent regions than higher up, closure of airways begins in the bottom of the lung. The crucial point is thus the creation of "positive" pleural pressure (Fig. 15-7). In young subjects it may not occur until they have expired to RV. However, with increasing age, pleural pressure becomes "positive" at higher and higher lung volume, and at an age of 65 to 70 years, airway closure may occur above FRC.[26] This means that in elderly subjects, dependent lung regions are intermittently closed during the breath. These regions will reopen during inspiration, when lung volume exceeds CC. The impediment to ventilation that closure of airways causes seems to be the major explanation of why arterial oxygenation decreases with age (see Chapter 71).

Airway closure plays an even greater role in the supine position because FRC is reduced whereas CC is not affected by body position. Closure of airways may occur above FRC, even at an age of 45 to 50, and in a 70-year-old subject, the airways may be continuously closed if CC exceeds FRC plus VT. This is illustrated in Figure 15-8.

Airway closure occurs at higher lung volumes in patients with obstructive lung disease. Secretions, edema of the airway wall, and increased bronchial muscle tone all reduce the lumen of the airway and facilitate premature closure.[25] Because these changes are thought to begin in the small airways, recording of CV has been considered an ideal test for early detection of airway disease. However, use of CV is not as popular as it was earlier because its reproducibility is not as good as that of conventional spirometry. However, even if recording of airway closure as a diagnostic and quantitative measure of lung disease may not have been as successful as hoped for, it should not obscure the fact that airway closure is a most important phenomenon. Its detection has taught us a lot of the physiologic principles governing the distribution of ventilation.

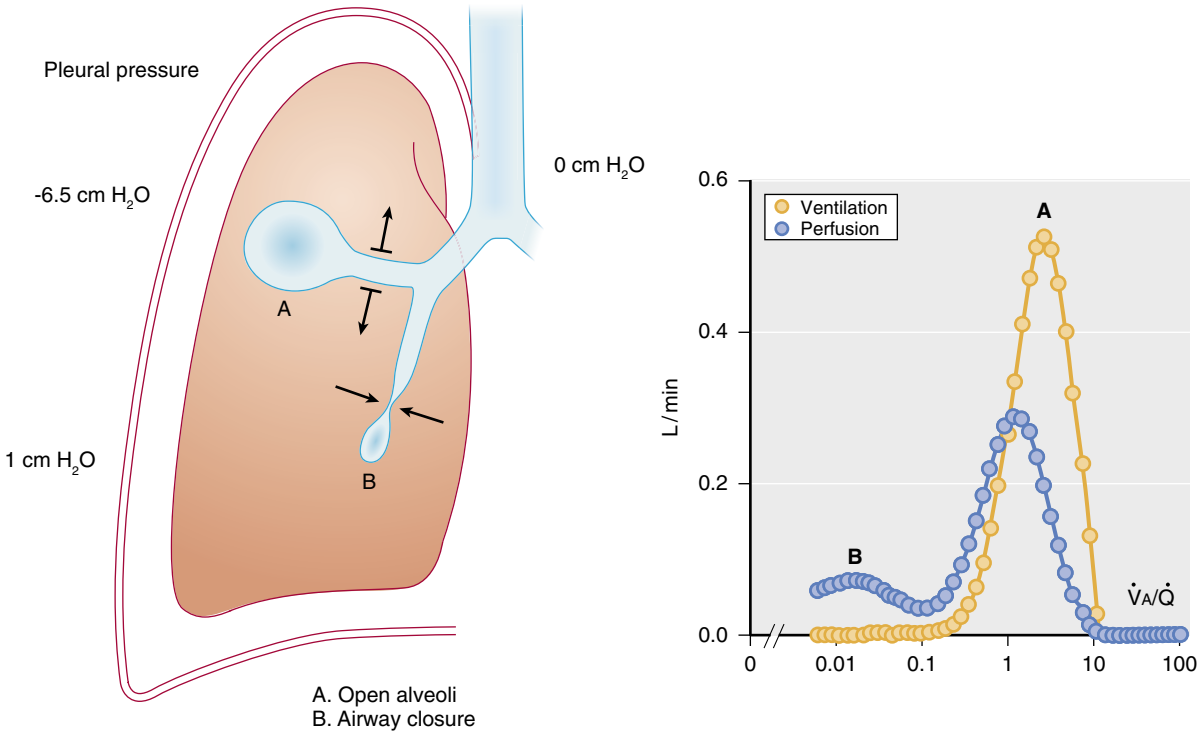

Figure 15-7 Schematic drawing of regional alveolar and airway volume at an upper (A) and a lower (B) lung level, *left panel*. There is a vertical pleural pressure gradient with a difference of approximately 7.5 cm H_2O between the uppermost and lowermost regions. This causes a transpulmonary pressure gradient with higher pressure inside the airway and alveolus in the upper part and higher pressure outside the alveolus and airway in the lower part. This results in closure of the airways with the potential for slow alveolar gas adsorption behind the occluded airway. The *right panel* shows a distribution of ventilation and perfusion ratios as obtained by the multiple inert gas elimination technique. A "normal" mode of ventilation and blood flow (A) can be seen corresponding to the open and ventilated alveoli in the upper parts of the lung. In addition, there is a mode of low $\dot{V}_A/\dot{Q}$ ratios with more perfusion than ventilation (B). This could apply to an elderly healthy subject with intermittent airway closure during breathing.

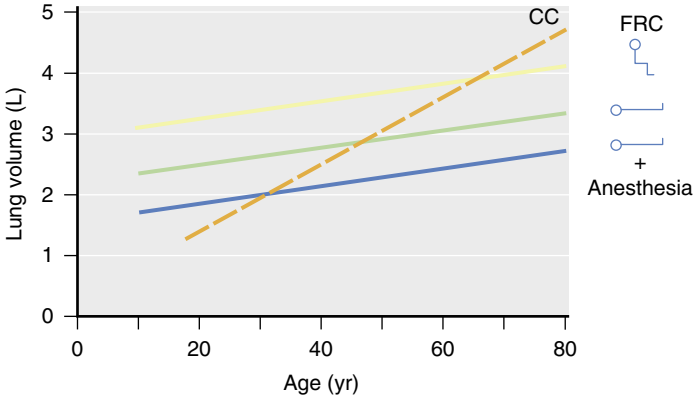

Figure 15-8 Resting lung volume (functional residual capacity [FRC]), upright and supine, and closing capacity (CC, unaffected by body position) at different ages in healthy subjects. Note the lower FRC, by approximately 0.7 to 0.8 L, in the supine position (an effect of cranial displacement of the diaphragm by the abdominal organs). As can be seen, there is also a slight increase in FRC with age at constant height and weight. This is an effect of the loss of elastic tissue with aging. Finally, observe the more rapid increase in CC with age. This results in airway closure above FRC in upright subjects at ages of 65 to 70 years or older. In the supine position, airways may close during breathing even at the age of 45 to 50 years! This relationship between CC and FRC is a likely explanation for the decreasing oxygenation of blood with age. The effect of anesthesia can also be seen with lowering of FRC so that airways may close already at 30-year-old subjects (see section on "Lung Volume and Respiratory Mechanics during Anesthesia"). The curves are based on pooled data from different studies.

As mentioned earlier, secretions, edema, and spasm reduce the airway lumen. This will affect gas distribution as well by decreasing or eliminating ventilation in regions that are affected by airway obstruction and by increasing it in other, less obstructed areas.

Expiring against resistance, such as against half-closed lips ("pursed-lips breathing"), is a technique sometimes taught to a patient with chronic obstructive disease. This may make breathing easier. Devices are also available to breathe out through that act as resistance. These devices build up higher pressure inside the airway, which prevents it from closing during expiration; this is the reason why breathing is more comfortable. Thus, the device "stabilizes" the airway and facilitates expiration.[27] Although the result may be the desired one, the explanation is wrong. The higher airway pressure can be generated only by increasing the expiratory effort, and this increases pleural pressure to the same extent as airway pressure. The decrease in pressure across the airway wall will be the same as without the expiratory resistance, and this will not make the airway more stable. What may explain a beneficial result is that the expiratory resistance increases lung volume and slows down expiration. The former (increase in lung volume) is the only way of increasing transpulmonary and transairway pressure, and this stabilizes the airway. Simultaneously, there is a general increase in airway caliber that further reduces resistance, as discussed earlier. The latter (slowed expiration) reduces the decrease in pressure from the alveoli toward the mouth because lower flow requires less driving pressure. By this means the point along the airway tree where pressure inside the airway has dropped to below that outside the airway (equal to pleural pressure) is moved toward the mouth (Fig. 15-9). Thus, slow expiratory flow may make it possible to move the "equal pressure point," where inside and outside airway pressure is equal, up to the larger airways or the mouth, which will prevent floppy airways from collapsing.[28]

Diffusion of Gas

Diffusion in Airways and Alveoli

Gas flow is convective in the larger and medium-sized airways, down to approximately the 14th generation. Airways at this level begin to be tapered with alveoli and participate in gas exchange with pulmonary blood. In the latter airway generations, from 15 to 23, the total cross-sectional area of the airway tree grows rapidly, from 2.5 cm^2 in the trachea, to 70 cm^2 in the 14th generation entering the acinus, to 0.8 m^2 in the 23rd generation.[29] The total alveolar surface is approximately 140 m^2. Gas flow velocity will decrease as the area increases. For an ordinary breath the average velocity of gas in the trachea will be around 0.7 m/sec, but at the alveolar surface it is no higher than 0.001 mm/sec. This is much slower than the diffusion rate of O_2 and CO_2 in the airway tree and the alveoli. Transport of O_2 and CO_2 is therefore accomplished by diffusion in the peripheral airways and in the alveoli, not by convective flow. CO_2 can be detected in the mouth after a few seconds of breath-holding. However, this is the result not only of diffusion but also of convection brought about by the beating heart, which acts as a mixing pump. Yet even in the absence of heartbeats, CO_2 appears within seconds at the airway opening. This rapid diffusion has an implication when measuring dead space by recording of the expiratory CO_2 curve—an inspiratory breath-hold reducing the measured dead space down to zero, if the breath is held for just a few seconds.

It has often been discussed whether gas mixing is complete in the alveoli of a normal lung during normal breathing or whether there are concentration gradients, often called "stratified inhomogeneity." Many consider alveolar concentrations to be homogeneous. However, if the alveolar dimensions grow, by expansion or confluence of several alveoli as in emphysema, the diffusion distance can be too great to allow complete mixing of inspired and alveolar gas during ordinary breathing. This will cause stratified inhomogeneity of respiratory gas concentrations within the alveolar unit and has an impeding effect on gas exchange, similar to uneven distribution of ventilation by other means.[30]

Diffusion Across Alveolar-Capillary Membranes

Oxygen diffuses passively from the alveolar gas phase into plasma and red cells, where it binds to hemoglobin. Carbon dioxide diffuses in the opposite direction, from plasma to the alveoli. The amount that can diffuse over the membranes for a given period is determined by (1) the surface area available for diffusion, (2) the thickness of the membranes, (3) the pressure difference of the gas across the barrier, (4) the molecular weight of the gas, and (5) the solubility of the gas in the tissues that it has to traverse.[31] These factors are discussed in the following paragraphs.

Surface Area. Lung volume will obviously be of importance. The smaller the lung, the less the overall diffusion. To this should be added that the lung surface can be used for diffusion only if there is circulating blood on the capillary side. Thus, pulmonary capillary blood volume is an important determinant of diffusion. The relative influence of membrane area and characteristics, as well as capillary blood volume, can be analyzed separately by performing a diffusion or transfer test at two different inspired oxygen concentrations. Carbon monoxide (CO) is normally used as the test gas. CO is inspired at a small concentration (0.3%) to TLC after a previous maximum expiration, and the

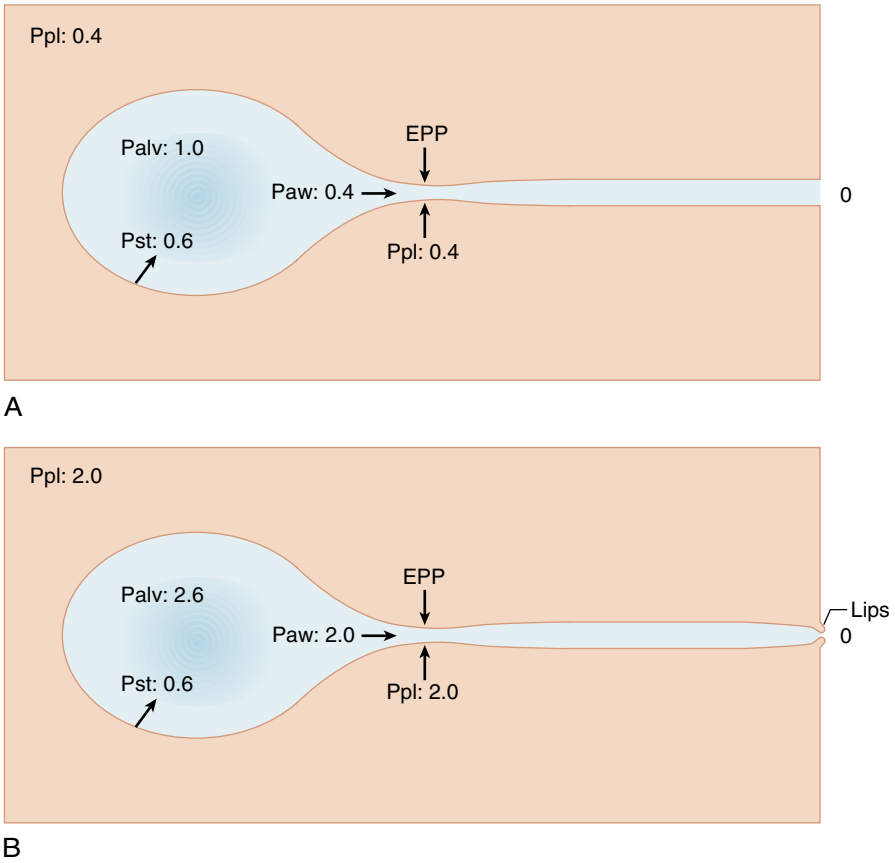

Figure 15-9 Schematic drawings of the "equal pressure point" (EPP) concept and dynamic compression of airways. **A,** Slightly forced expiration during otherwise normal conditions. With the application of some expiratory muscle effort, pleural pressure (Ppl) is positive, 4 cm H_2O (0.4 kPa). The elastic recoil pressure (Pst) of the alveoli (6 cm H_2O) and the pleural pressure add together to yield intra-alveolar pressure (Palv) (10 cm H_2O). This causes expiratory flow. At some point downstream toward the airway opening, airway pressure (Paw) has dropped by 6 cm H_2O, so intraluminal pressure and pleural, extraluminal pressure are the same. This is the EPP. From this point to the mouth, intraluminal airway pressure is lower than the surrounding, extraluminal pressure and the airway may be compressed. **B,** An attempt to stabilize the airway by so-called "pursed-lip" breathing. The increased resistance to expiratory flow requires increased expiratory effort to maintain gas flow. Thus, pleural pressure is increased in comparison to the normal conditions (Ppl = 20 cm H_2O). Alveolar elastic recoil pressure (Pst) is the same as in the earlier condition, provided that lung volume is the same. If expiratory flow is of the same magnitude as during normal breathing, pressure along the airway falls to the same extent as during normal breathing. Thus, the EPP will have the same location as during normal breathing, and no stabilization of the airway has been achieved. The two ways of moving the EPP toward the mouth and to less collapsible airways is by raising alveolar recoil pressure (Pst) by an increase in lung volume or by lowering the expiratory flow rate so that the pressure drop along the airway tree is slowed down.

breath is held for 10 seconds, followed by a deep expiration to RV. The amount of CO that has been taken up can be calculated from the difference between inspired and expired gas. Most of this CO has diffused to blood, where it binds easily to hemoglobin. However, a certain amount of the difference in concentration is due to dilution in the gas volume that was not expired (RV). This can be accounted for by inspiring another tracer gas that is poorly soluble or almost insoluble, such as helium. The dilution of helium (and CO) can be calculated, as can the diffusion or transfer factor of CO. Because oxygen and CO compete for binding to hemoglobin, measurement of diffusion at two different inspired oxygen concentrations as just described may enable distinction between capillary blood volume and the membrane in calculating the diffusion capacity or transfer factor. It is beyond the scope of this chapter to go into further details, but interested readers are referred to an article by Hughes and Bates.[32]

Membrane Thickness. The thicker the membrane, the longer the diffusion distance and the lower the diffusion capacity. In addition, solubility for O_2 (and CO_2) is lower in fibrotic tissue than in water. Thickening of the membranes may therefore impede diffusion even more than the increase in diffusion distance does.

Pressure Gradient. The larger the O_2 or CO_2 tension difference between the gas phase in the alveolus and plasma in the capillary, the greater the diffusion. The mixed venous blood entering the pulmonary capillary has a P_{O_2} of 40 mm Hg (5.3 kPa), and alveolar P_{O_2} is approximately 100 mm Hg (13.3 kPa), thus creating a driving pressure of 60 mm Hg (8 kPa). When blood flows through the capillary, it takes up oxygen (and delivers CO_2), but because oxygen pressure builds up in capillary blood, the diffusion rate slows down and becomes zero when pressure is equilibrated over the alveolar-capillary wall (Fig. 15-10). In a normal lung at low cardiac output, equilibrium has been reached within 25% to 30% of the capillary distance, and no or little gas transfer takes place in the remaining capillary. When cardiac output is increased, as during exercise, blood passes through the capillary faster, and a longer distance of the capillary is therefore required before equilibrium is reached, equilibration time being much the

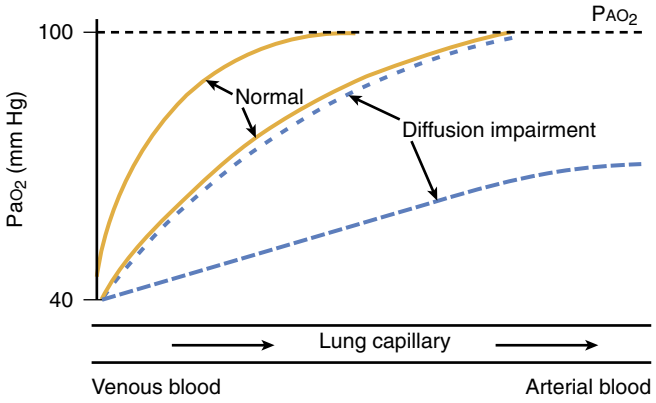

Figure 15-10 Oxygenation of pulmonary capillary blood at rest and during exercise in a normal subject and in a patient with fibrotic lung disease with impaired diffusion. In a normal subject, equilibration of oxygen tension in capillary blood with that in alveolar gas is rapid. This has been achieved within one third of the capillary distance. However, during exercise, most of the capillary distance must be used to reach equilibration between alveolar and pulmonary capillary oxygen tension. This is an effect of the shorter transit time of red blood cells caused by the increased cardiac output. Distention and recruitment of pulmonary capillaries may to some extent offset the effect of raised cardiac output on velocity of blood through the capillaries. With impaired diffusion, equilibration takes a longer time, but full equilibration may still be reached at rest. However, with increased blood velocity during exercise, equilibration of oxygen may be far from complete at the end of the pulmonary capillary, thereby causing desaturation of arterial blood, which may at times be severe.

same as during resting conditions (lower venous P_{O_2} speeds diffusion up in the beginning). Thickened alveolar-capillary membranes will prolong the equilibration process with the possible effect of causing hypoxemia.

It should also be mentioned that most of the oxygen that dissolves in plasma diffuses into the red cell and binds to hemoglobin. One gram of hemoglobin can bind 1.36 mL O_2 (numbers between 1.34 and 1.39 are used). This means that 1 L of blood with a hemoglobin content of 150 g/L can bind 204 mL of O_2 if fully saturated. With a saturation of 98%, which is normally achieved in arterial blood, the hemoglobin-bound oxygen amounts to 200 mL/L of blood. This should be compared with the mere 3 mL of O_2 that is physically dissolved in 1 L of blood at a P_{aO_2} of 100 mm Hg (13.3 kPa). The hemoglobin-bound oxygen creates no pressure in plasma, which is important because it allows much more oxygen to diffuse over the membranes before a pressure equilibration is reached. Anemia reduces and polycythemia increases diffusion capacity.

Molecular Weight. Diffusion is inversely related to the square root of the molecular weight of the gas. Thus, the larger the molecule, the more difficult it will be to pass through the membranes. O_2 is a relatively light gas with a molecular weight of 32. CO_2 is heavier with a molecular weight of 44 and should therefore be more limited in diffusion than O_2. However, taking the square root of the weights reduces the difference between the gases, and in practice, CO_2 is much more diffusible than O_2, as explained in the next paragraph.

Solubility. Diffusion is linearly related to solubility in tissue. It is usually set equal to that of water. CO_2 is almost 30 times more soluble in water than O_2 is and diffuses more than 20 times faster (the net effect of all previously mentioned factors).[31] In practice, this means that there is no lung disease compatible with life that causes measurable impairment in CO_2 diffusion.

Pulmonary Perfusion

Pressure-Flow Relationship

In contrast to the systemic circulation, the pulmonary circulation is a low-pressure system. The typical pulmonary artery pressure of 20 mm Hg systolic and 8 mm Hg diastolic is about 6 to 10 times lower than pressure in the systemic arteries. The lower pressure is achieved by the larger vascular diameter and shorter distance of the pulmonary vessels than the systemic ones. In particular, a large vascular lumen decreases the demand on driving pressure. According to Poiseuille's law, an increase in vascular radius reduces the pressure demand by an exponent of 4 to maintain a certain flow, if flow is linear. With turbulent flow, the dependence on vascular dimensions will be even higher. As a consequence of the lower resistance, pulmonary capillary blood flow is pulsatile, contrary to the steady flow in systemic capillaries.[33] Another, presumably more important consequence of the low pressure is that the capillary and alveolar walls can be made very thin without causing any leakage of plasma, and this facilitates diffusion of O_2 and CO_2. A sudden increase in pulmonary artery pressure to above a mean of 30 mm Hg causes effusion of plasma into the interstitial and alveolar spaces, thereby promoting lung edema. A slower increase in pressure, over a period of months or years, stimulates the growth of vascular smooth muscle ("vascular remodeling") with thickening of the vascular wall.[34] Edema is prevented better, despite even severe pulmonary hypertension, but diffusion capacity will be impaired.

Distribution of Lung Blood Flow

Blood flow through the lung is governed by driving pressure and vascular resistance. If these factors are unevenly distributed, perfusion may also be uneven. This seems to be the case. What the perfusion distribution looks like and the mechanisms behind it have become an interesting issue during recent years. Thus, the previously generally accepted explanation of a gravitational orientation of perfusion as demonstrated in the pioneering work by Permutt, West, Hughes and others (for a review, see Reference 35) has been challenged by others who propose a "fractal" distribution with gravity playing only a minor role.[36] Here we will first deal with the "gravitational" concept and then proceed to the "fractal" concept.

Gravitational Distribution of Blood Flow in the Lung

Pulmonary artery pressure increases down the lung, an effect of the hydrostatic pressure that builds up on the way from the top to the bottom of the lung. This pressure increases by 1 cm H_2O/cm distance down the lung (or 0.74 mm Hg/cm vertical distance; blood has a density close to 1, or 1.04). This causes a pressure difference in the pulmonary arterial vessels between the apex and the base of 11 to 15 mm Hg, depending on the height of the lung. There is thus less driving pressure to the top of the lung. Because mean pulmonary artery pressure is approximately 12 mm Hg at the level of the heart, it may approach zero in the apex of the lung in the upright position. Moreover, if alveolar pressure is increased, as during positive-pressure ventilation, it may exceed that in the pulmonary artery and compress the pulmonary capillaries. No blood will then flow through the vessels. That part of the lung is called zone I, according to the nomenclature introduced by West and associates (Fig. 15-11).[35] If arterial pressure and capillary pressure exceed alveolar pressure, as it will farther down the lung

$$\text{Pulmonary vascular resistance (PVR)} = \frac{\bar{P}_{PA} - P_{LA}}{\dot{Q}_T}$$

(true only if lung is in zone III)

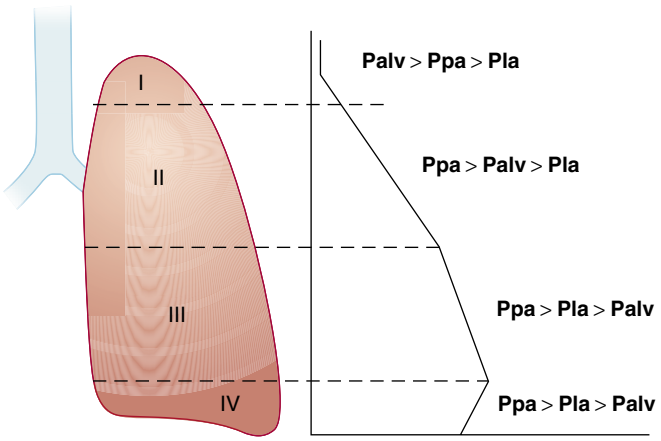

Figure 15-11 Vertical distribution of blood flow in the lung. The so-called zones I, II, III, and IV are indicated. As can be seen, zone I corresponds to a region in which alveolar pressure exceeds vascular pressure, which results in essentially no perfusion. Zone II is characterized by pulmonary artery pressure exceeding alveolar pressure, which in turn exceeds venous pressure. The driving pressure will then be arterial minus alveolar pressure. Farther down in zone III, both arterial pressure and venous pressure exceed alveolar pressure. The difference between arterial and venous pressure creates the driving force through this zone. In the bottom of the lung there is a decrease in blood flow that is explained by increasing interstitial pressure compressing extra-alveolar vessels. For further details see text. $\dot{Q}_T$, cardiac output; Palv, alveolar pressure; Pla, left atrial pressure; Ppa, pulmonary artery pressure.

because of the addition of hydrostatic pressure, blood flow will be established. Perfusion pressure will be arterial minus alveolar pressure, as long as the latter pressure exceeds that of the pulmonary veins. This is different from the systemic circulation, where perfusion pressure is arterial minus venous pressure. Moreover, the increasing pulmonary arterial pressure down the lung and the constant alveolar pressure increase the perfusion pressure down this part of the lung, called zone II. Blood flow therefore increases down this zone. Farther down the lung, both arterial pressure and venous pressure exceed that in the alveoli, so perfusion pressure is arterial minus venous pressure. This part of the lung is called zone III. Because both arterial pressure and venous pressure increase to the same extent down zone III, with hydrostatic pressure adding to both sides, perfusion pressure does not increase down the zone. Nonetheless, perfusion increases downward, albeit possibly less than the increase in zone II. The explanation proposed is that the increasing vascular pressure dilates the vessels down the lung and by this means reduces vascular resistance.[35]

A few years after these initial observations, it was noticed that blood flow decreases in the bottom of the lung, so a zone IV had to be added to the model of lung perfusion.[35] This called for a new explanation in which it was suggested that the increasing interstitial pressure down the lung presses on the extra-alveolar vessels and makes them narrower. The vertical distribution of blood flow could accordingly be explained by the influence of gravitation on vascular, alveolar, and interstitial pressure.

The homogeneity of blood flow distribution has also been tested during shuttle flights at zero gravity or microgravity. By using indirect techniques based on analysis of the variation in expired gas concentrations that are synchronous with heartbeats ("cardiogenic oscillations"), more uniform lung blood flow distribution has been recorded.[37]

Nongravitational Inhomogeneity of Blood Flow Distribution

In dog experiments, groups at the Mayo Clinic and subsequently in Seattle noticed that the vertical lung blood flow distribution was nearly even and did not change when position was altered between supine and prone.[36] This made the Seattle group conclude that gravity was of minor importance in determining the distribution of perfusion. The same group also showed that perfusion at a given vertical level is unevenly distributed on that horizontal plane, with an inhomogeneity far exceeding that in the vertical direction (Fig. 15-12). In carefully repeated experiments they could reproduce the same pattern of inhomogeneity.[38] This suggests that there are morphologic or functional differences (or both) between lung vessels that also—and perhaps more importantly than gravity—determine blood flow distribution. As an example, vascular resistance seems to be lower in the dorsal regions of horse lungs than in the anterior part.[39] Thus, in an animal that is standing or resting on its four legs most of the time, the vascular tree has adjusted to that position and, by increasing resistance in its anterior parts, has made blood flow more evenly distributed.

Other groups have also made observations that suggest an uneven distribution of blood flow that cannot be explained by gravity, with more blood going to the core of the lung and less to the periphery.[40] A longer distance to the peripheral bed was suggested as an explanation for the larger vascular resistance toward the periphery. However, others found less difference between central and peripheral lung regions. The application of positive end-expiratory pressure (PEEP) in anesthetized and mechanically ventilated dogs forced perfusion of the lung toward the periphery.[41] As always, the reliability of the techniques used is critical. It seems that the spatial distribution of blood flow as measured by single photon emission computed tomography (SPECT), a technique that has been used in some studies, suffers from reconstruction artifacts. Still others have used a microspheres technique and measured the distribution in excised lungs. Although it may suffer from other limitations, one may dare to conclude that enough evidence has accumulated to believe in a nongravitational inhomogeneity of lung perfusion.

Hypoxic Pulmonary Vasoconstriction

Hypoxic pulmonary vasoconstriction (HPV) seems to be a compensatory mechanism aimed at reducing blood flow in hypoxic

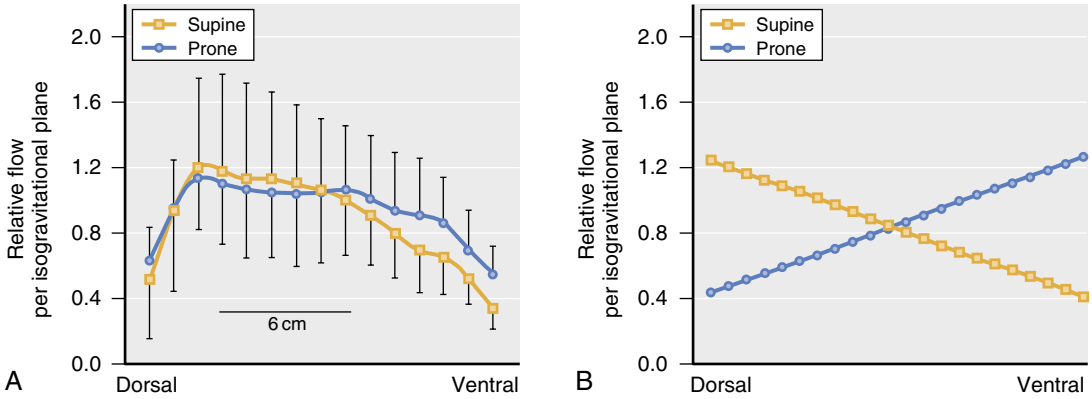

Figure 15-12 Distribution of blood flow from ventral to dorsal lung regions in a canine experiment with the animal supine and prone. Note the similar distributions from ventral to dorsal irrespective of posture. This may suggest that the distribution of perfusion in the vertical direction is determined by anatomic differences in the vasculature rather than by gravity. The *bars* show the spread of perfusion around the mean value. As can be seen, this nongravitational inhomogeneity is larger than that caused in the gravitational orientation. *(From Glenny RW, Lamm WJE, Albert RK, et al: Gravity is a minor determinant of pulmonary blood-flow distribution. J Appl Physiol 71:620-629, 1991.)*

lung regions. The major stimulus for HPV is low alveolar oxygen tension, whether caused by hypoventilation or by breathing gas with a low P_{O_2}. The stimulus of mixed venous P_{O_2} is much weaker.[42,43] The strength of the constriction is also dependent on the size of the lung segment exposed to the hypoxia, being stronger the smaller the region. Thus, in humans studied during intravenous anesthesia that was assumed to not affect the HPV, one-lung hypoxia with 8% and 4% O_2 during contralateral hyperoxia (F_{IO_2} of 1.0) caused blood flow to be diverted away from the hypoxic to the other, hyperoxic lung, from 52% to 40% and 30% of cardiac output.[44]

Pulmonary hypertension and pulmonary edema may develop in humans at high altitude because of more general pulmonary vasoconstriction.[45] Chronic lung disease with hypoxemia also causes HPV, but the slow progress of the disease allows time for remodeling of the pulmonary vascular wall, with thickening of the wall preventing edema formation.[32]

Causes of Hypoxemia and Hypercapnia

In the previous sections we discussed ventilation, gas distribution, and the respiratory mechanics that govern distribution, diffusion, and pulmonary perfusion. All these components of lung function can affect the oxygenation of blood, and all except diffusion can also measurably affect CO_2 elimination. The different mechanisms behind hypoxemia and CO_2 retention, or hypercapnia or hypercarbia, have been touched on in previous paragraphs but will be analyzed in more detail here.

Causes of hypoxemia can suitably be classified as hypoventilation, $\dot{V}_A/\dot{Q}$ mismatch, impaired diffusion, and right-to-left shunt. Hypercapnia can be caused by hypoventilation, $\dot{V}_A/\dot{Q}$ mismatch, and shunt, although in practice hypoventilation is the only cause of real importance (Tables 15-1 and 15-2).

Hypoventilation

If ventilation is low in proportion to metabolic demand, elimination of CO_2 will be inadequate and it will accumulate in the alveoli, blood, and other body tissues. Hypoventilation is often defined as ventilation that results in a P_{ACO_2} above 45 mm Hg (6 kPa). With this definition, hypoventilation can be present even when minute ventilation is high if the metabolic demand or dead space ventilation is increased more than minute ventilation.

The increased alveolar P_{CO_2} reduces the space available for oxygen in the alveoli. P_{AO_2} can be estimated by the alveolar gas equation, shown in Box 15-1. A simplified form is derived here. Thus, assuming a normal respiratory exchange ratio, P_{AO_2} can be calculated as

$$P_{AO_2} = P_{IO_2} - (1.25 \times P_{ACO_2})$$

The factor 1.25 is correct if the respiratory exchange ratio is 0.8, and this can reasonably be assumed under resting conditions. P_{ACO_2} can be assumed to equal P_{aCO_2}. Thus, with a P_{IO_2} of 149 mm Hg (19.9 kPa) and a P_{aCO_2} of 40 mm Hg (5.3 kPa), P_{AO_2} is 99 mm Hg (13.2 kPa), and during hypoventilation with a P_{aCO_2} of 60 mm Hg (8 kPa), P_{AO_2} is 74 mm Hg (9.9 kPa). That gives the highest possible P_{aO_2} that can exist at that level of alveolar ventilation. Thus, whether a low P_{aO_2} can be explained by hypoventilation can easily be tested with this simple formula. If there is a gap between the estimated P_{AO_2} and the measured P_{aO_2}, another or an additional cause of hypoxemia must be sought. It is also

Table 15-1 Causes of Hypoxemia

Disturbance	P_{aO_2} (breathing air) at Rest	P_{aO_2} (breathing oxygen) at Rest	P_{aO_2} (breathing air) with Exercise (Versus Rest)	P_{aCO_2}
Hypoventilation	Reduced	Normal	No change or further decrease	Increased
$\dot{V}_A/\dot{Q}$ mismatch	Reduced	Normal	No or minor increase or decrease	Normal
Shunt	Reduced	Reduced	No change or further decrease	Normal
Diffusion impairment	Reduced	Normal	Small to large decrease	Normal

Table 15-2 Mechanisms of Hypoxemia in Different Lung Disorders

Disorder	Hypoventilation	Diffusion Impairment	$\dot{V}_A/\dot{Q}$ Mismatch	Shunt
Chronic bronchitis	(+)	–	++	–
Emphysema	+	++	+++	–
Asthma	–	–	++	–
Fibrosis	–	++	+	+
Pneumonia	–	–	+	++
Atelectasis	–	–	–	++
Pulmonary edema	–	+	+	++
Pulmonary emboli	–	–	++	+
Acute respiratory distress syndrome	–	–	+	+++

obvious that the decrease in Pa_{O_2} that is caused by hypoventilation is easily overcome by increasing P_{IO_2} (which on the other hand, may decrease the stimulus to breath and cause further retention of CO_2).

Ventilation-Perfusion Mismatch

For optimum gas exchange, ventilation and perfusion must match each other in all lung regions. At rest, both ventilation and perfusion increase down the lung. Perfusion increases more than ventilation, the difference between the uppermost and lowermost 5-cm segments being 3 times for ventilation and 10 times for perfusion. This results in a mean $\dot{V}_A/\dot{Q}$ ratio of approximately 1 somewhere in the middle of the lung and a range of $\dot{V}_A/\dot{Q}$ ratios from 0.5 in the bottom of the lung to 5.0 in nondependent regions, as illustrated in Figure 15-13, upper panel (the perfusion distribution being a simplified drawing of what is shown in Fig. 15-11). Another way of showing the matching between ventilation and blood flow is by making a multicompartmental analysis of the ventilation distribution of blood flow against $\dot{V}_A/\dot{Q}$ ratios. This can be achieved by a multiple inert gas elimination technique (MIGET).[46] In short, MIGET is based on the constant infusion of a number (usually six) of inert gases with different solubilities in blood. When passing the lung, the different gases will be eliminated via alveoli and expired in proportion to their solubility. A poorly soluble gas will leave the bloodstream and be more or less completely eliminated (e.g., sulfur hexafluoride). A gas of medium solubility will be retained to some extent (e.g., halothane), and a gas with a very high solubility in blood will be retained to an almost full extent (e.g., acetone). This means that the concentration of the different gases in arterial blood will differ, with higher concentrations of gases with high solubility. Retention can be calculated as the ratio between arterial and mixed venous blood concentrations. Similarly, the ratio of expired gas concentration and mixed venous gas concentration can also be calculated and gives the excretion for each gas. With knowledge of the retention, excretion, and solubility of each gas, an essentially continuous distribution of blood flow against $\dot{V}_A/\dot{Q}$ ratios can be constructed. The lower panel in Figure 15-13 shows an example from a healthy subject. Note that ventilation and blood flow are well matched, being distributed to a limited number of compartments

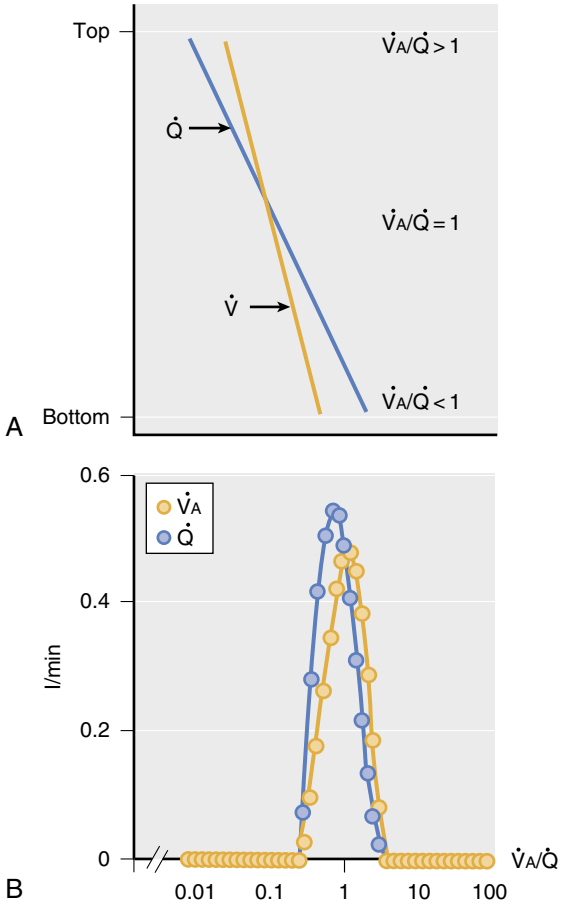

Figure 15-13 Schematic drawing of the vertical distributions of ventilation ($\dot{V}$) and blood flow through the lung ($\dot{Q}$) (**A**) and the resulting ventilation-perfusion distribution ($\dot{V}_A/\dot{Q}$) (**B**). Note the moderate increase in ventilation down the lung and the faster increase in perfusion. The $\dot{V}_A/\dot{Q}$ distribution is centered on a ratio of 1, which corresponds to the intersection of the ventilation and perfusion distribution curves. The slightly larger ventilation than perfusion in the upper lung regions contributes to the high $\dot{V}_A/\dot{Q}$ ratios above 1, whereas the larger perfusion than ventilation in the lower part of the lung is the cause of the lower $\dot{V}_A/\dot{Q}$ ratios, below 1.

centered on a $\dot{V}_A/\dot{Q}$ ratio of 1. MIGET has a high discriminatory capacity of detecting different ventilation/perfusion disturbances but does not have the potential of localizing where in the lung the impairment or variations are located. It is more like looking at a fingerprint of ventilation/perfusion match or mismatch. A number of variables that reflect the degree of mismatch can be calculated and are shown in Table 15-3. In the following paragraphs, examples of $\dot{V}_A/\dot{Q}$ mismatch are discussed.

If ventilation and perfusion are not matched, gas exchange will be affected. The most common cause of impaired oxygenation is indeed $\dot{V}_A/\dot{Q}$ mismatch. Low $\dot{V}_A/\dot{Q}$ will impede oxygenation because ventilation is too small to fully oxygenate the blood. The degree of impairment is dependent on the degree of mismatch, and even normally existing lung regions with a $\dot{V}_A/\dot{Q}$ ratio between 0.5 and 1 are unable to completely saturate the blood. Thus, Pa_{O_2} is seldom equal to alveolar P_{O_2}, but a difference ($P_{AO_2} - Pa_{O_2}$) of about 3 to 5 mm Hg (0.4 to 0.7 kPa) exists in the normal lung. With more $\dot{V}_A/\dot{Q}$ mismatch, the $P_{AO_2} - Pa_{O_2}$ difference is further increased. The $\dot{V}_A/\dot{Q}$ mismatch can account for all the hypoxemia seen in a severely obstructive patient.[47]

Table 15-3 Mean (SD) Ventilation-Perfusion Relationships with No Cardiopulmonary Disease (normal, $n = 45$), Awake and During General Anesthesia and Muscle Paralysis

	$\dot{Q}$mean	log SD$\dot{Q}$	$\dot{V}$mean	log SD$\dot{V}$	Shunt (% Q_T)	Dead Space (% V_T)	Pa_{O_2}/FI_{O_2}* (kPa)
Awake	0.76 (0-33)	0.68 (0.28)	1.11 (0.52)	0.52 (0.15)	0.5 (1.0)	34.8 (14.2)	59.5 (8.1)
Anesthetized	0.65 (0.34)	1.04 (0.36)	1.38 (0.76)	0.76 (0.31)	4.8 (4.1)	35.0 (9.9)	50.9 (15.2)

*FI_{O_2} (inspired oxygen fraction): awake, 0.21; anesthetized, 0.42.
log SD$\dot{Q}$, standard deviations of the logarithmic distribution of perfusion; log SD$\dot{V}$, standard deviations of the logarithmic distribution of ventilation; $\dot{Q}$mean, mean $\dot{V}_A/\dot{Q}$ of the perfusion distribution; $\dot{V}$mean, mean $\dot{V}_A/\dot{Q}$ of ventilation distribution.

Shunt, which is often claimed to exist in patients with COPD, is mostly absent when analyzed with more sophisticated technique such as MIGET. Indeed, shunt in an obstructive patient should be considered indicative of a complicating factor in the disease (Fig. 15-14, lower left panel).

In severe asthma it is common to see a distinct mode of low $\dot{V}_A/\dot{Q}$ ratios when using MIGET.[48] Thus, a bimodal distribution of $\dot{V}_A/\dot{Q}$ ratios can be seen (Fig. 15-14, upper right panel). The explanation is probably that alveoli behind completely obstructed airways (edema, mucous plug, spasm) can still be ventilated through alveolar pores and interbronchial communications, so-called collateral ventilation. This may also explain why shunting is not normally seen in patients with COPD. However, with standard techniques, such as calculation of shunt by the oxygen equation, low $\dot{V}_A/\dot{Q}$ cannot be separated from shunt. One should rather use the expression "venous admixture" in this case.

Airway obstruction is unevenly distributed over the lung, and a large variation in $\dot{V}_A/\dot{Q}$ ratios can be seen in a single patient. Indeed, ventilation is redistributed from regions with high airway resistance to other regions that may become overventilated in proportion to their perfusion. This causes high $\dot{V}_A/\dot{Q}$ ratios. There are normally regions in the upper part of the lung that have $\dot{V}_A/\dot{Q}$ ratios of up to 5, but in obstructive patients ratios of up to 100 or greater can be seen, thus making them practically indistinguishable from true dead space. This is what causes the increase in "physiologic" dead space in obstructive lung disease. The effect of high $\dot{V}_A/\dot{Q}$ is also the same as for airway dead space, that is, ventilation that seems to not participate in gas exchange ("wasted ventilation"). Consequently, at the same time an obstructive patient suffers from low $\dot{V}_A/\dot{Q}$, which causes hypoxemia, and high $\dot{V}_A/\dot{Q}$, which mimics dead space ventilation and impedes CO_2 elimination. However, the complexity of MIGET makes it essentially a research tool, and for clinical purposes and many scientific studies, calculation of dead space must rely on measurement of expired CO_2. Derivation of the CO_2 dead space is shown in Box 15-2.

$\dot{V}_A/\dot{Q}$ mismatch exists to varying degree in all patients with COPD and can, as said earlier, explain all hypoxemia in most of these patients. Hypoventilation may be a contributing factor, whereas impaired diffusion (to the extent that it causes hypoxemia) and shunt are less common (see later).

Pulmonary vessels can be affected by lung disease and cause $\dot{V}_A/\dot{Q}$ mismatch by impeding regional blood flow. Systemic diseases with vascular involvement such as periarteritis nodosa, disseminated lupus erythematosus, scleroderma, and rheumatoid diseases may cause severe pulmonary dysfunction with $\dot{V}_A/\dot{Q}$ mismatch, impaired diffusion, and shunt. $\dot{V}_A/\dot{Q}$ mismatch causes most of the hypoxemia that can be seen in pulmonary fibrosis at rest.[49] In addition, hypoxemia can be caused by impaired diffusion (in particular, during exercise, when it may dominate) and a varying degree of shunt (see later). Pulmonary emboli cause $\dot{V}_A/\dot{Q}$ mismatch because the occluded vascular bed forces blood flow to other, open regions, thus making these regions overperfused in relation to their ventilation. This, again, causes low $\dot{V}_A/\dot{Q}$. Shunt may be small unless pulmonary artery pressure is markedly increased.[50]

Pneumonia and various forms of acute respiratory failure are signified by shunt and to a varying extent by $\dot{V}_A/\dot{Q}$ mismatch (Fig. 15-14, lower right panel). This can easily be understood from the presence of atelectasis, fluid filling, and consolidation seen with these diseases.[51]

Is CO_2 removal less affected than oxygenation of blood by $\dot{V}_A/\dot{Q}$ mismatch? It is perhaps if the CO_2 content of blood is more linearly related to CO_2 tension than the O_2 content is related to P_{O_2}, according to the oxygen dissociation curve. However, this is not true. Elimination of CO_2 is even more limited by $\dot{V}_A/\dot{Q}$ mismatch than O_2 transfer is.[31] Still, it is rare to see hypercapnia caused by mismatch because any increase in CO_2 tension stimulates increased ventilation to bring Pa_{CO_2} back toward normal. If alveolar ventilation is already impaired and cannot be increased, the addition of $\dot{V}_A/\dot{Q}$ mismatch may make matters worse.

Impaired Diffusion

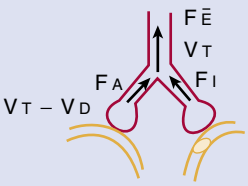
Impaired diffusion to the extent that it reduces Pa_{O_2} can occur if the alveolar-capillary membranes are thickened, as in fibrosis and systemic vascular diseases. Diffusion is slowed down and the whole capillary distance may be required before the capillary blood has been fully oxygenated, even in resting conditions. On

Box 15-2 Derivation of the Physiologic Dead Space Equation

$$F\bar{E} \times V_T = F_A(V_T - V_{DS}) + (F_I \times V_{DS})$$

By rearranging,

$$\frac{V_{DS}}{V_T} = \frac{F_A - F\bar{E}}{F_A - F_I}$$



If $F_I = 0$, F replaced by P, and P_A replaced by Pa, for CO_2,

$$\frac{V_{DS}}{V_T} = \frac{Pa_{CO_2} - P\bar{E}_{CO_2}}{Pa_{CO_2}}$$

where $F\bar{E}$, F_A, and F_I are mixed expired, alveolar, and inspired gas concentration, respectively, and V_T, V_{DS}, and V_A are tidal volume, dead space, and part of the tidal volume to perfused alveoli, respectively.

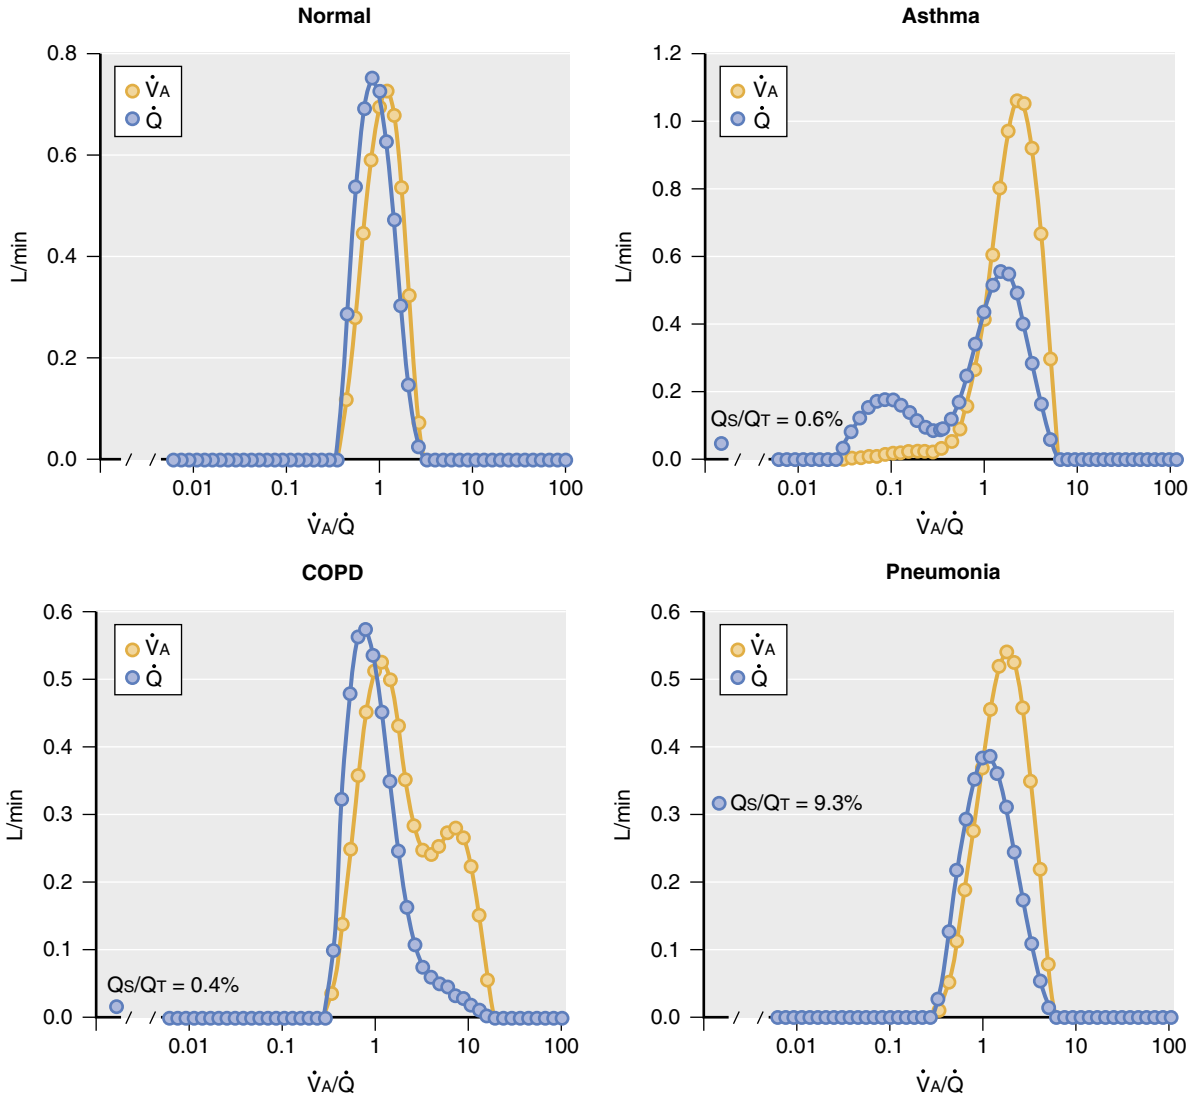


Figure 15-14 Ventilation-perfusion distributions in a normal subject (*upper left panel*), in a patient with asthma (*upper right panel*), in a patient with chronic obstructive pulmonary disease (COPD) (*lower left panel*), and in a patient with pneumonia (*lower right panel*). Note the good matching between ventilation and perfusion with a mode centered around a $\dot{V}_A/\dot{Q}$ ratio of 1 in the normal subject. This results in nearly optimal oxygenation of blood, as well as CO_2 removal. The asthmatic patient has broader distribution of $\dot{V}_A/\dot{Q}$ ratios, with some regions being ventilated well in excess of perfusion ($\dot{V}_A/\dot{Q}$ of 10 and higher), and there is another distinct mode of "low" $\dot{V}_A/\dot{Q}$ ratios centered around a $\dot{V}_A/\dot{Q}$ ratio of 0.1. This mode can reasonably be explained by collateral ventilation that maintains certain gas exchange behind otherwise occluded airways. Finally, no shunt can be seen. The chronic bronchitis patient may have a pattern that is not that different from the asthmatic patient, but there can also be a more clear "high"-$\dot{V}_A/\dot{Q}$ mode that adds to the dead space–like ventilation. A shunt cannot be seen, but if visible in the COPD patient, it indicates a complicating dysfunction (pneumonia, atelectasis, or something else?). The $\dot{V}_A/\dot{Q}$ pattern shown in the figure should not result in any considerable hypoxemia. The patient suffering from pneumonia shows minor widening of the $\dot{V}_A/\dot{Q}$ distribution, and the major finding is a pure shunt that is caused by consolidation of lung tissue that is still perfused but not ventilated. Q_S/Q_T, ratio of shunt blood flow to cardiac output.

the other hand, this means that a diffusion barrier may not cause hypoxemia as long as there is enough time and capillary distance to allow equilibration (see Fig. 15-10). However, when all reserve has been spent, Pao_2 begins to fall. This is particularly noticeable in patients with pulmonary fibrosis, who may have normal Pao_2 at rest but show dramatic decreases during exercise, down to 40 to 45 mm Hg (≈5 to 6 kPa).[31,49] There is almost no other condition that can cause such a decrease and, if found, should bring impaired diffusion into consideration. Obstructive lung disease does not cause such impairment of oxygenation; Pao_2 changes only a little and can even improve! The only condition that can lower Pao_2 to a similar extent is the appearance of or increase in right-to-left shunting in the heart, such as an atrial septal defect with a left-to-right shunt at rest that reverses during exercise because of increasing pulmonary hypertension.

Right-to-Left Shunt

If blood passes through the lung without coming into contact with ventilated alveoli, the blood will not be oxygenated or release CO_2. This is a shunt that lowers Pao_2 and increases, although less easy to observe, $Paco_2$. A small shunt of 2% to 3% of cardiac output can be seen in normal subjects and is caused by the thebesian veins that drain the heart and empty into the left atrium. In pathologic states, shunt may amount to anything between nearly normal to above 50% of cardiac output. Shunt may be considered an extreme of mismatch, with a $\dot{V}_A/\dot{Q}$ of zero. However, there

are clear differences between the concepts of mismatch and shunt. First, the anatomic basis differs. Regions with low $\dot{V}_A/\dot{Q}$ are caused by airway and vascular narrowing. This reduces ventilation and blood flow in some regions and increases them in others. Examples are obstructive lung disease and vascular disorders. Shunt is caused by the complete cessation of ventilation in a region, usually as a result of collapse (atelectasis) or consolidation (pneumonia, edema, obliterative processes). Contrary to what is normally said, asthma, bronchitis, and emphysema do not cause a shunt.[47] If a shunt is found, it indicates a complication. Second, the effect of "low $\dot{V}_A/\dot{Q}$" on oxygenation of blood can essentially be overcome by adding more oxygen to the inspired air. Even in a poorly ventilated lung unit, P_{AO_2} can be increased almost as much as in normal regions, the difference being caused by the higher P_{ACO_2} in the poorly ventilated units. The effect of a moderate shunt can be reduced, but not eliminated, by giving more oxygen because the nonventilated region cannot be reached by the inspired gas. Thus, shunt will always lower Pa_{O_2} at any P_{IO_2}, as compared with what would have been measured without shunt. When the shunt increases to 25%, the rise in Pa_{O_2} will be small, and with a shunt of 30% or greater, almost no effect of added O_2 can be seen.[51] This is the net effect of mixing blood with normal pulmonary end-capillary P_{O_2} and shunt blood with mixed venous P_{O_2}. If the latter is a large enough fraction of total lung blood flow, the additional O_2 that can be physically dissolved by the raised P_{IO_2} is so small that it is almost immeasurable. The shunt is said to be refractory.

Respiratory Function During Anesthesia

Anesthesia causes an impairment in pulmonary function, whether the patient is breathing spontaneously or is ventilated mechanically after muscle paralysis. Impaired oxygenation of blood occurs in most subjects who are anesthetized.[52] It has therefore become routine to add oxygen to the inspired gas so that the inspired oxygen fraction (F_{IO_2}) is maintained at around 0.3 to 0.4. Despite these measures, mild to moderate hypoxemia, defined as an arterial oxygen saturation of between 85% and 90%, may occur in approximately half of all patients undergoing elective surgery, and the hypoxemia can last from a few seconds to up to 30 minutes. About 20% of patients may suffer from severe hypoxemia, or oxygen saturation below 81% for up to 5 minutes.[53] Lung function remains impaired postoperatively, and clinically significant pulmonary complications can be seen in 1% to 2% after minor surgery in up to 20% after upper abdominal and thoracic surgery.[54]

In this section, the effect of anesthesia and mechanical ventilation on lung function will be described. The order of the different paragraphs will follow an order that relates to the sequence of events that affect the lung's ability to oxygenate the blood and to remove carbon dioxide. Thus, the first phenomenon that might be seen with anesthesia is loss of muscle tone with a subsequent change in the balance between outward forces (i.e., respiratory muscles) and inward forces (i.e., elastic tissue in the lung) leading to a fall in FRC. This causes or is paralleled by an increase in the elastic behavior of the lung (reduced compliance) and an increase in respiratory resistance. The decrease in FRC affects the patency of lung tissue with the formation of atelectasis (made worse with the use of high concentrations of inspired oxygen) and airway closure. This alters the distribution of ventilation and matching of ventilation and blood flow and impedes oxygenation of blood and removal of carbon dioxide.

Lung Volume and Respiratory Mechanics During Anesthesia

Lung Volume

Resting lung volume, or FRC, is reduced by 0.8 to 1.0 L by changing body position from upright to supine, and there is another 0.4- to 0.5-L decrease when anesthesia has been induced.[55] End-expiratory lung volume is thus reduced from approximately 3.5 to 2 L, the latter being close or equal to RV. The anesthesia per se causes a fall in FRC despite maintenance of spontaneous breathing,[56,57] and the decrease in FRC occurs regardless of whether the anesthetic is inhaled or given intravenously.[58] Muscle paralysis and mechanical ventilation cause no further decrease in FRC. The average reduction corresponds to around 20% of awake FRC and may contribute to an altered distribution of ventilation and impaired oxygenation of blood, as discussed later.

The decrease seems to be related to loss of respiratory muscle tone, which shifts the balance between the elastic recoil force of the lung and the outward force of the chest wall to a lower chest and lung volume. Maintenance of muscle tone, as during ketamine anesthesia, does not reduce FRC.[58] The influence of body position and anesthesia on FRC is shown in Figure 15-8. As can be seen in the figure, FRC increases with age if weight and height remain unaltered over the years.

The decrease in FRC is caused by a cranial shift of the diaphragm and a small decrease in the transverse thoracic area in a majority of studies as evidenced by repeated CT scanning.[58,59] However, somewhat conflicting results have been reported regarding the diaphragm, with only minor displacement of the diaphragm and the anterior part even being shifted caudally.[60] Such caudal displacement could in theory occur if the ribs are tilted downward during anesthesia.

Compliance and Resistance of the Respiratory System

Static compliance of the total respiratory system (lungs and chest wall) is reduced on average from 95 to 60 mL/cm H_2O during anesthesia.[61] Several studies on lung compliance have been carried out during anesthesia, and the vast majority of studies indicate a decrease in comparison to the awake state (e.g., static lung compliance fell from a mean of 187 mL/cm H_2O awake to 149 mL/cm H_2O during anesthesia when data from several studies were pooled).[61]

There are also studies on resistance of the total respiratory system and the lungs during anesthesia, most of them showing a considerable increase during both spontaneous breathing and mechanical ventilation.[61] However, the studies on resistance during anesthesia have been hampered by different experimental conditions during the awake and anesthetized situations. Thus, a study that enables comparison of resistance under both isovolume and isoflow conditions is still awaited. The possibility remains that the increased lung resistance merely reflects reduced FRC during anesthesia (Fig. 15-15).

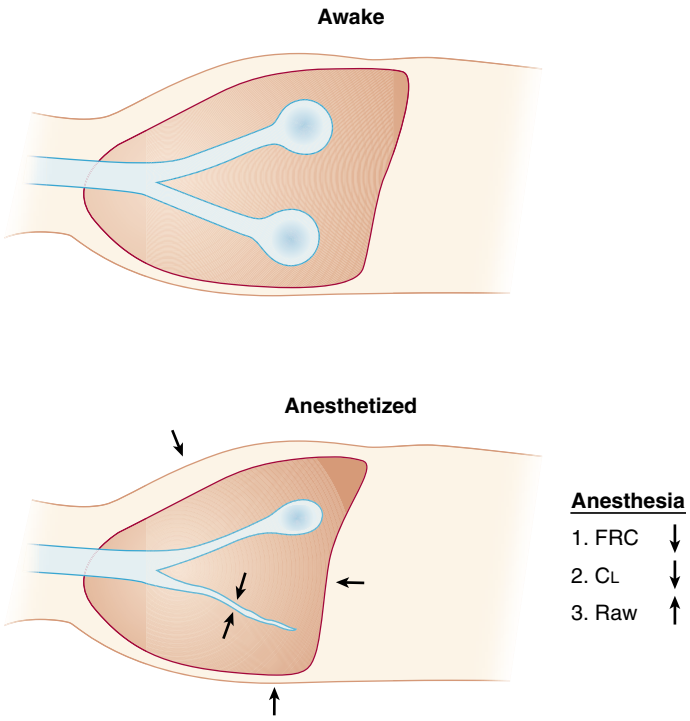

Figure 15-15 Cranial shift of the diaphragm and a decrease in transverse diameter of the thorax contribute to lowered functional residual capacity (FRC) during anesthesia. Decreased ventilated volume (atelectasis and airway closure) is a possible cause of reduced lung compliance (C_L). Decreased airway dimensions by the lowered FRC should contribute to increased airway resistance (Raw).

Atelectasis and Airway Closure During Anesthesia

Atelectasis

In their classic paper, Bendixen and coworkers proposed "a concept of atelectasis" as a cause of impaired oxygenation during anesthesia.[62] They had observed a successive decrease in compliance of the respiratory system and a similar successive decrease in arterial oxygenation in both anesthetized humans and experimental animals. This was interpreted as formation of atelectasis. However, other research groups who were unable to reproduce their findings noticed a more prompt fall in compliance and Pao_2 on induction of anesthesia. Moreover, atelectasis could not be shown on conventional chest radiography.

In the mid-eighties, new observations were made that may explain the altered function of the lung during anesthesia. On CT with transverse exposure of the chest, prompt development of densities in the dependent regions of both lungs could be shown during anesthesia. For a review with references from before 1990, see the ISPOCD1 study.[53] Morphologic studies of these densities in various animals supported the diagnosis of atelectasis. An example of atelectasis as seen on a CT scan is shown in Figure 15-16.

Atelectasis appears in approximately 90% of all patients who are anesthetized.[63] It is seen during spontaneous breathing and after muscle paralysis and whether intravenous or inhaled anesthetics are used.[58] The atelectatic area on a CT cut near the diaphragm is around 5% to 6% of the total lung area but can easily exceed 15% to 20%. It should also be remembered that the amount of tissue that is collapsed is even larger, the atelectatic area consisting of mainly lung tissue and the aerated lung consisting of only 20% to 40% tissue, the rest being air. Thus, 15% to 20% of the lung is regularly collapsed at the base of the lung during uneventful anesthesia, before any surgery has even been done! Abdominal surgery does not add much to the atelectasis, but it can remain for several days in the postoperative period.[64] It is likely that it is a focus of infection and can contribute to pulmonary complications.[65] It may also be mentioned that after thoracic surgery and cardiopulmonary bypass, more than 50% of the lung can be collapsed even several hours after surgery.[66] The amount of atelectasis decreases toward the apex, which is mostly spared (fully aerated) (Fig. 15-17).

There is a weak correlation between the size of the atelectasis and body weight or body mass index (BMI),[58,67] with obese patients showing larger atelectatic areas than lean ones do. Although this was expected, it came as a surprise that the atelectasis is independent of age, with children and young people showing as much atelectasis as elderly patients.[63] Another unexpected observation was that patients with COPD showed less or even no atelectasis during the 45 minutes of anesthesia that they were studied.[68] The mechanism that prevents the lung from collapse is not clear but may be airway closure occurring before alveolar collapse takes place, or it may be an altered balance between the chest wall and the lung that counters a decrease in lung dimensions.

There is good correlation between the amount of atelectasis and pulmonary shunt as measured by MIGET. A regression equation based on a total of 45 patients studied during anesthesia with inhaled anesthetics has been calculated as shunt = 0.8 × atelectasis + 1.7 ($r = .81$, $P < .01$), with atelectasis expressed as the percentage of lung area just above the diaphragm on CT scan and shunt expressed as the percentage of cardiac output. Interestingly, shunt did not increase with age.[63] By combining CT scanning and SPECT, the distribution of shunt and its location within the atelectatic area were confirmed (Fig. 15-18).[69]

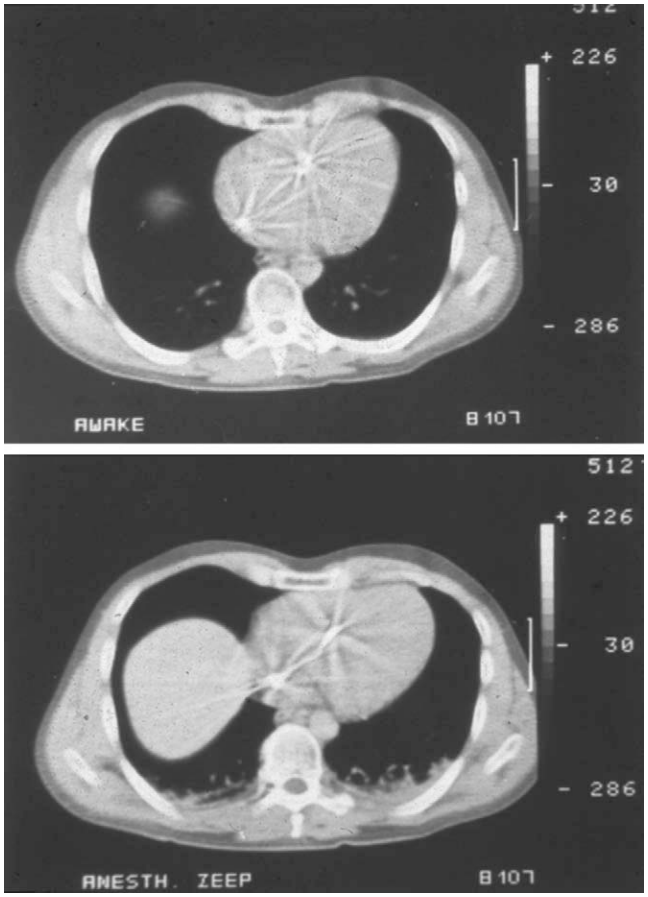

Figure 15-16 Computed tomography with transverse exposure of the chest when the subject is awake (*upper panel*) and then anesthetized (*lower panel*). Note the well-aerated lung in the awake condition. A few pulmonary vessels can be seen in the lower lung regions. The radiating beams in the heart are caused by a catheter that is positioned with its tip in the pulmonary artery. During anesthesia, atelectasis has developed in the most dependent regions of both lungs (seen as gray/white irregular areas). The large gray/white area in the middle of the right lung field is caused by a cranial shift of the diaphragm and the underlying liver. The exposure levels of the two scans are the same relative to the spine.

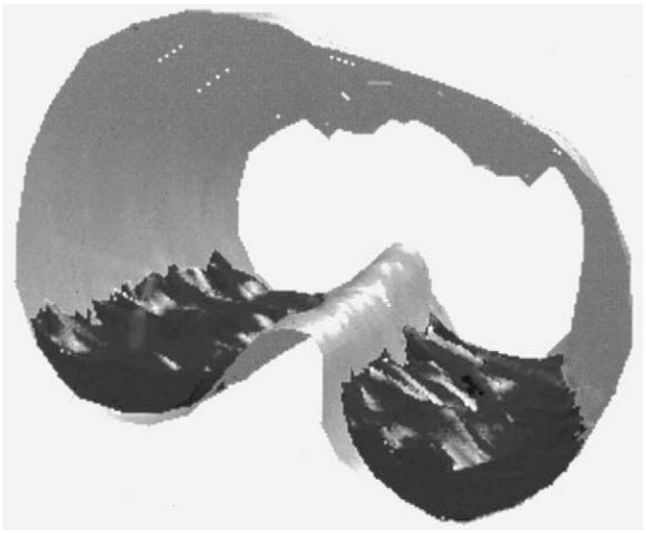

Figure 15-17 Three-dimensional reconstruction of the thorax of an anesthetized patient with atelectasis in the dependent regions of both lungs. Note the irregular shape of the atelectasis. There is a slight decrease in the amount of atelectasis toward the apex, which is at the distal end of the chest wall on the image. *(Redrawn from data in Reber A, Nylund U, Hedenstierna G: Position and shape of the diaphragm: Implications for atelectasis formation. Anaesthesia 53:1054-1061, 1998.)*

Prevention of Atelectasis During Anesthesia

Several interventions can help prevent atelectasis or even reopen collapsed tissue, as discussed in the following paragraphs.

Positive End-Expiratory Pressure. The application of 10–cm H_2O PEEP has been tested in several studies and will consistently reopen collapsed lung tissue. This is more likely an effect of increased inspiratory airway pressure than of PEEP per se.[58] However, some atelectasis persists in most patients. Whether a further increase in the PEEP will reopen this tissue was not analyzed in these studies. PEEP, however, does not appear to be the ideal procedure. First, shunt is not reduced proportionately, and arterial oxygenation may not improve significantly. Hewlett and coworkers warned even in 1974 of the "indiscriminate use of PEEP in routine anesthesia."[70] The persistence of shunt may be explained by a redistribution of blood flow toward more dependent parts of the lungs when intrathoracic pressure is increased by PEEP (Fig. 15-19). Under such circumstances, any persisting atelectasis in the bottom of the lung receives a larger share of the pulmonary blood flow than without PEEP.[71] Furthermore, increased intrathoracic pressure will impede venous return and decrease cardiac output. This results in a lower venous oxygen tension for a given oxygen uptake and reduces arterial oxygen tension. Second, the lung recollapses rapidly after discontinuation of PEEP. Within 1 minute after cessation of PEEP, the collapse is as large as it was before the application of PEEP.[58]

Maintenance of Muscle Tone. Use of an anesthetic that allows maintenance of respiratory muscle tone will prevent atelectasis from forming. Ketamine does not impair muscle tone and does not cause atelectasis. This is the only anesthetic thus far tested that does not cause collapse. However, if muscle relaxation is required, atelectasis will appear as with other anesthetics.[58]

Another technique used in an attempt to restore respiratory muscle tone is pacing of the diaphragm. This was tested by applying phrenic nerve stimulation, which did reduce the atelectatic area.[72] The effect was small, however, and this technique is certainly too complicated to be used routinely during anesthesia and surgery.

Recruitment Maneuvers. The use of a sigh maneuver, or a double V_T, has been advocated to reopen any collapsed lung tissue.[73] However, the atelectasis is not decreased by a double V_T or by a sigh up to an airway pressure of 20 cm H_2O.[67] Not until an airway pressure of 30 cm H_2O is reached does the atelectasis decrease to approximately half the initial size. For complete reopening of all collapsed lung tissue, an inflation pressure of 40 cm H_2O is required (Fig. 15-20). Such a large inflation corresponds to a maximum spontaneous inspiration, and it can thus be called a VC maneuver.

Because a VC maneuver may result in adverse cardiovascular events, the dynamics in resolving atelectasis during such a procedure was analyzed.[74] It was found that in adults with healthy lungs, inflation of the lungs to +40 cm H_2O maintained for no more than 7 to 8 seconds may re-expand all previously collapsed lung tissue.

Minimizing Gas Resorption. Ventilation of the lungs with pure oxygen after a VC maneuver that had reopened previ-

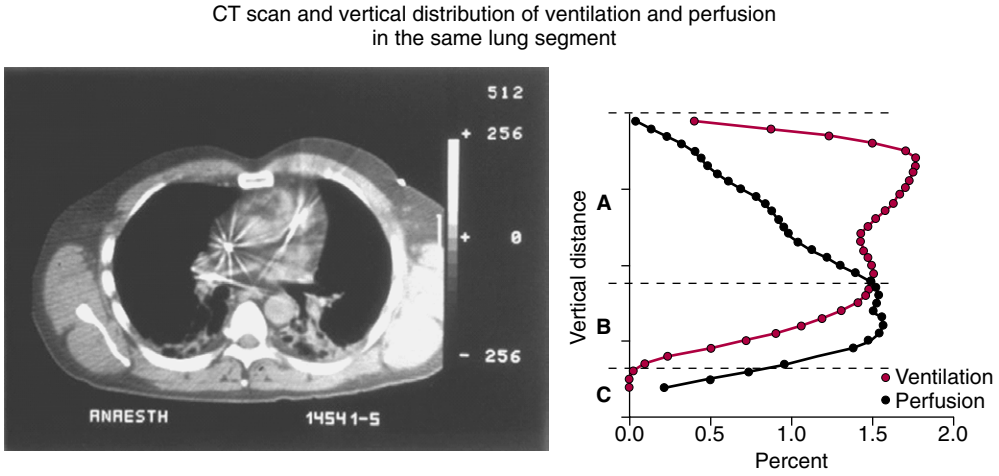

Figure 15-18 Transverse computed tomography (CT) scan with atelectasis visible in the dependent parts of both lungs (*left panel*) and corresponding vertical distributions of ventilation and lung blood flow (*right panel*) in an anesthetized subject. Note that ventilation is distributed preferentially to the upper lung regions, contrary to what is seen in an awake subject. Ventilation exceeds perfusion at that level, and this results in a dead space–like effect, or wasted ventilation (zone A in the *right panel*). Note also the decreasing ventilation in the lower half of the lung such that perfusion is larger at that level. This results in so-called low $\dot{V}_A/\dot{Q}$ and causes impaired oxygenation of blood. Intermittent airway closure is the probable mechanism behind the reduced ventilation (zone B). There is complete cessation of ventilation in the bottom, which corresponds to the atelectatic area. However, there is still perfusion producing a shunt (zone C). It can also be seen that perfusion increases down the lung, except for the bottom-most region, where a decrease can be seen. This so-called zone IV may be caused by increased interstitial lung pressure compressing extra-alveolar vessels and hypoxic pulmonary vasoconstriction. *(Redrawn from data in Tokics L, Hedenstierna G, Svensson L, et al: V/Q distribution and correlation to atelectasis in anesthetized paralyzed humans. J Appl Physiol 81:1822-1833, 1996.)*

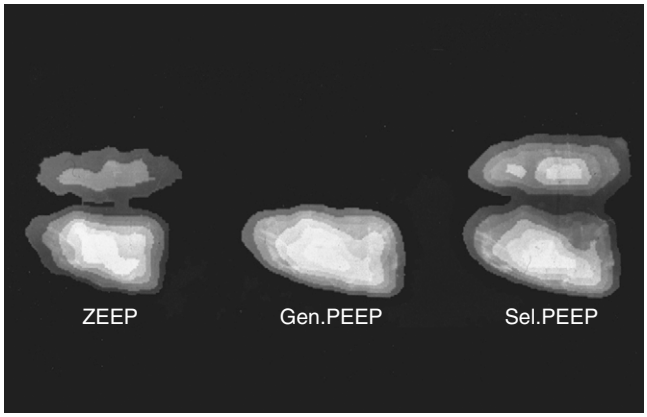

Figure 15-19 Gamma camera images of the distribution of lung blood flow in an anesthetized subject in the lateral position. During mechanical ventilation with zero end-expiratory pressure (ZEEP), perfusion goes mainly to the lower lung, but there is still perfusion of the upper lung, with the average distribution to the upper lung being 33% to 40% of total lung perfusion. With a general PEEP of 10 cm H_2O, perfusion is squeezed down to the lower lung, and in this particular example there is almost no perfusion at all in the upper lung. This causes a dramatic dead space–like effect. If, on the other hand, PEEP is applied selectively to the lower lung, in this example 10 cm H_2O, perfusion might be redistributed to the upper lung so that a more even distribution between the two lungs can be seen. It should be clear that the size of the upper and lower lungs, as shown on the image, does not reflect lung volume but perfused lung tissue. The upper lung should be expected to be larger than the lower lung in the lateral position. *(From Hedenstierna G, Baehrendtz S, Klingstedt C, et al: Ventilation and perfusion of each lung during differential ventilation with selective PEEP. Anesthesiology 61:369-376, 1984.)*

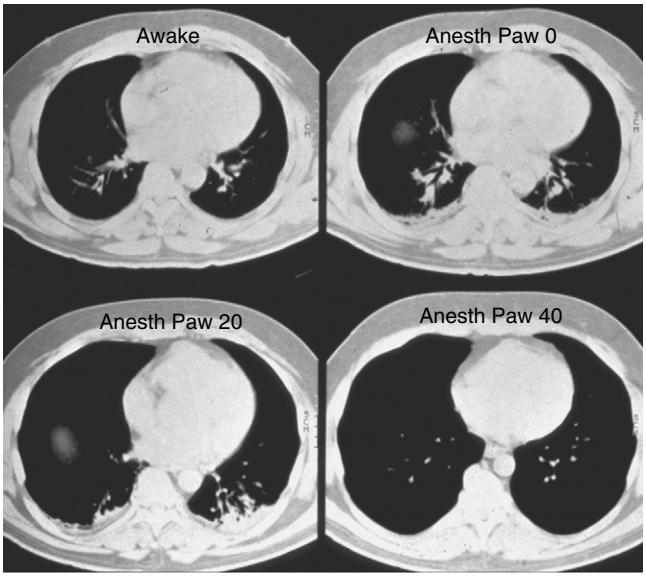

Figure 15-20 Computed tomography scans in a subject when awake (*upper left panel*); during anesthesia at zero end expiratory pressure (*upper right panel*); during anesthesia and an airway pressure of 20 cm H_2O, which corresponds to a double tidal volume (*lower left panel*); and during anesthesia at maximal inflation of the lungs to an airway pressure of 40 cm H_2O (*lower right panel*). Note that there is no atelectasis in the awake subject; only vessels can be seen in the lower part of the lung. During anesthesia with zero airway pressure, atelectasis can be seen in the dependent parts of both lungs. Inflation to 10 cm H_2O, corresponding to a regular tidal volume, does not open any tissue (not shown here). Inflation to 20 cm H_2O still did not open any lung tissue. Not until inflation to 30 cm H_2O (not shown here) did collapsed lung tissue start to open. A maximum inflation of 40 mm Hg airway pressure (Paw) was required to fully open the lung. Thus, a "vital" capacity maneuver was required to open the lung (the volume inflated corresponded to the maximum breath by the awake subject before anesthesia). *(From Rothen HU, Sporre B, Engberg G, et al: Reexpansion of atelectasis during general anaesthesia: A computed tomography study. Br J Anaesth 71:788-795, 1993.)*

ously collapsed lung tissue resulted in rapid reappearance of the atelectasis.[75] If, on the other hand, 40% O_2 in nitrogen is used for ventilation of the lungs, atelectasis reappears slowly, and 40 minutes after the VC maneuver only 20% of the initial atelectasis had reappeared. Thus, ventilation during anesthesia should be done with a moderate fraction of inspired oxygen (e.g., F_{IO_2} of 0.3 to 0.4) and should be increased only if arterial oxygenation is compromised.

The striking effects of oxygen during anesthesia raised the question of whether "preoxygenation" during induction of anesthesia has an effect on the formation of atelectasis. Breathing of 100% O_2, just for a few minutes before and during commencement of anesthesia, increases the safety margin in the event of difficult intubation of the airway with prolonged apnea. However, there turned out to be a price for it. Avoidance of the preoxygenation procedure (ventilation with 30% O_2) eliminated atelectasis formation during induction and subsequent anesthesia.[76] In a subsequent study, 12 patients were breathing 100% O_2 during induction of anesthesia, another 12 were breathing 80% O_2, and still another 12 breathed 60% O_2.[77] Atelectasis appeared in all patients receiving 100% O_2, was much smaller in the 80% O_2 group, and was almost absent in the 60% O_2 group (Fig. 15-21).

Preoxygenation can also be provided without producing atelectasis if undertaken with continuously increased airway pressure, as with continuous positive airway pressure (CPAP). By applying CPAP of 10 cm H_2O, Rusca and associates could induce anesthesia on 100% O_2 without any substantial atelectasis formation.[78] This technique might provide the greatest safety without atelectasis formation but it requires a tight system and might be complicated in clinical practice.

Postanesthetic Oxygenation. Preoxygenation promotes not only the formation of atelectasis but also the so-called postanesthetic oxygenation at the end of the surgery. This procedure is often combined with suctioning of the airway tree, and it is difficult to see how any other technique can be invented that is so likely to produce atelectasis as suctioning together with postanesthetic oxygenation! This will most likely deliver a patient to the postoperative ward with more atelectasis than at any other moment during anesthesia and surgery. Postanesthetic oxygenation (100% O_2) 10 minutes before termination of anesthesia together with a VC maneuver at the end of anesthesia did not protect against atelectasis at the end of anesthesia.[79] This is most likely the effect of first reopening collapsed tissue and then, under the influence of 100% O_2, derecruiting previously opened lung tissue. A VC maneuver followed by a lower O_2 concentration, 40%, kept the lung open after recruitment until the end of anesthesia. This is not unexpected in view of the findings earlier in the anesthesia procedure.

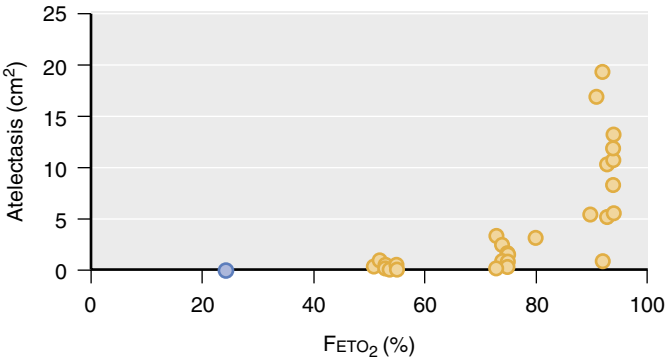

Figure 15-21 Formation of atelectasis in anesthetized subjects whose anesthesia has been induced with different inspired oxygen concentrations during the preoxygenation period. Twelve subjects were given 100% O_2, another 12 subjects 80%, and still another 12 subjects 60% O_2. The graph shows the expired oxygen concentration, which explains why the individual symbols are not at 60%, 80%, and 100%. Note the much larger atelectasis with preoxygenation of 100% (although there is large scatter) than at 80% and 60%, with almost no atelectasis at 60% preoxygenation. The *blue circle* at around an end-tidal oxygen concentration (F_{ETO_2}) of 25% corresponds to data obtained by Rothen and colleagues, who induced anesthesia in subjects given 30% O_2. *(From Rothen HU, Sporre B, Engberg G, et al: Prevention of atelectasis during general anesthesia. Lancet 345:1387-1391, 1995.)*

Airway Closure

In addition to atelectasis, intermittent closure of airways can be expected to reduce the ventilation of dependent lung regions. Such lung regions may then become "low-$\dot{V}_A/\dot{Q}$" units if perfusion is maintained or not reduced to the same extent as ventilation. Airway closure increases with age[25] (see also Fig. 15-7), as does perfusion to "low-$\dot{V}_A/\dot{Q}$" regions.[47] Because anesthesia causes a reduction in FRC of 0.4 to 0.5 L,[55] it may be anticipated that airway closure will become even more prominent in an anesthetized subject. There is accumulating evidence that such is the case.[80,81] The reduced ventilation in the lower half of the lung, just above the atelectasis, that can be seen in Figure 15-18 is reasonably explained by airway closure. It can also be seen that ventilation is smaller than perfusion, thereby causing "low-$\dot{V}_A/\dot{Q}$" regions. These regions contribute to impaired oxygenation during anesthesia.

As much as 74% of the impaired arterial oxygenation can be explained by atelectasis and airway closure taken together, according to the following equation[57]:

$$P_{aO_2}\,(\text{mm Hg}) = 218 - 22 \cdot \ln\ \text{atelectasis}\,(\text{cm}^2) - 0.06\,(\text{CV} - \text{ERV})\,(\text{mL})$$

($r = .86$, $P < .001$), where (CV − ERV) indicates the amount of airway closure occurring above FRC and ERV is expiratory reserve volume. A simple three-compartment lung model can be constructed to explain the impaired oxygenation during anesthesia. The model consists of one compartment with "normal" ventilation and perfusion, one compartment with airway closure that impedes ventilation, and a final compartment of collapsed lung with no ventilation at all. This is shown in Figure 15-22, left panel, together with the subsequent impact on $\dot{V}_A/\dot{Q}$ distribution.

Distribution of Ventilation and Blood Flow During Anesthesia

Distribution of Ventilation

Redistribution of inspired gas away from dependent to nondependent lung regions has been observed in anesthetized supine humans by isotope techniques. With the use of a radiolabeled aerosol and SPECT, ventilation was shown to be distributed mainly to the upper lung regions, and there was a successive decrease down the lower half of the lung.[69] Moreover, there was no ventilation at all in the bottom of the lung, a finding

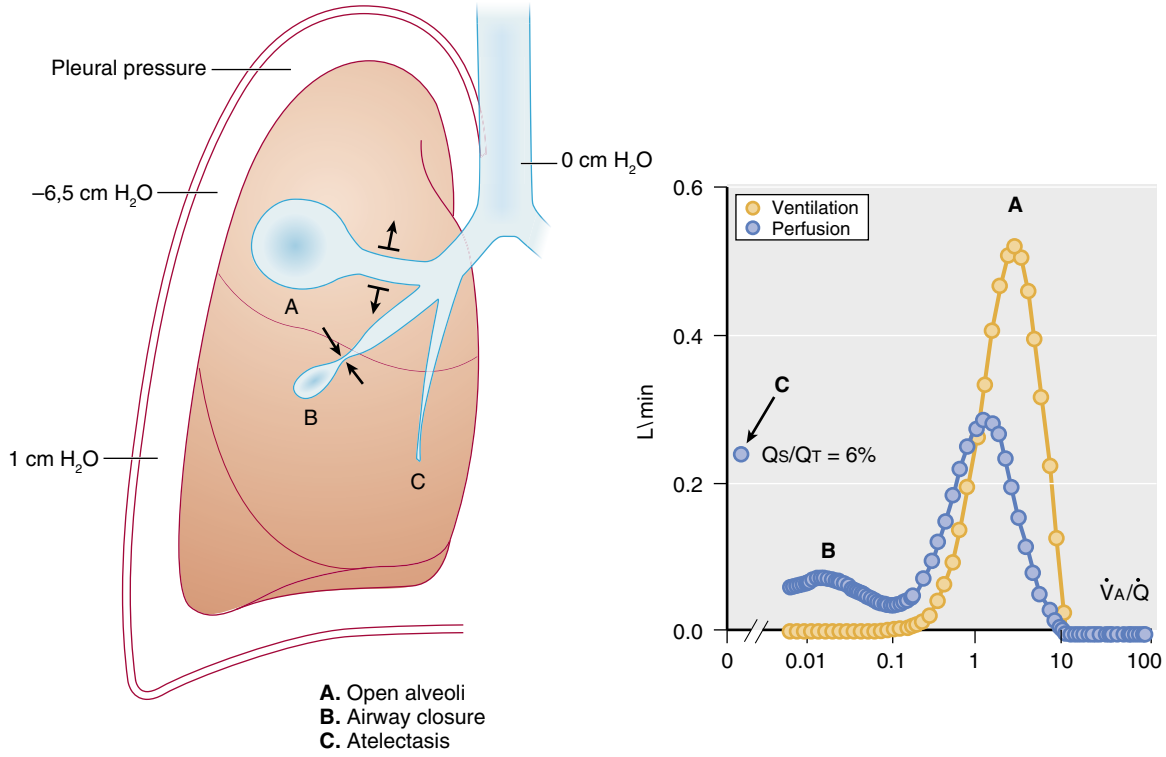

Figure 15-22 Three-compartment model of the lung in an anesthetized subject. In the upper part of the lung, the alveoli and airways are open (zone A). In the middle and lower parts of the lung, the airways are intermittently closed and impede ventilation (zone B), and in the bottom of the lung, the alveoli have collapsed (atelectasis, zone C). Compare with Figure 15-7. The corresponding ventilation-perfusion distribution as assessed by the multiple inert gas elimination technique can be seen in the *right panel*. Modes A and B correspond to a well-ventilated and perfused lung region and a region with intermittent airway closure, respectively, and are similar to what was shown in Figure 15-7. In addition, there is a shunt that is caused by perfusion of the atelectatic zone (C) in the bottom of the lung.

corresponding to the distribution of atelectasis that was simultaneously observed by CT (see Fig. 15-18).

PEEP increases dependent lung ventilation in anesthetized subjects in the lateral position, so the distribution of ventilation is more similar to that in the awake state.[82] Similar findings of more even distribution between the upper and lower lung regions have also been made in supine anesthetized humans after previous inflation of the lungs, similar to PEEP.[83] Thus, restoration of overall FRC toward or beyond the awake level returns gas distribution toward the awake pattern. It is reasonably an effect of the recruitment of collapsed, dependent lung regions (atelectasis), of reopening of closed airways in the lower lung regions, and possibly of increased expansion of the upper lung regions so that they become less compliant (and less ventilated).

Distribution of Lung Blood Flow

As discussed earlier, the distribution of lung blood flow has been studied by injection of radioactively labeled macroaggregated albumin and SPECT in anesthetized, mechanically ventilated patients.[69] A successive increase in perfusion down the lung, from the ventral to the dorsal aspect, was seen, with some reduction in the lowermost region. Thus, the lowermost portion of the lung, which was atelectatic as evidenced by simultaneous CT, was still perfused (see Fig. 15-18).

PEEP will impede venous return to the right heart and therefore reduce cardiac output. It may also affect pulmonary vascular resistance, although this may have less of an effect on cardiac output. In addition, PEEP causes a redistribution of blood flow toward dependent lung regions.[71,83] By this means, upper lung regions may be poorly perfused, thereby causing a dead space–like effect. Moreover, forcing blood volume downward to the dorsal side of the lungs may increase fractional blood flow through an atelectatic region.

Hypoxic Pulmonary Vasoconstriction

Several inhaled anesthetics have been found to inhibit HPV in isolated lung preparations. However, no such effect has been seen with intravenous anesthetics (barbiturates).[84] Results from human studies vary, reasonably explained by the complexity of the experiment, which causes several variables to change at the same time. The HPV response may thus be obscured by simultaneous changes in cardiac output, myocardial contractility, vascular tone, blood volume distribution, blood pH and CO_2 tension, and lung mechanics. In studies with no gross changes in cardiac output, isoflurane and halothane depress the HPV response by 50% at a minimum alveolar concentration (MAC) of 2 (Fig. 15-23).[85]

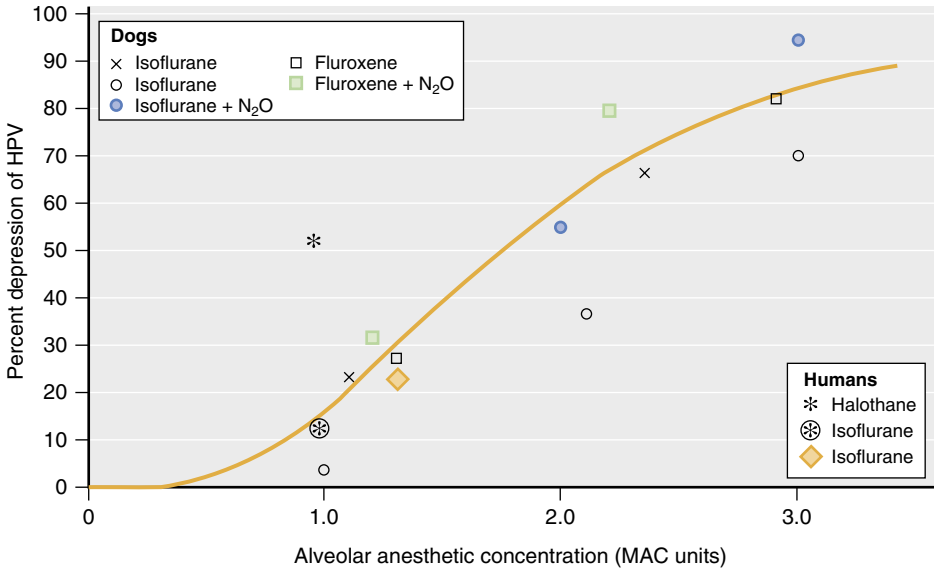

Figure 15-23 Attenuation of hypoxic pulmonary vasoconstriction (HPV) plotted against minimal alveolar anesthetic concentration (MAC units). Note that during anesthesia with different inhaled anesthetics at a MAC of 1, a depression of HPV of about 20% to 30% can be seen, and with higher anesthetic concentrations, HPV can be blunted much more. The consequence is that perfusion through a nonventilated region, as in atelectasis, will not be reduced at higher anesthetic concentrations. *(From Marshall BE. Hypoxic pulmonary Vasoconstriction. Acta Anaesthesiol Scand 94:37-41, 1990.)*

Ventilation-Perfusion Matching During Anesthesia

Dead Space, Shunt, and Ventilation-Perfusion Relationships

Both CO_2 elimination and oxygenation of blood are impaired in most patients during anesthesia. The impeded CO_2 elimination can be attributed to increased dead space ventilation. Single-breath washout recordings have demonstrated that "anatomic" dead space is unchanged, indicating that the "alveolar" or parallel dead space must have increased during anesthesia.[73] By MIGET, the increased CO_2 dead space during anesthesia is not really dead space but poorly perfused lung regions that are signified by so-called high $\dot{V}_A/\dot{Q}$ ratios (Fig. 15-24). Such "high $\dot{V}_A/\dot{Q}$" can be explained by the tiny perfusion of corner vessels in interalveolar septa in the upper lung regions (where alveolar pressure may exceed pulmonary vascular pressure [zone I]).[52] The impaired CO_2 elimination is most easily corrected by increasing the ventilation and is seldom a problem in routine anesthesia with mechanical ventilation.

The impairment in arterial oxygenation during anesthesia is generally considered to be more severe at higher ages, obesity worsens the oxygenation of blood, and smokers show more impairment in gas exchange than nonsmokers do.[86,87] Venous admixture, as calculated according to the standard oxygen "shunt" equation, is also increased during anesthesia to approximately 10% of cardiac output. However, the venous admixture includes not only perfusion of nonventilated lung tissue (true shunt) but also regions that are poorly ventilated or perfused in excess of their ventilation ("low-$\dot{V}_A/\dot{Q}$ regions"). The extent to which the venous admixture includes low-$\dot{V}_A/\dot{Q}$ regions depends on the inspired oxygen fraction (F_{IO_2}). The higher the inspired oxygen fraction, the less there are of the low-$\dot{V}_A/\dot{Q}$ regions. However, with high F_{IO_2}, regions with low $\dot{V}_A/\dot{Q}$ may collapse because of gas adsorption and be transformed to shunt regions.[88] A good correlation between venous admixture and the sum of "true" shunt and perfusion of "low-$\dot{V}_A/\dot{Q}$ regions" was seen in a study involving 45 anesthetized subjects (Fig. 15-25).[63] Derivation of the "oxygen shunt" or venous admixture is shown in Box 15-3.

In young healthy volunteers during anesthesia with thiopental and methoxyflurane, both ventilation and perfusion were distributed to wider ranges of $\dot{V}_A/\dot{Q}$ ratios, which can be expressed as an increase in the logarithmic standard deviation of the perfusion distribution (log SDQ). In a similar group of patients studied during halothane anesthesia and muscle paralysis, log SDQ was almost doubled, from 0.43 when awake to 0.80 during anesthesia. In addition, true shunt was increased to a mean of 8%. A similar increase in shunt from 1% awake to a mean of 9% during anesthesia was recorded in a study on middle-aged (37 to 64 years) surgical patients, and there was a widening of the $\dot{V}_A/\dot{Q}$ distribution (log SDQ of 0.47 when awake and 1.01 during anesthesia). In elderly patients with more severe impairment of lung function, halothane anesthesia with muscle paralysis, with or without nitrous oxide, caused considerable widening of the $\dot{V}_A/\dot{Q}$ distribution, with log SDQ increasing from 0.87 when awake to 1.73 during anesthesia. In addition, shunt increased to a mean of 15%, with large variation between patients (0% to 30%). Thus, the most consistent findings during anesthesia are an increased $\dot{V}_A/\dot{Q}$ mismatch, expressed as an increased log SDQ, and an increase in shunt. For review, see the article by Hedenstierna.[52]

Effects of Anesthetics on Respiratory Drive

Spontaneous ventilation is frequently reduced during anesthesia. Thus, inhaled anesthetics,[89] as well as barbiturates for intravenous use,[90] reduce sensitivity to CO_2. The response is dose dependent and entails decreasing ventilation with deepening anesthesia. Anesthesia also reduces the response to hypoxia. Attenuation of the hypoxic response may be attributed to an effect on the carotid body chemoreceptors.[91]

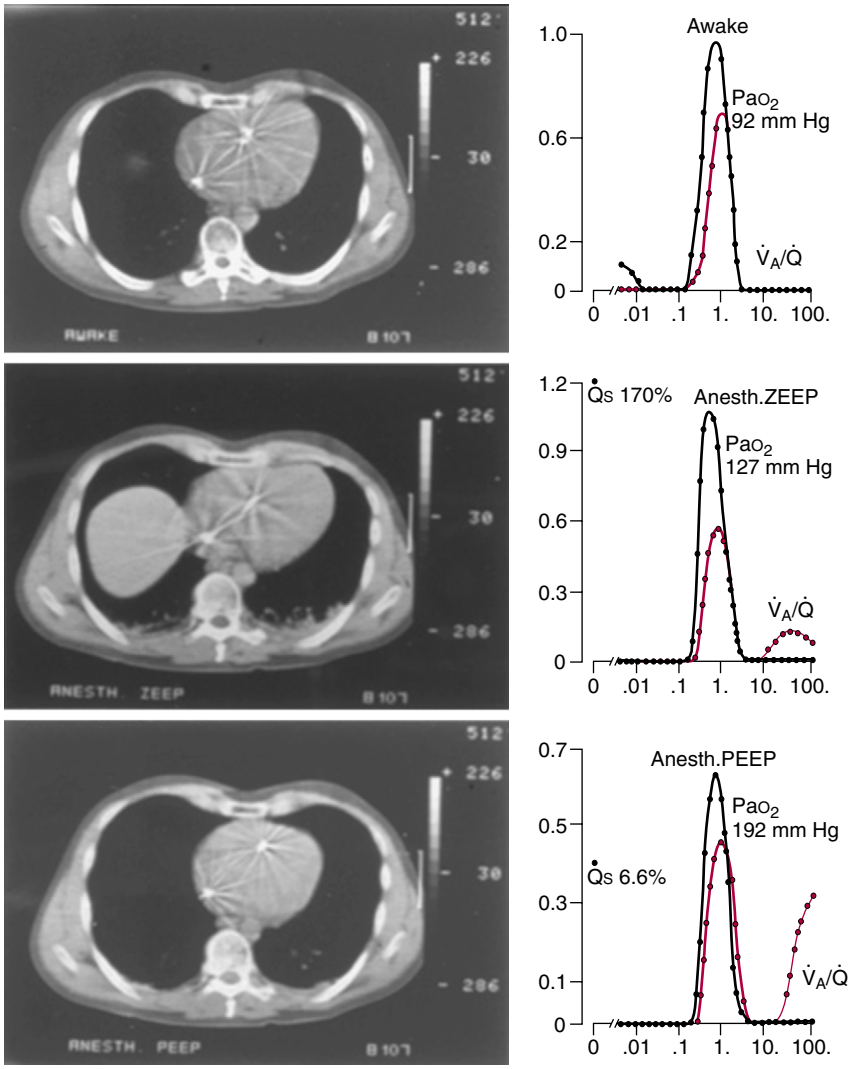

Figure 15-24 Computed tomography scans and $\dot{V}_A/\dot{Q}$ distributions in a lung-healthy subject when awake, during anesthesia with zero end-expiratory pressure (ZEEP), and during anesthesia with 10–cm H_2O positive end-expiratory pressure (PEEP). Note the absence of any atelectasis in the awake condition and the corresponding $\dot{V}_A/\dot{Q}$ distribution with a minor low-$\dot{V}_A/\dot{Q}$ mode that might be explained by intermittent airway closure. During anesthesia with ZEEP, atelectasis can be seen in the bottom of the lung, as well as the diaphragm in the middle of the right lung area (the diaphragm has been pushed cranially during anesthesia). A large shunt can be seen, whereas the "low" $\dot{V}_A/\dot{Q}$ has more or less disappeared, probably by conversion to atelectasis and shunt. Moreover, a small "high"-$\dot{V}_A/\dot{Q}$ mode can be seen that might reflect alveolar dead space in the upper lung regions. With PEEP, the collapsed lung tissue has been recruited and the shunt has been considerably reduced. Moreover, the "high"-$\dot{V}_A/\dot{Q}$ mode has increased in size and may reflect a further increase in nonperfused upper lung regions that has caused a dead space–like effect.

The effect of an anesthetic on respiratory muscles is nonuniform. Rib cage excursions diminish with deepening anesthesia.[92] The normal ventilatory response to CO_2 is produced by the intercostal muscles,[93,94] with no clear increase in rib cage motion with CO_2 rebreathing during halothane anesthesia. Thus, the reduced ventilatory response to CO_2 during anesthesia is due to impeded function of the intercostal muscles.

Factors That Influence Respiratory Function During Anesthesia

Spontaneous Breathing

Most studies on lung function have been performed on anesthetized, mechanically ventilated subjects or animals. Relatively few data have been obtained during spontaneous breathing. FRC is reduced to the same extent during anesthesia, regardless of whether a muscle relaxant is used,[56,58] and atelectasis occurs to almost the same extent in anesthetized spontaneously breathing subjects as during muscle paralysis.[95] Furthermore, the cranial shift of the diaphragm, as reported by Froese and Bryan in their classic paper,[96] was of the same magnitude both during general anesthesia with spontaneous breathing and with muscle paralysis, even though a difference in movement of the diaphragm from the resting position was noted. Thus, during spontaneous breathing, the lower, dependent portion of the diaphragm moved the most, whereas with muscle paralysis, the upper, nondependent part showed the largest displacement.

All these findings have raised the question of whether regional ventilation is different between spontaneous breathing and mechanical ventilation and whether mechanical ventilation worsens $\dot{V}_A/\dot{Q}$ as a consequence of poor ventilation of well-perfused, dependent lung regions. However, there is not much support for worsening of gas exchange by muscle paralysis in the literature, and there is also no support from the few studies on $\dot{V}_A/\dot{Q}$ distribution that have been performed. Dueck and coworkers[97] found the same increase in $\dot{V}_A/\dot{Q}$ mismatch in anesthetized sheep during anesthesia whether they were spontaneously breathing or mechanically ventilated. The log SDQ, indicating the degree of $\dot{V}_A/\dot{Q}$ mismatch, increased from 0.66 to 0.83 and 0.89 from awake to inhaled anesthesia with spontaneous breathing and mechanical ventilation, respectively. Shunt also increased with no significant difference between the two anesthesia conditions (from 1% awake to 11% and 14% during anesthesia with spontaneous breathing and mechanical ventilation). In a

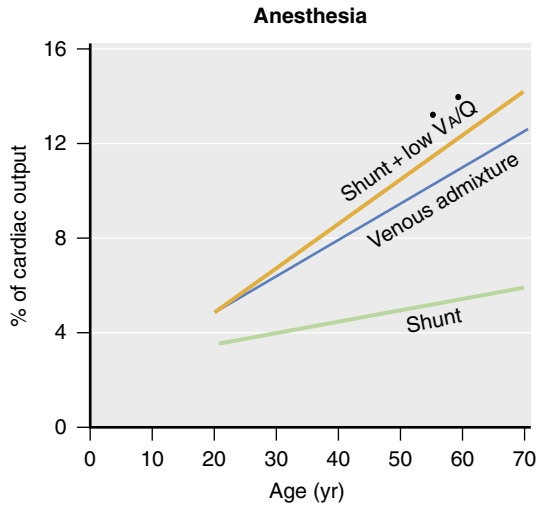

Figure 15-25 Influence of age on shunt, shunt + low $\dot{V}_A/\dot{Q}$, and venous admixture in anesthetized subjects. There is a slight and insignificant increase in shunt with age, whereas shunt + low $\dot{V}_A/\dot{Q}$ increases rapidly. Note also that venous admixture is more similar to shunt + perfusion of low $\dot{V}_A/\dot{Q}$ regions than to shunt alone. *(From Gunnarsson L, Tokics L, Gustavsson H, et al: Influence of age on atelectasis formation and gas-exchange impairment during general-anesthesia. Br J Anaesth 66:423-432, 1991.)*

study of anesthetized human subjects, shunt and log SDQ increased from 1% and 0.47 while awake to 6% and 1.03 during anesthesia with spontaneous breathing and 8% and 1.01 during mechanical ventilation.[52] Thus, most of the gas exchange effects of anesthesia can be seen even during spontaneous breathing, with little or no further derangement added by muscle paralysis and mechanical ventilation.

Increased Oxygen Fraction

In the studies cited thus far, an inspired oxygen fraction (F_{IO_2}) of around 0.4 was used. Anjou-Lindskog and associates[98] induced anesthesia on air (F_{IO_2} of 0.21) in middle-aged to elderly patients during intravenous anesthesia before elective lung surgery and found only small shunts of 1% to 2%, although log SDQ increased from 0.77 to 1.13. When F_{IO_2} was increased to 0.5, an increase in shunt of 3% to 4% was noticed. In another study on elderly patients during halothane anesthesia (see Hedenstierna[52]), an increase in F_{IO_2} from 0.53 to 0.85 caused an increase in shunt from 7% to 10% of cardiac output. Thus, a certain dependence on F_{IO_2} appears to exist, possibly explained by attenuation of the HPV response with increasing F_{IO_2}[85] or further development of atelectasis and shunt in lung units with low $\dot{V}_A/\dot{Q}$ ratios.[88]

Box 15-3 Derivation of the Venous Admixture ("Shunt") Equation

$$Ca \times \dot{Q}_T = (Cc' \times \dot{Q}c) + (C\bar{v} \times \dot{Q}s) \quad (1)$$

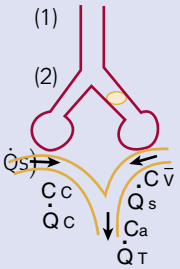
$$\dot{Q}c = \dot{Q}_T - \dot{Q}s \quad (2)$$

By inserting Equation 2 into Equation 1,

$$Ca \times \dot{Q}_T = (Cc \times [\dot{Q}_T - \dot{Q}s]) + (C\bar{v} \times \dot{Q}s)$$

Rearranging,

$$\frac{\dot{Q}s}{\dot{Q}_T} = \frac{Cc' - Ca}{Cc' - C\bar{v}}$$



where Cc', Ca, and $C\bar{v}$ are oxygen content in pulmonary end-capillary, arterial, and mixed venous blood, respectively; $\dot{Q}_T$ is cardiac output; $\dot{Q}c$ is capillary flow; and $\dot{Q}s$ is shunt.

Body Position

Because FRC is dramatically reduced by the combined effect of the supine position and anesthesia (see Chapter 36), it might be advantageous to choose a more upright position in an anesthetized subject to preserve FRC. This was tested by Heneghan and colleagues[99] in lung-healthy patients who underwent general anesthesia. However, no clear improvement in oxygenation was noticed when the patient was semirecumbent as opposed to the supine position. It is likely that pulmonary blood flow is impeded by the semirecumbent position because of a possible decrease in cardiac output and enhanced inhomogeneity of blood flow distribution. Fractional perfusion of the most dependent lung regions, which may still be poorly or not at all ventilated, may have been increased in the semirecumbent position. In the lateral position, differences in lung mechanics, resting lung volumes, and atelectasis formation between the dependent and nondependent portions of the lung have been demonstrated[100] and shown to result in further disturbance of the ventilation-perfusion match, with severe impairment in arterial oxygenation in some patients. However, there are large and unpredictable interindividual variations.[101] With the use of isotope techniques, an increase in $\dot{V}_A/\dot{Q}$ mismatch was also demonstrated in anesthetized, paralyzed patients in the lateral position,[102] and an improvement was noticed in the prone position.[103] There are findings suggesting that the vertical inhomogeneity of the distribution of perfusion is less obvious in the prone position.[104] This may indicate that there are regional differences in vascular configuration that promote perfusion of dorsal lung regions, regardless of whether they are in a dependent or nondependent position. It is also worthy of note that the ventilation distribution was more uniform in anesthetized subjects who were in the prone position.[105]

Age

It is well known that arterial oxygenation is further impeded with increasing age of the patient (see Chapters 71 and 82).[73] As mentioned earlier, formation of atelectasis does not increase with age in adults, and the sparse number of babies who have been studied in the CT scanner during anesthesia appear to have a larger percentage of atelectasis in the transthoracic area than patients of other ages do.[63] Similarly, shunt is independent of age in the tested range of 23 to 69 years. In contrast, there appears to be increasing $\dot{V}_A/\dot{Q}$ mismatch with age, with enhanced perfusion of low-$\dot{V}_A/\dot{Q}$ regions both in awake subjects and when they are subsequently anesthetized. Figure 15-25 shows the relationship between shunt, perfusion of low-$\dot{V}_A/\dot{Q}$ regions, and age of the patient. Thus, the major cause of impaired gas exchange during anesthesia at ages younger than 50 years is shunt, whereas at higher ages mismatch (increased log SDQ) becomes increasingly important. Because the correlation between log SDQ and age during anesthesia is almost parallel with that during the awake state, it can be said that anesthesia worsens the match of ventilation and blood flow by as much as 20 years of aging. Hopefully, log SDQ returns to the preanesthesia level after surgery!

Obesity

Obesity worsens the oxygenation of blood (see Chapter 64).[106,107] A major explanation appears to be a markedly reduced FRC, which promotes airway closure to a greater extent than in a normal subject.[108] The use of high inspired oxygen concentrations will promote rapid atelectasis formation behind closed airways.[57,77] Correlations between BMI and the size of atelectasis during anesthesia and postoperatvely[67,109] and between BMI and pulmonary shunt have been presented (Fig. 15-26).[108] Preventing a fall in FRC by CPAP during induction of anesthesia most likely prevents or reduces atelectasis formation and helps keep arterial oxygenation at a higher level.[87,110,111] The shorter time until desaturation during induction of anesthesia, as observed in morbidly obese patients, may also be prevented by PEEP or CPAP.[112] This can be explained by the increase in lung volume by PEEP or CPAP so that more oxygen is available for diffusion into the capillary blood.

The use of high inspired oxygen concentrations, regularly 100%, to keep an acceptable level of oxygenation during anesthesia and surgery may be the simplest but not necessarily the best method. It will promote further atelectasis formation,[75] and if the shunt is larger than 30%, which may well be the case in these patients, further oxygen will add little to arterial oxygenation.[51] The application of PEEP has been advocated as well. If high enough, PEEP may reduce the atelectasis[86,108,110] but will also have adverse effects such as reduced cardiac output and redistribution of blood flow toward dependent, still collapsed lung regions. Ventilation with near-VC inflations to reopen collapsed tissue, followed by PEEP ventilation, is another option. Body position may have a substantial effect on lung volume and should be considered to the extent that surgery allows.[113]

Preexisting Lung Disease

Smokers and patients with lung disease have more severe impairment of gas exchange in the awake state than healthy subjects do, and this difference also persists during anesthesia.[73] Interestingly, smokers with moderate airflow limitation may have less shunt as measured by MIGET than lung-healthy subjects do. Thus, in patients with mild to moderate bronchitis who were to undergo lung surgery or vascular reconstructive surgery in the leg, only a small shunt was noticed, but log SDQ was increased (for references, see the publication list in the article by Hedenstierna[52]). In patients with chronic bronchitis studied by MIGET and CT, no or very limited atelectasis developed during anesthesia and no or only minor shunt.[68] However, a considerable $\dot{V}_A/\dot{Q}$ mismatch was seen with a large perfusion fraction to low-$\dot{V}_A/\dot{Q}$ regions. Consequently, arterial oxygenation was more impaired than in lung-healthy subjects, but the cause was different from that in normal subjects. A possible reason for the absence of atelectasis and shunt in these patients may be chronic hyperinflation, which changes the mechanical behavior of the lungs and their interaction with the chest wall such that the tendency to collapse is reduced. It should be kept in mind that a patient with obstructive lung disease may have large regions with low $\dot{V}_A/\dot{Q}$ ratios that can be converted over time to resorption atelectasis. Thus, the "protection" against atelectasis formation during anesthesia by the obstructive lung disease need not last long. Regions with low $\dot{V}_A/\dot{Q}$ may be replaced by atelectasis as a result of slow resorption of gas behind occluded airways later during surgery and in the postoperative period.

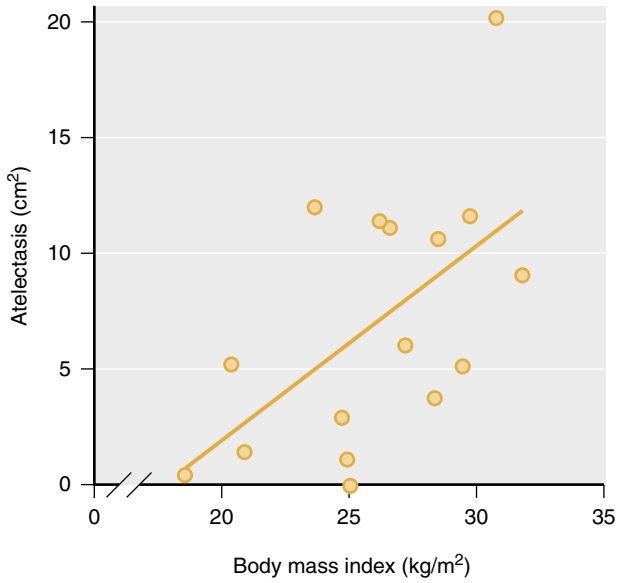


Figure 15-26 Plot of atelectasis during anesthesia versus body dimensions expressed as body mass index (BMI). Note that the larger the body mass index, the larger the atelectasis. *(From Rothen HU, Sporre B, Engberg G, et al: Reexpansion of atelectasis during general anaesthesia: A computed tomography study. Br J Anaesth 71:788-795, 1993.)*

Regional Anesthesia

The ventilatory effects of regional anesthesia depend on the type and extension of motor blockade (see Chapters 51 and 52). With extensive blocks that include all of the thoracic and lumbar segments, inspiratory capacity is reduced by 20% and expiratory reserve volume approaches zero.[114,115] Diaphragmatic function, however, is often spared, even in cases of inadvertent extension of subarachnoid or epidural sensory block up to the cervical segments.[114] Skillfully handled regional anesthesia affects pulmonary gas exchange only minimally. Arterial oxygenation and carbon dioxide elimination are well maintained during spinal and epidural anesthesia. This is in line with the findings of an unchanged relationship of CC and FRC[116] and unaltered distributions of ventilation-perfusion ratios assessed by MIGET during epidural anesthesia.[52]

Lung Function After Cardiac Surgery

Cardiac surgery produces the largest atelectasis in the postoperative period (see Chapter 60).[117] Cardiac surgery is generally undertaken with both lungs collapsed and the patient connected to an extracorporeal pump and oxygenator. If no precautions are taken in the immediate postoperative period, the lung will recruit slowly, and more than half the lung may be collapsed 1 to 2 days later with a shunt that is around 20% to 30% of cardiac output.[118,119] A recruitment maneuver consisting of inflating the lungs to an airway pressure of 30 cm H_2O for a 20-second period is sufficient to reopen the collapsed lung.[118] This lower airway pressure will do the same job as 40 cm H_2O in patients undergoing abdominal surgery because the maneuver is undertaken with an open chest before closure and return to mechanical ventilation. The clinical feasibility and effects on arterial oxygenation of doing such maneuvers were then tested in different clinical trials.[120-122] A few studies will be detailed. Dyhr and coworkers[123] studied 30 patients

after cardiac surgery, with (1) one group receiving a lung recruitment maneuver (LRM consisting of four 10-second insufflations to an airway pressure of 45 cm H_2O) and subsequent zero end-expiratory pressure (ZEEP) ventilation, (2) a 12–cm H_2O PEEP group, and (3) an LRM plus PEEP group. The patients were monitored for 75 minutes. Only transient improvement in Pao_2 and end-expiratory lung volume (EELV) was observed in the LRM group. In the PEEP group, no improvement in Pao_2 was seen, although EELV increased by more than 50%. Finally, in the LRM plus PEEP group, Pao_2 more than doubled, EELV increased by 75% to 80%, and both were maintained at these levels throughout the study period. The inspired oxygen fraction was 1.0. Application of 12–cm H_2O PEEP in the study by Dyhr and colleagues resulted in a considerable increase in EELV (+55%), but it was less than when both LRM and PEEP were applied (+80%). Respiratory compliance increased promptly with the recruitment maneuver but increased gradually over a 1-hour period in the PEEP group. These findings may suggest that the recruitment maneuver resulted in true opening of collapsed lung tissue whereas PEEP alone caused hyperinflation of already open alveoli but with slow recruitment over the following hour.

Pasquina and collaborators compared the effect of 30-minute periods four times a day of CPAP ventilation and noninvasive pressure support ventilation (NIPSV) after cardiac surgery.[124] They studied a large group of 150 patients equally distributed between the two treatment protocols. PEEP of 5 cm H_2O was used in both groups, and V_T was 8 to 10 mL/kg in the NIPSV group. Chest radiography showed a decrease in atelectasis in 60% of the patients on NIPSV versus 40% in the CPAP group. However, there was no difference in arterial oxygenation, any pulmonary function test, or length of stay between the groups. The authors concluded that there appears to be no clinical benefit with NIPSV. Nonetheless, it seems that the inspired oxygen fraction was adjusted according to the blood gas data, and with high FIO_2, a PEEP of 5 cm H_2O, as used in the present study, might be inappropriate to gain full effect on atelectasis formation. On the other hand, the patients might not have accepted a higher CPAP.

Miranda and colleagues focused on another potential effect of recruitment maneuvers after cardiac surgery—the possible increase in right ventricular afterload.[125] They used their open-lung concept technique with vigorous recruitment attempts at a peak airway pressure of 46 cm H_2O to achieve a Pao_2/FIO_2 of greater than 50 kPa. Moreover, to keep the lung open (i.e., without deterioration in Pao_2), PEEP of 17 cm H_2O was required. Despite this strong recruitment, neither pulmonary vascular resistance nor right ventricular ejection fraction changed significantly during the succeeding 3-hour observation period.

Another approach to cardiac surgery that is developing is off-pump coronary bypass grafting. Tschernko and coworkers[126] showed that patients who underwent surgery off-pump had a smaller increase in shunt. Moreover, the hospital stay was shorter in the off-pump group (7.5 versus 10.3 days in on-pump patients with a VC recruitment maneuver). Interestingly, a control group that did not receive any VC maneuver had an even longer hospital stay (12.6 days).

Respiratory Function During One-Lung Ventilation

In lung surgery, oxygenation may be a challenge even during anesthesia. One lung is nonventilated but still perfused, and in the postoperative period, restoration of lung integrity and ventilation/perfusion matching may take time (see Chapter 59).[127]

The technique of one-lung anesthesia and ventilation means that only one lung is ventilated and provides oxygenation of blood, as well as elimination of carbon dioxide from the blood. Persisting perfusion through the nonventilated lung causes a shunt and decreased Pao_2 (Fig. 15-27). Measures can be taken to reduce this blood flow by both mechanical and pharmacologic means, as summarized in a short review.[128] However, the dependent, ventilated lung will also contribute to the impeded oxygenation by formation of atelectasis in the dependent regions.[101] There are reasons to also consider a recruitment maneuver in one-lung ventilation (OLV). Tusman and colleagues[129] tested an "alveolar recruitment strategy" (ARS) in 10 patients who were undergoing open lobectomy first during two-lung ventilation and

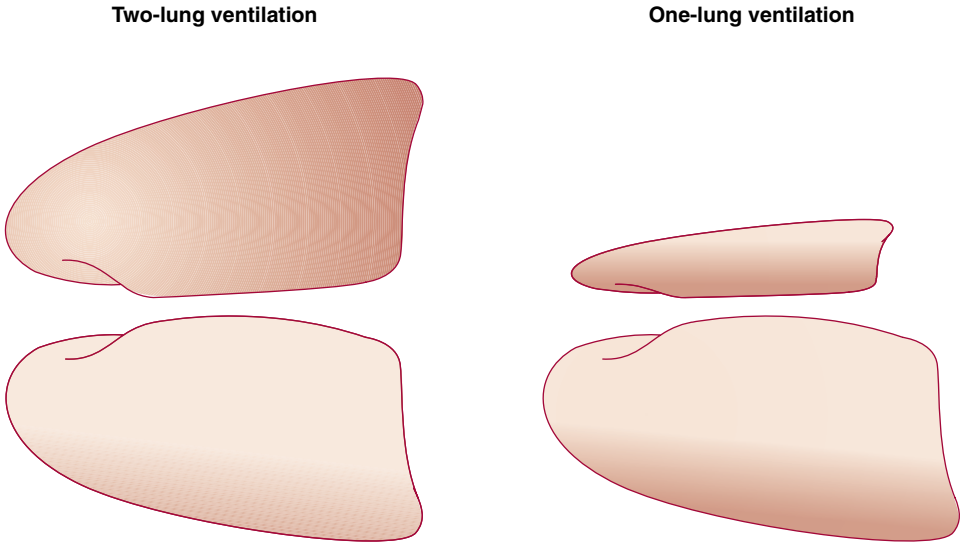

Figure 15-27 Schematic drawing of the distribution of shunt during anesthesia with two-lung ventilation and one-lung ventilation. The shunt region is indicated by the *dark area*, which can be seen in the lower lung during two-lung ventilation but in both the lower lung and in all of upper lung during one-lung ventilation. That the upper, nonventilated lung will act as a shunt region is well known, but one should not forget that the lower part of the dependent lung will also contribute to the shunting.

then during OLV before and then after ARS. The ARS maneuver was executed by increasing peak airway pressure minute by minute from 25 to 30, 35, and finally 40 cm H_2O and simultaneously increasing PEEP from 5 to 10, 15, and finally 20 cm H_2O. Airway pressure was then reduced to a peak of 25 and PEEP to 5 cm H_2O. This resulted in an increase in Pao_2 from 217 to 470 mm Hg after ARS. This substantial improvement in oxygenation suggests that more of the shunt is located in the dependent lung than is generally considered.

In another study by Tusman and associates, the effect of ARS on gas exchange and ventilation efficiency was studied, with a particular focus on dead space ventilation.[130] Again, ARS improved oxygenation. Moreover, dead space decreased and the slope of the CO_2 curve during a tidal expiration (phase III) was flatter, indicative of a more even distribution of inspired gas in relation to regional alveolar volume (or more synchronous alveolar emptying). The effect lasted for the total OLV period of 50 to 105 minutes. Thus, a secondary effect of recruiting collapsed lung tissue is more even distribution of ventilation and a decrease in the dead space fraction. If anything, this should facilitate the use of a smaller V_T.

Ishikawa and coworkers studied the effect of compressing the nondependent lung in patients who underwent esophagectomy.[131] By means of an intra-arterial sensor for continuous recording of arterial blood gas values, they noticed that by applying a retractor to expose the nonventilated right lung and subjecting it to compression, Pao_2 was increased, more so in some patients than in others. The mechanism has been proposed to be a shift of blood flow from the nondependent, nonventilated lung to the other lung. The clinical importance of the study is that it might indicate the value of deliberate compression of the nondependent lung during surgery to reduce shunting and improve oxygenation. However, whether manual compression of the nonventilated lung has any advantage over complete absorption atelectasis can be discussed.[132]

Patients who underwent OLV for thoracic surgery were receiving either ZEEP to the ventilated lung or PEEP adjusted to achieve the best respiratory compliance.[133] The PEEP that was applied was on average 4.3 cm H_2O during two-lung ventilation, 6.2 cm H_2O during closed-chest OLV, and 6.0 cm H_2O during open-chest OLV. This resulted in an average 10% higher compliance in the PEEP group, but Pao_2 was better in the ZEEP group (11.7 versus 10.5 kPa on an F_{IO_2} of 0.5). The opposing findings may not appear too surprising; PEEP should redistribute blood flow away from that lung to the other nonventilated lung with certain impairment of oxygenation. The rationale for identifying and using optimum PEEP has also been discussed by Slinger and associates.[134]

Other studies on oxygenation during OLV have focused on the sympatholytic effect of thoracic epidural anesthesia. Some studies report increased venous admixture and decreased Pao_2 with thoracic epidural anesthesia,[135] no effect,[136,137] or an improvement.[138] No clear conclusions can therefore be drawn.

Another method for control of deoxygenation during one-lung anesthesia is pharmacologic interference with pulmonary blood flow. In one study, the effects of 20 ppm inhaled nitric oxide (NO) alone or in combination with intravenous almitrine, a pulmonary vasoconstrictor, were studied. Almitrine has been shown to dose-dependently increase pulmonary artery pressure and to increase oxygenation in both patients with acute respiratory distress syndrome and those with sepsis. The effect has been attributed to enhancement of HPV, reduction of blood flow in nonventilated lung regions, and an improved ventilation-perfusion relationship. Little effect of NO alone was seen,[139] but oxygenation was significantly improved when NO was combined with almitrine.[140,141] The effect of almitrine alone during OLV has also been studied.[142] A significant improvement in oxygenation and a reduction in venous admixture in the almitrine group versus placebo were seen. Pulmonary artery pressure or cardiac output did not change at the dose of almitrine given.

Whether intravenous almitrine can be used to treat hypoxia has also been studied, and a moderate positive effect was observed.[143]

Careful analysis of the mechanical obstruction caused by kinking of pulmonary vessels and by HPV has shown that HPV is the important determinant of diversion of blood flow away from nonventilated lung (though not complete).[144] Moreover, positioning of the patient can affect the degree of shunting.[145]

The effects of selective vasodilation of the pulmonary circulation in OLV and in cardiac surgery have been reviewed in more detail in different publications, and two are referred to here.[146,147]

Pneumoperitoneum

Laparoscopic operations are becoming increasingly popular. They are usually performed by insufflation of CO_2 into the abdominal cavity (see Chapter 68). However, insufflation of CO_2 may interfere with cardiac and circulatory function, as well as respiratory function. CO_2 pneumoperitoneum may cause hypercapnia and acidosis.[148,149] The direct effects of carbon dioxide and acidosis lead to decreased cardiac contractility, sensitization of the myocardium to the arrhythmogenic effects of catecholamines, and systemic vasodilation.[150] There may even be long-lasting postoperative effects on breathing control. [151]

Pneumoperitoneum may also cause several respiratory changes, such as decreased FRC and VC,[152] formation of atelectasis,[153] reduced respiratory compliance,[154] and increased peak airway pressure.[155] Nonetheless, shunt is reduced and arterial oxygenation is mostly improved during CO_2 pneumoperitoneum.[156] This seeming paradox, more atelectasis and less shunt, suggests efficient redistribution of blood flow away from collapsed lung regions. CO_2 may enhance HPV, which may be the mechanism and explanation of the paradox.

Physiotherapy

Physiotherapy has often been debated after surgery, not the least after cardiac surgery (see Chapter 93). It has even been claimed in a recent review that physiotherapy may do more harm than good.[157] Westerdahl and colleagues showed with CT that breathing exercises consisting of maximum inspirations with the help of devices (flow bottle) or without (spontaneous VC maneuvers) did recruit collapsed lung tissue promptly after an exercise period.[158] Thus, as large an inspiration as possible and as early in the postoperative period as possible are presumably the two important factors in preventing postoperative lung complications. Whether the deep inspiration is done with or without a device for forced breathing is probably of little importance.

Normal Sleep

Ventilation is affected by sleep.[159] A significant reduction in V_T and inspiratory drive has been shown, and minute ventilation falls by approximately 5% to 16%, depending on the sleep stage, with the most marked fall occurring during rapid eye movement (REM) sleep. Lung volume is also reduced during sleep and manifested as a decrease in FRC.[160] The reduction in FRC occurs almost immediately after the onset of sleep, with the most marked fall taking place in REM sleep, during which time it amounts to approximately 0.3 L, or 10% of the awake value.[161]

The fall in FRC during sleep is accompanied by reduced aeration in the dependent lung regions, as shown in a CT study in healthy volunteers.[162] The loss of aeration was as marked as in anesthetized patients who were breathing gas with a moderate concentration of oxygen (F_{IO_2} of 0.3). When the anesthetized patients were switched to 100% O_2, atelectasis developed rapidly.[75] It is tempting to assume that normal sleep while breathing pure oxygen would also lead to the formation of atelectasis.

16 Cardiac Physiology

Key Points

1. The cardiac cycle is the sequence of electrical and mechanical events during the course of a single heartbeat.
2. Cardiac output is determined by the heart rate, myocardial contractility, and preload and afterload.
3. The majority of cardiomyocytes consist of myofibrils, which are rodlike bundles that form the contractile elements within the cardiomyocyte.
4. The basic working unit of contraction is the sarcomere.
5. Gap junctions are responsible for electrical coupling of small molecules between cells.
6. Action potentials have four phases in the heart.
7. The key player in cardiac excitation-contraction coupling is the ubiquitous second messenger calcium.
8. β-Adrenoreceptors stimulate chronotropy, inotropy, lusitropy, and dromotropy.
9. Hormones with cardiac action can be synthesized and secreted by cardiomyocytes or produced by other tissues and delivered to the heart.
10. Cardiac reflexes are fast-acting reflex loops between the heart and central nervous system that contribute to regulation of cardiac function and maintenance of physiologic homeostasis.

The modern concept of circulation and that the heart is the generator for the circulation was initially advanced by Harvey in 1628. Since that time, the field of cardiac physiology has developed to now include the physiology of the heart as a pump, cellular and molecular biology of the cardiomyocyte, and regulation of cardiac function by neural and humoral factors. Moreover, we now appreciate that physiology of the heart is only a component of the interrelated and integrated cardiovascular and circulatory physiology. This chapter discusses only the physiology of the heart. It begins with the physiology of the intact heart. The second part of the chapter focuses on cellular cardiac physiology. Finally, we briefly discuss the various factors that regulate cardiac function.

The basic anatomy of the heart consists of two atria and two ventricles that provide two separate circulations in series. The pulmonary circulation, a low-resistance and high-capacitance vascular bed, receives output from the right side of the heart, and its chief function is bidirectional gas exchange. The left side of the heart provides output for the systemic circulation. It functions to deliver oxygen and nutrients and remove CO_2 and metabolites from various tissue beds.

Physiology of the Intact Heart

To understand the mechanical performance of the intact heart, it is important to have knowledge of the phases of the cardiac cycle and determinants of ventricular function.

Cardiac Cycle

The cardiac cycle is the sequence of electrical and mechanical events during the course of a single heartbeat. Figure 16-1 illustrates (1) the electrical events of a single cardiac cycle represented by the electrocardiogram (ECG) and (2) the mechanical events of a single cardiac cycle represented by left atrial and left ventricular pressure pulses correlated in time with aortic flow and ventricular volume.[1]

The cardiac cycle begins with initiation of the heartbeat. Intrinsic to the specialized cardiac pacemaker tissues is automaticity and rhythmicity. The sinoatrial (SA) node is usually the pacemaker; it can generate impulses at the greatest frequency and is the natural pacemaker.

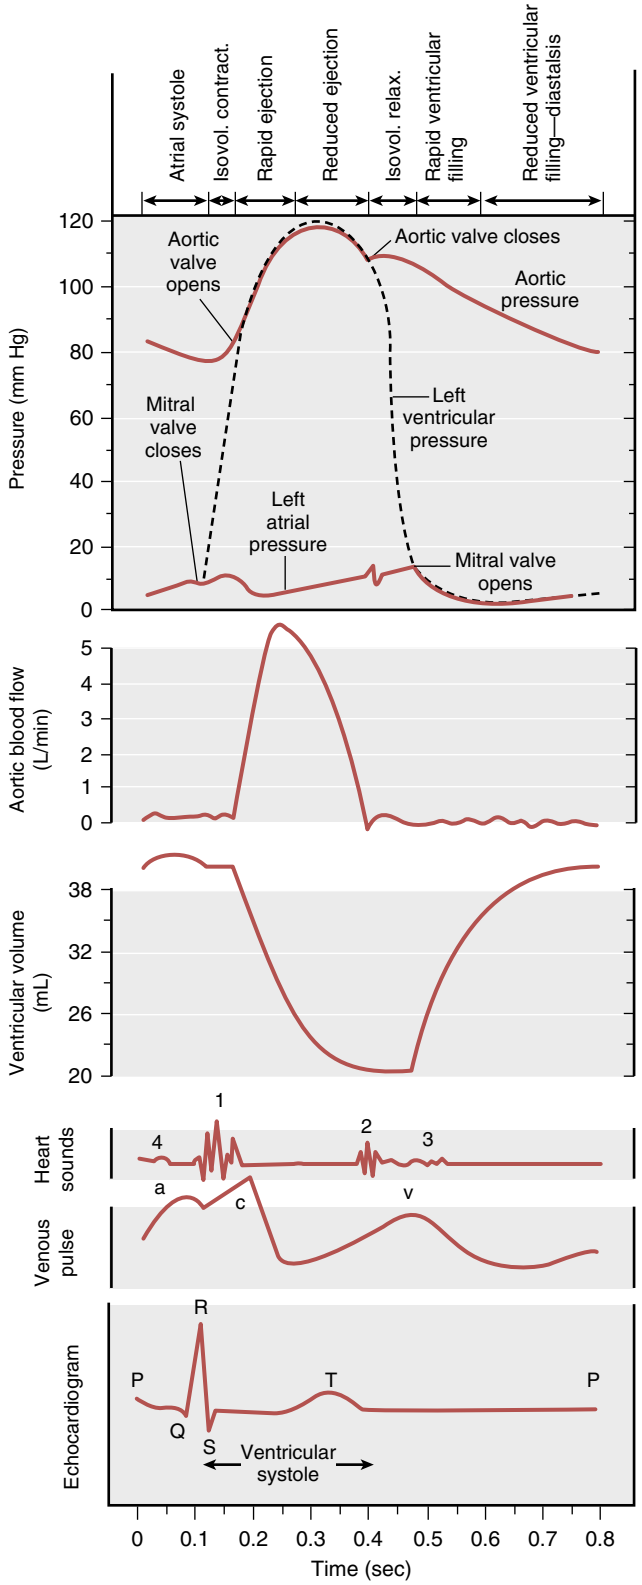

Figure 16-1 Electrical and mechanical events during a single cardiac cycle. Shown are the pressure curves of aortic blood flow, ventricular volume, venous pulse, and the electrocardiogram. *(From Berne RM, Levy MN: The cardiac pump.* In *Cardiovascular Physiology, 8th ed. St Louis, CV Mosby, 2001, pp 55-82.)*

Electrical Events and the Electrocardiogram

Electrical events of the pacemaker and the specialized conduction system are represented by the ECG at the body surface (also see Chapters 42 and 43). It is the result of differences in electrical potential generated by the heart at sites of the surface recording. The action potential initiated at the SA node is propagated to both atria by specialized conduction tissue, and it leads to atrial systole (contraction) and the P wave of the ECG. At the junction of the interatrial and interventricular septa, specialized atrial conduction tissue converges at the atrioventricular (AV) node, which is connected distally to the His bundle. The AV node is an area of relatively slow conduction, and a delay between atrial and ventricular contraction normally occurs at this locus. The PR interval can be used to measure the delay between atrial and ventricular contraction at the level of the AV node. From the distal His bundle, an electrical impulse is propagated through large left and right bundle branches and finally to the Purkinje system fibers, which are the smallest branches of the specialized conduction system. Finally, electrical signals are transmitted from the Purkinje system to individual ventricular cardiomyocytes. The spread of depolarization to the ventricular myocardium is manifested as the QRS complex on the ECG. Depolarization is followed by ventricular repolarization and appearance of the T wave on the ECG.[2]

Mechanical Events

The mechanical events of a cardiac cycle begin with return of blood to the right and left atria from the systemic and pulmonary circulation, respectively. As blood accumulates in the atria, atrial pressure increases until it exceeds the pressure within the ventricle, and the AV valve opens. Blood first flows passively into the ventricular chambers, and such flow accounts for approximately 75% of total ventricular filling.[3] The remainder of the blood flow is mediated by active atrial contraction or systole, known as the atrial "kick." The onset of atrial systole is coincident with depolarization of the sinus node and the P wave. While the ventricles fill, the AV valves are displaced upward and ventricular contraction (systole) begins with closure of the tricuspid and mitral valves, which corresponds to the end of the R wave on the ECG. The first part of ventricular systole is known as isovolumic or isometric contraction. The electrical impulse traverses the AV region and passes through the right and left bundle branches into the Purkinje fibers. This leads to contraction of ventricular myocardium and a progressive increase in intraventricular pressure. When intraventricular pressure exceeds pulmonary artery and aortic pressure, the pulmonic and aortic valves open and ventricular ejection occurs, which is the second part of ventricular systole.

Ventricular ejection can be further separated into the rapid ejection phase and the reduced ejection phase. During the rapid ejection phase, forward flow is maximal, and pulmonary artery and aortic pressure is maximally developed. In the reduced ejection phase, flow and great artery pressure taper with progression of systole. Pressure in both ventricular chambers falls as blood is ejected from the heart, and ventricular diastole begins with closure of the pulmonic and aortic valves. The initial period of ventricular diastole consists of the isovolumic/isometric relaxation phase. This phase is concomitant with repolarization of the ventricular myocardium and corresponds to the end of the T wave on the ECG. The final portion of ventricular diastole involves a rapid decrease in intraventricular pressure until it falls below

that of the right and left atria, at which point the AV valve reopens, ventricular filling occurs, and the cycle repeats itself.

Ventricular Structure and Function

Ventricular Structure

The specific architectural order of the cardiac muscles provides the basis for the heart to function as a pump. The ellipsoid shape of the left ventricle (LV) is a result of the laminar layering of spiraling bundles of cardiac muscles (Fig. 16-2). The orientation of the muscle bundle is longitudinal in the subepicardial myocardium and circumferential in the middle segment and again becomes longitudinal in the subendocardial myocardium. Because of the ellipsoid shape of the LV, there are regional differences in wall thickness that result in corresponding variations in the cross-sectional radius of the LV chamber. These regional differences may serve to accommodate the variable loading conditions of the LV.[4] In addition, such anatomy allows the LV to eject blood in a corkscrew-type motion beginning from the base and ending at the apex. The architecturally complex structure of the LV thus allows maximal shortening of myocytes, which results in increased wall thickness and generation of force during systole. Moreover, release of the twisted LV may provide a suction mechanism for filling of the LV during diastole. The LV free wall and the septum have similar muscle bundle architecture. As a result, the septum moves inward during systole in a normal heart. Regional wall thickness is a commonly used index of myocardial performance that can be assessed clinically, such as by perioperative echocardiography or magnetic resonance imaging.

Unlike the LV, which needs to pump against the higher-pressure systemic circulation, the right ventricle (RV) pumps against a much lower pressure circuit in the pulmonary circulation. Consequently, wall thickness is considerably less in the RV. In contrast to the ellipsoidal form of the LV, the RV is crescent shaped, as a result of which the mechanics of RV contraction are more complex. Inflow and outflow contraction is not simultaneous, and much of the contractile force seems to be recruited from interventricular forces of the LV-based septum.

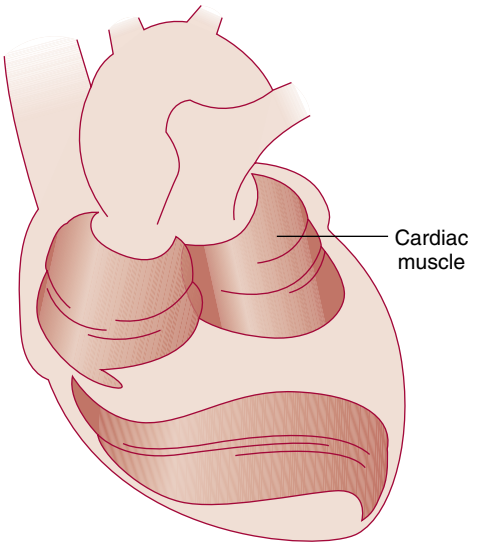

Figure 16-2 Muscle bundles. *(From Marieb EN: Human Anatomy & Physiology, 5th ed. San Francisco, Peason Benjamin Cummings, 2001, p 684.)*

An intricate matrix of collagen fibers form a scaffold of support for the heart and adjacent vessels. This matrix provides enough strength to resist tensile stretch. The collagen fibers are made up of mostly the thick collagen type I fiber, which cross-links with the thin collagen type III fiber, the other major type of collagen.[5] In close proximity to the collagen fibers are elastic fibers that contain elastin. They account for the elasticity of the myocardium.[6]

Systolic Function

The heart provides the driving force for delivering blood throughout the cardiovascular system to supply nutrients and remove metabolic waste. Because of the complexity of RV anatomy, the traditional description of systolic function is usually limited to the LV. Systolic performance of the heart is dependent on loading conditions and contractility. Preload and afterload are two interdependent factors extrinsic to the heart that govern cardiac performance.

Preload and Afterload

Preload is defined as the ventricular load at the end of diastole, before contraction has started. First described by Starling, a linear relationship exists between sarcomere length and myocardial force (Fig. 16-3). In clinical practice, surrogate representatives of LV volume such as pulmonary wedge pressure or central venous pressure are used to estimate preload.[3] With the development of transesophageal echocardiography, a more direct measure of ventricular volume is available.

Afterload is defined as systolic load on the LV after contraction has begun. Aortic compliance is an additional determinant of afterload.[1] Aortic compliance is the ability of the aorta to give way to systolic forces from the ventricle. Changes in the aortic wall (dilation or stiffness) can alter aortic compliance and thus afterload. Examples of pathologic conditions that alter afterload are aortic stenosis and chronic hypertension. Both impede ventricular ejection, thereby increasing afterload. Aortic impedance, or aortic pressure divided by aortic flow at that instant, is an accurate means of gauging afterload. However, clinical measurement of aortic impedance is invasive. Echocardiography can estimate aortic impedance noninvasively by determining aortic blood flow at the time of its maximal increase. In more general clinical practice, measurement of systolic blood pressure is adequate to approximate afterload, provided that aortic stenosis is not present.

Preload and afterload can be thought of as the wall stress that is present at the end of diastole and during LV ejection, respectively. Wall stress is a useful concept because it includes preload, afterload, and the energy required to generate contraction. Wall stress and heart rate are probably the two most relevant indices that account for changes in myocardial oxygen demand. The law of Laplace states that wall stress (σ) is the product of pressure (P) and radius (R) divided by wall thickness (h)[3]:

$$\sigma = P \times R/2h$$

The ellipsoid shape of the LV allows the least amount of wall stress such that as the ventricle changes its shape from ellipsoid to spherical, wall stress is increased. By using the ratio of the long axis to the short axis as a measure of the ellipsoid shape, a decrease in this ratio would signify a transition from ellipsoid to spherical.

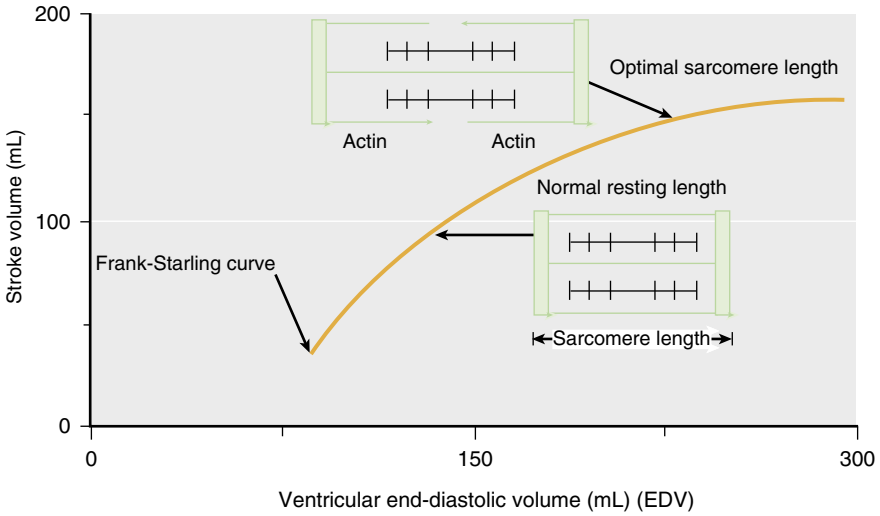

Figure 16-3 Frank-Starling relationship. The relationship between sarcomere length and tension developed in cardiac muscles is shown. In the heart, an increase in end-diastolic volume is the equivalent of an increase in myocardial stretch; therefore, according to Starling's law, increased stroke volume is generated.

Thickness of the LV muscle is an important modifier of wall stress. For example, in aortic stenosis, afterload is increased. The ventricle has to generate far higher pressure to overcome the increased load opposing systolic ejection of blood. To generate such high performance, the ventricle increases its wall thickness (LV hypertrophy). By applying Laplace's law, increased LV wall thickness will decrease wall stress despite the necessary increase in LV pressure to overcome the aortic stenosis (Fig. 16-4).[7] In a failing heart, the radius of the LV increases, thus increasing wall stress.

Frank-Starling Relationship

The Frank-Starling relationship is an intrinsic property of myocardium by which stretching of the myocardial sarcomere results in enhanced myocardial performance for subsequent contractions (see Fig. 16-3). Otto Frank first noted in 1895 that in skeletal muscle, the change in tension was directly related to its length and that in the heart, as pressure changed, a corresponding change in volume occurred.[8] E. H. Starling, using an isolated heart-lung preparation as a model, observed in 1914 that "the mechanical energy set free on passage from the resting to the contracted state is a function of the length of the muscle fiber."[9] If a strip of cardiac muscle is mounted in a muscle chamber under isometric conditions and stimulated at a fixed frequency, an increase in sarcomere length results in an increase in twitch force. Starling concluded that the increased twitch force was the result of a greater interaction of muscle bundles.

Electron microscopy has demonstrated that sarcomere length (2.0 to 2.2 μm) is positively related to the amount of actin and myosin cross-bridging and that there is an optimal sarcomere length at which the interaction is maximal. This concept is based on the assumption that the increase in cross-bridging is equivalent to an increase in muscle performance. Although this theory continues to hold true for skeletal muscle, the force-length relationship in cardiac muscle is more complex. When comparing force-strength relationships between skeletal and cardiac muscle, it is noteworthy that the reduction in force is only 10% even if cardiac muscle is at 80% sarcomere length.[8] The cellular basis of the Frank-Starling mechanism is still being investigated and will be discussed briefly later. A common clinical application of Starling's law is the relationship of left ventricular end-diastolic volume (LVEDV) and stroke volume. The Frank-Starling mechanism may remain intact even in a failing heart.[10] However, ventricular remodeling after injury or in heart failure may modify the Frank-Starling relationship.

Contractility

Each Frank-Starling curve specifies a level of contractility, or the inotropic state of the heart, which is defined as the work performed by cardiac muscle at any given end-diastolic fiber. Factors that modify contractility will create a family of Frank-Starling curves with different contractility (Fig. 16-5).[7] Among factors known to modify contractility are exercise, adrenergic

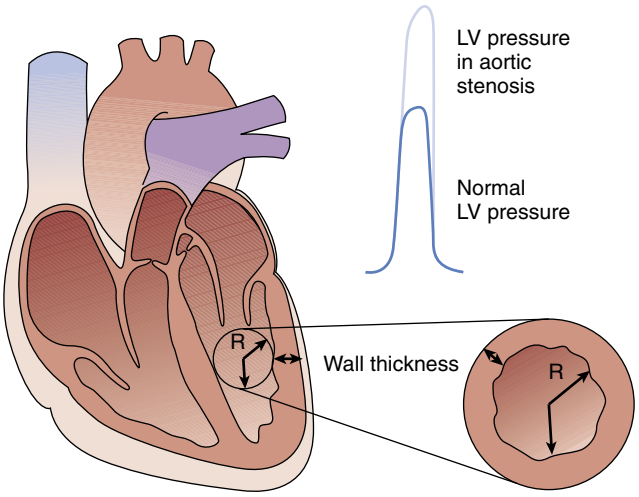

Figure 16-4 In response to aortic stenosis, left ventricular (LV) pressure increases. To maintain wall stress at control levels, compensatory LV hypertrophy develops. According to Laplace's law, wall stress = pressure × radius ÷ (2 × wall thickness). Therefore, the increase in wall thickness offsets the increased pressure, and wall stress is maintained at control levels. *(From Opie LH: Ventricular function.* In *The Heart. Physiology from Cell to Circulation, 4th ed. Philadelphia, Lippincott-Raven, 2004, pp 355-401.)*

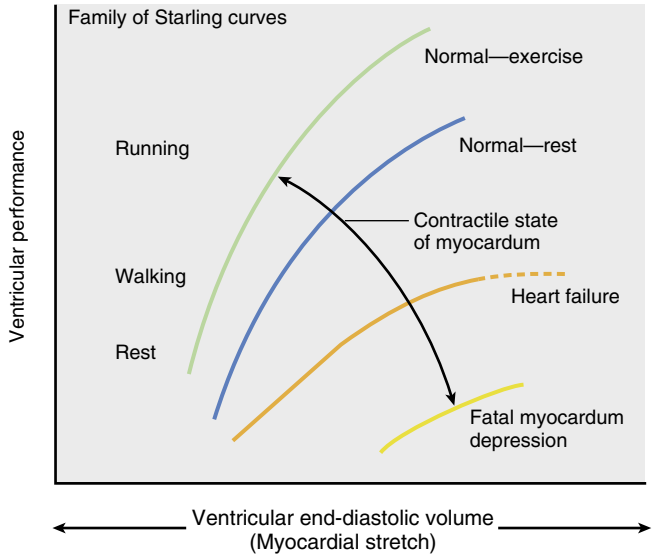

Figure 16-5 A family of Starling curves is shown. A leftward shift of the curve denotes enhancement of the inotropic state, whereas a rightward shift denotes decreased inotropy. *(From Opie LH: Ventricular function.* In *The Heart. Physiology from Cell to Circulation, 4th ed. Philadelphia, Lippincott-Raven, 2004, pp 355-401.)*

stimulation, changes in pH, temperature, and drugs such as digitalis. The ability of the LV to develop and generate pressure and sustain the pressure for ejection of blood is the intrinsic inotropic state of the heart.

In isolated muscle, the maximal velocity of contraction, or Vmax, is defined as the maximal velocity of ejection at zero load. Vmax is obtained by plotting the velocity of muscle shortening in isolated papillary muscle at varying degrees of force. Although this relationship can be replicated in isolated myocytes, Vmax cannot be measured in an intact heart because complete unloading is impossible. To measure the intrinsic contractile activity of an intact heart, several strategies have been attempted with varying success. Pressure-volume loops, albeit requiring catheterization of the left side of the heart, are currently the best way to determine contractility in an intact heart (Fig. 16-6).[7] The pressure-volume loop represents an indirect measure of the Starling relationship between force (pressure) and muscle length (volume). Clinically, the most commonly used noninvasive index of ventricular contractile function is the ejection fraction, which is assessed by echocardiography, angiography, or radionuclide ventriculography.

$$\text{Ejection fraction} = (\text{LVEDV} - \text{LVESV})/\text{LVEDV},$$

where LVESV is left ventricular end-systolic volume.

Cardiac Work

The work of the heart can be divided into external and internal work. External work is expended to eject blood under pressure, whereas internal work is expended within the ventricle to change the shape of the heart and prepare it for ejection. Internal work contributes to inefficiency in performance of the heart. Wall stress is directly proportional to the internal work of the heart.[11]

External work, or stroke work, is a product of the stroke volume (SV) and pressure (P) developed during ejection of the stroke volume.

$$\text{Stroke work} = \text{SV} \times \text{P or } (\text{LVEDV} - \text{LVESV}) \times \text{P}$$

The external work and internal work of the ventricle both consume O_2. The clinical significance of internal work is illustrated in the case of a poorly drained LV during cardiopulmonary bypass. Although external work is provided by the roller pump during bypass, myocardial ischemia can still occur because poor drainage of the LV creates tension on the LV wall and increases internal work.

The efficiency of cardiac contraction is estimated by the following formula[12]:

$$\text{Cardiac efficiency} = \text{External work}/\text{Engergy equivalent of oxygen consumption}$$

The corkscrew motion of the heart for the ejection of blood is the most favorable in terms of work efficiency based on the architecture in a normal LV (with the cardiac muscle bundles arranged so that a circumferentially oriented middle layer is sandwiched by longitudinally oriented outer layers). In heart failure, ventricular dilation reduces cardiac efficiency because it increases wall stress, which in turn increases oxygen consumption.[11]

Heart Rate and Force-Frequency Relationship

In isolated cardiac muscle, an increase in the frequency of stimulation induces an increase in the force of contraction. This relationship is termed the "treppe" (*Treppe* means staircase in German) phenomenon or the force-frequency relationship.[12,13] At between 150 and 180 stimuli per minute, maximal contractile force is reached in an isolated heart muscle at a fixed muscle length. Thus, an increased frequency incrementally increases inotropy, whereas stimulation at lower frequency decreases contractile force. However, when the stimulation becomes extremely rapid, the force of contraction decreases. In the clinical context, pacing-induced positive inotropic effects may be effective only up to a certain heart rate based on the force-frequency relationship. In a

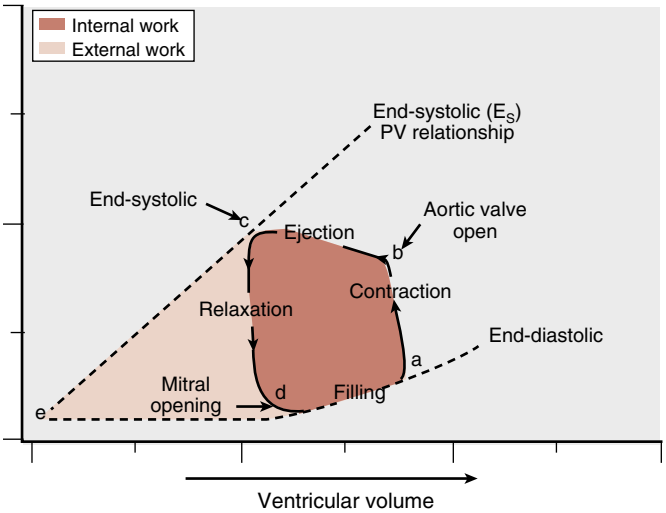

Figure 16-6 Pressure-volume loop. Point a depicts the start of isovolumic contraction. The aortic valve opens at point b, and ejection of blood follows (b→c). The mitral valve opens at d, and ventricular filling ensues. External work is defined by a, b, c, and d and internal work by e, d, and c. The pressure-volume area is the sum of external and internal work. *(From Opie LH: Ventricular function.* In *The Heart. Physiology from Cell to Circulation, 4th ed. Philadelphia, Lippincott-Raven, 2004, pp 355-401.)*

failing heart, the force-frequency relationship may be much less effective in producing a positive inotropic effect.[12]

Diastolic Function

Diastole is ventricular relaxation, and it occurs in four distinct phases: (1) isovolumic relaxation; (2) the rapid filling phase (i.e., the LV chamber filling at variable LV pressure); (3) slow filling, or diastasis; and (4) final filling during atrial systole. The isovolumic relaxation phase is energy dependent. During the auxotonic relaxation phases (phases 2 through 4), ventricular filling occurs against pressure. It encompasses a period during which the myocardium is unable to generate force and filling of the ventricular chambers takes place. The isovolumic relaxation phase does not contribute to ventricular filling. The greatest amount of ventricular filling occurs in the second phase, whereas the third phase adds only about 5% of total diastolic volume and the final phase provides 15% of ventricular volume from atrial systole.

To assess diastolic function, several indices have been developed. The most widely used index for examining the isovolumic relaxation phase of diastole is to calculate the peak instantaneous rate of decline in LV pressure ($-dP/dt$) or the time constant of isovolumic decline in LV pressure (τ). The aortic closing–mitral opening interval and the isovolumic relaxation time and peak rate of LV wall thinning as determined by echocardiography have both been used to estimate diastolic function during auxotonic relaxation. Ventricular compliance can be evaluated by pressure-volume relationships to determine function during the auxotonic phases of diastole.[12,14]

Many different factors influence diastolic function: systolic volume load, passive chamber stiffness, elastic recoil of the ventricle, the diastolic interaction between the two ventricular chambers, atrial properties, and catecholamines. Whereas systolic dysfunction is a reduced ability of the heart to eject, diastolic dysfunction is a decreased ability of the heart to fill. Abnormal diastolic function is now being recognized as the predominant cause of the pathophysiology of congestive heart failure.[15]

Ventricular interactions during systole and diastole are internal mechanisms that function as internal feedback to modulate stroke volume. Systolic ventricular interaction involves the effect of the interventricular septum on the function of both ventricles. Because the interventricular septum is anatomically linked to both ventricles, it will be part of the load against which each ventricle has to work. Therefore, any changes in one ventricle will also be present in the other. In diastolic ventricular interaction, dilatation of either the LV or RV will have an impact on effective filling of the contralateral ventricle and thereby modify function.

Cardiac Output

Cardiac output is the amount of blood pumped by the heart per unit of time $(\dot{Q})$ and is determined by four factors: two factors that are intrinsic to the heart—heart rate and myocardial contractility—and two factors that are extrinsic to the heart but functionally couple the heart and the vasculature—preload and afterload.

Heart rate is defined as the number of beats per minute and is influenced mainly by the autonomic nervous system. Increases in heart rate increase cardiac output as long as ventricular filling is adequate during diastole. Contractility can be defined as the intrinsic level of contractile performance that is independent of loading conditions. Contractility is difficult to define in an intact heart because it cannot be separated from loading conditions.[12,13] For example, the Frank-Starling relationship is defined as the change in intrinsic contractile performance based on changes in preload. Cardiac output in a living organism can be measured with the Fick principle, a schematic depiction of which is illustrated in Figure 16-7.[1]

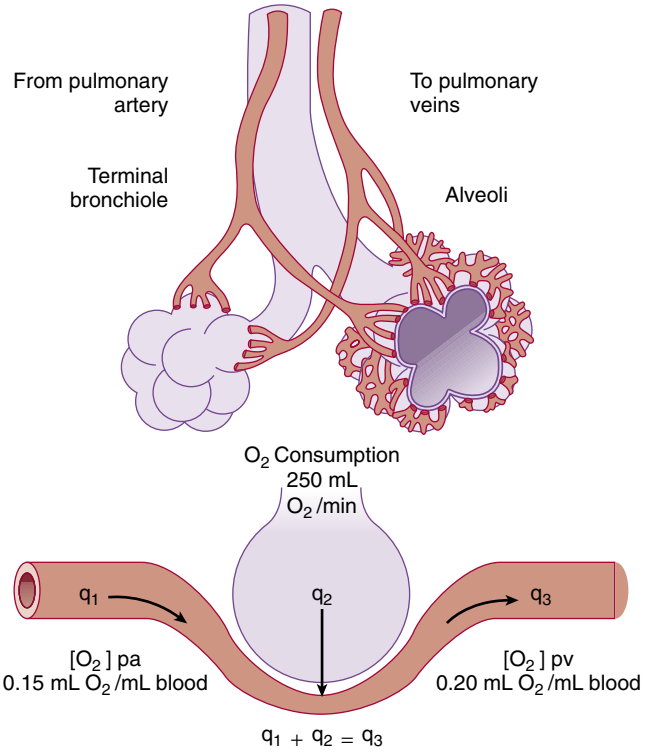

Figure 16-7 Illustration demonstrating the principle of determination of cardiac output according to the Fick equation. If the O_2 concentration of the pulmonary artery ($Cpao_2$), the O_2 concentration of the pulmonary vein ($Cpvo_2$), and O_2 consumption are known, cardiac output can be calculated. *(From Berne RM, Levy MN: The cardiac pump.* In *Cardiovascular Physiology, 8th ed. St Louis, CV Mosby, 2001, pp 55-82.)*

The Fick principle is based on the concept of conservation of mass such that the O_2 delivered from pulmonary venous blood (q_3) is equal to the total O_2 delivered to pulmonary capillaries through the pulmonary artery (q_1) and the alveoli (q_2).

The amount of O_2 delivered to the pulmonary capillaries by way of the pulmonary arteries (q_1) equals total pulmonary arterial blood flow $(\dot{Q})$ times the O_2 concentration in pulmonary arterial blood ($Cpao_2$):

$$q_1 = \dot{Q} \cdot Cpao_2$$

The amount of O_2 carried away from pulmonary venous blood (q_3) is equal to total pulmonary venous blood flow $(\dot{Q})$ times the O_2 concentration in pulmonary venous blood ($Cpvo_2$):

$$q_3 = \dot{Q} \cdot Cpvo_2$$

The pulmonary arterial O_2 concentration is the mixed systemic venous O_2, and the pulmonary venous O_2 concentration is the peripheral arterial O_2. O_2 consumption is the amount of O_2

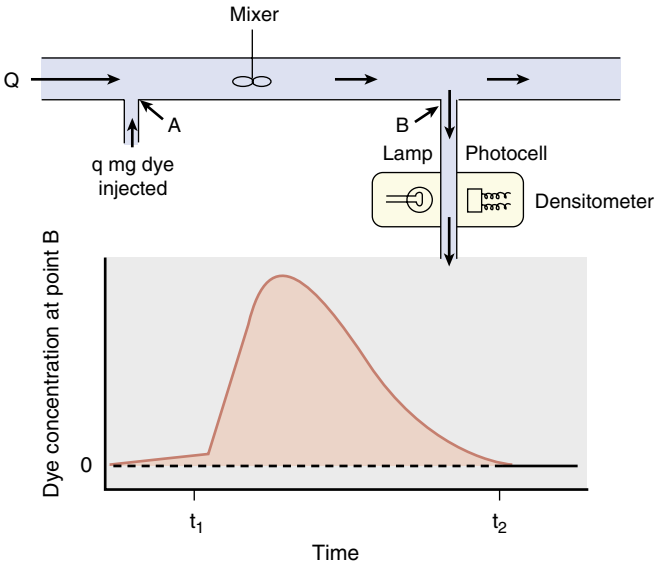

Figure 16-8 Illustration demonstrating the principle of determining cardiac output with the indicator dilution technique. This model assumes that there is no recirculation. A known amount of dye (q) is injected at point A into a stream flowing at $\dot{Q}$ (mL/min). A mixed sample of the fluid flowing past point B is withdrawn at a constant rate through a densitometer. The change in dye concentration over time is depicted in a curve. Flow may be measured by dividing the amount of indicator injected upstream by the area under the downstream concentration curve. *(From Berne RM, Levy MN: The cardiac pump. In Cardiovascular Physiology, 8th ed. St Louis, CV Mosby, 2001, pp 55-82.)*

delivered to the pulmonary capillaries from the alveoli (q_2). Because $q_1 + q_2 = q_3$,

$$\dot{Q}(Cpao_2) + q_2 = \dot{Q}(Cpvo_2)$$

$$q_2 = \dot{Q}(Cpvo_2) - \dot{Q}(Cpao_2)$$

$$q_2 = \dot{Q}(Cpvo_2) - Cpao_2$$

$$\dot{Q} = q_2 / (Cpvo_2 - Cpao_2)$$

Thus, if the O_2 concentration in the pulmonary artery ($Cpao_2$), the O_2 concentration in the pulmonary vein ($Cpvo_2$), and O_2 consumption (q_2) are known, cardiac output can be determined.

The indicator dilution technique is another method for determining cardiac output, and it is also based on the law of conservation of mass. The two most commonly used indicator dilution techniques are the dye dilution and the thermodilution methods. Figure 16-8 illustrates the principles of the dye dilution method.[1]

Cellular Cardiac Physiology

Cellular Anatomy

At the cellular level, the heart consists of three major components: cardiac muscle tissue (contracting cardiomyocytes), conduction tissue (conducting cells), and extracellular connective tissue. A group of cardiomyocytes with its connective tissue support network or extracellular matrix make up a myofiber (Fig. 16-9). Adjacent myofibers are connected by strands of collagen. The extracellular matrix is the synthetic product of fibroblasts and is made up of collagen, which is the main determinant of myocardial stiffness, and other major matrix proteins. One of the matrix proteins, elastin, is the chief constituent of elastic fibers. The elastic fibers account for, in part, the elastic properties of the myocardium.[6] Other matrix proteins include the glycoproteins or proteoglycans and matrix metalloproteins. Proteoglycans are proteins with short sugar chains, and they include heparan sulfate, chondroitin, fibronectin, and laminin. Matrix metalloproteins are enzymes that degrade collagen and other extracellular proteins. The balance between accumulation of extracellular matrix proteins by synthesis and their breakdown by matrix metalloproteins contributes to the mechanical properties and function of the heart.[6]

Cardiomyocyte Structure and Function

Individual contracting cardiomyocytes are large cells between 20 µm (atrial cardiomyocytes) and 140 µm (ventricular cardiomyocytes) in length. Approximately 50% of the cell volume in a contracting cardiomyocyte is made up of myofibrils, and the remainder consists of mitochondria, nucleus, sarcoplasmic reticulum (SR), and the cytosol. The myofibril is the rodlike bundle that forms the contractile elements within cardiomyocytes. Within each contractile element are contractile proteins, regulatory proteins, and structural proteins. Contractile proteins make up about 80% of the myofibrillar protein, with the remainder being regulatory and structural proteins.[16,17] The basic unit of contraction is the sarcomere, which will be described later.

The sarcolemma, or the outer plasma membrane, separates the intracellular and extracellular space. It surrounds the cardiomyocyte and invaginates into the myofibrils through an extensive tubular network known as transverse or T tubules, and it also forms specialized intercellular junctions between cells.[18,19]

Transverse or T tubules are in close proximity to an intramembrane system and the SR, which plays an important role in the calcium metabolism that is critical in excitation-contraction coupling (ECC) of the cardiomyocyte. The SR can be further divided into the longitudinal (or network) and the junctional SR. The longitudinal SR is involved in the uptake of calcium for initiation of relaxation. The junctional SR contains large calcium release channels (ryanodine receptors) that release SR calcium stores in

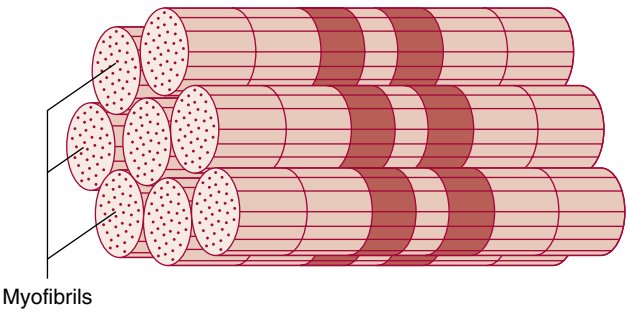

Figure 16-9 Organization of cardiomyocytes. Fifty percent of cardiomyocyte volume is made up of myofibrils; the remainder consists of mitochondria, nucleus, sarcoplasmic reticulum, and cytosol.

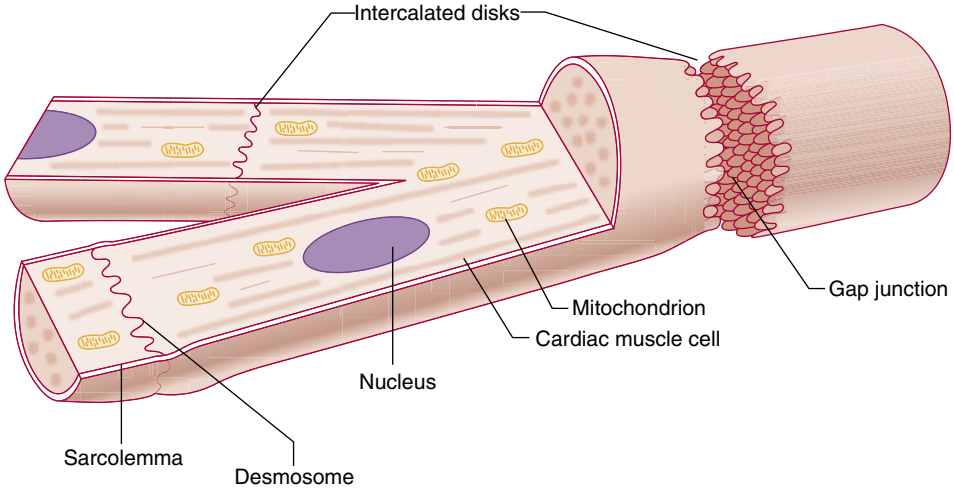

Figure 16-10 The sarcolemma that envelops cardiomyocytes becomes highly specialized to form the intercalated disks where ends of neighboring cells are in contact. The intercalated disks consist of gap junctions and "spot" and "sheet" desmosomes.

response to depolarization-stimulated calcium influx through the sarcolemmal calcium channels. The ryanodine receptors not only are calcium release channels but they also form the scaffolding proteins that anchor many of the key regulatory proteins.[20]

Mitochondria are found immediately beneath the sarcolemma, wedged between myofibrils within the cell. They contain enzymes that promote the generation of adenosine triphosphate (ATP), and they are the energy powerhouse for the cardiomyocyte. In addition, mitochondria can also function to accumulate calcium and thereby contribute to regulation of the cytosolic calcium concentration. Nearly all of the genetic information is found within the centrally located nucleus. The cytosol is the fluid-filled microenvironment within the sarcolemma, exclusive of the organelles and the contractile apparatus and proteins.

Cardiac muscle cells contain three different types of intercellular junctions: gap junctions, "spot" desmosomes, and "sheet" desmosomes (or fasciae adherens) (Fig. 16-10).[19,21] Gap junctions are responsible for electrical coupling and transfer of small molecules between cells, whereas desmosome-like junctions provide mechanical linkage. The adhesion sites formed by "spot" desmosomes anchor the intermediate filament cytoskeleton of the cell; those formed by the fasciae adherens anchor the contractile apparatus. Gap junctions consist of clusters of plasma membrane channels directly linking the cytoplasmic compartments of neighboring cells. Gap junction channels are constructed from connexins, a multigene family of conserved proteins. The principal connexin isoform of the mammalian heart is connexin 43; other connexins, notably connexins 40, 45, and 37, are also expressed, but in smaller quantities.[20,21]

The conducting cardiomyocytes, or Purkinje cells, are cells specialized for conducting propagated action potentials. These cells have a low content of myofibrils and a prominent nucleus and contain an abundance of gap junctions. Cardiomyocytes can be functionally separated into (1) the excitation system, (2) the ECC system, and (3) the contractile system.

Excitation System

The cellular action potential originating in the specialized conduction tissue is propagated to individual cells where it initiates the intracellular event that leads to contraction of the cell through the sarcolemmal excitation system.

Action Potential

Ion fluxes across plasma membranes result in depolarization (attaining a less negative membrane potential) and repolarization (attaining a more negative membrane potential). They are mediated by membrane proteins with ion-selective pores. Because these ion channel proteins open and close the pores in response to changes in membrane potential, the channels are voltage gated. In the heart, sodium, potassium, calcium, and chloride channels have been found to contribute to the action potential.

The types of action potential in the heart can be separated into two categories: fast-response action potentials, which are found in the His-Purkinje system and atrial or ventricular cardiomyocytes, and slow-response action potentials, which are found in the pacemaker cells in the SA and AV nodes. A typical tracing of an action potential in the His-Purkinje system is depicted in Figure 16-11.[12] The electrochemical gradient for potassium across the plasma membrane is the determinant for the resting membrane potential. Mostly as a result of the influx of Na^+, the membrane potential becomes depolarized, which leads to an extremely rapid upstroke (phase 0). As the membrane potential reaches a critical level, or threshold, during depolarization, the action potential is propagated. The rapid upstroke is followed by a transient repolarization (phase 1). Phase 1 is a period of brief and limited repolarization that is largely due to the activation of a transient outward potassium current, i_{to}. The plateau phase (phase 2) occurs with a net influx of Ca^{2+} through L-type calcium channels and efflux of K^+ through several potassium channels: the inwardly rectifying i_k, the delayed rectifier i_{k1}, and i_{to}. Repolarization (phase 3) is brought about when efflux of K^+ from the three outward potassium currents exceeds the influx of Ca^{2+}, thus returning the membrane to the resting potential. Very little ionic flux occurs during diastole (phase 4) in a fast-response action potential.

In contrast, during diastole (phase 4), pacemaker cells that show slow-response action potentials have the capability of spontaneous diastolic depolarization and generate the automatic

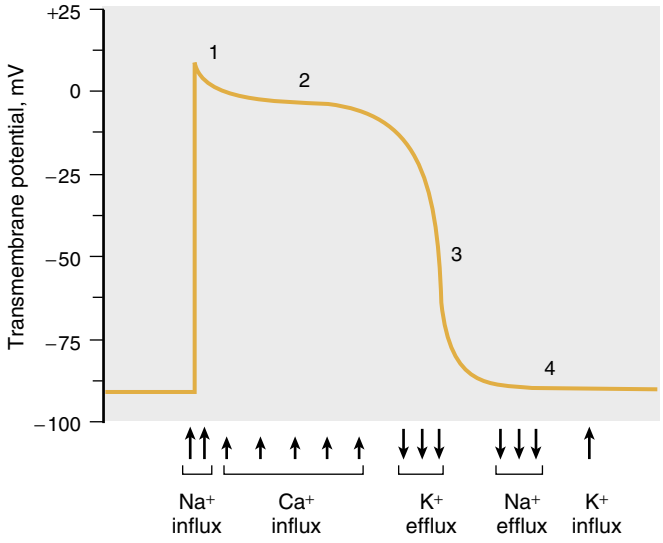

Figure 16-11 Phases of cellular action potentials and major associated currents in ventricular myocytes. The initial phase 0 spike and overshoot (1) are caused by a rapid inward Na^+ current, the plateau phase (2) by a slow Ca^{2+} current through L-type Ca channels, and repolarization (phase 3) by outward K^+ currents. Phase 4, the resting potential (Na^+ efflux, K^+ influx), is maintained by Na^+-K^+-ATPase. The Na^+-Ca^{2+} exchanger is mainly responsible for extrusion of Ca^{2+}. In specialized conduction system tissue, spontaneous depolarization takes place during phase 4 until the voltage resulting in opening of the Na channel is reached. *(From LeWinter MM, Osol G: Normal physiology of the cardiovascular system.* In *Fuster V [ed]: Hurst's The Heart, 10th ed. New York, McGraw-Hill, 2001, pp 63-94.)*

cardiac rhythm. Pacemaker currents during phase 4 are the result of an increase in the three inward currents and a decrease in the two outward currents. The three inward currents that contribute to spontaneous pacemaker activity include two carried by calcium, i_{CaL} and i_{CaT}, and one that is a mixed cation current, I_f. The two outward currents are the delayed rectifier potassium current i_k and the inward rectifying potassium current i_{k1}. When compared with the fast-response action potential, phase 0 is much less steep, phase 1 is absent, and phase 2 is indistinct from phase 3 in the slow-response action potential.[22]

During the cardiac action potential, movement of Ca^{2+} into the cell and Na^+ out of the cell creates an ionic imbalance. The Na^+-Ca^{2+} exchanger restores cellular ionic balance by actively transporting Ca^{2+} out of the cell against a concentration gradient while moving Na^+ into the cell in an energy-dependent manner.

Excitation-Contraction Coupling

Structures that participate in cardiac ECC include the sarcolemma, transverse tubules, SR, and myofilaments (Fig. 16-12A).[23] The process of ECC begins with depolarization of the plasma membrane and spread of electrical excitation along the sarcolemma of cardiomyocytes. Calcium enters through plasma membrane channels concentrated at the T tubules, and such entry triggers the release of calcium from the SR, which in turn stimulates myofibrillar contraction.[24]

The ubiquitous second messenger calcium is the key player in cardiac ECC (see Fig. 16-12B).[23] Cycling of calcium within the structures that participate in ECC initiates and terminates contraction. Activation of the contractile system depends on an increase in free cytosolic calcium and its subsequent binding to contractile proteins. Influx of calcium through the voltage-gated L-type calcium channels (dihydropyridine receptors) causes an initial small increase in intracellular calcium. The local increase in Ca^{2+} concentration as a result of entry of Ca^{2+} through the voltage-gated L-type calcium channels activates the calcium release channels (ryanodine receptors), induces further release of calcium from subsarcolemmal cisternae in the SR, and thus leads to a large increase in intracellular calcium. The increase in intracellular calcium, however, is transient inasmuch as calcium is removed by (1) active uptake by the SR calcium pump adenosine triphosphatase (ATPase), (2) extrusion of calcium from the cytosol by the Na^+-Ca^{2+} exchanger, and (3) binding of calcium to proteins.[25]

The SR provides the anatomic framework and is the major organelle for the cycling of calcium. It is the depot for intracellular calcium stores. The cyclic release plus reuptake of calcium by the SR regulates the cytosolic calcium concentration and couples excitation to contraction. The physical proximity between L-type calcium channels and ryanodine receptors at the SR membrane makes calcium-induced calcium release occur easily. The "foot" region of the ryanodine receptor is the part that extends from the SR membrane to the T tubules, where the L-type calcium channels are located.[16,25,26]

The SR is also concerned with the reuptake of calcium that initiates relaxation or terminates contraction. Sarcoplasmic/endoplasmic reticulum Ca^{2+}-ATPase (SERCA) is the ATP-dependent pump that actively pumps the majority of the calcium back into the SR after its release. SERCA makes up close to 90% of all of the SR proteins, and it is inhibited by the phosphoprotein phospholamban at rest. Phospholamban is an SR membrane protein that is active in the dephosphorylated form. Phosphorylation by a variety of kinases as a result of β-adrenergic stimulation or other stimuli inactivates phospholamban and releases its inhibitory action on SERCA. Positive feedback ensues and leads to further phospholamban phosphorylation and greater SERCA activity. Active reuptake of calcium by SERCA then promotes relaxation.[16,25,26]

Once taken up into the SR, calcium is stored until it is released during the next cycle. Calsequestrin and calreticulin are two storage proteins in the SR. Calsequestrin is a highly charged protein located in the cisternal component of the SR near the T tubules. Because it lies close to the calcium release channels, the stored calcium can be quickly discharged for release once the calcium release channels are stimulated.

Cytosolic calcium can also be removed by extrusion through the sarcolemmal calcium pump and the activity of the sodium-calcium exchanger. An important "sensor" and regulator of intracellular calcium is the protein calmodulin.[18]

Contractile System

Contractile Elements

The basic working unit of contraction is the sarcomere. A sarcomere is defined as the distance between Z lines (Z is an abbreviation for the German *Zuckung*, or "contraction"), which join the sarcomeres in series. Each sarcomere consists of a central A band that is separated by half of an I band from the Z lines on each side because the Z line bisects the I band. A schematic representation is depicted in Figure 16-13.[12] Within each sarcomere are two principal contractile proteins (see the next section) and one noncontractile protein, titin.[25] The two contractile proteins are actin, the thin filament, and myosin, the thick filament. Actin filaments and titin are both tethered to the Z line, but myosin

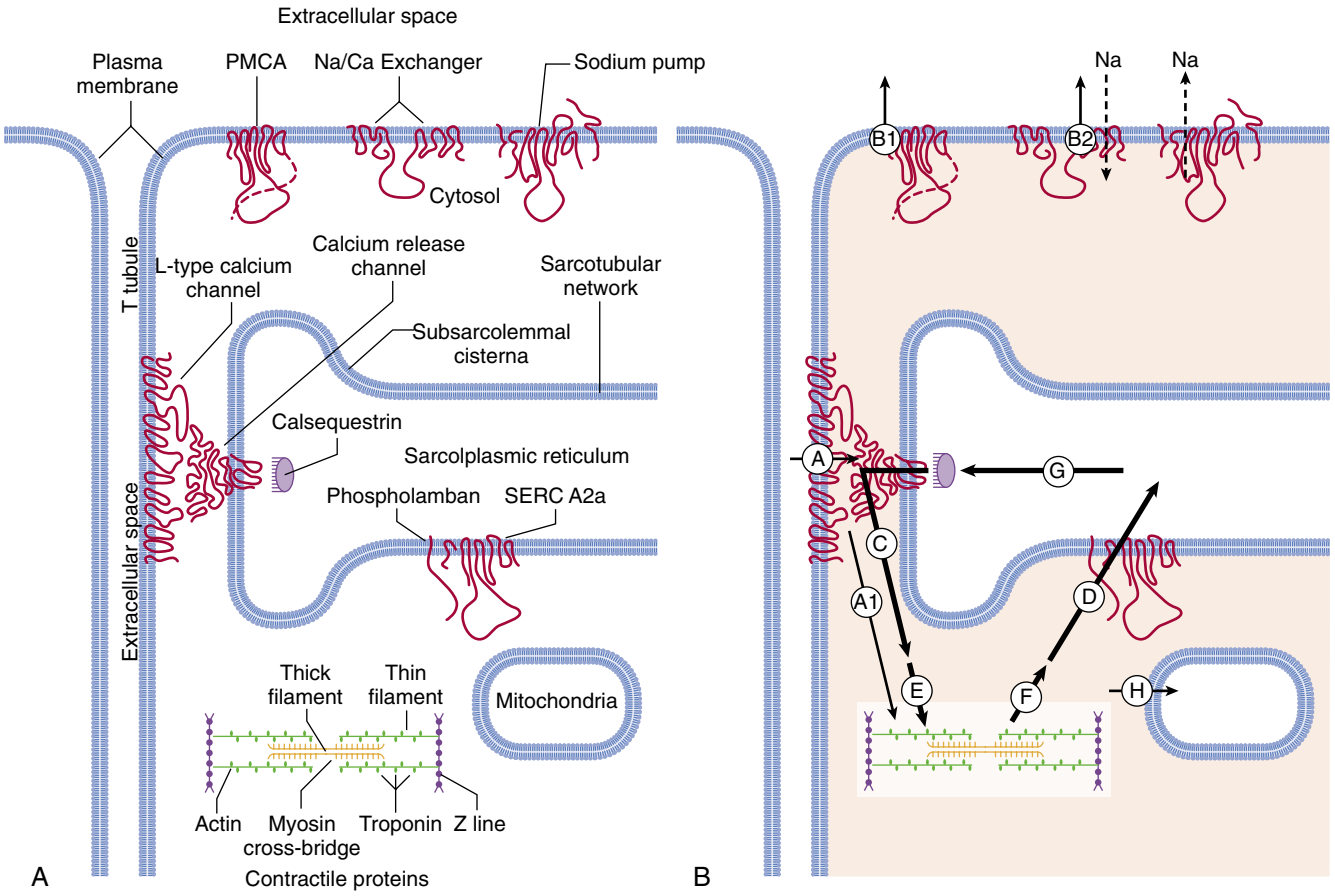

Figure 16-12 **A,** Diagram depicting the components of cardiac excitation-contraction coupling. Calcium pools are noted in **bold** letters. **B,** Extracellular (*arrows A*, *B1*, *B2*) and intracellular calcium flux (*arrows C*, *D*, *E*, *F*, *G*) is shown. The thickness of the *arrows* indicates the magnitude of the calcium flux, and the vertical orientations describe their energetics: *downward-pointing arrows* represent passive calcium flux, whereas *upward-pointing arrows* represent energy-dependent calcium transport. Calcium entering the cell from extracellular fluid through L-type calcium channels triggers release of calcium from the sarcoplasmic reticulum (SR). Only a small portion directly activates the contractile proteins (A1). *Arrow B1* depicts active transport of calcium into extracellular fluid by means of the plasma membrane pump ATPase and the Na^+-Ca^{2+} exchanger. Sodium that enters the cell in exchange for calcium (*dashed line*) is pumped out of the cytosol by the sodium pump. SR regulates calcium efflux from the subsarcolemmal cisternae (*arrow C*) and calcium uptake into the sarcotubular network (*arrow D*). *Arrow G* represents calcium that diffuses within the SR. Calcium binding to (*arrow E*) and dissociation from (*arrow F*) high-affinity calcium binding sites of troponin C activate and inhibit interactions of the contractile proteins. *Arrow H* depicts movement of calcium into and out of mitochondria to buffer the cytosolic calcium concentration. *(From Katz AM: Calcium fluxes.* In *Physiology of the Heart, 3rd ed. Philadelphia, Lippincott-Raven, 2001, pp 232-233.)*

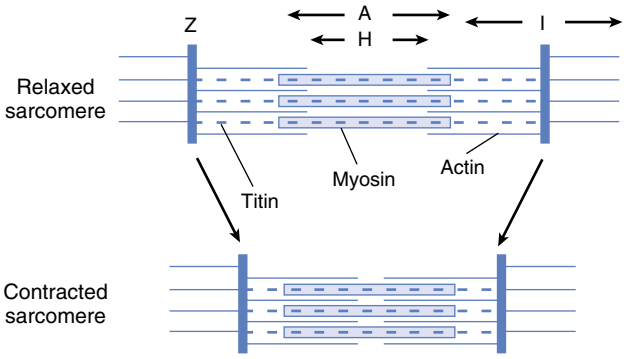

Figure 16-13 The basic unit of contraction is the sarcomere. A contracted and a relaxed sarcomere is depicted. Z lines are located at the ends of the sarcomere. The A band is the site of overlap between myosin and actin filaments. The I band is located on either side of the A band and contains only actin filament. The H zone is located in the center of the A band, and only myosin is present.

filaments do not actually reach the Z lines. Titin, the third filament protein, tethers the myosin thick filament to the Z line. The Z lines at the two ends of the sarcomere are brought closer together during contraction as the thick myosin filament heads interact with the thin actin filaments and slide over each other.[27,28]

Familial hypertrophic cardiomyopathy is an inherited autosomal dominant sarcomeric disease[29] that is the most common cause of sudden death in otherwise healthy individuals. Its clinical features are LV hypertrophy and myocyte/myofibrillar disarray. Mutations in at least eight different genes encoding sarcomere proteins have been identified to be the molecular basis for the disorder. These genes are β-cardiac myosin heavy chain, cardiac troponin T (TnT), α-tropomyosin, cardiac myosin binding protein C, essential or regulatory myosin light chain, cardiac troponin I (TnI), α-cardiac actin, and titin.[29]

Contractile Proteins

The contractile apparatus within the cardiomyocyte consists of contractile and regulatory proteins.[18,30,31] The thin-filament actin

and the thick-filament myosin are the two principal contractile proteins. Actin contains two helical chains. Tropomyosin, a double-stranded α-helical regulatory protein, winds around the actin array and forms the backbone for the actin thin filament. The myosin thick filament is made up of 300 myosin molecules. Each myosin molecule has two functional domains: the body or filament and the bilobar myosin head. The myosin head is composed of one heavy chain and two light chains. The heavy head chain has two domains: the larger one interacts with actin at the actin cleft and has an ATP binding pocket where myosin ATPase is located, and the other smaller one is flexible and attached to the two light chains. The regulatory troponin heterotrimer complex is found at regular intervals along tropomyosin. The heterotrimer troponins are made up of troponin C (TnC), the Ca^{2+} receptor; TnI, an inhibitor of actin-myosin interaction; and TnT, which links the troponin complex to tropomyosin. Tropomodulin is another regulatory protein. It is located at the end of the actin thin filament and caps the end to prevent any excessive elongation of the thin filament.[27,28]

Myocyte Contraction and Relaxation

At rest, cross-bridge cycling and generation of force do not occur because either the myosin heads are blocked from physically reacting with the thin filament or they are only weakly bound to actin (Fig. 16-14).[16] Cross-bridge cycling is initiated on binding of calcium to TnC, which increases TnC-TnI interaction and decreases the inhibitory TnI-actin interaction. These events that ensue from binding of Ca^{2+} to TnC lead to conformational changes in tropomyosin and permit attachment of the myosin head to actin. Cross-bridging involves detachment of the myosin head from actin and reattachment of myosin to another actin on hydrolysis of ATP by myosin ATPase. Binding of ATP to the

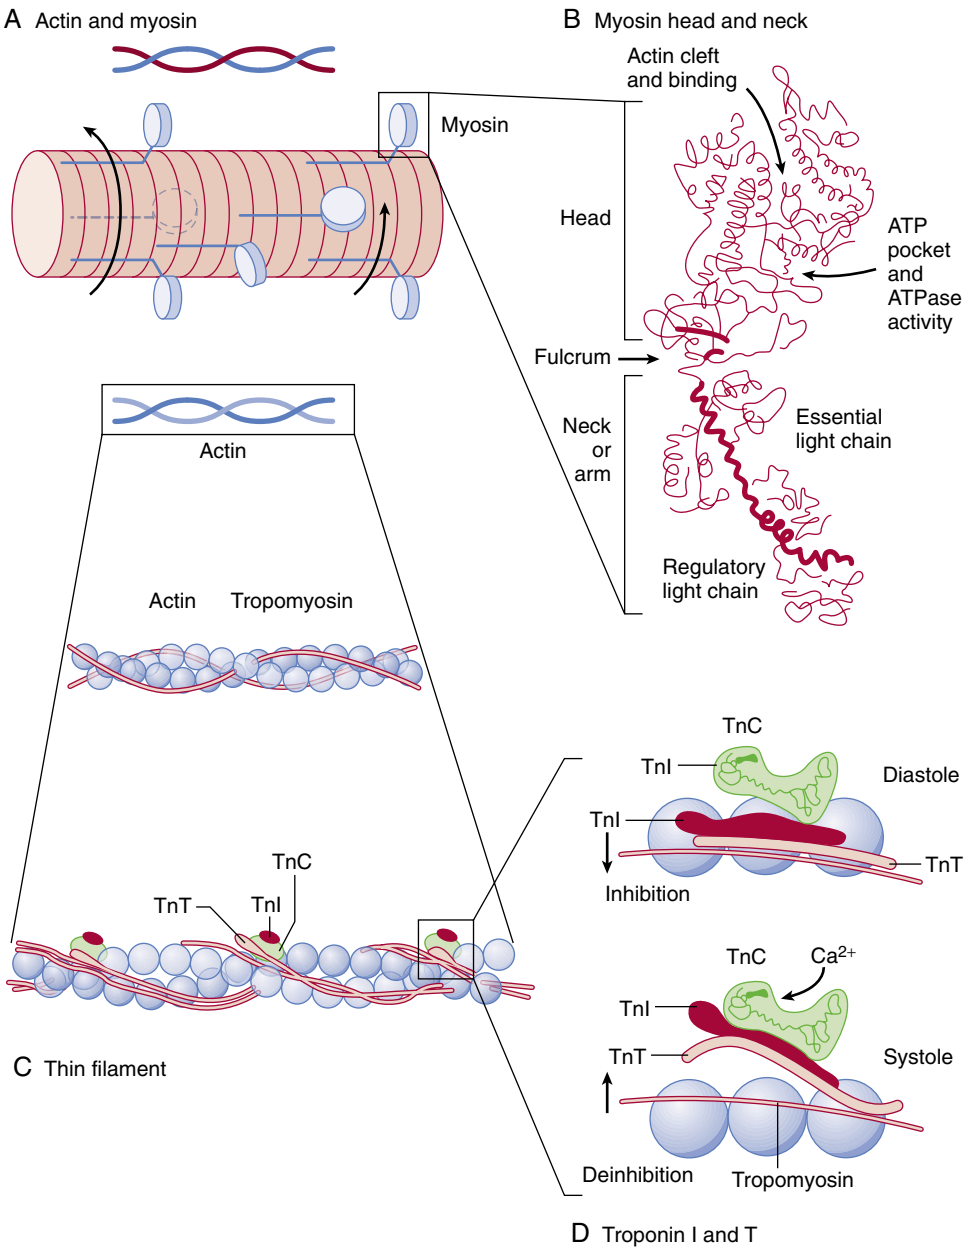

Figure 16-14 Molecules of the contractile system. TnC, TnI, TnT, troponin C, I, T. *(From Opie LH: Myocardial contraction and relaxation. In The Heart. Physiology from Cell to Circulation, 3rd ed. Philadelphia, Lippincott-Raven, 1998, pp 209-231.)*

nucleotide pocket of the myosin head leads to the activation of myosin ATPase,[26-28] ATP hydrolysis, and changes in configuration of the myosin head, all of which facilitate binding of the myosin head to actin and generation of the power stroke of the myosin head. Based on this model, it is apparent that the rate of cross-bridge cycling is dependent on the activity of myosin ATPase.[31] Turnoff of cross-bridge cycling is largely initiated by the fall in cytosolic calcium.

Myocyte relaxation is an energy-dependent process because restoration of cytosolic calcium to resting levels requires the expenditure of ATP. The fall in cytosolic calcium occurs through active reuptake of calcium into the SR by SERCA and extrusion of calcium by the Na^+-Ca^{2+} exchanger. This activity results in release of binding of Ca^{2+} to TnC and separation of the myosin-actin cross-bridge. Myocyte relaxation is dependent on the kinetics of cross-bridge cycling, the affinity of Ca^{2+} for TnC, and the activity of the calcium reuptake mechanisms. Relaxation is enhanced by the increased kinetics of cross-bridge cycling, decreased Ca^{2+} affinity for TnC, and increased activity of calcium reuptake mechanisms.[25]

Titin is a giant stringlike protein that acts as the third filament within the sarcomere. A single titin molecule spans half the sarcomere. Structurally, titin consists of an inextensible anchoring segment and an extensible elastic segment. Its two main functions involve muscle assembly and elasticity. Titin is the principal determinant of the passive properties of the myocardium at low ventricular volume.[32]

The Frank-Starling relationship states that an increase in end-diastolic volume results in enhanced systolic function.[33,34] At the cellular level, the key component for the Frank-Starling relationship is a length-dependent shift in Ca^{2+} sensitivity.[35-37] Several possible mechanisms for this change in Ca^{2+} sensitivity have been implicated, including (1) Ca^{2+} sensitivity as a function of myofilament lattice spacing, (2) Ca^{2+} sensitivity involving positive cooperativity in cross-bridge binding to actin, and (3) dependence of Ca^{2+} sensitivity on strain of the elastic protein titin.[31,36]

Cytoskeleton Proteins

The cytoskeleton is the protein framework within the cytoplasm that links, anchors, or tethers structural components inside the cell.[17,18] Microfilaments (actin filaments), microtubules, and intermediate filaments are three classes of cytoskeleton proteins found in the cytoplasm. Microfilament proteins are actin filaments, either sarcomeric or cortical, depending on their location. Sarcomeric actin filaments are the thin filaments in the contractile machinery that have already been described. Cortical actin filaments are found below the plasma membrane at the cell surface and are linked to several other microfilament proteins, including dystrophin, vinculin, and ankyrin. Microtubules assemble by polymerization of the α- and β-dimers of tubulin. They play a major role in intracellular transport and cell division.[38] Attachment of the ends of microtubules to cellular structures causes the microtubules to expand and contract, thereby pulling and pushing these structures around the cell. The intermediate filaments are relatively insoluble. They have been demonstrated to be important in normal mitochondrial function and behavior. The desmin intermediate filament in cardiomyocytes connects the nucleus to the plasma membrane and is important in transmission of the stress and strain of contractile force between cells.[39] The cytoskeleton provides the organization of microenvironments within the cell for enzyme/protein activity and interaction.

Whereas familial hypertrophic cardiomyopathy is a genetic sarcomeric disease, familial dilated cardiomyopathy (FDCM) is a disease of cytoskeleton proteins. The genetic basis of FDCM includes two genes for X-linked FDCM (dystrophin, G4.5) and four genes for the autosomal dominant form (actin, desmin, lamin A/C, δ-sarcoglycan).[17]

Control of Cardiac Function

Neural Regulation of Cardiac Function

The two limbs of the autonomic nervous system provide opposing input to regulate cardiac function.[40] The neurotransmitter of the sympathetic nervous system is norepinephrine, which provides positive chronotropic (heart rate), inotropic (contractility), and lusitropic (relaxation) effects. The parasympathetic nervous system has a more direct inhibitory effect in the atria and has a negative modulatory effect in the ventricles. The neurotransmitter of the parasympathetic nervous system is acetylcholine. Norepinephrine and acetylcholine both bind to seven-transmembrane–spanning G protein–coupled receptors to transduce their intracellular signals and effect their functional responses (Fig. 16-15).[41] At rest, the heart has a tonic level of parasympathetic cardiac nerve firing and little, if any, sympathetic activity. Therefore, the major influence on the heart at rest is parasympathetic. During exercise or stress, however, the sympathetic neural influence becomes more prominent.

Parasympathetic innervation of the heart is through the vagal nerve. Supraventricular tissue receives much greater vagal innervation than the ventricles do. The principal parasympathetic target neuroeffectors are the muscarinic receptors in the heart.[42,43] Activation of muscarinic receptors reduces pacemaker activity, slows AV conduction, decreases atrial contractile force directly, and exerts inhibitory modulation of ventricular contractile force. A total of five muscarinic receptors have been cloned.[44] M_2 receptors are the predominant subtype found in the mammalian heart. In the coronary circulation, M_3 receptors have been identified. Moreover, non-M_2 receptors have also been reported to exist in the heart. In general, for intracellular signaling, M_1, M_3, and M_5 receptors couple to $G_{q/11}$ protein and activate the phospholipase C–diacylglycerol–inositol phosphate system. On the other hand, the M_2 and M_4 receptors couple to the pertussis toxin–sensitive G protein $G_{i/o}$ to inhibit adenylyl cyclase. M_2 receptors can couple to certain K^+ channels and influence the activity of calcium channels, I_f current, phospholipase A_2, phospholipase D, and tyrosine kinases.

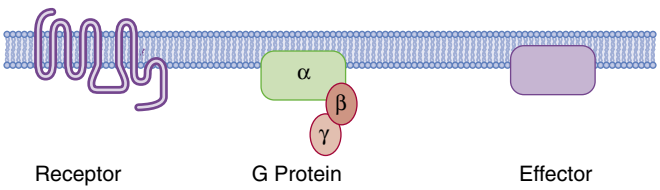

Figure 16-15 General scheme for a G protein–coupled receptor consisting of receptor, the heterotrimeric G protein, and the effector unit. *(Reprinted by permission from Bers DM: Cardiac excitation-contraction coupling. Nature 415:198-205, 2002. Copyright MacMillan Magazines Ltd.)*

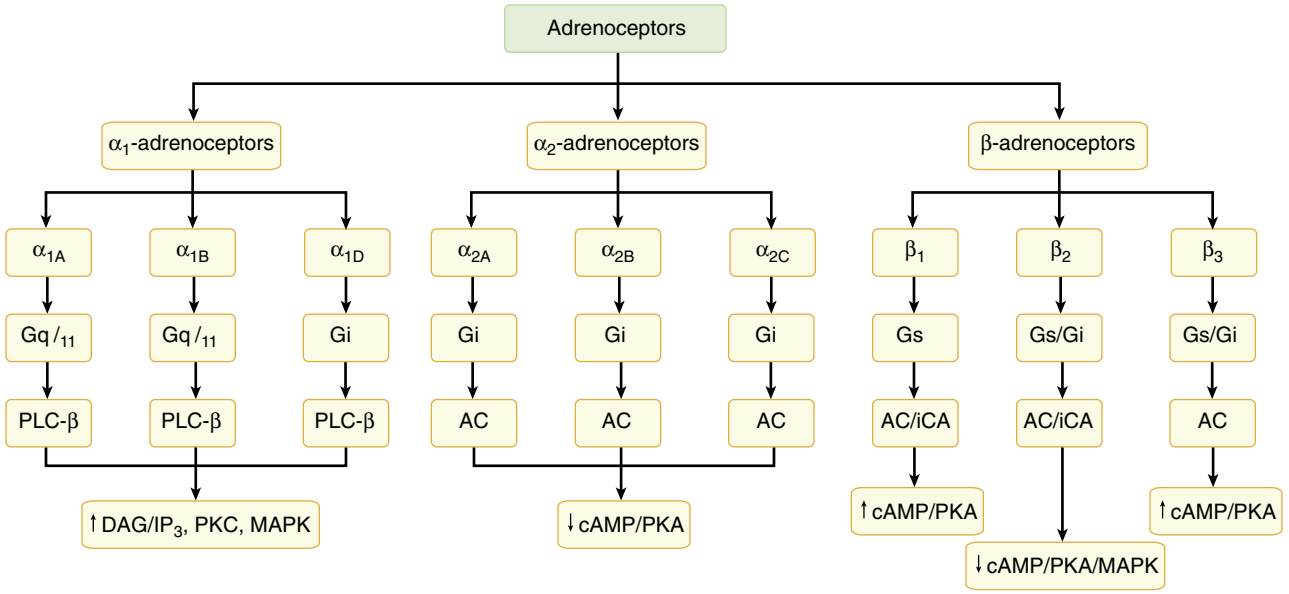

Figure 16-16 Adrenoceptor signaling cascades involving G proteins and effectors (AC, adenylyl cyclase; i_{CaL}, L-type calcium current; PLC-β, phospholipase β) in the heart. The intracellular signals are DAG (diacylglycerol), IP_3 (inositol 1,4,5-triphosphate), PKC (protein kinase C), cAMP (cyclic adenosine monophosphate), PKA (protein kinase A), and MAPK (mitogen-activated protein kinase).

In contrast to vagal innervation, sympathetic innervation of the heart is more predominant in the ventricle than in the atrium. Norepinephrine released from sympathetic nerve terminals stimulates adrenergic receptors (adrenoreceptors [ARs]) located in the heart. The two major classes of ARs are α and β, both of which are G protein–coupled receptors that transduce their intracellular signals by means of specific signaling cascades (Fig. 16-16).

βARs can be further divided into subpopulations of β_1, β_2, and β_3.[43,45] Although most mammalian hearts contain β_1ARs and β_2ARs, β_3ARs have also been demonstrated in many mammalian ventricular tissues. The relative contribution of each βAR subtype to modulation of cardiac function varies among species. In humans, β_1ARs are the predominant subtype in both the atria and ventricle, but a substantial proportion of β_2ARs are located in the atria and approximately 20% of β_2ARs are found in the LV. Much less is known about β_3ARs, but their existence has been documented in the human ventricle. Despite the fact that the β_1AR population is greater than the β_2AR population, the cardiostimulant effect is not proportional to the relative densities of these two subpopulations, which is largely attributable to the tighter coupling of β_2ARs than β_1ARs to the cyclic adenosine monophosphate (cAMP) signaling pathway. Both β_1ARs and β_2ARs activate a pathway that involves the stimulatory G protein (G_s), activation of adenylyl cyclase, accumulation of cAMP, stimulation of cAMP-dependent protein kinase A, and phosphorylation of key target proteins, including L-type calcium channels, phospholamban, and TnI.

Although traditional teaching is that both β_1ARs and β_2ARs are coupled to the G_s-cAMP pathway, more recent experimental evidence has indicated that β_2ARs also couple to the inhibitory G protein G_i to activate non–cAMP-dependent signaling pathways. Additionally, β_2ARs can couple to G protein–independent pathways to modulate cardiac function. βAR stimulation increases both contraction and relaxation, as summarized in Figure 16-17.

The two major subpopulations of αARs are α_1 and α_2. α_1ARs and α_2ARs can be further subdivided into different subtypes. α_1ARs are G protein–coupled receptors and include the α_{1A}, α_{1B}, and α_{1D} subtypes. The α_1AR subtypes are products of separate genes and differ in structure, G protein coupling, tissue distribution, signaling, regulation, and function. Both α_{1A}ARs and α_{1B}ARs mediate positive inotropic responses. However, the positive inotropic effect mediated by α_1ARs is believed to be of minor importance in the heart. α_1ARs are coupled to phospholipase C, phospholipase D, and phospholipase A_2; they increase intracellular Ca^{2+} and myofibrillar sensitivity to Ca^{2+}.

Cardiac hypertrophy is primarily mediated by α_{1A}ARs.[46,47] Cardiac hypertrophic responses to α_1AR agonists involve activation of protein kinase C and mitogen-activated protein kinase through G_q signaling mechanisms. Three subtypes of α_2ARs are recognized: α_{2A}, α_{2B}, and α_{2C}. In the mammalian heart, α_2ARs in the atrium play a role in the presynaptic inhibition of norepinephrine release. These prejunctional α_2ARs are believed to belong to the α_{2C} subtype.

Neural regulation of cardiac function involves a complex interaction between the different classes and subpopulations of adrenoceptors and their signaling pathways. Targeted therapeutics in cardiovascular medicine will involve the clinical application and manipulation of our basic understanding of adrenoceptor pharmacology.

Hormones Affecting Cardiac Function

Many hormones have direct and indirect actions on the heart (Table 16-1). Hormones with cardiac actions can be synthesized and secreted by cardiomyocytes or produced by other tissues and delivered to the heart. They act on specific receptors expressed in cardiomyocytes. The great majority of these hormone receptors are plasma membrane G protein–coupled receptors (GPCRs). Non-GPCRs include the natriuretic peptide receptors, which are

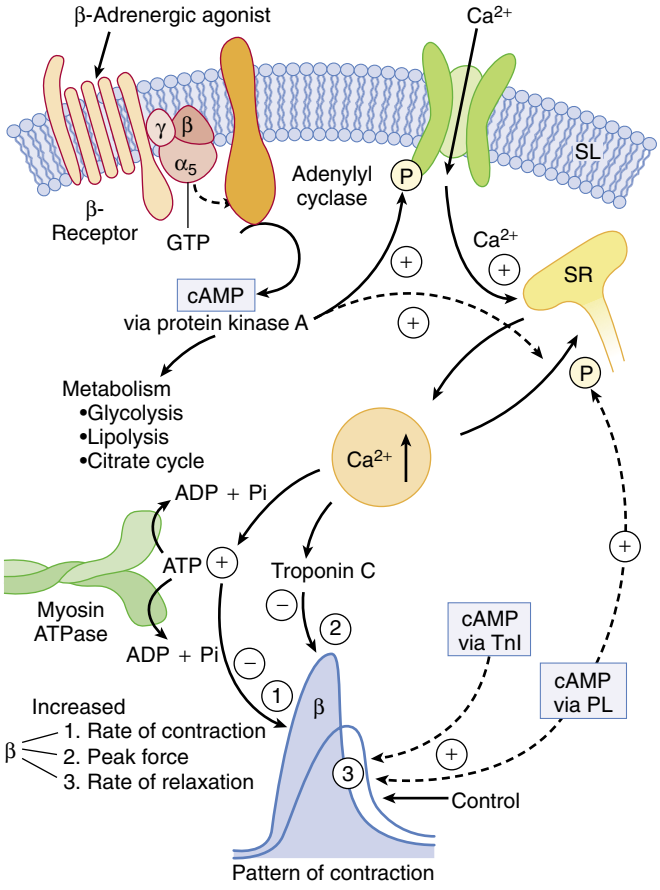

Figure 16-17 The β-adrenoceptor signaling system leads to an increased rate and force of contraction and increased relaxation. ADP, adenosine diphosphate; ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; GTP, guanosine triphosphate; PL, phospholipase; SL, sarcolemma; SR, sarcoplasmic reticulum; TnI, troponin I. *(From Opie LH: Receptors and signal transduction.* In *The Heart. Physiology from Cell to Circulation, 3rd ed. Philadelphia, Lippincott-Raven, 1998, p 195.)*

guanylyl cyclase–coupled receptors, and the glucocorticoid/mineralocorticoid receptors, which bind androgens and aldosterone and are nuclear zinc finger transcription factors. Hormones can have activity in normal cardiac physiology or are active only in pathophysiologic conditions, or both situations can apply. Much of the understanding that has been gained over the past decade on the action of hormones in the heart has been derived from the endocrine changes associated with chronic heart failure.

Cardiac hormones are polypeptides secreted by cardiac tissues into the circulation in the normal heart. Natriuretic peptides,[51,52] aldosterone,[53] and adrenomedullin[54] are hormones secreted by cardiomyocytes. Angiotensin II, the effector hormone in the renin-angiotensin system, is also produced by cardiomyocytes.[55,56] The renin-angiotensin system is one of the most important regulators of cardiovascular physiology. It is a key modulator of cardiac growth and function. Angiotensin II stimulates two separate receptor subtypes, AT_1 and AT_2, both of which are present in the heart. AT_1 receptors are the predominant subtype expressed in the normal adult human heart. Stimulation of AT_1 receptors induces a positive chronotropic and inotropic effect. Angiotensin II also mediates cell growth and proliferation in cardiomyocytes and fibroblasts and induces release of the growth factors aldosterone and catecholamines through stimulation of AT_1 receptors. Activation of AT_1 receptors is directly involved in the development of cardiac hypertrophy and heart failure, as well as adverse remodeling of the myocardium. In contrast, AT_2 receptor activation is counter-regulatory and is generally antiproliferative. Expression of AT_2 receptors, however, is relatively scant in the adult heart because they are most abundant in the fetal heart and decline with development. In response to injury and ischemia, AT_2 receptors become upregulated. The precise role of AT_2 receptors in the heart remains to be defined.

The beneficial effects of blockade of the renin-angiotensin system with angiotensin-converting enzyme inhibitors in the treatment of heart failure have been attributed to inhibition of AT_1 receptor activity. In addition to the renin-angiotensin system,

Table 16-1 Actions of Hormones on Cardiac Function

Hormone	Receptor	Cardiac Action	Increase with CHF
Adrenomedullin	GPCR	+Inotropy/+chronotropy	+
Aldosterone	MR	?	+
Angiotensin	GPCR	+Inotropy/+chronotropy	+
Endothelin	GPCR	?	+
Natriuretic peptides	GCCR		
ANP (ANF)			+
BNP			+
Neuropeptide Y[48,49]	GPCR	–Inotropy	+
Vasopressin	GPCR	+Inotropy/+chronotropy	+
Vasoactive intestinal peptide[50]	GPCR	+Inotropy	No
Sex steroid hormones			
Estrogen	ERR-α/ERR-β	Indirect	No
Testosterone	AR	Indirect	No
Progesterone	PR	Indirect	No

ANF, atrial natriuretic factor; ANP, atrial natriuretic peptide; AR, androgen receptor; BNP, B-type natriuretic peptide; CHF, congestive heart failure; ERR, estrogen-related receptor; GCCR, guanylyl cyclase–coupled receptor; GPCR, G protein–coupled receptor; MR, cytosolic or nuclear mineralocorticoid receptor; PR, progesterone receptor.

other cardiac hormones that have been shown to play pathogenic roles in the promotion of cardiomyocyte growth and cardiac fibrosis, development of cardiac hypertrophy, and progression of congestive heart failure include aldosterone,[53] adrenomedullin,[57-59] natriuretic peptides,[51,52] angiotensin,[60,61] endothelin,[62] and vasopressin.[63,64]

Increased stretch of the myocardium stimulates the release of atrial natriuretic protein (ANP) and B-type natriuretic protein (BNP) from the atria and ventricles, respectively. Both ANP and BNP bind to natriuretic peptide receptors to generate the second messenger cyclic guanosine monophosphate and represent part of the cardiac endocrine response to hemodynamic changes caused by pressure or volume overload. They also participate in organogenesis of the embryo heart and cardiovascular system.[51,52] In patients with chronic heart failure, elevation of serum ANP and BNP levels has been documented to be a predictor of mortality.

Adrenomedullin is a recently discovered cardiac hormone that was originally isolated from pheochromocytoma tissue. It increases accumulation of cAMP and has direct positive chronotropic and inotropic effects.[54,57,58] Adrenomedullin, with interspecies and regional variations, has also been shown to increase nitric oxide production and it functions as a potent vasodilator.

Aldosterone is one of the cardiac-generated steroids, although its physiologic significance remains to be defined. It binds to mineralocorticoid receptors and can increase the expression or activity (or both) of cardiac proteins involved in ionic homeostasis or regulation of pH, such as cardiac Na^+/K^+-ATPase, the Na^+-K^+ cotransporter, Cl^--HCO_3^{2+}, and the Na^+-H^+ antiporter.[53] Aldosterone modifies cardiac structure by inducing cardiac fibrosis in both ventricular chambers and thereby leads to impairment of cardiac contractile function.

Sex Steroid Hormones and the Heart

Cardiac contractility is greater in premenopausal women than in age-matched men, and withdrawal of hormone replacement therapy in postmenopausal women leads to a reduction in cardiac contractile function. The gender dimorphism in heart function and its adaptive responses to injury and disease states are in part mediated by sex steroid hormones.

The most extensively studied sex steroid hormones are estradiol-17β (E2) and its bioactive metabolites. They bind and act on the two subtypes of estrogen receptors in the heart: ERα and ERβ. Progesterone and testosterone (two other sex steroid hormones) and the enzyme aromatase, which converts testosterone to estrogen, are much less well investigated. Progesterone and testosterone bind and act on their respective progesterone receptors and androgen receptors in the heart. Sex steroid hormones interact with their receptors to effect postsynaptic target cell responses and influence presynaptic sympathoadrenergic function. Cardiomyocytes are not only targets for the action of sex steroid hormones but are also the source of synthesis and site of metabolism of these hormones.[65]

E2 is derived from testosterone and is primarily metabolized in the liver to form hydroxyestradiols, catecholestradiol, and methoxyestradiols. Estradiol metabolism also takes place in vascular smooth muscle cells, cardiac fibroblasts, endothelial cells, and cardiomyocytes. Cardiomyocytes express nuclear steroid hormone receptors that modulate gene expression and nonnuclear receptors for the nongenomic effects of sex steroid hormones. They interact with many different coregulators to confer tissue and temporal specificity in their transcriptional actions. These cell-specific coactivator and corepressor proteins are known as estrogen-related receptors.[66] Sex steroid hormones can activate rapid signaling pathways without changing gene expression (Fig. 16-18). One such example is stimulation of vascular endothelial nitric oxide synthase to mediate vascular dilatation. Estrogen's vasodilatory effect might explain the lower systolic blood pressures of premenopausal women than age-matched men. In men, aromatase-mediated conversion of testosterone to estrogen maintains normal vascular tone. In addition to sex steroid hormone stimulation of nuclear or non-nuclear receptors, sex steroid hormone receptors could also induce rapid signaling of growth factor pathways in the absence of ligands.

There are gender differences in cardiac electrophysiologic function. The modulatory actions of estrogen on calcium channels might be responsible for sex-based differences in repolarization of the heart, such as the faster resting heart rate of women, as well as the higher propensity of women to have prolonged QT syndrome.[67] Estrogen, through the activation of ERβ receptors, confers protection after ischemia and reperfusion in murine models of myocardial infarction. In contrast, testosterone, in the same model, has the opposite effect. Aromatase also has protective effects, probably through its action to increase estrogen and decrease testosterone.

Gender differences in cardiac physiology should include consideration of the cellular physiology of sex steroid hormones in males and females; intrinsic differences in the physiology of cardiomyocytes, vascular smooth muscle cells, and endothelial cells between males and females; and gender-based differences in the autonomic modulation of cardiac physiology.

Cardiac Reflexes

Cardiac reflexes are fast-acting reflex loops between the heart and central nervous system (CNS) that contribute to regulation of cardiac function and maintenance of physiologic homeostasis. Specific cardiac receptors elicit their physiologic responses by various pathways. Cardiac receptors are linked to the CNS by myelinated or unmyelinated afferent fibers that travel along the vagus nerve. Cardiac receptors can be found in the atria, ventricles, pericardium, and coronary arteries. Extracardiac receptors are located in the great vessels and carotid artery. Sympathetic and parasympathetic nerve input is processed in the CNS. After central processing, efferent fibers to the heart or the systemic circulation will provoke a particular reaction. The response of the cardiovascular system to efferent stimulation varies with age and duration of the underlying condition that elicited the reflex in the first instance.

Baroreceptor Reflex (Carotid Sinus Reflex)

The baroreceptor reflex is responsible for maintenance of blood pressure. This reflex is capable of regulating arterial pressure around a preset value through a negative-feedback loop (Fig. 16-19).[68,69] In addition, the baroreceptor reflex is capable of establishing a prevailing set point for blood pressure when the preset value has been reset because of chronic hypertension. Changes in blood pressure are monitored by circumferential and longitudinal stretch receptors located in the carotid sinus and aortic arch. The nucleus solitarius, located in the cardiovascular center of the

Pharmacol Ther 111:434-475, 2006.)*

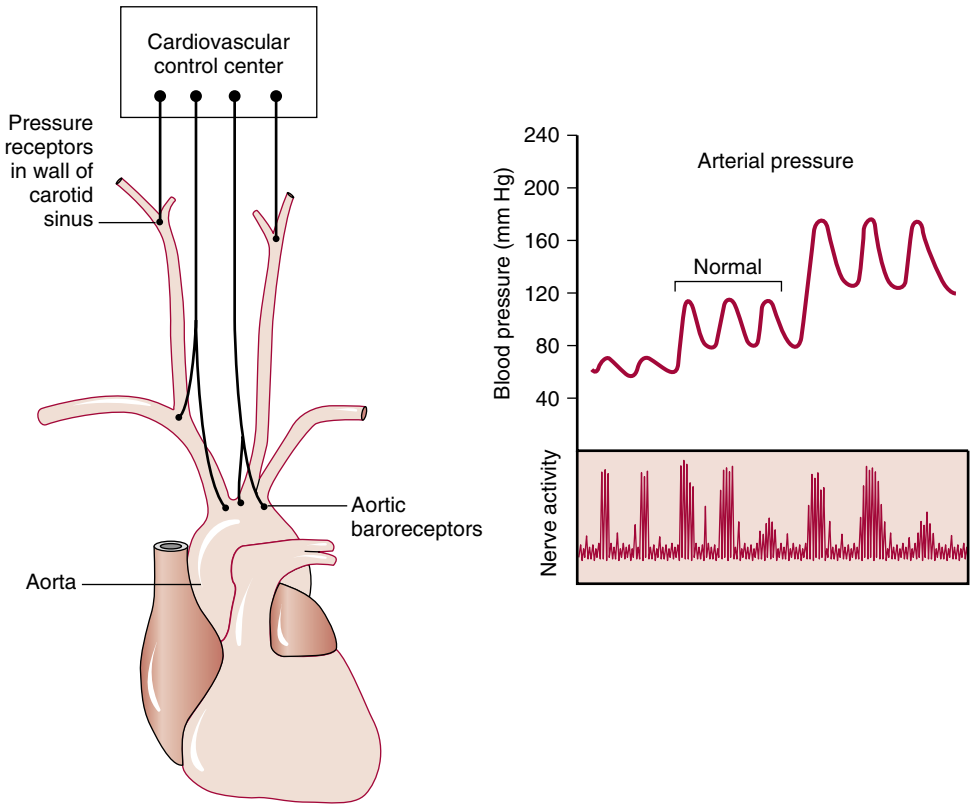

Figure 16-19 Anatomic configuration of the baroreceptor reflex. Pressure receptors in the wall of the carotid sinuses and aorta detect changes in arterial pressure in the circulation. These signals are conveyed to afferent receptive regions of the medulla through the Hering and vagus nerves. Output from effector portions of the medulla modulates peripheral tone and heart rate. The increase in blood pressure results in increased activation of the reflex (*right*), which effects a decrease in blood pressure. *(From Campagna JA, Carter C: Clinical relevance of the Bezold-Jarisch reflex. Anesthesiology 98:1250-1260, 2003.)*

medulla, receives impulses from these stretch receptors through afferents of the glossopharyngeal and vagus nerves. The cardiovascular center in the medulla consist of two functionally different areas: the area responsible for increasing blood pressure is located laterally and rostrally, whereas the area responsible for lowering arterial blood pressure is located centrally and caudally. The latter area also integrates impulses from the hypothalamus and the limbic system. Typically, stretch receptors are activated if systemic blood pressure is greater than 170 mm Hg. The response of the depressor system includes decreased sympathetic activity leading to a decrease in cardiac contractility, heart rate, and vascular tone. In addition, activation of the parasympathetic system further decreases the heart rate and myocardial contractility. Reverse effects are elicited with the onset of hypotension.

The baroreceptor reflex plays an important role during acute blood loss and shock. However, the reflex arch loses its functional capacity at a blood pressure lower than 50 mm Hg. Hormonal status and therefore sex differences have been implicated in altered baroreceptor responses.[70] Furthermore, volatile anesthetics (particularly halothane) inhibit the heart rate component of this reflex.[71] Concomitant use of calcium channel blockers, angiotensin-converting enzyme inhibitors, or phosphodiesterase inhibitors will lessen the cardiovascular response of raising blood pressure through the baroreceptor reflex. This lessened response is achieved by either their direct effects on the peripheral vasculature or, more importantly, their interference with CNS signaling pathways (calcium, angiotensin).[72] Patients with chronic hypertension often exhibit perioperative circulatory instability as a result of a decrease in their baroreceptor reflex response.

Chemoreceptor Reflex

Chemosensitive cells are located in the carotid bodies and the aortic body. These cells respond to changes in pH status and blood oxygen tension. At an arterial partial oxygen pressure (Pao_2) of less than 50 mm Hg or in conditions of acidosis, the chemoreceptors send their impulses along the sinus nerve of Hering (a branch of the glossopharyngeal nerve) and the 10th cranial nerve to the chemosensitive area of the medulla. This area responds by stimulating the respiratory centers and thereby increasing ventilatory drive. In addition, activation of the parasympathetic system ensues and leads to a reduction in heart rate and myocardial contractility. In the case of persistent hypoxia, the CNS will be directly stimulated, with a resultant increase in sympathetic activity.

Bainbridge Reflex

The Bainbridge reflex is elicited by stretch receptors located in the right atrial wall and the cavoatrial junction. An increase in right-sided filling pressure sends vagal afferent signals to the cardiovascular center in the medulla. These afferent signals inhibit parasympathetic activity, thereby increasing the heart rate. Acceleration of the heart rate also results from a direct effect on the SA node by stretching the atrium. The changes in heart rate are dependent on the underlying heart rate before stimulation.

Bezold-Jarisch Reflex

The Bezold-Jarisch reflex responds to noxious ventricular stimuli sensed by chemoreceptors and mechanoreceptors within the LV wall by inducing the triad of hypotension, bradycardia, and coronary artery dilatation.[69] The activated receptors communicate along unmyelinated vagal afferent type C fibers. These fibers reflexively increase parasympathetic tone. Because it invokes bradycardia, the Bezold-Jarisch reflex is thought of as a cardioprotective reflex. This reflex has been implicated in the physiologic response to a range of cardiovascular conditions such as myocardial ischemia or infarction, thrombolysis, or revascularization and syncope. Natriuretic peptide receptors stimulated by endogenous ANP or BNP may modulate the Bezold-Jarisch reflex. Thus, the Bezold-Jarisch reflex may be less pronounced in patients with cardiac hypertrophy or atrial fibrillation.[73]

Valsalva Maneuver

Forced expiration against a closed glottis produces increased intrathoracic pressure, increased central venous pressure, and decreased venous return. Cardiac output and blood pressure will be decreased after this (Valsalva) maneuver. This decrease will be sensed by baroreceptors and reflexively will result in an increase in heart rate and myocardial contractility through sympathetic stimulation. When the glottis opens, venous return increases and causes the heart to respond by vigorous contraction and an increase in blood pressure. This increase in blood pressure will in turn be sensed by baroreceptors, thereby stimulating the parasympathetic efferent pathways to the heart.

Cushing Reflex

The Cushing reflex is a result of cerebral ischemia caused by increased intracranial pressure. Cerebral ischemia at the medullary vasomotor center induces initial activation of the sympathetic nervous system. Such activation will lead to an increase in heart rate, blood pressure, and myocardial contractility in an effort to improve cerebral perfusion. As a result of the high vascular tone, reflex bradycardia mediated by baroreceptors will ensue.

Oculocardiac Reflex

The oculocardiac reflex is provoked by pressure applied to the globe of the eye or traction on the surrounding structures. Stretch receptors are located in the extraocular muscles. Once activated, stretch receptors will send afferent signals through the short and long ciliary nerves. The ciliary nerves will merge with the ophthalmic division of the trigeminal nerve at the ciliary ganglion. The trigeminal nerve will carry these impulses to the gasserian ganglion, thereby resulting in increased parasympathetic tone and subsequent bradycardia. The incidence of this reflex during ophthalmic surgery ranges from 30% to 90%. Administration of an antimuscarinic drug such as glycopyrrolate or atropine reduces the incidence of bradycardia during eye surgery (also see Chapter 75).

17 Hepatic Physiology and Pathophysiology

Key Points

1. Roughly 25% of cardiac output flows through the liver via a dual blood supply. The portal vein conveys 75% of total hepatic blood flow; the hepatic artery provides the rest. Each vessel, however, delivers about 50% of the total hepatic oxygen supply.
2. Hepatic sinusoids are the capillaries of the liver. Blood reaches the sinusoids via terminal branches of the portal vein and hepatic artery; it exits the sinusoids via hepatic venules (i.e., central veins) and travels through a venous network before draining in the inferior vena cava. Postsinusoidal vessels are a major source of total hepatic vascular resistance.
3. The acinus is the functional microvascular unit of the liver. It has three circulatory zones, defined by hepatocellular proximity to the portal axis. Blood perfusing zone 1 hepatocytes (periportal) is rich in oxygen and nutrients. By contrast, zone 3 hepatocytes (centrilobular) are perfused with effluent blood from zones 1 and 2, which is relatively oxygen poor.
4. Hepatocytes of zone 3, which have the highest density of cytochrome P450 proteins, are the most susceptible to injury from drug metabolism, oxidative stress, severe hypotension, or hypoxia.
5. The hepatic arterial buffer response (HABR) is the main intrinsic regulator of liver blood flow. Since the liver lacks pressure-flow autoregulation (in the fasted state), low systemic arterial pressure leads to low portal venous flow. HABR induces a compensatory increase of hepatic arterial flow, thereby preserving hepatic oxygen delivery despite decreases of total hepatic blood flow. Pathologic disruptions of HABR increase the susceptibility of the liver to hypoxic injury.
6. The liver is integral to the splanchnic blood reservoir, which can transfer up to 1 L of whole blood to the systemic circulation within 30 seconds of sympathoadrenal activation in healthy, euvolemic adults. If this reservoir is dysfunctional, abrupt, yet mild losses of intravascular volume (10% to 15%) may cause severe hypotension.
7. The liver regulates the pathways of intermediary metabolism. When hepatic glycogen is depleted (e.g., due to prolonged fasting), the body depends on hepatic gluconeogenesis to supply blood glucose. Stress induces catabolic changes, including increased lipolysis, fatty acid oxidation, and hepatic ketone production. Ketosis develops. But ketosis triggers insulin release, thereby decreasing substrate (fatty acids) availability for ketogenesis. Thus, stress-induced ketosis tends to be self-limited, except in insulin-deficient states, when diabetic ketoacidosis may occur.
8. Hepatocytes play a central role in nitrogen metabolism. They remove nitrogen from various molecules, incorporate it into ammonia, and convert ammonia to urea. If liver failure occurs (without severe renal dysfunction), blood urea nitrogen levels typically remain low, while nitrogenous wastes accumulate in blood and other tissues.
9. Albumin is the most abundant hepatic protein. It is the main determinant of plasma oncotic pressure and an essential plasma transporter of exogenous substances and endogenous compounds, such as unconjugated bilirubin and free fatty acids.
10. Liver produces most of the molecular participants in coagulation pathways (besides factors III, IV, VIII). Hepatic proteins—such as factors II, VII, IX, X, proteins C and protein S—require vitamin K–dependent, posttranslational modifications, which enables their extrahepatic activation and subsequent involvement in the coagulation cascade.
11. Hepatocytes make, and regulate production of, bile salts. These natural ionic detergents have many physiologic roles, including enteric absorption, transport, and secretion of lipids. Disruption of biliary circulation predisposes to vitamin K deficiency; hepatocytes continue to synthesize procoagulants but cannot γ-carboxylate them. Parenteral vitamin K therapy should therefore correct the coagulopathy of cholestasis, unless liver failure has supervened.

12. The liver is the main site of xenobiotic biotransformation. Multifarious, complex chemical reactions of hepatic drug disposition fit in at least one of three broad metabolic categories (or phases): Phase 1 oxidizes drugs via cytochrome P450-mediated redox reactions; phase 2 produces conjugates of endogenous polar molecules and drugs (or their metabolites); phase 3 uses adenosine triphosphate transport proteins to facilitate biliary elimination of endogenous and exogenous substances.
13. The liver is the largest reticuloendothelial organ in the human body. Kupffer cells (macrophages) account for nearly 10% of the liver's mass. These macrophages filter the venous effluent of the gastrointestinal tract and in the process phagocytose microbes, destroy toxins, process antigens, modulate immunity, and regulate inflammatory responses. Kupffer cells, activated by such processes, release nitro-radicals, reactive oxygen species, proteases, chemokines, and cytokines, which recruit neutrophils to the liver and intensify the hepatic inflammation. If uncontrolled, these activated macrophages can damage normal hepatic parenchyma.
14. Portosystemic shunting (as occurs with cirrhosis-induced portal hypertension) circumvents the hepatic filtering mechanism and thereby allows drugs, nitrogenous waste, and toxins to enter the central circulation. Some of these substances are putative mediators of hepatic encephalopathy.
15. Standard liver function tests are used to screen for hepatobiliary diseases and identify categories of pathologic events within the hepatobiliary system, such as hepatocellular injury or biliary dysfunction.
16. The onset of portal hypertension signals depletion of the normal physiologic reserve of the liver. At this stage, severe pathophysiologic derangements develop and can give rise to life-threatening complications such as variceal hemorrhage, hepatic encephalopathy, and renal failure.
17. The cardiovascular hallmark of cirrhosis and portal hypertension is a hyperdynamic circulation in which cardiac output increases, total peripheral resistance decreases, and systemic blood pressure is slightly below normal. The hemodynamic profile is reminiscent of a large arteriovenous fistula because of extensive arteriovenous communications within the splanchnic vasculature and in organs throughout the body. Splanchnic vasculature may be engorged with blood even though effective plasma volume is perilously low. Cardiovascular responses to physiologic and pharmacologic vasoconstrictors are attenuated because of a plethora of endogenous vasodilators, dysfunction of the splanchnic reservoir, and occasionally, cardiac failure (e.g., cirrhotic cardiomyopathy).

Overview

The liver is the largest internal organ and largest gland in the human body. It accounts for about 2% of the total mass of healthy adults and 5% of neonates.[1] Its location within the thoracic portion of the abdominal cavity reflects its physiologic importance as an interface between the gastrointestinal tract and pulmonary/systemic circulation. It filters, excretes, or modifies an enormity of gut-derived substances—it destroys bacteria, inactivates antigens, and detoxifies chemicals that might otherwise injure the heart, lungs, or other vital organs. The liver is at the epicenter of intermediary metabolism, with versatile and massive biochemical pathways for molecular transformations. Such pathways work to maintain homeostatic blood levels of nutrients during feast and famine. As described in this chapter, the multiple and diverse functions of the liver have an impact on every tissue in the body. A fundamental knowledge of hepatic anatomy and physiology is therefore a prerequisite for understanding liver disease, its clinical manifestations, and its therapeutic challenges.

Hepatic Anatomy

Macroscopic Anatomy

The liver is a reddish brown boomerang-shaped gland that occupies the right hypochondrium, most of the epigastrium, and a variable portion of the left hypochondrium (Fig. 17-1). In the right midaxillary line, the liver spans from the 7th to the 11th ribs; the gallbladder lies beneath to the 9th costal cartilage. The liver is highly vascular, friable, and easily lacerated. Because of its sponginess, it conforms to the contours of less malleable, adjacent structures. Based on postmortem studies—using chemicals to harden the liver in situ—the organ is shaped like a right-angled triangular prism (wedge), with a rounded right angle. The three faces of this prism are the superior, inferior, and posterior surfaces of the liver; they provide frames of reference for gross anatomy (Figs. 17-2 and 17-3).

The hepatic ligaments are connective tissue bands that attach the liver to adjacent tissues. Most of these bands are overlapping folds of peritoneal membranes (i.e., membranous ligaments), but two are fibrous cords derived from obliterated fetal vessels, namely, the umbilical vein (ligamentum teres or round ligament) and the ductus venosus (ligamentum venosum). Although a couple of ligaments attach to nearby viscera (e.g., the hepatogastric and hepatoduodenal ligaments, which connect to the lesser curvature of the stomach and duodenum, respectively), most serve to tether the liver to the anterior abdominal wall or the underside of the diaphragm. Among the latter group are the coronary, left lateral, right lateral, falciform, and round ligaments.

Several factors maintain the liver in proper anatomic position. For example, the main posterior supports are (1) the diaphragm, via the coronary and triangular ligaments and the matrix of connective tissue on the bare area, and (2) the inferior vena cava, hepatic veins, and embedded connective tissue. The superior surface of the liver is form-fitted to the underside of the dia-

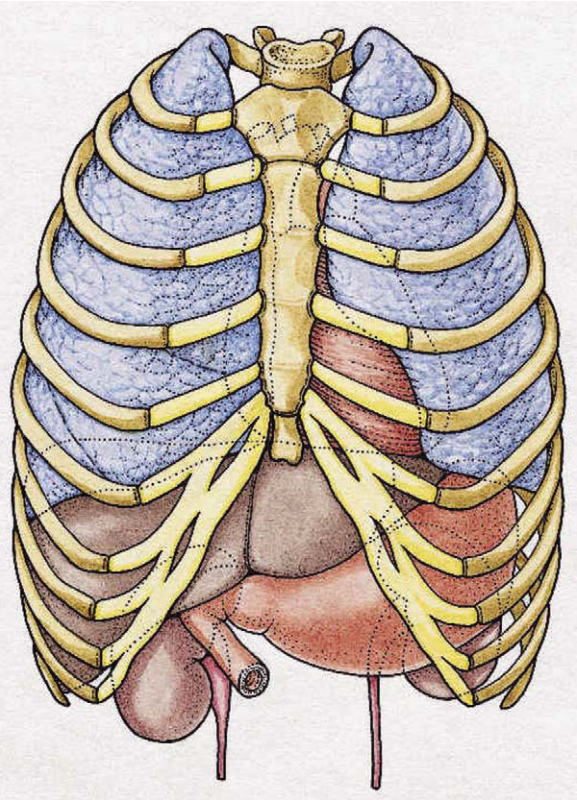

Figure 17-1 Anterior view of the liver and thoracic cage. The liver resides in the thoracic portion of the abdominal cavity; it occupies most of the right hypochondrium, much of the epigastrium, and a variable portion of the left hypochondrium. *(Reproduced © DK Images. phragm, which could keep these structures in apposition at atmospheric pressure. Because abdominal viscera fill the abdominal cavity, the muscular walls of the abdomen remain in a state of tonic contraction. This tonic contraction generates positive intra-abdominal pressure, which pushes the liver against the underside of the diaphragm and keeps their surfaces together, even as the subatmospheric pressure of the thoracic cavity exerts upward pressure on the diaphragm. Because of its laxity, the falciform ligament does little to anchor the liver, although it may limit its lateral displacement.

Traditional Anatomy

Traditional or classic liver anatomy uses topologic landmarks to partition the liver into four lobes: the left, right, caudate, and quadrate.[2] On the superior hepatic surface, the falciform ligament separates the left and right lobes (see Fig. 17-2). Demarcations on posterior-inferior hepatic surfaces (Fig. 17-3) results from (1) the left sagittal fossa (ligamenta venosum and teres hepaticus), which separates left and right lobes; (2) the transverse fissure (porta hepatis), which is a shared border of quadrate and caudate lobes; (3) fossae for the umbilical vein and gallbladder, which border the quadrate lobe; (4) fossae for the ductus venosus (ligamentum venosum) and inferior vena cava fossa, which further delineate the caudate lobe.[3]

Internal Anatomy

After ascending to the porta hepatis (hilum), the portal vein and proper hepatic artery divide into their first-order branches—the left and right portal veins and the left and right hepatic arteries. These vessels enter the liver and travel in parallel as they ramify within the organ (Fig. 17-4). Their terminal branches drain into sinusoids of liver (i.e., the hepatic capillaries). Blood egresses from the sinusoids through intralobular (central) veins; it is conveyed via a series of larger conduits (i.e., the sublobular, interlobular, and lobular veins) to the right, middle, or left hepatic veins. The hepatic veins connect to the inferior vena cava (see Fig. 17-4).

The intrahepatic flow of bile occurs in a direction opposite the flow of afferent blood within the liver. Hepatic parenchymal cells produce bile; they secrete it into canaliculi that connect to bile ductules of the portal areas. Bile egresses from the portal canals and flows via a series of ducts to the left or right hepatic bile duct. These ducts unite to form the common hepatic bile duct, which descends from the porta hepatis and gives rise to the cystic duct and the common bile duct.

Physiologic Anatomy

Physiologic anatomy—also called functional, segmental, modern, or surgical anatomy—focuses on singular, independent segments of the liver (Fig. 17-5). Each independent segment has its own afferent blood supply and routes for venous and biliary drainage,

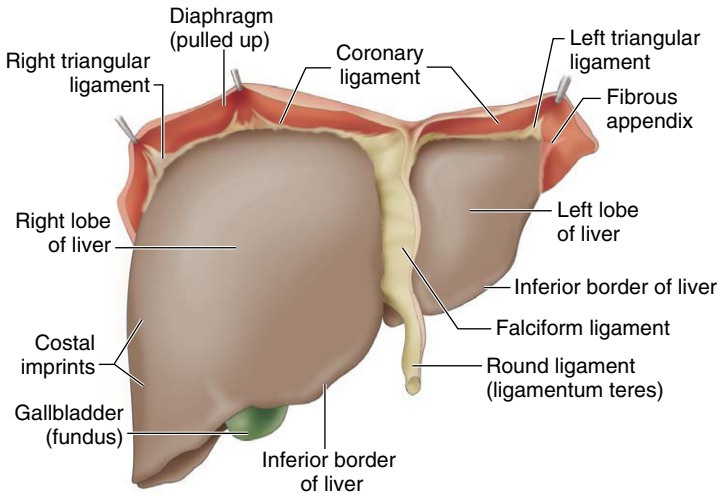

Figure 17-2 Superior hepatic surface: frontal view. The anterior hepatic edge (i.e., the inferior border of the liver) delineates the superior and inferior surfaces of the liver. A sickle-shaped peritoneal fold (falciform ligament) divides the liver into two parts of unequal size, the right lobe and the left lobe. Within the free margin or base of the falciform are paraumbilical veins and the round ligament (ligamentum teres), the latter being the remnant of the obliterated umbilical vein. *(From Strunk H, Stuckmann G, Textor J, et al: Limitations and pitfalls of Couinaud's segmentation of the liver in transaxial imaging. Eur Radiol 13:2472-2482, 2003.)*

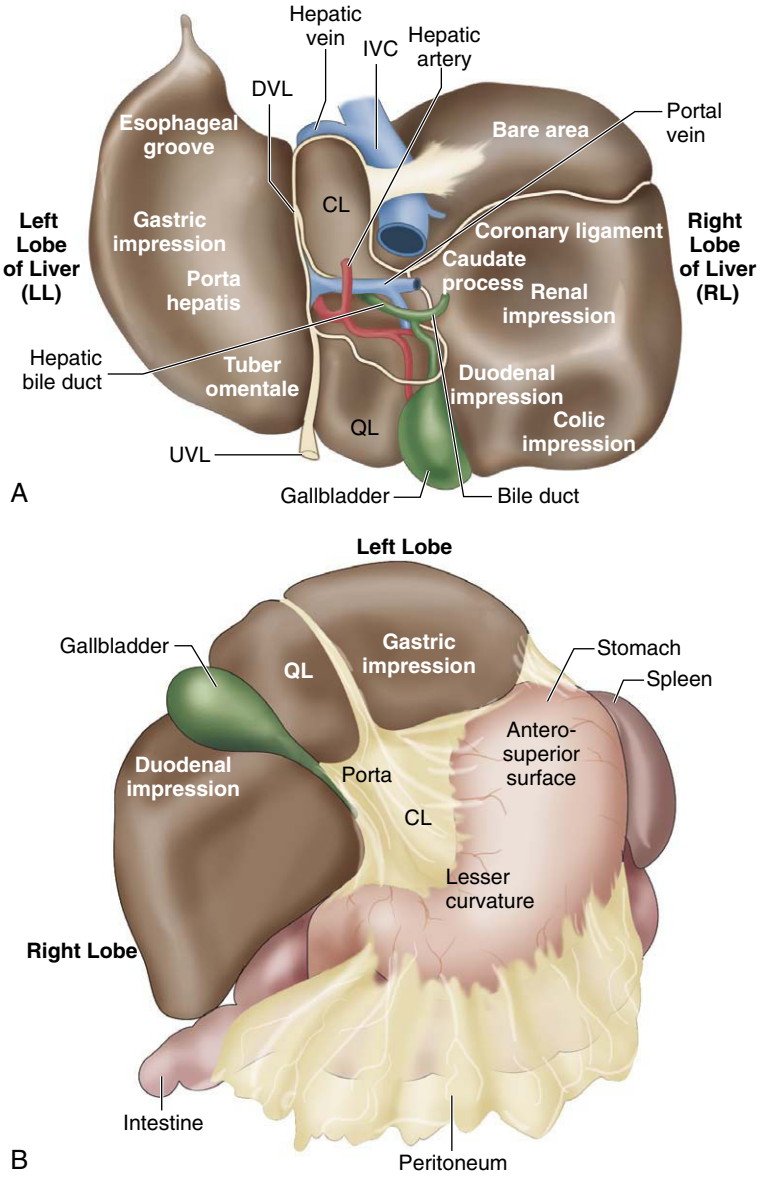

Figure 17-3 A, Posterior and inferior hepatic surfaces showing the relationship between four hepatic lobes: left lobe (LL), caudate lobe (CL), quadrate lobe (QL), right lobe (RL). They are delineated by five structures: the ductus venosus ligament (DVL), umbilical vein ligament (UVL), porta hepatis (PH), inferior vena cava (IVC), and gallbladder (GB). These structures can be envisaged as forming the letter H: • The two-part, left vertical bar (DVL in the back, UVL in the front) separates the LL from all the other lobes. • The three-part, right vertical bar (IVC in the back, caudate process in the middle, GB in the front) separates the RL from the others lobes. The caudate process, which connects the RL and CL, forms the upper boundary of the epiploic foramen (of the peritoneum). • The crossbar is the PH (or transverse fissure), which separates the CL in the back from the QL in the front. Notable anatomic features (left to right) are the narrow LL but broad and rounded RL. Protuberances and impressions (imp) on the hepatic surfaces result from contiguous viscera: the LL has an esophageal groove, gastric impression, and tuber omentale; the RL has duodenal, suprarenal, renal, and colic impressions. The vertebral column and crura of the diaphragm produce the deep concavity to the left of IVC. The omental bursa (upper part) lies between the papillary process (an elevation of the CL) and diaphragm. The surfaces of the liver are covered by peritoneum, with a few exceptions. Uncovered areas include (1) the GB attachment site; (2) the porta hepatis, with vessels and ducts splitting the two layers of the lesser omentum; (3) the right suprarenal impression; and (4) nonperitoneal surface (bare area of the liver) bounded by the coronary ligament (upper and lower lines of reflection), which is in direct contact with the diaphragm. **B,** Inferior (visceral) hepatic surface. The gastric impression on the liver molds to the convex, anterosuperior gastric surface. The tuber omentale (hepatic protuberance) fits in the concave, lesser curvature of stomach; it lies superficial to the anterior layer of lesser omentum and connects to the duodenum via the hepatogastric ligament. *(From Human Anatomy. http://theodora.com/anatomy/the_liver.html. Accessed February 11, 2009.)*

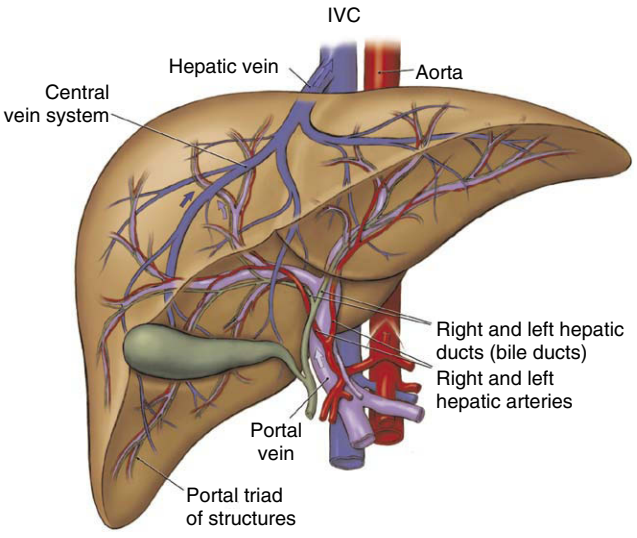

Figure 17-4 Internal anatomy of the liver. The portal vein (*lavender*) and proper hepatic artery (*red*) ascend to the porta hepatics (hilum), where they divide into their left and right main branches. These branches ramify within the liver before emptying into sinusoids. Blood exiting sinusoids is conveyed via central vein system to into hepatic veins (*blue*), which drain directly into the inferior vena cava (IVC; blue). Hepatocytes produce bile and secrete it into canaliculi; bile exits the liver flows though ductules of the portal triads, which drain into a series of intrahepatic ducts, and drains into the common hepatic bile duct (*gray*); the latter exits the liver at the porta hepatis and descends between peritoneal layers of the lesser omentum.

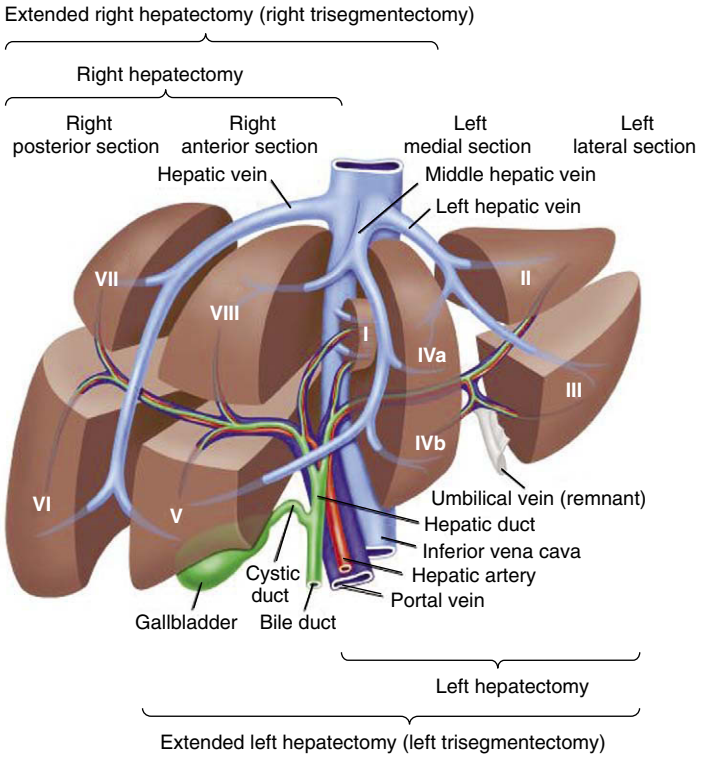

Figure 17-5 Schematic depiction of Couinaud segmental liver anatomy and the normal portal venous structures. Bracketed text shows hepatic segments resected during partial hepatectomies. *(Reproduced from Functional segments of the liver (Segmental_ anatomy_of_liver). Management of potentially resectable colorectal cancer liver metastases. Alan P Venook, MD. Steven A Curley, MD, FACS.©2007 UpToDate.)*

allowing it to remain functionally intact after surgical resection of neighboring segments. Owing to the manifold variations in branching patterns of the portal vein, hepatic artery, and hepatic bile duct, there is no universally accepted classification of segmental anatomy.[4] The most widely used classifications—such as those of Couinaud or Bismuth—are based on the anatomy of the portal and hepatic veins. The Couinaud system, for example, uses third-generation branches of the portal vein to partition the liver into eight physiologically independent segments (Fig. 17-5).[4] The geometry of dividing the liver into sectors and segments in accord with Bismuth's method is shown in Figure 17-6.[4]

Physiologic anatomy facilitates both planning and performance of hepatic surgery. For example, surgical incisions through the center of a segment would be likely to devitalize the

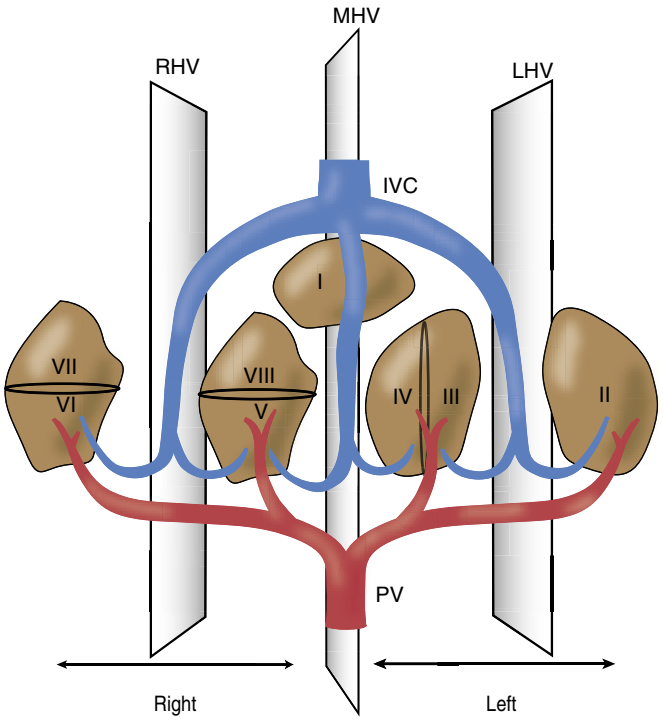

Figure 17-6 Physiologic liver anatomy: Bismuth classification. Three parallel planes host a single hepatic vein (right, RHV; middle, MHV; or left, LHV); each plane is split by a transverse plane (not shown) cutting through the right or left main portal veins (PV); this creates four sectors with portal pedicels (i.e., portal sectors). MHV divides the liver into a left and right hemiliver: LHV splits the former (into one lateral (II) and two medial (III, IV) segments) and RHV splits the latter (into two anterior (VI, VII) and two posterior (V, VIII) segments). In contrast to any other segment, segment I (the caudate lobe) gets its blood supply from both left and right main portal veins; and, its venous outflow—instead of entering a major hepatic vein—drains directly into the inferior vena cava (IVC). *(The authors are grateful to Jennifer Mushlin for designing and crafting this figure.)*

entire segment because therein lies the portal triads (portal vein, hepatic artery, bile duct). By contrast, incisions along the periphery of segments minimize unintentional injuries of major hepatic veins, which generally run in parallel to the segmental borders. If surgical disease affects any part of a segment, the goal is usually to remove the entire segment without disrupting its healthier neighbors. Clinical studies have shown lower rates of perioperative morbidity and mortality when liver surgery (resection of tumors, repair of traumatic injuries) is guided by the principles of physiologic anatomy.[5-7]

Real Anatomy

Because the human liver has so many anatomic variations, knowledge of an individual's real physiologic anatomy derives from advanced imaging techniques, such as contrast-enhanced helical computed tomography scans. These scans provide accurate information on the relationships of surface landmarks and internal hepatic anatomy. In fact, such scan data, when superimposed on normalized computer images of Couinaud segments, yield a data set with enough information to construct a three-dimensional model of a patient's liver. Accurate, see-through constructs can impart an instantaneous grasp of a patient's physiologic anatomy by detailing anatomic variants and precise locations of hepatic lesions. In addition, recent advances in ultrasonography have enabled real physiologic anatomy to be identified during surgical procedures.

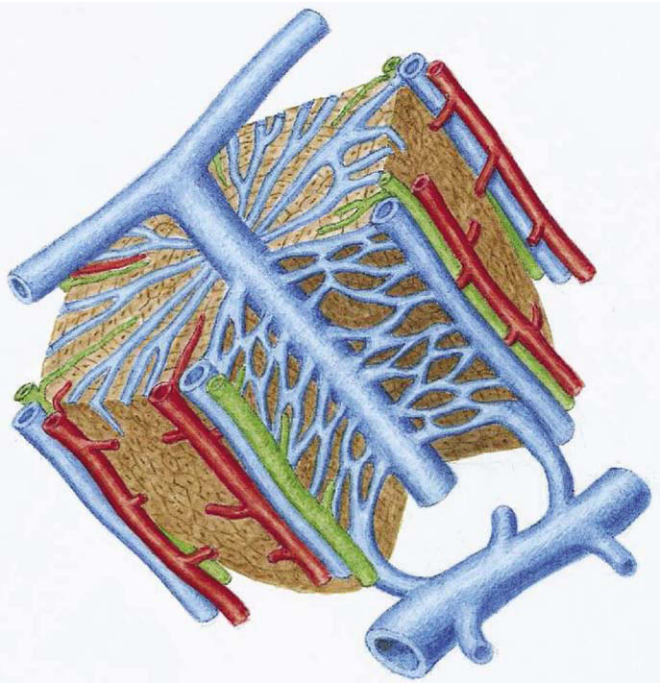

Figure 17-8 Idealized representation of a classic liver lobule. *(© DK Images.)*

Microanatomy

Classic Liver Lobule

The basic unit of the liver can be viewed as a classic lobule, a portal lobule, or a liver acinus; Figure 17-7 shows how these arbitrary units relate to one another. An idealized classic liver lobule is a hexagonal prism with a central vein at its center and six vertically aligned portal canals (Fig. 17-8). Each portal canal includes a connective tissue matrix, surrounding nerve fibers, lymphatic vessels, and a portal triad. The latter contains terminal branches of the portal vein and hepatic artery and a bile ductule.

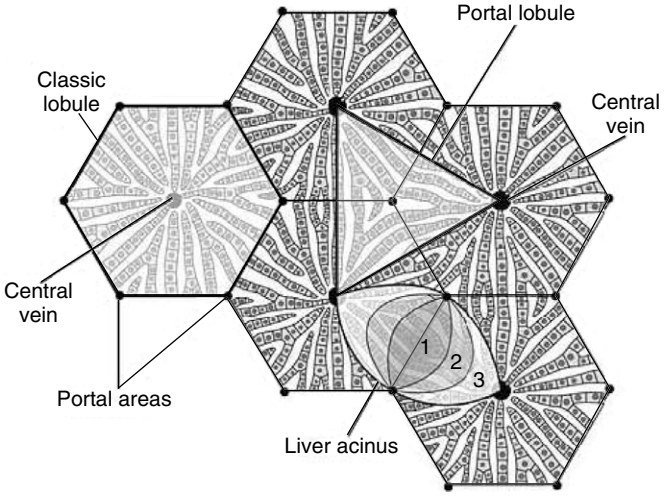

Figure 17-7 Schematic classifications of liver units: liver lobule, portal lobule, and liver acinus. Lobular units have well demarcated central structures (central vein or portal canal), whereas the liver acinus (zones 1, 2, 3; see Fig. 17-10) contains a central axis derived from two adjacent classic lobules. *(From Henrickson R, Kaye GI, Mazurkiewicz J: Liver and gallbladder. In Henrickson R, Kaye GI, Mazurkiewicz [eds]: NMS Histology, 3rd ed. Philadelphia, Lippincott Williams & Wilkins, 1997.)*

A transverse section of a liver lobule shows an array of anastomosing cords of cuboidal hepatocytes separated by vascular channels (lacunae) that radiate from the portal areas and converge on the central vein (see Fig. 17-8). The lacunar labyrinth permeates the entire lobule; it is confined, however, at the periphery of the lobule by a limiting plate of hepatocytes that form a nearly continuous wall. This wall separates the interior of the lobule from the portal canals. Only the tiniest branches of the hepatic artery, portal vein, and bile duct are able to penetrate fenestrae within the limiting plate.

Microscopic examination of the human liver, however, shows a lack of well-defined classic lobules because of a dearth of well-developed connective tissue between lobules. Indeed, the search for lobular boundaries led to the discovery of circumferential terminal hepatic arterioles, portal venules, and bile ductules (Fig. 17-9). This finding is fundamental to the acinar lobe concept, which posits that vessels encircling lobar peripheries, rather than those within portal canals, are the most immediate source of afferent blood to hepatocytes (Fig. 17-10; also see Fig. 17-7). In other words, blood flow to lobules originates along shared borders of classic lobules, which lie between two central veins (see Fig. 17-10).

The Liver Acinus

The acinus is the functional microvascular unit of the liver. It forms around a vertical axis (the portal canal) consisting of a portal venule, hepatic arteriole, bile ductule, lymph vessels, and nerves. Flow of blood within acini is directed radially toward the central veins and vertically to the portal canal.

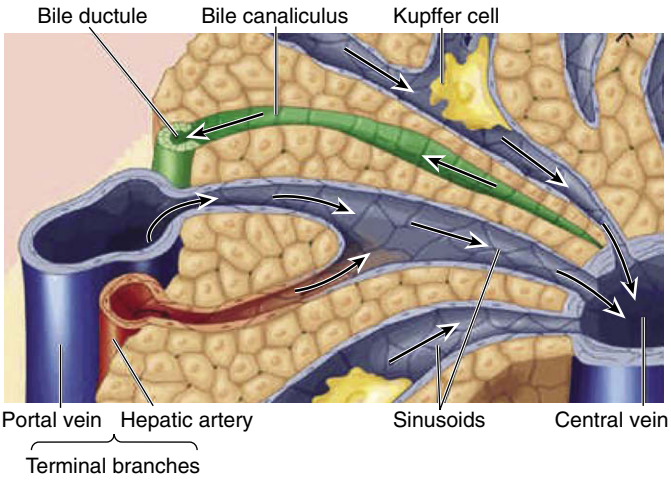

Figure 17-9 Diagram of a portal triad in cross section. Blood enters sinusoids (*blue*, *black arrows*) and egresses via a central vein (*blue*). Sinusoids contain Kupffer cells (*yellow*). Hepatocytes (*pinkish tan*) produce bile and secrete it into bile canaliculi (*green*, with *black arrows*), which drain into a bile ductule of the portal triad. *(From The Internet Encyclopedia of Science. http://daviddarling.info/encyclopedia/L/liver.html. Accessed February 11, 2009.)*

Microcirculation

The acinus has three heterogeneous circulatory zones[1] (see Fig. 17-10): zone 1 is periportal, zone 2 is the midzone, and zone 3 is pericentral. Blood supplied to zone 1, which is near the origin of the sinusoid, is rich in oxygen and nutrients. In contrast, zone 3, at the periphery of the acinus, receives blood that is oxygen poor because this blood has already perfused hepatocytes of zones 1 and 2 before it reaches zone 3.

The microvascular architecture of the acinus allows increases in the efficiency of substrate utilization and excretion of waste products.[8,9] Urea cycle enzymes are localized in zones 1 and 2. Hepatocytes within these zones convert amino acids to ketoacids and ammonia; the urea cycle (high capacity, low affinity) captures the ammonia and incorporates it into urea. Any ammonia that eludes the urea cycle is likely to encounter glutamine synthetase, which is expressed only in zone 3. This enzyme facilitates the capture of ammonia within the glutamine substrate. If glutamine substrate were present in zones 1 or 2, it would compete with urea cycle enzymes for ammonia and thereby decrease the liver's capacity to eliminate ammonia. By having glutamine synthetase localized in zone 3, pericentral hepatocytes more efficiently scavenge the ammonia that would otherwise reach the central circulation.[8]

Periportal hepatocytes have the highest density of mitochondria and are the major site of oxidative metabolism and glycogen synthesis. In contrast, pericentral hepatocytes—which have an abundance of smooth endoplasmic reticulum, reduced nicotinamide adenine dinucleotide phosphate (NADPH), and cytochrome P450 (CYP) proteins—are the major site of anaerobic metabolism and xenobiotic biotransformation. Not surprisingly, pericentral hepatocytes bear the brunt of injuries induced by reactive xenobiotic metabolites or hypoxic episodes. The clinical message is that ischemic injury or necrosis of the centrilobular region decreases the liver's capacity to excrete many drugs and other xenobiotics.

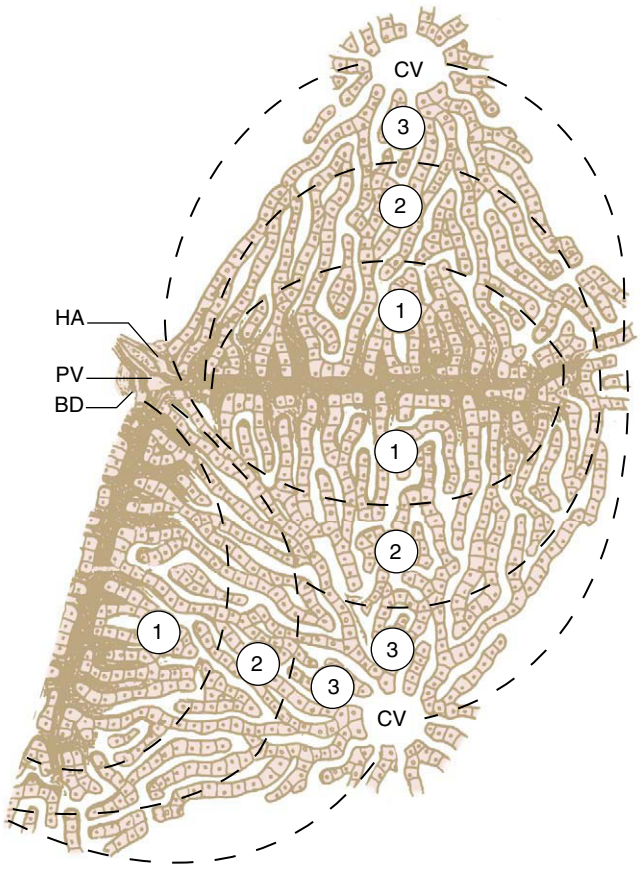

Figure 17-10 Blood supply of a liver acinus. Oxygen tensions and nutrient levels within sinusoids continuously decrease as blood flows from zone 1 through zone 3. The lower part of this figure shows zones 1, 2, and 3 of a neighboring acinus. BD, bile ductule; CV, central vein; HA, hepatic artery; PV, portal vein. *(Reprinted with permission from Jones AL: Anatomy of the normal liver.* In *Zakim D, Boyer T [eds]: Hepatology: A Textbook of Liver Disease, 3rd ed. Philadelphia, WB Saunders, 1996, p 3.)*

Splanchnic Circulation and Hepatic Blood Flow

Hepatic Blood Flow

The liver is at the hub of the splanchnic circulation. Hepatic blood flow is inextricably linked to and hence varies with the effects of intrinsic, extrinsic, and extrahepatic influences on the splanchnic vasculature. The liver receives roughly 25% of the total cardiac output (1 mL of blood per 1 g of liver) via a dual vascular supply. Arterial blood is supplied via the proper hepatic artery—a branch of the common hepatic artery that has its origin at the celiac trunk of the abdominal aorta (Fig. 17-11).[2,3] On the other hand, the portal vein has as its tributaries the superior mesenteric and splenic veins, which carry the entire venous drainage of the preportal splanchnic beds. The portal vein conveys about three fourths and the hepatic artery about one fourth of total hepatic blood flow. Each vessel, however, delivers about half of the total

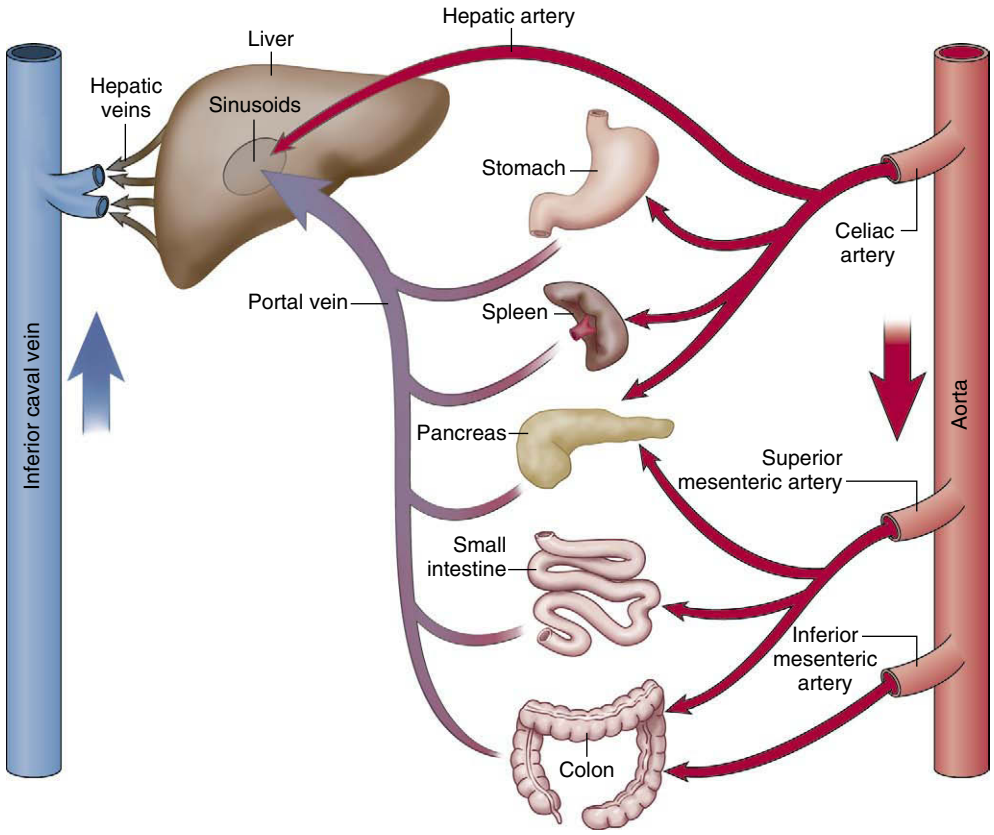

Figure 17-11 The splanchnic circulation. *(Redrawn with permission from Gelman S, Mushlin PS: Catecholamine induced changes in the splanchnic circulation affecting systemic hemodynamics. Anesthesiology 100:434-439, 2004.)*

oxygen supply because arterial blood carries much more oxygen than portal venous blood does.[10]

Splanchnic Reservoir

The vasculature of the splanchnic organs can retain up to 15% of the total blood volume rendering it the largest physiologic reservoir of whole blood in the human body.[11] Generally, 20% of blood volume resides in arterial vessels, 10% in capillaries, and 70% in veins.[10] Therefore, the effects of neuroendocrine, pharmacologic, and pathophysiologic factors on venous capacitance and resistance vessels determine, to a large extent, the instantaneous volume within the splanchnic reservoir. For example, increases in resistance within the postsinusoidal veins of the liver can promote transudation of plasma into lymphatic vessels and the peritoneal cavity (through Glisson's capsule) and thereby result in edema, ascites, and hypovolemia. Indeed, minor changes in hepatic venous pressure can have major consequences on the effective circulatory volume.[3,12]

Regulation of Hepatic Blood Flow

Intrinsic and extrinsic mechanisms play important roles in the regulation of hepatic blood flow. Intrinsic mechanisms—such as the hepatic arterial buffer response (HABR), metabolic control, and pressure-flow autoregulation—work independently of neurohumoral factors.

Intrinsic Regulation

Hepatic Arterial Buffer Response The HABR is the most important intrinsic mechanism. With an intact HABR, changes in portal venous flow cause reciprocal changes in hepatic arterial flow.[13] That is, when portal venous flow decreases, the HABR compensates by increasing hepatic arterial flow, and vice versa. The HABR mechanism involves the synthesis and washout of adenosine (i.e., a vasodilator) from periportal regions.[14] When portal venous flow decreases, adenosine accumulates in the periportal regions, which lowers arteriolar resistance and thereby increases hepatic arterial flow. Conversely, when portal venous flow increases, adenosine is washed out of the periportal regions, which increases arteriolar resistance and decreases hepatic arterial flow. At a maximum, the HABR can double hepatic arterial flow. Therefore, it cannot fully restore hepatic blood flow when portal venous flow falls by more than 50%. Yet because hepatic arterial blood carries more oxygen than portal venous blood does, the HABR more effectively preserves hepatic oxygen supply than hepatic blood flow does. Various disorders (e.g., endotoxemia, splanchnic hypoperfusion) may decrease or even abolish the HABR and render the liver more vulnerable to hypoxic injury.[15,16]

Metabolic Control Many constituents of blood affect hepatic arterial and portal venous blood flow.[17] Decreases in oxygen tension or the pH of portal venous blood typically lead to increases in hepatic arterial flow. Postprandial hyperosmolarity increases hepatic arterial and portal venous flow.[17] The underlying metabolic and respiratory status (e.g., hypercapnia, alkalosis, arterial hypoxemia) also modulates the distribution of blood flow within the liver.

Pressure-Flow Autoregulation Pressure-flow autoregulation enables tissue-specific regulators to govern organ blood flow despite fluctuations in systemic arterial pressure. The mechanism involves myogenic responses of vascular smooth muscle to stretch. For example, a hypertensive episode increases transmural pressure, thereby stretching arterial smooth muscle. The resultant increase in myogenic tone (i.e., vasoconstriction) prevents the increases in organ blood flow that would otherwise occur. Conversely, transient hypotension lowers transmural pressure and myogenic tone (i.e., vasodilation), which helps sustain organ perfusion during systemic hypotension.

The hepatic artery exhibits pressure-flow autoregulation in metabolically active liver (postprandial) but not in the fasting state, which is the most prevalent status of surgical patients.[18] Pressure-flow autoregulation is nonexistent in the portal circulation. Thus, decreases in systemic blood pressure—as often occur during anesthesia—typically lead to proportional decreases in portal venous flow.[19,20] Bottom line, pressure-flow autoregulation has little if any role as an intraoperative regulator of hepatic blood flow, with the possible exception of emergency surgery on patients in the fed state.

Extrinsic Regulation

Neural Control Fibers of the vagus, phrenic, and splanchnic nerves (postganglionic sympathetic fibers from T6 through T11) enter the liver at the hilum; they course through the liver alongside the afferent hepatic blood vessels and bile ducts. The fibers form an intercommunicating plexus that innervates the terminal arterioles and venules. The sympathetic nervous system is an important regulator of the splanchnic vasculature. When sympathetic tone decreases, splanchnic reservoir volume increases. On the other hand, sympathoadrenal stimulation translocates blood volume from the splanchnic reservoir to the central circulation. Within seconds of splanchnic nerve stimulation, up to 80% of the hepatic blood volume (400 to 500 mL) could be transferred to the central circulation in dogs.[10,21] Vagal stimulation alters the tone of the presinusoidal sphincters[22]; the net effect is a redistribution of intrahepatic blood flow without changing total hepatic blood flow.

Humoral Control The hepatic arterial bed has α_1-, α_2-, and β_2-adrenergic receptors, whereas the portal vein has only α-receptors (Fig. 17-12).[3,23] Direct injection of epinephrine into the hepatic artery induces a biphasic response: vasoconstriction (α-receptor stimulation) followed by vasodilation (β-receptor stimulation). However, an injection of epinephrine into the portal vein causes only vasoconstriction (α-receptor response). The dopamine released during sympathoadrenal activation has weak vasoactive effects in the liver that are dwarfed by those of epinephrine and norepinephrine.[17,23]

Glucagon induces dose-dependent relaxation of hepatic arterial smooth muscle and blocks the effects of physiologic vasoconstrictors on the hepatic artery.[24] By contrast, angiotensin II constricts the hepatic arterial and portal venous beds.[25] Pharmacologic doses of angiotensin II can cause hepatic blood flow to plummet because of its ability to markedly decrease both mesenteric arterial and portal venous flow. Vasopressin, on the other hand, elevates splanchnic arterial resistance, but it lowers portal venous resistance. Because of its vascular profile, vasopressin may have efficacy in treating portal hypertension.[26]

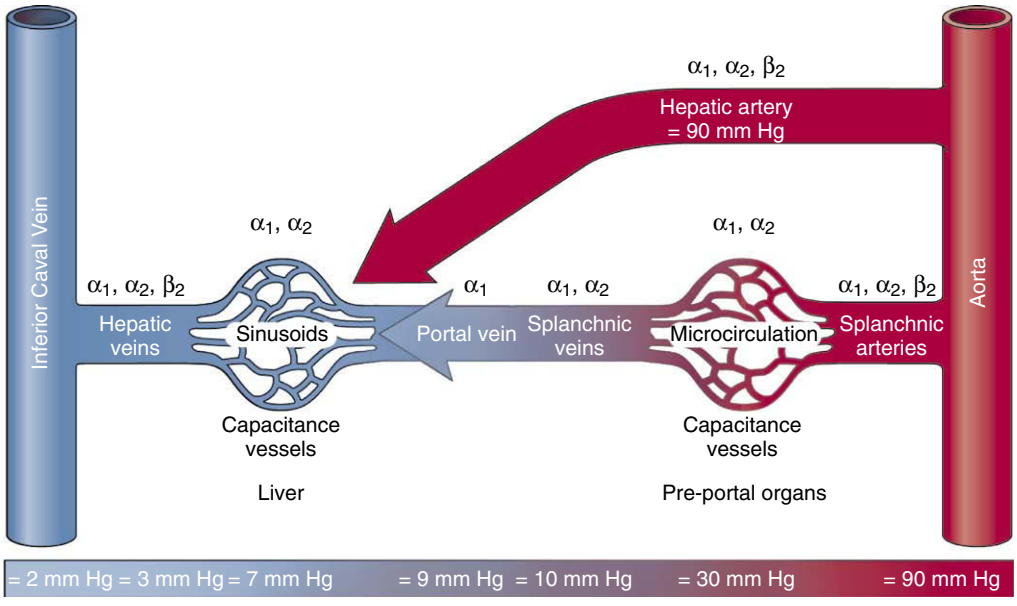

Figure 17-12 Adrenoceptor subtypes (α_1, α_2, β_2) and intravascular pressure within the splanchnic circulation. The splanchnic arteries represent the arterial supply to all preportal organs; the splanchnic veins represent the pooled venous blood from all these organs. *(Redrawn with permission from Gelman S, Mushlin PS: Catecholamine induced changes in the splanchnic circulation affecting systemic hemodynamics. Anesthesiology 100:434-439, 2004.)*

Biochemical and Physiologic Functions of the Liver

Intermediary Metabolism

Protein Metabolism

The liver plays a central role in the production and breakdown of amino acids, peptides, and proteins. Hepatocytes metabolize amino acids to keto acids, glutamine, and ammonia via transamination and oxidative deamination reactions. The Krebs-Henseleit cycle is the major pathway for removing ammonia and other nitrogenous wastes from the body. This pathway captures nitrogen in the form of urea. Thus, with a failing liver (and normal renal function), blood urea nitrogen remains low whereas nitrogenous wastes such as ammonia accumulate in blood and other tissues.

Liver-derived proteins have an impact on every organ in the body. Such proteins include procoagulants, hormones, cytokines, chemokines, acute-phase reactants, and transport proteins. The most abundant of them is albumin, which accounts for roughly 15% of the liver's total protein production. Healthy adults produce 12 to 15 g of albumin every day; the total-body pool of albumin has a mass of about 500 g.[27] Factors that modulate the synthesis of albumin include plasma oncotic pressure,[28] dietary amino acids,[29] and hormones.[30] The main regulator of intravascular albumin is oncotic pressure. Albumin binds to and transports a wide variety of substances—free fatty acids, unconjugated bilirubin, hormones, xenobiotics, and metals. In this way, albumin affects the biologic activity and clearance of a multiplicity of substances.

α-Fetoprotein (AFP) resembles albumin both genetically and functionally. AFP comes mainly from the yolk sac, hepatocytes, and enterocytes.[31] During fetal and neonatal life, AFP has importance as a transport protein and is the major determinant of plasma oncotic pressure. By the postpartum age of 1 year, albumin has largely replaced AFP. Thus, an elevation in AFP in later life typically reflects hepatocellular proliferation as a result of hepatic injury, inflammation, or neoplasia. For example, elevations in AFP occur in nearly all patients with acute hepatitis.[32] However, large, progressive increases in plasma AFP—levels above 400 ng/mL that continue to rise with time—are a hallmark feature of hepatocellular carcinoma (HCC).

Carbohydrate Metabolism

The liver is the epicenter of carbohydrate metabolism. It is an important homeostatic regulator of blood glucose.[33-35] Whether the liver is a net producer or consumer of glucose is dependent on many factors, including the neuroendocrine milieu (i.e., insulin, catecholamines, glucagon)[36-41] and glucose concentration in sinusoidal blood.[9,42-44] The severity of hyperglycemia or hypoglycemia also influences the rate of glucose uptake or release by hepatocytes. Hepatic production of glucose is inversely related to glycogen production by the liver. In the fed state, hepatocytes polymerize glucose and store it as glycogen; in the unfed state, hepatocytes depolymerize glycogen to glucose and release it into the bloodstream. Regulation of glycogen metabolism involves two rate-limiting enzymes: (1) glycogen synthase, which catalyzes the synthesis of glycogen from monomers of uridine diphosphate (UDP) glucose, and (2) glycogen phosphorylase, which catalyzes the sequential cleavage of glycogen to monomers of glucose 1-phosphate.

When liver glycogen stores are depleted—as is likely after prolonged exercise or a 24-hour fast—the body depends on hepatic gluconeogenesis to replenish blood glucose. Substrates for gluconeogenesis include (1) lactate; (2) glycerol from the hydrolysis of triglycerides; and (3) glucogenic amino acids such as alanine and glutamine, which are derived from protein catabolism in skeletal muscle.[9,45] Endocrine modulators of gluconeogenesis include glucagon, catecholamines, and insulin. Both glucagon and catecholamines stimulate gluconeogenesis. Glucagon works via cyclic adenosine monophosphate (cAMP)-dependent protein kinase, and catecholamines use both cAMP-dependent and cAMP-independent mechanisms.[46,47] By contrast, insulin inhibits gluconeogenesis, and it blocks the stimulatory effects of catecholamines and glucagon on this pathway.

Lipid Metabolism

The liver produces, takes up, retains, releases, and oxidizes fatty acids in accord with nutritional and endocrine influences.[48-52] Dietary fatty acids absorbed in the small intestines reach the liver via blood and the lymphatics, mainly in the form of chylomicrons. When replete with glycogen, hepatocytes convert glucose to fatty acids—and may store them as triglycerides (fat). Thus, the major sources of intrahepatic fatty acids include (1) free fatty acids extracted from blood, (2) de novo lipogenesis, (3) hydrolysis of cytoplasmic triglycerides, and (4) hepatocellular uptake and metabolism of blood-borne lipoproteins.[48]

Esterification and β-oxidation pathways have pivotal roles in the hepatic disposition of fatty acids. Esterification of glycerol and fatty acids produces triglycerides—the main storage form of free fatty acids. The liver may either retain triglycerides or package them into lipoproteins, primarily very-low-density lipoproteins (VLDLs), for transport to other tissues. Free fatty acids regulate VLDL production, but endocrine and nutritional factors govern VLDL secretion.[48,53] β-Oxidation is the pathway of fatty acid catabolism. Glucagon activates this pathway, whereas insulin inhibits it. β-Oxidation sequentially cleaves fatty acids to yield monomers of acetyl coenzyme A (acetyl CoA).

Acetyl CoA is at the epicenter of intermediary metabolism. It is a building block for lipids (triglycerides, phospholipids, cholesterol) and a product of the oxidative breakdown of fatty acids and carbohydrates. Mitochondria oxidize acetyl groups to yield carbon dioxide, water, and adenosine triphosphate (ATP). If more acetyl CoA is produced than the tricarboxylic acid cycle can handle, the surplus is metabolized to ketone bodies—namely, acetoacetate, β-hydroxybutyrate, and acetone.[9] Hepatocytes cannot extract energy from ketones, however, because they lack ketoacyl CoA transferase (acetoacetate:succinyl-CoA transferase). This enzyme exists in all organs except the liver.[8] Thus, ketones are an important extrahepatic energy source during catabolic states, most notably starvation. Insulin modulates ketogenesis by inhibiting lipolysis in adipocytes.[54] Stress-induced ketosis is typically a self-limited process because ketones stimulate the release of insulin, thereby limiting availability of substrate (fatty acid) for hepatic ketogenesis.[45] Without insulin, this feedback loop is nonexistent and diabetic ketoacidosis may ensue.[9]

Bile Metabolism and the Enterohepatic Circulation

Daily production of bile ranges from 600 to 800 mL. Although bile contains many different substances (e.g., electrolytes, organic

anions, lipids), bile salts (also called bile acids) account for about 85% of biliary solids.[55] Bile salts are natural ionic detergents with important roles in absorption, transport, and secretion of lipids.[56,57] They activate lipases (bile acid dependent), promote micelle formation, and enable the intestinal uptake of fat-soluble vitamins, cholesterol, and other lipids. Bile salts also facilitate the excretion of numerous lipophilic substances, including exogenous compounds such as xenobiotics and endogenous molecules such as bilirubin, cholesterol, and amphipathic steroid hormonal derivatives.

Bile salts are end products of cholesterol synthesis and regulators of lipid metabolism. Bile salts produce their regulatory effects by binding to and activating farnesoid X receptor (FXR). When activated, hormone nuclear receptors (such as FXR) are transferred from cytoplasm to the nucleus; they bind to hormone response elements on DNA to induce either expression or transrepression of specific gene products. An important effect of FXR activation is to decrease the transcription of cholesterol 7α-hydroxylase (CYP7A1), which catalyzes the rate-limiting step in the conversion of cholesterol to bile salts. Bile salts modulate plasma lipid levels by regulating the expression of lipoprotein receptors that enable hepatocytes to remove lipoprotein cholesterol from the bloodstream.[56,58]

The body avidly conserves bile salts by recycling them around 20 to 30 times daily in the enterohepatic circulation. Hepatocellular transport proteins (transporters) regulate both the uptake (from sinusoids) and secretion (into canalicular spaces) of bile salts. Activated transporters on canalicular surfaces overcome large osmotic gradients to pump bile salts into the intrahepatic bile ducts. As bile flows through the ductular collecting system, it is diluted and alkalinized.[55] After reaching the common hepatic bile duct, bile either enters the cystic duct (for storage in the gallbladder) or passes through the common bile duct into the small intestine. The terminal ileum (using sodium-dependent bile salt transporters) reclaims 95% of the bile salts, which it returns to the liver in the portal circulation. These bile salts are taken up by transporters on the sinusoidal surfaces of hepatocellular plasma membranes. Sometime later, the same bile salts are again pumped into the canalicular space, thereby completing one cycle of the enterohepatic circulation. Of note, opioid analgesics (μ-agonists) can disrupt bile flow by inducing intense, painful spasms of the bile ducts and sphincter of Oddi.[59] Fortunately, this opioid effect is usually rapidly reversed by medications, including glucagon, opioid antagonists (naloxone), smooth muscle relaxants (nitroglycerin), antimuscarinic drugs (atropine), and volatile anesthetics.

Coagulation

Coagulants and Procoagulants

Hepatocytes make most of the procoagulants, with notable exceptions such as factors III (tissue thromboplastin), IV (calcium), and VIII (von Willebrand factor). The liver also makes protein regulators of coagulation and the fibrinolytic pathways. Such regulators include protein S, protein C, protein Z, plasminogen activator inhibitor (PAI), and antithrombin III. To further elaborate, protein Z facilitates the degradation of factor Xa, and protein S is a cofactor of activated protein C that inactivates factor VIIIa-Va complexes; a deficiency of protein S increases the risk for venous thrombosis. PAI-1 is an indirect inhibitor of fibrinolysis. This serine protease inhibitor blocks the effects of plasminogen activators, such as urokinase or tissue plasminogen activator, to convert plasminogen to plasmin; a deficiency of PAI increases the risk for uncontrolled fibrinolysis. To summarize, hepatocytes make most of the procoagulants and many proteins that modulate the consumption of clotting factor.[60]

Vitamin K Cofactor and γ-Carboxylation

The vitamin K–dependent proteins include factors II, VII, IX, and X and proteins C and S. These proteins undergo a vitamin K–dependent, post-translational modification; the process involves carboxylation of the γ-position of glutamate residues at the amino terminus and produces the amino acid carboxyglutamate.[45,61] This modification (called γ-carboxylation) enables procoagulants to form complexes with calcium or other divalent cations.[62] Thus, γ-carboxylated procoagulants are primed for activation to serine proteases (e.g., via extrahepatic phospholipids) and for participation in the clotting cascade.[45,63]

The γ-carboxylation pathway holds the key to understanding how warfarin exerts its anticoagulant effect. γ-Carboxylation occurs in two stages.[63] The first involves γ-carboxylation of precursor proteins via vitamin K–dependent γ-carboxylase and the oxidation of vitamin K cofactor (naphthol hydroquinone) to 2,3-epoxide vitamin K. The second stage regenerates the vitamin K cofactor via reactions catalyzed by vitamin K 2,3-epoxide reductase.[64-67] Warfarin targets the second stage. It inhibits vitamin K epoxide reductase and thereby traps vitamin K in the epoxide form. This eventually depletes vitamin K cofactor and shuts down the γ-carboxylation pathway. Warfarin inhibits γ-carboxylation almost immediately after its absorption from the gut, but its anticoagulant effect takes longer than 1 day to develop. This disparity reflects low clearance of the prothrombin complex from the circulation (i.e., half-life of about 14 hours) and the insensitivity of the prothrombin time (PT) to falling blood levels of procoagulants. As a rule, the PT stays in the normal range until the prothrombin complex in blood is at least 70% below the lower limit of normal.

Therapeutic use of vitamin K may help uncover the cause of an unexplained prolongation in PT. For example, PT abnormalities caused by malnutrition or warfarin are correctable with enteral or parenteral vitamin K therapy. When PT abnormalities result from malabsorption syndromes, parenteral vitamin K is superior to oral therapy. However, if PT abnormalities result from liver dysfunction (acute hepatitis, cirrhosis), vitamin K will be ineffective because the problem is not a deficiency of vitamin K but rather a deficiency of hepatic procoagulants.

Erythropoiesis and Erythrocytosis

Heme Metabolism

The liver is the main site of erythrocyte production during fetal life through early infancy. As the bone marrow matures, hematopoietic cells begin to disappear from the liver; occasionally, however, they persist or reappear as a result of disorders such as congenital hemolytic anemias, bone marrow failure, or myeloproliferative diseases. Most of the protein in erythrocytes exists as globulin chains of hemoglobin; the heme portion of hemoglobin contains protoporphyrin IX and ferrous iron. In healthy adults, 20% of the total heme production is from liver; the rest comes

from bone marrow. The biochemical pathways that make heme are similar in the two organs.[64,68,69]

Heme synthesis begins with the condensation of glycine and succinyl CoA to produce 5-aminolevulinic acid (ALA). This reaction, catalyzed by ALA synthase, is the rate-limiting step in the heme pathway. Heme inhibits ALA synthase and thereby regulates its own synthesis. ALA is made in mitochondria; it diffuses into the cytoplasm and encounters ALA dehydratase. This enzyme joins two ALA molecules together to form porphobilinogen (PBG). PBG molecules are positioned in a linear arrangement by PBG deaminase to form hydroxymethylbilane (HMB). HMB is transformed to uroporphyrinogen III, which is the precursor of coproporphyrinogen III. The latter is taken up by mitochondria and converted—via coproporphyrinogen oxidase and protoporphyrin oxidase—to protoporphyrin IX. In the final step of the pathway, ferrochelatase catalyzes the formation of a complex of ferrous iron and protoporphyrin IX to produce heme.

Porphyrias Porphyrinogens exposed to O_2 are readily oxidized to the corresponding porphyrins. Accumulation of porphyrins in tissues leads to porphyrias. Porphyrias are rare, genetic diseases characterized by aberrations in heme production. Patients with these disorders are typically asymptomatic until some stressor (exogenous or endogenous) induces a porphyric crisis.[70] The clinical syndrome includes recurrent, dramatic, and occasionally fatal neurologic reactions, accompanied by abdominal pain (90%) and dark urine (80%).

Acute intermittent porphyria (AIP) is the most common porphyria. Its prevalence in the general population is about 1 in 10,000, but it may reach 1 in 500 in psychiatric patients. AIP has a fivefold higher frequency in women than in men.

Substances known to trigger porphyric crises include sex hormones, glucocorticoids, cigarette smoke, and various medications, most notably barbiturates and other CYP inducers.[57,71] Recall that induction of CYP entails the production of CYP hemoproteins. When heme is inserted into these newly minted CYP proteins, intracellular levels of heme decline.[71-74] The result is less feedback inhibition of ALA synthetase and therefore more ALA production.[75] Defects in the heme pathway cause the precursors of heme—made proximal to the site of the block—to accumulate. Consider, for example, patients with a genetic deficiency of PBG deaminase; when ALA synthetase activity increases, so too do tissue levels of ALA and PBG. These heme precursors, which have chemical structures similar to the inhibitory neurotransmitter γ-aminobutyric acid (GABA), are likely contributors to the neurotoxic effects of porphyrias.

Bilirubin Metabolism

The main source of serum bilirubin is heme metabolism. Healthy adults make about 300 mg of bilirubin daily, 80% of which is derived from phagocytosis of senescent erythrocytes by macrophages in the spleen, liver, and bone marrow. These reticuloendothelial cells extract protein from hemoglobin and convert heme to bilirubin.[57] The first step is rate limiting. Heme oxygenase (HO), with O_2 as a substrate, oxidatively cleaves the porphyrin macrocycle of heme to yield biliverdin-IXα, carbon monoxide (CO), and free divalent iron in equimolar amounts.

Most of the endogenous CO production is derived from HO reactions. Thus, the biologic importance of HO may extend beyond the breakdown of heme. To clarify, CO has many physiologic roles, including regulation of vascular tone (vasodilator), platelet aggregation, vascular myocyte proliferation, and neurotransmitter release.[76] Furthermore, CO exerts cytoprotective, antiapoptotic, and antioxidant effects in organs throughout the body.[77,78] Biliverdin also confers protection from oxidative stress[77]; it is rapidly converted to bilirubin by cytoplasmic reductases.[79]

After release from reticuloendothelial cells, bilirubin becomes tightly bound to plasma albumin. Hepatocytes avidly extract this bilirubin from albumin. They produce conjugates of bilirubin (through the action of glucuronic acid and bilirubin UDP-glucuronosyltransferase) and secrete these conjugates into canalicular bile. Although the gut excretes most of this bilirubin, a small amount returns to the liver in the enterohepatic circulation. Thus, the bloodstream normally has a modicum of bilirubin conjugates, which arrive directly via the enterohepatic circulation or indirectly from the bile ducts and lymphatics.

Endocrine Physiology

The liver is the largest gland in human beings and it plays important roles in the metabolism of hormones and hormone-binding proteins.[60] Hepatocytes produce a wide variety of endocrine substances, including angiotensinogen, thrombopoietin, and insulin-like growth factor I (IGF-I).[80] They take up thyroxine (T_4), the major product of the thyroid gland, and may activate it to triiodothyronine (T_3) or inactivate it. The liver inactivates many other hormones, including aldosterone, antidiuretic hormone, estrogens, androgens, and insulin. Nearly half of the insulin released by the pancreas may not reach the systemic circulation because of hepatic degradation.[81]

Immune and Inflammatory Responses

The liver is the largest reticuloendothelial organ in the human body. Hepatic macrophages (Kupffer cells) account for nearly 10% of the total liver mass. Kupffer cells protect and defend the body against foreign intrusions. Before splanchnic venous blood enters the central circulation, it is filtered by Kupffer cells, which degrade toxins, process antigens, and phagocytose bacteria.[82] In addition, Kupffer cells are important modulators of inflammation[83]: they attenuate inflammatory responses by removing inciting substances from the bloodstream; but they can also induce and intensify inflammation by producing and releasing proinflammatory mediators and recruiting neutrophils to the liver.[83] Among these mediators are various cytokines, chemokines, leukotrienes, proteases, nitro-radicals, and reduced oxygen species. If not properly controlled, these same mediators can induce or aggravate injuries to parenchymal and other liver cells.[83-87] For example, endothelial cells of the sinusoids and terminal hepatic veins—because of their low glutathione content—are highly vulnerable to oxidative stress and drug-induced vascular injury.[88] Stellate cells reside mainly in the perisinusoidal spaces and are the liver's major source of matrix deposition. When activated by oxidative stress or toxic chemicals, stellate cells may be transformed to collagen-synthesizing myofibroblasts, which can cause extensive fibrosis of the liver (e.g., methotrexate-induced hepatic fibrosis).

Xenobiotic (Drug) Metabolism and Excretion

Although xenobiotics may be in tissues through the body (lung, liver, kidney, intestines, skin); the liver is the epicenter for biotransformation reactions. Most oral medications contain lipophilic regions that increase their gastrointestinal absorption, membrane penetrability, and biologic activity. Lipid solubility also lowers drug excretion rates and increases drug retention by the body. Whereas the kidney readily excretes most small polar molecules, it cannot efficiently eliminate most lipophilic substances. Lipophilic molecules often bind tightly to plasma proteins, thereby evading glomerular filtration. Even when the glomerulus filters such molecules, the renal tubules usually reabsorb them. The liver, on the other hand, chemically transforms drugs in ways that increase their water solubility. Generally, hepatic biotransformations not only increase drug excretion but also inactivate or attenuate the biologic activity of drugs. However, xenobiotic metabolism produces reactive chemicals that cause severe liver damage (either directly or indirectly by immune sensitization, as is probably involved in the pathogenesis of halothane hepatitis).[89-91]

Pathways of Drug Metabolism

The myriad chemical reactions that hepatocytes use to eliminate drugs fit into three broad categories (or phases). Phase 1 metabolism uses CYP and mixed-function oxidases to increase the polarity of drugs. Phase 2 metabolism increases the polarity of drugs (or their metabolites) by conjugating them with endogenous water-soluble substrates. Phase 3 elimination uses energy-dependent transporters to excrete drugs into canalicular bile. The hepatic clearance of drugs involves at least one of these phases.[90,92,93]

Phase 1 Metabolism Phase 1 reactions (e.g., oxidations, reductions, hydrolysis) convert drugs to more polar compounds by inserting polar groups (e.g., OH, NH_2, SH) or removing nonpolar groups. Generally, the products of phase 1 metabolism are more readily excreted in bile or urine than their precursors are. Such products may also be substrates for phase 2 conjugations.

Microsomal Oxidases and Cytochrome P450. More than 90% of drug biotransformations involve microsomal oxidases and hemoproteins of the CYP gene superfamily. The human liver has more than 20 different CYP isozymes[90-94] that mediate redox reactions in diverse pathways, including steroid, lipid, and bile salt metabolism. Zone 3 (centrilobular) has the highest total CYP content. In fact, the acinar location of specific isozymes of CYP may clarify relationships between drug metabolism and liver injury.[90] For example, centrilobular necrosis is the classic acetaminophen-induced injury; the probable explanation is that CYP2E—the CYP isoform involved in acetaminophen metabolism—is localized in zone 3.

CYP reactions generate metabolites that are highly reactive and potentially toxic. In brief, the CYP reaction cycle begins with oxygen binding to heme iron; this oxygen becomes activated after receiving an electron from a flavoprotein reductase—NADPH: hemoprotein oxidoreductase (CYP).[91-94] Insertion of activated oxygen into lipophilic molecules (e.g., xenobiotics) produces substrates for mixed-function oxidase reactions. These oxidases transfer a singlet oxygen atom from O_2 to the target molecule; another substrate (e.g., NADPH) simultaneously delivers electrons that reduce the residual oxygen singlet, thereby enabling its incorporation into water. To summarize, oxidases promote the formation of highly active chemicals, including reduced oxygen species and free radical intermediates, which can cause or aggravate liver injury.[95]

A plethora of substances—drugs, nutritional supplements, contaminants, insecticides—alter hepatic microsomal drug metabolism.[91] Some chemicals, such as phenobarbital and phenytoin, induce many different CYP isoforms. Other chemicals are much more selective.[91-94] For example, alcohol selectively induces CYP2E1 and CYP3A4[90,96]; smoke from cigarettes or cannabis increases CYP1A2[97]; isoniazid increases CYP2E1; and rifampicin and hypericum (active ingredient of St. John's wort) selectively induce CYP3A4.[98] With long-term use, CYP inducers often increase their own metabolism while stimulating alkaline phosphatase (AP) and γ-glutamyl transpeptidase (GGTP) production. The latter effect which occurs via activation of transcriptional regulators of nuclear orphan receptors as part of the "hepatic adaptation" to chronic drug administration.[90]

Molecular Genetic Basis of CYP Induction. Studies of CYP3A4—the predominant CYP isoform in human liver—have clarified the molecular genetics of CYP induction.[99] For example, rifampin, a potent inducer of CYP3A4, activates the pregnane X receptor (PXR), which is a transcriptional regulator of the orphan nuclear receptor family. PXR works in concert with another xenobiotic nuclear receptor, constitutive androstane receptor (CAR), to coordinate protective hepatic responses to potentially toxic stimuli.[100] Activated PXR and the analogous CAR bind to cognate nucleotide sequences upstream of the CYP3A4 structural gene within a "xenobiotic responsive enhancer module" (XREM).[99,101] Such binding activates the CYP3A4 promoter (downstream) and thereby induces the synthesis of mRNA for CYP3A4 protein. Similar mechanisms are involved in regulating other CYP pathways.[99,101]

Phase 2 Metabolism Phase 2 reactions conjugate xenobiotics (or their metabolites) with endogenous hydrophilic molecules such as glucuronic acid, acetate, sulfates, amino acids, and glutathione.[90,102] Many conjugations involve glucuronic acid and UDP-glucuronosyltransferase. Other conjugations are catalyzed by sulfatases, glutathione-*S*-transferases, acetyl-*N*-transferases, or amino acid *N*-transferases. When compared with their precursors, conjugated xenobiotics are usually less efficacious, less toxic, more hydrophilic, and more readily excreted in bile or urine.

Phase 3 Elimination Phase 3 reactions involve specific molecular transporters—known as ATP-binding cassette (ABC) transport proteins—that facilitate the excretion of xenobiotics and endogenous compounds. These proteins use ATP hydrolysis to drive molecular transport. Major ABC transport proteins include cystic fibrosis transmembrane conductance regulator (CFTR), canalicular copper transporters, and multidrug resistance protein (MDR). MDR-1 (formerly called P-glycoprotein) resides on the canalicular surfaces of hepatocytes and enables biliary excretion of cationic compounds, including anticancer drugs.[103,104]

Another family of ABC proteins—multidrug resistance–related protein (MRP)—excretes conjugated molecules. MRP-1, located on the lateral surfaces of hepatocytes, can transport drug conjugates into the sinusoids. MRP-2 (formerly, canalicular mul-

tispecific organic anion transporter [cMOAT]), on the canalicular surfaces of hepatocytes, secretes conjugates of drugs and endogenous wastes (e.g., bilirubin diglucuronide, glutathionyl-leukotriene conjugates) into canalicular bile. Thus, dysfunction of ABC transport proteins can disrupt the flow of bile, impair excretion of xenobiotics and endogenous compounds, and induce cholestatic liver injury.[105,106]

Determinants of Drug Metabolism

Dose-related responses to drugs often vary considerably within individuals and populations. Much of this variability is due to the heterogeneity of drug disposition and metabolism, which is mainly influenced by genetic and environmental factors. Genetics control the expression of CYP isozymes. Environmental factors (e.g., drugs, other chemicals) modify genetic expression and thereby alter drug biotransformation.[90,92,93] Numerous conditions and disorders are capable of altering the production of CYP proteins.[107] For example, obesity, fasting, and diabetes mellitus may lead to upregulation of CYP2E1.[90,92,93] On the other hand, conditions that may result in downregulation of CYP include systemic inflammatory disorders,[108] fever,[109] nitrogen-free solutions,[110] nitrogen-rich solutions,[111] and hepatic cirrhosis.[92,93] Hypothyroidism and hypopituitarism may selectively downregulate CYP1A and CYP3A4, respectively.[92,93]

Pharmacokinetics

Perfusion models of drug elimination generally focus on three major parameters: intrinsic hepatic clearance, hepatic blood flow, and protein binding. The intrinsic hepatic clearance of a drug divided by hepatic blood flow is the drug's extraction ratio (ER); ER provides a measure of the relative efficiency with which the liver extracts or eliminates a given drug.[112-116] Box 17-1 shows a compilation of drugs with high and low ERs.[116] Such information enables general rules to be made about pharmacologic categories and intrinsic clearances. For example, hepatocytes are efficient extractors of calcium channel blockers, β-adrenoceptor blockers (except atenolol), opioid analgesics, tricyclic antidepressants, and organic nitrates. On the other hand, the liver poorly extracts warfarin, aspirin, alcohol, and many anticonvulsants. For low-ER drugs, hepatic elimination rates are capacity limited. Such rates often change when protein binding or intrinsic hepatic clearance changes, but they are insensitive to fluctuations in hepatic blood flow. For high-ER drugs, hepatic elimination rates are flow dependent. These elimination rates are highly dependent on and directly related to liver blood flow; they are unaffected by changes in either protein binding or the activity of drug-metabolizing enzymes (Table 17-1).

Box 17-1 Drugs that are Efficiently Versus Poorly Extracted from Blood Flowing through the Liver

Efficiently Extracted Drugs	Poorly Extracted Drugs
Amitriptyline	Acetaminophen
Desipramine	Amobarbital
Imipramine	Antipyrine
Labetalol	Aspirin
Lidocaine	Clindamycin
Meperidine	Diazepam
Metoprolol	Digitoxin
Morphine	Ethanol
Nortriptyline	Hexobarbital
Pentazocine	Phenobarbital
Propoxyphene	Phenytoin
Propranolol	Tolbutamide
Ranitidine	Valproic acid
Verapamil	Warfarin
Zidovudine	

Evaluation of the Liver

Clinical Assessment

The only clues to liver disease may be mild, nonspecific symptoms, such as loss of appetite, easy fatigability, malaise, altered sleep patterns, or subtle changes in personality. The history addresses major risk factors for liver disease: (1) alcoholism; (2) illicit drug use; (3) sexual promiscuity; (4) blood transfusions; (5) occupational exposure to hepatotoxins; (6) prior bouts of jaundice, particularly after anesthesia; and (7) genetic diseases such as hemochromatosis, α_1-antitrypsin (α_1-AT) deficiency, and Wilson's disease. Clinical findings consistent with liver disease include nonspecific symptoms (as just mentioned), pruritus, abdominal pain, indigestion, and changes in urine or stool color. The physical examination focuses on stigmata of advanced liver disease, such as icterus, jaundice, ascites, spider angiomas, xanthelasma, encephalopathy, palmar erythema, and fetor hepaticus.

Table 17-1 Flow-Dependent Versus Capacity-Limited Elimination of Drugs by the Liver

Type of Hepatic Elimination	Extraction Ratio (ER)	Rate of Hepatic Drug Metabolism
Flow-dependent elimination	*High ER*: At clinically relevant concentrations, most of the drug in the afferent hepatic blood is eliminated on first pass through the liver	*Rapid*: Because drugs with a high ER are metabolized so rapidly, their hepatic clearances roughly equal their rates of transport to the liver (i.e., hepatic blood flow)
Capacity-limited elimination (also referred to as dose-dependent, nonlinear, saturable, or zero-order elimination)	*Low ER*: Hepatic elimination of these drugs is determined by their plasma concentration	*Slow*: When the capacity of the liver to eliminate a drug is less than the dosing rate, a steady state is unachievable; plasma levels of drug will continue to rise unless the dosing rate is decreased. Drug clearance has no real meaning in such settings

Standard Laboratory Tests

Standard test panels used to evaluate hepatobiliary status are often called "liver function tests" (Table 17-2).[27,117] To be precise, this terminology is a misnomer because none of the tests measure any specific liver function. Instead, they point to broad categories of hepatobiliary pathology: hepatitis, hepatobiliary dysfunction, or insufficient protein synthesis. These categories include large subsets of diseases—for example, all possible causes of hepatitis.

Detection of Hepatocellular Injury

Aminotransferases Hepatocellular injury is the usual cause of elevated serum levels of alanine aminotransferase (ALT) and aspartate aminotransferase (AST), formerly named serum glutamic-pyruvic transaminase (SGPT) and serum glutamic-oxaloacetic transaminase (SGOT), respectively. Both enzymes are involved in gluconeogenesis. They catalyze the transfer of an amine group to α-ketoglutarate to yield glutamate and either pyruvate (via ALT) or oxaloacetate (via AST). ALT is mainly a cytoplasmic liver enzyme. In contrast, cytoplasmic and mitochondrial isozymes of AST are found in most extrahepatic tissues, including the heart, skeletal muscle, brain, kidney, pancreas, adipose tissue, and blood. It is rare to encounter concomitant elevations in AST and ALT when the liver is normal and disease free. In those rare instances, the elevations in AST and ALT levels would most likely result from muscle injury.[117]

Elevated ALT and AST levels are sometimes described in qualitative terms: mild (100 to 249 IU/L), moderate (250 to 999 IU/L), large (1000 to 1999 IU/L), and extreme (>2000 IU/L). Mild elevations in AST and ALT may arise from any disorder that injures hepatocytes. Common causes include steatosis, medications, alcohol consumption, hemochromatosis, cholestasis, chronic viral hepatitis, neoplasms, and cirrhosis. Moderate ALT and AST elevations are characteristic of acute viral hepatitis, drug-induced liver injury, and flare-ups of chronic liver disease (e.g., viral hepatitis, steatohepatitis). Large elevations often reflect acute hepatitis superimposed on chronic active liver disease. Extreme elevations signify massive hepatic necrosis. Typical causes are fulminant viral hepatitis, severe drug-induced liver injury (e.g., from acetaminophen), shock liver or hypoxic hepatitis, and in rare instances, autoimmune hepatitis or acute biliary obstruction.[117]

Ratios of aminotransferases may hold keys to the diagnosis of hepatic disorders. For example, when both AST and ALT are elevated, an AST-to-ALT ratio higher than 4 is characteristic of Wilson's disease, ratios between 2 and 4 are typical of alcoholic liver disease, and a ratio below 1 suggests nonalcoholic steatohepatitis (without cirrhosis). When elevations of AST and ALT are mild, ratios above 2 are consistent with alcoholic liver disease or cirrhosis of any etiology.[117] If the ratio is elevated and ALT is normal, the elevation in AST is most likely from an extrahepatic source of AST.

Although concomitant elevations in AST and ALT are a reliable indicator of hepatocellular injury, aminotransferase levels by themselves seldom reveal the extent of liver damage. For instance, patients with florid liver failure can have normal enzyme levels—when the liver damage is so extensive that too few viable hepatocytes remain to bring about increases in ALT or AST. In addition, chronic, smoldering liver diseases such as hepatitis C can destroy the liver, slowly and silently, without overt increases in ALT or AST.

Lactate Dehydrogenase Elevated serum lactate dehydrogenase (LDH) levels may reflect hepatocellular injury, extrahepatic disorders, or both. Extreme increases signify massive liver damage, which may result from fulminant viral hepatitis, drug-induced liver failure, or hypoxic hepatitis. Prolonged, concurrent elevations in LDH and AP suggest malignant infiltration of the liver. Notable extrahepatic disorders that cause moderate elevations in LDH include hemolysis, rhabdomyolysis, tumor necrosis, renal

Table 17-2 Liver Blood Tests and the Differential Diagnosis of Hepatobiliary Disorders

	Predominant Abnormality		
Blood Test	**Bilirubin Overload (Hemolysis)**	**Hepatocellular Injury**	**Cholestasis**
Aminotransferases	Normal	Increased—may be normal or decreased in advanced stages	Normal—may be increased in advanced stages
Serum albumin	Normal	Decreased—may be normal in acute fulminant hepatic failure	Normal—may be decreased in advanced stages
Prothrombin time*	Normal	Prolonged	Normal—may be prolonged in advanced stages
Bilirubin (main form present)	Unconjugated (also mild increase in conjugates)	Conjugated	Conjugated
Alkaline phosphatase	Normal	Normal—may be increased by hepatic infiltrative disease	Increased
γ-Glutamyl transpeptidase 5′-nucleotidase	Normal	Normal	Increased
Blood urea nitrogen	Normal—may be increased by renal dysfunction	Normal—may be decreased by severe liver disease and normal kidney function	Normal
BSP/ICG (dye)	Normal	Retention of dye	Normal or retention of dye

*Used interchangeably with the international normalized ratio.
BSP/ICG, bromsulphalein/indocyanine green.

infarction, acute cerebrovascular accident, and myocardial infarction. Such disorders cause more pronounced LDH elevations in patients with acute liver injury (e.g., severe preeclampsia). An elevation in LDH that is solely due to hepatocellular injury is typically accompanied by elevations in AST and ALT. Thus, LDH rarely yields information about liver injury beyond that already provided by AST and ALT.[27,117]

Glutathione-S-Transferase Glutathione-*S*-transferase (GST) is a sensitive and specific test for some patterns of drug-induced liver injury.[118] The enzyme has a brief plasma half-life (90 minutes) and is released rapidly into the circulation after hepatocellular injury. Thus, serial GST measurements can reveal the time course of hepatic injury, from its onset to its resolution. In contrast to AST and ALT, which reside in acinar zone 1, GST localizes in acinar zone 3 (centrilobular region).[119] The zone contains the hepatocyte population with the highest susceptibility to injury from hypoxia or reactive drug metabolites. Accordingly, GST would be more sensitive than AST or ALT as a marker of centrilobular necrosis in its incipient stages.

Assessment of Hepatic Protein Synthesis

Serum Albumin Serum albumin yields information about hepatocellular function (i.e., protein synthesis) and is used to evaluate chronic liver disease—with notable caveats. First, hypoalbuminemia has many causes besides low rates of albumin synthesis; examples include renal losses of albumin, increased albumin catabolism, expansion of plasma volume, and maldistribution of total body albumin. In fact, the total body mass of albumin (in the exchangeable pool) is often normal in patients with liver cirrhosis, ascites, and hypoalbuminemia.[120] Second, there is no clear relationship between serum albumin and the instantaneous rate of albumin synthesis because plasma albumin has a half-life of nearly 3 weeks. Thus, if hepatic protein synthesis came to an abrupt and permanent halt, this change would not be reflected as a decrease in the serum albumin level for at least a few days.

Prothrombin Time When compared with albumin, liver-derived procoagulants have short half-lives, which range from 4 hours for factor VII to 4 days for fibrinogen. Plasma levels of such procoagulants start to descend shortly after the liver begins to fail. PT (or the international normalized ratio [INR]) is widely used to evaluate and monitor patients with acute liver dysfunction. A prolonged PT secondary to liver failure generally reflects a low blood level of factor VIIa, which has the shortest plasma half-life of hepatic coagulant factors.[117] Besides diagnostic utility, PT is used as a prognostic indicator. It is a common parameter of models or algorithms designed to facilitate timely, yet correct decisions about the need for liver transplantation. In this regard, PT is of value for patients with drug-induced liver failure[121] or those with active liver disease and a surgical condition that needs immediate attention.[122]

Detection of Cholestatic Disorders

Alkaline Phosphatase Serum AP is used to screen for disorders of the liver or biliary tree, including hepatitis, malignancies, and cholestatic diseases. Because AP isoenzymes exist in plasma membranes throughout the body, AP lacks specificity for hepatobiliary disease.[117] Mild, transient increases in AP may occur in up to a third of those subjected to routine laboratory testing. Major sources of AP include bone, intestine, kidney, leukocytes, placenta (third trimester of gestation), and neoplasms. Increased metabolic activity in one or more of these tissues may lead to elevations in AP. Increased serum AP usually reflects increased production or release of AP rather than decreased clearance of AP. For example, fatty meals increase serum AP by inducing the release of AP isozymes from the plasma membranes of enterocytes in the small bowel.

The AP elevations in cholestatic disorders may reflect the action of bile salt on the plasma membranes of hepatocytes. Serum AP may remain normal for a couple of days after the onset of biliary obstruction—not increasing until hepatocytes produce (and release) more AP. Because it has a half-life of nearly a week, serum AP may remain elevated for days after bile flow is restored.[117] Extreme increases in AP suggest (1) a major block in biliary flow as a result of disorders such as primary biliary cirrhosis and choledocholithiasis or (2) a hepatic malignancy (primary or metastatic) that is compressing small intrahepatic bile ducts. Multifocal blocks of intrahepatic ducts can increase serum AP without increasing serum bilirubin. On the other hand, AP may be normal despite extensive hepatic metastasis or large duct obstruction. The bottom line is that serum AP does not reliably distinguish between bile duct obstruction (intrahepatic or extrahepatic) and malignant infiltration of the liver.[117]

Identifying the Source of Increased Alkaline Phosphatase. Finding the origin of an elevated AP level seldom requires more than a history, physical examination, and imaging studies. The history helps sort through the usual extrahepatic sources of increased AP, including (1) normal bone, especially during puberty and growth spurts; (2) placenta, mainly in the third trimester of pregnancy; (3) bone disorders such as Paget's disease, rickets, and osteomalacia; and (4) intestines (see Table 17-2).

5′-Nucleotidase and γ-Glutamyl Transpeptidase Laboratory tests used to distinguish between hepatic and extrahepatic sources of AP include 5′-nucleotidase (5′-NT) or leucine aminopeptidase (LAP) and GGTP. With regard to 5′-NT, it is as sensitive as AP in detecting hepatobiliary disorders, and it is a much more specific test for such disorders. Although 5′-NT exists in many tissues—placenta, bone, brain, intestine, heart, blood vessels, endocrine pancreas—most of the serum 5′-NT is derived from the hepatobiliary tree. One explanation is that release of 5′-NT from the plasma membranes of hepatocytes requires the detergent action of bile salts. Changes in AP that are secondary to hepatobiliary disease are usually followed by commensurate changes in 5′-NT.[117]

However, increases in AP and 5′-NT have differing time courses—most notably during onset and resolution of biliary disease. For example, shortly after bile flow becomes disrupted, serum AP and GGTP begin to increase in tandem, whereas 5′-NT may not change for days.[117] In this regard, GGTP is preferable to 5′-NT because it more closely tracks AP. However, GGTP also has disadvantages. First, it is an inducible microsomal enzyme (e.g., by alcohol, anticonvulsants, warfarin), which may confound interpretation of elevations in serum GGTP. Second, GGTP is less specific than 5′-NT for hepatobiliary disease. Serum GGTP may come from many extrahepatic sites, including the kidney, spleen, pancreas, heart, lung, and brain. Bone, however, contains very little GGTP. Thus, serum GGTP may be used to distinguish between osseous and hepatobiliary sources of AP.[117]

Serum Bilirubin Serum bilirubin is the most widely used test for hepatic excretory dysfunction. Total bilirubin is normally below 1 mg/dL, but up to 10% of healthy adults have higher levels, mainly in the form of unconjugated bilirubin. This is usually a benign condition (Gilbert's syndrome) that reflects genetically low levels of bilirubin UDP-glucuronosyltransferase. Serum bilirubin levels above 4 mg/dL are discernible on physical examination as jaundice—a yellowish discoloration of body tissues. With natural light, scleral icterus is detectable at bilirubin levels of or below 3 mg/dL.[117,123]

Conjugated hyperbilirubinemia generally results from one or two fundamental problems: (1) flow of bile is blocked within the hepatobiliary tree, or (2) hepatocytes produce more bilirubin conjugates than they can efficiently transport into the canalicular space. Massive hemolysis causes unconjugated and conjugated hyperbilirubinemia. Increases in unconjugated bilirubin occur because hepatocytes are presented with more bilirubin than they can conjugate. Increases in conjugated bilirubin result because hepatocytes conjugate bilirubin faster than hepatocellular transporters can secrete them into canalicular bile. Bilirubinuria usually reflects conjugated hyperbilirubinemia. The kidneys readily excrete bilirubin conjugates, whereas unconjugated bilirubin, which binds tightly to plasma albumin, is neither filtered nor excreted by normal kidneys.[117,123]

Testing for Specific Diseases

Targeted testing is used to identify specific hepatic or biliary diseases. Examples include (1) serologic testing to identify viral, microbial, and autoimmune causes[124,125]; (2) genetic testing to diagnose heritable metabolic disorders; and (3) tumor marker assays to detect hepatic malignancies.

Identifying viral markers—antibodies, antigens, and genetic material—is the key for diagnosis of hepatitis from hepatotropic viruses (A, B, C, E) and herpesviruses such as cytomegalovirus and Epstein-Barr virus.[32] Patients infected with hepatitis B or C virus often have markers of immune pathology, including anti–smooth muscle antibodies, antinuclear antibodies, and mixed cryoglobulins.[32,126] Autoimmune hepatitis and hepatitis A virus infection are commonly associated with anti–asialoglycoprotein receptor antibodies. Autoimmune cholangitides have distinctive serologic profiles.[127] For example, antimitochondrial antibodies usually develop with primary biliary cirrhosis[125,128-130] but are typically absent with primary sclerosing cholangitis. Characteristic findings of primary sclerosing cholangitis include anti–smooth muscle and antinuclear antibodies.[125,131,132]

Special tests are needed to confirm diagnoses of inborn errors of metabolism. Tests for α_1-AT deficiency include serum α_1-AT and phenotype analysis. Hallmarks of Wilson's disease (an autosomal recessive disorder of copper overload) include low serum ceruloplasmin and high urinary copper levels, particularly after the administration of penicillamine.

Markers for hepatic malignancy include AFP and des-γ-carboxylated prothrombin.[60,133-136] As a test for HCC, plasma AFP is 90% specific; its sensitivity ranges from 50% to 90%, depending on population subgroups.[60] Another test for HCC is the plasma γ-carboxylated prothrombin level. HCC cells usually make procoagulants without γ-carboxylating them.[133,136] High levels of des-γ-carboxylated, vitamin K–dependent proteins occur in up to 91% of patients with HCC. In at least two thirds of these patients, levels are above 300 ng/mL, which far exceeds the typical value in patients with liver cirrhosis or acute hepatitis. After surgical removal of HCC, levels of des-γ-carboxylated factors begin to decrease. Subsequent increases suggest tumor recurrence.[137]

Quantitative Liver Tests

Total hepatocellular mass can be estimated by measuring the clearance of a substance that is avidly extracted by the liver, such as bromsulphalein, indocyanine green (ICG), and rose Bengal.[138] However, these are rough estimations because clearance is subject to many influences and unknowns. For example, hepatic clearance of highly extracted substances (1) changes in direct proportion to variations in liver blood flow, (2) is altered by extrahepatic retention or clearance of the substance, and (3) may be affected by anomalous hepatobiliary function.

Drug-metabolizing capacity of the liver can be measured by several methods, such as caffeine clearance, galactose elimination capacity, aminopyrine breath test, antipyrine clearance, and monoethylglycinexylidide (MEGX).[117,139-142] Techniques are available for measuring caffeine clearance noninvasively.[140] For example, subjects take an oral dose of caffeine (150 to 300 mg), and caffeine metabolites in saliva are measured for up to 24 hours. MEGX is an invasive method that has recently gained popularity for measuring liver blood flow in critically ill patients. Fifteen minutes after an intravenous injection of lidocaine (1 mg/kg), a blood sample is obtained and assayed for MEGX, the major metabolite of lidocaine. Currently, quantitative tests are in the domain of research tools; when compared with standard liver chemistry tests, they are expensive and time consuming, with no compelling evidence of being superior, either diagnostically or prognostically.

Measurement of Liver Blood Flow

Methods used to measure hepatic blood flow fall into three broad categories: clearance techniques, indicator dilution techniques, and direct measurements.

Clearance Techniques

Extraction methods using the indirect Fick principle closely approximate hepatic blood flow and are valid for substances with high intrinsic hepatic clearance and total body clearance. Such substances include ICG dye, propranolol, lidocaine, and colloidal particles. Constant infusion of ICG is among the most reliable extraction methods. Hepatocytes take up nearly all of the ICG infused and excrete it unchanged in bile. Clearance methods may also be based on the ability of Kupffer cells to avidly phagocytose radiolabeled colloidal particles such as gold 198. After injecting such particles, one can compute the area under the initial curve (of radioactivity versus time) to obtain a valid measurement of hepatic blood flow—assuming that the reticuloendothelial system is functioning normally.[143] The bottom line is that severe liver disease renders clearance techniques unreliable because of indeterminable disease-related effects on liver blood flow and hepatic capacity to eliminate substances. The latter decreases in direct proportion to the loss of hepatocellular mass.[144]

Indicator Dilution Techniques

Unlike clearance methods, measurements of liver blood flow by indicator dilution techniques are unaffected by liver disease. After

a radiolabeled indicator (e.g., iodinated albumin) is injected into the spleen, hepatic flow is computed from indicator dilution curves. These curves are obtained by continuous sampling from one of the hepatic veins or by external γ-scintillation counting. For this technique to be valid, the indicator must be uniformly mixed upon injection and resistant to hepatic clearance.[145]

Direct Measurements

Electromagnetic flow probes provide direct measurements of blood flow through the hepatic artery or portal vein.[146] However, the surgical procedures used to implant the probes can themselves alter hepatic blood flow. Thus, the probes are often left in place after the implantation procedure, and blood flow is subsequently measured via telemetry.

Radiologic and Endoscopic Methods

Radiologic and endoscopic techniques offer therapeutic alternatives to surgery. Endoscopic retrograde cholangiopancreatography (ERCP) and percutaneous transhepatic cholangiography (PTHC) are used to evaluate hepatobiliary disorders. ERCP provides intraductal access to the biliary tree and pancreatic duct. Its main use is to diagnose and treat extrahepatic biliary disorders such as gallstones, tumors, inflammatory strictures, or postsurgical anastomotic leaks. Successful endoscopic papillotomy can obviate surgical removal of stones in the common bile duct.[147] ERCP is less invasive than surgery, but it too can lead to major complications, most notably pancreatitis. Radionuclide and ultrasonic scanning detect space-occupying lesions of the hepatobiliary tree.[147,148] PTHC provides a means of evaluating the intrahepatic bile ducts of patients with unexplained intrahepatic cholestasis or jaundice. Dilated intrahepatic bile ducts on PTHC indicate mechanical blockage of intrahepatic ducts. When no such blockage exists, the most likely cause of intrahepatic cholestasis is hepatic parenchymal disease.

Esophagogastroscopy is an important technique for evaluating and treating submucosal varices in patients with cirrhosis and portal hypertension. Splenoportography provides information about the status of the splenic and portal veins. Portal venography, via three-dimensional computed tomography with a multidetector row technique, can render vascular maps that are superior to those obtained by classic angiography.[149] Such vascular maps show the extent and location of portosystemic collateral communications, which may include abnormalities in gastric, paraumbilical, and abdominal wall veins; esophageal varices; and splenorenal and gastrorenal shunts.

Hepatic Pathophysiology

Mechanisms of Cell Death

Necrosis

Hepatocellular death often results from hypoxia or anoxia. Hypoxia decreases intracellular ATP. This stimulates breakdown of glycogen and anaerobic glycolysis, which raises lactic acid levels and lowers intracellular pH. Sudden, precipitous decreases in ATP initiate a series of events that may culminate in hepatocellular necrosis. Such events include abrupt failure of the energy-dependent ion pumps that regulate intracellular fluid and electrolyte homeostasis. Plasma membranes become dysfunctional, and hepatocytes swell rapidly and then rupture and extrude their contents. This cellular debris, which contains hepatic enzymes and reactive chemicals such as aldehydes, lipid peroxides, and eicosanoids, incites an inflammatory response. The release of cytokines and chemoattractants recruits circulating neutrophils to the liver and augments the hepatic inflammation.

Apoptosis

In contrast to necrosis, apoptosis is an energy-dependent process. Most agents of liver disease (toxins, viruses, oxidants) can activate proapoptotic intracellular signaling pathways or proapoptotic cell-surface receptors such as Fas, tumor necrosis factor receptor (TNFR), and other members of the TNFR superfamily.

Apoptosis has several ultrastructural hallmarks, including (1) a shrunken cell and nucleus; (2) condensed, marginated nuclear chromatin; (3) blebs on the plasma membrane; and (4) apoptotic bodies, which consist of membrane-bound cellular fragments and intact organelles. Epithelial and mesenchymal cells engulf the apoptotic bodies, and their lysosomes digest and recycle the contents of apoptotic bodies, such as intact mitochondria and nucleic acids. Apoptosis and necrosis may be related events at opposite ends of a spectrum of overlapping morphologic and mechanistic cell death processes.[85,150]

Oxidative Stress and the Glutathione System

Hepatocytes continuously produce reactive oxygen species. During aerobic metabolism, mitochondria work nonstop transferring electrons from reduced substrates to molecular oxygen (O_2). This process involves the tetravalent reduction of O_2; the reduced oxygen atoms are incorporated into water. However, small amounts of O_2 undergo univalent or divalent reductions that give rise to superoxide and hydrogen peroxide.[151] Nonparenchymal cells in the liver—Kupffer cells, endothelial cells, polymorphonuclear leukocytes, macrophages—can also generate large amounts of reduced oxygen species and nitro-radicals.[86,152-154]

In health, hepatocytes have many ways to keep oxidant concentrations within a safe range (<1 μM).[90,155] Their defenses against oxidative injury include (1) micronutrients, such as vitamins C and E; (2) metal-sequestering proteins, such as ferritin; (3) enzymes that dispose of reactive oxygen species, such as catalase and superoxide dismutase; (4) enzymes that detoxify lipid peroxides, such as glutathione peroxidase; and (5) thiol-rich peptides, most notably glutathione (γ-glutamyl-cysteine-glycine). Glutathione is the single most important intracellular antioxidant.[150,156-160]

The liver is the main site of glutathione synthesis. Accordingly, hepatocytes have high cytoplasmic concentrations of glutathione, ranging from 5 to 10 mmol/L.[90] Glutathione serves as a cofactor for major enzymes involved in the elimination of oxidants—notably glutathione peroxidase and thiol/disulfide exchangers. Glutathione peroxidase plays a key role as a detoxifier of organic peroxides and free radicals. Another enzyme, GST, helps eliminate toxic electrophiles by attaching them to the free thiol of reduced glutathione (GSH). GSH also participates in

nonenzymatic detoxification reactions, which yield oxidized glutathione (GSSG) and mixed disulfides of glutathione and protein.

GSH is the predominant form of glutathione under normal conditions; it is the main determinant of the redox capacity of hepatocytes. Oxidative stress decreases GSH levels by converting GSH to GSSG. The enzyme glutathione reductase helps regenerate GSH and restore the normal redox state. NADPH is the cofactor for glutathione reductase, and its synthesis requires ATP. High-energy phosphates are also needed to actively transport GSH into mitochondria. Disruption of this transport process leads to mitochondrial damage.[150] Thus, conditions that decrease ATP render hepatocytes more susceptible to oxidative injury.[156] Adverse conditions, such as malnutrition, hepatitis, and chemically induced liver injury, can quickly exhaust hepatic GSH. In such instances, therapy with thiol-rich agents such as cysteamine (mercaptoethylamine) or *N*-acetylcysteine may be lifesaving. The beneficial effects of thiol-rich agents relate to their ability to increase glutathione synthesis, replenish the intracellular GSH pool, and restore the capacity of the liver to combat oxidative stress.[156]

Ischemia-Reperfusion Injury

Ischemia-reperfusion (I/R) injury results from both hypoxia during an ischemic episode and cytotoxic events during reperfusion.[153,161-163] Reperfusion induces the production of highly reactive chemicals that can cause necrosis or apoptosis, such as superoxide, hydrogen peroxide, and hydroxyl radicals. After relatively brief ischemic intervals, most of the injury is due to reperfusion. With more prolonged ischemia, hypoxia accounts for a larger fraction of the overall injury from I/R.

Role of Xanthine Dehydrogenase/Xanthine Oxidase

The liver and intestines contain large amounts of xanthine dehydrogenase/xanthine oxidase (XDH/XO).[164] XDH catalyzes the rate-limiting step in nucleic acid degradation by using nicotinamide adenine dinucleotide (NAD) rather than O_2 as the electron acceptor. Thus, no oxygen radicals are produced in healthy tissue. However, ischemic conditions transform XDH to XO. Because XO reactions involve O_2, they produce free radicals. During reperfusion, XO-derived oxidants increase the production and release of leukotriene B_4 and platelet-activating factor, which promote neutrophil adherence and migration. When activated, neutrophils can wreak havoc on the microvascular circulation as they release proteases and physically disrupt the endothelial barrier. Liver injury, independent of the cause, imperils extrahepatic tissue because damaged hepatocytes spew out XO and other inflammatory mediators.[151,155,165-170] XO enters the bloodstream and binds to vascular endothelial cells in many organs.[164,171-173] Endothelial cells produce superoxide, which reacts with nitric oxide (NO·) to form peroxynitrite ($OONO^-$).[152,174] Peroxynitrite is intensely reactive and can increase the severity of injuries to local and remote tissues.

Therapeutic agents that may confer protection from I/R-induced injury include (1) antioxidants, (2) oxygen radical scavengers such as superoxide dismutase and dimethyl sulfoxide, (3) inhibitors of leukocyte adherence and migration,[175-177] and (4) inhibitors of XO. For example, laboratory studies show that allopurinol (inhibits XO) treatment before induction of I/R prevents the usual I/R-related increases in microvascular permeability and epithelial cell necrosis.[175,178]

Hepatic Injury from Liver Transplantation

Preservation Injury. The University of Wisconsin solution protects the donor liver for about 1 day. However, use of this solution for more than 24 hours may lead to microcirculatory disturbances (e.g., leukocyte and platelet adhesion) after liver transplantation. The adverse effects result from (1) depletion of hepatocellular antioxidants over time and (2) biochemical changes that lead to a profusion of reactive oxidants during reperfusion of the transplanted liver.[178] Hypothermic preservation solutions also induce apoptotic changes in endothelial cells, which may engineer their destruction after graft implantation.

The pathogenesis of I/R injury is complex.[179-182] Characteristic events include (1) Kupffer cell activation[183,184]; (2) XO formation[170,185]; (3) profusion of oxidants—superoxide, nitric oxide, peroxynitrite, and hydroxyl radicals; (4) release of proinflammatory cytokines into the bloodstream[186]; and (5) destruction of endothelial cells.[187-190] Flushing grafts (after storage in preservation solution) with various rinse solutions can decrease Kupffer cell activation, reduce endothelial cell damage, and improve graft survival.[191] Contents of the Carolina rinse solution include antioxidants, adenosine, a calcium channel blocker, energy substrates, and glycine, at pH 6.5. Another way to improve graft survival might be through downregulation of Kupffer cells with agents such as pentoxifylline, gadolinium, or calcium channel blockers.

Bacterial, Viral, and Immune Injury

Endotoxins are lipopolysaccharide complexes of the outer membranes of gram-negative bacteria. All endotoxins have a common lipid component (lipid A), a core R antigen, and two variable polysaccharide regions—bacterial strain-specific O-antigen. Lipid A binds to high-density lipoproteins in blood and other tissues, and it mediates the biologic actions common to endotoxins. Endotoxins bind more extensively to Kupffer cells than to hepatic parenchyma. They can induce hepatocellular or cholestatic injury directly or indirectly via activation of Kupffer cells and release of proinflammatory mediators (e.g., cytokines, eicosanoids).[192]

Like endotoxins, viruses may cause direct and indirect hepatocellular injury. Hepatotropic viruses and some herpesviruses can induce cytokine production leading to lymphocyte- or macrophage-dependent cytotoxicity. Antigens on hepatocellular membranes may be primary targets of cell-mediated injury. Antibodies to such antigens are often increased selectively in patients with autoimmune hepatitis and primary biliary cirrhosis. Other potential antigenic focuses for cell-mediated cytotoxicity include liver-specific lipoproteins and hepatic lectins, which may be targets in hepatitis B and other liver diseases.

Drug-Induced Liver Injury

Adverse reactions to drugs fall into two general categories: dose-related toxicity and idiosyncratic drug-induced injury. The former is predictable and develops in all individuals with escalation of the drug dose. The latter is a rare event, inducible with subclinical doses of the drug; it is most likely an immune-mediated injury that occurs in just a tiny fraction of those receiving the drug.

Although obvious differences exist between the two categories of drug reactions, there are also remarkable similarities. For example, both categories involve covalent binding of drugs (or their metabolites) to endogenous macromolecules. Such binding can lead to inactivation of important enzymes, depletion of intracellular antioxidants, and peroxidation of membrane lipids. The body's response to such molecular perturbations determines whether a drug-induced injury is categorized as dose related or idiosyncratic. When drug-induced subcellular damage induces immune sensitization, re-exposure to even a very low dose of the sensitizing drug can cause severe liver injury (e.g., halothane hepatitis).

The hepatotoxic effects of drugs and environmental substances usually involve CYP-mediated production of oxidants such as reduced oxygen species, carbon-based radicals, and nitro-radicals. Examples include (1) carbon tetrachloride metabolism via CYP, which yields trichloromethyl radical—a highly toxic intermediate that induces centrilobular necrosis; and (2) metabolism of nitrofurantoin or other aromatic compounds, which generates free radical intermediates that induce hepatic injury. Similar to CYP of the smooth endoplasmic reticulum, mitochondrial electron transporters transform xenobiotics to reactive metabolites. For example, the nitro-radicals that form during cocaine or nitrofurantoin metabolism[90,150] reduce O_2 via flavoprotein reductases to yield superoxide and other oxidizing species. Redox cycling, as occurs with anthracycline chemotherapeutics and imidazole antimicrobials, is yet another source of toxic oxidizing species.

Oxidant formation during drug metabolism contributes to or causes liver injury by weakening the antioxidant defenses of hepatocytes. For example, acetaminophen and bromobenzene cause dose-related decreases in hepatocellular GSH, rendering the liver increasingly susceptible to necrosis.[193,194] This increases the likelihood of oxidants damaging (1) proteins and enzymes, (2) phospholipids in membranes, and (3) nucleotides via activation of proteases, phospholipases, and endonucleases. Oxidative stress can also induce pathologic increases in cytosolic Ca^{2+} by increasing Ca^{2+} uptake by hepatocytes while inducing release of Ca^{2+} from the endoplasmic reticulum or mitochondria. These events can lead to apoptosis, necrosis, or both.

Occasionally, conjugation reactions generate hepatotoxic by-products.[95,195-197] For example, phase 2 metabolism of carboxylate drugs yields acyl glucuronides. These molecules can induce hepatic injury as they covalently bind to and inactivate nucleophiles, thiol-rich proteins, and nucleic acids. Intermediates of phase 2 metabolism can also deplete hepatocellular antioxidants and promote the formation of neoantigens and autoantigens, which trigger immune-mediated liver injury after re-exposure to the inciting agent.

Drug-Induced Apoptosis

Apoptotic pathways can be activated by drug-induced mitochondrial injury.[150,156,198] The sequence of events may be as follows: (1) drug metabolism produces oxidants and depletes GSH; (2) oxidants induce mitochondrial injury, with release of cytochrome *c* and initiation of the mitochondrial membrane permeability transition; and (3) caspase is activated and triggers apoptosis.[198-201] The hepatic pathology of Reye's syndrome may involve mitochondrial injury from drugs such as tetracycline, aspirin, valproic acid, and nucleoside analogs (e.g., zidovudine).[201] Mitochondrial enzymes are likely to be pathogenic targets of *N*-acetyl-*p*-benzoquinone imine (NAPQI), the acetaminophen metabolite associated with hepatocellular necrosis. Whether mitochondrial injury will lead to apoptosis or necrosis depends on the intracellular energy state and the severity of the injury.[150]

Immunopathology

Immunopathology often underlies idiosyncratic adverse drug reactions, such as halothane hepatitis. The clinical syndrome often includes fever, rash, lymphadenopathy, eosinophilia, and inflammatory infiltrates in the liver. Characteristically, the syndrome has a delayed onset after the first-ever dose of the drug, but with subsequent exposures, the onset is more rapid and the syndrome is more severe. Immunopathologic events may include (1) production of antibodies that lyse hepatocytes via molecular mimicry with host enzymes[202]; (2) antibody-dependent cell-mediated immunity, as with diclofenac[203]; (3) dysregulation of the immune system; and (4) drug-induced autoimmunity.[204,205]

According to the altered-antigen concept, drugs (or their metabolites) chemically react with and thereby modify certain intracellular proteins, which gives rise to neoantigens or antigenic drug-protein adducts. The pathogenesis of halothane hepatitis, for example, seems to involve trifluoroacylated (TFA) adducts that form during exposure to halogenated anesthetics.[206] Patients recovering from halothane-induced liver injury typically have circulating antibodies directed against TFA protein adducts. Yet the specificity and pathogenicity of these antibodies remain unclear[206] because such antibodies develop in most individuals after halothane anesthesia without liver injury developing.

Dysregulation of the immune system contributes to the formation of autoantibodies. Some lack tissue specificity (e.g., antinuclear and smooth muscle antibodies). Others are organ specific, such as the liver-kidney microsomal (LKM) antibodies that target microsomal enzymes; halothane hepatitis is associated with LKM antibodies directed against CYP2E1.

Alcohol-Induced Disease

Alcoholism (five or more drinks per day) induces several patterns of liver injury—notably steatosis (fatty liver), alcoholic hepatitis, and cirrhosis. Steatosis develops in nearly everyone who drinks excessively, but cirrhosis develops in only 10% to 20% of these individuals.[207] When compared with the general population, people with alcoholic liver disease have a higher prevalence of health-related disorders—malnutrition, immune incompetence, fluid and electrolyte imbalance. Such individuals are at increased risk for postoperative morbidity secondary to hemorrhage, sepsis, or cardiopulmonary decompensation (from alcoholic or cirrhotic cardiomyopathy).[208]

Characteristic pathologic findings of alcoholic liver disease include (1) acetaldehyde-induced subcellular injury, (2) abnormalities in metabolism, (3) microvascular hypoxia, (4) increased oxygen and nitrogen radical formation, and (5) depletion of antioxidant defenses. Alcohol metabolism is integral to the pathology of alcoholic liver disease.[209-213] The rate-limiting step in ethanol metabolism is catalyzed by alcohol dehydrogenase (ADH). This polymorphic zinc metalloenzyme has more than 20 different isozymes.[207,214] Although it exists in many tissues, hepatocytes metabolize more than 95% of the alcohol consumed. Genetic polymorphisms of ADH explain much of the variability in the relationship between ethanol consumption (dose) and liver

disease (response).[214-216] For example, the risk of alcoholic cirrhosis developing relates directly to polymorphisms at the *ADH2* gene locus (i.e., high frequency of the B allele).[217]

Cytoplasmic ADH is the main enzyme involved in oxidizing ethanol to acetaldehyde. Liver disease can decrease ADH activity and cause a higher proportion of ethanol oxidation to occur in peroxisomes via catalase and in endoplasmic reticulum via ethanol-induced CYP2E1.[218] Liver disease can also depress the mitochondrial enzyme aldehyde dehydrogenase (ALDH), which catalyzes the conversion (detoxification) of acetaldehyde to acetate.[215,218,219] Deficiency of ALDH leads to increased acetaldehyde levels in blood and other tissues, which amplifies the intrahepatic and extrahepatic toxicity of alcohol.[220] Acetaldehyde may induce tissue injury by (1) forming adducts with intracellular proteins,[221] (2) binding to GSH, (3) depleting intracellular antioxidant levels,[222] (4) altering plasma membranes to increase superoxide formation,[223] (5) promoting collagen production and fibroplasia,[224] and (6) stimulating the release of chemotactic agents that recruit neutrophils to the liver.[224,225]

Similarities in Hepatic Injuries from Hypoxia and Ethanol

Hepatic injuries from hypoxic episodes and ingestion of ethanol are similar in many respects. Hypoxic injuries promote the release of proinflammatory cytokines, tumor necrosis factor-α, and interleukin-1 and interleukin-6. These signaling molecules lead to increased expression of adhesion molecules, decreased velocity and increased margination of neutrophils, increased platelet adherence, and decreased hepatic blood flow.[226] Hepatoenteric ischemia releases cytokines and XO and leads to activation of complement. This intensifies the local inflammation and can induce systemic inflammatory responses, with subsequent pulmonary and cardiac injury.[151,155,227,228]

Similarly, alcoholic-related liver injury promotes the release of proinflammatory mediators.[229] Alcohol ingestion can markedly increase hepatic oxygen consumption, which would predispose to hypoxic injury.[207,230] The earliest manifestations of ethanol-induced injury occur in acinar zone 3 (the centrilobular region), which has the highest ADH content and the lowest oxygen supply.[90,218,231,232] Prolonged ethanol use leads to increased expression of NO· synthase, increased NO· production, and vasodilation. Such effects of alcohol on the nitric oxide pathway may represent a microcirculatory adaptive response to ethanol-induced vasoconstriction.[233,234]

The notion that ethanol imposes a significant oxidant stress on hepatocytes is strongly supported by indirect (lipid peroxidation)[235] and direct (electron spin resonance data) evidence.[236] Alcohol stimulates the formation of oxidants, and it disrupts antioxidant defenses. It increases consumption of antioxidants while decreasing their production.[213,235] Alcohol use can decrease the genetic expression of antioxidant enzymes because of its intrinsic hepatotoxicity or because of alcohol-related disorders such as malnutrition.[237] The major source of oxidant formation after alcohol intake is alcohol metabolism rather than alcohol itself. Metabolism of alcohol via microsomal and cytosolic oxidases yields superoxide and other reactive compounds. Such chemicals activate inflammatory cells (including Kupffer cells),[238] which stimulates nitric oxide synthetase (iNOS) and peroxynitrite formation[174] in hepatic parenchymal cells, macrophages, endothelial cells, and vascular myocytes.[239] Peroxynitrite—the product of NO· and $O_2{\cdot}^-$ reactions—is an unstable anion that oxidizes and nitrosylates lipids and proteins.[240-244] When intracellular antioxidants such as GSH and α-tocopherol are depleted, alcohol metabolism becomes a more potent inducer of liver injury.[235,245]

Cirrhosis and Portal Hypertension

Liver cirrhosis is a chronic disease in which normal hepatic tissue is replaced by fibrotic scar tissue or regenerative nodules. With advancing hepatic fibrosis, there is progressive loss of liver function, and portal hypertension develops. The usual causes of cirrhosis include alcoholism, viral hepatitis, and metabolic disorders, although many other causes exist.[246] Although the etiologic agents of cirrhosis are disparate, the patterns of injury that they produce are remarkably similar and thus suggest similar or overlapping subsets of molecular mechanisms. Alcoholic- and nonalcoholic steatohepatitis–related cirrhosis involves similar patterns of fibrosis despite its overtly disparate etiologic categories.

Characteristic precirrhotic changes include cellular hypertrophy, fatty metamorphosis, mitochondrial and lysosomal dysfunction, disrupted transport and storage processes, and increased fibroplasia. When hepatocytes throughout the liver are encircled by fibrous tissue, cirrhosis exists.[247]

Cirrhosis can develop and progress in an insidious, indolent manner. Indeed, this is prerequisite for cryptogenic cirrhosis and is characteristic of hepatitis C–induced cirrhosis, which often remains clinically silent while destroying up to 70% of the liver. What enables this to happen is the substantial physiologic reserve of the liver, which compensates well for the progressive loss of viable hepatocytes. The development of portal hypertension signals depletion of this reserve. Signs and symptoms include anorexia, nausea, vomiting, abdominal discomfort, weakness, jaundice, spider nevi, ascites, splenomegaly, a firm liver, esophageal varices, and portosystemic encephalopathy. The pathophysiology of this condition can lead to sudden, devastating complications, including massive hemorrhage, sepsis, renal failure, coma, and death.[248]

Pulmonary Dysfunction

Advanced liver disease often leads to pulmonary dysfunction. Hypoxemia may develop for several reasons.[249,250] First, extensive intrapulmonary arteriovenous communications are common. Second, impairment of hypoxic pulmonary vasoconstriction develops secondary to disease-related increases in endogenous vasodilators such as NO·, glucagon, adenosine, and prostacyclin. Third, erythrocyte 2,3-diphosphoglycerate levels often increase and shift the oxyhemoglobin dissociation curve rightward. Fourth, ventilation-perfusion mismatching occurs because of atelectasis or restrictive pulmonary pathophysiology—secondary to ascites or pleural effusions. In fact, hepatic hydrothorax (pleural effusions without coexisting cardiopulmonary disease) develops in up to 10% of patients with cirrhosis.[251]

Renal Dysfunction

Renal dysfunction typically develops in patients with cirrhosis and portal hypertension. The glomerular filtration rate (GFR) steadily decreases, and the renal tubules avidly retain sodium, with no overt glomerular or tubular injury. Urinalysis is unremarkable except for a low urine sodium level.

The main causes of acute renal failure (ARF) in this patient population are prerenal failure and acute tubular necrosis (ATN).

Prerenal failure usually results from hypovolemia, sepsis, or type 1 hepatorenal syndrome (HRS).[252-255] End-stage liver disease puts patients at high risk for systemic hypovolemia as a result of (1) the formation of profuse ascites, (2) aggressive diuretic therapy, (3) gastrointestinal hemorrhage, and (4) sequestration of blood in the splanchnic vasculature. Therapy for prerenal ARF is straightforward; all that is generally required is to restore renal blood flow.

The most common cause of ATN is prerenal ARF—when it is protracted and severe enough to cause ischemic renal tubular injury. Other causes of ATN include nephrotoxic substances such as radiocontrast agents and nonsteroidal anti-inflammatory drugs. Unlike prerenal ARF, there is no specific therapy for ATN; treatment is mainly supportive.[256]

Prerenal failure secondary to type I HRS has a poor prognosis. In many instances, the only effective therapy is liver transplantation. Interventions that may transiently improve renal performance in such patients include (1) intravenous vasoconstrictors, notably terlipressin, norepinephrine, and midodrine, in combination with octreotide, and (2) devices or procedures that support the liver, such as a molecular adsorbent recirculation system (MARS) or transjugular intrahepatic portosystemic shunt (TIPS).[256-258]

Hematologic Dysfunction

Coagulopathies and other hematologic abnormalities are common with end-stage liver disease.[60] Anemia often develops for many reasons, including gastrointestinal bleeding, hemolysis, hypersplenism, malnutrition, vitamin deficiencies, bone marrow depression, and plasma volume expansion. As the liver begins to fail, it cannot make enough vitamin K–dependent procoagulants. When factor VII drops by 70% of the normal level, the PT becomes prolonged. Thrombocytopenia and thrombopathy develop as a result of (1) splenic sequestration syndrome, (2) bone marrow suppression secondary to alcoholism or medications such as interferon, or (3) platelet destruction from immune-mediated, platelet-associated IgG. Dysfibrinogenemia—the activation of fibrinolysis—may develop. Laboratory results typically include increased D-dimer levels, increased fibrin degradation products, and normal or nearly normal fibrinogen levels. However, before attributing any fibrinolytic disorder to liver failure, it is essential to conduct a thorough search for all possible reversible causes of disseminated intravascular coagulation.

Gastrointestinal Complications

Gastrointestinal hemorrhage is always a concern; nearly a third of cirrhosis-related deaths are due to ruptured esophagogastric varices. Portal hypertensive gastropathy, esophageal varices, or gastric varices develop in most patients with cirrhosis and portal hypertension.[259] Hemorrhage from esophageal varices occurs more often than hemorrhage from gastric varices, but the latter is generally more severe than the former. Variceal size is a good predictor of when varices will rupture, and rates of variceal enlargement parallel the severity of liver disease. Less than 2 years after cirrhosis and portal hypertension are diagnosed, 20% to 30% of patients suffer a variceal hemorrhage.[259] The first hemorrhage is acutely lethal in about 7% of cases, with a 6-week mortality rate of around 30%. Untreated survivors of variceal hemorrhage have a 60% chance of rebleeding within 2 years; if this should occur, the death rate would be 40% to 50%.

Endocrinopathies

Because the liver produces, processes, and metabolizes many endocrine substances, advanced liver disease leads to endocrine abnormalities. For example, plasma levels of glucagon and growth hormone increase with liver disease and contribute to insulin resistance. IGF-I decreases in children with liver disease and adversely affects their growth and development.[80] Gonadal dysfunction develops in men and women because of disruptions in the metabolism of sex hormones. Men undergo feminization, with the development of gynecomastia, testicular atrophy, infertility, and impotence. In women, oligomenorrhea, amenorrhea, and infertility are common.

Central Nervous System Dysfunction

Hepatic encephalopathy is a complex neuropsychiatric syndrome that develops in 50% to 70% of patients with cirrhosis.[252] Pathophysiologic phenomena that contribute to the syndrome include (1) hepatobiliary dysfunction, (2) decreased hepatic blood flow, and (3) extrahepatic diversion of portal venous flow through collateral vessels (i.e., portacaval blood flow). Various gut-derived chemicals, including mercaptans, phenols, ammonia, short-chain fatty acids, and manganese, may play a role in the pathogenesis of hepatic encephalopathy. Central nervous system depression may result from false neurotransmitters (e.g., octopamine) or endogenous ligands that increase central inhibitory outflow, such as activators of GABA benzodiazepine receptors. Other possible contributors to encephalopathy are disruptions of the blood-brain barrier and defective cerebral energy metabolism. The pathogenesis and management of hepatic encephalopathy are described in detail elsewhere.[60,252]

Cardiovascular Dysfunction

A hyperdynamic circulation, with high cardiac output and low total peripheral resistance, is a hallmark of cirrhosis and portal hypertension.[260] Generally, systemic arterial pressure is slightly below normal, the heart rate is mildly increased, and central filling pressure is normal. Mixed venous O_2 saturation is elevated, and the arteriovenous O_2 content gap is low. Overall, the hemodynamic profile resembles a peripheral arteriovenous (AV) fistula. Indeed, advanced liver disease causes extensive, widespread AV communications (collateral vessels) within the splanchnic organs, lungs, muscle, and skin. High blood flow through these collateral vessels may result from cirrhosis-induced increases in endogenous vasodilators, such as glucagon, NO·, vasoactive intestinal polypeptide (VIP), and ferritin.[261-265]

Endogenous vasodilators may also explain why severe liver disease diminishes cardiovascular responses to physiologic and pharmacologic vasoconstrictors.[266] Laboratory studies show that NO·, by itself, can induce quintessential cardiovascular and renal hallmarks of cirrhosis and portal hypertension.[267,268] Experimental models of chronic portal hypertension—via partial portal vein ligation or CCl_4-induced cirrhosis—show that NO· induces elevations in cyclic guanosine monophosphate (cGMP), which correlate directly with peripheral arterial dilation.[268,269] Inhibitors of NO· synthase can (1) prevent the characteristic increases in cardiac output and decreases in vascular resistance, (2) restore plasma aldosterone and arginine vasopressin levels, and (3) correct the derangements in sodium and water excretion. In addition, clinical studies comparing healthy subjects and patients with liver cirrhosis show a positive correlation between exhaled NO· and the cardiac index.[270]

Pathogenesis of Portal Hypertension

Characteristic features of cirrhosis-induced portal hypertension include (1) high resistance to intrahepatic blood flow, (2) high preportal blood flow, and (3) high blood flow through portacaval collateral vessels. The pathogenesis of cirrhosis-induced portal hypertension is complex. Putative mechanisms include the "backward" and "forward" concepts, which are not mutually exclusive. According to the backward concept, proliferating intrahepatic fibrosis leads to increased resistance to the flow of blood through the portal vein; this elevates portal venous pressure (i.e., at constant rates of portal venous flow). Experimental narrowing of the portal vein induces portal hypertension characterized by (1) increased mesenteric vascular resistance, (2) decreased mesenteric blood flow, (3) decreased splanchnic venous oxygen saturation, and (4) an increased AV oxygen content gap of mesenteric blood. However, such changes are exactly opposite those that occur when portal hypertension develops in patients with cirrhosis. The forward concept regarding vasodilation may explain this[271]; portal hypertension develops because of cirrhosis-induced changes in the systemic and splanchnic arterial circulations. The hypothesis is supported by observations in cirrhotic patients, including (1) increased blood levels of endogenous vasodilators, (2) widespread AV shunt formation, and (3) high cardiac output with low total peripheral resistance. Putative mediators of the hyperdynamic circulation include NO·, glucagon, prostacyclin, adenosine, CO, and hydrogen sulfide.[272] These substances not only induce direct vasodilation but may also support the formation and patency of extensive AV shunts (AV fistulas) in the intestines, spleen, and other organs. Activation of K_{ATP} channels in arterial smooth muscle cells may mediate increased blood flow in the systemic and splanchnic arterial circulations.[272]

Control of Circulatory Volume

Avid renal retention of sodium is integral to the pathophysiology of cirrhosis and portal hypertension. Volume receptors that detect low effective plasma volume stimulate the sympathetic nervous system and lead to release of renin from the kidney.[273] This increases the production of angiotensin II and aldosterone, which enhances renal tubular uptake of sodium. Norepinephrine levels in blood correlate inversely with renal blood flow. Both norepinephrine and angiotensin II redistribute intrarenal blood flow in a manner that increases retention of sodium by the kidney. Additional factors that may augment sodium retention include the kallikrein-kinin system and some extremely potent renal vasoconstrictors, such as $F_{2\alpha}$-isprostanes[274] and endothelin. Renal vasoconstrictors are likely inducers of the renal dysfunction that accompanies cirrhosis and ascites. In such settings, endogenous vasodilators (e.g., prostaglandins) become increasingly important to counteract the intense vasoconstriction and protect renal blood flow. Accordingly, inhibitors of prostaglandin synthesis can significantly decrease renal plasma flow and GFR and thereby increase the risk for acute renal injury.

Pathogenesis of Ascites

Cirrhosis-induced portal hypertension leads to massive increases in total body water, edema, and ascites formation.[275] The problem can be traced to excessive sodium retention by the kidney (Fig. 17-13).[2,276] However, the principal driver of the sodium retention is unclear. One explanation—the overflow model—is that hepatic cirrhosis gives rise to chemicals that stimulate the kidney to retain sodium. A second explanation—the underfill model—is that renal retention of sodium is a normal physiologic response to a low effective blood volume.[273]

The essence of the overflow model is that excessive renal retention of sodium causes intravascular volume to expand, with two major and direct consequences: (1) plasma oncotic pressure decreases, with the liver unable to produce sufficient albumin to correct the hypoalbuminemia, and (2) portal hydrostatic pressure increases (i.e., portal hypertension). The combination of low oncotic pressure and portal hypertension accelerates the formation of edema and ascites. A pivotal assumption of the overflow model is that a cirrhosis-induced mediator causes normal kidneys to retain sodium and water despite an overfilled intravascular compartment. At present, no such mediator (or process) has been identified.

The underfill model recognizes that homeostatic reflexes work in concert with the kidney to tightly regulate intravascular volume. This model posits that cirrhosis causes the effective plasma volume to decrease, which activates homeostatic mechanisms to retain sodium and water. As Schrier and Abraham point out,[273] "the integrity of the arterial circulation, as determined by cardiac output and peripheral arterial resistance, is the primary determinant of renal sodium and water excretion." That is, with decreases in arterial volume, whether from arterial dilation or low cardiac output, the kidney is instructed to retain sodium and water. Cirrhosis-induced decreases in effective plasma (or arterial) volume can result from arterial dilation or intravascular volume depletion, or both. Although the latter has many possible causes, edema and ascites formation from unbalanced Starling forces are sufficient to significantly decrease intravascular volume. The overflow and underfill models are not mutually exclusive; a primary defect in sodium excretion could be the major factor in earlier stages of cirrhosis, whereas a low effective plasma volume could be the more important factor in progression to end-stage liver disease.[275]

Cholestatic Disease

Cholestasis refers to impaired biliary flow and has a complex pathogenesis[106,277-295] (Box 17-2). The usual cause of intrahepatic cholestasis, whether inherited or acquired, is dysfunction of the bile transporter.[295,296] In contrast, extrahepatic cholestasis most often results from mechanical blockage of the biliary tree. With cholestasis, there are high blood levels of biliary constituents, including hepatocellular enzymes (AP, GGTP, 5′-NT, LAP),

Box 17-2 Etiology of Intrinsic Cholestatic Disorders

- Genetic cholestatic liver diseases[292-295]

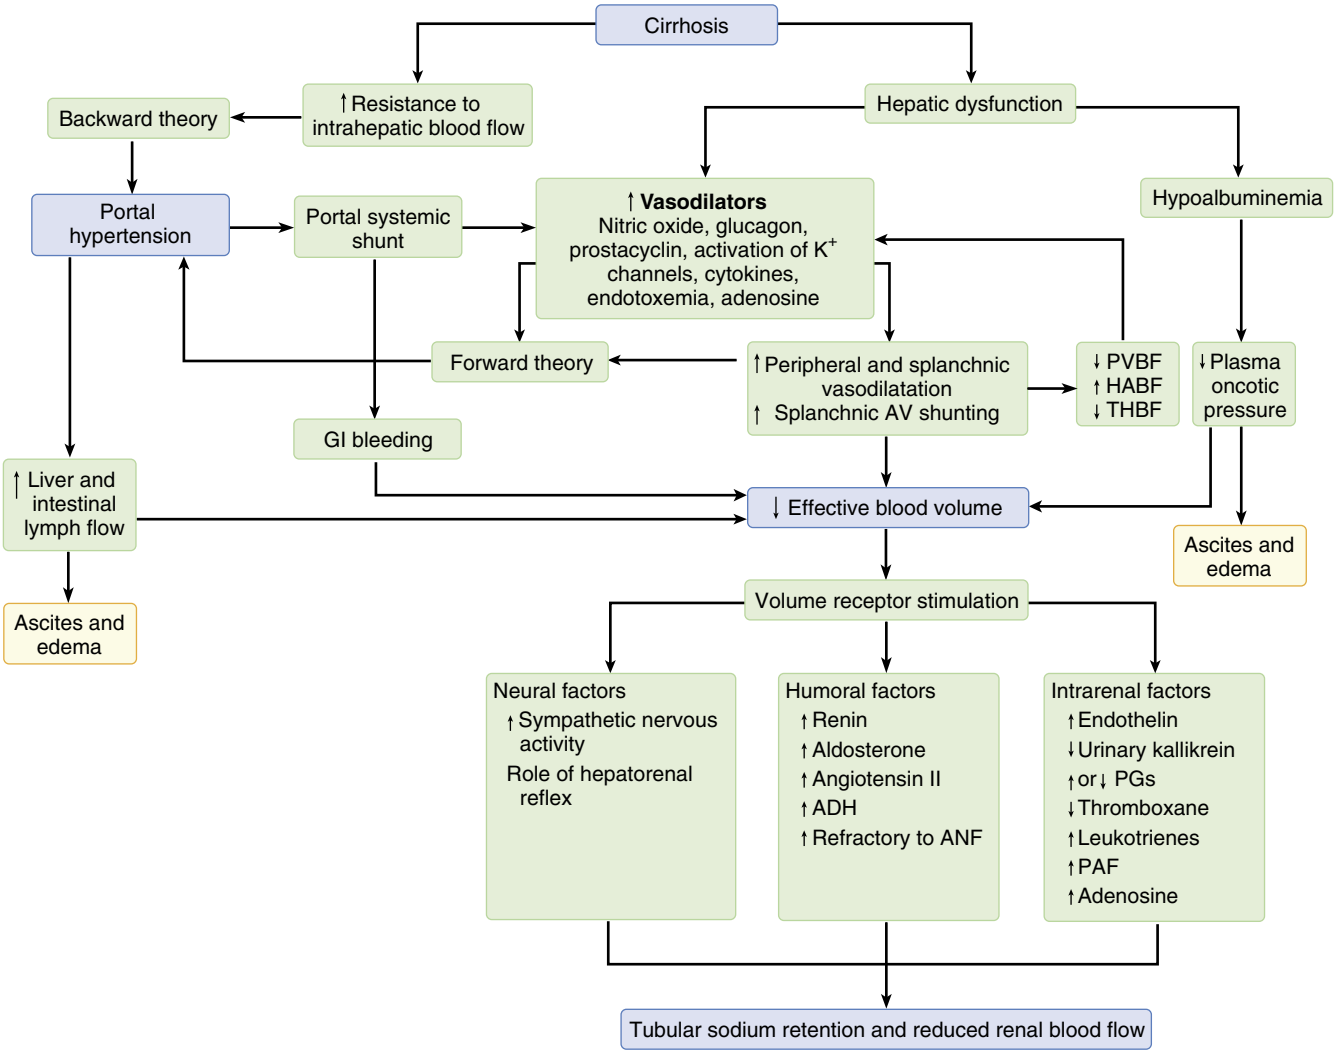

Figure 17-13 Schematic of pathways for cirrhosis-induced portal hypertension: the forward and backward theories. Cirrhosis and portal hypertension induce circulatory changes that decrease effective blood volume. This activates volume receptors and stimulates neurohumoral and intrarenal reflexes, which decreases renal blood flow and increases renal retention of sodium. ADH, antidiuretic hormone; ANF, atrial natriuretic factor; AV, arteriovenous; HABF, hepatic arterial blood flow; PAF, platelet-activating factor; PGs, prostaglandins; PVBF, portal venous blood flow; THBF, total hepatic blood flow. *(Reprinted with permission from Mushlin PS, Gelman S: Anesthesia and the liver.* In *Barash PG, Cullen BF, Stoelting RK* [eds]*: Clinical Anesthesia, 4th ed. Philadelphia, Lippincott Williams & Wilkins, 2001, p 1088.)*

immunoglobulin A, cholesterol, and various forms of bile salts and bilirubin. The most toxic of these is unconjugated bilirubin; high concentrations of unconjugated bilirubin cause membrane dysfunction and disrupt major metabolic pathways such as the tricarboxylic acid cycle and oxidative phosphorylation. Patients with cholestatic syndromes typically have marked increases in serum bile salts, but normal or slightly elevated serum bilirubin.

The clinical findings in cholestatic syndromes are dependent on the severity of the cholestatic disorder and its pathogenesis.[297-301] Pruritus is a hallmark feature and results mainly from retained bile salts.[277,284,302,303] As cholestatic disorders increase in severity, jaundice develops.[304] The stool becomes lighter in color and the urine darkens as bile pigments are diverted from the gut to the kidney for excretion.

Coagulation Disorders

Enteric absorption of lipids such as vitamin K requires bile salts and an intact enterohepatic circulation. With cholestasis-induced coagulopathies, the liver continues to make procoagulants. However, without vitamin K, hepatocytes cannot add the γ-carboxyl glutamate residues that these procoagulants need for subsequent activation. Parenteral vitamin K should correct this coagulopathy, but if it does not, there must be another cause of the problem. Prolonged cholestasis can induce liver dysfunction and a coagulopathy that would not be cured by vitamin K therapy.

Renal Dysfunction

Cholestatic disorders can cause dysfunction of the splanchnic reservoir. Because the reservoir cannot effectively transfer blood volume to the central circulation, severe hypotension and renal hypoperfusion can result from even mild losses of plasma volume. This predisposes to prerenal ARF and ATN from the prerenal ARF. If liver dysfunction supervenes, ATN may result from unconjugated bilirubin, which can directly cause renal tubular injury.

Cardiovascular Dysfunction

Cholestatic syndromes induce hemodynamic changes that are similar, but less severe than the changes associated with cirrhosis and portal hypertension. Cardiac output increases and peripheral vascular resistance decreases. Portal venous blood flow may decrease as portal venous resistance increases. Yet the mechanisms by which cholestasis alters cardiovascular parameters are incompletely understood and challenging to study for several reasons. First, bile is a heterogeneous fluid with variable compositions and many different forms of bile salts and bilirubin. Second, individual constituents of bile exert dissimilar cardiovascular effects. Third, differing causes of cholestatic syndromes lead to disparate pathophysiologic conditions, which can confound the direct and indirect cardiovascular actions of specific constituents of bile.

The direct cardiac effects of bile salts (primary, conjugated, and secondary) have been studied in isolated heart preparations to obviate concern about the indirect cardiovascular effects of biliary constituents. In isolated ventricular muscle, bile salts, at concentrations similar to those in patients with cholestatic jaundice, exert negative inotropic effects. They decrease (1) peak tension, (2) the maximum rate of tension development, (3) the duration of contraction, and (4) the action potential duration. Electrophysiologic actions of sodium taurocholate, ascertained from voltage clamping of ventricular myocytes, include decreases in the slow inward current and slight increases in the outward potassium current. Taken collectively, these data suggest that bile salts directly induce negative inotropic effects, which could result from altered membrane currents.[305]

Experiments in animals show that high blood levels of bile salts (cholemia) can block the cardiovascular effects of agents such as norepinephrine, angiotensin II, and isoproterenol. It is possible that cholemia exerts such effects by disrupting receptor complexes in plasma membranes.[305-307] On the other hand, acute cholestasis can decrease cardiac contractility without affecting cardiac β-adrenoceptors, as shown in animal studies in which acute cholestasis was induced by bile duct ligation.[306] After experiencing 3 days of extrahepatic cholestasis, myocardial contractility was impaired globally, but β-adrenoceptors were intact.

Studies in animals show that cholestasis can alter homeostatic circulatory reflex responses.[307] For example, removal of 10% of the blood volume of healthy rats had little effect on their arterial blood pressure, whereas removing this same volume of blood from rats with cholestasis caused a 50% decrease in blood pressure. Healthy animals compensated for the blood loss by mobilizing 15% of the blood volume of the pulmonary and splanchnic vasculature; however, animals with cholestasis mobilized only 7% of their pulmonary blood volume, with no contribution from the splanchnic reservoir.[307] These data show that cholestasis induces dysfunction of physiologic blood reservoirs. Whether such laboratory findings are relevant for patients with cholestasis is unclear. A final note of caution about patients with cholestatic disorders is warranted: decompression of the biliary tract, by itself, may lead to significant cardiovascular depression.[308]

18 Renal Physiology

Key Points

1. To cross the filtration barrier between plasma and tubular fluid, a molecule must pass in succession through the endothelial fenestrations, the glomerular basement membrane, and the epithelial slit diaphragm. The capillary endothelium restricts the passage of cells, but the basement membrane filters plasma proteins. All three layers contain negatively charged glycoproteins, which retard the passage of other negatively charged proteins. Thus, the filtration barrier is size selective and charge selective.[1]
2. A primary determinant of glomerular filtration rate (GFR) is the glomerular filtration pressure, which depends not only on the renal artery perfusion pressure but also on the balance between afferent and efferent arteriolar tone. In the presence of decreased afferent arteriolar pressure or blood flow, low levels of catecholamines, angiotensin, and arginine vasopressin (AVP) induce preferential efferent arteriolar constriction, which maintains glomerular filtration pressure. This is reflected by an increase in calculated filtration fraction (FF), which is the GFR expressed as a fraction of the renal plasma flow (RPF), that is, FF = GFR/RPF. High levels of catecholamines and angiotensin (but not AVP) increase afferent arteriolar tone and decrease glomerular filtration pressure (and GFR) out of proportion to RPF, and FF decreases (see Fig. 18-4).
3. Tubuloglomerular feedback may be a primary mechanism in renal autoregulation.[3] When GFR is increased, distal tubular NaCl delivery is enhanced. The increase in chloride is sensed by the macula densa, which triggers the release of renin from the adjacent afferent arteriole. Angiotensin is elaborated and arteriolar constriction ensues, which decreases GFR. When the thick ascending loop becomes ischemic, reabsorption of NaCl ceases, the ability of the tubule to concentrate urine is lost, and, theoretically, intractable polyuria should result. Thurau and Boylan[5] suggested that the increased delivery of NaCl to the macula densa triggers angiotensin-mediated arteriolar constriction, which decreases GFR, induces oliguria, conserves intravascular volume, and protects the organism from dehydration—so-called acute renal success.
4. Autoregulation enables the kidney to maintain solute and water regulation independently of wide fluctuations of arterial blood pressure. It is noteworthy that urinary flow rate is not subject to autoregulation. Tubular water reabsorption determines urinary flow rate and is closely related to the hydrostatic pressure in the peritubular capillaries. Hypotension, whether induced or inadvertent, results in decreased urinary flow rate that may be correctable only when the arterial blood pressure is restored toward normal.
5. The tubule has an enormous capacity for reabsorption of water and NaCl. Each day, 180 L of protein-free glomerular ultrafiltrate is formed, of which almost 99% of the water and 99% of the sodium is reabsorbed. Many other filtered substances are completely reabsorbed, but some, such as glucose, have a maximum rate of tubular reabsorption (tubular maximum). Tubular reabsorption of glucose increases at a rate equal to that of the filtered load.
6. The ability of the kidney to concentrate urine is dependent on the interaction of at least three processes: (1) the generation of a hypertonic medullary interstitium by the countercurrent mechanism and urea recycling, (2) concentration and then dilution of tubular fluid in the loop of Henle, and (3) the action of antidiuretic hormone (now known as arginine vasopressin [AVP]) in increasing water permeability in the last part of the distal tubule and collecting ducts.
7. Serum creatinine reflects the balance between creatinine production by muscle and creatinine excretion by the kidney, which is dependent on the GFR. Creatinine generation rate varies with muscle mass, physical activity, protein intake, and catabolism. However, when these processes are in equilibrium and renal function is stable, serum creatinine is a useful marker of GFR. The relationship between serum creatinine and GFR is inverse and exponential. A doubling of the serum creatinine implies a halving of the GFR. An increase in serum creatinine from 0.8 to 1.6 mg/dL may not generate much attention, but it indicates a 50% decrease in GFR. A much larger increase from 4 to 8 mg/dL also

represents a 50% decrease in GFR, but by this time renal insufficiency is well established (see Fig. 18-11). After a transient renal insult (e.g., suprarenal aortic cross-clamping), serum creatinine may increase for a few days while GFR is actually recovering.

8. The juxtaglomerular apparatus consists of three groups of specialized tissues. In the afferent arteriole, modified fenestrated endothelial cells produce renin; in the juxtaposed distal tubule, cells of the macula densa act as chemoreceptors; and in the glomerulus, mesangial cells have contractile properties (see Fig. 18-3). Together these provide an important regulating system for blood pressure, salt, and water homeostasis.[46]

9. Hypothalamic osmoreceptors are sensitive to increases in serum osmolality of as little as 1% above normal. As illustrated in Figure 18-21A, the threshold for AVP secretion (and the sensation of thirst) is between 280 and 290 mOsm/kg. When this is exceeded, the secretion rate has a very steep gain.[52] Even mild dehydration results in a rapid antidiuresis, and urine osmolality can increase from 300 to 1200 mOs/kg as plasma AVP levels rise from 0 to 5 pg/mL (see Fig. 18-21B). Decreases in intravascular volume also stimulate AVP secretion, mediated by stretch receptors with vagal afferents in the left atrium and pulmonary veins. Hypovolemia-induced secretion of AVP overrides osmolar responses and contributes to the perioperative syndrome of inappropriate antidiuretic hormone secretion (SIADH): fluid retention, hypo-osmolality, and hyponatremia. The situation is exacerbated by administration of large volumes of hypotonic solutions that decrease serum osmolality. Psychic stress, via cortical input, also induces AVP release and can override osmotic and volume sensors.

10. All anesthetic techniques and drugs tend to decrease GFR and intraoperative urine flow. Some drugs also decrease renal blood flow (RBF), but filtration fraction is usually increased, which implies that angiotensin-induced efferent arteriolar constriction limits the decrease in GFR. However, these effects are much less significant than those caused by surgical stress or aortic cross-clamping and after emergence from anesthesia usually resolve promptly. Any anesthetic technique that induces hypotension will result in decreased urine flow because of altered peritubular capillary hydrostatic gradients, even if renal autoregulation is preserved (as it usually is during anesthesia). Permanent injury seldom results, unless the kidneys are abnormal to begin with or the hypovolemic insult is prolonged and exacerbated by nephrotoxic injury.

11. Clinically significant renal injury with the use of low-flow sevoflurane anesthesia has not been reported in patients, even with moderate preexisting renal dysfunction. The relationship between compound A formation, biochemical injury, and clinically relevant renal dysfunction remains unclear and unproven. Nonetheless it appears prudent to follow current FDA guidelines, which recommend a fresh gas flow of at least 2 L/min to inhibit compound A formation and its rebreathing and to enhance its washout.

12. Regardless of the position of the aortic cross-clamp, RBF is decreased to 50% of normal during surgical preparation of the aorta, presumably due to direct compression or reflex spasm of the renal arteries. After release of the suprarenal cross-clamp, RBF increases above normal (reflex hyperemia), but GFR remains depressed to one third of control for up to 2 hours. After 24 hours, GFR is still only two thirds of control. Tubular functions (concentrating ability, sodium, and water conservation) are markedly impaired, but urine flow is maintained. Myers and Moran[106] observed that these changes resemble an attenuated form of acute tubular necrosis. In the above study all patients received mannitol pretreatment, which probably limited the tubular insult because oliguria was uncommon and recovery was relatively rapid. Cross-clamp times longer than 50 minutes are associated with prolonged depression of GFR and transient azotemia.[107]

13. In contrast to dopamine, there does appear to be increasing evidence to support a renoprotective effect for infusion of low-dose fenoldopam infusion (0.1-0.3 μg/kg/min) during cardiac surgery. A meta-analysis of 13 randomized and case-matched studies on 1059 patients found that fenoldopam infusion is associated with a significant decrease in dialysis requirement, intensive care unit length of stay, and in-hospital mortality.[136] Most studies have been relatively small and identified improved serum creatinine and creatinine clearance rather than renal outcome.[137,138] The most convincing evidence thus far comes from a randomized, double-blinded study in 193 high-risk patients by Cogliati and associates.[139] Risk factors included elevated preoperative serum creatinine (>1.5 mg/dL), age older than 70 years, diabetes, and previous cardiac surgery. Patients who received fenoldopam had a decreased incidence of acute kidney injury (12.6 versus 27.6%, $P = .02$) and requirement for dialysis (0 versus 8.2%, $P = .004$).

14. The beneficial effect of AVP on renal function in sepsis may in part be due to its ability to increase low renal perfusion pressure back into the autoregulatory range. Another important factor is that, unlike norepinephrine, even at high local concentrations AVP preferentially constricts the efferent arteriole, thereby improving filtration fraction and GFR.[53] However, in a large, prospective, randomized, blinded trial in 778 patients with severe septic shock, low-dose AVP (0.01-0.03 unit/min) did not provide a mortality benefit or decrease the requirement for dialysis when compared with an infusion of norepinephrine (5-15 μg/min).[194]

The kidneys contain approximately 2 million nephrons, each of which consists of a glomerulus and a tubule, which empties into a collecting duct. Together they regulate intravascular volume, osmolality, and acid-base and electrolyte balance and excrete end products of metabolism and drugs. Urine is formed by the combination of glomerular ultrafiltration and tubular reabsorption and secretion. The nephron also elaborates hormones that contribute to fluid homeostasis (renin, prostaglandins, kinins), bone metabolism (1,25-dihydroxycholecalciferol), and hematopoiesis (erythropoietin). The function of the nephron is closely integrated with the vascular supply of the kidney (Fig. 18-1).

Anatomy and Physiology

The Glomerulus (Renal Corpuscle)

The glomerulus consists of five distinct components: capillary endothelium, glomerular basement membrane, visceral epithelium (which together make up the filtration barrier), parietal epithelium (Bowman's capsule), and mesangium (interstitial cells).[1,2] The glomerular tuft, a highly convoluted series of capillary loops, is fed by the afferent arteriole and drains into the efferent arteriole (Fig. 18-2).

The capillary endothelium synthesizes nitric oxide and endothelin-1, which, by governing vasodilation and vasoconstriction, control renal blood flow. The endothelium has fenestrations about 70 to 100 nm in diameter and lies atop the glomerular basement membrane, which has a total cross section of about 350 nm. The visceral epithelium, which is applied to the underside of the basement membrane, consists of podocytes with filamentous, interdigitating foot processes that contain contractile actin filaments. Filtration slits form 25- to 60-nm gaps between the foot processes and are bridged by a protein membrane slit diaphragm, whose size and permeability are altered by contraction of the foot processes.

The blind parietal epithelial sac of the renal tubule is invaginated around the capillary tuft as Bowman's capsule and meets the visceral epithelium at the vascular pole of the glomerulus. Bowman's space, between the visceral and parietal layers of the capsule, becomes the lumen of the proximal tubule at the urinary pole of the glomerulus, and the parietal endothelium merges with the cuboidal cells of the proximal tubule.

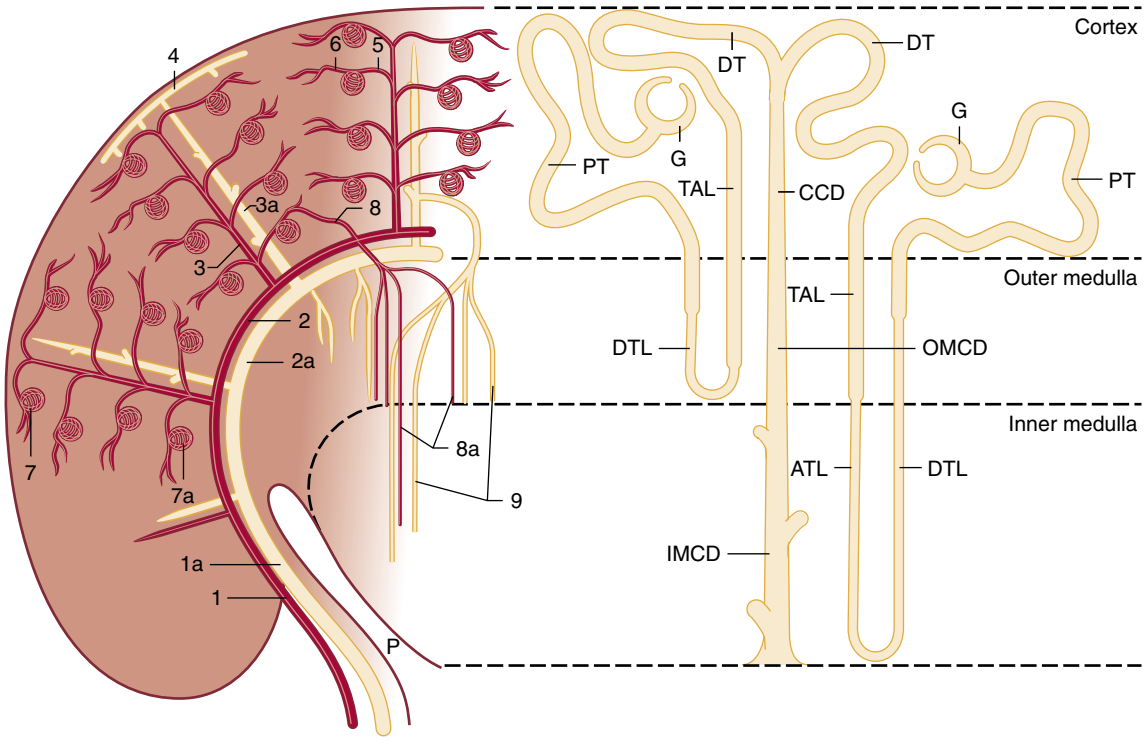

Figure 18-1 Anatomic relationships of the nephron and the renal vasculature. The left side of the diagram represents the renal vasculature as distributed through the inner medulla, outer medulla, and cortex. Arteries are drawn as *solid lines,* veins as *hollow tubes.* The renal artery divides serially into interlobar arteries (1), arcuate arteries (2), and interlobular arteries (3). The afferent arterioles (5) branch off laterally and provide the capillary tufts of the renal glomeruli in the outer cortex (7), whose efferent arterioles (6) supply the cortical capillary network (not shown). In the juxtamedullary zone (7a), the efferent arterioles become the vasa recta, which are closely applied to the long loops of Henle (8, 8a, 9). The venous drainage consists of stellate veins (4), interlobular veins (3a), arcuate veins (2a), and interlobar veins (1a). The right side of the diagram represents two nephrons. On the left is the more numerous superficial cortical nephron with a short loop of Henle. On the right is the juxtamedullary nephron with a long loop of Henle, which dives deep into the inner medulla to generate the hyperosmotic interstitium required for tubular urine concentration. ATL, ascending thin loop of Henle; CCD, cortical collecting duct; DT, distal tubule; DTL, descending thin loop of Henle; G, glomerulus; IMCD, inner medullary collecting duct; OMCD, outer medullary collecting duct; PT, proximal tubule; TAL, thick ascending loop. *(From Kriz W: A standard nomenclature for structures of the kidney. Kidney Int 33:1-7, 1988.)*

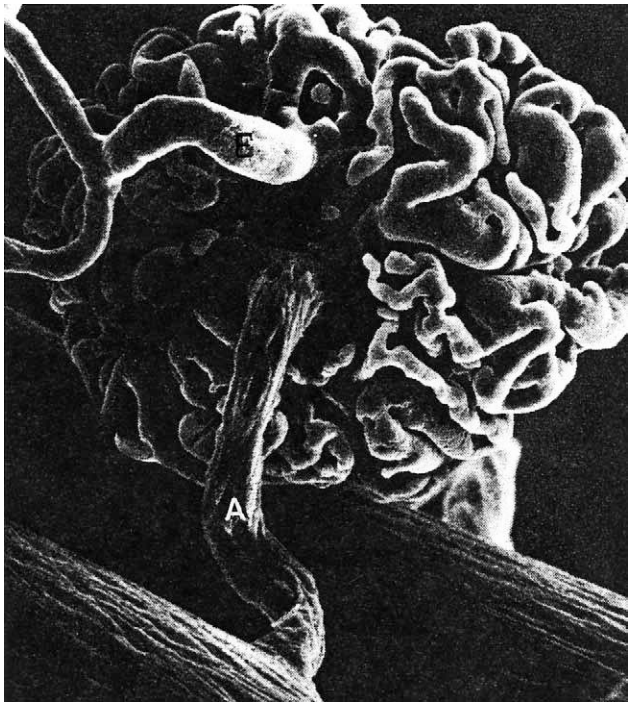

Figure 18-2 Photomicrograph of a cast of a glomerulus without Bowman's capsule. At lower left the afferent arteriole (A) originates from an interlobular artery and enters the glomerulus with its many capillary loops. At upper left the efferent arteriole (E) leaves the glomerulus and branches to form the peritubular capillary plexus (×300). (*From Tisher CC, Madsen KM: Anatomy of the kidney.* In *Brenner BM [ed]: Brenner & Rector's The Kidney, 6th ed. Philadelphia, WB Saunders, 2000, pp 3-67.*)

The central or interstitial mesangial cells are specialized pericytes with numerous functions, including structural support, matrix elaboration, and phagocytosis. They contain myofilament-like threads of actin and myosin. Mesangial contraction in response to vasoactive substances such as angiotensin II restricts blood flow to fewer capillary loops. The mesangial cells thereby regulate the effective glomerular surface area for filtration and, as a consequence, glomerular permeability.[3]

Formation of the Glomerular Ultrafiltrate

To cross the filtration barrier between plasma and tubular fluid, a molecule must pass in succession through the endothelial fenestrations, the glomerular basement membrane, and the epithelial slit diaphragm. The capillary endothelium restricts the passage of cells, but the basement membrane filters plasma proteins. All three layers contain negatively charged glycoproteins, which retard the passage of other negatively charged proteins. Thus, the filtration barrier is both size selective and charge selective.[1] Molecules with an effective radius of less than 1.8 nm (e.g., water, sodium, urea, glucose, inulin) are freely filtered. Molecules larger than 3.6 nm (e.g., hemoglobin, albumin) are not filtered. Filtration of molecules between 1.8 and 3.6 nm depends on their electrical charge. Cations are filtered, whereas anions are not. In glomerulonephritis, the negatively charged glycoproteins are destroyed, polyanionic proteins are filtered, and proteinuria ensues.

Glomerular ultrafiltration is governed by the balance of Starling forces regulating fluid flux across the filtration barrier.[4] Glomerular filtration rate (GFR) depends on the permeability of the filtration barrier and the net difference between the hydrostatic forces pushing fluid into Bowman's space and the osmotic forces keeping fluid in the plasma:

$$GFR = K_{uf}\left[\left(P_{gc} - P_{bs}\right) - \left(\pi_{gc} - \pi_{bs}\right)\right]$$

where uf = ultrafiltration, gc = glomerular capillary, and bs = Bowman's space.

The ultrafiltration coefficient, K_{uf}, reflects capillary permeability and glomerular surface area. Renal arterial pressure determines the hydrostatic pressure in the glomerular capillary, P_{gc}. Afferent arteriolar plasma flow determines the plasma oncotic pressure (π_{gc}): rapid blood flow washes out osmotically effective molecules and lowers π_{gc}, and vice versa.

The Juxtaglomerular Apparatus

The juxtaglomerular apparatus provides a remarkable integration of tubular and glomerular structure and function (Fig. 18-3). A modified portion of the thick ascending limb, the macula densa, is applied to the glomerulus at the vascular pole between the afferent and efferent arterioles.[1] The cells of the macula densa are chemoreceptors and sense the tubular concentration of sodium chloride (NaCl). The juxtaposed segments of the afferent and efferent arterioles contain modified smooth muscle cells (granular cells), which produce renin. The arterioles are innervated by sympathetic nerve fibers and contain baroreceptors that respond

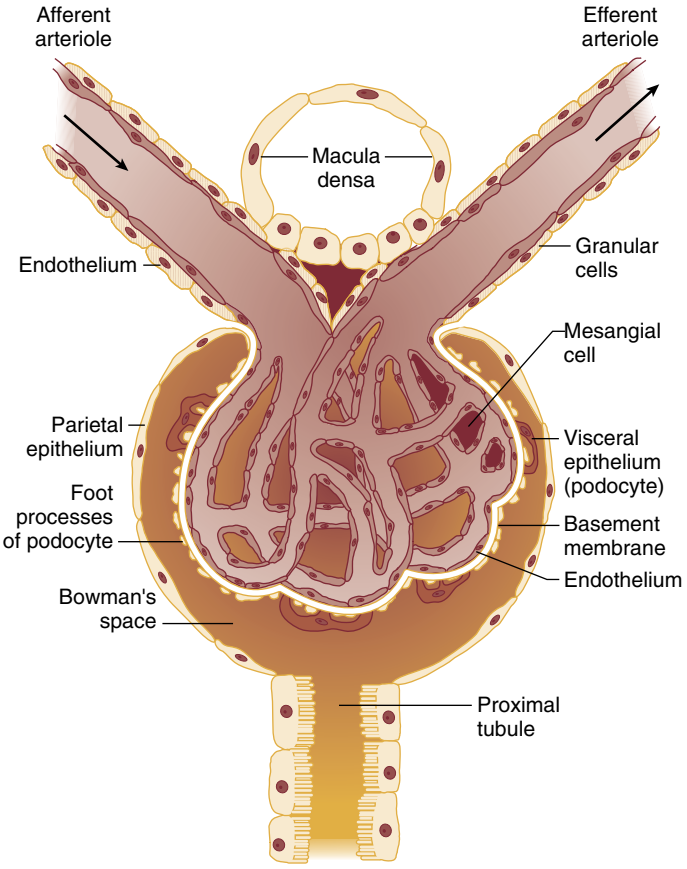

Figure 18-3 The juxtaglomerular apparatus. (*From Stanton BA, Koeppen BM: Elements of renal function.* In *Berne RM, Levy MN [eds]: Physiology, 4th ed. St. Louis, Mosby, 1998, pp 677-698.*)

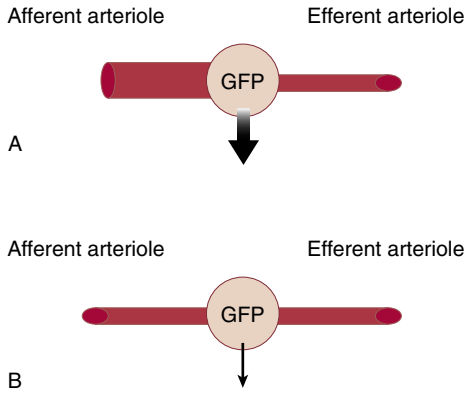

Figure 18-4 Afferent and efferent arteriolar control mechanisms. (*From Sladen RN, Landry D: Renal blood flow regulation, autoregulation, and vasomotor nephropathy. Anesthesiol Clin North Am 18:791-807, ix, 2000.*)

to changes in intraluminal blood pressure. Renin catalyzes the formation of angiotensin, which modulates efferent and afferent arteriolar tone and GFR (see later).

Afferent and Efferent Arteriolar Control Mechanisms

A primary determinant of GFR is the glomerular filtration pressure, which depends not only on the renal artery perfusion pressure but also on the balance between afferent and efferent arteriolar tone. In the presence of decreased afferent arteriolar pressure or blood flow, low levels of catecholamines, angiotensin, and arginine vasopressin (AVP) induce preferential efferent arteriolar constriction, which maintains glomerular filtration pressure (Fig. 18-4A). This is reflected by an increase in calculated filtration fraction (FF), which is the GFR expressed as a fraction of the renal plasma flow (RPF), that is, FF = GFR/RPF. High levels of catecholamines and angiotensin (but not AVP) increase afferent arteriolar tone and decrease glomerular filtration pressure (and GFR) out of proportion to RPF, and FF decreases (Fig. 18-4B).

Tubuloglomerular Feedback

Tubuloglomerular feedback may be a primary mechanism in renal autoregulation.[3] When GFR is increased, distal tubular NaCl delivery is enhanced. The increase in chloride (Cl^-) is sensed by the macula densa, which triggers the release of renin from the adjacent afferent arteriole. Angiotensin is elaborated and arteriolar constriction ensues, which decreases GFR.

When the thick ascending loop becomes ischemic, reabsorption of NaCl ceases, the ability of the tubule to concentrate urine is lost and, theoretically, intractable polyuria should result. Thurau and Boylan[5] suggested that the increased delivery of NaCl to the macula densa triggers angiotensin-mediated arteriolar constriction, which decreases GFR, induces oliguria, conserves intravascular volume, and protects the organism from dehydration—so-called acute renal success.

Renal Autoregulation

Autoregulation enables the kidney to maintain solute and water regulation independently of wide fluctuations of arterial blood pressure. In 1951, the classic dog studies of Shipley and Study[6] demonstrated that the kidney maintains a constant renal blood flow and GFR through an arterial pressure range of 80 to 180 mm Hg (Fig. 18-5). Urinary flow rate is not subject to autoregulation. Tubular water reabsorption determines urinary flow rate and is closely related to the hydrostatic pressure in the peritubular capillaries. Hypotension, whether induced or inadvertent, results in decreased urinary flow rate that may be correctable only when the arterial blood pressure is restored toward normal.

There is considerable evidence to support two major mechanisms for renal autoregulation.[3] As mean arterial pressure decreases, renal vascular resistance decreases and renal blood flow (RBF) is maintained. The most plausible explanation is a myogenic response, that is, the arterioles constrict in response to increased arterial pressure and vice versa. Tubuloglomerular feedback via the juxtaglomerular apparatus also plays a role.[3,4,7] When arterial pressure increases through the autoregulatory range, delivery of sodium chloride is enhanced to the chemosensors of the macula densa, which generate adenosine triphosphate (ATP) and adenosine that stimulate the adenosine A_1 receptor and induce afferent arteriolar constriction (Fig. 18-6). This, in turn, decreases RBF and GFR back to the previous levels. The opposite effect occurs when arterial pressure declines. Local release of nitric oxide attenuates tubuloglomerular feedback, whereas release of angiotensin II enhances it.[4]

Autoregulation is impaired by calcium channel blockade, implying that a calcium-dependent mechanism is involved but not by most anesthetic agents. It is reset in chronic hypertension and may be lost in the diabetic kidney. There is experimental evidence that autoregulation is lost in acute renal failure[8]; in part this may be due to endothelial dysfunction through excessive nitric oxide because inducible nitric oxide synthase is activated by renal ischemia-reperfusion injury.[9] Pressure-dependence of RBF is observed during cardiopulmonary bypass (CPB)[10] and in severe sepsis,[11] but this may simply be due to hypotension below the autoregulatory range, rather than abnormal autoregulation

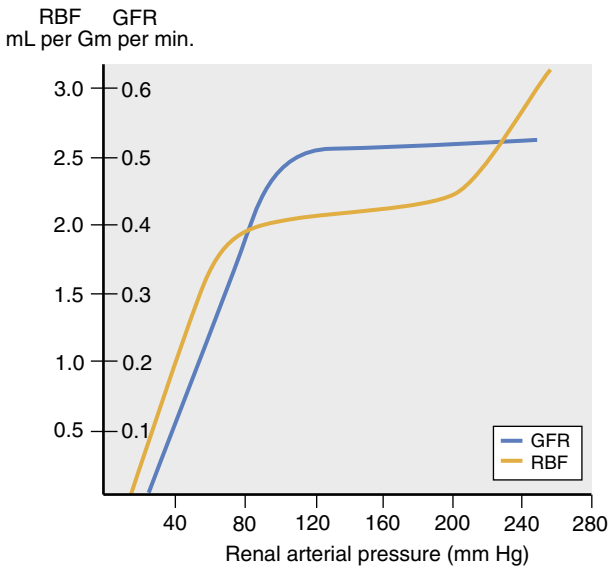

Figure 18-5 Autoregulation of glomerular filtration rate (GFR) and renal blood flow (RBF). GFR and RBF remain constant between renal arterial pressures of 80 and 180 mm Hg. (*Based on the original work of Shipley and Study.*[5] *From Pitts RF: Physiology of the Kidney and Body Fluids. Chicago, Year Book Medical Publishers, 1974.*)

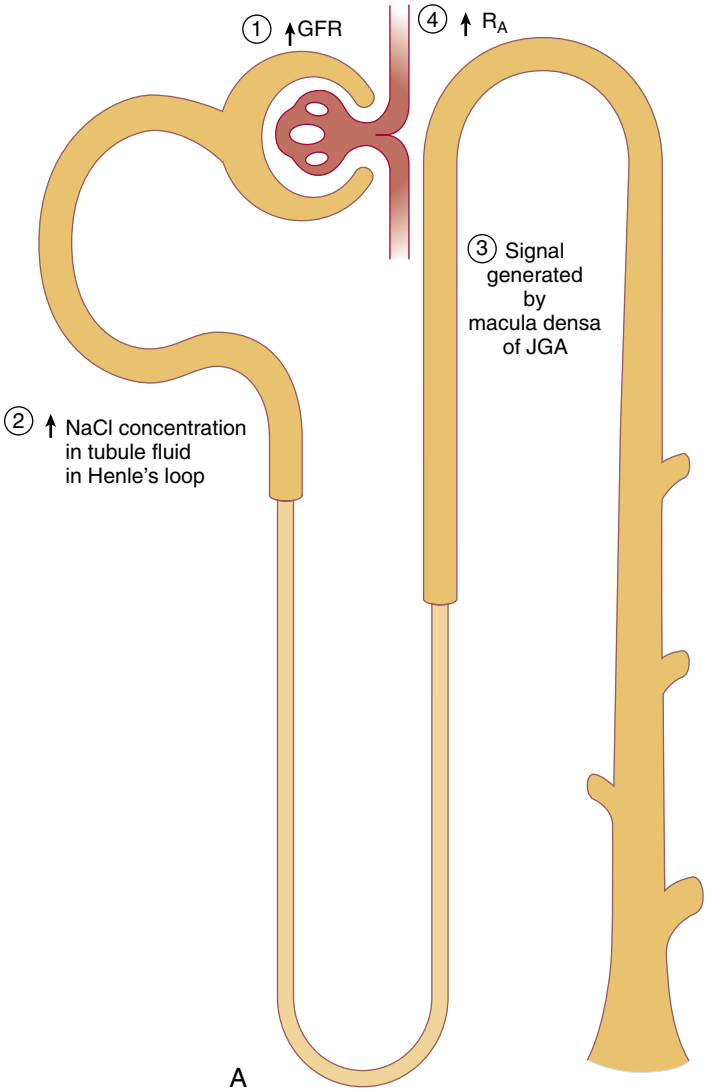

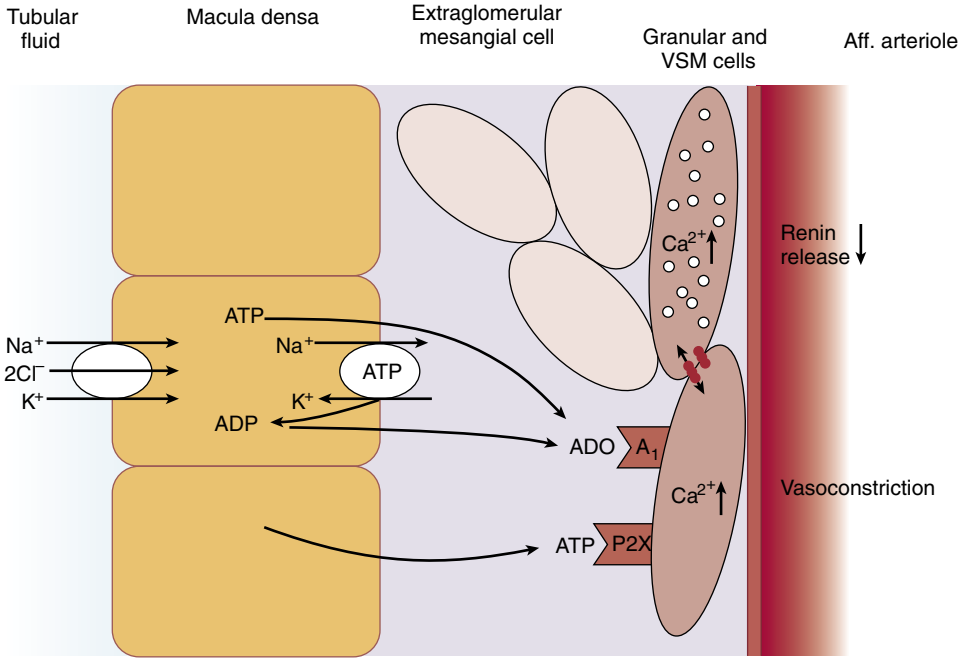

Figure 18-6 **A** and **B,** Tubuloglomerular feedback. An increase in glomerular filtration rate (GFR) (1) increases sodium chloride (NaCl) concentration in the tubular fluid in the loop of Henle. This is sensed by chemosensors in the modified distal tubular cells of the macula densa in the juxtaglomerular apparatus (JGA) (3). The cells of the macula densa generate adenosine triphosphate (ATP) and adenosine (ADO) that induces afferent arteriolar constriction and increases its resistance (R_A) (4). This returns the GFR to its former level. A decline in the GFR has the opposite effect. (*From Koeppen BM, Stanton BA: Glomerular filtration and renal blood flow.* In *Koeppen BM, Stanton BA [eds]: Renal Physiology, 4th ed. Philadelphia, Mosby Elsevier, 2007, pp 31-46.*)

per se. Normalization of renal perfusion pressure improves RBF, even if this is achieved by vasoconstrictor therapy.

The Tubule

The tubule has four distinct segments: the proximal tubule, the loop of Henle, the distal tubule, and the connecting segment. The loop of Henle itself is divided into the pars recta (the straight portion of the proximal tubule), the descending and ascending thin limb segments, and the thick ascending limb. Each distal tubule drains into a collecting duct, which courses through the cortex, outer medulla, and inner medulla before entering the renal pelvis at the papilla (see Fig. 18-1).

There are two populations of nephrons. The cortical nephrons populate the outer and middle renal cortex, are far more numerous, receive about 85% of the renal blood flow, and have short loops of Henle. The juxtamedullary nephrons populate the inner renal cortex, receive about 10% of the RBF, and have larger glomeruli and long loops of Henle, which dive deeply into the inner medulla.[2] Their efferent arterioles drain into elongated vascular conduits, the vasa recta, which are closely applied to the loops of Henle. Although the vasa recta receive less than 1% of the RBF, they play an important role in generating the countercurrent mechanism for medullary hypertonicity and renal concentrating ability (see later).

Tubular Reabsorption and Secretion

The tubule has an enormous capacity for reabsorption of water and NaCl. Each day, 180 L of protein-free glomerular ultrafiltrate is formed, of which almost 99% of the water and 99% of the sodium is reabsorbed.

Many other filtered substances are completely reabsorbed, but some, such as glucose, have a maximum rate of tubular reabsorption (tubular maximum). Tubular reabsorption of glucose increases at a rate equal to that of the filtered load. If the GFR is constant, the rate is directly proportional to the plasma glucose. Once plasma glucose exceeds the tubular maximum (375 mg/dL), no further glucose is reabsorbed and glycosuria results. Thereafter, the amount of glucose excreted in the urine increases in direct proportion to the filtered load.

Many important endogenous and exogenous solutes are secreted into the tubular lumen from the capillary blood. Some also have a tubular maximum for secretion, such as *p*-aminohippurate (PAH), which is used to calculate RPF. There is a striking relationship between the structure and function of the different segments of the tubule (Fig. 18-7). The most metabolically active components of the tubule are the proximal tubule, the thick ascending loop of Henle, and the first part of the distal tubule.

Figure 18-8 illustrates a tubular cell in the thick ascending loop of Henle, which encompasses all the major mechanisms of reabsorption and secretion. From each apical cell membrane pro-

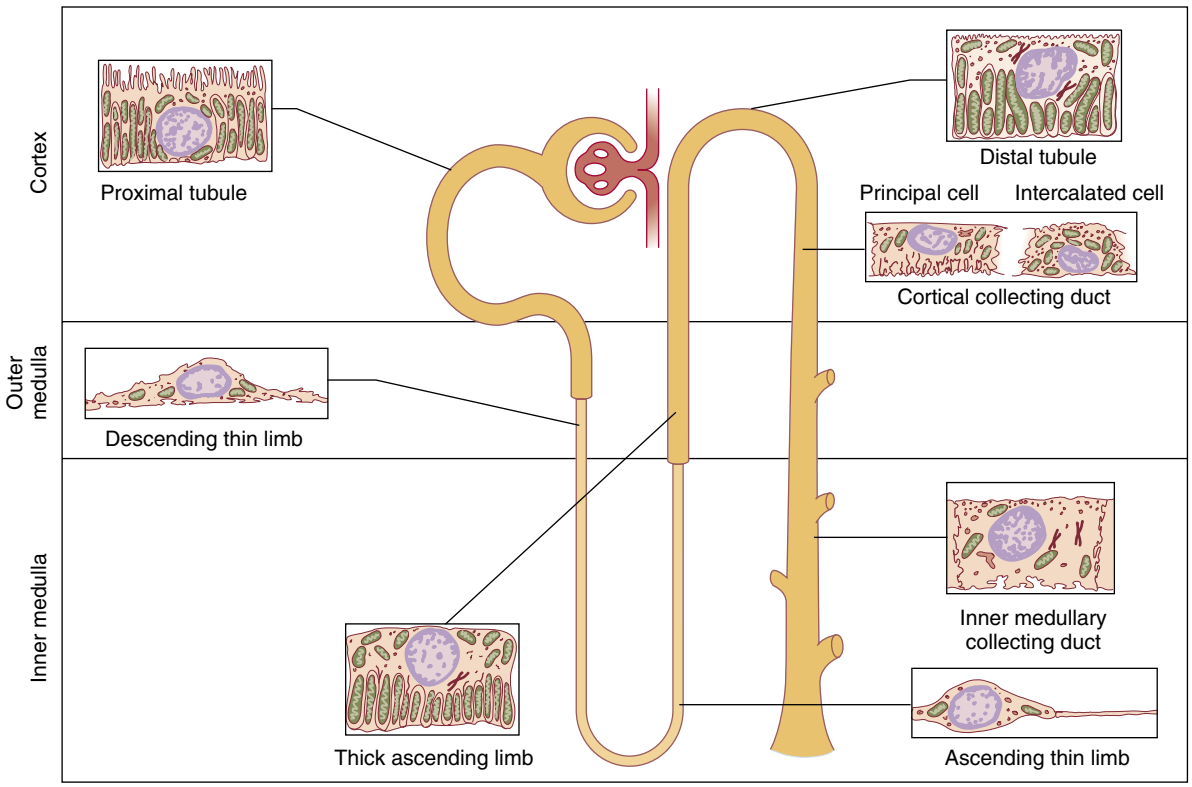

Figure 18-7 Structure-function relationships in the renal tubule. The most metabolically active components of the tubule are the proximal tubule, the thick ascending loop of Henle, and the first part of the distal tubule. Their cells are large, and on the capillary surface (basolateral membrane) there are many invaginations rich in mitochondria. The cells of the proximal tubule have a brush-border on the luminal surface (apical cell membrane), whereas the cells of the descending and thin ascending loops of Henle are flattened with few mitochondria. The second part of the distal tubule and collecting duct are intermediate in nature. The intercalated cells of the distal tubule have many mitochondria; the principal cells are few. (*From Stanton BA, Koeppen BM: Elements of renal function. In Berne RM, Levy MN [eds]: Physiology, 4th ed. St. Louis, Mosby, 1998, pp 677-698.*)

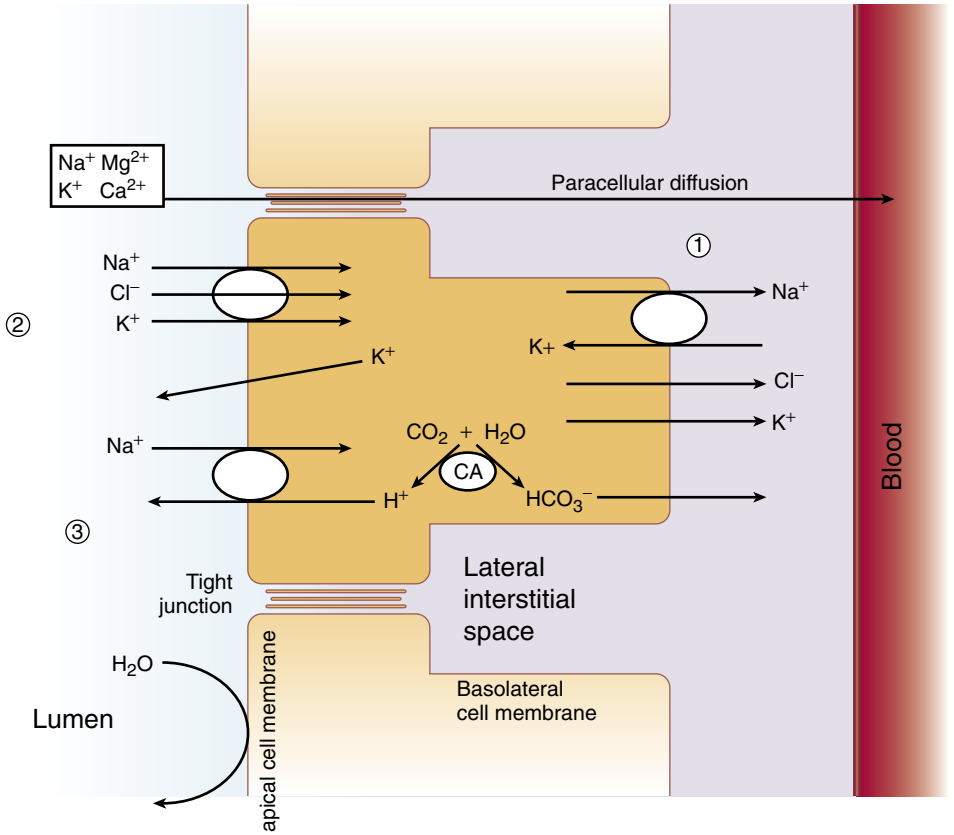

Figure 18-8 Mechanisms of tubular secretion and reabsorption. This tubular cell in the thick ascending loop of Henle encompasses the major mechanisms of secretion and reabsorption, one or more of which is used by various segments of the tubule. The most ubiquitous and important transport mechanism is the energy-requiring Na^+-K^+-ATPase pump in the basolateral cell membrane (1), which pumps sodium out into the interstitium against its concentration gradient and maintains a low intracellular concentration. This favors inward movement of sodium from the tubular lumen, facilitated by a sodium chloride symporter system on the apical cell membrane (2), which creates enough potential energy to draw in potassium against its concentration gradient and which is the primary inhibitory site of action of loop diuretics. An Na^+-H^+ antiporter system on the apical cell membrane (3) aids sodium reabsorption and extrudes H^+, thereby promoting reaction of water with carbon dioxide to form H^+ and HCO_3^- under the influence of carbonic anhydrase (CA). HCO_3^- diffuses out into the capillary. Sodium reabsorption is thereby coupled to H^+ loss and HCO_3^- reabsorption. The transport proteins create a positive charge in the lumen, which drives ions such as sodium, calcium, potassium, and magnesium passively through the tight junctions by paracellular diffusion. The thick ascending loop of Henle is uniquely highly water impermeable so that luminal osmolality progressively falls to less than 150 mOsm/kg (the "diluting segment"). *(Modified from Stanton BA, Koeppen BM: Elements of renal function.* In *Berne RM, Levy MN [eds]: Physiology, 4th ed. St. Louis, Mosby, 1998, pp 677-698.*)

trudes a primary cilium equipped with a flow-sensitive mechanosensor and a chemosensor, both linked to calcium-dependent signaling pathways that control kidney cell function and apoptosis.[1]

There are a number of protein-based active transport systems. Of these, the most important is the sodium-potassium adenosine triphosphatase (Na^+-K^+-ATPase) system, situated in the basolateral membrane. It pumps sodium out of the tubular cell into the interstitial fluid (and capillary blood) against a concentration and an electrical gradient, in exchange for potassium from inside the tubular cell. The consequent decrease in intracellular sodium concentration facilitates passive reabsorption of sodium from the tubular lumen into the cell. The transport of virtually all solutes is coupled to that of sodium.

Active transport systems that move solutes in the same direction into or out of the cell are called symporter systems, whereas those that move solutes in opposite directions are called antiporter systems. Solutes are transported by active and passive mechanisms, but water always diffuses passively along an osmotic gradient.

Proximal Tubule

The first part of the proximal tubule reabsorbs about 100% of the filtered glucose, lactate, and amino acids as well as some phosphate by coupling with sodium-symporter systems.[12] Hydrogen ions are extruded into the tubule by an Na^+/H^+ antiporter system in exchange for bicarbonate. The absorption of organic anions and bicarbonate in the first part of the proximal tubule results in a relatively high chloride concentration downstream, promoting passive ingress of chloride. This leaves the tubular fluid positively charged relative to blood, further promoting the movement of sodium from the tubular fluid into the cell.

Most NaCl is absorbed transcellularly by an Na^+/H^+ and chloride-based antiporter system in the apical cell membrane. The Na^+/K^+-ATPase system pumps sodium into the interstitial space, and a K^+/Cl^- symporter system pumps chloride. The resulting increase in osmolality draws water across as well. In all, about two thirds of the filtered water, chloride, and potassium are reabsorbed by the proximal tubule, coupled with, and strongly influenced by, sodium absorption.[12]

The proximal tubule is also an important site of secretion of many endogenous anions (bile salts, urate), cations (creatinine,

dopamine), and drugs (diuretics, penicillin, probenecid, cimetidine). Organic ions compete with each other for protein transport systems. Thus, administration of probenecid impairs tubular secretion of penicillin and prolongs its action. In chronic renal insufficiency there is an accumulation of organic acids that competes with drugs such as furosemide for secretor proteins, thereby conferring an apparent "resistance" to loop diuretics.

Thick Ascending Loop of Henle

The metabolically active component of the loop of Henle is the thick ascending loop, which reabsorbs about 20% of the filtered sodium, chloride, potassium, and bicarbonate. Only the descending loop is permeable to water. In the water-impermeable thick ascending loop, sodium is actively reabsorbed, but water remains. In this so-called diluting segment of the kidney, tubular fluid osmolality decreases to less than 150 mOsm/kg H_2O.

As in the proximal tubule, the Na+/K+-ATPase pump in the basolateral membrane is the engine that drives the resorptive capacity of the thick ascending loop.[12] Sodium moves from the tubular lumen by passive diffusion along its concentration gradient. An Na^+/H^+ antiporter system in the apical cell membrane mediates the net secretion of H^+ and reabsorption of bicarbonate.

An important symporter protein system couples the reabsorption of sodium, chloride, and potassium (the latter against its concentration gradient) across the apical membrane. Blockade of this system is the major site of action of loop diuretics in inhibiting NaCl reabsorption in the thick ascending loop of Henle.

Oxygen Balance in the Medullary Thick Ascending Loop

The kidneys receive 20% of the total cardiac output but extract relatively little oxygen. The renal arteriovenous oxygen difference $[(a\text{-}v)O_2]$ is only 1.5 mL/dL. However, there is a marked discrepancy between the renal cortex and medulla with regard to blood flow, oxygen delivery, and oxygen consumption (Fig. 18-9 and Table 18-1). The medulla receives only 6% of the RBF and has an average oxygen tension (Po_2) of 8 mm Hg. Thus, it is possible that severe hypoxia could develop in the medulla despite a relatively adequate total RBF, and the metabolically active medullary thick ascending loop of Henle is particularly vulnerable.[13]

Table 18-1 Distribution of Renal Blood Flow Between Cortex and Medulla

	Cortex	Medulla
Percent of renal blood flow	94	6
Blood flow (mL/min/g)	5.0	0.03
Po_2 (mm Hg)	50	8
O_2 extraction ratio (Vo_2/Do_2)	0.18	0.79

The renal medulla receives only a small fraction of the total renal blood flow, and flow rates are extremely slow. As a result, the tissue oxygen tension is extremely low and the medulla extracts almost 80% of the oxygen delivered to it. A very mild reduction in total and cortical renal blood flow may therefore induce ischemia and hypoxia in the renal medulla.
Do_2, oxygen delivery; O_2, oxygen; Vo_2, oxygen consumption; Po_2, oxygen tension.
Data from Brezis M, et al: The pathophysiological implications of medullary hypoxia. Am J Kidney Dis 13:253-258, 1989.

The medullary thick ascending loop is also a potential site for nephrotoxic injury. Intrarenal blood flow is regulated by endogenous vasoactive compounds. In the outer cortex, at variance to its vasodilator actions elsewhere, adenosine induces vasoconstriction by stimulation of the adenosine A_1 receptor. In the deep juxtamedullary zone, endogenous prostaglandins and nitric oxide promote vasodilation. The net effect is to direct as much available blood flow to the medulla as possible. Drugs that inhibit prostaglandin synthesis, such as nonsteroidal anti-inflammatory agents (NSAIDs), can upset this compensatory mechanism and result in medullary ischemia.

Stress (pain, trauma, hemorrhage, hypoperfusion, sepsis, congestive heart failure) activates the sympathoadrenal system and results in renal cortical constriction and potential tubular ischemia. The kidney is relatively devoid of β_2-receptors so epinephrine release induces predominant vasoconstriction through α-receptor or angiotensin activation.

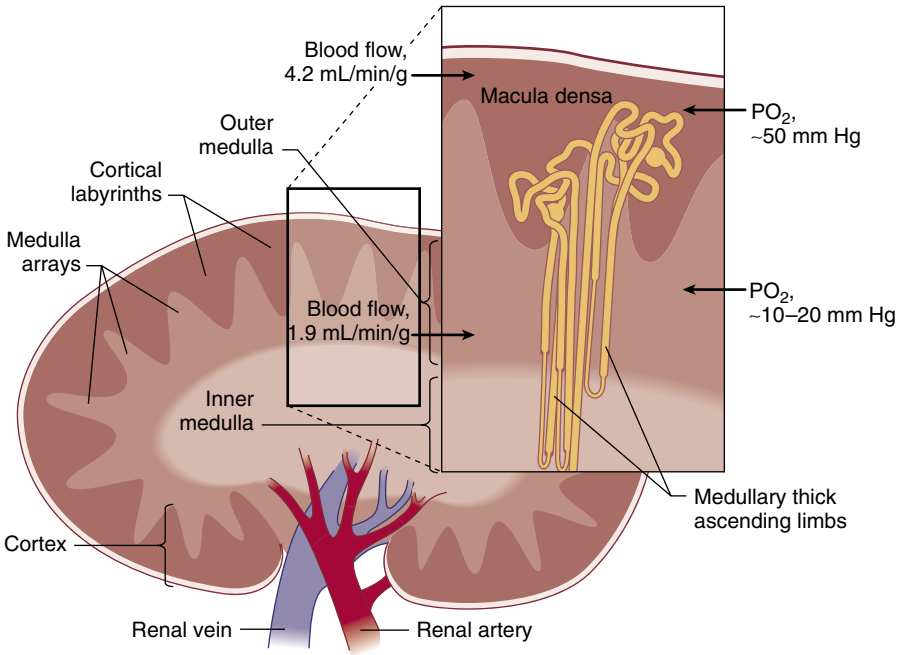

Figure 18-9 Medullary oligemia. To generate and maintain the countercurrent exchange that provides urinary concentrating ability, medullary blood flow must be slow. The juxtamedullary and medullary regions are zones of low blood flow and relative tissue hypoxia. Components of the nephron that have high oxygen consumption such as the medullary thick ascending limb (mTAL) are at high risk of oxygen supply-demand imbalance and ischemic injury. (*From Brezis M, Rosen S: Hypoxia of the renal medulla—its implications for disease. N Engl J Med 332:647-655, 1995.*)

In hemodynamically mediated renal injury, the initial response to renal hypoperfusion is increased active NaCl absorption in the thick ascending limb. This increases oxygen consumption in the presence of decreased oxygen delivery. Subsequent sympathoadrenal responses and renal cortical vasoconstriction may be a compensatory attempt to redistribute blood flow to the medulla. Ultimately, ATP stores become depleted and active NaCl reabsorption winds down. This increases the NaCl concentration in tubular fluid reaching the macula densa in the distal tubule, resulting in angiotensin release and afferent arteriolar constriction (i.e., tubuloglomerular feedback). Teleologically, the resultant decrease in GFR benefits renal oxygen balance by decreasing solute reabsorption and oxygen consumption in the medullary thick ascending loop of Henle.[13]

This hypothesis implies that ischemic or nephrotoxic insults to the renal tubules could be alleviated by the administration of loop diuretics or dopaminergic agents. These drugs inhibit active sodium reabsorption in the thick ascending limb, thereby decreasing oxygen consumption and enhancing tubular oxygen balance.

Distal Tubule and Collecting Duct

Sodium reabsorption is mediated by an apical cell membrane NaCl symporter system, which is the site of action of thiazide diuretics.[12] The last part of the distal tubule is composed of two types of cells. Principal cells reabsorb sodium and water and secrete potassium via the Na^+/K^+-ATPase pump, and intercalated cells secrete H^+ and reabsorb bicarbonate by an H^+-ATPase pump in the apical cell membrane.

Regulatory Mechanisms in Salt and Water Reabsorption

Osmotic Equilibrium

The ability of the kidney to concentrate urine is dependent on the interaction of at least three processes: (1) the generation of a hypertonic medullary interstitium by the countercurrent mechanism and urea recycling, (2) concentration and then dilution of tubular fluid in the loop of Henle, and (3) the action of antidiuretic hormone (now known as arginine vasopressin [AVP]) in increasing water permeability in the last part of the distal tubule and collecting ducts.

The medullary interstitium is rendered hypertonic by the countercurrent multiplier effect of the loop of Henle. The primary mechanism is the separation of solute from water (the single effect) by the combination of NaCl reabsorption and water impermeability in the ascending limb. This results in increased NaCl concentration and osmolality in the medullary interstitium. The descending limb is freely permeable to water, which diffuses into the interstitium along the osmotic gradient; and the tubular fluid becomes progressively hyperosmotic at the bend of the loop.

The vasa recta, which are closely applied to the long loops of Henle of juxtamedullary nephrons, maintain this condition by removing water and adding solute as they pass through the medullary interstitium. A standing osmotic gradient is thereby set up between the cortex (300 mOsm/kg), juxtamedullary zone (600 mOsm/kg), and deep medulla (1200 mOsm/kg). This process is enhanced by the passive recycling of urea, which diffuses out of the inner medullary collecting duct into the interstitium and thence into the distal loop of Henle. These processes are summarized in Figure 18-10.

Tubular Concentration and Dilution

Hypovolemia

Contraction of the extracellular volume (hypovolemia) activates a series of vasoconstrictor, salt-retaining neurohormonal systems: the sympathoadrenal system, the renin-angiotensin-aldosterone axis, and AVP. Initially, the GFR and filtered load of sodium decrease. Sodium reabsorption in the proximal tubule is increased from about 66% to 80% by sympathetic activity and angiotensin II as well as by the decline in peritubular capillary pressure induced by renal vasoconstriction. Sodium delivery to the thick ascending loop of Henle, distal tubule, and collecting duct is decreased, but aldosterone promotes reabsorption of sodium at these sites. Under the influence of AVP, water is also avidly reabsorbed in the collecting duct so that the urine becomes highly concentrated (osmolality, 600 mOsm/kg) but with virtually no sodium (10 mEq/L).

Diuretics abolish the kidney's ability to concentrate urine by washing out the hypertonic medulla. They do this either by an osmotic effect that prevents water reabsorption (e.g., mannitol) or by inhibition of active NaCl transport in the thick ascending loop (e.g., furosemide) or the first part of the distal tubule (e.g., hydrochlorothiazide). An early and important manifestation of acute tubular necrosis is the loss of urinary concentrating ability caused by the breakdown of the energy-requiring Na^+/K^+-ATPase pump in the thick ascending loop of Henle.

Hypervolemia

Expansion of the extracellular volume or hypervolemia is controlled by a series of vasodilator, salt-excreting neuropeptides, of which atrial, or A-type, natriuretic peptide (ANP) is predominant. The GFR and filtered sodium load increase because of a combination of reflex decreases in sympathetic and angiotensin II activity and the release of ANP. Together with the increase in peritubular capillary hydrostatic pressure, these responses cause sodium reabsorption in the proximal tubule to decrease from 67% to 50%. The decline in plasma aldosterone decreases sodium absorption from the thick ascending loop of Henle to the collecting duct. The presence of ANP and absence of AVP impairs water absorption at the collecting duct so that dilute urine (osmolality, 300 mOsm/kg) with abundant sodium (80 mEq/L) is produced.

Loop diuretics, which depress tubular resorptive capacity, and acute tubular necrosis, which abolishes it completely, may generate an identical urinary profile (low osmolality, high urinary sodium) even in the presence of hypovolemia.

Evaluation of Renal Function

Clinical Markers of Renal Function

Urine Output

Perioperative oliguria is common, is almost always prerenal, and rarely implies acute renal failure. On the other hand, the absence of oliguria does not exclude it. Perioperative oliguria is defined as a urine flow rate less than 0.5 mL/kg/hr and is often interpreted as a sign of renal dysfunction. However, in the perioperative

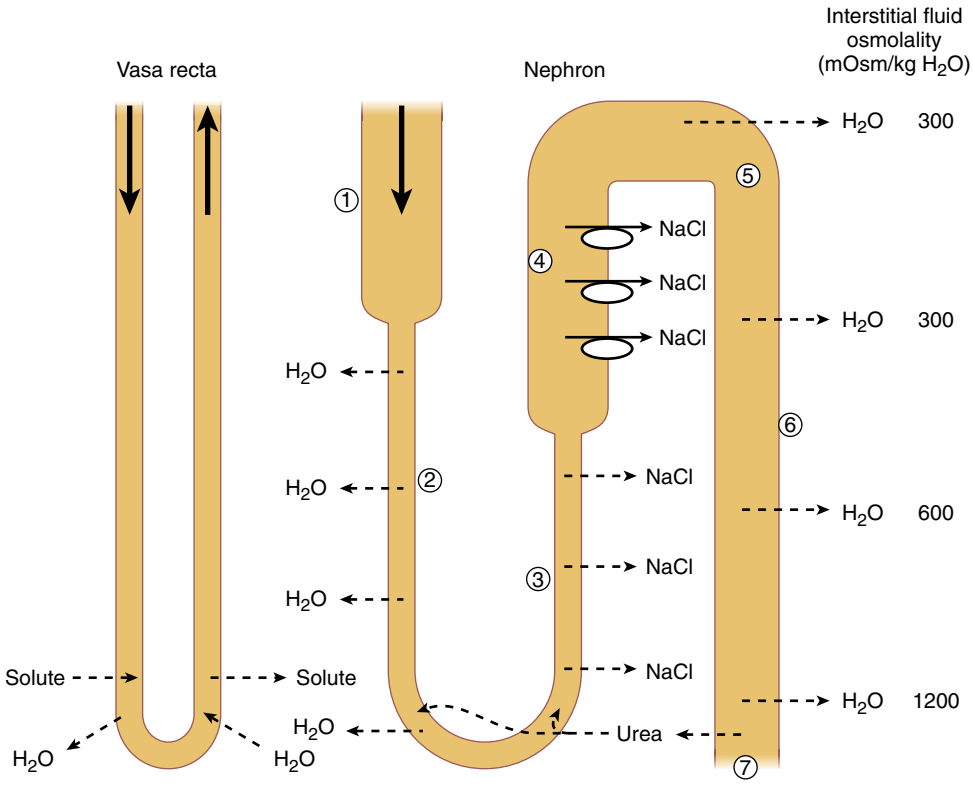

Figure 18-10 Tubular concentration of urine. The juxtamedullary nephrons have long loops of Henle associated with the vasa recta. *Dashed arrows* represent passive movement of fluid or solutes along concentration or osmolar gradients; *solid arrows* represent active transport. (1) Tubular fluid enters the distal proximal tubule iso-osmotic with plasma (300 mOsm/kg). In the descending limb of Henle (2), water rapidly diffuses out into the increasingly hypertonic medulla and is removed by the vasa recta so that the tubular fluid becomes hypertonic, owing largely to concentration of sodium chloride (NaCl). Urea diffuses in from the hypertonic interstitium, further increasing tubular fluid osmolality (1200 mOsm/kg). In the thin ascending loop of Henle (3), NaCl passively diffuses into the interstitium along its concentration gradient but water is trapped in the water-impermeable tubule, which progressively decreases tubular fluid osmolality. Urea passively diffuses into the tubular fluid (urea recycling). Tubular dilution is accelerated by active reabsorption of NaCl in the thick ascending loop (the diluting segment) and proximal distal tubule (4). The fluid entering the distal tubule is quite hypo-osmotic (100 mOsm/kg). In the collecting segment (5), the osmolality of the tubular fluid returns to that of plasma (300 mOsm/kg) but, unlike the contents of the proximal tubule, the solute component consists largely of urea, creatinine, and other excreted compounds. Increased plasma antidiuretic hormone renders the cortical and medullary collecting ducts (6) permeable to water, which passively diffuses into the hypertonic medullary interstitium. Even though some urea diffuses out into the medulla, the maximal osmolality of concentrated urine (7) approaches that of the hypertonic medullary interstitium, about 1200 mOsm/kg. In the absence of antidiuretic hormone, the collecting ducts remain impermeable to water and the urine is diluted. (*From Stanton BA, Koeppen BM: Control of body fluid osmolality and volume.* In *Berne RM, Levin HR [eds]: Physiology, 4th ed. St. Louis, Mosby, 1998, pp 715-743.*)

period, oliguria is almost inevitable. It is induced by hypotension, occurs as an (appropriate) prerenal response to intravascular hypovolemia, or is a manifestation of the physiologic response to surgical stress[14] (see "Neurohormonal Regulation of Renal Function").

Complete, often abrupt cessation of urine flow suggests a postrenal obstruction, which could occur at the level of the renal pelvis, ureters, bladder, urethra, or urinary catheter. However, subtotal obstruction may also develop into acute renal failure even though urine flow persists, albeit at a decreased rate.

Urine flow rate is an unreliable marker of acute renal failure and may vary from anuric (zero flow), to oliguric (urinary flow rate <15 mL/hr), to nonoliguric (15-80 mL/hr), to polyuric (>80 mL/hr). An attempt has been made to unify the definition of acute kidney injury by the RIFLE criteria, based on changes in serum creatinine and urine flow.[15] The first three categories (Risk, Injury, Failure) are defined in part by oliguria (<0.5 mL/kg/hr) for 6, 12, and 24 hours, respectively. However, this does not take into consideration that nonoliguric renal failure is the most common manifestation of perioperative acute kidney injury.

Blood Urea Nitrogen

Urea is continuously formed by the metabolism of ammonia in the liver. Hepatic deamination implies the splitting off of amide ($-NH_2$) groups from amino acids, and their conversion to ammonia, which enters the arginine cycle and is converted to urea. Urea nitrogen is a small, uncharged molecule, not protein bound, that is rapidly cleared from the blood by glomerular filtration. It subsequently undergoes reabsorption by the tubules so the blood urea nitrogen (BUN) does not correlate directly with GFR.

The normal range of BUN is 5 to 10 mg/dL; given the normal range of serum creatinine (0.5-1.0 mg/dL), the normal ratio of BUN to serum creatinine is about 10:1. An increase in BUN to serum creatinine ratio of greater than 20:1 implies the existence of a prerenal syndrome (prerenal azotemia). However, elevation of BUN out of proportion to decreases in GFR occurs whenever there is increased protein catabolism and formation of urea nitrogen. This scenario occurs with absorption of blood from the gastrointestinal tract, corticosteroid therapy, major trauma, and sepsis. In contrast, the BUN may be misleadingly low

when its production is impaired by severe malnutrition (protein depletion) or severe liver disease (inability to convert ammonia to urea).

Serum Creatinine

Serum creatinine reflects the balance between creatinine production by muscle and creatinine excretion by the kidney, which is dependent on the GFR. Creatinine generation rate varies with muscle mass, physical activity, protein intake, and catabolism. However, when these processes are in equilibrium and renal function is stable, serum creatinine is a useful marker of GFR.

The relationship between serum creatinine and GFR is inverse and exponential. A doubling of the serum creatinine concentration implies a halving of the GFR. An increase in the serum creatinine value from 0.8 to 1.6 mg/dL may not generate much attention, but it indicates a 50% decrease in GFR. A much larger increase from 4 to 8 mg/dL also represents a 50% decrease in GFR, but by this time renal insufficiency is well established (Fig. 18-11). After a transient renal insult (e.g., suprarenal aortic cross-clamping), the serum creatinine level may increase for a few days while GFR is actually recovering. In oliguric acute renal failure, the serum creatinine value is directly proportional to the creatinine generation rate. Creatinine clearance is reliably low but is associated with a wide variability of serum creatinine concentration.

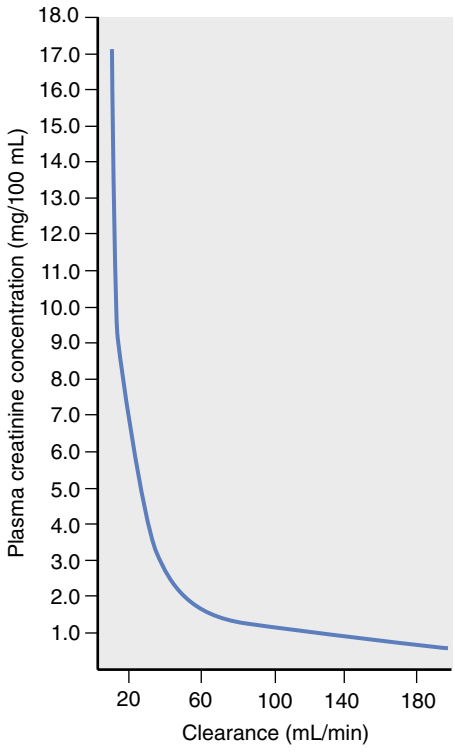

Figure 18-11 Relationship between serum creatinine and GFR. The relationship between serum creatinine and GFR as measured by creatinine clearance is reciprocal and exponential. Doubling of the serum creatinine corresponds to halving of the GFR. Relatively large declines in GFR from normal are associated with small increases in serum creatinine until GFR decreases below 60 mL/min; further decrements are associated with large increases in serum creatinine. (*From Alfrey AC, Chan L: Chronic renal failure: Manifestations and pathogenesis.* In *Schrier RW [ed]: Renal and Electrolyte Disorders, 4th ed. Boston, Little, Brown, 1992, p 541.*)

Limitations to Serum Creatinine as a Reflection of GFR

Serum creatinine is usually measured by the Jaffé reaction, a chromogenic assay based on the red color of the creatinine complex with alkaline picrate. It also picks up other normally occurring chromogens, such as glucose, protein, ketones, and ascorbic acid, which represent about 14% of total creatinine when renal function is normal, although substantially less when the serum creatinine level is elevated. Ketoacidosis, barbiturates, and cephalosporin antibiotics may artifactually increase the serum creatinine level by as much as 100%, and cimetidine and trimethoprim block its secretion by the tubule. *N*-acetylcysteine, an antioxidant advocated as a renoprotective agent in contrast nephropathy,[16] decreases serum creatinine levels, which may in part account for its apparently beneficial effect on renal function.[17]

The serum creatinine concentration does not increase above the normal range until the GFR declines below 50 mL/min, and large declines in GFR may occur above this level without a concomitant increase in the serum creatinine value. The creatinine generation rate is relatively consistent in a given individual, but it varies with muscle mass, rate of catabolism, physical activity, and protein intake.[18] In a cachectic patient with very low muscle mass, creatinine generation may be so feeble that the serum creatinine level remains "normal" (<0.9 mg/dL) even in the presence of a GFR less than 25 mL/min. The GFR declines progressively and predictably with age, from about 125 mL/min in a healthy 20-year old to about 60 mL/min in an 80-year old (or a 60-year old with atherosclerosis). Because these changes occur at a GFR greater than 50 mL/min, the impairment induced by aging is not reflected by the serum creatinine concentration.

Creatinine is soluble, freely distributes through the total body water, and is diluted by the 10% to 15% increases in total body water that occur with fluid administration and retention during major surgery. It is not uncommon for the serum creatinine concentration to be decreased from baseline on the first postoperative day (e.g., 1.5 to 1.2 mg/dL). Subsequently, when total body water is decreased by fluid mobilization and diuresis, the serum creatinine value increases (e.g., from 1.2 to 1.5 mg/dL). This does not necessarily imply acute kidney injury and a decline in GFR but may simply represent hemoconcentration and a re-equilibration to baseline.

Serum creatinine is a useful marker of stable renal function, but it is unreliable when GFR is rapidly changing.[18] If there are no changes in its volume of distribution (see earlier), the serum creatinine concentration represents an equilibrium between the creatinine generation rate, dependent on muscle mass and catabolic activity, and the creatinine excretion rate, dependent on (and reflective of) the GFR. An intervention such as suprarenal aortic cross-clamping causes instantaneous cessation of renal blood flow, GFR, and urinary creatinine excretion. However, measured serum creatinine would still be at baseline and would not detectably increase for several hours. Because it may take up to 48 hours for GFR to return to baseline, in the postoperative period the serum creatinine value may still increase for a few days while GFR is actually recovering.

Cystatin C

There is great interest in defining endogenous plasma markers that provide a more reliable, early indicator of changing GFR, especially in acute kidney injury.[19] One that has received prominence is cystatin C, a cysteine-protease inhibitor that is released into the circulation by all nucleated cells. It is completely filtered

by the glomerulus and not secreted by the tubular epithelium so that its serum levels bear a close relationship to serum creatinine, and thereby GFR.[20] Unlike creatinine, however, serum cystatin C is not affected by muscle mass, age, or gender and in certain clinical situations appears to be a more accurate predictor of low GFR than serum creatinine does.[21,22] However, there is also evidence that factors such as cigarette smoking, inflammation (elevated C-reactive protein), and immunosuppressive therapy affect cystatin C levels independently of GFR.[23] At this stage, cystatin C remains an investigational marker and has not supplemented serum creatinine in clinical practice.

Assessment of Glomerular Filtration Rate

Serum Creatinine–Based Nomograms

In clinical investigation, nomograms based on population studies are commonly used to estimate GFR while avoiding the necessity of a timed urine collection. One example is that formulated by Cockroft and Gault utilizing age, weight, serum creatinine concentration, and gender:

$$\mathrm{GFR}\left(\text{in mL/min}\right)=\left(140-\text{age}\right)\times\text{weight in kg}/\text{serum creatinine}\times 72$$

For females, the result is multiplied by 0.85 to obtain the derived GFR.

In this formula, the body weight that is used may substantially alter the derived GFR. In obese or edematous patients, the total body weight is much greater than the lean body mass from which creatinine is derived, and GFR is overestimated. In cachectic patients with depleted lean body mass, creatinine production is so low that serum creatinine is frequently less than 1.0 mg/dL and overestimates the true GFR. Robert and associates[24] adjusted the Cockroft-Gault equation to incorporate ideal body weight from a nomogram and serum creatinine concentration corrected to 1.0 mg/dL (if < 1.0 mg/dL). Using this modification they found that single measurements in hemodynamically stable patients correlate more closely with inulin clearance than either a 30-minute or a 24-hour creatinine clearance.

A more complex nomogram, based on a study called Modification of Diet in Renal Disease (MDRD),[25] is independent of body weight:

$$\mathrm{GFR}\left(\text{in mL/min}\right)=170\times\text{serum creatinine}^{-0.999}\times\text{age}^{-0.176}\times\text{BUN}^{-0.170}\ \text{albumin}^{0.318}$$

For females, the derived GFR is multiplied by 0.762; and for black patients, by 1.18.

When renal function is rapidly changing, serum creatinine–based nomograms are subject to the same limitations as serum creatinine itself. In fact, serum creatinine levels do not begin to increase above normal until the GFR declines below 50 mL/min/1.73 m^2, and occasionally they will remain normal even when the GFR dips as low as 20 to 40 mL/min/1.73 m^2.

Renal Clearance Techniques

Clearance is the most commonly used technique to estimate GFR, using compounds that are predominantly filtered by the glomerulus and neither secreted nor reabsorbed by the renal tubules.[26]

Based on the Fick principle, the amount of substance *x* excreted by the kidney equals the amount delivered in the arterial supply minus the amount in the venous return:

$$\text{Excretion}_x=\text{delivery}_x-\text{return}_x$$

Therefore,

$$\text{Delivery}_x=\text{return}_x+\text{excretion}_x$$

The amount of substance *x* delivered to the kidney is the product of the arterial plasma concentration (Pa_x) and RBF. The amount returning from the kidney is the product of the venous plasma concentration (Pv_x) and RBF. The urinary excretion rate of substance *x* is the product of its urinary concentration (U_x) and the urine flow rate in milliliters per minute (V).

Therefore,

$$\left(\mathrm{Pa}_x\cdot\ \mathrm{RBF}\right)=\left(\mathrm{Pv}_x\cdot\ \mathrm{RBF}\right)+\left(\mathrm{U}_x\cdot\ \mathrm{V}\right)$$

However, in practice, RBF and venous return are not measured. Instead, the removal of substance *x* from the plasma by the kidney is expressed in the concept of clearance. Clearance (C) is defined as the virtual volume of plasma cleared of substance *x* per unit time, in milliliters per minute. This allows the urinary excretion rate of *x* to be equated to its renal arterial plasma concentration:

$$\mathrm{Pa}_x\cdot\ \mathrm{C}=\mathrm{U}_x\cdot\ \mathrm{V}$$

If the assumption is made that the concentration of *x* in renal arterial and venous plasma is identical, the clearance of substance *x* may be calculated using a urine sample, arm venous sample, and measured urinary flow rate:

$$\mathrm{C}_x\cdot\ =\mathrm{U}_x\cdot\ \mathrm{Pa}_x/\mathrm{V}$$

Inulin Clearance

Inulin is an inert polyfructose sugar that is completely filtered by the glomerulus and is neither secreted nor reabsorbed by the renal tubules. The volume in milliliters of plasma cleared of inulin per minute represents the GFR (in mL/min). After an intravenous loading dose of 30 to 50 mg/kg, a continuous infusion of inulin is given to establish a steady-state plasma concentration of 15 to 20 mg/dL. The bladder is usually flushed with air to eliminate any pooled urine. After a carefully timed urine collection (which can be as short as 30 minutes), urine and plasma inulin concentration (U_{IN}, P_{IN}) are measured and inulin clearance (C_{IN}) is calculated:

$$\mathrm{GFR}=\mathrm{C}_{\mathrm{IN}}=\mathrm{U}_{\mathrm{IN}}\cdot\ \mathrm{V}/\mathrm{P}_{\mathrm{IN}}$$

Normal values for inulin clearance are 110 to 140 mL/min/1.73 m^2 (males) and 95 to 125 mL/min/1.37 m^2 (females).

Although inulin clearance is the "gold standard" for measurement of GFR, it is seldom used clinically because its accurate measurement is laborious and requires meticulous attention to detail. Large changes in blood glucose during the test may interfere with its measurement. The predicted variability of inulin clearance is 20% when measurements are compared at two different times in the same individual and 40% when measurements are compared between two individuals.[26]

Sodium iothalamate, a radiocontrast dye, has been substituted for inulin and facilitates accurate assessment of rapid changes in GFR in acute kidney injury.[27]

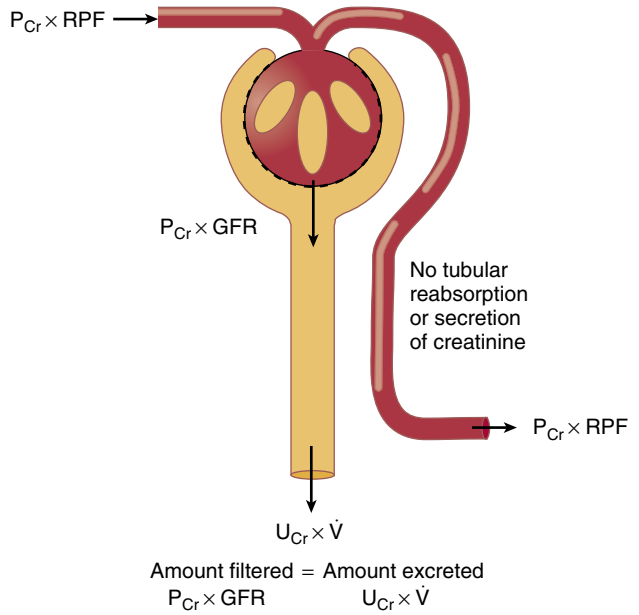

Figure 18-12 Renal handling of creatinine. Creatinine is freely filtered by the glomerulus and there is normally an inconsequential amount secreted or reabsorbed by the tubules. Thus, the amount of creatinine filtered is equivalent to the amount excreted in the urine. For a more detailed explanation, see text. P_{Cr}, plasma creatinine concentration; RPF, renal plasma flow; U_{Cr}, urinary concentration of creatinine; V, urine flow rate. (*From Koeppen BM, Stanton BA: Glomerular filtration and renal blood flow In Koeppen BM, Stanton BA [eds]: Renal Physiology, 4th ed. Philadelphia, Mosby Elsevier, 2007, pp 31-46.*)

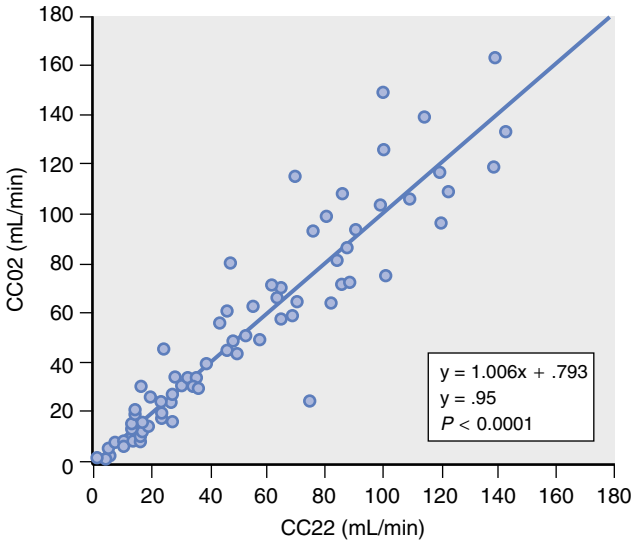

Figure 18-13 Creatinine clearance: 2-hour versus 22-hour values. There is a close and significant correlation in creatinine clearance estimation from a 2-hour and a 22-hour urine collection. CC02, 2-hour urine collection; CC22, 22-hour urine collection. (*From Sladen RN, Endo E, Harrison T: Two-hour versus 22-hour creatinine clearance in critically ill patients. Anesthesiology 67:1013-1016, 1987.*)

Creatinine Clearance

Creatinine, the endogenous end product of creatine phosphate metabolism, is normally generated from muscle at a very uniform rate and is handled by the kidney in a manner similar to that of inulin (Fig. 18-12). Thus, creatinine clearance (C_{CR}) provides a simple, inexpensive bedside estimate of GFR. A single blood sample is drawn at the midpoint of a carefully timed urine collection, and urine and plasma creatinine (U_{CR}, P_{CR}) and urinary flow rate in mL/min (V) are used to calculate GFR:

$$GFR = C_{CR} = U_{CR} \cdot V/P_{CR}$$

The creatinine clearance is far more accurate in tracking rapid alterations in GFR than the serum creatinine alone, because changes in GFR immediately alter the *creatinine excretion rate,* which is incorporated into the equation above as $U_{CR} \times V$.

The precise timing, not the duration, of the urine collection is the critical issue. If a brisk urine flow is induced by diuresis, and care is taken to empty the bladder, the variability of creatinine clearance is no greater with a 1-hour urine collection than with a 24-hour collection. In catheterized patients with urine flow rates of more than 15 mL/hr, creatinine clearance obtained with a 2-hour urine collection gives values equivalent to those obtained with a 22-hour collection.[28] In the previous example, a 2-hour creatinine clearance obtained at the beginning and end of the 24-hour period would truly reflect the halving of GFR represented by a doubling of the serum creatinine value from 1 to 2 mg/dL. In critically ill patients, a changing GFR can be closely tracked by serial estimations of using a short, carefully timed urine collection (Figs. 18-13 to 18-15). In trauma patients, a 1-hour creatinine clearance of less than 25 mL/min determined within 6 hours of surgery reliably predicted postoperative acute renal failure, despite the absence of oliguria.[29]

There is considerable variation in the normal range of creatinine clearance. Tobias and associates reported a variation in creatinine clearance between 88 and 148 mL/min and in serum creatinine concentration between 0.9 and 1.5 mg/dL in a single healthy individual over 5 years. There is also a diurnal variation, with higher values in the afternoon and a variance of up to 25% around mean values. It is prudent to obtain short-collection creatinine clearance estimations at the same time each day to minimize diurnal variability. "Normal" creatinine clearance is related to body surface area and weight, so values may fluctuate widely in patients with cachexia or edema.

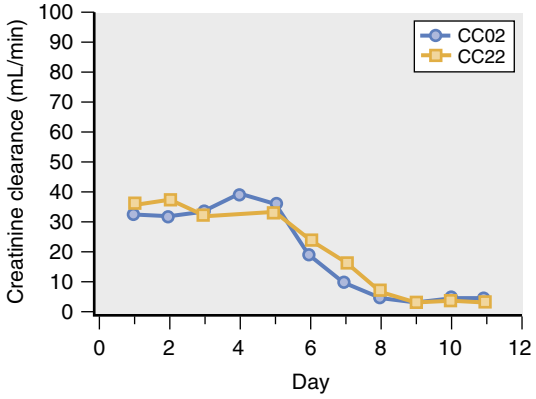

Figure 18-14 New-onset acute renal failure. In a patient developing acute renal failure in the intensive care unit, the exponential decline in creatinine clearance is tracked equally well whether a 2-hour (CC02) or a 22-hour (CC22) urine collection is used. However, data from the 2-hour collection are available well before those from the 22-hour collection.

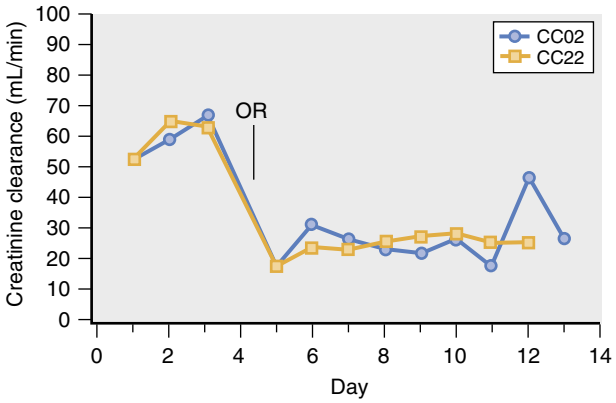

Figure 18-15 Renal revascularization. A patient with renovascular hypertension and renal insufficiency was admitted to the intensive care unit for preoperative monitoring and stabilization. Bilateral renal revascularization was performed, and after return from the operating room there was a substantial decline in renal function. These changes were tracked equally well by creatinine clearance derived from a 2-hour (CC02) and a 22-hour (CC22) collection.

Creatinine clearance has a number of inherent limitations even if collection error is carefully avoided. First, it is subject to many of the limitations imposed by the measurement of creatinine itself (see earlier). Unlike inulin, about 20% of creatinine is secreted by the proximal tubule, so that creatinine clearance overestimates GFR, and the ratio between the clearance of creatinine and inulin is 1.2:1. As the GFR declines, tubular secretion of creatinine increases. When GFR is less than 40 mL/min/1.73 m^2, a creatinine:inulin clearance ratio as high as 1.81 to 2.51 may be achieved. In patients with normal renal function, the underestimate of GFR induced by the Jaffé reaction is balanced by the overestimate of GFR induced by tubular creatinine secretion, and creatinine clearance provides a reasonable representation of GFR. However, widely used drugs such as trimethoprim, H_2-antagonists, and salicylates block tubular secretion of creatinine and may elevate serum creatinine and decrease creatinine clearance. When serum levels of creatinine are very high, it is excreted into the gut and undergoes extrarenal metabolism by intestinal organisms.

Given these constraints, an isolated creatinine clearance estimation may not reveal early renal dysfunction. Nonetheless, serial estimations of creatinine clearance provide a useful clinical guide to alterations in renal function and prognosis. Postoperatively, daily measurement of creatinine clearance is useful in guiding the dosing of renally excreted, potentially nephrotoxic aminoglycoside antibiotics (gentamicin, tobramycin, amikacin) or calcineurin antagonists (cyclosporine, tacrolimus). Because the GFR may decline to less than 50% of normal before serum creatinine increases above the normal range, an observed decrease in creatinine clearance may allow down-adjustment of drug dosing before nephrotoxicity becomes established and the drug accumulates even further.

The variability of creatinine clearance diminishes as GFR declines; in fact, loss of variability is a clue to deteriorating renal function. Directional changes between creatinine clearance and inulin clearance show good agreement. At low levels of GFR, a creatinine:inulin clearance ratio as high as 2:1 (e.g., 12 versus 6 mL/min) would induce little actual difference in clinical management.

Plasma Clearance

Measurement of the rate of disappearance (plasma clearance) of a substance that is completely eliminated by glomerular filtration is an alternate method for measuring GFR without the need for a simultaneous urine collection. It involves an intravenous bolus dose and/or infusion of the marker, followed by measurement of multiple plasma levels to calculate its disappearance rate. The methodology does depend on the achievement of a steady-state plasma concentration of the marker, which is difficult to achieve with rapid changes in GFR.[27]

Numerous markers are used, including nonradioactive inulin and iothalamate, as well as radioisotopes such as ^{51}Cr-ethylenediaminetetraacetic acid (EDTA), ^{99m}Tc-diethylenetriamine pentaacetic acid (DTPA), and ^{125}I-iothalamate. The latter two markers, which utilize measurement of decay in radiation, have shown promise in the rapid assessment of GFR.

Tubular Function Tests

Tests of renal tubular function measure urinary concentrating ability and sodium and urea handling. As such, they can distinguish oliguria due to dehydration (prerenal syndrome) from that due to tubular injury (acute tubular necrosis).

In prerenal oliguria, tubular function is preserved; in fact, it is "switched on" to retain salt and water, resulting in concentrated urine that is low in sodium. With the exception of refractory prerenal states such as severe sepsis and end-stage liver failure (see later), normalization of hemodynamic status reverses oliguria and tubular activation. The administration of potent diuretics may override tubular conservation, resulting in dilute urine that is high in sodium (natriuresis), indistinguishable from acute tubular necrosis (see later). However, if intravascular hypovolemia is severe enough, tubular sodium retention and low urinary sodium may persist despite the administration of diuretics such as low-dose dopamine.[30]

In established acute tubular necrosis, concentrating ability and sodium conservation are lost, resulting in dilute urine with high sodium that is not reversed by restoration of normal RBF. However, in nonoliguric renal failure, which accounts for as much as 75% of cases of acute tubular necrosis encountered clinically,[31] the changes in tubular function are less distinct from those of the prerenal syndrome.

Urinary Concentrating Ability

Concentrating ability is a very sensitive barometer of tubular function. In prerenal states, urinary osmolar concentration is markedly increased. In acute tubular necrosis, the ability to concentrate urine may be lost 24 to 48 hours before serum creatinine or BUN starts to increase.

Urine-to-Plasma Osmolar Ratio

The normal tubular response to dehydration or hypovolemia is to concentrate the urine and increase urine osmolality above 450 mOs/kg, compared with a normal serum or plasma osmolality of 280 to 300 mOs/kg. Thus, a prerenal syndrome is indicated by a urine-to-plasma osmolar ratio ($U:P_{OSM}$) of greater than 1.5. Loss of concentrating ability, or isosthenuria ($U:P_{OSM} = 1.0$), in the presence of oliguria implies tubular damage and established acute renal failure. However, isosthenuria can be induced in a prerenal state when diuretics are administered (see earlier).

Free Water Clearance

Free water clearance (C_{H_2O}) is a measure of renal water regulation by tubular dilution or concentration of urine. In essence, free water is cleared by the tubules in response to hypervolemia ("positive free water clearance") or retained in response to hypovolemia ("negative free water clearance"). The kidney's capacity for water regulation is enormous, and C_{H_2O} can vary from +18 L to −8 L/day.[32] C_{H_2O} is calculated by distinguishing the renal clearance of solute from that of free water.

The solute or osmolar clearance (C_{OSM}) is calculated by standard methods, using urine osmolality in mOs/kg (U_{osm}), plasma osmolality in mOs/kg (P_{OSM}), and urine flow in mL/min (V):

$$C_{OSM} = \left(U_{OSM} \cdot V\right) / P_{OSM} \left(\text{in mL/min}\right)$$

Then, the osmolar clearance is subtracted from the urine flow rate to give free water clearance:

$$C_{H_2O} = V - C_{OSM} \left(\text{in mL/min}\right)$$

This implies that when urine is diluted and flow is greater than osmolar clearance, C_{H_2O} is positive, and when urine is concentrated and flow is less than osmolar clearance, C_{H_2O} is negative. Negative free water clearance (i.e., free water retention) is also known as tubular conservation of water (TC_{H_2O}) and represents the volume of fluid that would have to be added to the urine to make its osmolality equivalent to that of plasma.[32]

With the onset of acute tubular necrosis and loss of concentrating ability, the urine becomes isosmotic, and C_{H_2O} approaches zero (± 0.25 mL/min). However, in distinguishing between prerenal and intrarenal oliguria, C_{H_2O} does not really provide any more information about concentrating ability than $U:P_{OSM}$, and, in addition, it requires a timed urine collection.

Water Conservation

Urine-to-Plasma Creatinine Ratio

The urine-to-plasma creatinine ratio ($U:P_{CR}$) represents the proportion of water filtered by the glomerulus that is abstracted by the entire tubule. Normally, about 98% of water is abstracted and urine creatinine is much greater than plasma creatinine. The ratio can increase 100-fold in severe prerenal states. When tubular function is lost, the ratio declines to less than 20:1.

For example, two patients have oliguria with a serum creatinine elevated to 2.0 mg/dL. In patient A, the urine creatinine is 100 mg/dL, and in patient B, it is 20 mg/dL. Patient A likely has a prerenal state because tubular water abstraction is high (U:P creatinine = 50:1), whereas patient B likely has acute tubular necrosis because tubular water abstraction is impaired (U:P creatinine = 10:1).

Sodium and Urea Conservation

Urine Sodium

Dehydration or hypovolemia markedly stimulates tubular sodium reabsorption at the medullary thick ascending limb and distal tubule. In the prerenal syndrome, oliguria is characterized by a very low urine sodium (U_{Na}) value, less than 20 mEq/L. Typically, this response is reversed by restoration of intravascular volume. However, in two situations, severe sepsis and the hepatorenal syndrome of liver failure, refractory oliguria with low urine sodium persists despite aggressive fluid resuscitation. The pathogenesis is multifactorial, but common to both syndromes is endotoxemia, which induces renal vasoconstriction and avid tubular sodium reabsorption.

In established acute renal failure, the tubular ability to conserve sodium and protect the intravascular volume is lost and urine sodium exceeds 60 to 80 mEq/L. Note that after recent diuretic therapy a high urine sodium value cannot be interpreted as tubular injury but a persistently low urine sodium value implies the existence of an intense prerenal state (see earlier).[30]

Fractional Excretion of Sodium

Fractional excretion of sodium (FE_{Na}) is an additional means of evaluating tubular responses to hypovolemia and hypervolemia. FE_{Na} expresses sodium clearance as a percentage of creatinine clearance. The implication is that in hypovolemia, sodium clearance (and thus FE_{Na}) declines to reflect tubular sodium conservation; in hypervolemia, the opposite occurs.

FE_{Na} is calculated as follows:

$$FE_{Na} = \left(\text{sodium clearance/creatinine clearance}\right) \cdot 100\%$$

Based on the relationship expressed earlier:

$$FE_{Na} = \left(U_{Na} \cdot V / P_{Na}\right) / \left(U_{Cr} \cdot V / P_{Cr}\right) \times 100\%$$

Urine flow rate (V) is identical in the numerator and denominator and it cancels out:

$$FE_{Na} = \left(U_{Na} / P_{Na}\right) / \left(U_{Cr} / P_{Cr}\right) \cdot 100\%$$

Thus, FE_{Na} may be calculated from a spot sample of blood and urine without requiring a timed urine collection.

During dehydration or hypovolemia, sodium clearance and FE_{Na} are decreased to less than 1% of creatinine clearance. When tubular ability to conserve sodium is lost in acute renal failure, FE_{Na} increases to more than 3%. However, FE_{Na} increases with normal tubular function after diuretic therapy and during postoperative sodium mobilization. Sequential increases in FE_{Na} associated with a declining creatinine clearance provide a more reliable indicator of deteriorating renal function than an isolated high FE_{Na}.

Fractional Excretion of Urea Nitrogen

Unlike sodium, handling of urea in the ascending loop of Henle and distal tubule is subject to passive forces and is little influenced by loop diuretic therapy. Fractional excretion of urinary nitrogen (FE_{UN}) is related to water reabsorption in the proximal tubules, which increases to compensate for impaired renal perfusion in a prerenal state. Urea is also reabsorbed, leading to an increased BUN:SCr ratio and decreased FE_{UN}. It has been suggested that the FE_{UN} is more sensitive and specific than the FE_{Na} in differentiating oliguria due to acute tubular necrosis from a prerenal syndrome, especially in the presence of loop diuretic therapy.[33] The FE_{UN} is calculated identically to FE_{Na}:

$$FE_{UN} = \left(U_{UN} / BUN\right) / \left(U_{Cr} / P_{Cr}\right) \cdot 100\%$$

where U_{UN} is the urinary urea nitrogen, U_{Cr} is urine creatinine, and P_{Cr} is plasma creatinine.

In oliguric patients, an FE_{UN} of less than 35% indicates a prerenal syndrome, whereas an FE_{UN} of 50% to 65% suggests established acute renal failure, even in the presence of loop diuretic therapy.[33]

The major limitation to the FE_{UN} is the concomitant administration of proximal tubule diuretics such as acetazolamide and

of osmotic diuretics such as mannitol. These agents impair water reabsorption in the proximal tubule and ameliorate a decrease in FE_{UN} in a prerenal state. Excessive urea production in highly catabolic states may itself induce an osmotic diuresis and render the FE_{UN} inaccurate.

Indices of Tubular Injury

β_2-Microglobulin

β_2-Microglobulin is a small protein component of the major histocompatibility complex that is present on the surface of almost all cells. It is normally filtered by the glomerulus and then undergoes partial tubular reabsorption. The ratio of β_2-microglobulin between serum and urine may help distinguish glomerular from tubular injury, although the relationship between increased urinary β_2-microglobulin and subsequent acute tubular necrosis has not been characterized.

In glomerular injury, serum β_2-microglobulin levels increase and urine levels decrease. This assessment has been utilized as an early sign of rejection in renal transplantation.[34]

In primary tubular injury, reabsorption of β_2-microglobulin is impaired, so urinary levels increase and serum levels decline. In a study in which CPB with pulsatile flow was used, there was a significant decrease in plasma renin activity but urinary β_2-microglobulin increased on CPB with pulsatile or nonpulsatile flow.[35] The implication is that although pulsatile flow maintains better renal perfusion it does not prevent a subclinical renal tubular injury.

Urinary N-Acetyl-β-D-glucosaminidase

The assay of increased urinary concentrations of the tubular enzyme *N*-acetyl-β-D-glucosaminidase (NAG) is a well-established method of identifying subclinical tubular injury. Urinary NAG levels, or the ratio of its isoenzymes, have been used in the early detection of rejection in transplant patients or to follow the course of chronic renal disease (e.g., lupus nephritis).[36] However, there are few data on the relationship between tubular enzymuria and clinical indices of perioperative renal outcome, such as the need for renal replacement therapy.

Neutrophil Gelatinase-Associated Lipocalin

Neutrophil gelatinase-associated lipocalin (NGAL) is a small 25-kDA polypeptide expressed in proximal tubular cells whose mRNA undergoes dramatic upregulation after ischemic tubular injury.[37] Upregulation can be detected within minutes of ischemia-reperfusion injury and increases threefold to fourfold within 2 to 3 hours and up to 10,000-fold by 24 hours. NGAL is protease resistant and is readily detected in tiny (micromilliliter) amounts of urine almost immediately after renal injury, preceding the appearance of NAG and β_2-microglobulin.

Urinary NGAL has been demonstrated to increase significantly within 2 hours of CPB in pediatric or adult patients who subsequently went on to develop a 50% increase in postoperative serum creatinine, whose peak was delayed until 1 to 3 days after surgery.[38,39] Aprotinin is an antifibrinolytic kallikrein inhibitor that is associated with acute kidney injury.[40] In a study on 369 patients undergoing cardiac surgery, urinary NGAL levels were 18 times higher 3 hours after CPB in the 205 patients given aprotinin compared with those who had received ε-aminocaproic acid.[41] These data suggest that urinary NGAL may represent an early, sensitive, noninvasive urinary biomarker for ischemic and nephrotoxic renal injury.

Renal Hemodynamics

Renal Plasma Flow and Renal Blood Flow

p-Aminohippurate Clearance

p-Aminohippurate (PAH) is an organic anion filtered by the glomerulus and secreted by the tubule that is almost completely cleared from the plasma in a single pass through the kidney. Thus, clearance of PAH (C_{PAH}) represents RPF.

Like inulin clearance, the test is laborious and requires intravenous and urinary catheters. A PAH infusion is set up to maintain a steady-state PAH concentration of about 2 mg/dL, together with a carefully timed catheter urine collection.[26] Because 10% of the RPF bypasses the peritubular capillaries, C_{PAH} underestimates the true RPF and is referred to as *effective* RPF.

$$\text{Effective RPF} = C_{PAH} = U_{PAH} \cdot V/P_{PAH}$$

In young healthy adults, effective RPF is 660 mL/min/1.73 m^2.

Effective renal blood flow (RBF) may be derived if the hematocrit level (Hct) is known and expressed as a decimal (i.e., 35% = 0.35):

$$\text{Effective RBF} = \text{Effective RPF}/1 - \text{Hct}$$

As an example, if effective RPF is 600 mL/min and Hct is 30% (0.3), effective RBF is 600/0.7, i.e., 860 mL/min.

Unfortunately, C_{PAH} is an unreliable indicator of RPF during surgical stress because hypovolemia and oliguria induce sequestration of PAH in the kidney. Ironically, the most important limitation of C_{PAH} is renal injury, because about 80% of PAH is cleared by tubular secretion. In the presence of proximal tubular injury, PAH secretion declines and C_{PAH} underestimates RPF.[42]

These errors can be overcome if renal vein sampling is accessible (e.g., during major abdominal vascular surgery). Measurement of the difference between arterial and renal vein PAH allows calculation of the renal extraction of PAH (E_{PAH}), an index of proximal tubular function:

$$E_{PAH} = \text{arterial PAH} - \text{renal vein PAH}/\text{arterial PAH}$$

When renal function is normal, renal vein PAH is close to zero and E_{PAH} approaches 100% (1.0). With worsening proximal tubular function, renal vein PAH concentration progressively increases and E_{PAH} progressively declines.

True RPF is calculated by dividing PAH clearance by PAH extraction:

$$\text{RPF} = C_{PAH}/E_{PAH}$$

Filtration Fraction

The fraction of the RPF that is filtered by the glomerulus is called the filtration fraction (FF) and can be measured indirectly via the C_{PAH} and C_{IN}:

$$\text{FF} = \text{GFR}/\text{RPF} = C_{IN}/C_{PAH}$$

Normally, GFR is about 125 mL/min and RPF is about 660 mL/min, so that the filtration fraction approximates 125/660, or about 0.2. Changes in filtration fraction are considered to represent changes in periglomerular arteriolar tone (see "Afferent and Efferent Arteriolar Control Mechanisms," earlier). An increase in filtration fraction indicates that GFR is increased relative to RPF. This could be achieved by efferent arteriolar constriction or

afferent arteriolar dilation and maintains glomerular filtration pressure in the presence of decreased RPF. Conversely, a decrease in filtration fraction implies that GFR is decreased relative to RPF by afferent arteriolar constriction or efferent arteriolar dilation.

Total Renal Blood Flow

Flow Probes

Flow measurement by electromagnetic flow probes is based on the creation of a magnetic field around the circumference of the vessel. The field is disrupted by blood flow, and a voltage output proportional to blood velocity is generated. Ultrasonic flow probes use the Doppler technique, in which high-frequency sound is transmitted across the lumen of the vessel. A shift in sound frequency is created by the movement of blood and is proportional to blood velocity.

$$\text{Flow}\,(\text{in mL/min}) = \text{blood velocity}\,(\text{in cm/min}) \cdot \text{area of vessel}\,(\text{in cm}^2)$$

Flow-probe placement is invasive and requires direct surgical exposure of the renal arteries. Probes must be calibrated in vitro before and after measurements. However, they are generally accurate.

Thermodilution Estimation of Renal Vein Effluent

Schaer and associates[43] used a double-lumen pigtail catheter with a thermistor placed in the renal vein of dogs under direct vision or with fluoroscopy. RBF was calculated by thermodilution with cold saline, which allowed repeated measurements in conscious animals. The effect of the presence of the probe itself on RBF is unknown. A similar technique was used by Haywood and associates[44] to measure RBF for the assessment of renal oxygen delivery and consumption during septic shock in pigs.

Contrast Ultrasonography

Aronson and coworkers[45] attempted to measure RBF in vivo using contrast ultrasonography. They injected sonicated albumin microspheres into the aorta of anesthetized dogs and then recorded simultaneous ultrasonograpic images of the kidney and aorta and calculated RBF using a mathematical model. RBF was altered by means of a renal artery occluder or vasoactive drugs (dopamine or fenoldopam), and the results were compared with direct measurements by electromagnetic flow probe. Although the correlation between ultrasonography and flow probe measurements of RBF was reasonable (0.84), there was a large bias (in many cases greater than 200 mL/min) and variance. Ultrasonography tended to overestimate RBF, especially when cardiac output was changing. The authors concluded that this method allows estimation of trends in RBF and may be helpful in the qualitative assessment of regional distribution of blood flow between the renal cortex and medulla.

Neurohormonal Regulation of Renal Function

Two mutually dependent but opposing neurohormonal systems maintain blood pressure, intravascular volume, and salt and water homeostasis (Fig. 18-16). The sympathoadrenal axis, the renin-angiotensin-aldosterone system, and AVP defend against hypotension and hypovolemia by promoting vasoconstriction and salt and water retention. The prostaglandins and natriuretic peptides defend against hypertension and hypervolemia by promoting vasodilation and salt and water excretion (Fig. 18-17).

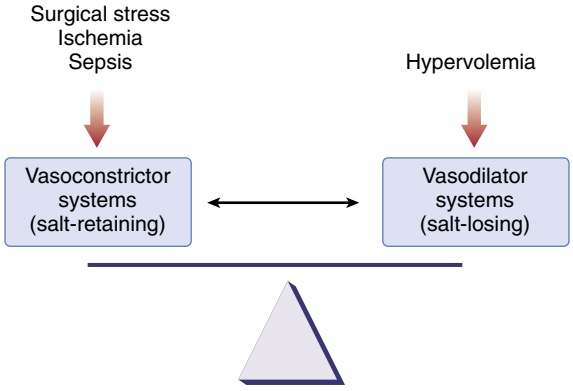

Figure 18-16 Neurohormonal regulation of renal function. Normally, there is a balance between those systems promoting renal vasoconstriction and sodium retention versus those systems promoting renal vasodilation and sodium excretion. Surgical stress, ischemia, and sepsis tip the balance in favor of vasoconstriction and sodium retention. On the other hand, hypervolemia (or the induction of atrial stretch) tips the balance in favor of vasodilation and sodium excretion.

Anesthesia does not perturb these systems to any substantial degree. In the intact organism, anesthetics appear to affect renal function through extrarenal circulatory changes rather than by their direct actions on the kidney. Surgical or traumatic injury, on the other hand, induces profound vasoconstriction and salt and water retention, which may persist for several days. The clinical sequel is postoperative oliguria and edema. Renal vasoconstriction also predisposes the kidney to further perioperative ischemic and nephrotoxic insults. Release of endogenous natriuretic peptides by atrial and ventricular stretch reinforces the notion that renal vasoconstriction can be prevented or modified by maintenance of normal or increased intravascular volume.

Vasoconstrictor Systems	Vasodilator Systems
Sympathoadrenal system Renin-angiotensin system Aldosterone Antidiuretic hormone (ADH)	Prostaglandins Kinins Atrial natriuretic peptide (ANP)
↓ RBF ↓ GFR ↓ Urine flow ↓ Na excretion	↑ RBF ↑ GFR ↑ Urine flow ↑ Na excretion

Figure 18-17 Neurohormonal renal regulatory systems. GFR, glomerular filtration rate; Na, sodium; RBF, renal blood flow; ↓, decreased; ↑, increased. (*Modified from Sladen RN: Effect of anesthesia and surgery on renal function. Crit Care Clin 3:380, 1987.*)

Systems Promoting Vasoconstriction and Salt Retention

The Sympathoadrenal Axis

Sympathetic effects on the kidney are mediated by circulating epinephrine and neuronal release of norepinephrine. The renal cortex has a dense plexus of autonomic nerve fibers derived from the T12 to L4 spinal segments via the celiac plexus. The primary stimulus to the sympathetic response is a decrease in arterial blood pressure sensed by baroreceptors in the aortic arch, carotid sinus, and afferent arteriole. Afferent fibers travel via the vagus nerve and decrease impulse transmission rate to the mediating centers in the hypothalamus, which results in increased adrenergic nerve activity. The kidney does not have any parasympathetic innervation.

A G protein–coupled phospholipase-C receptor populates vascular smooth muscle and the mesangium and responds to α-adrenergic stimulation by epinephrine and norepinephrine. It also mediates vasoconstriction induced by a variety of other hormones and peptides, including angiotensin II, vasopressin, endothelin, platelet-activating factor, and leukotrienes.[3] The receptor subunit in the cell membrane is coupled through G_q protein to phospholipase C, which hydrolyzes phosphatidylinositol biphosphate (PIP_2) to inositol triphosphate (IP_3) and diacylglycerol (DAG). In turn, DAG activates protein kinase, opening up a calcium channel in the membrane, and IP_3 triggers the release of calcium from the sarcoplasmic or endoplasmic reticulum. Both mechanisms result in a rapid increase in intracellular calcium, which binds with calmodulin and thereby activates myosin light-chain kinase, resulting in smooth muscle contraction. The calcium-calmodulin complex simultaneously activates phospholipase A_2, resulting in the production of vasodilator prostaglandins (see later).

Mild α-adrenergic stimulation appears to cause preferential efferent arteriolar constriction, which preserves the filtration fraction. Severe α-adrenergic stimulation causes predominant afferent arteriolar constriction and decreases filtration fraction. Thus, the adrenergic response to a moderate decrease in renal perfusion (e.g., general anesthesia) favors the preservation of the GFR. In contrast, the adrenergic response to shock exacerbates the decrease in GFR already induced by renal hypoperfusion (see Fig. 18-4).

Adrenergic nerves also supply the proximal tubule, thick ascending limb of the loop of Henle, and collecting duct, and their stimulation enhances NaCl reabsorption at these sites. Gas tracer studies suggested that sympathetic activation caused sodium retention by intrarenal redistribution of RBF from the outer cortex to salt-retaining juxtamedullary nephrons, but this was not confirmed by microsphere studies.

There is a close relationship between sympathetic stimulation and activation of the renin-angiotensin system. Adrenergic stimulation releases renin from the juxtaglomerular apparatus, and adrenergically induced vasoconstriction can be blocked by angiotensin-converting enzyme (ACE) inhibitor drugs such as captopril.

The effects of the administration of exogenous adrenergic drugs depend on their agonist activity. Drugs with predominantly α-adrenergic effects, such as norepinephrine, epinephrine, phenylephrine, and high-dose dopamine (>10 μg/kg/min) exacerbate the endogenous sympathetic responses to hypotension. Drugs with predominantly β_1- and β_2-adrenergic activity, such as dobutamine or isoproterenol, cause marked increases in cardiac output and thus RBF, but it is difficult to ascertain their intrarenal effects. Dopaminergic agonists (Table 18-2) selectively increase RBF and may oppose α-adrenergic renal vasoconstriction.[43]

Table 18-2 Dopamine and its Analogs

Receptor	DA_1	DA_2	β_1	β_2	α_1
Dopamine	+++	++	++	±	+++
Dobutamine	0	0	+++	++	±
Dopexamine	++	+	±	+++	0
Fenoldopam	++++	0	0	0	0

Dobutamine, dopexamine, and fenoldopam are all pharmacologic analogs of dopamine. However, dobutamine is devoid of dopaminergic activity; dopexamine has about one third of the dopaminergic activity of dopamine; and fenoldopam is a pure, selective $dopamine_1$-receptor agonist. α_1, $alpha_1$-receptor; β_1, $beta_1$-receptor; β_2, $beta_2$-receptor; DA_1, $dopamine_1$-receptor; DA_2, $dopamine_2$-receptor.

The Renin-Angiotensin-Aldosterone System

Renin and Angiotensin

The juxtaglomerular apparatus consists of three groups of specialized tissues. In the afferent arteriole, modified fenestrated endothelial cells produce renin; in the juxtaposed distal tubule, cells of the macula densa act as chemoreceptors; and in the glomerulus, mesangial cells have contractile properties (see Fig. 18-3). Together these provide an important regulating system for blood pressure, salt, and water homeostasis.[46]

Renin secretion is stimulated by hypovolemia that may be overt (hemorrhage, diuresis, sodium loss or restriction) or covert (positive-pressure ventilation, congestive heart failure, sepsis, or cirrhosis with ascites). A decrease in renal artery perfusion pressure triggers baroreceptors in the afferent arterioles. Sympathetic nerve stimulation and circulating catecholamines act on β-adrenergic receptors in the afferent arterioles. An increase in chloride concentration in the distal tubular fluid activates the cells of the macula densa, which trigger renin release from the afferent arteriole. This tubuloglomerular feedback appears to play a role in modulating GFR during normal and abnormal renal function through a continuous feedback loop.[4,5]

Renin acts on angiotensinogen, a large circulating glycoprotein released from the liver, and cleaves off a decapeptide, angiotensin I. In the kidney and in the lung angiotensin I is further cleaved by endothelial-based ACE to form an octapeptide, angiotensin II, a potent vasoconstrictor (Fig. 18-18). Renin is the rate-limiting enzyme in the production of angiotensin II.[47]

Activation of modest amounts of angiotensin II causes renal cortical vasoconstriction predominantly at the level of the efferent arterioles (see Fig. 18-4). This acts to maintain glomerular filtration fraction in the presence of mild to moderate decreases in RBF or perfusion pressure. The importance of this protective mechanism is emphasized by the deterioration in GFR that occurs when angiotensin-converting enzyme inhibitors are administered to patients with hypotension, renal insufficiency, or unilateral renal artery stenosis.[48,49] Severe stress induces the release of high levels of angiotensin II, which constricts the glomerular mesangial cells and decreases the glomerular filtration fraction. Angiotensin II promotes systemic vasoconstriction at about one tenth of its renal effect. The effect of angiotensin II in causing salt and

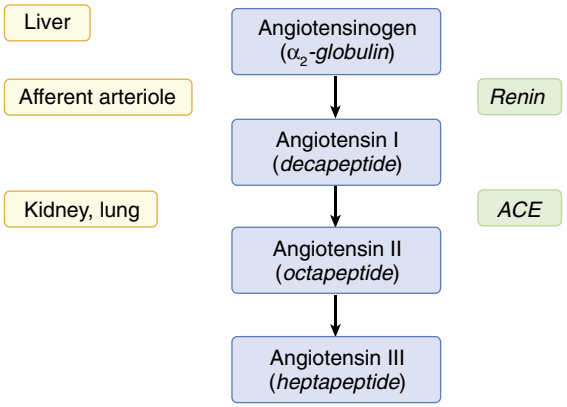

Figure 18-18 Renin-angiotensin system. For explanation, see text. ACE, angiotensin-converting enzyme.

water retention is enhanced by its actions in stimulating aldosterone secretion by the adrenal cortex, AVP secretion by the posterior pituitary, and NaCl reabsorption by the proximal tubule.[46]

Angiotensin II triggers a number of responses that modulate or oppose its own actions. It inhibits renin secretion by a negative feedback mechanism. Blockade of angiotensin formation by ACE inhibitors causes vasodilation but increases plasma renin levels. Angiotensin II activates phospholipase A_2, which triggers the synthesis of intrarenal prostaglandins. Vasodilator prostaglandins modulate the action of angiotensin II and may be responsible for its preferential activity on the efferent arteriole at low plasma levels.[47] Angiotensin-induced vasoconstriction increases atrial pressure and releases ANP, which opposes the renin-angiotensin-aldosterone system.

The consequences of ACE inhibition on renal function depend on the patient's volume status, systemic hemodynamics, and baseline renal perfusion. In the long-term treatment of hypertension and congestive heart failure, especially in diabetics, the administration of ACE inhibitors decreases renal vascular resistance and appears to benefit renal function. Short-term pretreatment with captopril may prevent a decrease in RBF and GFR and preserve sodium excretion during CPB.[50] However, deterioration in renal function and hyperkalemia have been reported with the use of ACE inhibitors in patients with hypotension, renal insufficiency, or unilateral renal artery stenosis, probably related to the blockade of compensatory angiotensin-mediated efferent arteriolar constriction.[49] It may be prudent to avoid their use when hemodynamics are unstable in the immediate perioperative period.

Aldosterone

Aldosterone is a steroid hormone secreted by the zona glomerulosa of the adrenal cortex in response to hyperkalemia or hyponatremia. Angiotensin II and adrenocorticotropic hormone (ACTH) also trigger its release. It acts at the thick ascending limb of the loop of Henle, the principal cells of the distal tubule, and the collecting duct to increase active absorption of sodium and passive absorption of water, culminating in an expanded blood volume. Sodium retention in vessel walls appears to enhance their response to vasoconstrictor agents.

In contrast to the immediate sympathetic angiotensin II response to hypovolemia, there is a delay of 1 to 2 hours from the secretion of aldosterone to its action on sodium reabsorption. As illustrated in Figure 18-19, aldosterone forms a complex with a receptor at the cell membrane in the principal cells of the distal tubule. The aldosterone-receptor complex travels to the cell nucleus, where it induces cytoplasmic transcription of messenger ribonucleic acid (mRNA). This fosters synthesis of proteins that form sodium channels in the apical cell membrane and enhance the Na+/K+-ATPase pump in the basolateral cell membrane.[51] Sodium is transported from the tubular fluid into the peritubular capillary in exchange for potassium. Long-standing stimulation of aldosterone secretion, characteristically induced by the intravascular volume depletion of chronic ascites, culminates in potassium depletion and hypokalemic alkalosis.

Arginine Vasopressin

Arginine vasopressin (AVP), previously known as antidiuretic hormone (ADH), regulates urinary volume and osmolality and controls diuresis and antidiuresis. It is a 9-amino-acid peptide, 8-arginine vasopressin, that is synthesized in the supraoptic and paraventricular nuclei of the anterior hypothalamus.[51] These nuclei are essentially the cell bodies of neurons whose axons extend down into nerve terminals in the posterior pituitary, together comprising the neurohypophysis (Fig. 18-20). When

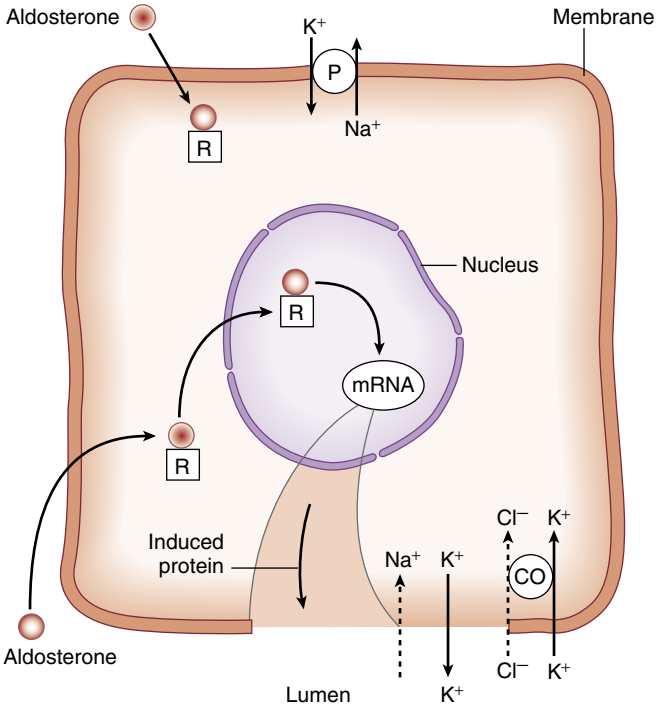

Figure 18-19 Action of aldosterone. Aldosterone enters the distal tubular cytoplasm and attaches to a receptor, then migrates to the nucleus where it induces the formation of a messenger RNA (mRNA). The mRNA in turn induces the synthesis of a protein that enhances the permeability of the apical (luminal) membrane to sodium and potassium. The reabsorption of sodium stimulates the basolateral membrane Na-K-ATPase pump, the intracellular concentration of potassium rises, and it follows its concentration gradient out into the lumen. The net effect of aldosterone's action is sodium reabsorption and potassium loss. Cl^-, chloride; CO, cotransporter (= symporter); K^+, potassium; mRNA, messenger ribonucleic acid; Na^+, sodium; P, sodium-potassium ATPase pump; R, receptor. (*From Wingard LB, Brody TM, Larner J, Schwartz A: Diuretics: Drugs that increase excretion of water and electrolytes.* In *Wingard LB, Brody TM, Larner J, Schwartz A [eds]: Human Pharmacology: Molecular-to-Clinical. London, Wolfe Publishing, 1991, p 249.*)

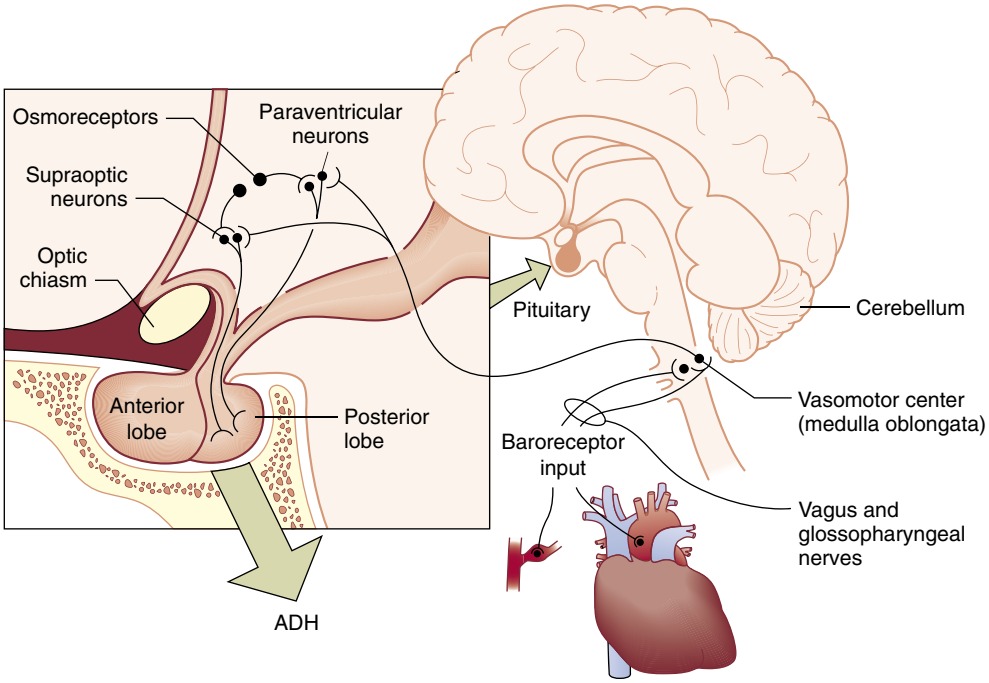

Figure 18-20 Elaboration and control of arginine vasopressin (AVP). *Osmotic control.* An increase in serum osmolality is detected by osmoreceptors in the supraoptic and paraventricular neurons of the hypothalamus. Granules of AVP are elaborated and axonally transported to the posterior lobe of the pituitary gland. From there they are released into the circulation to reach the V_2 receptors in the distal tubule, where they retain water and restore the serum osmolality. *Hemodynamic control.* Decreases in venous volume are sensed by stretch receptors in the atria and great veins, and decreases in arterial pressure are sensed by baroreceptors in the aortic arch and carotid sinus. The afferent arc is via the vagal and glossopharyngeal nerves to the solitary nucleus in the medulla oblongata (vasomotor center). The efferent arc, from the vasomotor center to the hypothalamic nuclei, induces AVP release. At low levels (< 5 pg/mL), AVP stimulation of V_2 receptors may cause inappropriate water retention. At high levels (> 20 pg/mL), AVP stimulation of V_{1a} receptors causes vasoconstriction and participates in the baroreceptor reflex. (*From Koeppen BM, Stanton BA: Regulation of body fluid osmolality: regulation of water balance.* In *Koeppen BM, Stanton BA [eds]: Renal Physiology, 4th ed. Philadelphia, Mosby Elsevier, 2007, pp 71-90.*)

AVP is synthesized it undergoes neuroaxonal transport to the posterior pituitary gland, where it is stored in granules. Neural stimulation of the cell bodies triggers exocytosis of AVP from the terminal vesicles into the circulation.

AVP acts on specific V_2-receptors in the collecting ducts to induce water reabsorption and a decreased flow of concentrated urine. It also increases NaCl reabsorption from the thick ascending loop of Henle into the medullary interstitium, which maintains its hypertonicity and facilitates movement of water out of the collecting duct along the osmotic gradient. This results in tubular conservation of water and free water retention (i.e., negative free water clearance). The net effect is that AVP increases urine osmolality and decreases plasma osmolality, without significant alteration in solute excretion.

The V_2-receptor on the basolateral cell membrane of the collecting duct responds to AVP via a receptor mechanism analogous to the β-adrenergic receptor.[51] Through activation of G protein–coupled adenylyl cyclase, ATP is converted to cyclic adenosine monophosphate (cAMP). This, in turn, activates a protein kinase that causes preformed vesicles containing aquaporin-2 water channels to migrate and fuse with the apical cell membrane. This results in a dramatic increase in membrane permeability to water, which is reabsorbed into the cell and thence into the peritubular capillary. AVP has a short plasma half-life of between 5 and 15 minutes, and this process rapidly reverses as plasma AVP levels decline.

Regulation of AVP Secretion

Hypothalamic osmoreceptors are sensitive to increases in serum osmolality of as little as 1% above normal. As illustrated in Figure 18-21A, the threshold for AVP secretion (and the sensation of thirst) is between 280 and 290 mOsm/kg. Once this is exceeded, the secretion rate has a very steep gain.[52] Even mild dehydration results in a rapid antidiuresis, and urine osmolality can increase from 300 to 1200 mOs/kg as plasma AVP levels rise from 0 to 5 pg/mL (see Fig. 18-21B).

Decreases in intravascular volume also stimulate AVP secretion, mediated by stretch receptors with vagal afferents in the left atrium and pulmonary veins. Hypovolemia-induced secretion of AVP overrides osmolar responses and contributes to the perioperative syndrome of inappropriate antidiuretic hormone secretion (SIADH): fluid retention, hypo-osmolality, and hyponatremia. The situation is exacerbated by administration of large volumes of hypotonic solutions that decrease serum osmolality. Psychic stress, via cortical input, also induces AVP release and can override osmotic and volume sensors.

By far, the most potent trigger for AVP release is systemic arterial hypotension, mediated by aortic and carotid baroreceptors. It overrides all other triggers, and plasma AVP may reach levels 10- to 1000-fold greater than normal (see Fig. 18-21C). At these concentrations AVP acts as a vasoconstrictor, especially in the outer renal cortex. It does so by stimulating the V_{1a} receptor, which exists on vascular smooth muscle, glomerular mesangial

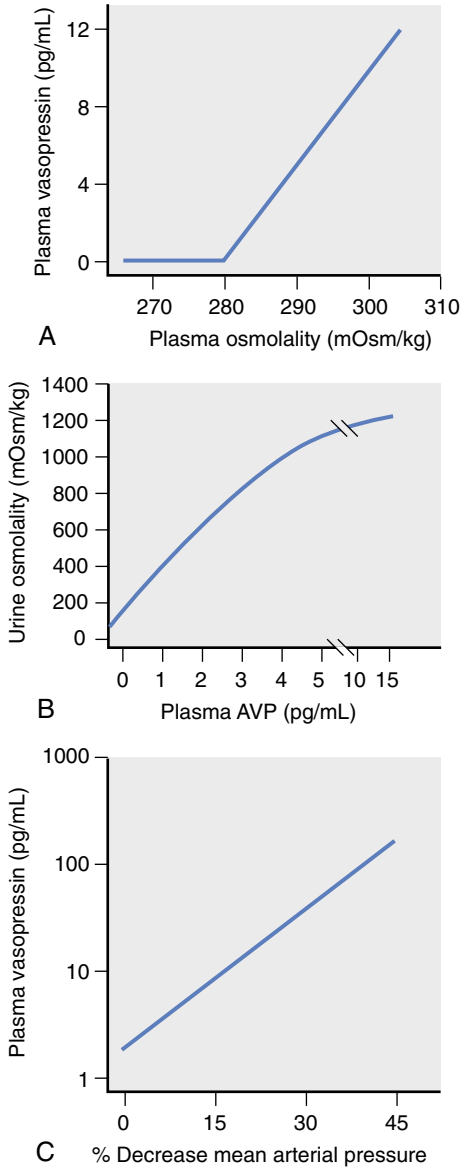

Figure 18-21 **A** to **C,** Physiologic regulation of arginine vasopressin (AVP). For explanation, see text. (*From Landry DW: Vasopressin deficiency and hypersensitivity in vasodilatory shock: Discovery of a new clinical syndrome. P & S Med Rev 3:3-7, 1996.*)

cells, and the vasa recta and promotes vasoconstriction via the phosphatidylinositol pathway.[52] AVP maintains effective glomerular filtration pressure because it is an extremely potent constrictor of the efferent arteriole and, unlike catecholamines and angiotensin, it has little effect on the afferent arteriole even at high plasma levels.[53]

Anesthetic agents have little direct effect on AVP secretion, except via the changes that they induce in arterial blood pressure, venous volume, and serum osmolality. Surgical stimulation is a major stimulus to AVP secretion. This stress response, whether mediated by pain or by volume changes, is profound and lasts at least 2 to 3 days after the surgical procedure.

Systems Promoting Vasodilation and Salt Excretion

Prostaglandins and Kinins

Prostaglandins

Intrarenal prostaglandins play an important role in endogenous renal protection, largely by vasodilating juxtamedullary blood vessels and maintaining inner cortical blood flow.[54] Prostaglandins are called autocoids because unlike true hormones they are produced in minute amounts and have a local, evanescent action. Because their structure is based on a 20-carbon fatty acid they are also referred to as eicosanoids, after *eicosa*, the Greek word meaning "twenty." The synthesis of intrarenal prostaglandins is summarized in Figure 18-22.

Phospholipase A_2, which resides in the inner lipid layer of the cell membrane, controls prostaglandin production through its formation of the prime precursor arachidonic acid. It is stimulated by ischemia and hypotension and also by norepinephrine, angiotensin II, and AVP. Thus, the factors that induce and mediate the stress response simultaneously activate prostaglandins, which defend the kidney against their actions. Cyclooxygenase-1 acts on arachidonic acid to form prostaglandin G_2, the precursor of the family of vasodilator prostaglandins that includes prostaglandins D_2, E_2, and I_2 (prostacyclin). They induce vasodilation through activation of cyclic adenosine monophosphate (AMP), which blocks distal tubule sodium reabsorption, and they oppose the actions of norepinephrine, angiotensin II, and AVP. Prostaglandins may be particularly important in decreasing the vasoconstrictor activity of angiotensin II on the afferent arteriole and glomerular mesangial cells.[47] Production of prostaglandins promotes renal vasodilation, maintains intrarenal hemodynamics, and enhances sodium and water excretion. The renal vasodilator response to mannitol during hypoperfusion appears to be mediated through prostaglandin activation.[55] At the same time, prostaglandins also stimulate renin secretion so that there is a constant "yin and yang" between the two systems.[56]

Cyclooxygenase-2 forms derivatives of arachidonic acid that induce inflammation and renal vasoconstriction and are important in pathologic states. Thromboxane (TXA_2) is derived from cyclic endoperoxides by the action of thromboxane synthetase. It induces vasoconstriction and platelet aggregation, and in the kidney it causes mesangial cell contraction. This decreases GFR by diminishing the effective glomerular surface area and filtration constant (K_f). Renal levels of thromboxane are increased in experimental acute renal failure and sepsis. In animal experiments, the administration of a specific thromboxane synthetase inhibitor prevents the deterioration in renal function induced by the injection of endotoxin.[57] Another vasoconstrictor prostaglandin, PGF_2, which acts on the thromboxane receptor, is formed when arachidonic acid is oxidized by free radicals liberated by leukostasis during acute inflammation. The leukotrienes, which are arachidonic acid derivatives formed by lipooxygenase, are also released from endotoxin-activated leukocytes. Like thromboxane, leukotrienes C_4 and D_4 induce mesangial cell contraction and decrease GFR.

Kinins

Kinins act as vasodilators that interact with and enhance the actions of prostaglandins while modulating the renin-angiotensin system.[58,59] For example, kinins stimulate phospholipase A_2 and

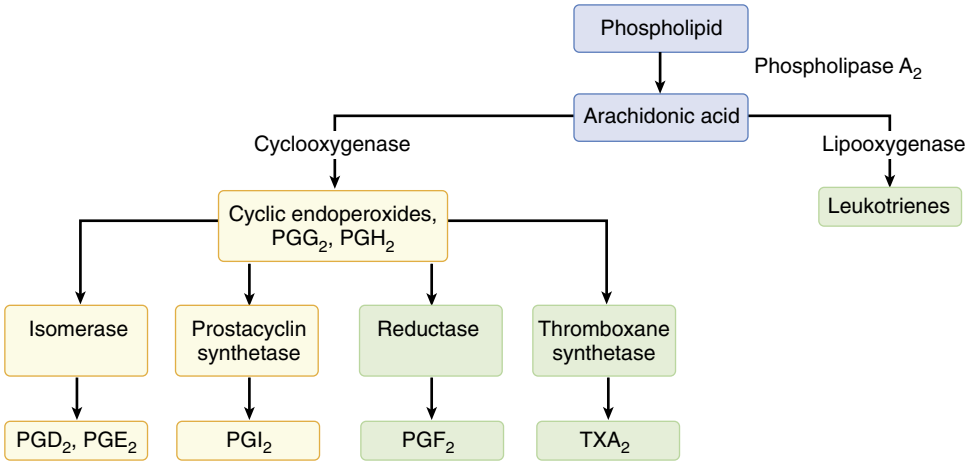

Figure 18-22 Synthesis of renal prostaglandins. Phospholipase A_2 is stimulated by ischemia, norepinephrine, and angiotensin II and cleaves arachidonic acid from its bond with membrane phospholipid. Cyclooxygenase acts on arachidonic acid to form evanescent cyclic endoperoxides (prostaglandins G_2 and H_2). Action of isomerase and prostacyclin synthetase culminates in the formation of vasodilator prostaglandins D_2, E_2, and I_2 (prostacyclin), which oppose the actions of the renin-angiotensin system on the kidney and protect against ischemic stress. Inhibition of cyclooxygenase by nonsteroidal anti-inflammatory drugs predisposes the kidney to damage. Under hypoxic or ischemic conditions, cyclic endoperoxides undergo reduction to the vasoconstrictor PGF_2, which acts on thromboxane receptors. Endotoxin increases the activity of leukocyte lipooxygenase and thromboxane synthetase. Leukotrienes (especially C_4 and D_4) and thromboxane (TXA_2) induce renal vasoconstriction and contribute to the vasomotor nephropathy of sepsis.

prostacyclin formation as well as endothelial nitric oxide formation. Kininase, which controls intrarenal kinin concentration, is blocked by angiotensin-converting enzyme inhibitors, resulting in increased bradykinin levels. This may be beneficial in diseases such as diabetes and hypertension, because two important intrarenal kinins, bradykinin and kallidin, decrease renal vasoconstriction and sodium retention induced by adrenergic hormones and angiotensin II.

Natriuretic Peptides

In 1972, Gorfinkel and colleagues[59a] demonstrated a profound difference in the canine renal response to shock depending on concomitant atrial pressure. Hypovolemic shock resulted in rapid diminution of RBF to 10% of control, whereas in cardiogenic shock RBF was preserved at 75% of control. The primary difference was that in cardiogenic shock atrial pressures were elevated, suggesting that atrial distention caused the release of a renal protective hormone. In 1981, de Bold and associates[60] confirmed the existence of ANP by demonstrating that an extract of atrial tissues caused natriuresis in rats, and the important actions of ANP on renal hemodynamics and sodium excretion were characterized.[61,62]

Subsequently, an entire series of peptides with a similar precursor was identified, with a common 25 to 32 amino acid core. These include ANP (atrial or A-type natriuretic peptide), released from electron-dense granules in atrial myocytes in response to local wall stretch and increased atrial volume, BNP (brain or B-type natriuretic peptide), released from the ventricles when they are distended, CNP (C-type natriuretic peptide) released from the endothelium of major vessels, and urodilatin, a natriuretic peptide produced in the lower urinary tract.[63] Human recombinant analogs have been developed for exogenous administration, including anaritide, derived from ANP, and nesiritide, derived from BNP. All these compounds induce arterial and venous dilation, increase RBF and GFR, and suppress the actions of norepinephrine, angiotensin, and endothelin.[64]

Natriuretic peptides dilate vascular smooth muscle through activation of guanylate cyclase and formation of cyclic guanosine monophosphate (GMP). At the phospholipase C-linked receptor, natriuretic peptides competitively block norepinephrine and noncompetitively block angiotensin II, thus reversing vascular smooth muscle constriction. They cause a prompt, sustained increase in GFR and glomerular filtration fraction, even when RBF is not increased or when arterial pressure is decreased. This suggests that natriuretic peptides promote afferent arteriolar dilation with or without efferent arteriolar constriction. The increased GFR increases the filtered load of sodium, but natriuresis may be due to increased medullary blood flow, which washes out the concentration gradient.

Natriuretic peptides appear to have a mutually antagonistic interaction with endothelin, the endogenous vasoconstrictor peptide produced by vascular endothelium.[47] They oppose the renin-angiotensin-aldosterone system on several fronts (Fig. 18-23). Natriuretic peptides inhibit renin secretion and decrease angiotensin-stimulated aldosterone release. They also inhibit aldosterone release directly at the zona glomerulosa of the adrenal cortex and block the salt-retaining action of aldosterone at the distal tubule and collecting duct. Through cyclic GMP activation, they inhibit NaCl reabsorption at the medullary portion of the collecting duct.[12] Natriuretic peptides also promote diuresis by inhibiting AVP secretion from the posterior pituitary and antagonizing its effect on the antidiuretic V_2-receptor in the collecting duct.

The renal protective role of endogenous ANP was elucidated by Shannon and colleagues,[65] who noticed that patients undergoing mitral valve replacement had lower urine output after cardiac surgery than those undergoing aortic valve replacement or coronary revascularization. They discovered that patients whose postoperative mean left atrial pressure declined by more than 7 mm Hg from preoperative values (which commonly occurs with correction of mitral valve disease) had significantly decreased postoperative urine sodium excretion and flow rate. Furthermore,

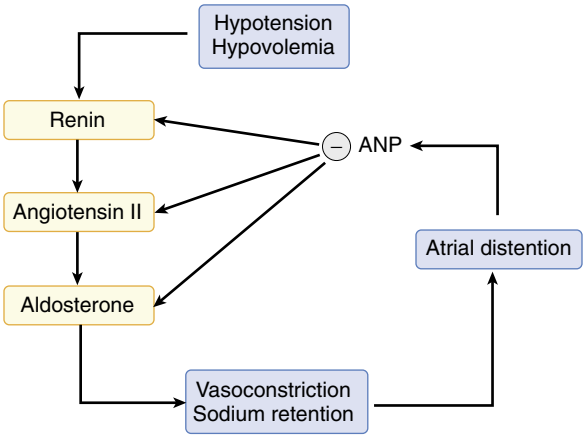

Figure 18-23 Interactions between ANP and the renin-angiotensin-aldosterone system. Hypotension or hypovolemia triggers release of renin from the afferent arteriole, causing the formation of angiotensin II, which stimulates release of aldosterone from the adrenal cortex. Angiotensin II and aldosterone cause vasoconstriction and sodium retention, ultimately resulting in reexpansion of the intravascular volume; this causes atrial distention, which triggers release of ANP. ANP inhibits release of renin, renin's action on angiotensinogen to form angiotensin II, angiotensin- induced vasoconstriction, stimulation of aldosterone secretion by angiotensin II, and the actions of aldosterone on the collecting duct. Thus, the actions of ANP promote vasodilation and sodium excretion. Therapeutic administration of fluids to distend the atrium and release ANP is an important intervention to curtail renal vasoconstriction and sodium retention. ANP, atrial natriuretic pressure.

there was a direct correlation between the quantitative decrease in left atrial pressure and a postoperative decline in circulating ANP levels (Fig. 18-24). In other words, patients with mitral valve disease and high left atrial pressure have a constant stimulus to ANP release. Valve replacement or repair results in decreased left atrial pressure, decreased ANP, and therefore decreased sodium excretion and urinary flow rate.

The Dopaminergic System

There are two subtypes of dopaminergic (DA) receptors (see Chapter 12).[66] At the end organ, DA_1-receptors occur not only on the renal and splanchnic vasculature but also on the proximal tubule itself.[67] Stimulation of the DA_1-receptor activates cyclic AMP and induces renal vasodilation, increased RBF and GFR, natriuresis, and diuresis. However, natriuresis can occur independently of increases in RBF and GFR and is abolished by specific DA_1 receptor antagonists.[68] In the proximal tubule, dopamine inhibits the Na^+/H^+ antiporter system at the brush-border membrane. In the medullary thick ascending limb, it also inhibits the Na^+/K^+-ATPase pump at the basolateral membrane.[68]

Neuronal DA_2-receptors exist on the presynaptic terminal of postganglionic sympathetic nerves. Stimulation inhibits the release of norepinephrine from presynaptic vesicles, a mechanism analogous to stimulation of the presynaptic α_2-receptor. Through inhibition of norepinephrine, DA_2-receptor activation facilitates vasodilation.

The dopaminergic system plays an integral role in the endogenous vasodilator-natriuresis system and the maintenance of normal blood pressure. Endogenous dopamine appears to constitutively activate the DA_2-receptor, which synergistically enhances the activation of the DA_1-receptor.[69] It acts as an autocrine and paracrine natriuretic factor by inhibiting tubular Na^+/K^+-ATPase activity, especially when sodium intake is increased.[70] It also opposes the anti-natriuretic effects of norepinephrine, angiotensin II and aldosterone. There is some evidence that endogenous ANP acts via the renal dopamine system by recruiting "silent" DA_1-receptors from the interior of the cell toward the plasma membrane[70] and also enhances dopamine accumulation.[71]

Urinary dopamine excretion is increased with salt loading; decreased dopaminergic activity may contribute to the pathogenesis of idiopathic edema, which manifests as retention of salt and water in the upright position. There is evidence that the endogenous dopamine system is activated in compensated cirrhosis and helps to maintain renal sodium excretion.[72]

Nitric Oxide

Endogenous formation of nitric oxide (see Chapter 31) is controlled by the enzyme nitric oxide synthase (NOS), which catalyzes the hydroxylation of the nonessential amino acid L-arginine to L-citrulline.[73] Most actions of nitric oxide are mediated through its activation of soluble guanylate cyclase, which catalyzes the

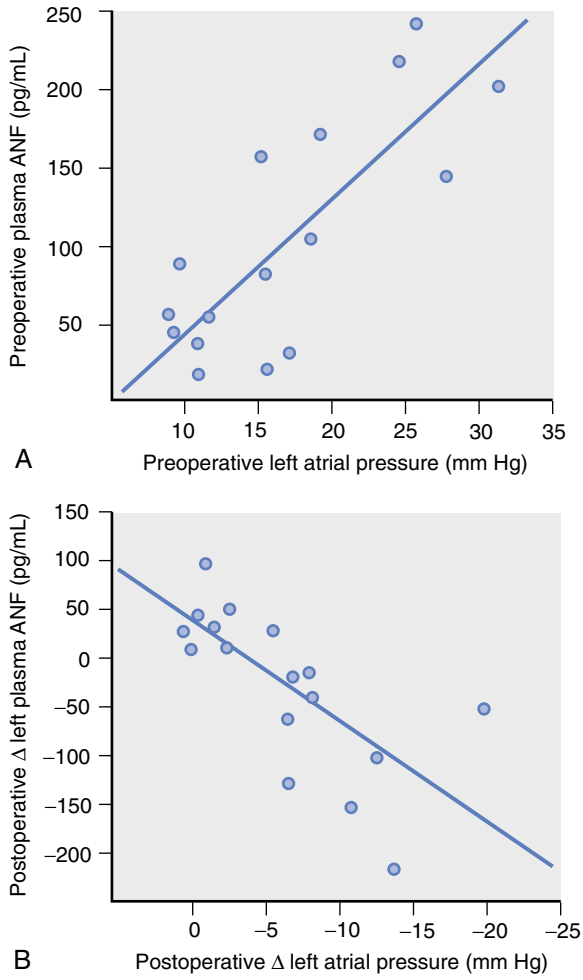

Figure 18-24 Correlation between left atrial pressure and plasma ANP in a group of patients undergoing cardiac surgery. **A,** There is significant correlation ($r = 0.8$, $P < .001$) between absolute preoperative left atrial pressure and plasma ANP. **B,** There is a significant correlation ($r = 0.72$, $P < .002$) between the postoperative decrease in left atrial pressure and postoperative decrease in plasma ANP. ANF, atrial natriuretic factor, synonymous with ANP; ANP, atrial natriuretic pressure; Δ, change. (*From Shannon RP, Libby E, Elahi D, et al: Impact of acute reduction in chronically elevated left atrial pressure on sodium and water excretion. Ann Thorac Surg 46:430-437, 1988.*)

conversion of guanidine triphosphate (GTP) to cyclic GMP. Cyclic GMP has two major actions: relaxation of vascular smooth muscle and suppression of the inflammatory response. It inhibits leukocyte adhesion, platelet activation and aggregation, and cellular proliferation. Cyclic GMP is converted to GMP by phosphodiesterase I and V. Thus, the local action of nitric oxide can be enhanced by the administration of a selective phosphodiesterase V inhibitor, such as sildenafil. Nitric oxide itself is rapidly inactivated by binding to intracellular heme and heme proteins (oxyhemoglobin, oxymyoglobin, guanylate cyclase, cyclooxygenase, cytochrome P_{450}).

Nitric Oxide Synthase (NOS)

There are several distinct subtypes of NOS that determine the site and function of nitric oxide synthesis. Constitutive NOS is calcium and calmodulin dependent and releases small amounts of nitric oxide for short periods of time ("tonic" release). Constitutive NOS has two subtypes: neuronal NOS, which acts as a peripheral neurotransmitter and induces cerebral vasodilation, and endothelial NOS, which exists in the vascular endothelium and mediates the activity previously ascribed to endothelium derived relaxing factor (EDRF). The latter is an important modulator of systemic and pulmonary vascular resistance. In the kidney, endogenous nitric oxide preserves blood flow to the oligemic juxtamedullary cortex and medulla and may also provide endogenous protection against ischemic and nephrotoxic medullary injury.[74-76]

Inducible NOS is calcium and calmodulin independent and is induced by cytokines predominantly in inflammatory cells (macrophages, granulocytes) but also in vascular smooth muscle. At low levels of activation, inducible NOS enhances the response to infection and promotes inflammation and wound healing. In severe sepsis, inducible NOS produces huge amounts of nitric oxide for protracted periods of time ("phasic" release) and is largely responsible for the characteristically profound systemic vasodilation that is refractory to norepinephrine.[77] High levels of nitric oxide, and its reactive products nitrogen dioxide and peroxynitrite, induce lipid peroxidation and denaturation of proteins that drive the systemic inflammatory response syndrome (SIRS) and its attendant acute renal injury.

Duality of Nitric Oxide in Renal Function and Injury

Goligorsky and coworkers[78] have framed the hypothesis that an imbalance between the expression and activity of constitutive and inducible NOS plays an important role in the pathophysiology of acute renal failure. In experimental models of sepsis, nonselective inhibitors of both constitutive and inducible NOS improve blood pressure but worsen overall perfusion, including renal perfusion. Selective inhibitors of inducible NOS show promise in suppressing severe inflammation and vasodilation while maintaining tonic perfusion to vital organs, including the kidneys.[79]

The Renal Adenosine System

Adenosine Receptors

Adenosine, the endogenous degradation product of ATP, is produced by every mammalian cell type and is normally thought of as a potent vasodilator. However, in the kidney, it plays an essential role in regulating intrarenal blood flow by inducing outer cortical vasoconstriction and preserving juxtamedullary perfusion. This variance in function is explained by the identification of at least four subtypes of adenosine receptor: A_1, A_{2a}, A_{2b}, and A_3 (Table 18-3). Activation of the A_1 adenosine receptor induces outer cortical vasoconstriction; it also decreases renin release and inhibits diuresis and natriuresis. In contrast, A_{2a} adenosine receptors increase medullary renal blood flow and enhance renin release, diuresis, and natriuresis.

Table 18-3 Adenosine Receptor Subtypes and Functions

Receptor	Agonist Function	Ischemic Injury
A_1	Outer cortical vasoconstriction	Highly protective
	Decreased renin release	
	Inhibition of diuresis and natriuresis	
A_{2a}	Juxtamedullary vasodilation	Highly protective
	Increased renin release	
	Promotion of diuresis and natriuresis	
A_{2b}	Unknown	
A_3	Unknown	Potentiates injury

Perioperative Ischemic and Nephrotoxic Injury

This section will review perioperative agents and events that may disrupt normal renal physiology. If the disruption is severe enough or occurs in susceptible individuals, it may induce ischemic or nephrotoxic acute tubular necrosis, the most common form of perioperative acute kidney injury.

Pathogenesis

Ischemia-Reperfusion Injury

In many clinical situations (e.g., hypovolemic shock, suprarenal aortic-cross clamping) the kidney is subject to a classic ischemia-reperfusion injury that involves several distinct phases.[80] Acute injury to the tubular epithelium and vascular endothelium initiates a rapid decline in GFR. The injury is extended by epithelial and endothelial cell apoptosis and necrosis. The injury becomes stabilized during the maintenance phase, with the beginning of cellular reorganization that culminates in the recovery phase. The initiation phase is often transient, so the extension phase is the most important "window of opportunity" for therapeutic intervention that might reverse acute kidney injury. This emphasizes the importance of early, sensitive detection of rapid declines in GFR.[27]

Nephrotoxic Injury

The putative mechanisms of nephrotoxic tubular injury have been previously discussed (see "Oxygen Balance in the Medullary Thick Ascending Loop"). The risk of nephrotoxic acute kidney injury is exponentially related to the number of nephrotoxic insults.[13] An isolated nephrotoxin (e.g., radiocontrast dye) is unlikely to cause acute kidney injury when the kidney is well perfused. In animal models of nephrotoxic acute tubular necrosis,

injection of radiocontrast dye predictably injures more than 50% of the renal medullary thick ascending limb only when the kidney is previously "primed" by a sequence of three other insults: dehydration, LMMA (a nitric oxide synthase inhibitor), and indomethacin (a prostaglandin synthesis inhibitor).[81]

Anesthetic Drugs

The choice of an anesthetic technique to preserve renal function during and after surgery is predicated on the preservation of RBF and perfusion pressure, the suppression of vasoconstrictor, salt-retaining stress responses to surgical stimulation and postoperative pain, and the avoidance or curtailment of nephrotoxic insults. No single anesthetic drug alone meets these criteria.

Regional Anesthesia

Spinal or epidural anesthesia that achieves sympathetic blockade of the fourth through tenth thoracic segments (see Chapters 51 and 52) is extremely effective in suppressing the sympathoadrenal stress response and release of catecholamines, renin, and AVP. During major surgery, RBF and GFR are preserved as long as adequate renal perfusion pressure is maintained.[82] This implies careful titration of the block, especially in elderly patients with cardiovascular disease, and may necessitate a 25% to 50% increase in intraoperative fluid administration. However, Gamulin and coworkers[83] found that renal sympathetic blockade obtained by epidural anesthesia did not block increases in renal vascular resistance induced by infrarenal aortic cross-clamping, nor did it prevent postoperative decreases in creatinine clearance. Combined spinal-epidural anesthesia for nephrectomy in living related donors appeared to promote graft renal blood flow more than general anesthesia, but there was no difference in renal function or outcome in recipients.[84]

General Anesthesia

The overall effect on renal function of anesthetic drugs in common use has been well reported.[85,86] All anesthetic techniques and agents tend to decrease GFR and intraoperative urine flow. Some drugs also decrease RBF, but filtration fraction is usually increased, which implies that angiotensin-induced efferent arteriolar constriction limits the decrease in GFR. However, these effects are much less significant than those caused by surgical stress or aortic cross-clamping and after emergence from anesthesia usually resolve promptly. Any anesthetic technique that induces hypotension will result in decreased urine flow because of altered peritubular capillary hydrostatic gradients, even if renal autoregulation is preserved (as it usually is during anesthesia). Permanent injury seldom results, unless the kidneys are abnormal to begin with or the hypovolemic insult is prolonged and exacerbated by nephrotoxic injury (see Chapter 24).

Halothane, enflurane, or isoflurane with nitrous oxide induce mild to moderate reductions in RBF and GFR, primarily due to their effects on the central circulation (myocardial depression, peripheral pooling).[85] These effects can be attenuated by prior hydration. High-dose opioid techniques using fentanyl or sufentanil do not depress myocardial contractility and have minimal effect on RBF and GFR. They are also considerably more effective in suppressing the release of catecholamines, angiotensin II, aldosterone, and AVP during surgery than are volatile agents. However, during CPB both AVP and catecholamine levels rise markedly despite high-dose opioid anesthesia. Intravenous agents such as thiopental and diazepam cause minor changes in renal function, about 10% to 15% deviation from control. Ketamine increases RBF but decreases urine flow rate, possibly through sympathetic activation; it preserves RBF during hemorrhagic hypovolemia.[86]

Nephrotoxicity of Volatile Anesthetics

The potential nephrotoxicity of volatile anesthetics (see Chapter 24) is due to their metabolic breakdown to free fluoride ions, which cause a tubular lesion that results in loss of concentrating ability and polyuric acute renal failure. Toxicity is exacerbated by aminoglycosides or prior renal dysfunction. Peak fluoride levels less than 50 μm/L seldom induce injury, whereas levels greater than 150 μm/L are associated with a high incidence of polyuric acute renal failure.[87] Administration of methoxyflurane at more than one minimum alveolar concentration (MAC) for more than 2 hours is capable of generating a peak fluoride level greater than 100 μm/L and for this reason this anesthetic is no longer used. Enflurane is metabolized more rapidly, and most studies indicated that peak fluoride levels seldom rose above 25 μm/L. The antituberculotic agent isoniazid enhances fluoride production, but only isolated reports of fluoride-induced nephrotoxicity due to enflurane ever appeared. Isoflurane produces peak fluoride levels less than 4 μm/L, and halothane is not metabolized to fluoride at all.[88]

The potential nephrotoxicity of sevoflurane remains controversial. Although its metabolism generates more fluoride than enflurane does, clinically significant fluoride-induced nephrotoxicity has not been detected. Compound A, a vinyl ether formed by degradation of sevoflurane at low flow through carbon dioxide absorbents, is capable of inducing renal injury in rats. Although acute renal failure has not been reported in humans, Eger and associates reported evidence of transient renal injury (albuminuria, tubular enzymuria) in volunteers subjected to 8 hours of 1.25 MAC sevoflurane at 2 L/min gas flow.[89] There were no changes in urinary concentrating ability, serum creatinine, or BUN. Subsequently, Eger and associates[90] described a dose-response relationship between biochemical markers of glomerular and tubular injury (urinary albumin, α-glutathione-*S*-transferase) and compound A exposure expressed as parts per million-hours (ppm/h). They suggested that the threshold of renal injury is 80 to 168 ppm/h based on their observation of altered biochemical markers with 1.25 MAC sevoflurane at 2 L/min for 4 hours, which was not seen after 2 hours, and not seen at all with desflurane.

Other laboratories have disputed Eger's findings. Bito and coworkers compared 6-hour patient exposure to low- and high-flow sevoflurane with exposure to low-flow isoflurane and found no differences in BUN, creatinine, or tubular enzymes for 3 days postoperatively.[91] Kharasch and coworkers[92] had similar results with the use of sevoflurane or isoflurane at 1 L/min in 73 patients undergoing procedures lasting longer than 2 hours, and they concluded that moderate duration of low-flow sevoflurane anesthesia, even with the formation of compound A, is as safe as low-flow isoflurane anesthesia. Ebert and associates[93] attempted to duplicate the original 8-hour Eger sevoflurane study in volunteers at two sites with blinded laboratory analyses. Biochemical derangements were minimal and transient, and there were no significant changes in BUN, creatinine, or creatinine clearance. Despite the similarity in experimental design, the mean level of compound A was about 25% lower, and the mean arterial pressure was about

10% higher than the Eger study and may have accounted for the difference in results.

In summary, clinically significant renal injury with the use of low-flow sevoflurane anesthesia has not been reported in patients, even with moderate preexisting renal dysfunction. The relationship between compound A formation, biochemical injury, and clinically relevant renal dysfunction remains unclear and unproven. Nonetheless it appears prudent to follow current U.S. Food and Drug Administration (FDA) guidelines, which recommend a fresh gas flow of at least 2 L/min to inhibit compound A formation and its rebreathing and to enhance its washout.

Volatile Anesthetics and Ischemia-Reperfusion Injury

There is experimental evidence that volatile anesthetics can ameliorate ischemia-reperfusion injury in the kidney. In a murine model, Lee and Emala demonstrated that anesthesia with desflurane, sevoflurane, isoflurane, and halothane significantly attenuated the rise in serum creatinine compared with pentobarbital or ketamine.[94] The mechanism appears to be independent of K^+-ATP channels but related to suppression of the proinflammatory cytokine and chemokine activation in response to ischemia-reperfusion.

Mechanical Ventilation

Mechanical ventilation (see Chapter 93) and positive end-expiratory pressure (PEEP) may cause decreased RBF, GFR, sodium excretion, and urine flow rate or even acute renal injury.[95] Transmission of increased airway and intrapleural pressures to the intravascular space leads to decreases in venous return, transmural (i.e., effective) cardiac filling pressures, and cardiac output. Transmission may actually be attenuated in acute lung injury because of poor lung compliance. High levels of mean airway pressure may compress the pulmonary arterial circulation, increase right ventricular afterload, and induce the intraventricular septum to shift into the left ventricle and decrease its filling and cardiac output.[96] Positive-pressure ventilation increases inferior vena caval pressure and renal venous pressure and may increase tubular sodium reabsorption by increases in peritubular capillary pressure.

The decrease in cardiac output and systemic arterial pressure results in a carotid and aortic baroreceptor-mediated increase in sympathetic nerve tone to the kidney, with renal vasoconstriction, antidiuresis, and anti-natriuresis. Volume receptors in the atria respond to decreased filling by decreased ANP secretion, resulting in increased sympathetic tone, renin activation, and AVP activity.

Salt and water retention during airway pressure therapy was originally thought to be due to an AVP effect,[97] but it is now considered that sympathetic responses are more important and that sodium retention is largely the result of decreased sodium delivery to the tubules. The renin-angiotensin-aldosterone system undoubtedly augments the renal responses to positive-pressure ventilation. Annat and coworkers[98] found that 15 cm H_2O PEEP depressed cardiac output, RBF, GFR, and urine volume by 20% to 30% and was associated with increases in renin and aldosterone but not AVP. The impairment in renal function induced by airway pressure therapy can be prevented or reversed by preserving normal circulatory status, either by hydration[99] or by use of dopamine.[100]

Although theoretically the extent of depression of renal function depends on the mean airway pressure, there appears to be no difference in creatinine clearance and FE_{Na} whether volume-control ventilation or pressure-support ventilation is used.[101] Therapeutic maneuvers used in severe acute lung injury such as permissive hypercapnia or permissive hypoxemia may promote renal vasoconstriction.[95]

Finally, in experimental lung injury there is evidence that an injurious ventilatory mode induces acute inflammation associated with renal epithelial cell apoptosis and dysfunction.[102] These findings appear to be in keeping with the clinical observation of multiorgan dysfunction in patients with acute respiratory distress syndrome and with its amelioration when a lung protective strategy of mechanical ventilation is used.[95]

Induced Hypotension

During anesthesia with induced hypotension, substantial reduction of GFR and urine flow rate is common. However, when the duration of hypotension is less than 2 hours, no permanent impairment of renal function occurs, even in elderly patients.[103] Vasodilator agents used to induce hypotension differ in their effect on RBF. Administration of sodium nitroprusside decreases renal vascular resistance but tends to shunt blood flow away from the kidney. Moreover, its administration is associated with marked renin-angiotensin activation and catecholamine release, which results in rebound hypertension if the infusion is suddenly discontinued. Nitroglycerin decreases RBF less than sodium nitroprusside.[104] The selective DA_1-dopaminergic agonist fenoldopam is capable of providing induced hypotension without any significant decrease in RBF.[105]

Aortic Cross-Clamping

The relative effects of suprarenal and infrarenal aortic cross-clamping (see Chapter 62) on renal function in patients undergoing major vascular surgery have been studied. Regardless of the position of the aortic cross-clamp, RBF is decreased to 50% of normal during surgical preparation of the aorta, presumably owing to direct compression or reflex spasm of the renal arteries. After release of the suprarenal cross-clamp, RBF increases above normal (reflex hyperemia) but GFR remains depressed to one third of control for up to 2 hours. After 24 hours, GFR is still only two thirds of control. Tubular functions (concentrating ability, sodium, and water conservation) are markedly impaired, but urine flow is maintained. Myers and Moran[106] observed that these changes resemble an attenuated form of acute tubular necrosis. In this study all patients received mannitol pretreatment, which probably limited the tubular insult because oliguria was uncommon and recovery was relatively rapid. Cross-clamp times longer than 50 minutes are associated with prolonged depression of GFR and transient azotemia.[107]

In animal models, suprarenal aortic cross-clamping induces a decrease in renal endothelial nitric oxide; nitric oxide synthesis and cortical blood flow are enhanced by the administration of its substrate arginine.[108] Whether this intervention might attenuate the renal consequences of cross-clamping awaits further investigation.

Infrarenal aortic cross-clamping may also impair RBF and GFR by inducing decreases in cardiac output in response to increased systemic vascular resistance.[109] Atheromatous embolism of the renal arteries may be induced by cross-clamping or manipulation in areas of dense aortic plaque. Partial or complete cortical necrosis may occur, which is usually irreversible.

Renal Protection During Aortic Cross-Clamping

Mannitol has been used for more than 40 years to provide renal protection during aortic cross-clamping (see Chapter 62). Its protective effects have been clearly demonstrated in animal models of ischemic acute tubular necrosis,[110] but few prospective controlled human studies exist. Low-dose dopamine has commonly been used during major vascular surgery. In a canine study of thoracic aortic cross-clamping, RBF, GFR, and urine flow remained impaired for a considerable time after cross-clamp release. This delay was not prevented by prophylactic administration of dopamine.[111] In a human study of infrarenal cross-clamping, Paul and colleagues[112] compared diuretic therapy with a combination of mannitol and dopamine versus fluid loading with saline to a pulmonary artery occlusion pressure (PAOP) of 12 to 15 mm Hg. Although mannitol and dopamine substantially increased urine flow and sodium excretion during cross-clamping, they were no better than saline in attenuating residual GFR depression after cross-clamp release.

Fenoldopam, a synthetic phenolated dopamine analog that is a selective agonist of the DA1-receptor, increases renal blood flow in a dose-dependent manner.[113] Infusion of fenoldopam has demonstrated a renoprotective effect in experimental suprarenal aortic cross-clamping.[114] In a controlled, randomized, blinded study in 28 patients undergoing infrarenal aortic cross-clamping, fenoldopam, 0.1 μg/kg/min, or placebo was infused intravenously before surgical skin incision and continued until release of the aortic cross-clamp.[115] Fenoldopam significantly attenuated the decrease in creatinine clearance and increase in serum creatinine observed in patients who received placebo. Larger studies with this agent appear warranted.

Cardiopulmonary Bypass

The incidence of acute renal failure is very low (< 2%) after uncomplicated cardiac surgery in patients with previously normal renal function. It increases with the complexity of surgery (e.g., combined procedures versus simple revascularization). In a prospective review of more than 4000 cases at the Cleveland Clinic, Higgins and associates observed that the risk of renal morbidity and mortality increases exponentially when the preoperative serum creatinine value is greater than 1.9 mg/dL.[116] When it does occur after cardiac surgery, acute renal failure has a devastating effect on mortality, increasing it 15-fold with acute kidney injury (peak postoperative SCr > 1 mg/dL) and 30-fold when renal replacement therapy is required.[117] During CPB (see Chapter 60), hypotension with nonpulsatile flow promotes renal vasoconstriction and decreases RBF. Norepinephrine levels increase progressively during bypass, and the renin-angiotensin system is activated. Acute renal failure has been associated with persistent elevation of plasma renin levels.[106] Thromboxane, released from activated platelets, and vascular elaboration of endothelin could add to renal vasoconstriction during extracorporeal circulation. Tubular enzymuria and microalbuminuria, an index of subclinical injury to the nephron, is consistently observed during CPB.[118]

Renal Protection during Cardiopulmonary Bypass

Pulsatile Perfusion During CPB

In animal and human studies, pulsatile perfusion during CPB enhances renal cortical blood flow and decreases circulating catecholamines, endothelin, and cytokine activation (see Chapter 60).[119,120] However, these physiologic advantages have not translated into clinical benefit. Although plasma renin activity is suppressed by pulsatile perfusion, evidence of glomerular injury (in this case, microalbuminuria) persists.[35] In a randomized prospective study on 215 pediatric patients undergoing repair of congenital heart disease, the use of pulsatile flow during CPB was associated with decreased inotropic requirement, shorter intensive care unit and hospital length of stay, and greater urine output, but there was no difference in serum creatinine value.[121] Intra-aortic balloon counterpulsation was used to provide pulsatile flow during CPB in a randomized, prospective study on 100 adult patients undergoing cardiac surgery.[122] Pulsatile flow attenuated the decline in GFR, but there was no difference in urine flow or renal outcome. In a large nonrandomized observational study, pulsatile flow was provided during CPB in 915 of 1820 patients but did not appear to provide increased protection against perioperative renal injury.[123]

Avoidance of CPB

The benefit to renal function of off-pump coronary artery bypass (OPCAB, also known as beating heart surgery) also remains equivocal. In low-risk patients, there appears to be little difference in the incidence of acute kidney injury whether or not CPB is used.[124] Most published studies to date have been small (<60 patients), and although they demonstrate that OPCAB is associated with less evidence of acute kidney injury, as manifested by lower levels of serum creatinine, cystatin C, microalbuminuria, and NAG, this has not translated into a benefit to renal outcome, morbidity, or mortality.[125,126] In a larger study on 201 patients, the use of CPB resulted in a significant increase in acute kidney injury, defined as a greater than 50% increase in postoperative serum creatinine concentration (27.7 versus 14.0%, $P < .03$).[127] Although the OPCAB technique was identified as the only independent factor associated with a lower incidence of acute kidney injury, the study was not randomized and all procedures were performed by the same experienced surgeon.

Perfusion Pressure During CPB

It has been observed in animal studies of CPB that RBF is dependent on renal perfusion pressure and that infusion of dopamine does not increase RBF during low-pressure states.[10] This suggests that autoregulation may be impaired during CPB. However, Hilberman and colleagues[128] found no relationship between low flow (<50 mL/kg/min) and low mean arterial pressure (<50 mm Hg) and postoperative acute renal failure. Instead, the severity of postoperative renal dysfunction and its outcome correlated with the severity of cardiac dysfunction after CPB.[129]

Dopaminergic and Diuretic Drugs

In a study comparing equi-inotropic doses of dopamine and dobutamine after cardiac surgery, the two agents had similar effects on GFR, RBF, renal vascular resistance, and filtration fraction but dopamine caused greater urine flow rate, natriuresis, FE_{Na}, and potassium excretion, indicating a diuretic effect independent of

changes in RBF and GFR.[130] However, there is no evidence that the "prophylactic" administration of low doses of dopamine has a protective role during CPB in patients with previously normal[131,132] or impaired renal function.[124,133]

In part, the lack of benefit may be due to the variable pharmacokinetic effect of dopamine. In a study on normal volunteers, McGregor and coworkers found a 30-fold intersubject variability in plasma dopamine levels.[134] Some subjects given an infusion of "low dose" dopamine had plasma levels consistent with those associated with doses in the high, α-adrenergic range. Even at low doses it can cause unwanted tachycardia, and its postoperative infusion is associated with a higher incidence of supraventricular and ventricular arrhythmias.[135]

In contrast to dopamine, there does appear to be increasing evidence to support a renoprotective effect for infusion of low-dose fenoldopam infusion (0.1-0.3 μg/kg/min) during cardiac surgery. A meta-analysis of 13 randomized and case-matched studies on 1059 patients found that fenoldopam infusion is associated with a significant decrease in dialysis requirement, intensive care unit length of stay, and in-hospital mortality.[136] Most studies have been relatively small and identified improved serum creatinine and creatinine clearance rather than renal outcome.[137,138] The most convincing evidence thus far comes from a randomized, double-blinded study in 193 high-risk patients by Cogliati and colleagues.[139] Risk factors included elevated preoperative serum creatinine (>1.5 mg/dL), age older than 70 years, diabetes, and previous cardiac surgery. Patients who received fenoldopam had a decreased incidence of acute kidney injury (12.6 versus 27.6%, $P = .02$) and requirement for dialysis (0 versus 8.2%, $P = .004$).

Prophylactic administration of diuretics during CPB may actually be harmful: in a study on 126 patients undergoing elective cardiac surgery, perioperative infusion of furosemide (0.5 μg/kg/min) worsened serum creatinine level compared with low-dose dopamine and placebo.[131]

Natriuretic Peptides

Exogenous administration of anaritide (human recombinant ANP) decreases systemic blood pressure through arterial and venous dilation. There has been considerable interest in the ability of infused anaritide to reverse established acute renal failure ("renal rescue"). Animal studies of ischemic and nephrotoxic acute tubular necrosis,[140] as well as preliminary clinical studies,[141] offered promise. A large prospective study demonstrated significantly greater dialysis-free survival with anaritide infusion in oliguric acute renal failure, but in nonoliguric acute renal failure survival actually worsened.[31] Subsequently, a randomized, double-blind, placebo-controlled trial on 222 patients with oliguric acute renal failure found no differences in dialysis requirement, dialysis-free survival, or 60-day mortality between anaritide and placebo.[142] However, patients receiving anaritide had significantly more hypotension during infusion of the study drug.

Infusion of anaritide has been studied during CPB.[143] Compared with controls, patients who received anaritide had significantly lower plasma levels of renin, angiotensin II, and aldosterone and higher GFR and urine output.

Nesiritide (human recombinant BNP) is approved by the FDA for the parenteral treatment of advanced decompensated congestive heart failure. It decreases elevated cardiac preload and afterload, enhances cardiac function, and promotes diuresis and relieves symptoms related to pulmonary congestion and edema.[144] The major adverse effect is dose-related hypotension, which if excessive, can impair renal function.[145] A meta-analysis of studies of nesiritide infusion in patients with advanced decompensated heart failure suggested that its use is associated with worsening serum creatinine.[146] However, there is evidence that perioperative infusion of low doses (0.01 μg/kg/min) of nesiritide in high-risk patients undergoing cardiac surgery may have a renoprotective effect.[147] In a prospective, randomized, blinded study of 279 patients with left ventricular dysfunction (ejection fraction < 40%) undergoing coronary revascularization or mitral valve surgery, patients who received nesiritide had increased urine output, an attenuated postoperative increase in serum creatinine concentration, and improved survival 6 months after surgery. Further studies of nesiritide appear warranted.

N-Acetylcysteine

N-Acetylcysteine is an antioxidant that directly scavenges reactive oxygen species, and there is considerable evidence to support its use to prevent radiocontrast nephropathy (see later). However, a similar benefit has not been demonstrated by its perioperative administration in cardiac surgery. In two prospective, blinded randomized studies, neither intermittent injection[148] nor continuous infusion[149] of *N*-acetylcysteine had any impact on renal function or outcome after cardiac surgery. A large study on 254 patients with chronic renal insufficiency (GFR < 60 mL/min) was similarly unable to demonstrate any significant benefit from intermittent injection of *N*-acetylcysteine.[150]

Nephrotoxic Insults

Drug-Induced Nephrotoxicity

Nephrotoxic injury by drugs or contrast dyes seldom occurs without the presence of coexisting risk factors,[13] including shock, hypovolemia, congestive heart failure or advanced age, diabetes, or chronic renal insufficiency. The risk of nephrotoxicity increases exponentially with the number of risk factors and nephrotoxic combinations.

Nephrotoxic acute renal failure is usually nonoliguric, with loss of concentrating ability and slowly progressive azotemia. As GFR declines, accumulation of renally excreted drugs exacerbates nephrotoxicity, unless drug levels are carefully monitored and dosage is repeatedly adjusted. However, the prognosis for recovery is good if these agents are discontinued in time and when no coexistent organ failure exists.[151]

Aminoglycosides

Aminoglycosides (gentamicin, tobramycin, amikacin) are polycationic compounds that are filtered into the proximal tubule, where they bind to anionic brush-border membrane phospholipids. Their nephrotoxicity is directly related to their polycationic status, so that neomycin (six cationic sites) is more destructive than gentamicin (five sites) or streptomycin (three sites).[152] They are absorbed into intracellular lysosomes by endocytosis and thence released into the cytosol. Within the cell they induce the formation of reactive oxygen metabolites that injure lysosomes, plasma membranes, and mitochondria and, in particular, inhibit oxidative phosphorylation and the synthesis of high-energy phosphate compounds such as ATP. Aminoglycoside-induced nephrotoxicity is directly related to sustained high trough serum levels, especially when associated with advanced age, preexisting renal disease, renal vasoconstrictive states (sepsis, hypovolemia, liver

disease, congestive heart failure), adjuvant drug therapy (loop diuretics, vancomycin, cephalosporins, NSAIDs, cyclosporine, amphotericin B), and electrolyte disorders (hypokalemia, hypomagnesemia, hypercalcemia, and metabolic acidosis).[153]

Prevention of aminoglycoside nephrotoxicity depends on maintenance of adequate hydration, avoidance or removal of the risk factors just listed, and careful monitoring of serum aminoglycoside levels. A daily 2-hour creatinine clearance can also be helpful in the early detection of aminoglycoside-induced nephrotoxicity and appropriate dose adjustment for GFR. Once-daily administration of aminoglycosides to achieve a high therapeutic level with an adequate trough period for renal recovery may limit the occurrence of nephrotoxicity.[154]

Nonsteroidal Anti-inflammatory Drugs

Cyclooxygenase-1 is inhibited by NSAIDs (see Chapter 26) such as indomethacin, meclofenamate, and ketorolac for about 8 to 24 hours. A single dose of aspirin causes its irreversible acetylation. In platelets, the impact lasts for the lifetime of these cells (7 to 10 days), but the kidney resynthesizes cyclooxygenase within 24 to 48 hours. The renal protective function of prostaglandins is "switched on" by injury, illustrated by the fact that NSAIDs cause nephrotoxicity in ischemic but not in normal kidneys. During conditions of stress, impaired prostaglandin activity results in decreased RBF and GFR, increased renal vascular resistance, attenuated diuretic responsiveness, and hyperkalemia.

Adverse effects of NSAIDs and aspirin occur in animal models of hemorrhage, endotoxemia, increased venous pressure, and low cardiac output and in humans with mild underlying renal dysfunction who also have congestive heart failure, ascites, or systemic lupus erythematosus.[155] Postoperative analgesia with a single analgesic such as ketorolac is extremely unlikely to cause injury in a relatively young, healthy, well-hydrated patient. The risk of nephrotoxic injury increases exponentially with the addition of concomitant nephrotoxins (e.g., contrast dye, aminoglycosides) in the presence of acute or chronic cardiovascular instability.

NSAIDs selective for cyclooxygenase-2 (celecoxib, rofecoxib, valdecoxib) appear to be less likely to cause gastric irritation and erosion. However, there is no evidence that they decrease the risk of nephrotoxic injury compared with nonselective cyclooxygenase inhibitors.[156] Their use has been severely curtailed after reports of increased adverse cardiovascular events in clinical trials.

Calcineurin Antagonists (Cyclosporine, Tacrolimus)

Cyclosporine is a remarkably potent immunosuppressive agent and, together with corticosteroids and azathioprine, is routinely used to prevent rejection after organ transplantation. Indeed, heart, lung, and liver transplantation increased exponentially after its release in 1981. It causes renal injury, in part because it induces sympathetic hyperreactivity, hypertension, and renal vasoconstriction. Preexisting renal dysfunction, hypovolemia, and other nephrotoxic insults exacerbate its nephrotoxic effects. Many transplant patients must tolerate a moderately elevated serum creatinine (1.5-2 mg/dL) to sustain adequate immunosuppression. A related calcineurin immunosuppressive agent, tacrolimus (FK506), is somewhat less nephrotoxic than cyclosporine and has largely replaced it in liver transplantation.

In patients undergoing cadaveric renal transplantation, the calcium channel blocker diltiazem was added to the graft preservative solution, infused into the donor for 48 hours, and then given orally.[157] The incidence of transplant acute tubular necrosis decreased from 41% to 10%, and when acute renal failure did occur, hemodialysis requirement was significantly less. Diltiazem impairs cyclosporine metabolism so that plasma cyclosporine levels are higher, with fewer episodes of early acute rejection, but it protects against cyclosporine nephrotoxicity.[158] Cyclosporine dosage may be reduced by 30% to achieve the same drug levels, representing a substantial savings to patients.

An alternative approach that is gaining some traction is to replace cyclosporine or tacrolimus with the non-calcineurin agent sirolimus, which appears to have similar immunosuppressive effects with considerably less potential to induce renal injury.[159]

Radiocontrast Nephropathy

The nephrotoxicity of contrast dyes (see Chapter 79) probably involves microvascular obstruction by crenated red cells as well as direct tubular toxicity by release of free oxygen radicals. The risk is markedly increased in diabetic renal insufficiency, hypovolemia, congestive heart failure, and myeloma.[160] Radiocontrast dyes are hypertonic and cause an osmotic diuresis, which induces a false sense of security but exacerbates hypovolemia and renal damage. Azotemia commences 24 to 48 hours after exposure and peaks at 3 to 5 days. Surgery performed during this period greatly increases the risk of perioperative acute renal failure.

Prevention of radiocontrast nephropathy depends on adequate hydration (e.g., 1 mL/kg normal saline initiated at least 4 hours before and continued for 12 hours after radiocontrast administration).[161] Elective surgical procedures should be deferred until the effects of the dye have been evaluated and treated.[162] Nonionic, low-, or iso-osmolar radiocontrast media are less nephrotoxic but are expensive and offer optimal cost-benefit ratio when used in high-risk situations only (e.g., diabetic nephropathy).[154]

A number of pharmacologic agents have possible roles in preventing or attenuating contrast nephropathy but none replaces hydration as first-line protection. Intravenous mannitol has been used for many years but may exacerbate injury if it induces dehydration though excessive osmotic diuresis.

N-Acetylcysteine

Tepel and associates reported that prophylactic administration of the antioxidant *N*-acetylcysteine (600 mg orally twice daily) attenuated renal injury in a study on 83 patients with chronic renal insufficiency (mean serum creatinine, 2.4 mg/dL) undergoing contrast radiography.[163] Only 2% of patients receiving *N*-acetylcysteine had an increase in serum creatinine of more than 0.5 mg/dL, compared with 21% of patients receiving saline placebo, and mean serum creatinine concentrations actually decreased. Subsequent studies either did not confirm these results[164] or found that *N*-acetylcysteine provided better protection than saline alone only when a low dose of contrast dye was used.[165] Moreover, there is evidence that *N*-acetylcysteine itself decreases serum creatinine levels.[17] However, in a study on 354 patients undergoing primary angioplasty, *N*-acetylcysteine significantly decreased the incidence of radiocontrast nephropathy, dialysis requirement, and hospital mortality in a dose-dependent manner.[166]

Fenoldopam

Preliminary evidence demonstrated that fenoldopam infusion prevented the decrease in RPF induced by radiocontrast media.[167] However, a large, multicenter randomized clinical trial on 315 patients with preexisting renal insufficiency (creatinine clearance < 60 mL/min) showed that it had no benefit on renal function compared with placebo.[168]

Pigment Nephropathy

Pigment nephropathy implies acute renal injury due to the nephrotoxic effect of the heme pigments myoglobin, hemoglobin, and bilirubin.

Rhabdomyolysis and Myoglobinemia

Muscle necrosis (rhabdomyolysis) occurs most commonly with direct trauma involving major crush or thermal injury (see Chapter 72). However, it also occurs with acute muscle ischemia induced by vascular disease or injury or by prolonged immobilization. Compartment syndromes exacerbate rhabdomyolysis. They are particularly likely to occur with major hemorrhage in an extremity or when vascular insufficiency coexists with tissue edema (e.g., femoral placement of an intra-aortic balloon after vein harvesting). Dramatic increases in metabolic rate (severe exercise, prolonged fever, status epilepticus, or myoclonus), severe hypophosphatemia, or direct proteolysis (acute pancreatitis) can all precipitate rhabdomyolysis.[169]

Myoglobin, the oxygen-carrying heme pigment of muscle, is released into the bloodstream (myoglobinemia) and rapidly excreted by the glomerulus at a plasma threshold of 0.03 mg/dL. Delivery of myoglobin to the proximal tubule is greater in a well-muscled individual with normal GFR than in a cachectic patient with low GFR. At a urine pH less than 5.6, myoglobin is transformed into ferrihematin, which precipitates in the proximal tubule.[170] Renal damage is facilitated by hypovolemia (i.e., low tubular flow) and acidic urine. Because of the associated hypercatabolic state, oliguria is associated with acute hyperkalemia, hypocalcemia, anion-gap metabolic acidosis, and rapid azotemia. Serum creatinine and BUN increase very rapidly (1.0-1.5 mg/dL/day and 20-30 mg/dL/day, respectively).

The most important aid to the diagnosis of rhabdomyolysis is a high index of suspicion. The affected muscle may be obviously ischemic or swollen, painful, and edematous. Urine myoglobin often tests positive without reddish urine. The serum is clear because of the low renal threshold for myoglobin excretion, whereas hemoglobinemia is associated with pink serum. Serial total creatinine phosphokinase (CPK) is a helpful guide to the severity of rhabdomyolysis (i.e., CPK-MM release).[171] Renal damage is much more likely when total CPK exceeds 10,000 units/L.

Prevention of acute nephrotoxic tubular necrosis is dependent on the maintenance of high RBF and tubular flow. Urine flow should be kept between 100 to 150 mL/hr by osmotic diuresis with intravenous mannitol, 6.25 to 12.5 g every 6 hours, with or without intravenous furosemide, 10 to 20 mg as required.[172] Urine pH should be kept above pH 5.6 with intravenous sodium bicarbonate, 50 mEq intravenously, as required, and/or acetazolamide, 250 mg every 6 hours. However, because there are no prospective data that confirm the beneficial effect of urinary alkalinization, urine pH should not be increased at the expense of causing significant acid-base imbalance. Calcium should be given to treat hyperkalemia only.

Hemolysis and Hemoglobinemia

Acute intravascular hemolysis (see Chapter 52) due to mismatched blood transfusion (ABO incompatibility) represents a direct and devastating renal insult. Renal damage is thought to be predominantly due to red blood cell stroma rather than to free hemoglobin. Management is essentially the same as for rhabdomyolysis.

Jaundice and Bilirubinemia

There is a direct correlation between the degree of preoperative obstructive jaundice and postoperative renal dysfunction.[173] When cholestasis causes the conjugated bilirubin to increase above 8 mg/dL, bile salt excretion effectively ceases, resulting in portal septicemia and renal damage. This situation is analogous to hepatorenal syndrome and sepsis, in which circulating endotoxins induce renal vasoconstriction and damage (vasomotor nephropathy).

Administration of preoperative oral bile salts (e.g., sodium taurocholate) or intravenous mannitol may provide perioperative renal protection in patients with severe obstructive jaundice. In a prospective, randomized study in patients with obstructive jaundice undergoing surgery, Plusa and Clark[174] found no difference in renal outcome between these two regimens. However, mannitol provokes a brisk osmotic diuresis and it is important to replace urinary losses appropriately. Diuresis-induced hypovolemia negates the protective effect of mannitol.[175]

Sepsis

Sepsis is the most common cause of new-onset acute renal failure in the postoperative period (see Chapters 91 and 92). Renal function may deteriorate progressively without defined episodes of hypotension. In addition, sepsis predisposes the kidney to further ischemic and nephrotoxic insults (e.g., from concomitant aminoglycoside usage).[176] Acute renal failure itself and hemodialysis perpetuate sepsis by activating leukocytes. There is a reasonable amount of evidence to suggest that renal autoregulation may be impaired in sepsis and that RBF and GFR decline pari passu with systemic vascular resistance and mean arterial pressure. Hypotension sets off a cascade of neurohormonal responses (sympathoadrenal activity; renin-angiotensin, vasopressin, and thromboxane activation) that result in decreased RBF, GFR, sodium excretion, and urine flow. The severity of renal dysfunction is directly related to the severity of sepsis and the degree of plasma renin activation.[177]

Renal dysfunction in sepsis is characterized as a vasomotor nephropathy, which implies renal vasoconstriction in the presence of increased total cardiac index. Renal vasoconstriction, mesangial cell contraction, decreased ultrafiltration coefficient, and decreased GFR are induced by endotoxin and by compounds activated in sepsis.[178] These include endothelin and eicosanoids, such as thromboxane, prostaglandin F_2, and the leukotrienes C4 and D4. Prostaglandin F_2, which mimics the action of thromboxane, is formed during leukostasis when arachidonic acid is oxidized by free oxygen radicals.

It has been estimated that 10% to 26% of septic patients receiving aminoglycoside antibiotics will develop nephrotoxic renal insufficiency.[153] Aminoglycoside nephrotoxicity is enhanced by the interaction of fever, renal vasoconstriction, hypovolemia, and endotoxin. In the presence of these and other risk factors (see earlier), alternative non-nephrotoxic antibiotics should be con-

sidered to treat gram-negative infections, including penicillins (ticarcillin), cephalosporins (ceftazidime), carbapenems (imipenem), or monobactams (aztreonam).

Renal Protection in Septic Shock

Anti-inflammatory Agents

Cumming and coworkers[179] demonstrated a marked renal protective effect of a selective thromboxane synthetase inhibitor (U63557A) in laparotomy on a volume-loaded sheep peritonitis model. Administration of the selective inhibitor either before or 30 minutes after surgery prevented deterioration in creatinine clearance, urinary sodium excretion, and urine flow rate. Beneficial effects have also been observed with aprotinin, perhaps through its anti-inflammatory action.[57] In contrast, nonselective cyclooxygenase inhibition by NSAIDs worsens renal function in sepsis by decreasing the synthesis of the renal vasodilator prostacyclin.[180]

The use of pharmacologic doses of methylprednisolone in septic shock was discredited by two large multicenter studies showing no beneficial effect on outcome.[181,182] Moreover, patients who received corticosteroids had significant increases in BUN but not in serum creatinine concentration, suggesting a prerenal state induced by increased protein catabolism.[183] Other potentially adverse effects of high-dose corticosteroids include impaired mitochondrial function, impaired leukocyte function, and inhibition of phospholipase A_2, resulting in decreased synthesis of intrarenal vasodilator prostaglandins.

Supranormal Oxygen Delivery

Over the past decade there has been considerable controversy in the concept of supranormal oxygen delivery to the tissues to overcome the defect that exists in oxygen utilization by septic tissues.[184] This approach utilizes inotropic support and blood transfusion to drive global oxygen delivery (Do_2) to one of three end points: a Do_2 level consistently found in survivors (600 mL/min/m^2), or when global oxygen consumption (Vo_2) no longer increases with increasing Do_2 (consumption independence), or when blood lactate levels start to decline. The benefits on outcome of supranormal oxygen delivery have been disputed, and high-dose inotropic and vasopressor support may themselves have adverse consequences. Moreover, renal Do_2 and Vo_2 differ markedly from systemic indices. Renal Vo_2 is largely determined by tubular metabolic function, which is regulated by fluid and electrolyte changes. In a volume-loaded septic porcine model, inotropic support with dobutamine increased systemic Do_2 and Vo_2 but did not increase renal indices.[44] Furthermore, decreased global renal Do_2 does not appear to cause tubular damage, possibly because tubular work and Vo_2 are decreased when GFR declines.[185]

Dopaminergic Agents

Low-dose dopamine (1-3 μg/kg/min) is frequently administered to septic patients in the belief that it confers renal protection through renal vasodilation or perhaps by inhibition of the Na^+/K^+-ATPase pump and decreases in renal tubular Vo_2.

In patients with sepsis syndrome (signs of sepsis without hypotension), low-dose dopamine infusion doubled urine flow rate and increased creatinine clearance by 60% without any change in systemic hemodynamics.[186] However, the renal response to dopamine decreased significantly after 48 hours of dopamine infusion, possibly owing to downregulation of the renal dopaminergic receptors or diuresis-induced contraction of the intravascular volume. In patients with established septic shock who required catecholamines for blood pressure support, low-dose dopamine did not alter systemic hemodynamics or renal function.

The prophylactic administration of low-dose dopamine in sepsis appears to have been laid to rest by a large prospective controlled study conducted by the Australian and New Zealand Intensive Care Society (ANZICS). They randomized 328 patients with signs of the systemic inflammatory response syndrome (SIRS) and early renal dysfunction (oliguria or increasing serum creatinine) to dopamine, 2 μg/kg/min, or placebo. They found no differences in serum creatinine, dialysis requirement, intensive care unit or hospital length of stay or overall mortality.[187]

The potential role of dopexamine in septic shock remains speculative. Most studies have examined its role in splanchnic and hepatic perfusion rather than in renal protection. In animal models of sepsis, dopexamine has improved splanchnic and hepatic Do_2, but its β_2-adrenergic activity in causing tachycardia and hypotension may limit its application in clinical sepsis. Smithies and colleagues[188] administered dopexamine to patients with sepsis syndrome, acute respiratory failure, and at least one other organ system failure. Cardiac index increased and gastric intramucosal pH (an index of splanchnic perfusion) improved significantly.

Norepinephrine

In patients with septic shock, profound hypotension, and oliguria, vasopressor therapy with norepinephrine may actually improve renal function by enhancing renal perfusion pressure. Desjars and coworkers[11] evaluated a group of septic patients who remained oliguric despite volume resuscitation and the use of dopamine up to doses of 15 μg/kg/min. The addition of norepinephrine and reduction of dopamine to a low-dose level resulted in an improvement in mean arterial pressure from 50 to 70 mm Hg, a tripling of urine flow, and a doubling of creatinine clearance. Norepinephrine increased the systemic vascular resistance (SVR) with little change in cardiac index or Do_2. Subsequent studies have confirmed that the use of norepinephrine to keep mean arterial pressure greater than 60 mm Hg results in improved cardiac function (increase in stroke volume and decrease in heart rate) and GFR without deleterious effects on cardiac index, Vo_2, or oxygen extraction.[189] Large doses of norepinephrine may be required to achieve these goals, because in septic shock, the peripheral vasculature is notoriously refractory to norepinephrine-induced vasoconstriction. This occurs because of massive inducible nitric oxide release as well as vasopressin deficiency (see later). Nonetheless, these findings strongly support the concept that renal autoregulation is impaired in sepsis and that maintenance of adequate renal perfusion pressure is an important component of renal protection.

Arginine Vasopressin

Patients in vasodilatory shock have inappropriately low plasma levels of AVP and marked vascular sensitivity to its exogenous administration at low doses.[190] Vasodilatory shock is defined as hypotension, increased cardiac index, and low systemic vascular resistance refractory to pressors such as norepinephrine. Septic shock is its most common manifestation, but it is also characteristic of the contact activation syndrome induced by CPB or ventricular assist devices.[191]

Landry and coworkers[192] observed unusual sensitivity to the vasoconstrictor effects of infused AVP in patients with septic shock with profound hypotension despite catecholamine infusion. Infusion of AVP at doses of 2.4 units/hr, less than one tenth of those used in the treatment of bleeding esophageal varices, resulted in a dramatic increase in systolic blood pressure from 92 ± 4 to 146 ± 4 mm Hg (mean ± SEM, $P < .001$), and catecholamine infusions were able to be discontinued. In an associated report,[193] the authors observed that urine flow increased concomitantly in three of five patients, from an average of 30 mL/hr to 110 mL/hr.

Plasma AVP levels were remarkably low (3.1 ± 1.0 pg/mL) and significantly lower than in a cohort of patients in cardiogenic shock also receiving catecholamines (22.7 ± 2.2 pg/mL, $P < .001$).[192] It has been postulated that this "AVP deficiency" may be the result of excessive baroreceptor-mediated AVP release from sustained hypotension. This is strongly supported by a canine study demonstrating almost complete depletion of radiolabeled AVP in the posterior pituitary after 1 hour of hemorrhagic shock.[190]

A second mechanism for sensitivity to AVP in septic patients is explained by its effect on the potassium-ATP (K_{ATP}) channel.[190] Intracellular acidosis, lactic acid accumulation, and ATP depletion close K_{ATP} channels in the sarcolemma of vascular smooth muscle. This traps potassium outside the cell and hyperpolarizes the membrane, which in turn closes calcium channels essential for norepinephrine-induced vasoconstriction. AVP binds at the K_{ATP} channel and opens it, reversing membrane hyperpolarization and restoring sensitivity to norepinephrine.

The beneficial effect of AVP on renal function in sepsis may in part be due to its ability to increase low renal perfusion pressure back into the autoregulatory range. Another important factor is that, unlike norepinephrine, even at high local concentrations, AVP preferentially constricts the efferent arteriole, thereby improving filtration fraction and GFR.[53] However, in a large, prospective, randomized, blinded trial in 778 patients with severe septic shock, low-dose AVP (0.01-0.03 unit/min) did not provide a mortality benefit or decrease the requirement for dialysis when compared with an infusion of norepinephrine (5-15 µg/min).[194]

19 Basic Principles of Pharmacology

Key Points

1. The fundamental pharmacokinetic processes are dilution into volumes of distribution and clearance. These processes are governed by the physical properties of the drug and the metabolic capacity of the patient. Anesthetic drugs tend to be highly bound to protein in plasma and highly bound to lipid in peripheral tissues. Most anesthetic drugs are metabolized in the liver.
2. The pharmacokinetics of anesthetic drugs are typically described by mathematical models with a central compartment and one or two peripheral compartments. These compartments do not directly correspond to any anatomic or physiologic structures. Computer simulations can be used to predict the time course of plasma concentration and drug effect after any dose.
3. Drugs exert their effects through binding to receptors. The fraction bound is determined by the law of mass action, which yields a sigmoidal relationship between fractional occupancy and drug concentration.
4. Drugs can be agonists, partial agonists, neutral antagonists, or inverse agonists. Receptors can exist in many states, but for simplicity, one can think of them as having just two states: activated and inactivated. The intrinsic efficacy of a drug is determined by the extent to which it stabilizes the active form of the receptor (agonists) or the inactive form (inverse agonists) or simply displaces agonists from the binding site without favoring either form (neutral antagonists).
5. A fraction of receptors are in the activated state when drug is present. Thus, a "baseline effect" in the absence of drug does not represent the true baseline if all receptors are inactivated. This can be observed only by giving an inverse agonist that forces nearly all receptors into the inactivated state.
6. Four main receptor types of relevance in anesthesia are G protein–coupled receptors (opioids, catecholamines), ligand-gated ion channels (hypnotics, benzodiazepines, muscle relaxants, ketamine), voltage-gated ion channels (local anesthetics), and enzymes (neostigmine, amrinone, caffeine). The first three are located in cell membranes. Enzymes can be located anywhere.
7. Many drugs act through second messengers, which amplify drug action. Common second messengers are G proteins, which can release stimulating or inhibitory subunits in response to drug binding at the receptor; cyclic adenosine monophosphate, which is frequently a target of G protein stimulation or inhibition; inositol 1,4,5-triphosphate and diacylglycerol, also targets of G-protein regulation; and intracellular ions, especially calcium.
8. Advances in molecular pharmacology are helping identify the specific function of individual receptors, the role of individual amino acids in mediating receptor action, and the specific sites of action of many anesthetic drugs. Tools to explore the mechanism of drug action include site-directed mutagenesis to create "designer" receptors and knock-out/knock-down (underexpressed) or transgenic (overexpressed) murine models to understand the physiologic action of individual receptors.
9. The fundamental properties of the concentration-versus-response relationship are potency and efficacy. Potency is the concentration associated with a 50% drug effect. Efficacy is the maximal possible drug effect.
10. Drugs can interact both pharmacokinetically, through enzymatic induction or inhibition, or pharmacodynamically, through synergy or antagonism. Anesthetic techniques typically take advantage of the synergy between hypnotics and opioids to produce the anesthetic state at far lower doses of each drug than would be required if they were used alone.
11. Pharmacogenetics is gradually explaining some of the variability in response to drugs. Genetic variability in pharmacokinetics can be attributed to variability in hepatic cytochromes (e.g., CYP2D6, CYP2C19), circulating enzymes (e.g., pseudocholinesterase), or transporters. Genetic variability in pharmacodynamics can be attributed to alterations in receptors, as has been demonstrated for multiple adrenergic receptor variants. Malignant hyperthermia has been clearly linked to variability in the ryanodine receptor.

12. Variability in response to drugs can also be attributed to nongenetic causes, such as aging, disease, exposure to environmental toxins, and the pharmacokinetic or pharmacodynamic influence of other drugs. Variability is also introduced through continuous exposure to a single drug, which can trigger desensitization (tolerance) or, if the drug is an antagonist, increased receptor sensitivity to the agonist.

Anesthesiologists administer drugs to produce hypnosis, amnesia, analgesia, and muscle relaxation, and to support physiologic homeostasis while minimizing side effects and toxicity. Anesthesiologists select appropriate doses through a combination of scientifically guided administration and empirical titration. Both approaches are enhanced by a thorough understanding of the basic principles of pharmacology.

This chapter is divided into three major sections: pharmacokinetic principles, pharmacodynamic principles, and the principles that underlie variability in drug response. Pharmacokinetics is the relationship between drug administration and drug concentration at the site of action. The fundamental concepts include volumes of distribution, drug clearance, transfer of drugs between plasma and tissues, and binding of drugs to circulating plasma proteins. The section on pharmacokinetics introduces both the physiologic processes that determine pharmacokinetics and the mathematical models used to relate dose to concentration. Pharmacodynamics is the relationship between drug concentration and pharmacologic effect. The broad areas of transduction of biologic signals, fundamental receptor theory and structure, the role of new developments in molecular biology, and clinical evaluation of drug effects are all presented. The last section explores processes that contribute to variability in drug response, including pharmacogenetics, the influence of patient physiology on pharmacokinetics and pharmacodynamics, and drug interactions.

Pharmacokinetics

Pharmacokinetics is the relationship between drug dose and drug concentration in plasma or at the site of drug effect. The processes of absorption, distribution, and clearance govern this relationship. Absorption is not relevant to intravenously administered drugs but is relevant to all other routes of drug delivery. The time course of intravenously administered drugs is a function of volumes of distribution and clearance. We will first discuss the physiologic basis of pharmacokinetics and then review pharmacokinetic models that relate dose to plasma or tissue concentration.

Fundamental Pharmacokinetic Concepts

Volume of Distribution

The distribution of a drug throughout plasma and tissues can be viewed as a process of dilution from the highly concentrated solution in the syringe to the dilute concentration in plasma. This dilution follows the mixing of drug into blood and transfer into tissues. The pharmacokinetic concept of volume is simply the apparent size of the tank required to explain the observed drug concentration. Figure 19-1 shows the dilution of administered drug into a tank of fluid. By definition, the concentration in the tank is the amount of drug administered divided by the volume of the tank. If we do not know the volume beforehand but can measure the concentration, we can rearrange the definition of concentration to calculate the volume of the tank:

$$\text{Volume} = \frac{\text{Amount (or dose)}}{\text{Concentration}} \quad (1)$$

As soon as the volume of the tank is known, the concentration after any bolus of drug can be calculated as the dose per volume. Just as the tank has a volume regardless of whether there is drug in it, the volume of distribution of a drug is an intrinsic property of the drug and individual regardless of whether any drug has been given.

Central Volume of Distribution

If we assume that the drug is injected into an arm vein and that the initial concentration is measured in an artery, the central volume of distribution reflects the volume of the heart, great vessels, and the venous volume of the upper part of the arm. It also reflects drug uptake by the lungs. For example, alfentanil is less lipophilic than fentanyl or sufentanil, which results in less pulmonary uptake and a smaller central volume for alfentanil than fentanyl or sufentanil. The central volume also reflects any metabolism that occurs between the venous injection site and the arterial sample.

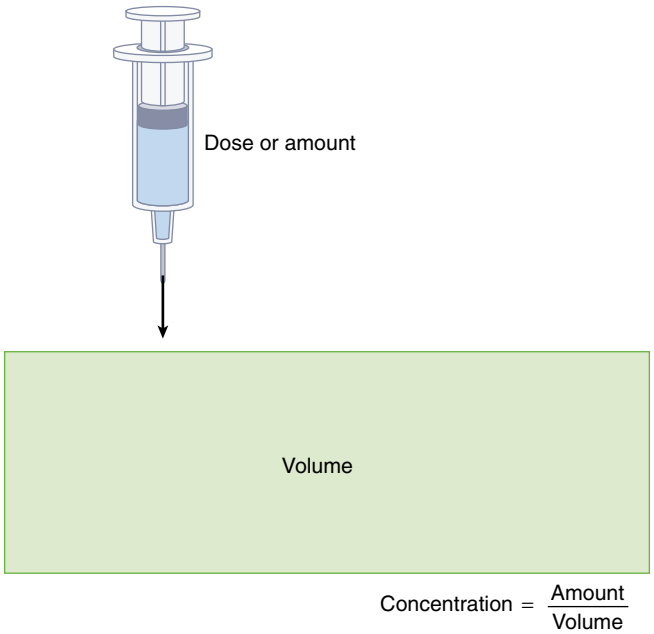

Figure 19-1 Volume represents the dilution of drug from the more concentrated form in the syringe to the dilute form in blood.

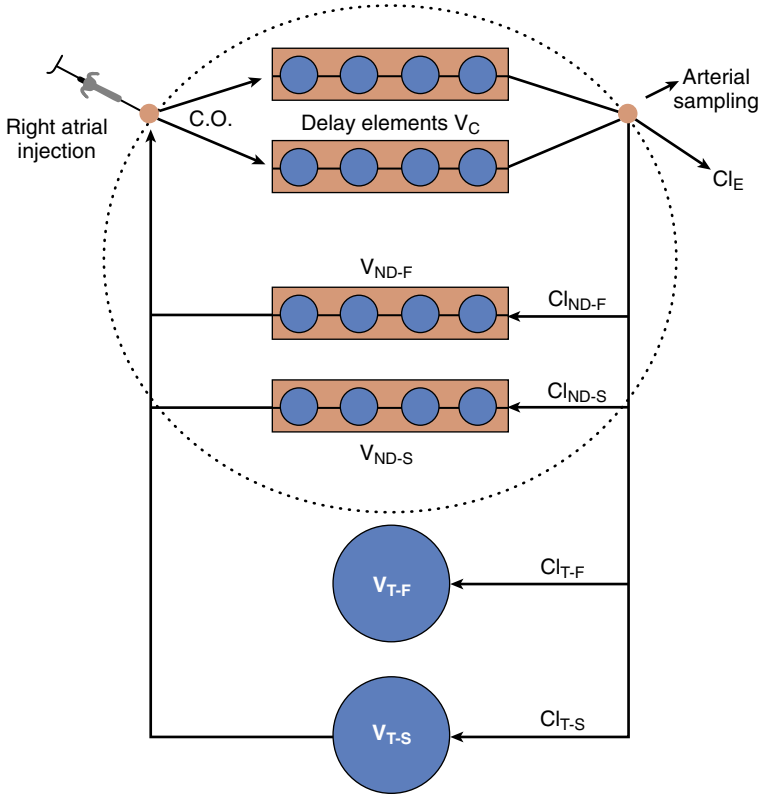

Figure 19-2 A recirculatory model accounting for cardiac output (C.O.), transit delays and pulmonary uptake (Delay Elements V_C), and nondistributive mixing pathways (V_{ND} and Cl_{ND}).[1] All the components within the *dashed circle* are required to accurately model the central volume of distribution. In most situations, this complexity is not required, and the simpler approach of assuming instantaneous mixing within the central volume is an adequate approximation. Cl_{ND-F} and Cl_{ND-S}, fast and slow nondistributive clearance; Cl_{T-F} and Cl_{T-S}, fast and slow tissue clearance; V_{ND-F} and V_{ND-S}, fast and slow nondistributive volume; V_{T-F} and V_{T-S}, fast and slow tissue volume. (*From Krejcie TC, Avram MJ, Gentry WB, et al: A recirculatory model of the pulmonary uptake and pharmacokinetics of lidocaine based on analysis of arterial and mixed venous data from dogs. J Pharmacokinet Biopharm 25:169-190, 1997.*)

The central volume of distribution is the most problematic pharmacokinetic concept. The central volume assumes that an intravenous bolus instantly mixes in this volume, with the peak concentration occurring at the moment of injection. Obviously, mixing is not instantaneous, and drug appears in the arterial circulation 30 to 40 seconds after injection. This 30- to 40-second delay is of no consequence outside anesthesia, but within the field of anesthesia the pharmacokinetic determinants of anesthetic induction are clinically important. The mathematics of the true time course, including the time delay and recirculatory peaks, have been worked out in detail by Henthorn, Avram, and Krejcie, as shown in Figure 19-2.[1]

Despite the assumption of instantaneous mixing, the concept of central volume of distribution is useful. The central volume represents the backward (and upward) extrapolation of the concentration-versus-time curve from its peak at about 30 seconds to the *y* axis. It can be thought of as the initial concentration, had circulation been infinitely fast. Because of this backward extrapolation, estimates of central volume are highly influenced by study design. A study with arterial samples will have higher initial concentrations and thus estimate a smaller central volume than a study with venous samples will. The timing of blood samples also influences estimation of the central volume of distribution. Over the first few minutes after bolus injection, the concentration of anesthetic drugs falls very rapidly, possibly by an order of magnitude. If the first sample is drawn at 30 seconds, backward extrapolation of the concentration-versus-time curve to the *y* axis predicts a high concentration at time 0 and thus a small central volume. If the first sample is drawn at 5 minutes, backward extrapolation of the concentration-versus-curve to the *y* axis predicts a much lower concentration and thus a larger central volume.

Peripheral Volumes of Distribution

Anesthetic drugs distribute extensively into peripheral tissues. This distribution into the periphery is represented pharmacokinetically as additional volumes of distribution that are attached to the central volume. Peripheral volumes are linked to the central compartment (plasma) by blood flow, a process called "intercompartmental clearance." The linkage of peripheral volumes to a central volume is called a "mammillary" model. This name refers to the structure of the plumbing: peripheral piglets suckling off a central (mother) pig. At least that is how the term was explained to us.

The size of the peripheral volumes of distribution reflects the drug's solubility in tissue relative to blood or plasma. The more soluble a drug is in peripheral tissue relative to blood or plasma, the larger the peripheral volumes of distribution. Because tissue solubility depends on simple physiochemical constants, it would seem likely that variability in peripheral volumes of distribution reflects differences in body habitus.

Peripheral volumes of distribution explain the apparent dilution of the drug into all body tissues. However, we usually do not know the actual solubility of drugs in peripheral tissues, nor do we care. The convention in pharmacokinetics is to assume that the solubility of the drug in tissue is the same as the solubility in plasma. This assumption does not compromise the role of peripheral compartments in characterizing the dilution of drugs into tissues, but it does lead to very large volumes of distribution for highly soluble drugs (e.g., 5000 L for propofol).

The volume of distribution at steady state (Vd_{ss}) is the volume that relates the plasma drug concentration at steady state (i.e., during a very long infusion) to the total amount of drug in the body. Vd_{ss} is the total amount of drug in the body at steady state divided by the plasma drug concentration. Hence, Vd_{ss} equals the central volume plus the peripheral volumes.

Clearance

Clearance removes drug from a volume. Systemic clearance permanently removes drug from the body, either by eliminating the parent molecule or by transforming it into metabolites. Intercompartmental clearance moves drug between plasma and peripheral tissues. Clearance is defined in units of flow, that is, the volume completely cleared of drug per unit of time (e.g., liters/minute). Clearance is most easily envisioned as flow to a clearing organ, as shown in Figure 19-3.[2] Clearance describes the body's capacity to remove drug, regardless of whether there is any drug in the body. The actual rate of drug removal is clearance times the concentration of the drug. If clearance is 1 L/min, the actual rate of drug elimination is 0 if the concentration is 0, 1 mg/min if the concentration is 1 mg/L, 10 mg/min if the concentration is 10 mg/L, and so on.

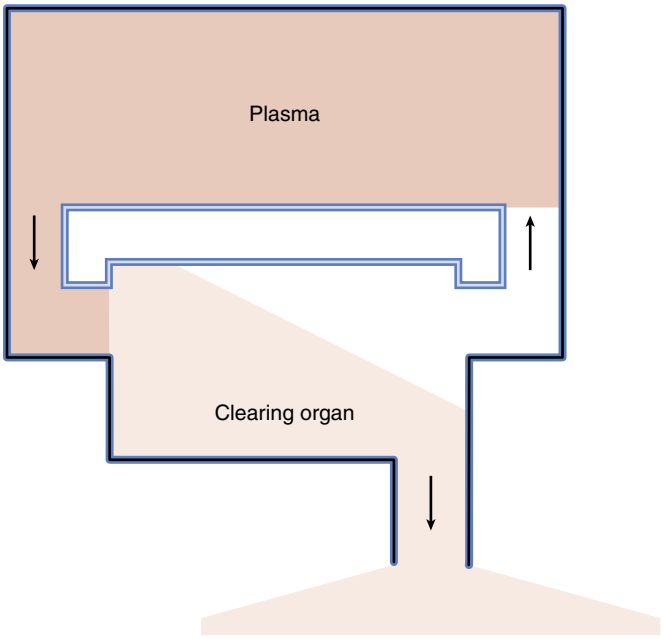

Figure 19-3 Clearance represents the flow of blood or plasma that is completely cleared of drug. If all of the drug is extracted by the clearing organ (i.e., extraction ratio ≈ 1), clearance is simply the flow to the organ, as illustrated here. *(Modified from Shafer S: Principles of pharmacokinetics and pharmacodynamics.* In *Longnecker DE, Tinker JH, Morgan GE [eds]: Principles and Practice of Anesthesiology, 2nd ed. St. Louis, Mosby–Year Book, 1997.)*

Hepatic Clearance

Most anesthetic drugs are cleared by hepatic biotransformation. The synthetic pathways for biotransformation are covered in detail in many biochemistry texts. Briefly, the liver metabolizes drugs through oxidation, reduction, hydrolysis, or conjugation. Oxidation and reduction occur in the cytochrome P450 system. These enzymes can be induced by exposure to certain drugs and increase the liver's intrinsic metabolic capacity. On the other hand, drugs or hepatic disease can inhibit these enzymes. Routes of oxidative metabolism include hydroxylation, dealkylation, deamination, desulfuration, epoxidation, and dehalogenation. Conjugation and hydrolysis often occur outside the P450 system, although glucuronidation involves the P450 system as well. The effect of conjugation is to transform hydrophobic molecules into water-soluble molecules through the addition of polar groups and thus render the metabolites easier to excrete via the kidneys. The metabolites generated by the liver are generally inactive, although some drugs (e.g., morphine, midazolam) have metabolites that are as potent as the parent drug. Genetic polymorphism can occur in all of these pathways, and this accounts for part of the variability in clearance in the population, as discussed in detail in the last section of this chapter.

Although most anesthetic drugs are cleared by hepatic metabolism, remifentanil, succinylcholine, and esmolol are cleared in the plasma and tissues by ester hydrolysis, and pancuronium is cleared via the kidney. The relationship between metabolism and clearance is complex. The following exploration of this relationship will assume hepatic metabolism, although the principles apply to the metabolism of drug in any tissue.

The rate of metabolism for most anesthetic drugs is proportional to the concentration of drug distributed via circulation to the liver. As will be shown later, this means that metabolic clearance is usually constant and independent of dose. This is such a common and fundamental assumption for anesthetic pharmacokinetics that we will explore the conditions that must be satisfied for it to be valid.

It cannot be true that metabolism is always proportional to concentration because the metabolic capacity of the liver is not infinite. At some rate of drug flow into the liver the metabolic capacity becomes saturated, and the rate of metabolism is no longer proportional to concentration. To understand the rate of metabolism quantitatively, we will start with a simple observation of mass balance: the rate at which drug flows *out* of the liver must be the rate at which drug flows *into* the liver minus the rate of metabolism. The rate at which drug flows into the liver is liver blood flow, $\dot{Q}$, times the concentration of drug flowing in, C_{inflow}. The rate at which drug flows out of the liver is liver blood flow, $\dot{Q}$, times the concentration of drug flowing out, $C_{outflow}$. Putting this together, the rate of hepatic metabolism by the liver, R, is the difference between the drug concentration flowing into the liver and the drug concentration flowing out of the liver, times the rate of liver blood flow:

$$\text{Rate of drug metabolism} = R = \dot{Q}\left(C_{inflow} - C_{outflow}\right) \qquad (2)$$

This relationship is illustrated in Figure 19-4. Because hepatic metabolism does not have infinite capacity, the relationship between the rate of hepatic metabolism, R, and concentration must be saturable. The saturation equation shows up repeatedly in pharmacokinetics and pharmacodynamics, so we will inspect it carefully:

$$\text{Response} = \frac{C}{C_{50} + C} \qquad (3)$$

"Response" in this equation varies from 0 to 1, depending on the value of C. When C is 0, the response is 0. If C is greater than 0 but much less than C_{50}, the response is nearly proportional to C: $\text{Response} \approx \frac{C}{C_{50}}$. If C equals C_{50}, the

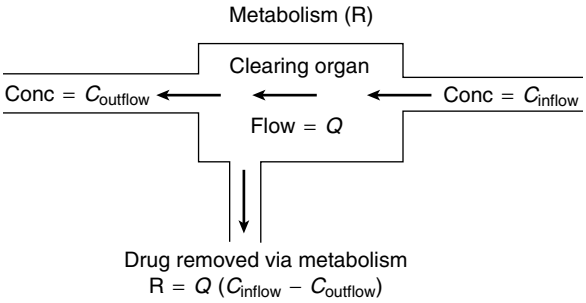

Figure 19-4 The rate of metabolism can be computed as the rate of liver blood flow times the difference between the inflowing and outflowing drug concentrations. This is a common approach to analyzing metabolism or tissue uptake across an organ in mass-balance pharmacokinetic studies.

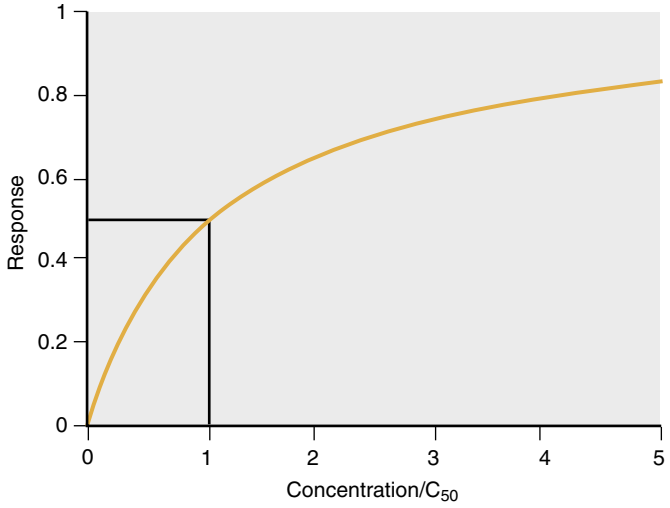

Figure 19-5 The saturation equation, response = C/(C_{50} + C), shows the decreasing incremental response as the system approaches saturation. Variations of this equation show up repeatedly in pharmacokinetics and pharmacodynamics.

response is $\frac{C_{50}}{C_{50}+C_{50}}$, which is simply 0.5. This is where the term "C_{50}" comes from; that is, it is the concentration associated with a 50% response. As C becomes much greater than C_{50}, the equation approaches $\frac{C}{C}$, which is 1.0. The shape of this relationship is shown in Figure 19-5. It is linear at low concentrations, but at high concentrations the response saturates at 1.

We can model the relationship between hepatic metabolism and drug concentration by using the saturation equation, but what concentration determines the rate of metabolism: the concentration flowing into the liver, the average concentration within the liver, or the concentration flowing out of the liver? All three have been used, but the most widely used model of metabolism views the rate of metabolism as a function of the concentration flowing *out* of the liver, $C_{outflow}$. This is discussed extensively by Wagner.[3]

We can expand our equation of metabolism to include the observation that the rate of metabolism, R, approaches saturation at the maximum metabolic rate, V_m, as a function of $C_{outflow}$:

$$\text{Rate of drug metabolism} = R = \dot{Q}\left(C_{inflow} - C_{outflow}\right) = V_m \frac{C_{outflow}}{K_m + C_{outflow}} \quad (4)$$

V_m is the maximum possible metabolic rate. The saturation part of this equation, $\frac{C_{outflow}}{K_m + C_{outflow}}$, determines the fraction of the maximum metabolic rate. K_m, also called the Michaelis constant, is the outflow concentration at which the metabolic rate is 50% of the maximum rate (V_m). This relationship is shown graphically in Figure 19-6. The *x* axis is the outflow concentration, $C_{outflow}$, as a fraction of K_m, the concentration that yields 50% of the maximum metabolic rate. The *y* axis is the rate of drug metabolism as a fraction of V_m, the maximum rate of drug metabolism. By normalizing $C_{outflow}$ to K_m and the metabolic rate to V_m, the relationship in Figure 19-6 is true for all values of V_m and K_m. Figure 19-6 shows that as long as the outflow concentration is less than half of K_m, there is a nearly proportional change in metabolic rate with a proportional change in outflow concentration. For most anesthetic drugs, the clinical concentrations do not exceed half of K_m, and thus metabolism of anesthetic drugs is nearly proportional to concentration. We can also interpret Figure 19-6 in terms of the metabolic rate (*y* axis). As long as the metabolic rate is less than a third of the maximum metabolic capacity, the rate of metabolism increases proportionally with concentration. The clinical message is that metabolism will be proportional to concentration and therefore the pharmacokinetics will remain

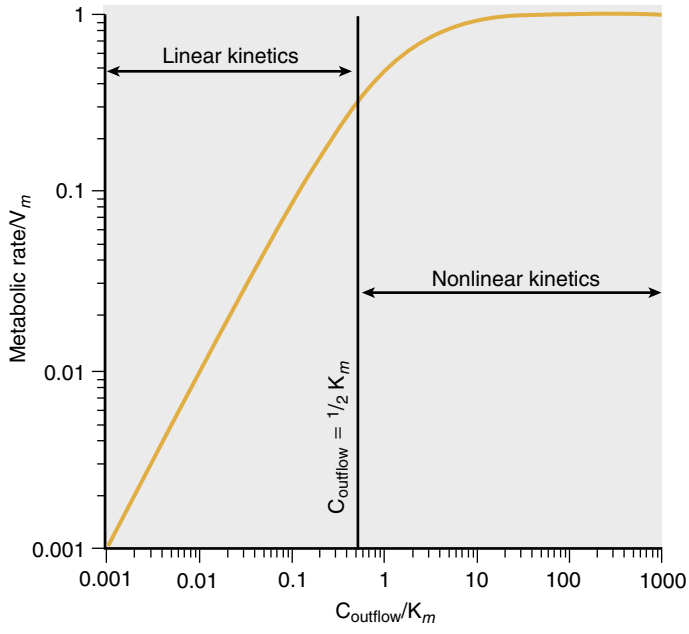

Figure 19-6 Relationship between concentration as a fraction of K_m (Michaelis constant) and drug metabolism as a fraction of V_m (maximum rate). As long as the outflow concentration is less than half K_m, a change in concentration is matched by a proportional change in metabolic rate. This is true of nearly all anesthetic drugs. *(From Shafer S: Principles of pharmacokinetics and pharmacodynamics.* In *Longnecker DE, Tinker JH, Morgan GE [eds]: Principles and Practice of Anesthesiology, 2nd ed. St. Louis, Mosby–Year Book, 1997.)*

linear, provided that the rate of intravenous administration at steady state does not exceed a third of the maximum metabolic capacity.

If the liver could completely extract the drug from the afferent flow, clearance would equal liver blood flow, $\dot{Q}$. However, the liver cannot remove every last drug molecule. There is always some drug in the effluent plasma. The fraction of inflowing drug extracted by the liver is $\frac{C_{inflow} - C_{outflow}}{C_{inflow}}$. This is called the extraction ratio. Clearance is the amount of blood completely cleared of drug per unit time. We can calculate clearance as liver blood flow times the extraction ratio:

$$\text{Clearance} = \dot{Q} \times ER = \dot{Q}\left(\frac{C_{inflow} - C_{outflow}}{C_{inflow}}\right) \quad (5)$$

With this basic understanding of clearance, let us divide each part of Equation 4 by C_{inflow}:

$$\begin{aligned}\frac{\text{Rate of drug metabolism}}{C_{inflow}} &= \frac{R}{C_{inflow}} \\ &= \dot{Q}\left(\frac{C_{inflow} - C_{outflow}}{C_{inflow}}\right) \\ &= \frac{C_{outflow}}{C_{inflow}}\left(\frac{V_m}{K_m + C_{outflow}}\right)\end{aligned} \quad (6)$$

The third term is clearance as defined in Equation 5: $\dot{Q}$ times the extraction ratio. Thus, each term must be clearance. Consider the first term, $\text{Clearance} = \frac{\text{Rate of drug metabolism}}{C_{inflow}}$. This indicates that clearance is a proportionality constant that relates inflowing (e.g., arterial) concentration to the rate of metabolism. If we want to maintain a given steady-state arterial drug concentration, we must infuse drug at the same rate that it is being metabolized. Thus, the infusion rate to maintain a given concentration is clearance times the desired concentration.

What should we make of the third and fourth terms, $\text{Clearance} = \dot{Q}\left(\frac{C_{inflow} - C_{outflow}}{C_{inflow}}\right)$ and $\text{Clearance} = \frac{C_{outflow}}{C_{inflow}}\left(\frac{V_m}{K_m + C_{outflow}}\right)$? Taken together, these equations relate clearance to liver blood flow and the extraction ratio, as shown in Figure 19-7.[4] For drugs with an extraction ratio of nearly 1 (e.g., propofol), a change in liver blood flow produces a nearly proportional change in clearance. For drugs with a low extraction ratio (e.g., alfentanil), clearance is nearly independent of the rate of liver blood flow. This makes intuitive sense. If nearly 100% of the drug is extracted by the liver, this implies that the liver has tremendous metabolic capacity for the drug. In this case, the rate-limiting step in metabolism is flow of drug to the liver, and such drugs are said to be "flow limited." Any reduction in liver blood flow, such as usually accompanies anesthesia, can be expected to reduce clearance. However, moderate changes in hepatic metabolic function per se will have little impact on clearance because hepatic metabolic capacity is overwhelmingly in excess of demand.

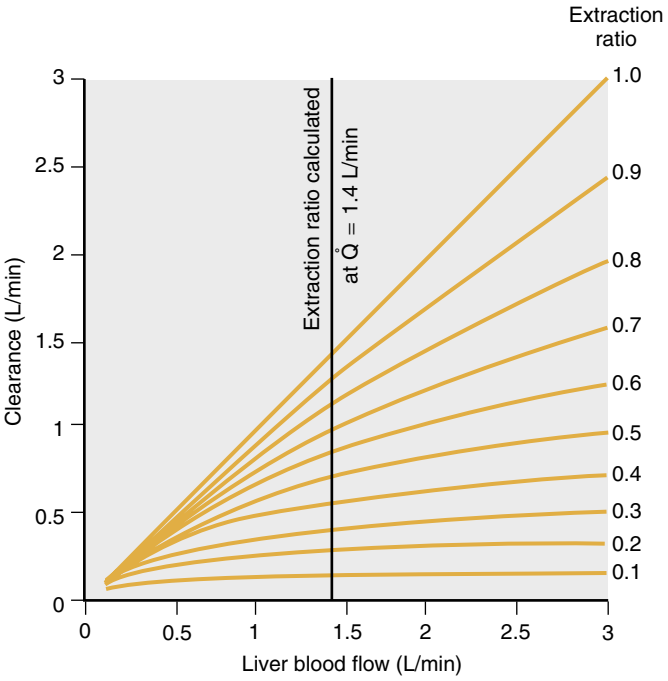

Figure 19-7 Relationship between liver blood flow ($\dot{Q}$), clearance, and extraction ratio. For drugs with a high extraction ratio, clearance is nearly identical to liver blood flow. For drugs with a low extraction ratio, changes in liver blood flow have almost no effect on clearance. *(Adapted from Wilkinson GR, Shand DG: Commentary: A physiological approach to hepatic drug clearance. Clin Pharmacol Ther 18:377-390, 1975.)*

For many drugs (e.g., alfentanil), the extraction ratio is considerably less than 1. For these drugs, clearance is limited by the capacity of the liver to take up and metabolize the drug. These drugs are said to be "capacity limited." Clearance will change in response to any change in the capacity of the liver to metabolize such drugs, as might be caused by liver disease or enzymatic induction. However, changes in liver blood flow, as might be caused by the anesthetic state itself, usually have little influence on clearance because the liver handles only a fraction of the drug that it sees anyway.

The last two components of Equation 6 can also be used to show how the extraction ratio governs the response of clearance to changes in metabolic capacity (V_m). Figure 19-8 shows the clearance of drugs with an extraction ratio ranging from 0.1 to 1, based on a liver blood flow of 1.4 L/min. The extraction ratios were calculated for a V_m of 1. Changes in V_m, as might be caused by liver disease (reduced V_m) or enzymatic induction (increased V_m), have little effect on drugs with a high extraction ratio. However, drugs with a low extraction ratio have a nearly linear change in clearance with a change in intrinsic metabolic capacity (V_m).

Inasmuch as V_m and K_m are often not known, it is occasionally useful to condense them into a single term that summarizes hepatic metabolic capacity: "intrinsic clearance." Because $\text{clearance} = \frac{C_{outflow}}{C_{inflow}}\left(\frac{V_m}{K_m + C_{outflow}}\right)$, consider what happens if hepatic blood flow increases to infinity with no change in hepatic

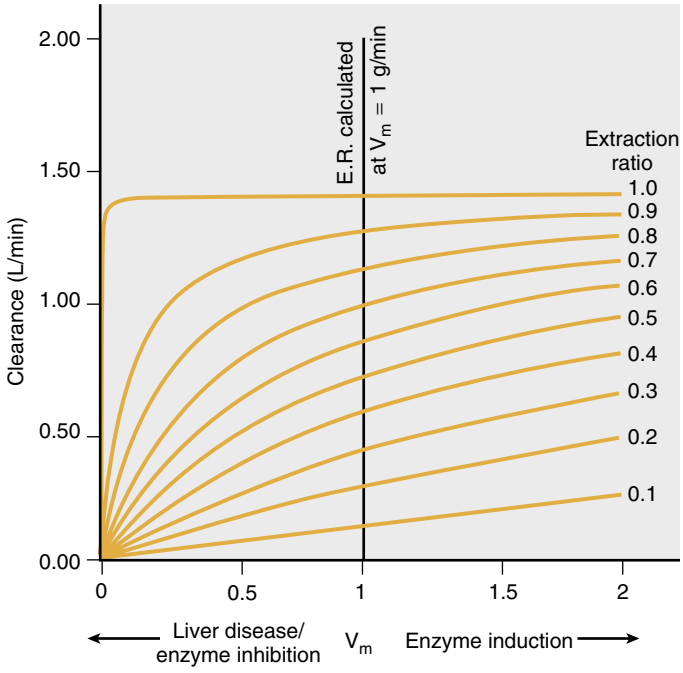

Figure 19-8 Corollary to Figure 19-7 showing the relationship between metabolic capacity, clearance, and extraction ratio (E.R.). Changes in maximum metabolic velocity (V_m) have little effect on drugs with a high extraction ratio, but they cause a nearly proportional decrease in clearance of drugs with a low extraction ratio.

metabolic capacity. $C_{outflow}$ becomes indistinguishable from C_{inflow} because the finite hepatic capacity metabolizes only an infinitesimal fraction of the drug flowing through the liver. As a result, clearance becomes $\frac{V_m}{K_m + C_{inflow}}$. We can solve for this in the "linear range" by finding clearance when $C_{inflow} = 0 : \frac{V_m}{K_m}$. This is the intrinsic clearance, Cl_{int}. In brief, it can be readily demonstrated (although we will spare you the details) from the definition of Cl_{int} that in the linear range, Cl_{int} is directly related to the extraction ratio:

$$\text{Extraction ratio} = \frac{Cl_{int}}{\dot{Q} + Cl_{int}} \tag{7}$$

Combining this with Equation 6 yields the relationship between hepatic clearance and Cl_{int}:

$$\text{Hepatic clearance} = \frac{\dot{Q}\, Cl_{int}}{\dot{Q} + Cl_{int}} \tag{8}$$

The relationship between intrinsic clearance and extraction ratio is shown in Figure 19-9 and was calculated at a hepatic blood flow of 1400 mL/min. In general, true hepatic clearance and extraction ratio are more useful concepts for anesthetic drugs than intrinsic clearance is. However, intrinsic clearance is introduced here because it is occasionally used in pharmacokinetic analysis of anesthetic drugs.

Thus far we have focused on linear pharmacokinetics, that is, the pharmacokinetics of drugs whose metabolic rate at clinical doses is less than $V_m/3$. Clearance of such drugs is generally expressed as a constant (e.g., propofol clearance = 1.6 L/min). Some drugs, such as phenytoin, exhibit saturable pharmacokinetics (i.e., have such low V_m that typical doses exceed the linear portion of Fig. 19-6). Clearance of drugs with saturable metabolism is a function of drug concentration rather than a constant.

Renal Clearance

The kidneys clear drug from plasma by filtration at the glomerulus and direct transport into the tubules. Renal blood flow is inversely correlated with age, as is creatinine clearance, which can be predicted from age and weight according to the equation of Cockroft and Gault[5]:
Men:

$$\text{Creatinine clearance } (\text{mL/min}) = \frac{(140 - \text{Age [yr]} \times \text{Weight [kg]})}{72 \times \text{Serum creatinine (mg\%)}} \tag{9}$$

Women:
85% of the above.

Equation 9 shows that age is an independent predictor of creatinine clearance. Thus, elderly patients have decreased creatinine clearance, even in the presence of normal serum creatinine levels. Inhaled anesthetics also decrease renal blood flow. Decreased renal clearance will delay the offset of effect for renally excreted drugs or their metabolites.

Tissue Clearance

Some anesthetic drugs are cleared in other tissues, such as blood, muscle, and the lungs. For example, remifentanil is cleared by nonspecific esterases located primarily in muscle and intestines, with the lungs, liver, kidneys, and blood each contributing minimally to clearance of remifentanil. Succinylcholine, mivacurium, and 2-chloroprocaine are all metabolized by plasma butyrylcho-

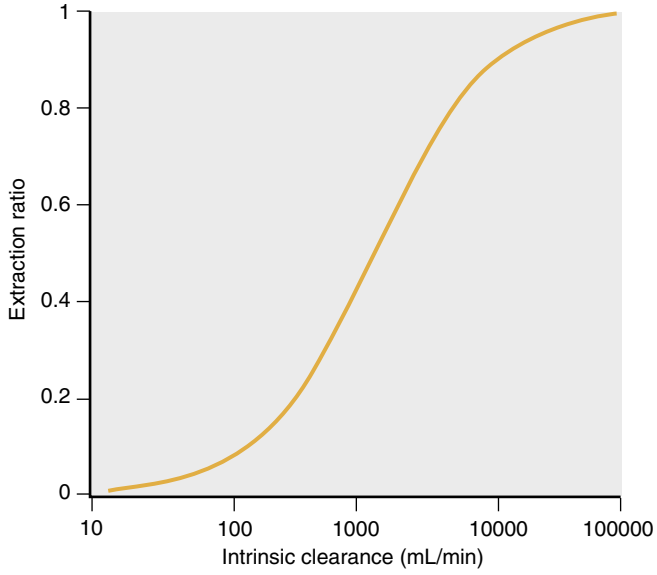

Figure 19-9 Relationship between intrinsic clearance and extraction ratio, calculated for a liver blood flow of 1400 mL/min.

linesterases (formerly called pseudocholinesterase). The half-life of succinylcholine, mivacurium, and 2-chloroprocaine in plasma is about 3 minutes, 5 minutes, and 25 seconds, respectively. About half of atracurium's metabolism is hepatic, and the balance occurs in blood via nonspecific cholinesterases (but not by butyrylcholinesterases). Hofmann degradation is a spontaneous process in plasma at normal pH and temperature and does not depend on any circulating esterases. Hofmann degradation is a minor route of metabolism of atracurium but is the major route of metabolism of cisatracurium, an isomer of atracurium. This is an important distinction: unlike atracurium and mivacurium, metabolism of cisatracurium is unaffected by disease or genetic variants of cholinesterase metabolism.

Clearance by tissues other than blood can be analyzed by using models similar to those for hepatic clearance. Tissue clearance can be flow limited, capacity limited, or both. Clearance within the blood itself cannot be flow limited and thus is entirely dependent on the intrinsic metabolic capacity of the blood.

Distribution Clearance

Distribution clearance is the transfer of drug between blood or plasma and peripheral tissues. Unlike metabolic clearance, distribution clearance does not permanently remove drug from the body. Distribution clearance is a function of cardiac output, tissue blood flow, and permeability of the capillary walls to the drug. For a drug that readily crosses into peripheral tissues, such as propofol, the sum of metabolic clearance and distribution clearance approaches cardiac output. For drugs that are metabolized directly in plasma or in many peripheral tissues, such as succinylcholine and remifentanil, the sum of metabolic clearance and distribution clearance can exceed cardiac output.

Protein Binding

Many drugs are bound to plasma proteins, particularly to albumin and α_1-acid glycoprotein. The relationship between drugs and their binding proteins can be described as

$$[\text{Free drug}] + [\text{Unbound protein binding sites}] \underset{k_{off}}{\overset{k_{on}}{\rightleftharpoons}} [\text{Bound drug}]$$

where [Free drug] is the free drug concentration, [Unbound protein binding sites] is the concentration of the available unbound protein binding sites, [Bound drug] is the concentration of drug bound to plasma proteins, k_{on} is the rate constant for binding of drug to plasma protein, and k_{off} is the rate constant for dissociation of bound drug from plasma protein. It can be inferred from this relationship that the rate of formation of bound drug is

$$\frac{d[\text{Bound drug}]}{dt} = [\text{Free drug}][\text{Unbound protein binding sites}]k_{on} - [\text{Bound drug}]k_{off} \quad (10)$$

At equilibrium (which is nearly instantaneous), d[Bound drug]/dt = 0, which permits us to solve for k, the ratio of k_{on}/k_{off}, as

$$k = \frac{k_{on}}{k_{off}} = \frac{[\text{Bound drug}]}{[\text{Free drug}][\text{Unbound protein binding sites}]} \quad (11)$$

Plasma proteins may have more than one binding site. Therefore, the total number of binding sites is the protein concentration, [Protein], times n, the average number of binding sites per protein molecule. For drugs used in anesthesia, the number of binding sites actually bound is only a trivial fraction of the total available binding sites, and thus we can reasonably approximate [Unbound protein binding sites] by n [Protein]. Because n, the number of binding sites per molecule, is constant, we can fold it into our rate constant k by defining the association constant K_a as

$$K_a = n\frac{k_{on}}{k_{off}} = \frac{[\text{Bound drug}]}{[\text{Free drug}][\text{Protein}]} \quad (12)$$

Let us define f_u as the free fraction of drug:

$$f_u = \frac{[\text{Free drug}]}{[\text{Bound drug}] + [\text{Free drug}]} \quad (13)$$

By combining Equations 12 and 13, we can solve for f_u in terms of the unbound drug concentration:

$$f_u = \frac{1}{1 + K_a[\text{Protein}]} \quad (14)$$

Two observations can be drawn from Equation 14. First, the fraction bound to plasma protein solely depends on the protein concentration, not on the drug concentration, provided that [Bound drug] << n[Protein]. This approximation is always true for anesthetic drugs because of their high potency. Even for thiopental, possibly the least potent drug used in contemporary anesthetic practice, [Bound drug] << n[Protein], and protein binding is independent of the concentration of thiopental. Second, if we solve Equation 14 for $f_u = 0.5$, we find that

$$K_a = \frac{1}{[\text{Protein}]_{50}} \quad (15)$$

where $[\text{Protein}]_{50}$ is the concentration of protein at which 50% of the drug is bound. Thus, another way of thinking about the association constant is that it is the inverse of the protein concentration associated with 50% binding. If we substitute $\frac{1}{[\text{Protein}]_{50}}$ for K_a in Equation 14, we get the relationship

$$f_u = \frac{[\text{Protein}]_{50}}{[\text{Protein}]_{50} + [\text{Protein}]} \quad (16)$$

This relationship is shown graphically in Figure 19-10. On the left side of Figure 19-10, [Protein] is much smaller than $[\text{Protein}]_{50}$. In this situation the drug has little affinity for protein binding, so there is far less protein around than required to bind 50% of the drug. The drug is mostly free, and f_u is nearly 1. On the right side of Figure 19-10, [Protein] is much greater than $[\text{Protein}]_{50}$. This means that there is far more protein present than would be required to bind 50% of the drug. The result is that drug will be mostly bound to plasma proteins, and f_u will be nearly 0.

The association constant K_a and its inverse $[\text{Protein}]_{50}$ reflect the affinity of the drug for plasma protein. They should not change in the presence of disease. However, [Protein] can change with disease, age, or concurrent drugs. Figure 19-11 shows the relationship between changes in protein concentration and

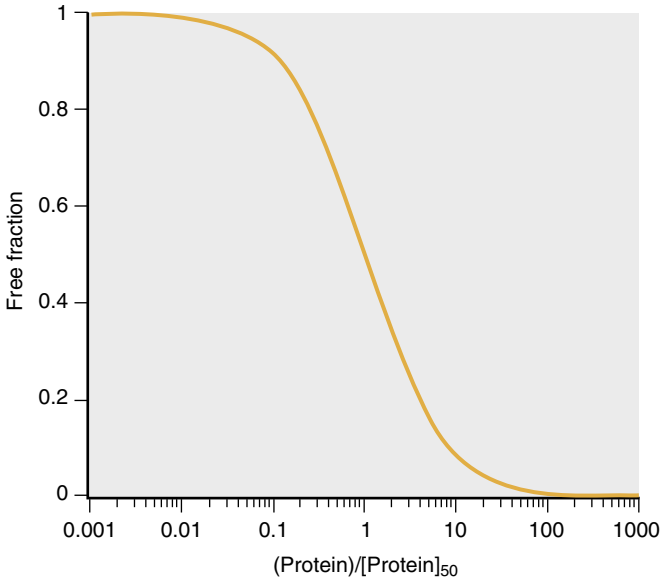

Figure 19-10 Relationship between plasma protein concentration as a fraction of the concentration associated with 50% binding and the fraction of drug that is unbound. This is another example of the saturation equation shown in Figure 19-5.

changes in the free fraction of drug for drugs with different degrees of protein binding in normal clinical use. The lines on the graph correspond to different drugs whose free fraction in normal plasma ranges from 1.0 (horizontal line) to approximately 0.0 (straight diagonal line).

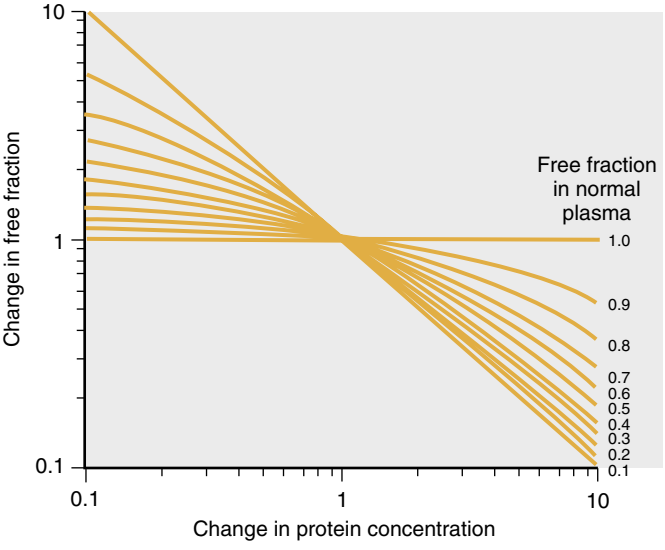

Figure 19-11 Relationship between changes in protein concentration and changes in free fraction. The relationship depends on the free fraction in normal plasma at typical clinical doses. For a drug that is not bound (free fraction ≈ 1), there is no change in free fraction with a change in protein concentration. For a highly bound drug with a free fraction that is nearly 0, any change in protein causes a nearly inversely proportional change in free fraction. *(From Shafer S: Principles of pharmacokinetics and pharmacodynamics.* In *Longnecker DE, Tinker JH, Morgan GE [eds]: Principles and Practice of Anesthesiology, 2nd ed. St. Louis, Mosby–Year Book, 1997.)*

For drugs that are not bound (free fraction = 1.0), there is no relationship between free fraction and protein concentration, as indicated by the flat horizontal line. For drugs whose free fraction is typically 90%, there will be a small change in free drug concentration with changes in protein concentration. For drugs that are highly protein bound, the free drug concentration changes nearly inversely with the change in protein concentration. As the proportion of binding approaches 100% (free drug → 0.0), the relationship between change in protein concentration and change in free fraction becomes inversely proportional. Note that there is never a greater than proportional change in free drug concentration with a change in plasma concentration. For example, the most that a 10% change in protein concentration would produce is a 10% change in free drug concentration, and that would be the case only if the drug were nearly 100% bound to plasma protein.

The in vitro observation that changing protein concentration results in changing free drug concentration, as shown in Figure 19-11, does not necessarily apply to the in vivo situation. It is the free (e.g., unbound) drug that equilibrates between plasma and tissues. If plasma protein binding is decreased, the free drug concentration gradient between plasma and peripheral tissues will increase. As a result, when protein binding decreases, equilibrium is achieved between plasma and the tissue free drug concentration at a lower total plasma drug concentration. This lower concentration gives the appearance that the drug has distributed into a larger total space. Thus, decreased protein binding causes an increase in the apparent volume of distribution when referenced to total, rather than free, drug concentration.

The increased volume of distribution at steady state, Vd_{ss}, seen with decreased plasma protein binding is mostly an illusion. Were only the unbound drug concentration measured, there would be almost no change in the apparent volume of distribution for lipophilic drugs (such as most of those in anesthesia practice) because it is partitioning of drug within peripheral tissues that primarily governs the free concentration of lipophilic drugs.

Changes in protein binding may affect the clearance of drugs. If a drug has a high extraction ratio, the liver is going to remove nearly all the drug flowing to it, regardless of the extent of protein binding. However, if the drug has a low hepatic extraction ratio, an increase in the free fraction of drug will result in an increase in the driving gradient along with an associated increase in clearance. Protein binding also affects the apparent potency of a drug when referenced to the total plasma drug concentration. An increase in free fraction increases the driving pressure to the site of drug effect. Thus, a change in free fraction will increase the concentration at the effect site. Because of this change in apparent potency, decreased protein binding may decrease the dose required to produce a given drug effect, even in the absence of other pharmacokinetic changes.

Stereochemistry

Typical pharmacokinetic analyses describe fictitious drugs. For example, the pharmacokinetics and pharmacodynamics of thiopental, ketamine, and bupivacaine describe drugs that do not exist. The reason is that many anesthetic drugs are chiral and supplied as racemic mixtures. The body is a chiral environment, and drugs interact stereospecifically with enzymes, proteins, and receptors. The pharmacokinetics and pharmacodynamics of the enantiomers may differ. The enantiomers of bupivacaine and

ketamine have been particularly well studied, and the levo-isomer of bupivacaine is available commercially as levobupivacaine. Although the importance of studying the pharmacokinetics and pharmacodynamics of individual stereoisomers is widely appreciated, the difficulty of performing such studies has precluded widespread use.

Pharmacokinetic Models

Zero- and First-Order Processes

The body's consumption of oxygen and production of carbon dioxide are processes continuing at a constant rate. These are called zero-order processes. The rate of change (dx/dt) for a zero-order process is

$$\frac{dx}{dt} = k \tag{17}$$

Equation 17 states that the rate of change is constant. If x represents an amount of drug and t represents time, the unit of k is amount/time. If we want to know the value of x at time t, x(t), we can compute it as the integral of Equation 17 from time 0 to time t:

$$x(t) = x_0 + k \cdot t \tag{18}$$

where x_0 is the value of x at time 0. This is the equation of a straight line with a slope of k and an intercept of x_0.

Many processes occur at a rate proportional to the amount. For example, the interest payment on a loan is proportional to the outstanding balance, and the rate at which water drains from a bathtub is proportional to amount (height) of water in the tub. These are examples of first-order processes. The rate of change in a first-order process is only slightly more complex than that for a zero-order process:

$$\frac{dx}{dt} = k \cdot x \tag{19}$$

Here, the unit of k is 1/time because the x on the right-hand side already includes the unit for amount. If we want to know the value of x at time t, x(t), it can be computed as the integral from time 0 to time t:

$$x(t) = x_0 \cdot e^{kt} \tag{20}$$

where x_0 is the value of x at time 0. If k is greater than 0, x(t) increases exponentially. If k is less than 0, x(t) decreases exponentially. In pharmacokinetics, k is negative because concentrations decrease over time. For clarity, the minus sign is usually explicit, so k is expressed as a positive number. Thus, the identical equation for pharmacokinetics, with the minus sign explicitly written, is

$$x(t) = x_0 \times e^{-kt} \tag{21}$$

Figure 19-12 shows the relationship between x and time, as described by Equation 21. In Figure 19-12, x continuously decreases over time. However, the slope of the curve continuously increases (i.e., becomes less negative). Taking the natural logarithm of both sides of Equation 21 gives

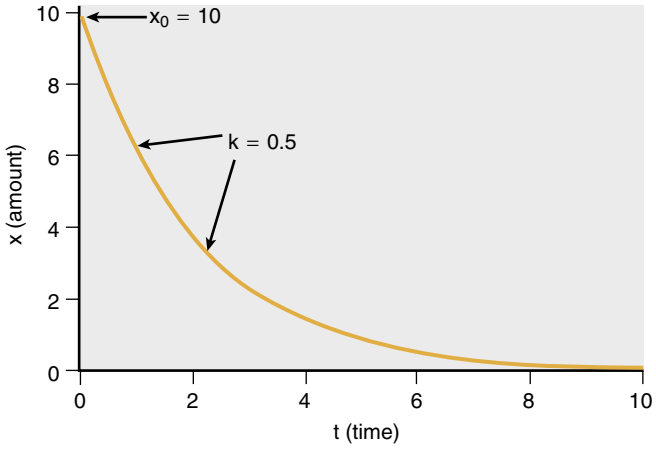

Figure 19-12 Exponential decay curve, as given by $x(t) = x_0 e^{-kt}$, plotted on standard axes, with $x_0 = 10$ and $k = 0.5$.

$$\begin{aligned} \ln(x[t]) &= \ln\left(x_0 \times e^{-kt}\right) \\ &= \ln(x_0) + \ln(e^{-kt}) \\ &= \ln(x_0) - (k \times t) \end{aligned} \tag{22}$$

This is the equation of a straight line, as shown in Figure 19-13, where the vertical axis is ln(x[t]), the horizontal axis is *t*, the intercept is $\ln(x_0)$, and the slope of the line is $-k$.

How long will it take for x to go from a certain value, x_1 to half that value, $(x_1/2)$? Because k is the slope of a straight line relating ln(x) to time,

$$k = \frac{\Delta \ln(x)}{\Delta t} = \frac{\ln(x_1) - \ln\left(\frac{x_1}{2}\right)}{t_{1/2}} \tag{23}$$

where $t_{1/2}$ is the "half-life", or the time required for a 50% decrease in *x*. We can simplify the numerator to

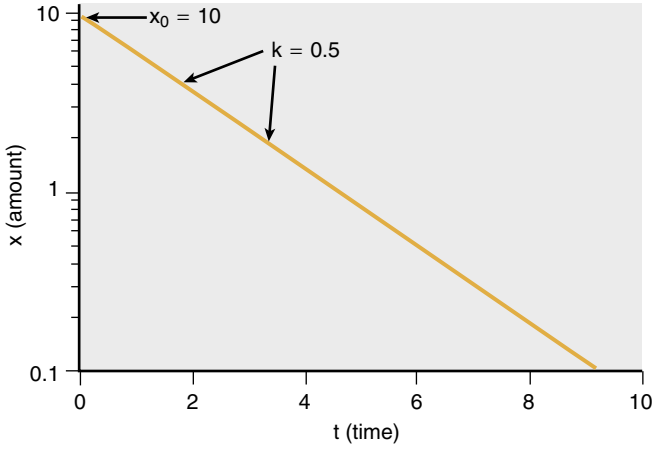

Figure 19-13 The same exponential decay curve, $x(t) = x_0 e^{-kt}$, as in Figure 19-12, but now plotted on a log *y* axis.

$$\ln(x_1) - \ln\left(\frac{x_1}{2}\right) = \ln\left(\frac{x_1}{\frac{x_1}{2}}\right) = \ln(2) \approx 0.693 \quad (24)$$

This succinctly relates slope (or "rate constant"), k, to half-life, $t_{½}$:

$$k = \frac{0.693}{t_{½}} \quad (25)$$

Thus, if we measure the time that it takes for x to fall by 50%, $t_{½}$, we know the rate constant k. If we know k, we can easily calculate from Equation 25 the time that it will take for x to fall by 50%:

$$t_{½} = \frac{0.693}{k} \quad (26)$$

Physiologic Pharmacokinetic Models

It is possible to analyze volumes and clearances for each organ in the body and construct models of pharmacokinetics by assembling the organ models into physiologically and anatomically accurate models of the entire animal. Figure 19-14 shows such a model for thiopental in rats.[6] Subsequent studies have shown that individual tissue volumes and blood flow can be scaled up from rats to humans to result in accurate models of human pharmacokinetics.[7] This illustrates the potential utility of physiologically based pharmacokinetic models in developing human pharmacokinetic models from animal models.

Models that work with individual tissues are mathematically cumbersome and do not offer a better prediction of plasma drug concentration than models that lump the tissues into a few compartments. If the goal is to determine how to give drugs to obtain therapeutic plasma drug concentrations, all that is needed is to mathematically relate dose to plasma concentration. For this purpose, conventional "compartmental" models are usually adequate.

Compartmental Pharmacokinetic Models

Compartmental models are built on the same basic concepts as physiologic models, but with gross simplifications. The "one-compartment model" seen in Figure 19-15 contains a single volume and a single clearance, as though we were built like buckets. For anesthetic drugs, we resemble several buckets connected by pipes. These are usually modeled by two- or three-compartment models, also shown in Figure 19-15. The volume to the right in the two-compartment model—and in the center of the three-compartment model—is the central volume. The other volumes are peripheral volumes. The sum of the all volumes is the volume of distribution at steady state, Vd_{ss}. Clearance in which the central compartment is left for the outside is the "central" or "metabolic" clearance. Clearances between the central compartment and the peripheral compartments are the "intercompartmental" clearances.

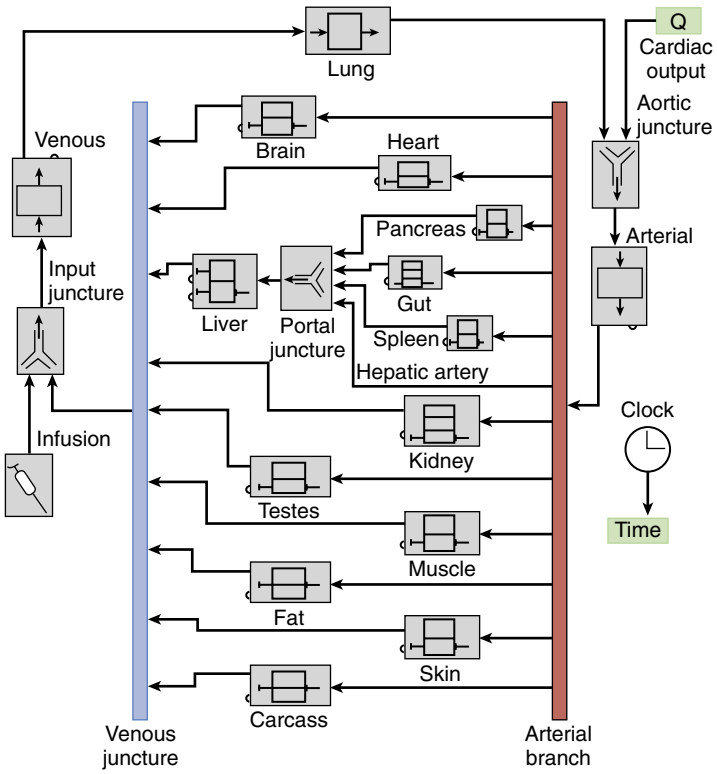

Figure 19-14 Physiologic model for thiopental in rats. The pharmacokinetics of distribution into each organ has been determined individually. The components of the model are linked by zero-order (flow) and first-order (diffusion) processes. *(From Ebling WF, Wada DR, Stanski DR: From piecewise to full physiologic pharmacokinetic modeling: Applied to thiopental disposition in the rat. J Pharmacokinet Biopharm 22:259-292, 1994.)*

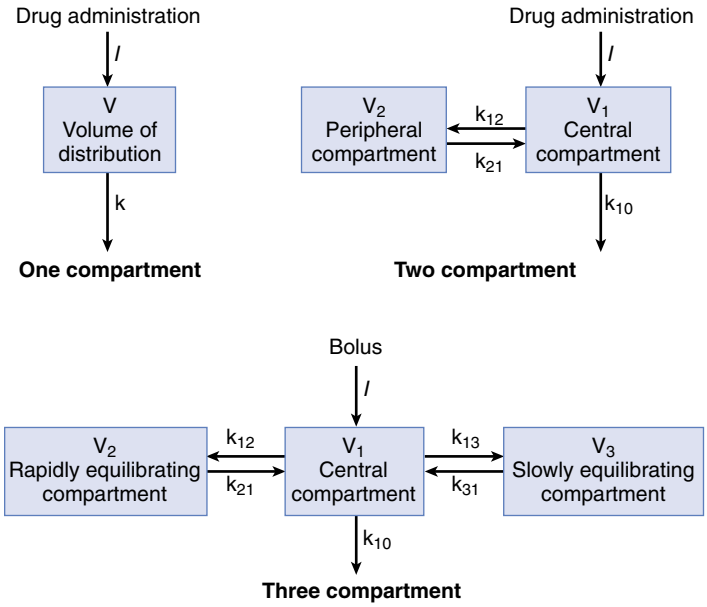

Figure 19-15 One-, two-, and three-compartment mammillary models.

One-Compartment Model

Bolus Pharmacokinetics. Think of the body as a bucket into which we pour drug. Let us call the amount of drug that we pour into the bucket x_0 (x at time 0). The initial concentration is x_0/V, where V is the volume of fluid within the bucket. Returning to Equation 1, if we know the concentration that we want to achieve, C_T (target concentration), and V, the volume in the bucket, we can calculate the dose to achieve C_T by rearranging the definition of concentration: Dose = $C_T \times V$.

Let us assume that the fluid is being circulated through a clearing organ at a constant rate, which we call clearance, Cl. What is the rate, dx/dt, by which the drug leaves the bucket? Because concentration is x/V and Cl is the rate that the fluid in the bucket is flowing out through the clearing organ, the rate at which the drug is leaving must be $x/V \times Cl$. This rate is a first-order process if—and only if—it equals a constant, *k*, times the amount of drug in the bucket. Does it?

$$\begin{aligned}\frac{dx}{dt} &= \frac{x}{V}Cl \\ &= \frac{Cl}{V}x \\ &= kx?\end{aligned} \tag{27}$$

We stated earlier that flow through the clearing organ, Cl, was constant. The volume, V, is constant because the clearing organ returns the flow to the bucket. Because Cl and V are both constants, $\frac{Cl}{V}$ is also a constant. Referring back to Equation 27, k, a constant by definition of first-order processes, equals $\frac{Cl}{V}$, a constant by definition of clearance and volume. This can be rearranged to yield the fundamental identity of linear pharmacokinetics:

$$\begin{aligned}Cl\ (\text{clearance}) &= k\ (\text{rate constant}) \\ &\cdot\ V\ (\text{volume of distribution})\end{aligned} \tag{28}$$

What does this identity tell us about the relationship between half-life, volume, and clearance? Rearranging the above as $k = \frac{Cl}{V}$ and remembering that $t_{1/2} = \frac{0.693}{k}$, we can conclude that half-life is proportional to volume and inversely proportional to clearance:

$$\begin{aligned}t_{1/2} &= 0.693\frac{V}{Cl} \\ t_{1/2} &\propto \frac{V}{Cl}\end{aligned} \tag{29}$$

Figure 19-16 shows a one-compartment model with an identical clearance but a bigger volume than is seen in Figure 19-3. It takes longer to clear drug from this bigger volume, so the half-life will increase, as predicted by Equation 29. Figure 19-17 shows a one-compartment model with an identical volume but faster clearance than is seen in Figure 19-3. The concentrations will fall more quickly (shorter half-life) with the larger clearance, as predicted by Equation 29.

Because this is a first-order process, $\frac{dx}{dt} = k\,x$, and the integral of this process gives us the amount of drug at time t in terms of the amount at time 0, $x(t) = x_0\ e^{-kt}$. If we divide both sides by V and remember that x/V is the definition of concentration, we get the equation that relates concentration after an intravenous bolus to time and initial concentration:

$$C(t) = C_0 e^{-kt} \tag{30}$$

This equation defines the "concentration-over-time" curve for a one-compartment model and has the log-linear shape seen in

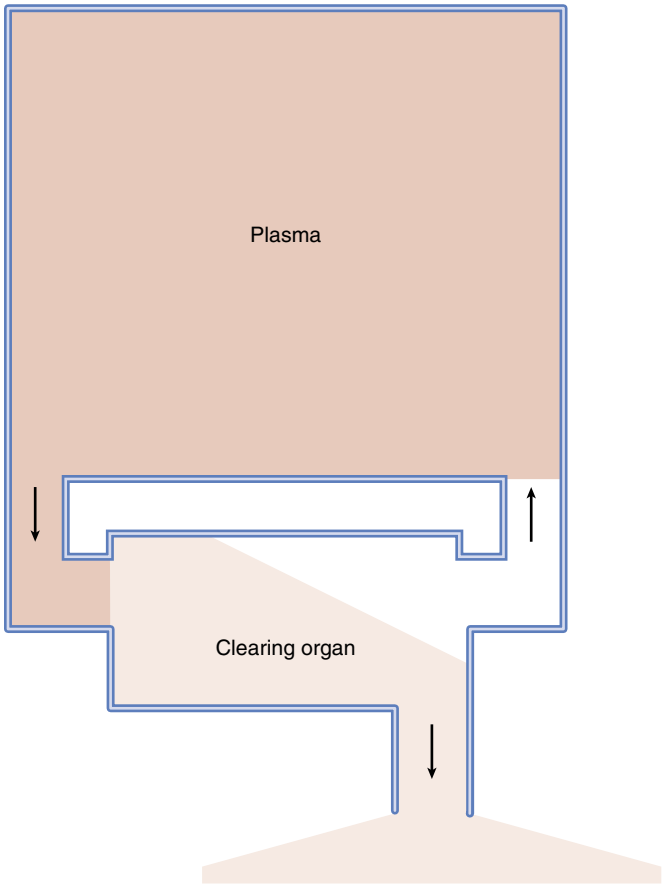

Figure 19-16 A one-compartment model similar to Figure 19-3, but with an increased volume of distribution. After drug administration, concentrations will fall more slowly in this model than in the model shown in Figure 19-3.

Figure 19-13. We can calculate the clearance, Cl, in one of two ways. First, we can calculate V by rearranging the definition of concentration, V = dose/initial concentration = dose/C_0. Referring back to Equation 28, if we measure the slope, –k, we can calculate clearance as k × V. A more general solution is to consider the integral of the concentration-over-time curve, Equation 30, known in pharmacokinetics as the area under the curve (AUC):

$$\begin{aligned} AUC &= \int_0^\infty C_0 e^{-kt} dt \\ &= \int_0^\infty \frac{x_0}{V}\left(e^{-\frac{Cl}{V}t}\right) dt \,(\text{substituting for } C_0 \text{ and } k) \\ &= \frac{x_0}{V} \times \frac{V}{Cl} (\text{evaluating the above integral}) \\ &= \frac{x_0}{Cl} \end{aligned} \tag{31}$$

We can rearrange Equation 31 to solve for clearance, Cl:

$$Cl = \frac{x_0}{AUC} \tag{32}$$

Because x_0 is the dose of drug, clearance equals the dose divided by AUC. This fundamental property of *linear* pharmacokinetic models applies to one-compartment models, multicompartment models, and any type of intravenous drug dosing (provided that the *total* dose administered systemically is used as the numerator). It directly follows that AUC is proportional to dose for linear models (i.e., models in which Cl is constant).

Infusion Pharmacokinetics. If we give an infusion at a rate of I (for input), the plasma concentration will rise as long as the rate of drug going in the body, I, exceeds the rate at which drug leaves the body, C × Cl, where C is the drug concentration. When I = C × Cl, drug is going in and coming out at the same rate, and the body is at steady state. We can calculate the concentration at steady state by observing that the rate of drug going in must equal the rate of drug coming out. From Equation 6 we know that rate of drug metabolism at steady state is

$$\text{Metabolic rate} = C_{ss} \cdot Cl \tag{33}$$

where C_{ss} is the arterial concentration at steady state. Because by definition at steady state the infusion rate must equal the metabolic rate, the infusion rate, I, at steady state must be $I = C_{ss} \times Cl$. Solving this for the concentration at steady state, C_{ss}, gives $\frac{I}{Cl}$. Thus, the steady state concentration during an infusion is the rate of drug input divided by clearance. It follows that if we want to calculate the infusion rate that will achieve a given target concentration, C_T, at steady state, the infusion rate must be $C_T \times Cl$.

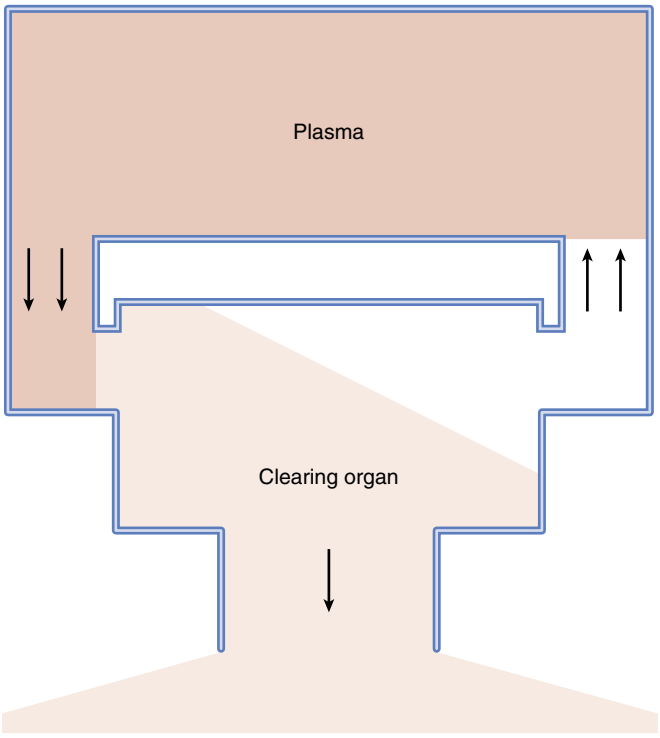

Figure 19-17 A one-compartment model similar to Figure 19-3, but with increased clearance. After drug administration, concentrations will fall faster in this model than in the model shown in Figure 19-3.

$C_\infty = \frac{I}{Cl}$ is similar in form to the equation describing the concentration after a bolus injection: $C_0 = \frac{x_0}{V}$. Thus, volume is a scalar relating bolus to initial concentration, and clearance is a scalar relating infusion rate to steady-state concentration. It follows that the initial concentration after a bolus is independent of clearance and that the steady-state concentration during a continuous infusion is independent of volume.

During an infusion, the rate of change in the amount of drug, x, is rate of inflow, I, minus the rate of outflow, $k \times x$.

$$\frac{dx}{dt} = I - k\,x \tag{34}$$

We can calculate x at any time t as the integral from time 0 to time *t*. Assuming that $x_0 = 0$ (i.e., we are starting with no drug in the body), the result is

$$x(t) = \frac{I}{k}\left(1 - e^{-kt}\right) \tag{35}$$

As $t \to \infty$, $e^{-kt} \to 0$, and Equation 35 reduces to

$$x_{ss} = \frac{I}{k} \tag{36}$$

How long does it take to reach 50% of the final steady-state concentration (i.e., to reach a concentration of $\frac{x_{ss}}{2}$) during an infusion? From Equation 36 we know that $\frac{x_{ss}}{2} = \frac{I}{2k}$. Substituting $\frac{I}{2k}$ for x(t) in Equation 35, we get

$$\frac{I}{2k} = \frac{I}{k}\left(1 - e^{-kt}\right) \tag{37}$$

Solving Equation 37 for t, we get $\frac{\ln(2)}{k}$. In Equation 26 we found that the half-life, $t_{1/2}$, after a bolus injection was $\frac{\ln(2)}{k}$. Here, we again have a parallel between boluses and infusions. During an infusion it takes one half-life to reach 50% of the steady-state concentration. Similarly, it takes two half-lives to reach 75%, three half-lives to reach 87.5%, and five half lives to reach 97% of the steady-state concentration. By four to five half-lives we typically consider the patient to be at steady state, although the concentrations only asymptotically approach the steady-state value.

Absorption Pharmacokinetics. When drugs are given intravenously, all of the drug reaches the systemic circulation. When drugs are given by a different route, such as orally, transdermally, epidurally, or intramuscularly, the drug must first reach the systemic circulation. Oral drugs may be only fractionally absorbed, and what is absorbed may be subjected to first-past hepatic metabolism before reaching the systemic circulation. Transdermally applied drugs may be sloughed off with the stratum corneum without being absorbed. We cannot assume that the dose given to the patient is the same as the dose that reaches the systemic circulation when using alternative routes of drug delivery. The dose that reaches the systemic circulation is the administered dose times f, the fraction "bioavailable."

Alternative routes of drug delivery are often modeled by assuming that the drug is absorbed from a reservoir or depot, which is usually modeled as an additional compartment with a monoexponential rate of transfer to the systemic circulation:

$$A(t) = f \times D_{oral} \times k_a \times e^{-k_a t} \tag{38}$$

where A(t) is the absorption rate at time t, f is the fraction bioavailable, D_{oral} is the dose taken orally (or intramuscularly, applied to the skin, etc.), and k_a is the absorption rate constant. Because the integral of $k_a \times e^{-k_a t}$ is 1, the total amount of drug absorbed is $f \times D_{oral}$. To compute the concentrations over time, we first reduce the problem to differential equations, (e.g., Equations 19 and 34) and integrate. The differential equation for the amount, x, with oral absorption into a one-compartment disposition model is

$$\begin{aligned} \frac{dx}{dt} &= \text{inflow} - \text{outflow} \\ &= A(t) - k \times x \\ &= D_{oral} \times f \times k_a \times e^{-k_a t} - k \times x \end{aligned} \tag{39}$$

This is simply the rate of absorption at time t, A(t), minus the rate of exit, $k \times x$. To solve for the amount of drug, x, in the compartment at time t, we integrate this from 0 to time t, knowing that $x(0) = 0$:

$$x(t) = \frac{D_{oral} \times f \times k_a}{k - k_a}\left(e^{-k_a t} - e^{-kt}\right) \tag{40}$$

Equation 40 describes the amount of drug in the systemic circulation after first-order absorption from a depot, such as the stomach, an intramuscular injection, the skin, or even an epidural dose. To describe concentrations rather than amounts of drug, it is necessary to divide both sides of Equation 40 by V, the volume of distribution.

This covers the standard pharmacokinetic equations for one-compartment models. The one-compartment model introduces the concepts of rate constants and half-lives and relates them to the physiologic concepts of volume and clearance. Unfortunately, none of the drugs used in anesthesia can be accurately characterized by one-compartment models. The distribution of anesthetic drugs into and out of peripheral tissues plays a crucial role in the time course of anesthetic drug effect. To describe intravenous anesthetics, we must extend the one-compartment model to account for distribution into tissues.

Multicompartment Models

Plasma concentrations over time after an intravenous bolus resemble the curve in Figure 19-18. In contrast to Figure 19-13, Figure 19-18 is not a straight line, even though it is plotted on a log *y* axis. This curve has the characteristics common to most drugs when given by intravenous bolus. First, the concentrations continuously decrease over time. Second, the rate of decline is initially steep but continuously becomes less steep, until we get to a portion that is "log-linear."

For many drugs, three distinct phases can be distinguished, as suggested by Figure 19-18. There is a "rapid-distribution" phase (solid line in Fig. 19-18) that begins immediately after injection

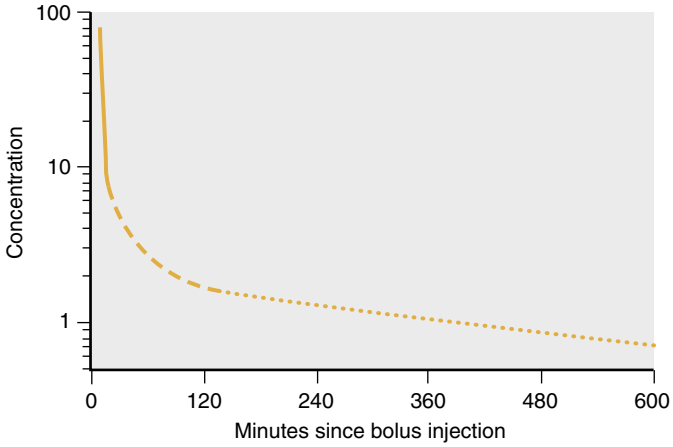

Figure 19-18 Concentration-versus-time relationship showing a very rapid initial decline after injection of a bolus. The terminal log-linear portion is seen only after most of the drug has left the plasma. This is characteristic of most anesthetic drugs. Different line types highlight the rapid, intermediate, and slow (log-linear) portions of the curve.

of the bolus. Very rapid movement of the drug from plasma to the rapidly equilibrating tissues characterizes this phase. Frequently there is a second "slow-distribution" phase (dashed line in Fig. 19-18) that is characterized by movement of drug into more slowly equilibrating tissues and return of drug to plasma from the most rapidly equilibrating tissues. The terminal phase (dotted line in Fig. 19-18) is a straight line when plotted on a semilogarithmic graph. The terminal phase is often called the "elimination phase" because the primary mechanism for decreasing drug concentration during the terminal phase is elimination of drug from the body. The distinguishing characteristic of the terminal elimination phase is that the plasma concentration is lower than tissue concentrations and the relative proportion of drug in plasma and peripheral volumes of distribution remains constant. During this "terminal-phase" drug returns from the rapid- and slow-distribution volumes to plasma and is permanently removed from plasma by metabolism or excretion.

The presence of three distinct phases after bolus injection is a defining characteristic of a mammillary model with three compartments. It is possible to develop hydraulic models, as shown in Figure 19-19, for intravenous drugs.[8] In this model, there are three tanks corresponding (from left to right) to the slowly equilibrating peripheral compartment, the central compartment (the plasma, into which drug is injected), and the rapidly equilibrating peripheral compartment. The horizontal pipes represent intercompartmental clearance or (for the pipe draining onto the page) metabolic clearance. The volumes of each tank correspond to the volumes of the compartments for fentanyl. The cross-sectional areas of the pipes correlate with fentanyl systemic and intercompartmental clearance. The height of water in each tank corresponds to drug concentration.

By using this hydraulic model we can follow the processes that decrease drug concentration over time after bolus injection. Initially, drug flows from the central compartment to both peripheral compartments via intercompartmental clearance and completely out of the model via metabolic clearance. Because there are three places for drug to go, the concentration in the central compartment decreases very rapidly. At the transition between the solid line and the dashed line, there is a change in the role of the most rapidly equilibrating compartment. At this transition, the concentration in the central compartment falls below the concentration in the rapidly equilibrating compartment, and the direction of flow between them is reversed. After this transition (dashed line), drug in plasma has only two places to go: into the slowly equilibrating compartment or out the drain pipe. These processes are partly offset by the return of drug to plasma from the rapidly equilibrating compartment. The net effect is that once the rapidly equilibrating compartment has come to equilibration, the concentration in the central compartment falls far more slowly than before.

Once the concentration in the central compartment falls below both the rapidly and slowly equilibrating compartments (dotted line), the only method of decreasing the plasma concentration is metabolic clearance, the drain pipe. Return of drug from both peripheral compartments to the central compartment greatly slows the rate of decrease in plasma drug concentration.

Curves that continuously decrease over time, with a continuously increasing slope (i.e., curves that look like Figs. 19-18 and 19-19), can be described by a sum of negative exponentials. In pharmacokinetics, one way of denoting this sum of exponentials is to say that the plasma concentration over time is

$$C(t) = Ae^{-\alpha t} + Be^{-\beta t} + Ce^{-\gamma t} \qquad (41)$$

where t is the time since the bolus, C(t) is the drug concentration after a bolus dose, and A, α, B, β, C, and γ are parameters of a pharmacokinetic model. A, B, and C are called coefficients, whereas α, β, and γ are called exponents. After a bolus injection, all six of the parameters in Equation 41 will be greater than 0.

The main reason that polyexponential equations are used is that they describe the plasma concentrations observed after

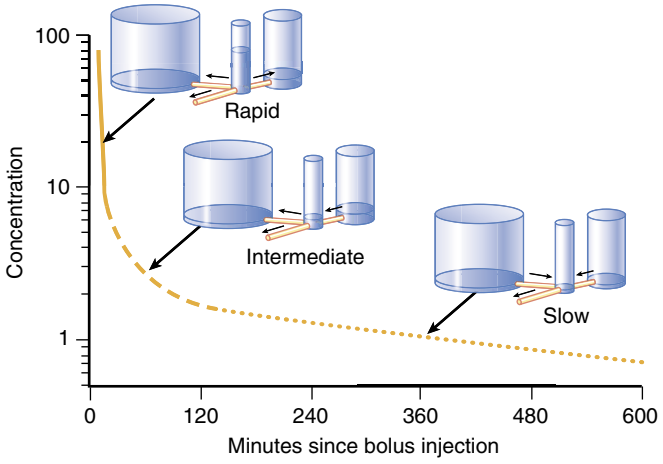

Figure 19-19 Hydraulic model of fentanyl pharmacokinetics. Drug is administered into the central tank, from which it can distribute into two peripheral tanks, or it may be eliminated. The volume of the tanks is proportional to the volumes of distribution. The cross-sectional area of the pipes is proportional to clearance. *(Modified from Youngs EJ, Shafer SL: Basic pharmacokinetic and pharmacodynamic principles.* In *White PF [ed]: Textbook of Intravenous Anesthesia. Baltimore, Williams & Wilkins, 1997, p 10.)*

bolus injection, except for the mis-specification in the first few minutes mentioned previously. Compartmental pharmacokinetics is strictly empirical: the models describe the data, not the processes by which the observations came to be. Fortunately, polyexponential equations permit us to use the one-compartment ideas just developed, with some generalization of the concepts. This involves translating Equation 41 into a model of volumes and clearances that has an appealing, though inaccurate physiologic flavor.

Equation 41 says that concentrations over time are the algebraic sum of three separate functions, $Ae^{-\alpha t}$, $Be^{-\beta t}$, and $Ce^{-\gamma t}$. Typically $\alpha > \beta > \gamma$ by about 1 order of magnitude. We can describe each of these functions separately as graphs, as well as their sum, as shown in Figure 19-19. At time 0 (t = 0), Equation 41 reduces to

$$C_0 = A + B + C \tag{42}$$

The sum of the coefficients A, B, and C, equals the concentration immediately after a bolus. It follows that A + B + C = bolus amount V_1.

Special significance is often ascribed to the smallest exponent. This exponent determines the slope of the final log-linear portion of the curve. When the medical literature refers to the half-life of a drug, unless otherwise stated, the half-life will be the terminal half-life (i.e., 0.693/smallest exponent). However, the terminal half-life for drugs with more than one exponential term is nearly uninterpretable. The terminal half-life sets an upper limit on the time required for the concentrations to decrease by 50% after drug administration. Usually, the time needed for a 50% decrease will be much faster than that upper limit. This is discussed further in Chapter 28.

Constructing pharmacokinetic models represents a trade-off between accurately describing the data, having confidence in the results, and mathematical tractability. Adding exponents to the model generally provides a better description of the observed concentrations. However, adding more exponent terms usually decreases our confidence in how well we know each coefficient and exponential and greatly increases the mathematical burden of the models. This is why most pharmacokinetic models are limited to two or three exponents.

Part of the continuing popularity of polyexponential models of pharmacokinetics is that they can be mathematically transformed from the admittedly unintuitive exponential form in Equation 41 to a more easily intuited compartmental form, as shown in Figure 19-15. Micro rate constants, expressed as k_{ij}, define the rate of drug transfer from compartment i to compartment j. Compartment 0 is the compartment outside the model, so k_{10} is the micro rate constant for processes acting through metabolism or elimination that irreversibly remove drug from the central compartment (analogous to k for a one-compartment model). The intercompartmental micro rate constants (k_{12}, k_{21}, etc.) describe movement of drug between the central and peripheral compartments. Each peripheral compartment has at least two micro rate constants, one for drug entry and one for drug exit. The micro rate constants for the two- and three-compartment models can be seen in Figure 19-15. The differential equations describing the rate of change for the amount of drugs in compartments 1, 2, and 3 follow directly from the micro rate constants. For the two-compartment model, the differential equations for each compartment are

$$\begin{aligned} \frac{dx_1}{dt} &= I + x_2 k_{21} - x_1 k_{10} - x_1 k_{12} \\ \frac{dx_2}{dt} &= x_1 k_{12} - x_2 k_{21} \end{aligned} \tag{43}$$

where I is the rate of drug input. For the three-compartmental model, the differential equations for each compartment are

$$\begin{aligned} \frac{dx_1}{dt} &= I + x_2 k_{21} + x_3 k_{31} - x_1 k_{10} - x_1 k_{12} - x_1 k_{13} \\ \frac{dx_2}{dt} &= x_1 k_{12} - x_2 k_{21} \\ \frac{dx_3}{dt} &= x_1 k_{13} - x_3 k_{31} \end{aligned} \tag{44}$$

An easy way to model pharmacokinetics is to convert these differential equations to difference equations so that dx becomes Δx and dt becomes Δt. With a Δt of 1 second, the error from linearizing the differential equations is less than 1%. In this way, desktop computers can easily simulate pharmacokinetics by using a spreadsheet.

For the one-compartment model, k was both the rate constant and the exponent. For multicompartment models, the relationships are more complex. The interconversion between micro rate constants and exponents becomes exceedingly complex as more exponents are added because every exponent is a function of every micro rate constant and vice versa. Individuals interested in such interconversions can find them in the Excel spreadsheet convert.xls, which can be downloaded from http://www.opentci.org/doku.php?id=code:code.

The Time Course of Drug Effect

The plasma is not the site of drug effect for anesthetic drugs. There is a time lag between plasma drug concentration and effect-site drug concentration. For example, one significant difference between fentanyl and alfentanil is the more rapid onset of alfentanil's drug effect. The orange bar in the top graph of Figure 19-20 shows the duration of a fentanyl infusion.[9] Rapid arterial samples document the rise in fentanyl concentration. The time course of the electroencephalographic effect (spectral edge) lags 2 to 3 minutes behind the rapid rise in arterial concentration. This lag is called hysteresis. The plasma concentration peaks at the moment that the infusion is turned off. After the peak plasma concentration (and the "Mickey Mouse" silhouette that appears at the peak plasma concentration), the fentanyl concentration decreases rapidly. However, the offset of fentanyl drug effect again lags well behind the decrease in concentration. The lower graph in Figure 19-20 shows the same study design in a patient receiving alfentanil. Because of alfentanil's rapid blood-brain equilibration, there is less hysteresis with alfentanil than with fentanyl.

Typically, the relationship between plasma and the site of drug effect is modeled with an "effect-site" model, as shown in Figure 19-21. The site of drug effect is connected to plasma by a first-order process. The equation that relates effect-site concentration to plasma concentration is

$$\frac{dCe}{dt} = k_{e0} \times Cp - k_{e0} \times Ce \tag{45}$$

where Ce is the effect-site concentration, Cp is the plasma drug concentration, and k_{e0} is the rate constant for elimination of drug

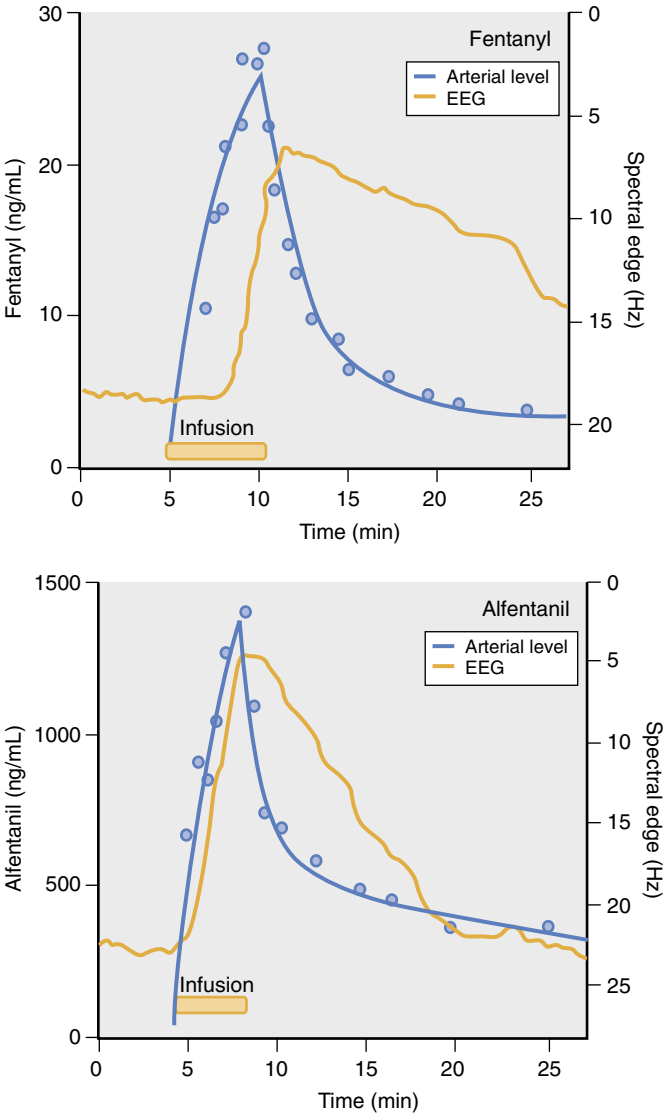

Figure 19-20 Fentanyl and alfentanil arterial concentrations (*circles*) and electroencephalographic (EEG) response (*irregular line*) to an intravenous infusion. With each drug there is a time lag between the rise and fall in arterial concentration and the EEG response, but the time lag is much greater for fentanyl than for alfentanil. *(Modified from Scott JC, Ponganis KV, Stanski DR: EEG quantitation of narcotic effect: The comparative pharmacodynamics of fentanyl and alfentanil. Anesthesiology 62:234-241, 1985.)*

from the effect site. It is most easily understood in terms of its reciprocal, $0.693/k_{e0}$, the half-time for equilibration between plasma and the site of drug effect.

The constant k_{e0} has a large influence on the rate of rise in drug effect, the rate of offset of drug effect, and the dose that is required to produce the desired drug effect. The mathematical basis of these relationships is explored in Chapter 28.

Summary

Pharmacokinetics involves fundamental physiologic processes, including metabolism, protein binding, tissue distribution, and drug transport to the site of drug effect. Pharmacokinetic models are mathematical relationships between dose and concentration, either in plasma or at the site of drug effect. Such models can be used to determine how best to give drugs to achieve a therapeutic objective, but only when the relationship between drug concentration and drug effect is understood. This is the subject of the next section.

Pharmacodynamics

Pharmacodynamics describes the relationship between plasma drug concentration and pharmacologic effect. Simply stated, pharmacokinetics describes what the body does to the drug, whereas pharmacodynamics describes what the drug does to the body. Although the study of clinically important drug effects is multifaceted, we will divide pharmacodynamics into three general areas: transduction of biologic signals (receptor theory and structure), developments in molecular pharmacology, and clinical evaluation of drug effects.

Transduction of Biologic Signals

Receptor Theory

Definition

In the broadest sense, a receptor is a component of a cell that interacts selectively with an extracellular compound to initiate a cascade of biochemical events that culminate in the pharmacologic effects of the compound. Binding of a drug to a receptor

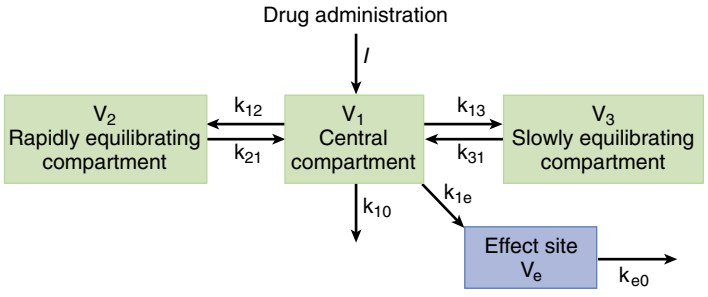

Figure 19-21 A three-compartment model with an added effect site to account for the delay in equilibration between the rise and fall in arterial drug concentrations and the onset and offset of drug effect. The effect site is assumed to have a negligible volume.

determines (1) the quantitative relationship between a given dose of a drug and the resulting effect, (2) the selectivity of a given drug's activity and effect, and (3) the pharmacologic activity of receptor agonists, antagonists, and inverse agonists. Receptors therefore serve to mediate and amplify the effect of a drug on the biologic system.

Historical Perspective

Although the overall concept of receptors is generally attributed to Paul Erhlich (1854-1915), earlier work performed by Claude Bernard (1813-1878) paved the way for receptor theory. This earlier work is of particular interest to anesthesiologists because it centered on elucidation of the mechanism of action of curare in poisoned arrows. In his experiments, Claude Bernard ligated vessels leading to one hind limb of a frog while leaving nerve input intact. He then administered intravenous curare. Pinching the paralyzed hind limb produced reflex movements in the opposite unparalyzed vessel-ligated hind limb. These experiments and others demonstrated for the first time the separation between the sensory and motor nervous systems and also revealed that circulating "substances" produce selective effects on organ systems, a concept important in the development of receptor theory.

The concept of selectivity of effect eventually led Paul Erhlich to his conclusion that "agents cannot act unless they are bound," a cornerstone of receptor theory. Erhlich's contemporary, J. N. Langley (1852-1926), coined the phrase "receptive substance." Langley showed that nicotine and curare have mutually antagonistic effects on the same receptive substance and that the substance was neither nerve nor muscle. Today, we recognize this "receptive substance" as the nicotinic acetylcholine receptor in the neuromuscular junction. Several decades of research has refined receptor theory to the point that receptors are now recognized as discrete excitable proteins.

Classic Receptor Theory

Binding of a ligand, L, to its receptor, R, follows the laws of mass action and can be summarized by the relationship

$$[L]+[R]\underset{k_{off}}{\overset{k_{on}}{\rightleftharpoons}}[LR] \qquad (46)$$

where k_{on} is the rate constant for binding of the ligand to the receptor, k_{off} is the rate constant for the dissociation of the ligand from the receptor, [L] is the concentration of the ligand, [R] is the concentration of the unbound receptor, and [LR] is the concentration of the bound receptor. Note that the units for k_{on} are time^{-1} · units of [L]$^{-1}$. The units of L are typically nanomoles per liter. The units for k_{off} are time^{-1}. The rate of formation of [LR] is $\frac{d[LR]}{dt} = [L][R]k_{on} - [LR]k_{off}$. At steady state, which is nearly instantaneous, the net rate of formation is 0, and thus [L] [R] k_{on} = [LR] k_{off}. The term K_d, or dissociation constant, defines the characteristics of ligand/receptor interactions at equilibrium. Mathematically,

$$K_d = \frac{[L][R]}{[LR]} = \frac{k_{off}}{k_{on}} \qquad (47)$$

The units of K_d are the units of [L], that is, units of concentration. When enough drug is administered to occupy exactly 50% of the receptors (i.e., [R] = [LR]), the measured K_d is equal to the drug concentration. A low K_d indicates that less drug is required to occupy 50% of the receptors, implying that each molecule of drug is tightly associated with the receptor. A high K_d indicates that more drug is required to occupy 50% of receptors, implying weak binding to the receptor. The reciprocal of K_d is K_a, the association constant, which is exactly analogous to the K_a defined for protein binding. K_a is a measure of the affinity of the drug for the receptor. Hence, a drug with a low K_d has a high K_a and therefore high affinity for the receptor.

In practice, it is difficult to measure precise drug-receptor occupancy. It is often assumed that the drug-receptor complex represents an intermediate step in the production of a specific effect. Therefore, many investigators apply pharmacodynamic theory to compare a given dose of a drug with a resulting effect. An effect can be any biochemical or physiologic variable that is measurable. A measured effect can be an alteration in a biochemical compound or an enzyme level, a physiologic variable such as heart rate or blood pressure, or a response to any graded input into the biologic system. For example, in evaluating the pharmacodynamics of muscle relaxants, the measured effect is not a direct measurement of drug-receptor complexes, but rather a response to a neuromuscular stimulus as delivered by a nerve stimulator.

The amount of drug at the receptor is a function of dose, time, and pharmacokinetic properties of the drug. If the receptor is located within the central compartment, there may be nearly instantaneous equilibration after an intravenous injection, and hence the peak effect may occur immediately. If drug must cross from the central compartment into a tissue to reach the site of drug effect, there will be a delay in onset. The onset of drug effect can also be delayed by the time required for the body to respond to the drug. This delay may occur anywhere on the path between drug-receptor binding and clinical manifestation of drug effect. Examples of post-transduction time delays are drug-receptor complex–induced changes in secondary messengers, increased enzyme synthesis, and the time required for physiologic change (e.g., reduced fluid content).

Receptor Agonists and Antagonists. Drugs that are agonists mimic endogenous hormones or neurotransmitters when bound to a receptor. This effect may be excitatory or inhibitory. As described earlier, the term *affinity* as related to a given agonist is a measure of the attraction between the given drug and receptor. A drug with low affinity for a given receptor tends not to bind to the receptor and hence produces little or no effect. An agonist that binds avidly (or with high affinity) to a given receptor produces the receptor-determined effect at a lower given dose.

Full agonists completely activate a receptor, whereas partial agonists only partially activate a receptor, even at very high concentrations (Fig. 19-22). The difference between full and partial agonists results from differing intrinsic efficacy for each drug. Efficacy should not be confused with affinity. Two drugs can have identical affinity for a receptor (and therefore bind to the same extent at a given drug concentration), yet they may produce different levels of activation of the receptor. Both are agonists, but the drug that produces maximal receptor activation is called a full agonist and has high efficacy, whereas the drug that produces less than maximal receptor activation is called a partial agonist with less intrinsic efficacy. The mechanisms underlying whether a drug is a full versus a partial agonist are unclear, but they may be related to the ability of the drug to stabilize the high-activity state

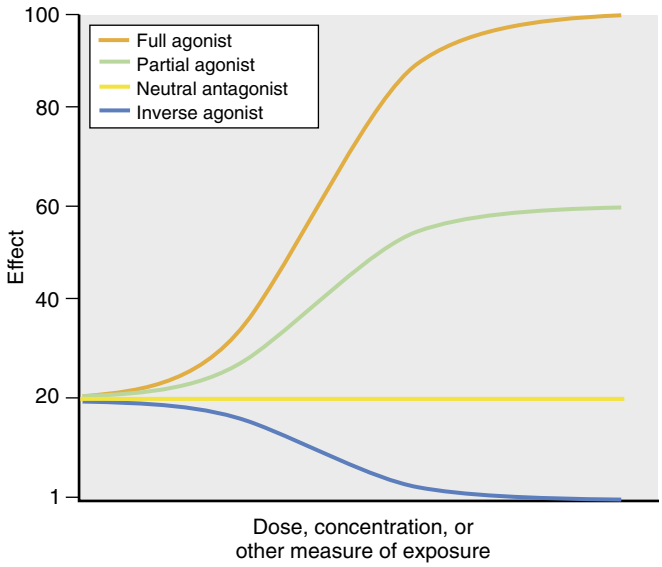

Figure 19-22 Effect of various types of ligands on receptor responses. A full agonist produces complete (100%) activation of a receptor at high concentrations, whereas partial agonist binding results in less than 100% activation, even at very high concentrations. A neutral antagonist has no activity of its own. However, note that in the absence of drug there is still a 20% effect because some receptors are in the activated state in the absence of drug. Inverse agonists can be thought of as "super antagonists" inasmuch as binding of these ligands produces a response below the baseline response measured in the absence of drug because nearly all of the receptors are forced into the unactivated state by the inverse agonist. If the physiologic effect of the baseline levels of activated receptor is small, antagonists and inverse agonists may not be clinically distinguishable.

of the receptor (described under the next heading, "Receptor States").

Drugs that are competitive antagonists inhibit or prevent receptor-mediated agonist effects by competing for the binding site at the receptor. A competitive antagonist can generally be displaced from the receptor complex by the administration of a large enough concentration of receptor agonist, thus permitting the agonist to produce the expected effect despite the presence of antagonist. A noncompetitive antagonist usually binds irreversibly to the receptor complex and produces loss of the expected effect that cannot be compensated by administration of high concentrations of receptor agonist. For example, vecuronium is a competitive antagonist of acetylcholine. Acetylcholine mediates muscle contraction via the postsynaptic nicotinic acetylcholine receptor at the neuromuscular junction. When vecuronium occupies the postsynaptic acetylcholine receptor, acetylcholine agonism is blocked, and neuromuscular transmission is inhibited. The result is flaccid paralysis. Neuromuscular transmission may be reinstated by administering an acetylcholine esterase inhibitor. Acetylcholine esterase inhibitors prevent the breakdown of acetylcholine, thereby effectively raising the concentration of the agonist, acetylcholine, at the receptor, which then displaces vecuronium from the receptor complex. When enough vecuronium is displaced, muscle contraction is reinstated. Most antagonist drugs used in clinical medicine are competitive antagonists.

Inverse agonists can be thought of as "superantagonists" because they decrease receptor responses to less than the "baseline" (see Fig. 19-22) response seen in the absence of drug. Figure 19-23 shows the electroencephalographic response to four different benzodiazepines.[10] Midazolam is a full agonist, whereas RO

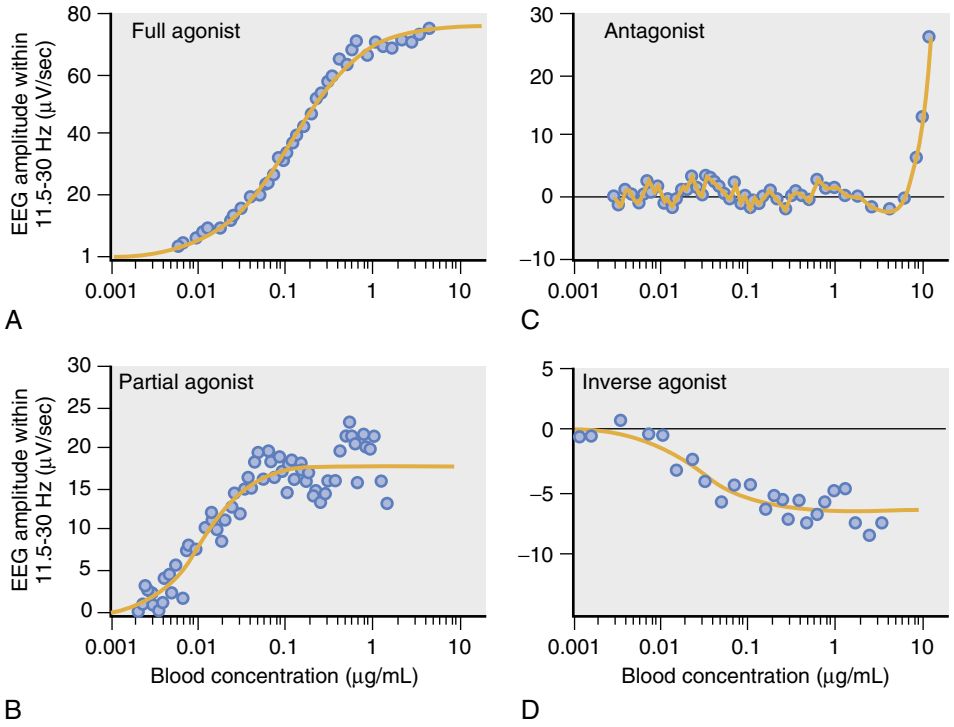

Figure 19-23 The concentration-electroencephalographic (EEG) response relationship for four benzodiazepines: midazolam (full agonist) (**A**), bretazenil (partial agonist) (**B**), flumazenil (antagonist) (**C**), and RO 19-4063 (an inverse agonist) (**D**). The maximum effect seen on the electroencephalogram correlates with clinical action (full agonist > partial agonist > antagonist > inverse agonist). *(From Shafer S: Principles of pharmacokinetics and pharmacodynamics.* In *Longnecker DE, Tinker JH, Morgan GE [eds]: Principles and Practice of Anesthesiology, 2nd ed. St Louis, Mosby–Year Book, 1997; based on Mandema JW, Kuck MT, Danhof M: Differences in intrinsic efficacy of benzodiazepines are reflected in their concentration-EEG effect relationship. Br J Pharmacol 105:164-170, 1992.)*

19-4063 is an inverse agonist. Note that in Figure 19-22, the "baseline" effect in the absence of drug is 20% effect because some receptors are in the activated state. Only in the presence of the inverse agonist are nearly all of the receptors forced into the unactivated state, thereby revealing the physiologic response in the complete absence of receptor activation.

Receptor States. Classic receptor theory describes the interaction between ligand and receptor according to the laws of mass action. At a molecular level, this interaction has been interpreted over the years to suggest that binding of agonist to receptor initiates a change in receptor conformation that converts the receptor from an inactive (R) to an activated (R*) state (Fig. 19-24). In this model the change in receptor conformation facilitates coupling of activated receptor to intermediary proteins (e.g., guanine nucleotide [G] proteins) or second messengers (effectors, E), which then initiate a rapid cascade of cellular responses.

Transgenic animal experiments have shed light on ligand and receptor interactions. In an elegant set of experiments, β_2-adrenergic receptors (β_2ARs) were massively overexpressed in mouse myocardium.[11] Second messenger responses were increased in the absence of ligand when compared with normal mouse myocardium. In fact, adenylyl cyclase activity (the second messenger most commonly studied for β_2ARs) was the same at baseline in transgenic animals (in the absence of drug) as in normal mice stimulated with isoproterenol (a β_2AR agonist). Furthermore, stimulation of transgenic animals with isoproterenol failed to further increase adenylyl cyclase activity higher than this elevated baseline. This finding suggests that a subpopulation of receptors was already fully activated in the transgenic animals.

These findings imply that a small percentage of receptors spontaneously exist in the activated (R*) state. Because a fraction of the receptors are normally activated, the activity of these R* receptors is part of the baseline effect measured in the absence of drug. However, after massive overexpression of β_2ARs in a transgenic animal, this fraction of total receptors becomes a very large number of activated receptors. This mimics the effect of a maximal dose of agonist, which would produce similar numbers of receptors in the R* state.

These findings have broad implications for understanding receptor states and drug-receptor interactions. Instead of ligand binding causing a change from R to R* (as suggested by Fig. 19-24), these data suggest spontaneous conversion from the R to the R* state (Fig. 19-25). The effect of the ligand is to stabilize the R* state, which increases the fraction of activated receptors. In most tissues, the concentration of R* represents a small fraction of the total overall receptor population (hence the large arrow pointing toward R in Fig. 19-25). This finding explains the action of inverse agonists as drugs that stabilize R, thereby reducing the number of receptors in the activated state and decreasing the physiologic response to less than the "clinical baseline." It also suggests that there is a "true baseline," which is the clinical state in the complete absence of activated receptors. The biggest differences between "clinical baseline" and "true baseline" would probably occur in tissues with the highest concentrations of spontaneous R*. Inverse agonists would therefore be most efficacious in such tissues.

Figure 19-23D illustrates a tissue, the central nervous system (CNS), with enough activated type A γ-aminobutyric acid ($GABA_A$) ligand-gated ion channels (R*) to see electroencephalographic changes with an inverse agonist. Finally, it is important to note that the discussion thus far assumes only two receptor states, R (completely inactive) and R* (fully activated). There may be many transition states between R and R* (hence the use of curved lines in addition to straight lines in Fig. 19-25). However, in the interest of simplicity, this chapter discusses only R and R*.

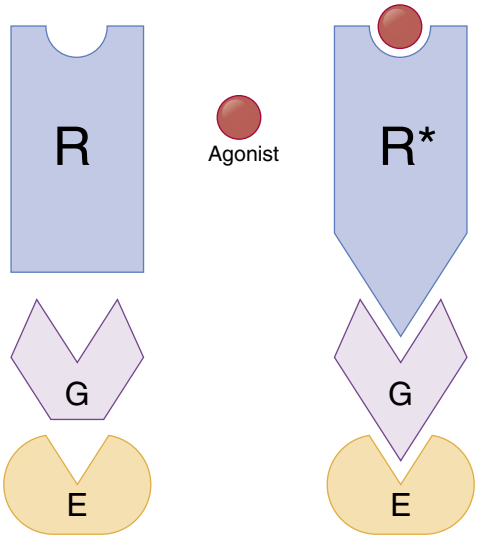

Figure 19-24 Schematic of classic receptor activation. For years, binding of ligand was thought to cause receptors to change from an inactive state (R) to an activated state (R*). The activated receptor then interacts with intermediary guanine nucleotide (G) proteins or directly with second messenger cascades (effectors, E), or with both. More recent information suggests a more complicated equilibrium between R and R*, as shown in Figures 19-25 to 19-27.

As shown in Figure 19-26, agonists stabilize (or energetically favor) the R* state, thereby removing the receptor from instantaneous equilibration with R and driving (by mass action) more receptors toward R* (Fig. 19-27). Hence the probability of being in the R* state increases in the presence of agonist. Inverse agonists drive the equation to the left, thereby stabilizing the R configuration. Neutral antagonists bind equally to R and R*, thereby preventing agonist binding without altering the equilib-

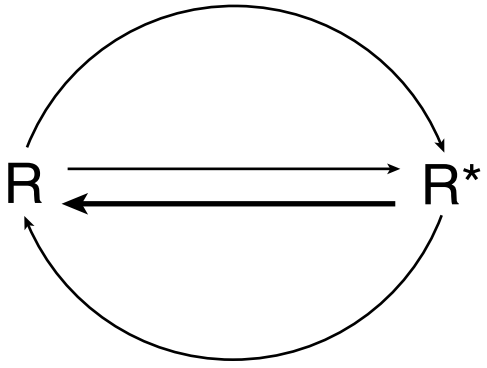

Figure 19-25 Spontaneous conversion of receptors from an inactive (R) to an active (R*) state. In most tissues, R* represents a small fraction of the total receptor population.

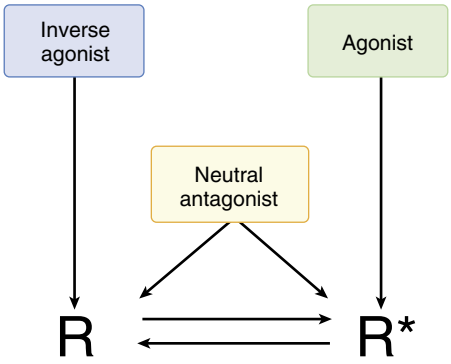

Figure 19-26 Ligand stabilization of receptor states. Agonists stabilize active receptors (R*), inverse agonists stabilize inactive receptors (R), and neutral antagonists bind equally to R and R* without affecting the equilibrium between the two receptor states.

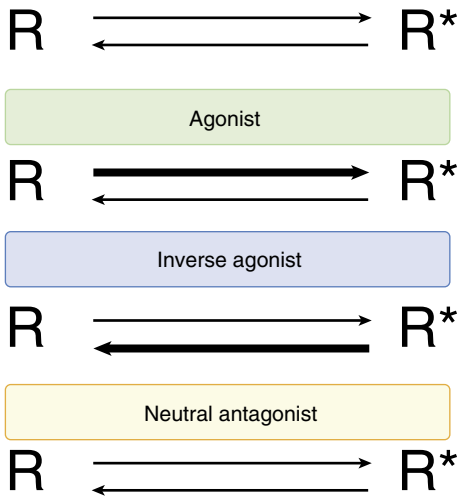

Figure 19-27 Equilibrium between inactive receptors (R) and active receptors (R*) is tissue specific and depends on the type of ligand administered. By stabilizing R*, agonists drive the equilibrium to the right. In contrast, inverse agonists stabilize R, which drives the equilibrium to the left. Because neutral antagonists bind equally to R and R*, they do not affect tissue-specific equilibrium between R and R*.

rium between R and R*. Hence, neutral antagonists do not change the observed baseline response (see Fig. 19-22).

Many classic "antagonists" have been found to be inverse agonists rather than neutral antagonists. For example, the common used β_2AR antagonists, metoprolol and bisoprolol, show significant inverse agonist activity. Carvedilol has weaker inverse agonist properties at β_2ARs and displays neutral antagonist activity at β_1ARs. Alprenolol has even weaker (20%) inverse agonist activity at β_2ARs. Xamoterol displays partial agonist activity at β_1ARs.[12,13] Because inverse agonists may have theoretical advantages in treating certain diseases (e.g., seizures, congestive heart failure), clinicians should critically evaluate recent pharmacologic data before using an antagonist to distinguish whether the drug is a neutral antagonist or an inverse agonist.

Receptor Structure

Receptors are ubiquitous in the cell, being present in cell membranes, cytoplasm, intracellular organelle membranes, and the nucleus. The overall physical structure of a receptor depends on the type of receptor and its location. Cytoplasmic and nuclear receptors bind ligands that readily traverse cell membranes. These ligands must therefore contain significant hydrophobic (lipophilic) components. Examples of cytoplasmic and nuclear receptors include steroid and thyroid hormone receptors. In contrast, the receptors of most interest to anesthesiologists are located on the cell membrane and include membrane receptors, ligand-gated ion channels, and voltage-gated ion channels (Fig. 19-28). Receptors on the cell membrane bind water-soluble ligands that are typically unable to cross lipid bilayers and mediate a cellular response via intermediary proteins (e.g., G protein–coupled receptors) or by causing changes in ion flux (e.g., ligand-gated ion channels). Each of these types of membrane receptor has a role in mediating the action of various drugs important in anesthesiology. It is beyond the scope of this chapter to list all currently identified receptor proteins. However, prototypical examples are used to illustrate important pharmacodynamic principles.

Structure-activity relationships between drug and the three-dimensional configuration of the receptor binding site are critically important in determining binding properties. Though perhaps obvious, the chemical structure of a drug must match the three-dimensional configuration of the binding area of a receptor. Hence, subtle changes in drug structure may dramatically alter the ability of a drug to bind to a specific receptor population. In addition, two drugs with seemingly unrelated two-dimensional chemical structures may bind to the same receptor if their three-dimensional structures and charged areas are similar. The three-dimensional components of a ligand that interact with

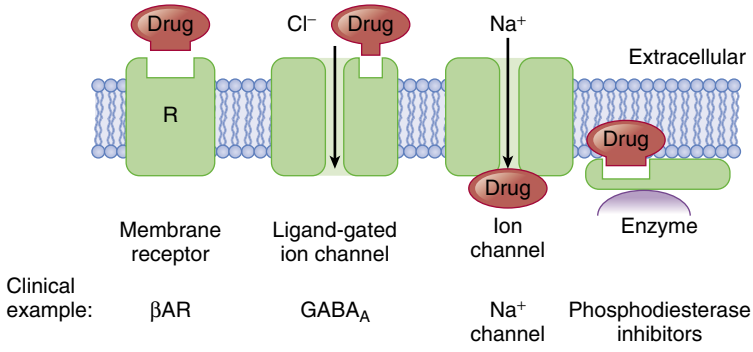

Figure 19-28 Schematic of four types of membrane-associated drug targets in anesthesia: membrane (G protein–coupled) receptor, ligand-gated ion channel, voltage-sensitive ion channel, and an enzyme. Potential sites of drug action are shown. βAR, β-adrenergic receptor; GABA$_A$, γ-aminobutyric acid.

ligand recognition portions of a receptor are called the "pharmacophore."

Guanine Nucleotide (G) Protein–Coupled Receptors

One of the most common methods by which membrane receptors translate agonist occupancy into intracellular "action" is via intermediary G proteins. G protein–coupled receptors are the most abundant type of receptor known. The overall structure of G protein–coupled receptors is shown schematically in Figure 19-29. Two-dimensional representation reveals an extracellular amino terminus containing glycosylation sites, an intracellular carboxyl terminus, fatty acid attachment (usually via palmitoylation or myristoylation of a carboxyl-terminal cysteine residue), three extracellular loops, and four intracellular loops. Major sites of G protein interaction with the receptor occur in the third and fourth (and to a lesser extent the second) intracellular loops, whereas major sites of phosphorylation (often correlated with desensitization [or dampening of receptor responses]) generally occur in the third intracellular loop and carboxyl terminus.

Even though a two-dimensional schematic is shown in Figure 19-29, it is important to remember that G protein–coupled receptors are three-dimensional structures with transmembrane segments coalescing around a central binding pocket (Fig. 19-30).[14] Although transmembrane amino acids must be hydrophobic overall (to be energetically favored in the lipid membrane), side chains on individual amino acids may be charged to act as counter ions for anchoring charged (water-soluble) hormone or drug to the receptor.

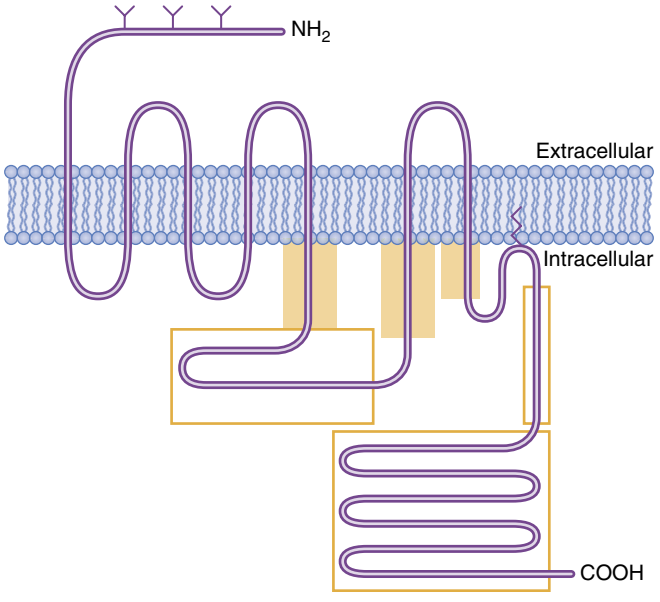

Figure 19-29 Schematic of G protein–coupled receptors. A two-dimensional version of receptor structure is shown with seven transmembrane domains, an extracellular amino (NH_2) terminus (with associated glycosylation sites [Y]), an intracellular carboxyl (COOH) terminus, palmitoylated cysteine residue (denoted by the *crooked line* extending into the membrane), three extracellular loops, and four intracellular loops. Major sites of G protein interactions with the receptor are *speckled*; potential sites of phosphorylation in the third intracellular loop and carboxyl terminus are enclosed in *boxes*.

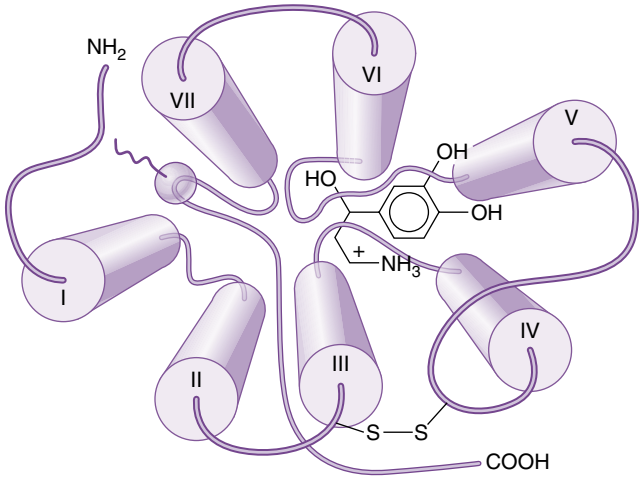

Figure 19-30 Schematic of the three-dimensional structure of the β_2-adrenergic receptor (a prototypical G protein–coupled receptor), looking from the outside of the cell inward. Transmembrane domains (denoted by *cylinders* and numbered with *Roman numerals*) coalesce to form a binding pocket. The correct orientation of the agonist norepinephrine is shown. Note that agonist affinity is determined by specific amino acids located in transmembranes III, IV, and VII. These critical sites in transmembrane domains have been determined experimentally via chimeric receptor and mutagenesis approaches combined with sophisticated computer modeling techniques. Ultimate confirmation of these structures will require crystallographic data. This is currently being attempted by several laboratories. *(From Stapelfeldt WH: The autonomic nervous system.* In *Schwinn DA [ed]: Scientific Principles of Anesthesia, vol 2. Philadelphia, Current Medicine, 1998.)*

Ion Channels

Some anesthetic drugs target voltage-gated ion channels. These receptors mediate neural signaling by modulating ion permeability in electrically excitable membranes in response to changes in membrane potential. Voltage-gated ion channels such as the sodium channel have charged regions that span the cell membrane. The formation of ion pairs between many positive and negative charges helps stabilize the ion-conducting pore. Voltage-dependent gating of the sodium channel is made possible by the presence of a voltage sensor, a collection of charges that move under the influence of the cell-membrane electrical field, hence the name voltage-gated ion channel. During depolarization, positively charged sodium ions move intracellularly. The change in membrane potential causes a conformational change in the central pore consisting of rearrangement of ion pairs that favors sodium permeability. Local anesthetics work by blocking voltage-gated sodium channels, as discussed in detail in Chapter 30.

The ligand-gated ion channel is a combination of a classic receptor protein and an ion channel. Ligand-gated ion channels permit certain drugs to directly alter membrane potentials. Many anesthetic drugs act on ligand-gated ion channels, such as the nicotinic acetylcholine receptor and the $GABA_A$ receptor. The structure of the $GABA_A$ receptor is shown in Figure 19-31.[15,16] Ligand-gated ion channels have both hydrophobic and charged transmembrane regions. The hydrophobic regions stabilize the structure in the membrane, whereas the centrally charged region serves as the pore for ion flux. Binding of drugs to ligand-gated ion channels usually enhances or dampens an already existing neurotransmitter-induced ion flux. For example, the neurotransmitter GABA binds to its receptor within the $GABA_A$ ligand-

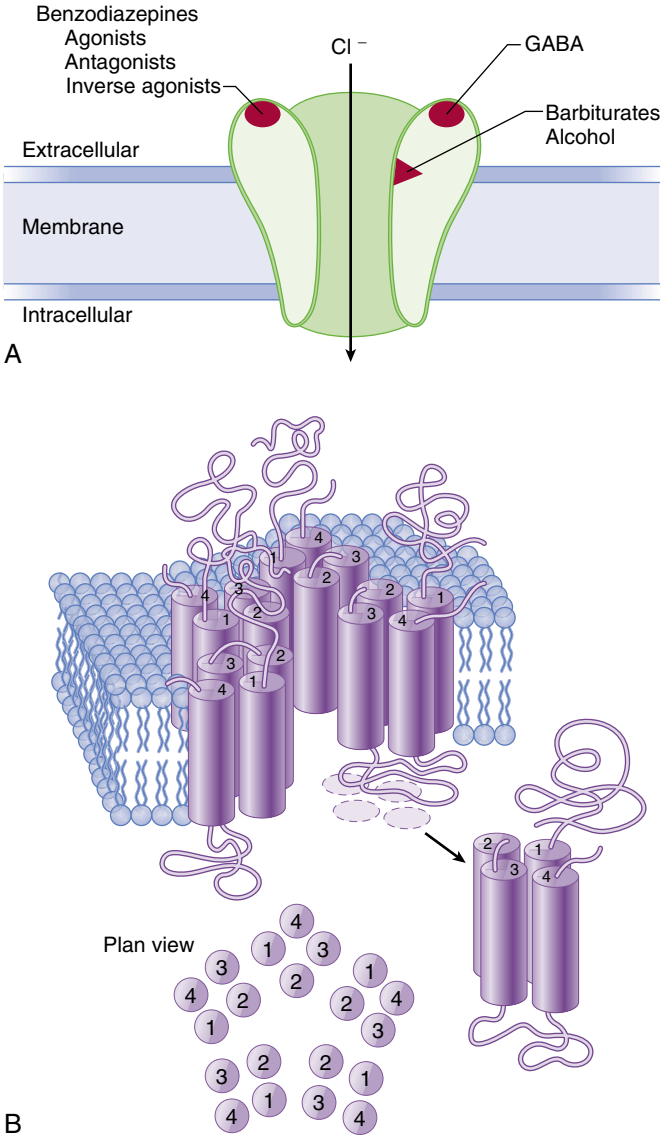

Figure 19-31 Cross section of a schematized γ-aminobutyric acid (GABA)-benzodiazepine receptor complex (a prototypical ligand-gated ion channel complex). Binding of benzodiazepine agonists to the $GABA_A$ ligand-gated ion channel facilitates the action of endogenous GABA. This results in increased inhibitory chloride ion flux in the central nervous system. **A,** Schematic of the $GABA_A$ ligand-gated ion channel complex showing receptor sites for benzodiazepines and GABA, as well as distinct receptor sites for barbiturates and alcohol. **B,** Model of the $GABA_A$ receptor–chloride ion channel protein complex composed of a hetero-oligomer of five subunits, including α, β, and γ, as well as δ or ρ polypeptides. Each subunit has four putative membrane-spanning domains (numbered 1 to 4, represented by *cylinders*). (***A,*** *From Berkowitz DE: Cellular signal transduction.* In *Schwinn DA [ed]: Scientific Principles of Anesthesia, vol 2. Philadelphia, Current Medicine, 1998;* ***B,*** *from Firestone L, Quinlan J, Gyulai F: Mechanisms of anesthetic action.* In *Schwinn DA [ed]: Scientific Principles of Anesthesia, vol 2. Philadelphia, Current Medicine, 1998.)*

gated ion channel complex and causes the intracellular flux of chloride ions. This action results in hyperpolarization of the membrane potential, a hallmark of inhibitory neurotransmission. Drugs binding to other sites on the $GABA_A$ receptor facilitate the action of the endogenous ligand GABA (see Fig. 19-31). Most hypnotics (benzodiazepines, barbiturates, propofol, etomidate, and possibly the hypnotic action of inhaled anesthetics) act through potentiation of endogenous GABA at the $GABA_A$ ligand-gated ion channel.

Ion Pumps

Another type of excitable membrane protein is the ion pump. The sodium-potassium–adenosine triphosphatase (ATPase) pump is perhaps the most familiar ion pump to the anesthesiologist because it is inhibited by digitalis. Extracellular fluid is high in sodium and low in potassium, whereas intracellular fluid is high in potassium and low in sodium. Because the nerve at rest is selectively permeable to potassium but not to sodium, potassium moves extracellularly and creates a net positive extracellular charge and a net negative intracellular charge. Action potentials activate sodium channels, thereby allowing sodium to flux intracellularly along a combined chemical and electrical gradient. The sodium-potassium-ATPase pump then rapidly pumps sodium out of the cell in exchange for potassium, thereby returning the cell to its original cation composition and electrical gradient. Drugs that act on ion pumps alter intracellular/extracellular cation ratios, which results in altered membrane resting potential.

Digitalis acts by inhibiting the sodium-potassium-ATPase pump. This is of special importance in the myocardial cell, where sodium-potassium-ATPase exchange is replaced by slower sodium-calcium exchange, thereby increasing intracellular calcium concentrations. Because calcium increases myocardial contractility, improved myocardial pump function results.

Second Messengers

Binding of a ligand to a receptor does not instantly produce its clinical effects. Instead, a series of rapid biochemical events couples receptor binding to ultimate clinical effects. These biochemical events are called second messengers. Because alterations in second messenger coupling can change the effectiveness of a drug, it is important that the anesthesiologist understand the general principles of second messenger action.

Many membrane receptors couple to their second messenger through G proteins, which are intermediate regulatory molecules. Coupling of G proteins to receptor-hormone complexes requires energy in the form of guanosine triphosphate (GTP). The hydrolysis of G protein–associated GTP to guanosine diphosphate (GDP) is regulated by yet another set of proteins called *RGS proteins*. Once the receptor interacts with the G protein, the biochemical reaction in the effector cascade is triggered. There are stimulating (e.g., G_s, G_q) and inhibitory (e.g., G_i, G_o) G proteins. The physiologic effect is determined by the specific G protein and subsequent cellular response. G proteins are heterotrimeric, composed of three subunits—α, β, and γ. Receptor–G protein interactions result in dissociation of the G protein subunits into α and βγ. The α-subunit of most G proteins confers specificity between receptor and effectors. Although βγ-subunits were originally thought to simply anchor G proteins to the cell membrane, it is now clear that dissociated βγ-subunits are capable of directly stimulating second messengers. In addition, βγ-subunits play a role in anchoring regulatory kinases to the cell membrane, which leads to enhanced phosphorylation of membrane receptors.

One of the best-understood second messenger systems is the adenylyl cyclase system. In this system, stimulatory G protein–

receptor-hormone complexes increase activity of the enzyme adenylyl cyclase, which results in increased levels of cyclic adenosine 3′,5′-monophosphate (cAMP) in the cell (Fig. 19-32). Inhibitory G protein–receptor-hormone complexes decrease the activity of adenylyl cyclase, thereby resulting in decreased levels of cellular cAMP. In general, intracellular cAMP activates protein kinases that phosphorylate various proteins, ion channels, and second messenger enzymes.

Another example of a second messenger system is the phosphatidylinositol system. Here, hydrolysis of phosphatidylinositol 4,5-bisphosphate (PIP_2) in the cell membrane, catalyzed by activation of phospholipase C by G_q, generates two main second messenger molecules, inositol 1,4,5-trisphosphate (IP_3) and 1,2-diacylglycerol (DAG). IP_3 then mobilizes intracellular calcium from nonmitochondrial intracellular stores by interacting with distinct IP_3 receptors on the surface of these organelles. The resulting increase in intracellular calcium levels produces biologic effects such as smooth muscle contraction. α_1-Adrenergic agonists, endothelin, and muscarinic (M_1, M_3, M_5) agonists all mediate hydrolysis of phosphatidylinositol.

Stimulation of receptors and second messengers ultimately leads to physiologic effects in a given tissue. The physiologic effects produced depend on the presence of specific receptor subtypes, G proteins, and second messengers within that tissue. An example of the wide-ranging cardiovascular effects produced by the predominant sympathetic neurotransmitter norepinephrine can be seen in Figure 19-33.

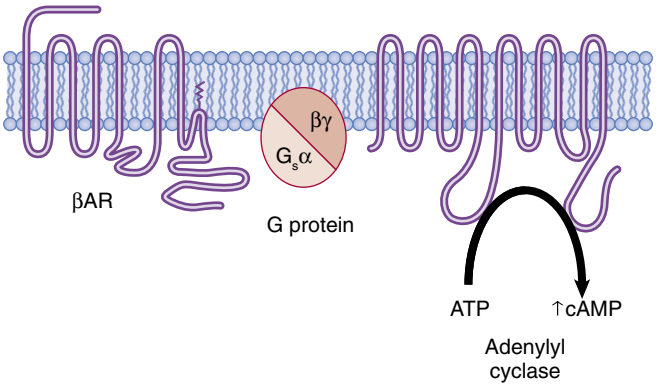

Figure 19-32 Schematic of the β-adrenergic receptor signal transduction cascade. βAR, β-adrenergic receptor; ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; $G_s\alpha$, α subunit of the stimulatory G protein (G_s); βγ, stimulatory G protein, βγ-subunit.

Developments in Molecular Pharmacology

The field of molecular pharmacology has advanced our understanding of excitable membrane proteins and their mechanisms of action. Novel molecular techniques provide unique opportunities to learn more about receptors, including their structure and function down to the DNA level. Hitherto unknown receptors and receptor subtypes continue to be discovered, paving the way for future development of receptor-specific pharmacologic agents. We will briefly review the general field of molecular pharmacology because future drugs for perioperative use will probably target receptor and receptor subtypes discovered by such molecular approaches.

Molecular pharmacology takes advantage of the finding that all proteins, including excitable membrane proteins, are encoded in the human genome as nucleic acids. Every amino acid present in a protein is encoded by a specific combination of three nucleotides in DNA. Therefore, if the DNA sequence that encodes a receptor protein can be determined, the putative primary structure (amino acid sequence) of the receptor can be deduced. In addition, encoding DNA sequences (i.e., genes) can be inserted into special cells that will express (manufacture, assemble, and deliver to the appropriate location in the cell) the receptor protein in high quantity. This approach has several advantages.

First, studies on the receptor itself can be performed. By changing (mutating) nucleotide sequences, an abnormal (synthetic or "designer") receptor can be created. This abnormal receptor can then be compared with the original receptor to see whether the changes made affect binding of drug to the receptor or coupling of it to second messengers. In this manner, the function of each portion of the receptor can be studied. This type of

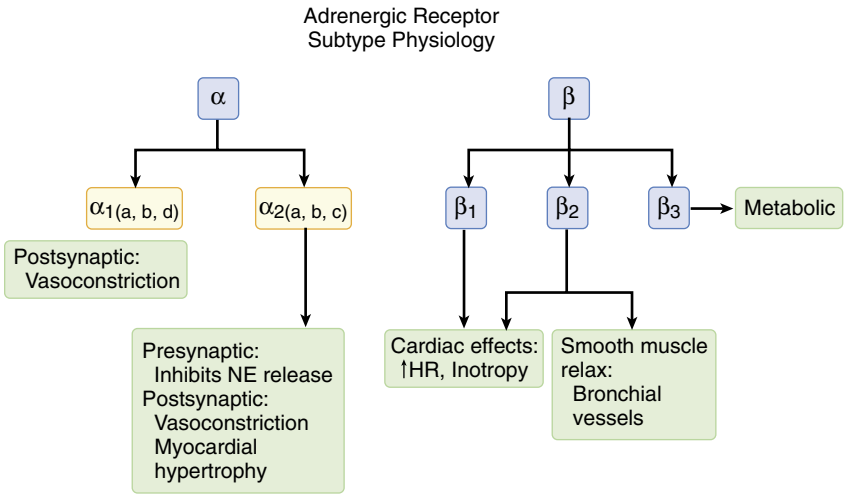

Figure 19-33 Adrenergic receptor subtype physiology. HR, heart rate; NE, norepinephrine.

information is often called structure-activity relationships. G proteins and second messengers can be investigated in a similar manner. More recently, naturally occurring human receptor variants have been investigated and tested for alterations in pharmacologic properties (see the later section "Pharmacogenetics").

The second advantage of using molecular techniques in pharmacology is that new receptors and receptor subtypes can be discovered by searching the genome for DNA sequences similar to those of known receptors. Once these new receptors are discovered, they can easily be characterized because high expression in cells enables them to be screened by various pharmacologic agents. The recent availability of DNA sequences for the full human genome has accelerated the discovery of new receptors through DNA homology searching.

Finally and perhaps the most immediately clinically relevant, new investigational drugs can be rapidly screened for effects on a spectrum of native and variant receptors. In this way, the pharmacologic effects of individual receptors can be studied in a controlled manner, isolated from other receptors and receptor subtypes. Such studies have the potential to lead to the development of new drugs for use in the perioperative period, as well as understanding of the effects of these drugs in patients with receptor variants.

Although there are many advantages to using molecular approaches for understanding the physiologic pathways of individual receptors and for drug discovery, there are also some disadvantages. Cell lines are not integrated organisms, so the function of the receptor protein in a network of physiologic systems cannot be assessed. An approach to understanding the function of previously identified and new gene products that is now classic is to develop mouse (murine) models in which the gene of interest has been eliminated (knock-out mice) or overexpressed (transgenic mice). The physiologic consequence of such altered protein expression is then examined. Although details of these technologies are beyond the scope of this chapter, they have become standardized and are widely available. The transgenic and knock-out mouse models are robust and useful, but they also have important limitations. First, the genetic background of the animals created must be examined carefully. If not carefully controlled, altered phenotypes may result from differences in animal "strain" (or genetic background) rather than from an overexpressed or knocked-out gene product. Second, elimination of specific receptors may be compensated by alterations in other gene products. In this case, the final phenotype represents not only the effect of the absent gene but also the compensatory expression of other genes. Compensation is of particular concern when elimination of a gene is lethal because surviving progeny by definition have compensated in a way that enhances survival and therefore may not be representative of the results of the single gene that was knocked-out. Finally, some receptors and proteins have different tissue localization in humans versus other animal species. Therefore, results from transgenic and knock-out animal studies should be extrapolated cautiously to humans.

Despite these potential limitations, transgenic and knock-out animal models have proved very important in elucidating novel functions of receptors and proteins. Many unexpected physiologic roles for gene products have been discovered, and important physiologic questions have been answered and confirmed with these approaches. Table 19-1 lists conclusions drawn from transgenic and knock-out mice based on alterations in adrenergic receptors and their signal transduction cascade. Novel functions for specific adrenergic receptor subtypes (e.g., the role of α_{2A}ARs in sedation and CNS-mediated hypotension, α_{2B}ARs in mediating vasoconstriction, and α_{2C}ARs in temperature control) have been discovered. Table 19-1 illustrates that alterations in adrenergic receptor signal transduction pathways and modulating kinases have physiologic consequences in the whole animal.

As a result of these advances, we now know the precise location of action of many anesthetic drugs (Table 19-2).[17] This includes identifying the receptor, characterizing the binding site, and studying the downstream consequences of receptor binding responsible for the drug effect. For example, Jurd and colleagues have demonstrated that etomidate and propofol both bind to the same pocket of the β_3-subunit of the $GABA_A$ receptor and have created a genetically altered mouse that is relatively resistant to the hypnotic effects of both drugs.[18] Although most hypnotics and sedatives act by potentiating the action of GABA (the most important inhibitory neurotransmitter in the CNS), the search for the site of action continues for inhaled anesthetics.

Clinical Evaluation of Drug Effects

General Principles

Once pharmacologic agents have exerted their actions on a molecular level, stimulated their targets, and produced a physiologic effect, it is important to evaluate the effect on the whole organism. This section focuses on methods of evaluating clinical drug effects such as dose-response curves, efficacy, potency, the median effective dose (ED_{50}), the median lethal dose (LD_{50}), and the therapeutic index.

Concentration-Versus-Response Relationships

The standard comparison of a drug with its clinical effect is the concentration-versus-response curve, shown in Figure 19-34. The relationship illustrated is the time-independent relationship between dose, concentration, or some other measure of exposure to the drug (*x* axis) and the measured effect (*y* axis). The measured effect can be an absolute response (e.g., twitch height), a normalized response (e.g., percentage of twitch height depression), or a population response (e.g., fraction of subjects moving upon incision). The standard equation for this relationship is the "Hill" equation, sometimes called the "sigmoid-E_{max} relationship":

$$\text{Effect} = E_0 + (E_{max} - E_0)\frac{C^\gamma}{C_{50}{}^\gamma + C^\gamma} \qquad (48)$$

This is another example of the saturation equation shown in Figure 19-5. In this equation, E_0 is the baseline effect in the absence of drug and E_{max} is the maximum possible drug effect. C is typically concentration or dose, although other measures of drug exposure (e.g., peak concentration, area under the concentration-versus-time curve) can be used. C_{50} is the concentration associated with 50% of peak drug effect and is a measure of drug potency. The exponent γ, also called the "Hill coefficient," relates to the sigmoidicity and steepness of the curve. If γ is less than 1 and the curve is plotted on a standard *x* axis, the curve appears hyperbolic (see Figure 19-5). If γ is greater than 1, the curve appears sigmoidal, as in Figure 19-34. If the *x* axis is plotted on

Table 19-1 Summary of Results from Knock-Out and Transgenic Mice in Which Various Portions of Adrenergic Receptor Signaling Pathways were Targeted (Emphasis on Cardiovascular Effects)

Model	Target	Result
Transgenic	↑β_2AR	↑Basal AC, ↑LV fn, ↑atrial contractility, ↑supraventricular premature beats, ↓HR variability
Knock-out	↓β_2AR	No observable effects (except mild exercise effects)
Transgenic	↑β_1AR	Dilated cardiomyopathy and early death, fibrosis
Knock-out	↓β_1AR	70% prenatal death rate, survivors: nl AC, ↓ISO-stim
Transgenic	↑AC-V	↑HR, ↑fractional shortening, no ISO-stim effects
Transgenic	↑GRK2	↓AC activity, ↓fn βARs, ↓ISO-stim (rescued with βARK-ct peptide, which inhibits GRK2)
Transgenic	↑GRK5	Enhanced βAR desensitization, but not angiotensin II desensitization
Transgenic	↑GRK2 inhibitor	Enhanced cardiac contractility with ISO (functional ↓GRK2)
Knock-out	↓GRK2	Lethal phenotype, gestational hyperplasia of LV, LVEF ↓70% in embryos
Transgenic	↑$G_s\alpha$	No Δ baseline EF, ↑ ISO-stim, myocardial fibrosis
Knock-out	↓Phospholamban	↓βAR-mediated contractile responses
Transgenic	↑α_{1A}AR	Hypertension, ↑inotropy
Transgenic	↑α_{1B}AR	Myocardial hypertrophy, hypertension, nociception, memory (constitutively active)
Transgenic	↑α_{1B}AR	No myocardial hypertrophy, hypertension (wild type)
Transgenic	↑α_{1D}AR	Nociception, memory
Transgenic	↑G_q	Myocardial hypertrophy ≈4-fold overexpression, higher expression give heart failure
Transgenic	↑G_q inhibitor	Prevention of myocardial hypertrophy (functional ↓G_q)
Knock-out	↓α_{2A}AR	Presynaptic α_2AR, mediates sedation/hypnosis, ↓BP (central hypotension), analgesia, regulation of DA/5-HT, antiepileptogenic effects of NE
Knock-out	↓α_{2B}AR	Mediates ↑BP (peripheral vasoconstriction)
Knock-out	↓α_{2C}AR	Mediates hypothermia, DA synthesis/metabolism, presynaptic α_2AR also (low-frequency stimulation)

a log scale, the curve will always appear sigmoidal regardless of the value of γ.

Potency and Efficacy

Considerable confusion exists around the definition of potency because of competing definitions of the term. One use of potency is to describe the effect of a given dose of the drug. Consider two different oral preparations of an identical drug: one that dissolves quickly in the stomach and is rapidly absorbed and one that never completely dissolves and is poorly absorbed. A given dose of the rapidly absorbed formulation would produce a more profound drug effect and thus be considered more potent than an identical dose of the slowly absorbed formulation. Consequently, from a therapeutic perspective, potency is often defined in terms of the dose-versus-response relationship.

However, from a pharmacologic perspective, potency is best described in terms of the concentration-versus-response relationship. As shown in Figure 19-34, a drug with a left-shifted concentration-versus-response curve (i.e., lower C_{50}) is considered more potent, whereas a right-shifted dose-versus-response curve renders it less potent. To be precise, potency should be defined in terms of a specific drug effect (e.g., 50% of maximal effect). This is particularly important if the two drugs have different Hill coefficients or efficacies (E_{max}).

Efficacy is a measure of the intrinsic ability of a drug to produce a given physiologic or clinical effect (Fig. 19-35). For example, in G protein–coupled receptors, efficacy is influenced by coupling of receptor to G proteins, activation of second messengers, and the ability to generate maximal physiologic responses. The scale used to describe intrinsic efficacy at a given receptor ranges from 0 to 1. Efficacy is 1.0 for full agonists, 0 for neutral antagonists, and between 0 and 1.0 for partial agonists. In contrast, the term *potency* refers to the quantity of drug that must be administered to produce a specific effect. Two drugs may have the same efficacy, but if one drug produces the maximum effect at 1 mg whereas the second drug produces the maximum effect only at 100 mg, the second drug is less potent. The difference between a full agonist and a partial agonist (see Figs. 19-22 and 19-23) represents a difference in efficacy.

Effective Dose and Lethal Dose

The ED_{50} is the dose of a drug required to produce a specific effect in 50% of individuals to whom it is administered. The LD_{50} is the dose of a drug required to produce death in 50% of patients (or,

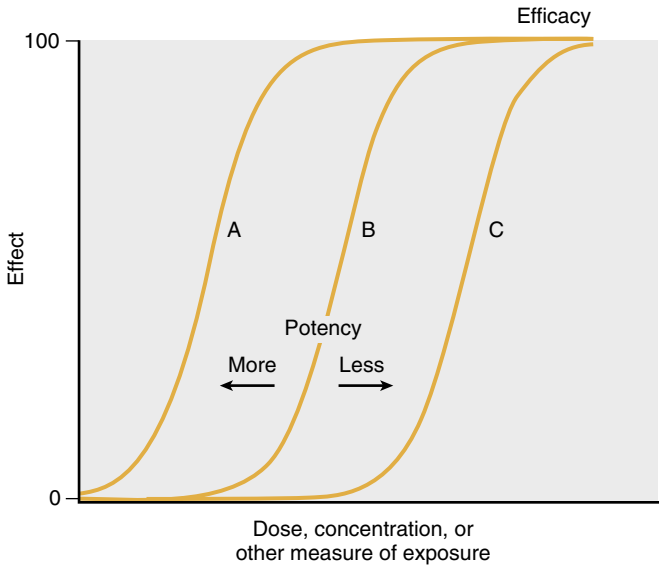

Figure 19-34 Dose- or concentration-versus-response relationships. A sigmoidal concentration-response curve is generated when the log drug concentration is plotted against the clinical response or effect. The concentration-response curve is shifted to the right (B→C) in the presence of a competitive antagonist after desensitization. Curve C might also represent an agonist with lower receptor affinity (K_a) or potency than curve B (or both). Curve A represents an agonist with higher receptor affinity or potency than curve B.

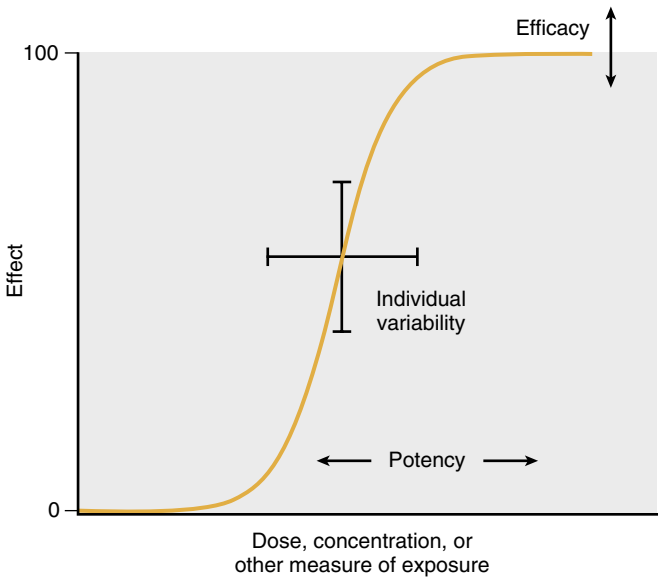

Figure 19-35 Relationship among efficacy, potency, and individual variability as they relate to a typical sigmoidal dose- or concentration-versus-response curve.

more often, animals) to whom it is administered. The therapeutic index of a drug is the ratio between the LD_{50} and the ED_{50} (LD_{50}/ED_{50}). The larger the therapeutic index of a drug, the safer the drug for clinical administration. The relationship among ED_{50}, LD_{50}, and therapeutic index is shown in Figure 19-36.

Drug Interactions

Actions at the Same Receptor

Agonists and antagonists modify dose-response relationships for concurrently administered drugs. If two agonists have identical affinity (K_a) for a given receptor and identical effectiveness in coupling to second messengers, their resultant dose-response curves should be superimposable. However, if two agonists have different receptor affinities despite identical effectiveness in coupling to second messengers, their dose-response curves will be parallel (with the rightward-shifted curve corresponding to the drug with lower receptor affinity; see Fig. 19-34, curves B and C). When two agonists are administered simultaneously, the clinical effect depends on the total amount of drug-receptor complexes generated.

As stated earlier, full agonists produce maximal responses, whereas partial agonists produce less than maximal response at the same receptor occupancy. The precise molecular mechanism that explains this blunting of the maximal response by partial agonists is not known, but it may relate to the ability of full agonists to stabilize the activated state, R*, most effectively. Partial agonists shift the dose-response curve of the agonist to the right (B → C in Fig. 19-34).

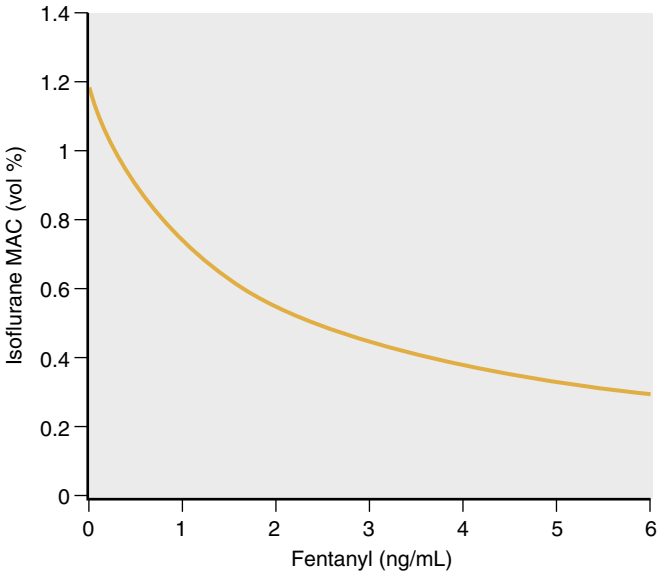

Figure 19-37 Influence of fentanyl on the minimum alveolar concentration (MAC) of isoflurane associated with a 50% probability of movement on incision. Modest amounts of fentanyl greatly reduce the MAC of isoflurane, but a ceiling in MAC reduction is quickly reached. Even with large opioid doses, some isoflurane is required to ablate the movement response. *(Adapted from McEwan AI, Smith C, Dyar O, et al: Isoflurane minimum alveolar concentration reduction by fentanyl. Anesthesiology 78:864-869, 1993.)*

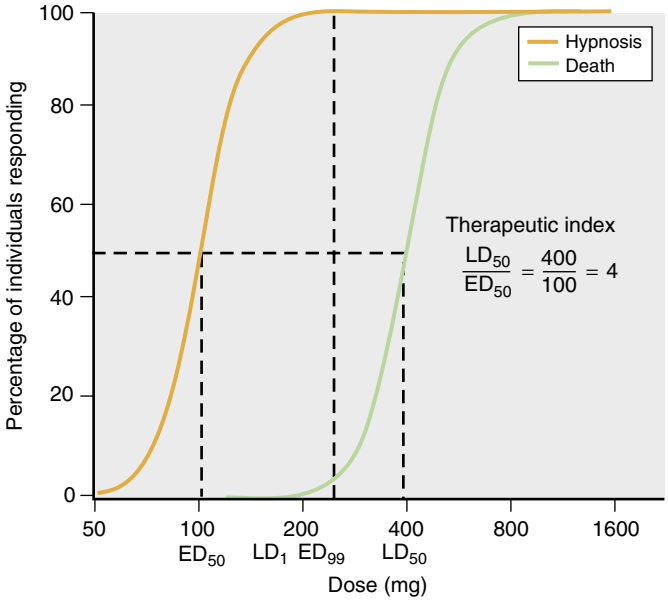

Figure 19-36 Relationship between median effective dose (ED_{50}), median lethal dose (LD_{50}), and therapeutic index. These curves were generated from data in which animals were injected with varying doses of a sedative-hypnotic and clinical responses were determined. ED_{50} is the dose of drug required to produce a specific effect (hypnosis) in 50% of animals to which it is administered (*left curve*). LD_{50} is the dose of drug required to produce death in 50% of animals to which the drug is administered (*right curve*). The therapeutic index of the drug is the ratio between LD_{50} and ED_{50} (LD_{50}/ED_{50}). LD_1 is the lethal dose in 1% of the population. ED_{99} is the effective dose in 99% of the population. As drawn, LD_1 is less than ED_{99}, which would not be clinically acceptable.

The addition of a competitive antagonist also shifts the dose-response curve to the right (B → C in Fig. 19-34). By contrast, the addition of a noncompetitive agonist shifts the dose response curve to the right and reduces the efficacy of the agonist because maximal response cannot be achieved at any agonist dose since blockade of effect (noncompetitive antagonism) cannot be reversed.

Actions at Different Receptors

Anesthesia is the practice of applied drug interactions. As discussed in Chapter 39, general anesthesia is, at a minimum, a combination of hypnosis, immobility, and antinociception. As such, there has been extensive work looking at the interaction of hypnotic drugs, which include inhaled anesthetics and GABA agonists (propofol, barbiturates, etomidate, and benzodiazepines), muscle relaxants, and analgesic drugs.

A prototypical study of the relationship between inhaled anesthetics and opioids is the study of McEwan and colleagues, who characterized the interaction between isoflurane and fentanyl.[19] The isoflurane concentration associated with a 50% chance of moving on incision (minimum alveolar concentration [MAC]) versus the plasma fentanyl concentration is shown in Figure 19-37. Initially, the interaction is profound, with a 50% reduction in isoflurane MAC at a plasma fentanyl concentration of 1.7 ng/mL and a 63% reduction in isoflurane MAC associated with a plasma fentanyl concentration of 3 ng/mL. Beyond 3 ng/mL, there is very little benefit from additional fentanyl. The first clinical implication of this interaction is that a modest amount of opioid dramatically reduces the concentration of inhaled anesthetic required to prevent movement. The second clinical implication is that even with huge doses of opioids, some hypnotic

component must be added to the anesthetic to prevent movement.

Similar work has been done for propofol. In a series of elegant studies, Vuyk and colleagues characterized the interaction of propofol with alfentanil.[20] As shown in Figure 19-38, the interaction is markedly synergistic, with modest amounts of alfentanil greatly decreasing the amount of propofol associated with a 50% chance of response to intubation or surgical incision. Vuyk and colleagues also documented the interaction of propofol and alfentanil on return of consciousness, likewise shown in Figure 19-38. As discussed in Chapter 28, studies such as these provide the basis for rational selection of opioids and design of optimal opioid infusion regimens.

Hendrickx and colleagues have recently surveyed the interaction of anesthetic drugs that affect nociception, analgesia, and hypnosis.[21] They examined two end points: "hypnosis," defined as loss of consciousness in humans and loss of the righting reflex in animals, and immobility, defined as loss of the movement response to noxious stimulation in a nonparalyzed subject.[21] As shown in Figure 19-39, the interaction between pairs of intravenous drugs and between intravenous drugs and inhaled anesthetics is typically synergistic. The exception is the *N*-methyl-D-aspartate (NMDA) antagonists, ketamine and nitrous oxide, which demonstrate synergy, additivity, or infra-additivity in different models. By contrast, the inhaled anesthetics are strictly additive in their interactions with other inhaled anesthetics, suggesting a common mechanism of action.

Classic interaction studies such as those just described examine the concentrations associated with a particular response (such as a 50% chance of moving) for two drugs evaluated separately and in combination. However, a more general view is that any combination of two drugs is associated with a response. This is best viewed as a "response surface" in which the *x* and *y* axes of the surface are concentrations (or doses) of drugs A and B and the *z* axis is the response to the particular combination. Minto and colleagues have proposed a mathematical framework for response surfaces for a variety of interaction surfaces of interest to anesthesiologists.[22] Figure 19-40 shows six examples of possible response surfaces, depending on the nature of the interaction.

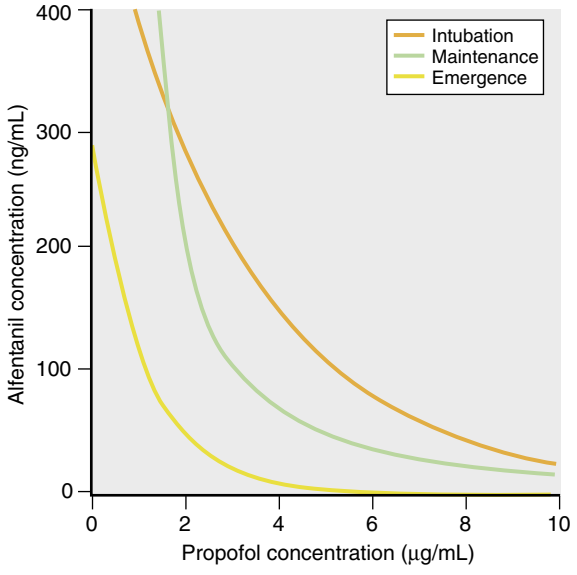

Figure 19-38 Influence of alfentanil on the concentration of propofol associated with a 50% probability of response to intubation and incision, as well as a 50% probability of awakening at the end of surgery. Moderate doses of alfentanil greatly reduce the dose of propofol required to ablate the response to noxious stimulation. However, below propofol concentrations of approximately 2 μg/mL, even large doses of alfentanil cannot reliably ablate the response to noxious stimulation. *(Adapted from Vuyk J, Lim T, Engbers FH, et al: The pharmacodynamic interaction of propofol and alfentanil during lower abdominal surgery in women. Anesthesiology 83:8-22, 1995.)*

Variability in Drug Response

Anesthesiologists observe individual variation in clinical response to administered drugs every day. This variability can occur as a result of differences in pharmacokinetic processes such as absorption, distribution, metabolism, and excretion of a drug. Individual variation can also be due to differences in pharmacodynamics, such as intrinsic differences in receptor sensitivity, upregulation and downregulation, and alterations in other targets that affect drug action. The relationship between patient variability and a typical dose-response curve is shown in Figure 19-35. Sources of pharmacokinetic and pharmacodynamic variability include genetics, patient physiology, and drug interactions.

Pharmacogenetics

The field of pharmacology that describes effects of genetic variation on drug action is called *pharmacogenetics*. Pharmacogenetics refers to genetic diversity in the body's absorption, metabolism, and distribution of drugs (inborn pharmacokinetic variability) or in the body's response to the drug, as might be caused by differences in receptor structure or patient physiology (inborn pharmacodynamic variability). To understand the effect of genetic variation on pharmacokinetics and pharmacodynamics, it is important to first define genetic variants, or polymorphisms.

Genetic polymorphism refers to any type of variation in a gene. More precise language is used to describe each specific type of genetic variant. When one nucleotide is exchanged for another, this variant is called a *single-nucleotide polymorphism* (SNP). The rare substituted nucleotide is defined as the minor allele, whereas the more common "wild-type" nucleotide is defined as the major allele. Most SNPs are biallelic, with only two nucleotides possible, either the minor or the major allele. In rare cases, SNPs can be triallelic, with two possible minor alleles and three total possible nucleotides present. With four total nucleotides available in DNA, it is theoretically possible to have each of the four nucleotides represented, but this almost never happens. We will confine our discussion to biallelic SNPs because they are the most common.

Allele frequency refers to the frequency of the minor allele, notated $f(-)$. The frequency of the major allele is therefore $1-f(-)$. Because this is the minor allele, by definition $f(-)$ is less than 0.5. Individuals have two copies of each allele, so there are three possible combinations of biallelic SNPs: AA, Aa, aa, in which A is a major allele and a is a minor allele. The Hardy-Weinberg equation provides the frequency of each of these combinations based on the generally correct assumption that paring of alleles is random:

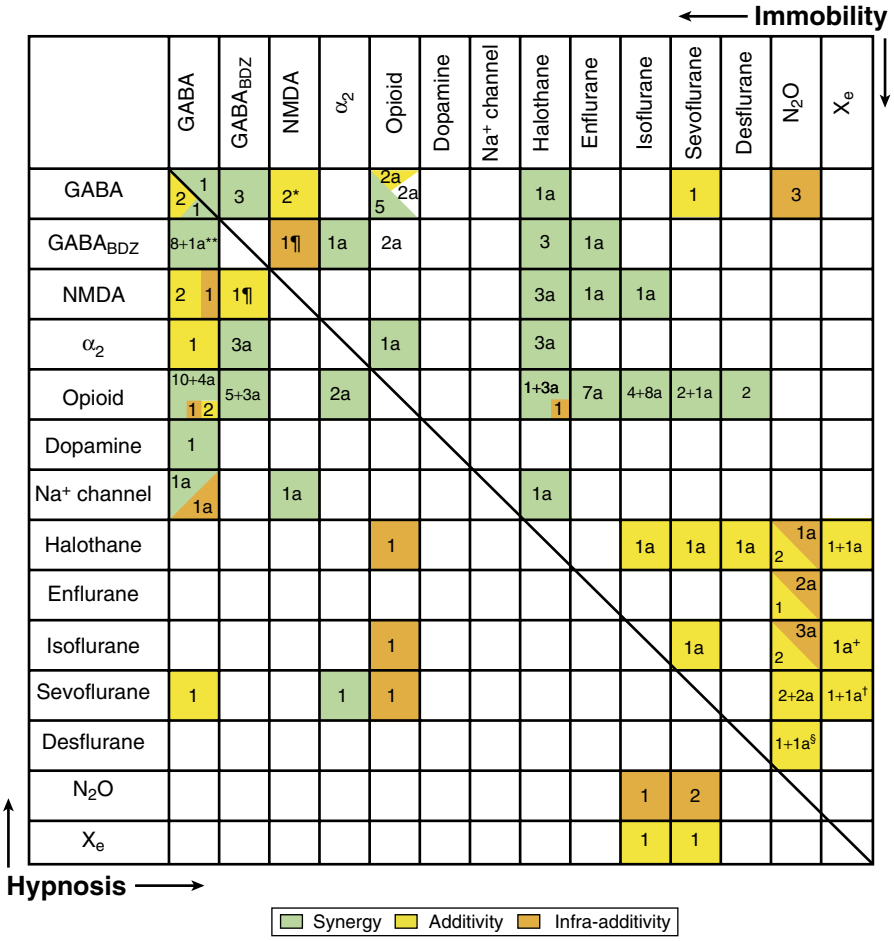

Figure 19-39 Summary of drug interactions in humans and animals for hypnosis (loss of consciousness in humans, loss of righting reflex in animals) and immobility (loss of movement response to noxious stimulation). The numbers in each cell refer to the number of papers supporting the finding. γ-Aminobutyric acid (GABA) = propofol, thiopental, methohexital, etomidate; GABA$_{BDZ}$ = midazolam, diazepam; *N*-methyl-D-aspartate (NMDA) = ketamine; α_2 = dexmedetomidine, clonidine; opioid = morphine, alfentanil, fentanyl, sufentanil, remifentanil; dopamine = droperidol, metoclopramide; Na$^+$ channel = lidocaine, bupivacaine. *(From Hendrickx JFA, Eger EI, Sonner JM, Shafer SL: Is synergy the rule? A review of anesthetic interactions producing hypnosis and immobility. Anesth Analg 107:494-506, 2008.)*

aa (homozygous minor allele): $f(-)^2$
AA (homozygous major allele): $(1-f[-])^2$
Aa (heterozygous): $2\,f(-)\,(1-f[-])$

The sum of these frequencies is 1.

In addition to SNPs, other types of genetic variants include insertions/deletions, in which stretches of genomic DNA are missing or added, and microsatellite repeats, in which several nucleotides repeat (e.g., the dinucleotide repeat GCGCGCGC [*n* = 4 GC repeats] or the trinucleotide repeat TACTACTACTAC-TACTAC [*n* = 6 TAC repeats]). The number of repeats in a microsatellite correlates with some diseases and can be used in genome-wide scans to identify chromosome regions associated with disease.

Catastrophic DNA changes often include DNA deletions or insertions that are not multiples of three in the coding region. Such changes result in a frameshift in the triplet nucleotide sequence used to encode amino acids in proteins, with the probable result being a nonsense protein. SNPs that change an encoded amino acid to a stop codon may also be catastrophic because they could result in a truncated protein.

Not all genetic variants have biologic consequences. Just as differences in eye color or fingerprint pattern do not have medical consequences, many genetic variants provide "background" variation without overt biologic consequences. In fact, genetic variants with biologic/medical effects represent the minority of all genetic variants known to exist. The sum total of genetic variation (with and without biologic implications) does provide a unique genetic fingerprint, a fact used in forensic science to identify suspects or relatives (or both).

Determining the association between genetic variants and disease, drug therapy, or patient outcome is not straightforward and ideally should involve the help of a statistical geneticist. Clinical covariants and even genetic population structure (loosely defined as genetic variation caused by global population movement) must be carefully taken into account in pharmacogenetic studies. Depending on the number of genes to be examined, statistical testing for association ranges from straightforward simple analyses (using the chi-square approach to test whether a variant or haplotype [a group of SNPs] is enriched in the target population) to very complicated analyses (complex modeling, permutation testing, prospective sequential testing, etc.). In clinical association studies it is important to ensure that clinical end point data are reproducible and ideally include intermediate end points such as protein levels or enzyme activity. As more clinically relevant human genetic variants become known, our knowledge of the role of genetics in drug response and patient outcome should be significantly enhanced.

Genetic Variability in Pharmacokinetics

Naturally occurring genetic variants can affect the activity of enzymes responsible for drug metabolism, most often by altering

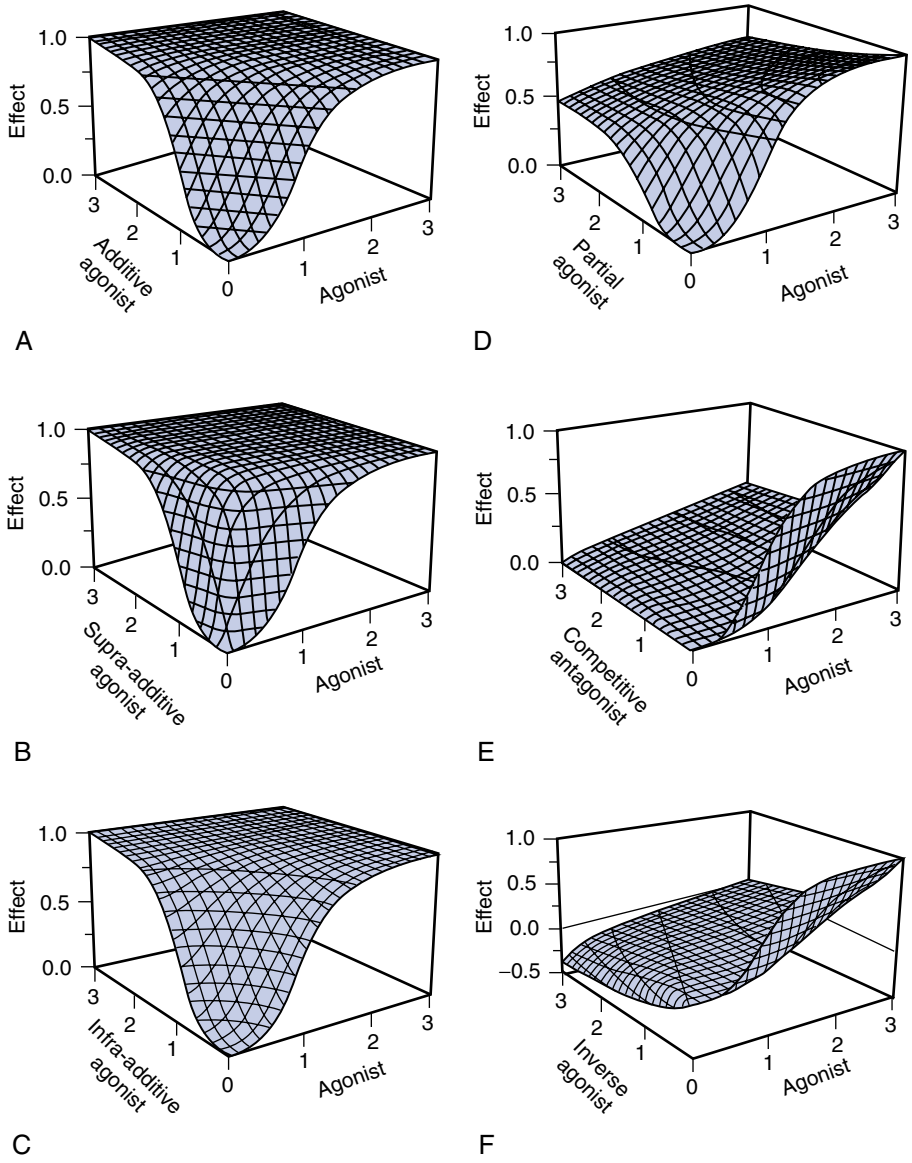

Figure 19-40 Response surfaces for potential pharmacodynamic interactions of anesthetic drugs. **A,** Additive interaction between two agonists that have the same mechanism of action (e.g., interaction of fentanyl and alfentanil). **B,** Supra-additive interaction between two agonists (e.g., isoflurane and fentanyl). **C,** Infra-additive interaction between two agonists (reported for cyclopropane and nitrous oxide). **D,** Partial agonist and full agonist (e.g., hypothetical interaction of nalbuphine and fentanyl). **E,** Competitive antagonist and full agonist (e.g., naloxone and fentanyl). **F,** Inverse agonist and full agonist (e.g., RO 19-4063 and midazolam).

a key amino acid in or near the site of enzymatic action. In practical terms, this enzymatic diversity is rarely evident in the absence of drug therapy. In the presence of drug therapy, pharmacogenetic variation in metabolism is evident as unexpected toxicity, duration of action, or lack of efficacy of administered drugs.

Of particular interest to anesthesiologists is the activity of cytochrome P450 (CYP) 3A4. This is the most abundant cytochrome in the liver and intestines and is responsible for the metabolism of almost half of all drugs, including many important drugs in anesthesia: opioids (fentanyl, alfentanil, sufentanil, methadone), benzodiazepines (diazepam, midazolam, alprazolam, triazolam), local anesthetics (cocaine, lidocaine, ropivacaine), steroids, calcium channel blockers, haloperidol, and halothane. Of the many described genetic mutants of the CYP3A4 enzyme, however, only two alter enzyme activity, with CYP3A4*18 decreasing and CYP3A4*19 increasing drug turnover.[23,24] It is important to note that most of these CYP3A4 studies have examined only heterozygous (Aa genotype) individuals thus far. This enzyme is readily inducible and inhibited by multiple substances. CYP3A4 induction and inhibition significantly overshadow the effects of currently described genetic variants.

In contrast to the lack of genetically important CYP3A4 variants, a different story exists for CYP2C19, the enzyme system responsible for metabolizing mephenytoin, omeprazole, diazepam, proguanil, propranolol, and certain antidepressants. Newly described SNPs in this gene, expressed most commonly in African Americans, appear to decrease the metabolism of these drugs in vitro.[25] Effects on drug plasma concentrations, clinical efficacy, and toxicity need further testing in prospective human clinical trials.

One of the best-studied pharmacogenetic variants is CYP2D6, also called "debrisoquine hydroxylase" or "sparteine oxygenase." About 7% to 10% of white individuals are homozygous for an inactive variant of CYP2D6. This alters metabolism for at least 40 drugs. For example, codeine is a prodrug with no intrinsic analgesic efficacy. Codeine, oxycodone, and hydrocodone all undergo *O*-demethylation to morphine, oxymorphone, and hydromorphone, their more pharmacologically active metabo-

lites, via CYP2D6. Individuals who are homozygous for inactive CYP2D6 have little to no analgesic efficacy from codeine.[26] Such individuals are likely to receive very little anesthesia from oral codeine and need to be rescued by another analgesic agent. CYP2D6 polymorphisms have also been shown to impair dextromethorphan and metoprolol metabolism. In contrast, other CYP2D6 polymorphisms result in a rapid metabolizer phenotype that is associated with high morphine levels after codeine administration that can lead to toxicity. When patients can be assayed for CYP2D6 activity, this will become a useful screen before initiating pain therapy with opioids.

Anesthesiologists are familiar with the role of genetics in determining butyrylcholinesterase (pseudocholinesterase) activity. Subjects with abnormal butyrylcholinesterase are at risk for prolonged paralysis from succinylcholine and exaggerated systemic effects from ester-based local anesthetics. Not surprisingly, there are ethnic differences in cholinesterase activity. For example, individuals of Middle Eastern descent are likely to have less butyrylcholinesterase activity than those of European descent. Molecular approaches have permitted extensive characterization of plasma cholinesterase variants. Most of these variants are not "all or none" but rather reflect a spectrum of enzymatic activity.

There may be an evolutionary explanation for pharmacogenetic variability in metabolism. It is probable that variability in drug metabolism is a natural adaptive response to an environment that can present a huge variety of toxins. Enzymatic diversity is probably maintained through natural selection to ensure survival when we are confronted with novel environmental toxins.

Genetic Variability in Pharmacodynamics

In addition to variants that affect drug pharmacokinetics, it is now well recognized that genetic variants can alter drug activity by pharmacodynamic mechanisms. Biologically active genetic polymorphisms have been found in numerous receptors, second messenger systems, and ion channels. One of the most intensively studied receptors in this regard is β_2AR. Several β_2AR SNPs have particular relevance to this discussion.[27] One variant, located at –47(T/C) in the 5′-untranslated sequence (referred to as the 5′-leader cistron), increases levels of normal (nonvariant) β_2AR mRNA and protein by 72%. This increase in airway wild-type β_2AR expression is protective against methacholine challenge. Another β_2AR SNP present in the amino terminus is Arg16Gly. Expression of Gly at position 16 increases sensitivity to agonists[28] and enhances agonist-promoted downregulation.[29] Because β_2AR stimulation in vessels is important in mediating vasodilation, an SNP such as Gly16 that enhances desensitization (and therefore dampens receptor responsiveness) is not surprisingly associated with a higher incidence of higher blood pressure, hypertension, and cardiomyopathy. In contrast, patients who are homozygous for Arg at position 16 are poorly responsive to β-agonist therapy for asthma.[30] Interestingly Arg16Gly usually travels together with yet another β_2AR, Gln27Glu, such that Gly16 usually occurs with Glu27. The Glu27 variant is also associated with enhanced responsiveness to β_2AR agonists.[29] This region of the β_2AR is said to be in linkage disequilibrium, with the three SNPs defining a haplotype (regions of DNA that travel together). Gly16, Arg19 (another SNP variant), and Glu27 or Arg16, Cys19, and Gln27 are the two possible haplotypes. This has practical implications because only one of the SNPs in the haplotype needs to be genotyped to infer the entire haplotype. This greatly enhances power and decreases cost in genetic association studies. Finally, another β_2AR SNP (Thr164Ile), located in the fourth membrane-spanning domain, has altered catecholamine binding (lower affinity for isoproterenol, epinephrine, and norepinephrine), along with markedly depressed basal and agonist-stimulated adenylyl cyclase activity in comparison to wild-type Thr164. This poorer coupling appears to result in depressed myocardial function and congestive heart failure, with the variant particularly enriched in heart transplant candidates.

It is likely that many forms of genetically based variability in response to drugs reflect the interaction of many polymorphisms that subtly affect receptor structure, cellular function, and physiologic response. Understanding the interaction of multiple genes on the variability of drug response presents daunting technical challenges in pharmacogenetic research.

Patient Physiology

Age

Total body water is decreased in the elderly. One pharmacokinetic result is a reduced initial mixing volume. This smaller central volume of distribution leads to higher peak concentrations after a bolus or during the early part of an infusion in elderly patients. A decreased central volume of distribution partly accounts for the increased sensitivity of elderly patients to many anesthetic drugs (also see Chapter 71).

Aging is also associated with decreased lean body mass and increased body fat. Because the lipid content of elderly patients is higher than that of young patients, elderly patients have more potential for lipophilic drugs to accumulate in peripheral volumes of distribution, which may be one factor behind the increased duration of effect for many anesthetic drugs seen in the elderly.

Liver volume, liver blood flow, and hepatic metabolic capacity decrease with advanced age. These changes in hepatic physiology account for the decreased clearance of opioids, hypnotics, benzodiazepines, and muscle relaxants and contribute to the increased sensitivity of elderly subjects to anesthetic drugs.

Age per se only modestly reduces cardiac output in the absence of hypertension, coronary artery disease, valvular heart disease, or other cardiovascular pathology. Advancing age can thus be expected to modestly reduce intercompartmental clearance of anesthetic drugs. The effect of decreased intercompartmental clearance is to increase initial plasma concentrations during drug administration. After termination of drug administration, the role of decreased intercompartmental clearance is complex. In general, plasma concentrations will decrease more rapidly after long infusions when intercompartmental clearance is decreased.

Albumin and α_1-acid glycoprotein are the primary sites of protein binding. The albumin concentration decreases with advancing age, hepatic disease, and malnutrition. In contrast, the α_1-acid glycoprotein concentration increases with advancing age and acute disease. Thus, the effects of age and disease on protein binding depend on which protein binds the drug. For example, because diazepam binds primarily to albumin, the free fraction of diazepam increases in elderly patients. This may partly explain the increased sensitivity in elderly subjects. In contrast, lidocaine binds primarily to α_1-acid glycoprotein. In elderly patients,

increased α_1-acid glycoprotein reduces the free fraction of lidocaine, which may contribute to reduced lidocaine clearance.

Although important age-related pharmacokinetic differences have been investigated in detail, there is a paucity of data addressing pharmacodynamic differences between age groups. Overall, the presence or absence of age-related pharmacodynamic differences appears to depend on the drug. For example, both antiepileptic agents and digoxin have been examined in adults and children, and the effective plasma concentration is the same. This finding suggests that for these two types of drugs, no age-related differences in pharmacodynamic responses occur. However many drugs with CNS effects (e.g., thiopental,[31] midazolam,[32] opioids,[33,34] propofol[35]) appear to be intrinsically more potent in the elderly, and this change in potency has been quantitated in pharmacodynamic models. Understanding the biologic basis of increased sensitivity in the elderly to anesthetic and perioperative drugs is an area of active investigation by many researchers.

Disease States

Various diseases contribute to variation in drug response. Although diseases frequently result in pharmacokinetic variations (e.g., decreased liver perfusion in heart failure or decreased elimination in renal failure), pharmacodynamic variation is also observed. Conditions such as diabetes, thyroid disease, adrenal disease, myasthenia gravis, and hypertension alter receptor function and therefore represent pharmacodynamic effects. Some diseases directly affect drug receptors. For example, in patients with myasthenia gravis, antibodies to the postsynaptic nicotinic acetylcholine receptor effectively decrease the number of receptors present. Muscle weakness characterizes the disease. As a result, these patients have less reserve at the neuromuscular junction and are exquisitely sensitive to muscle relaxants that act on the nicotinic acetylcholine receptor.

Drug Interactions

Pharmacokinetic Interactions

Historically, certain foods and drugs were known to inhibit drug metabolism. The inhibition of CYP3A4 by grapefruit juice is among the more dramatic of such interactions. As previously mentioned, CYP3A4 is responsible for nearly half of all drug metabolism. Ingestion of grapefruit juice has been shown to increase the plasma concentration of drugs metabolized by CYP3A4.[36] Many drugs also inhibit CYP3A4, including the antifungal drugs ketoconazole and itraconazole; the protease inhibitors ritonavir, indinavir, and saquinavir; the antibiotics troleandomycin, clarithromycin, erythromycin; and the selective serotonin reuptake inhibitors (SSRIs) fluoxetine and sertraline. Propofol also inhibits CYP3A4, although it is unclear whether there is any clinical consequence. Conversely, several drugs induce CYP3A4, thereby increasing the metabolism of 3A4 substrates. Such drugs include rifampin, rifabutin, tamoxifen, glucocorticoids, carbamazepine, and barbiturates and the herb Saint John's wort.

CYP2D6, responsible for the conversion of codeine to morphine, is also subject to inhibition. In particular, quinidine and the SSRIs fluoxetine and paroxetine produce significant inhibition at standard clinical doses. Thus, codeine, oxycodone, or hydrocodone would be relatively poor analgesic choices for patients taking SSRIs.

Anesthetics also interact pharmacokinetically with many drugs by reducing cardiac output and hepatic blood flow. The reduction in cardiac output probably decreases intercompartmental clearance of most drugs, whereas the reduction in hepatic blood flow would be expected to decrease the metabolic clearance of drugs with high hepatic extraction ratios.

Pharmacodynamic Drug Interactions

Drug-Time Interaction: Desensitization

Desensitization is broadly defined as waning of physiologic responsiveness to a drug over time. For example, acute desensitization ("tachyphylaxis") typically occurs to sodium nitroprusside. Therefore, it is often necessary to increase the nitroprusside infusion rate over time to maintain the desired amount of vasodilation.

In general, stimulation of receptor pathways results in the activation of kinases (e.g., protein kinase A, G protein–coupled receptor kinases, protein kinase C) that phosphorylate specific regions of the receptor and thereby prevent further interaction of the receptor with G proteins or second messengers, or with both. Thus, continuous stimulation of a receptor provides a negative-feedback mechanism for receptor stimulation that results in desensitization. Although desensitization was initially thought to occur only at the receptor level, it is now well recognized that alterations in G proteins and second messengers also occur in response to agonist stimulation. Effectively, desensitization shifts the dose-response curve to the right (e.g., Fig. 19-34, curve B → C) or decreases the maximal drug effect (or both). Thus, both efficacy and potency can be diminished by desensitization.

Desensitization of receptor responses is a feature of many diseases present in the aging population and is therefore relevant to consider during the perioperative period. Common diseases in which desensitization is important include congestive heart failure, hypertension, and diabetes. A hallmark of each of these diseases is elevation of hormone (agonist) concentrations. In the case of congestive heart failure, poor cardiac output induces compensatory sympathetic nervous system stimulation, which often results in a doubling of circulating catecholamine concentrations (in particular, the sympathetic neurotransmitter norepinephrine). On a long-term basis, this results in desensitization of the myocardial βAR signal transduction pathway; specifically, β_1AR density and function decrease (75%) with relative sparing of β_2ARs (25%). G_i levels also increase without a change in G_s. Furthermore, G protein–coupled receptor kinase concentrations increase and modulation of adenylyl cyclase isoforms occurs. The physiologic effects of changes important in desensitization of myocardial βARs have been examined with the use of transgenic and knock-out mice (see Table 19-1 and the earlier discussion of molecular pharmacology). To break the cycle of elevated agonist exposure and resultant desensitization, cardiologists now cautiously use long-term, low-dose βAR antagonists (approximately a 10th the usual dose for hypertension or myocardial ischemia) in patients with congestive heart failure. This therapy has been shown to improve functional classification and longevity.

Drug-Time Interaction: Increased Receptor Sensitivity

The opposite of desensitization is increased receptor sensitivity. Long-term exposure to a drug often results in compensatory

responses by the receptor system. For example, when a receptor antagonist is administered on a long-term basis, receptor number (density) often increases. If the receptor antagonist is suddenly discontinued, exaggerated responsiveness to agonist may occur. This is the rationale for continuing long-term βAR antagonists during the perioperative period. Abrupt discontinuation of these drugs leaves the myocardium vulnerable to an exaggerated heart rate and inotropic responses to routine procedures such as tracheal intubation, thereby potentially leading to myocardial ischemia and infarction. Finally, a much-feared anesthetic example of increased receptor sensitivity is the upregulation of nicotinic receptors at the neuromuscular junction in patients with spinal cord injuries, burns, or prolonged immobilization. The potential for such patients to have a life-threatening hyperkalemic response to succinylcholine is described in detail in Chapter 29.

Drug-Drug Interactions

There are a huge variety of mechanisms by which drugs can interact pharmacodynamically. The nature of pharmacodynamic drug-drug interactions is so diverse that an anesthesiologist can safely assume that there will be some interaction between anesthetic drugs and virtually all drugs that have action on either the CNS or the cardiovascular system.

Some of these drug interactions, such as those between opioids and hypnotics, are fundamental to the practice of anesthesia and were discussed earlier. An example of interactions between anesthetics and nonanesthetics is the influence of nonanesthetic drugs on the MAC of inhaled anesthetics. Drugs that increase central catecholamines in general increase MAC. This has been clearly demonstrated for amphetamines (acute exposure), ephedrine, and monoamine oxidase inhibitors. Conversely, drugs that decrease central catecholamines decrease MAC. This has been shown for methyldopa, reserpine, and α_2-adrenergic agonists. It has also been demonstrated for chronic amphetamine use.

Summary

This chapter reviews general pharmacology by examining the basic principles of pharmacokinetics, pharmacodynamics, and sources of pharmacologic variability. Careful consideration of these principles should permit the anesthesiologist to understand drug movement from the site of administration through various body compartments to the site of action and the mechanisms by which drugs act on receptors to bring about the desired clinical effect. Many factors may alter the pharmacokinetic and pharmacodynamic processes by which drugs exert their effects, including genetics, age, disease, and concurrent drug therapy. Understanding basic pharmacologic processes and how they may differ between individuals should facilitate drug titration for each patient. There is a biologic basis for finding just the right drug in just the right dose to provide safe and effective care of perioperative patients. Our knowledge of the biologic basis for finding the right dose of the right drug for each individual is currently in its infancy but is rapidly growing with new discoveries.

20 Inhaled Anesthetics: Mechanisms of Action

Key Points

1. Anesthesia consists of separable and independent components or substates, each of which involves distinct, but possibly overlapping, mechanisms at different sites in the central nervous system.
2. The potency of general anesthetics correlates with their solubility in oil, indicating the importance of their interaction with hydrophobic targets.
3. General anesthetics act by binding directly to amphiphilic cavities in proteins. Binding sites are being identified by a combination of site-directed mutagenesis and high-resolution structural analysis of anesthetic binding.
4. The effects of inhaled anesthetics cannot be explained by a single molecular mechanism. Rather, multiple targets contribute to the effects of each agent.
5. The immobilizing effect of inhaled anesthetics involves a site of action in the spinal cord, whereas sedation/hypnosis and amnesia involve supraspinal mechanisms.
6. Volatile inhaled anesthetics enhance inhibitory synaptic transmission postsynaptically by potentiating ligand-gated ion channels activated by γ-aminobutyric acid (GABA) and glycine, extrasynaptically by enhancing GABA receptors and leak currents, and presynaptically by enhancing basal GABA release.
7. Inhaled anesthetics suppress excitatory synaptic transmission presynaptically by reducing glutamate release (volatile agents) and postsynaptically by inhibiting excitatory ionotropic receptors activated by glutamate (gaseous agents).
8. No comprehensive theory of anesthesia describes the sequence of events leading from the interaction between an anesthetic molecule and its targets to the behavioral effects.

Despite widespread clinical use, current understanding of the molecular and cellular mechanisms of general anesthetic action is incomplete. This critical gap in the pharmacology of one of medicine's most important drug classes not only impedes rational use of available anesthetics but also hinders the development of newer agents to selectively achieve the desirable end points of anesthesia with fewer adverse cardiovascular, respiratory, and neuropsychological side effects. Although major progress has been made in understanding the pharmacology of the intravenous anesthetics by molecular genetic approaches (see Chapter 26), the actions of the inhaled anesthetics at the molecular and cellular levels are more enigmatic. It is still not possible to trace precisely the sequence of events that leads from inhaled anesthetic-target interactions, through ascending levels of biologic complexity, to the various behavioral effects that characterize the composite state of clinical anesthesia in humans. Nevertheless, investigations continue to reveal fundamental principles of action and have led to a framework for understanding anesthetic effects at different organizational levels. The focus of this chapter is on the mechanisms involved in the principal therapeutic effects (anesthesia) and on the side effects of the inhaled anesthetics (Fig. 20-1), a chemically and pharmacologically diverse group that includes the potent halogenated ether (isoflurane, sevoflurane, desflurane, enflurane) and alkane (halothane) volatile anesthetics and the gaseous anesthetics (nitrous oxide and xenon). This critical summary of the current state of knowledge begins with an historical overview and a review of the behavioral end points of anesthesia. We then trace, where possible, inhaled anesthetic effects through ascending levels of organization from molecules, cells, circuits, networks, and organs to mammalian behavior; an overview is provided in Table 20-1. A large body of work on anesthetic effects in model organisms, for which the correct anesthetic end points are unclear, is touched on briefly.[1]

History

Unitary, Lipid-Based Theories

Inhaled general anesthetics were first used clinically more than 160 years ago, and interest in the mechanisms responsible for their remarkable effects was immediately kindled. The affinity of anesthetic drugs for lipids was soon recognized, which led to early lipid-based hypotheses of anesthetic action. The formulation of the Meyer-Overton correlation at the end of the 19th century was a watershed event, introducing a rigorous scientific approach into anesthesia research. Meyer concluded in 1899 that "All chemically indifferent substances that are soluble in fat are anesthetics … their relative potency as anesthetics will depend on their affinity to fat on the one hand and water on the other hand, that is, on the fat/water partition coefficient,"[2] a conclusion that was reached

Table 20-1 Overview of Proposed Sites of Anesthetic Action

	Site	Effect	Target(s)
Proteins	Amphiphilic binding sites	Conformational flexibility, ligand binding	Ion channels, receptors, signaling proteins
Action Potential	Nervous system	Small reduction in amplitude	Na^+ channels
	Cardiovascular system	Reduced amplitude, duration	Ca^{2+} channels, K^+ channels
Synaptic Transmission			
Inhibitory	Presynaptic terminal	Enhanced transmitter release	?
	Postsynaptic receptors	Enhanced transmitter effects	Glycine, $GABA_A$ receptors
Excitatory	Presynaptic terminal	Reduced transmitter release	Na^+ channels, K_{2P} channels
	Postsynaptic receptors	Reduced transmitter effects	NMDA receptors, nicotinic acetylcholine receptors
Neuronal Networks	Neuronal circuit	Altered LTP/LTD	Synaptic plasticity
	Neuronal integration	Altered rhythmicity, coherence	HCN channels, K_{2P} channels, extrasynaptic $GABA_A$ receptors, etc.
Central Nervous System	Neocortex, hippocampus, amygdala	Sedation, amnesia	θ-rhythms, γ-rhythms, synchrony
	Diencephalon (thalamus), brainstem (reticular formation)	Unconsciousness	γ-band transfer entropy?
	Spinal cord	Immobility	Thalamic deafferentation?
			Nocifensive reflex
Cardiovascular System			
	Myocardium	Negative inotropy	Excitation-contraction coupling
	Conduction system	Dysrhythmias	Action potential
	Vasculature	Vasodilation	Direct and indirect vasoregulation

independently by Overton.[3] The striking simplicity of the Meyer-Overton correlation (Fig. 20-2A) of anesthetic potency with solubility in olive oil led to the conclusion that lipids must be the anesthetic target. This focused attention on anesthetic effects on the bulk physical properties of cell membranes, which were known at that time to consist primarily of lipid molecules. Such nonspecific or "unitary" anesthetic mechanisms dominated the field for the ensuing decades.

Minimum Alveolar Concentration: A Bridge Between Past and Present

The introduction of the minimum alveolar concentration (MAC) concept as a universal measure for inhaled anesthetic potency in the 1960s had far-reaching implications for both clinical anesthesia and anesthesia research. The potencies of inhaled anesthetics for immobilization were established in the classic studies of Eger and colleagues,[4,5] who defined the "minimum alveolar concentration" of an inhaled anesthetic at atmospheric pressure required to prevent movement in response to a noxious stimulus in 50% of subjects. Because inhaled anesthetic concentrations reflect concentrations in other organs after equilibration, which is most rapidly achieved for well-perfused organs such as the brain and heart, MAC is analogous to the plasma EC_{50} (concentration for 50% effect) for intravenous anesthetics. In clinical applications, MAC is usually expressed as volume percent, which varies considerably with temperature due to changes in aqueous solubility, whereas the equivalent liquid-phase molar concentration is temperature-independent.[6] The MAC concept provided researchers and clinicians with a universal standard to measure a defined anesthetic end point (immobility), making meaningful comparisons of experimental results possible and accelerating laboratory and clinical research into anesthetic mechanisms. Today, a more nuanced understanding of MAC takes into account the structural and functional diversity of the biologic substrates of the different components of the anesthetic state.

Evolution from Lipid- to Protein-Centered Mechanisms

The formulation of the MAC concept was followed by evidence that proteins are plausible alternatives to lipids as anesthetic targets. Noncompetitive inhibition of the soluble firefly enzyme luciferase[7] demonstrated direct interference by anesthetics with the function of a lipid-free protein. Accurate measurements of anesthetic potency also revealed contradictions in lipid-based theories of anesthetic action such as the cutoff in anesthetic potency in homologous series of long-chain anesthetic alcohols and the identification of drugs that do not obey the Meyer-Overton correlation.[8,9] A focus on protein targets gained momentum in the 1980s owing largely to the work of Franks and Lieb,[10] who convincingly demonstrated that protein targets are also compatible with the Meyer-Overton correlation (see Fig. 20-2B) and proposed that anesthetics competitively antagonize protein function.[11] The enantiomeric selectivity of several anesthetics further strengthened the case for specific binding sites on proteins, such as ion channels, as the principal molecular targets of inhaled

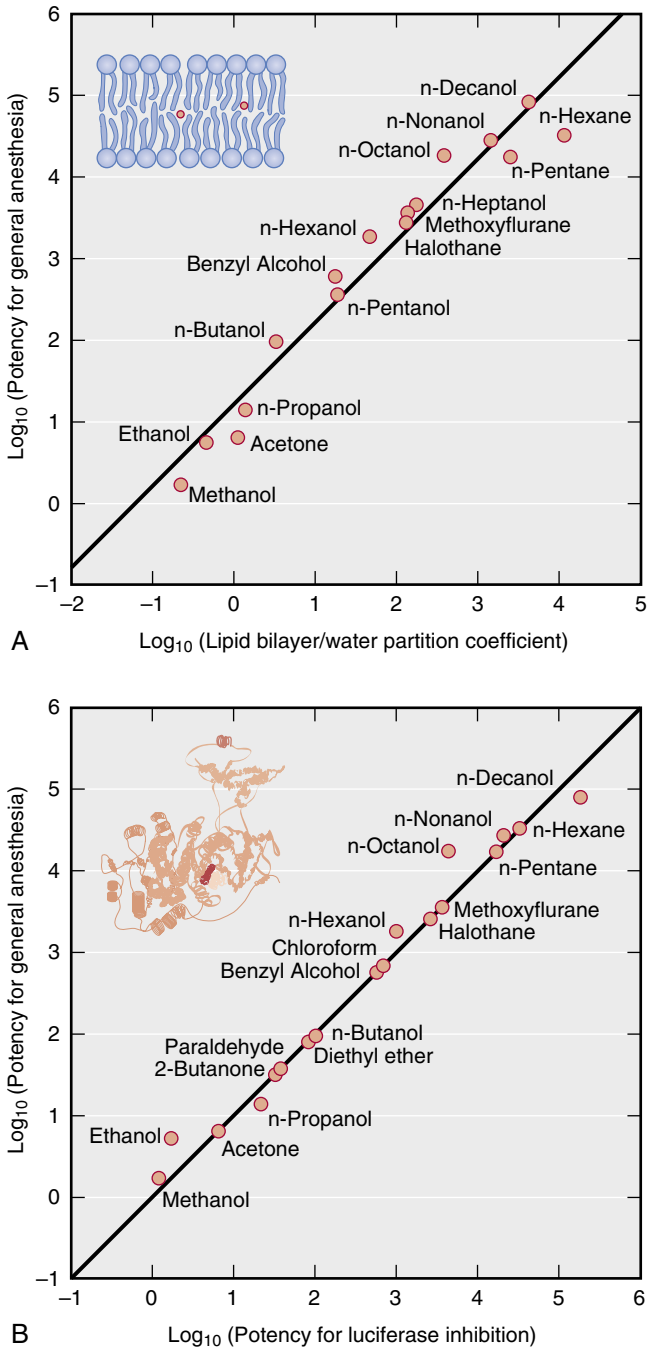

Figure 20-2 General anesthetics act by binding directly to proteins. **A,** The iconic Meyer-Overton correlation (c. 1900) was initially interpreted as evidence that lipids of nerve membranes were the principal anesthetic target sites based on the correlation between anesthetic potency and lipid-water partition coefficient. **B,** Progress in the 20th century showed that general anesthetic potencies correlate equally well with their ability to inhibit activity of the soluble firefly enzyme luciferase. The crystal structure of luciferase is shown in the *inset* with bound anesthetic in *red.* (*Reprinted with permission from Franks NP, Lieb WR: Molecular and cellular mechanisms of general anesthesia. Nature 367:607-614, 1994.*)

anesthetics.[12] Today, there is widespread (but not universal) acceptance of the notion that critical signaling proteins (e.g., ion channels and receptors) are the relevant molecular targets of anesthetic action even though the mechanisms of their modulation by anesthetics are debated, and much of the current work in

the field seeks to determine which proteins contribute to which anesthetic end points.

A Confusing Diversity of Anesthetic Targets

At high concentrations in vitro, most inhaled anesthetics affect multiple proteins, many of which can be plausibly connected to the anesthetic state. However, when considering a specific end point, anesthetics are effective in vivo over a quite narrow concentration range. This makes the concentration at which an effect is observed a critical consideration.[13] The mechanistic relevance of subtle effects observed in vitro at relevant concentrations is less clear, that is, what effect is too small to be considered relevant to anesthesia.[13-15] Whether anesthesia results from the sum of minor perturbations at multiple sites that are amplified in cascades across multiple levels of integration to produce the macroscopic effect or from strong effects on a small number of targets should be resolved as results of reductionist molecular studies are integrated into more complex molecular and cellular networks and as genetic studies are extended to encompass inhaled anesthetics. The emerging realization of the complexity of anesthesia is consistent with the modern concept that multiple cellular and molecular targets in distinct brain regions are involved in their desired and their adverse effects.

Anesthesia: A Complex Composite State

Along with progress in identifying the molecular mechanisms of anesthesia, our understanding of the nature of the anesthetic state has evolved. Whereas a coma-like state of general anesthesia can be induced by inhaled anesthetics administered at appropriate concentrations (approximately 1.3 times MAC, equivalent to the EC_{95} of a volatile anesthetic), the use of such high concentrations is fraught with short- and possibly long-term side effects. It is now clear that anesthesia consists of separable and at least partially independent components or substates, each of which involves distinct, but possibly overlapping, mechanisms at different sites in the central nervous system (CNS) and with variations in relative potencies between specific agents.[16] Immobilization, the core measure of MAC, is mediated largely at the level of the spinal cord by inhaled anesthetics[17,18] but not by barbiturates.[19] On the other hand, the spinal cord is unlikely to be the major site of anesthetic actions, producing such phenomena as amnesia, sedation, and unconsciousness, which are associated with cerebral cortical function (Fig. 20-3). A functional separation between amnesia and sedation has been demonstrated for intravenous anesthetics[20] and is likely for inhaled anesthetics as well. These and similar findings have led to the concept that general anesthesia consists of multiple independent components that are experimentally and clinically identifiable. Theoretically, each component can be preferentially induced in a concentration and agent-specific manner employing individual cellular/molecular pathways in various regions of the CNS. For example, injections of pentobarbital into discrete sites in the mesopontine tegmentum induce an anesthetic state,[21] whereas sedation induced by systemic administration of propofol can be reversed by microinjections of $GABA_A$ receptor antagonists into the tuberomammillary nucleus, a sleep-regulating nucleus in the hypothalamus.[22] Thus, general anesthetics produce separate identifiable anesthetic substates via agent-specific actions at discrete anatomic sites in the CNS by different molecular targets. An important consequence of this complexity is that MAC, which is based exclusively on the motor response, might not proportionately reflect other components of anesthesia. Although this heterogeneity of anesthetic action complicates a mechanistic understanding, it does open the possibility of developing substate-specific drugs.

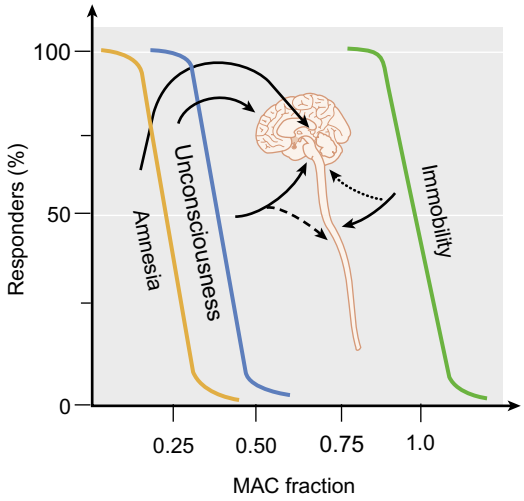

Figure 20-3 Multiple behavioral end points and sites of action underlie inhaled anesthetic action. Amnesia, the most sensitive anesthetic end point, probably involves the hippocampus, amygdala, mediotemporal lobe, and possibly other cortical structures. Unconsciousness likely involves the cerebral cortex, thalamus, and reticular formation. Sedation and hypnosis are part of the consciousness-unconsciousness continuum and are not shown. Immobility occurs by anesthetic action in the spinal cord, although supraspinal effects (*dotted arrow*) are likely important for some anesthetics. Anesthetic action in the spinal cord blunts ascending impulses arising from noxious stimulation and might indirectly contribute to anesthetic-induced unconsciousness and amnesia (*dashed arrow*). Cardiovascular responses occur at even greater MAC fractions (not shown). (*Courtesy of Joseph Antognini, University of California, Davis.*)

Integrated Effects on Central Nervous System Function

Immobility

Failure to find a correlation between quantitative measures of electroencephalographic activity and immobility in response to noxious stimulation spawned the somewhat radical (at the time) hypothesis that immobility was not a "cerebral" phenomenon.[23] Experimental demonstration that volatile anesthetics act on the spinal cord to suppress movement[17,18] supported this hypothesis and was a major factor leading to the contemporary separation of anesthetic substates, of which immobility requires the highest anesthetic concentrations (see Fig. 20-3). Taking advantage of the unusual blood supply to the goat CNS that allows separate perfusion of brain and spinal cord, Antognini and coworkers showed that immobility requires anesthetic delivery to the spinal cord because selective delivery of isoflurane or halothane only to the brain required 2.5- to 4-fold higher concentrations.[17,24] Surgical separation of the forebrain from the spinal cord in rats confirmed

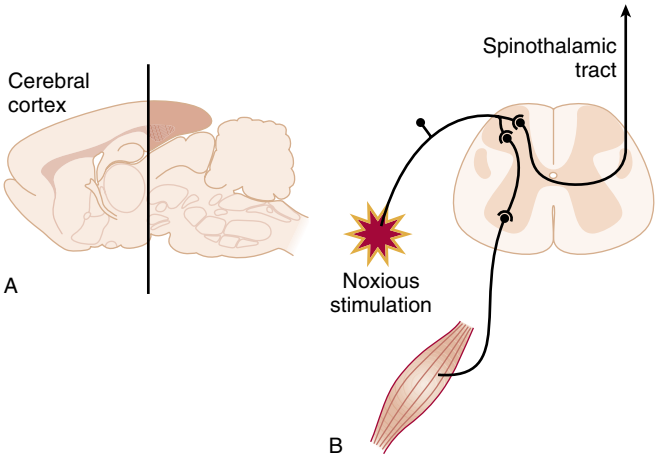

Figure 20-4 Inhaled anesthetics produce immobility at the spinal level. **A,** Decerebration by removal of the forebrain rostral to the *heavy black line* does not alter the MAC of isoflurane in rats, indicating that volatile anesthetic immobilization does not depend on the cerebral cortex. **B,** Anesthetics suppress the nocifensive withdrawal reflex response to noxious stimulation transmitted to the dorsal horn by sensory nerves at the spinal level. Current efforts are focused on identifying the molecular, cellular, and anatomic substrates for this effect. (***A** modified from Rampil IJ, Mason P, Singh H: Anesthetic potency [MAC] is independent of forebrain structures in the rat. Anesthesiology 78:707-712, 1993.*)

that immobilization involves primarily suppression of the nocifensive withdrawal reflex arc at the level of the spinal cord (Fig. 20-4).[18]

Recent studies have focused on the mechanisms by which inhaled anesthetics produce immobility. A pharmacologic approach to identify receptor-level contributions to MAC involves intrathecal administration of selective antagonists of neurotransmitter receptors in vivo. This strategy revealed that actions at spinal *N*-methyl-D-aspartate (NMDA)–type glutamate receptors[25] and glycine receptors[26] contribute to isoflurane-induced immobilization, whereas actions at $GABA_A$ receptors appear to be unimportant.[27] Glycine and $GABA_A$ receptors also appear to play little role in immobilization by cyclopropane,[26] which derives at least in part from antagonism of NMDA receptors.[28] Complementary research strategies have excluded other possible targets. Sensitivity to nonimmobilizer compounds excluded a role for inhibition of nicotinic acetylcholine receptors in immobilization,[29] and anesthetic-resistant transgenic mice confirmed that $GABA_A$ receptors containing α_1- or α_3-subunits do not contribute to the immobilizing action of isoflurane.[30,31] In contrast, mutant mice lacking the TASK-1, TASK-3, and TREK-1 K_{2P} channels have higher MAC values for volatile anesthetics but not intravenous anesthetics,[32-34] indicating a role for these channels, possibly by a presynaptic mechanism.[35] Even though the gross anatomic site for immobility has been identified and specific molecular targets have been implicated, an integrated hypothesis of the mechanism of inhaled anesthetic-induced immobility is still lacking (see reference 36 for review).

Unconsciousness

Consciousness, as a quality of the mind, is easy to recognize but difficult to define (see Chapter 39). As a neurobiologic process realized in the brain, it is within the reach of objective science but is currently poorly understood. Loss of consciousness (or hypnosis) is a hallmark of the onset of anesthesia, which raises the exciting possibility that anesthetic drugs will be useful as tools for understanding consciousness by defining the "neural correlates of consciousness" (NCC).[37] Although there is no universally accepted scientific definition, consciousness consists of inner, qualitative, subjective states of "sentience or awareness"[38] or "explicit awareness."[39]

Understanding how anesthetics ablate consciousness is entwined with theories of how consciousness is generated, many of which lack either experimental support or testable predictions. In contrast, neuroscientific approaches to consciousness are experimentally tractable. The "thalamic theory" of anesthesia proposes a somatosensory deafferentation by anesthetic action in the thalamus as a mechanism of unconsciousness.[40] In support of this hypothesis, isoflurane hyperpolarizes and shunts thalamic neurons,[41] an action consistent with impaired thalamic transfer of information observed in vivo.[42] Functional human brain imaging shows preferential suppression of thalamic activity by some, but not all, anesthetics, and this has led to the "thalamic switch" hypothesis.[43] However, loss of consciousness occurs within a very narrow range of anesthetic concentrations,[44,45] typically at less than 0.5 MAC,[46,47] whereas quantifiable effects in the thalamus occur above this concentration range and are typically incremental (dimmer-like) rather than sudden (switch-like). A comprehensive theory of anesthetic-induced unconsciousness must be more inclusive than a simple block of information transfer through the thalamus to be compatible with existing evidence[48] and must also explain the suppression of endogenous cortical activity that is generated without external stimulation.

Contemporary neuroscience has replaced the cartesian view of an anatomically discrete brain structure as the center of consciousness with the concept that consciousness requires integration of information between multiple brain regions across large-scale cerebral networks.[49,50] Anesthetic interference with the operational synchronicity and coherence of these networks with consequent disruption of cortical functional connectivity, as observed during natural sleep[51] and vegetative states, could result in "cognitive unbinding"[52] with loss of consciousness.[38] Unconsciousness[53] would be characterized not by the absence but by the disintegration of cortical processing.[39] Although the mechanism of "binding" (i.e., creating the unity of perception) is uncertain, synchronicity of neuronal activity in the 40- to 90-Hz range across functionally connected cortical areas (commonly referred to as 40 Hz- or γ-rhythm) is a viable candidate. Animal[54-56] and human[44] data implicate activity in the γ-band throughout the cortex as a network-level target of general anesthetics. Anesthetic actions on cortical information processing probably consist not merely of suppression of responses but of reduced complexity and variability reflected counterintuitively in increased reliability and precision of evoked responses.[57]

Learning and Memory

Anterograde amnesia, one of the core desirable anesthetic effects, is achieved at lower anesthetic concentrations (~0.25 MAC) than those required for unconsciousness (~0.5 MAC). Perhaps the closest analog in rodents to explicit memory in humans is hippocampus-dependent spatial learning. This can be tested by a variety of experimental paradigms, including fear conditioning to

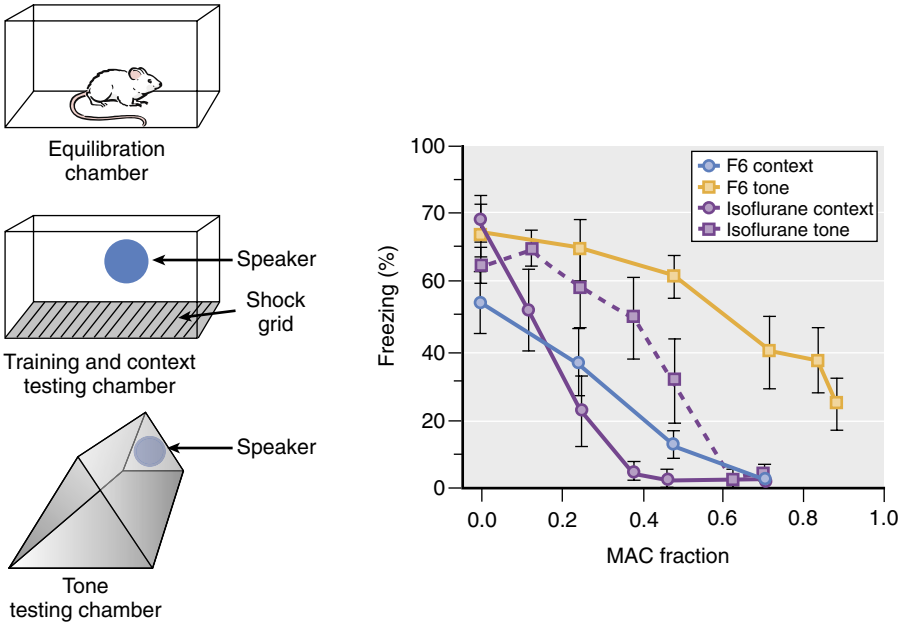

Figure 20-5 Differential sensitivity of different types of learning to anesthetics and nonimmobilizers. Freezing in anticipation of a noxious stimulus is a measure of learning in rats; less freezing indicates less learning. **Left,** The learning protocol involves pre-equilibration of rats in the equilibration chamber to isoflurane or the nonimmobilizer F6 at the desired concentration before placement into the training chamber. For testing of memory to context, training and test chamber are identical. For testing of memory to tone, training and testing take place in different chambers. **Right,** Hippocampus-dependent learning (fear conditioning to context, *closed symbols*) is inhibited by isoflurane (*purple circles*) at lower concentrations than hippocampus-independent learning (fear conditioning to tone, *purple squares*). This differential sensitivity is mirrored by the non-immobilizer F6 (*blue circles* and *yellow squares* for context and tone, respectively). (***Left panel*** *adapted with permission from Eger EI 2nd, et al: Isoflurane antagonizes the capacity of flurothyl or 1,2-dichlorohexafluorocyclobutane to impair fear conditioning to context and tone. Anesth Analg 96: 1010-1018, 2003;* ***Right panel*** *data points reconstructed from Dutton RC, et al: Short-term memory resists the depressant effect of the nonimmobilizer 1-2-dichlorohexafluorocyclobutane (2N) more than long-term memory. Anesth Analg 94:631-639, 2002, and Dutton RC, et al: The concentration of isoflurane required to suppress learning depends on the type of learning.*

context (Fig. 20-5). Other learning paradigms, such as fear conditioning to tone, are, by contrast, independent of the hippocampus. Isoflurane and the nonimmobilizer F6 both inhibit hippocampus-dependent learning at about half the concentration necessary for hippocampus-independent learning.[58] Because anesthetic concentrations that inhibit explicit memory in humans are similarly lower than concentrations that impair implicit memory,[47] anesthetic effects on hippocampal function are implicated in explicit memory suppression. Effects on other structures, such as the amygdala, may be crucial to anesthetic impairment of implicit or other types of memory.[59]

Comparison of the amnesic potency of five inhaled anesthetics using the inhibitory avoidance paradigm revealed that nitrous oxide was the most potent and halothane the least potent amnestic (expressed in MAC fractions), with the halogenated ethers of intermediate potency.[60] Because inhaled anesthetics affect multiple cellular targets at amnesic concentrations, it is difficult to attribute amnesia to specific cellular mechanisms. It is also unclear whether inhibition of learning and memory by drugs known to have different receptor affinities shares common mechanisms at some level of integration. Comparison with more selective drugs provides some insight. Abundant evidence indicates that θ-rhythms (4-12 Hz) are important for hippocampus-dependent learning and memory.[61] Benzodiazepines[62] and cannabinoids[63] slow and suppress hippocampal θ-rhythms in proportion to their ability to impair hippocampus-dependent learning. Isoflurane and the nonimmobilizer F6 have comparable effects on θ-rhythms at amnesic concentrations while having different receptor-level profiles and opposite effects on sedation.[56] Thus, alterations in neuronal synchrony provide a common network-level substrate for memory impairment. The synchronization between amygdalar and hippocampal θ-rhythms that occurs during fear memory retrieval indicates that this principle might also apply to other forms of memory and their impairment by anesthetics.[64] As with other components of the anesthetic state, the precise mechanisms of memory impairment by anesthetics, and of memory itself, remain to be fully elucidated.

Sedation

Sedation (defined as a decrease in activity, alertness, arousal, and/or vigilance) and its behavioral continuum hypnosis are achieved at low anesthetic concentrations (<0.5 MAC), near those that produce amnesia. There is no clear mechanistic or clinical separation between sedation and hypnosis. By contrast, even though sedation can be difficult to separate from amnesia, evidence obtained for intravenous anesthetics supports separate but overlapping substrates for these two end points.[20,65] The mechanisms involved in these behavioral effects probably resemble those of less promiscuous drugs, for which genetic approaches have been informative. An amino acid knock-in mutation (H101R) in mice that renders the α_1 $GABA_A$ receptor subunit insensitive to modulation by benzodiazepines produces resistance to the sedative and amnesic effects of benzodiazepines while maintaining other behavioral effects, among them anxiolysis.[66] The α_1 subunit is abundantly expressed in the CNS, mainly in cortical areas and thalamus. Volatile anesthetics have qualitatively similar effects on α_1-containing $GABA_A$ receptors (but also those containing other subunits) at low concentrations. The observation that the nonim-

mobilizer F6, which is devoid of sedative properties,[56] is amnesic[67] but does not modulate benzodiazepine-sensitive α_1-containing $GABA_A$ receptors[68,69] is compatible with a role for α_1-containing receptors in volatile anesthetic-induced sedation, because few other targets are affected at purely sedative concentrations. Possible targets for the sedative effects of the gaseous anesthetics nitrous oxide and xenon, which do not affect $GABA_A$ receptors, include NMDA receptor antagonism[70,71] and K_{2P} channel activation.[72] Consistent with this distinct pharmacologic profile, nitrous oxide has strikingly different effects from benzodiazepines in behavioral tests aimed at evaluating sedation in mice.[73]

Recognizing that there may be more than a superficial similarity between natural sleep and anesthetic-induced sedation and hypnosis, some anesthetics apparently "hijack" natural sleep mechanisms by directly activating discrete sleep-promoting nuclei in the hypothalamus.[22,74] The observations that electroencephalographic patterns during natural slow-wave sleep and anesthesia show some similarities[75] and that recovery from sleep deprivation can occur during propofol anesthesia[76] support this concept. Anesthetic effects on other cortical[77] and subcortical structures[21] also contribute to anesthetic-induced sedation and hypnosis.

Anesthetic Neurotoxicity and Neuroprotection

Recent animal experiments indicate that general anesthetics can cause persistent neurologic effects beyond their classic reversible production of anesthesia (see Chapter 46). The clinical significance of these changes is largely unknown, but attention has been drawn to the potential for adverse effects.[78] Possible anesthetic damage to the developing rodent CNS has attracted particular scrutiny recently, although clinical evidence in humans is lacking. Postnatal exposure of the developing rodent brain to high doses of commonly used anesthetic drugs, in isolation or in combination, for a period of several hours, can induce apoptotic cell death with potentially long-term functional consequences.[79] However, this appears not to occur with postnatal exposure in precocial species.[80] It is also unclear whether anesthetics contribute to the clinical syndrome of postoperative cognitive dysfunction in the aged brain, primarily owing to difficulty in establishing a robust animal model. More evidence supports a deleterious effect of nitrous oxide than of volatile anesthetics in aged animals.[81] Recent evidence also points to immune-mediated changes triggered by surgical trauma as a potential mechanism of postoperative cognitive dysfunction (see also Chapter 89).[82]

Pharmacologic neuroprotection from cerebral ischemia is a rapidly evolving area of research that is characterized by great potential but comparable disappointments as promising animal studies have failed to translate into clinical benefits. Despite considerable research, clinical evidence for ischemic brain protection by inhaled anesthetics remains controversial.[83] Ischemic neuronal injury results from early excitotoxic cell death mediated by excessive release of excitatory amino acid transmitters such as glutamate together with delayed cell death due to apoptosis.[84,85] Volatile anesthetics (e.g., isoflurane) and xenon exhibit early neuroprotection in animal models that is sustained only for mild insults. This is consistent with a beneficial effect on excitotoxicity but minimal effects on delayed cell death due to apoptosis. A therapeutic strategy to extend this early neuroprotection is suggested by the finding that isoflurane combined with caspase inhibitors to prevent apoptosis results in more sustained neuroprotection.[86] In contrast, xenon appears to have an intrinsic antiapoptotic action that contributes to its neuroprotective properties consistent with its distinct molecular mechanisms.[87] In addition, volatile anesthetics probably protect by suppression of brain energy requirements due to inhibition of excitatory transmission and potentiation of inhibitory receptors and ion channels.[84] The potential for beneficial effects from anesthetic-induced cardiac preconditioning has also received considerable recent attention (see the following section).

Integrated Effects on the Cardiovascular and Respiratory Systems

The cardiovascular effects of the volatile anesthetics are classically recognized as deleterious and undesired side effects that limit their use in the critically ill, but recent studies indicate direct cardioprotective effects of inhaled anesthetics.[88] All volatile anesthetics produce agent- and dose-dependent reductions in myocardial contractility, systemic vascular resistance, and cardiac preload with consequent reduction in mean arterial pressure, but significant differences exist in the relative potencies of these effects among agents (see Chapter 23).[89] Volatile anesthetics depress contractility by reducing Ca^{2+} availability and/or Ca^{2+} sensitivity of the contractile apparatus.[90] The major targets responsible for the negative inotropic effects of volatile anesthetics are cardiac Ca^{2+} channels, sarcoplasmic Ca^{2+} handling, and the contractile apparatus. Inhibition of depolarization-induced increases in myoplasmic Ca^{2+} concentration occur primarily via inhibition of cardiac L-type voltage-gated Ca^{2+} currents and shortening of action potential duration.[91] Volatile anesthetics also inhibit the sarco-endoplasmic Ca^{2+} ATPase (SERCA), while halothane, but not isoflurane or sevoflurane, opens sarcoplasmic reticulum (SR) Ca^{2+} release channels (ryanodine receptors), depleting SR Ca^{2+} content and reducing excitation-evoked SR Ca^{2+} release.[90] The resulting negative inotropic effect of this reduced Ca^{2+} availability is enhanced by reductions in the Ca^{2+} sensitivity of myofibrils. In contrast, xenon has no effects on ventricular contractility, conduction, or major cation currents,[91,92] consistent with its lack of significant cardiovascular effects. Nitrous oxide causes mild reductions in ventricular function[92] by poorly characterized effects on Ca^{2+} availability. This is usually accompanied by sympathetic nervous system stimulation that increases vascular resistance and counteracts the myocardial depression.[93,94]

Volatile anesthetics can produce vasodilation at clinical concentrations.[95] The vascular effects of volatile anesthetics are multifactorial and tissue specific, and the precise cellular mechanisms are poorly understood.[96,97] Peripheral vasodilation is mediated both by direct endothelium-independent vasodilating effects on vascular smooth muscle cells and indirect effects involving the sympathetic nervous system and the vascular endothelium. The mechanisms of these effects involve agent-specific effects on presynaptic norepinephrine release, inhibition of smooth muscle Ca^{2+} influx via L-type Ca^{2+} channels, activation of hyperpolarizing K_{ATP} and K_{Ca} channels, and endothelium-dependent factors, including nitric oxide.[98]

As with the CNS, cardiovascular function depends on the integrated function of multiple ion channels, many of which are expressed in both of these excitable tissues. Volatile anesthetics have agent-specific effects on heart rate and induction of arrhythmias due to actions on cardiac ion channels. Because multiple cardiac ion channels are sensitive to volatile anesthetics at clinical concentrations, and because most manipulations of cardiac ion channel function are potentially proarrhythmic, it is difficult to link anesthetic arrhythmogenicity to actions on specific channels.[99] Electrophysiologic studies indicate that cardiac L-type Ca^{2+} channels, which are critical to the plateau phase of the cardiac action potential and electromechanical coupling, are inhibited by volatile anesthetics, leading to shortening of the refractory period. Multiple voltage-gated K^+ channels are also inhibited and might predispose to arrhythmias by delaying repolarization. On the other hand, inhaled anesthetics can protect the heart against ischemia and reperfusion injury, possibly involving antioxidant, anti-inflammatory, and/or preconditioning mechanisms.[100,101] Volatile anesthetics[102] and xenon[103] can mimic the strong cardioprotective effects produced by ischemic preconditioning (termed *anesthetic preconditioning* by analogy) through activation of various cytoprotective G-protein–coupled receptors and protein kinases, including protein kinase C (PKC), mitogen-activated protein kinases (MAP kinases), extracellular signal-regulated kinases (ERK), Akt (protein kinase B), and tyrosine kinases.[88,104] Although not entirely clarified, sarcolemmal and putative mitochondrial adenosine triphosphate (ATP)-sensitive K^+ (K_{ATP}) channel activation, involving PKC activation and increased formation of free radicals and nitric oxide, are the likely end effectors of anesthetic preconditioning in the heart.

Inhaled anesthetics also have important effects on the respiratory system. All volatile anesthetics cause significant respiratory depression at concentrations necessary for surgical anesthesia. The peripheral chemoreflexes and upper airway patency are particularly sensitive to subanesthetic concentrations of volatile anesthetics.[105] The mechanisms involved in these potentially serious effects involve depression of central respiratory networks mediated by depression of excitatory and facilitation of inhibitory transmission. The precise molecular targets responsible for the exquisite sensitivity of these networks to low concentrations of volatile anesthetics remain to be elucidated (see Chapter 22).

Identification of Molecular Sites of Anesthetic Action

Criteria for Identifying Sites Relevant to Anesthesia

Specific criteria have been proposed to evaluate the relevance of the many potential molecular targets of anesthetics.[106] These criteria include:

1. Reversible alteration of target function at clinically relevant concentrations. This criterion requires comparable in vivo and in vitro sensitivity and depends on the anesthetic end point under consideration. For example, targets involved in immobility must be sensitive to anesthetics near MAC, whereas targets mediating memory impairment must be affected at a fraction of MAC. Recent evidence for persistent effects of inhaled anesthetics demonstrable in the absence of continued anesthetic exposure is challenging the notion of reversibility for certain effects.
2. Expression of the target in appropriate anatomic locations to mediate the specific anesthetic end point. For example, immobilization by inhaled agents appears to involve primarily depression of reflex pathways in the spinal cord independent of drug actions in the brain.
3. Concordant stereoselectivity of anesthetic effects in vivo and on the target in vitro. In the absence of a specific pharmacologic antagonist of anesthesia, correlation between the stereoselective actions of general anesthetics in vivo and in vitro is a useful test of pharmacologic relevance of putative molecular targets. Stereoselectivity data correlating in vivo potency and in vitro receptor actions implicate $GABA_A$ receptors as a target for the anesthetic actions of etomidate, pentobarbital, neurosteroid anesthetics, and possibly isoflurane and the NMDA receptor for the actions of ketamine.
4. Appropriate sensitivity or insensitivity to model anesthetic and nonanesthetic compounds. Anesthetic halogenated cyclobutanes together with structural analogs that do not produce anesthesia at concentrations predicted to be anesthetic by the Meyer-Overton correlation (nonimmobilizers) can be used to discriminate relevant volatile anesthetic targets in vitro. For example, the anesthetic F3 (1-chloro-1,2,2-trifluorocyclobutane), but not the structurally similar nonanesthetic F6 (1,2-dichlorohexafluorocyclobutane), affect $GABA_A$, glycine, AMPA, kainate, and $5\text{-}HT_3$ receptors, and Na^+ channels, consistent with a role in immobility, whereas both F3 and F6 affect neuronal nicotinic, M1 muscarinic, $5\text{-}HT_{2C}$, and mGluR5 receptors, indicating that these targets are not involved in immobility. F6 is interesting in that it lacks sedative and immobilizing effects but does possess amnesic effects, hence the more accurate term "nonimmobilizer", thus making it a useful pharmacologic tool for discriminating targets for these actions.

Physicochemical Properties of Anesthetic Binding Sites

A convergence of x-ray crystallography, molecular modeling, and structure-function data indicate that inhaled anesthetics bind in hydrophobic cavities formed within proteins.[107] The lipophilic (or hydrophobic) nature of these binding sites explains their adherence to the Meyer-Overton correlation. An element of amphiphilicity (possessing both polar and nonpolar characteristics) is also required for effective interaction with these cavities, as indicated by improvements in the Meyer-Overton correlation with more polar solvents.

From Model Proteins to Receptors

Identifying inhaled anesthetic binding sites on plausible target proteins is difficult due to their low-affinity interactions and the paucity of atomic resolution structures of pharmacologically rel-

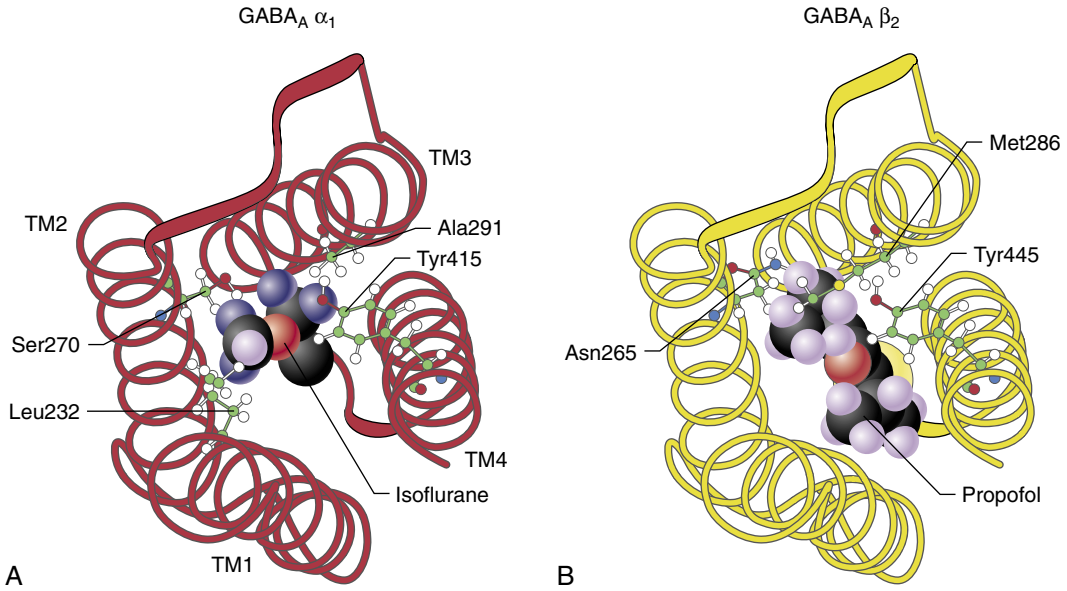

Figure 20-6 Putative anesthetic binding sites on GABA$_A$ receptors. **A,** Model of rat GABA$_A$ α_1-subunit with Leu232, Ser270, Ala291, and Tyr415 rendered in ball-and-stick. A molecule of isoflurane built at the same scale is positioned in the putative binding site. The transmembrane (TM) α-helices are numbered 1-4. **B,** Corresponding model of GABA$_A$ β_2-subunit with Asn265, Met286, and Tyr445 rendered in ball-and-stick. A model of propofol built at the same scale is positioned in the putative binding site. evant target proteins. Consequently, most anesthetic binding sites have been identified in well-characterized model proteins for which three-dimensional atomic resolution structures are available, such as luciferase and albumin.[107] These studies indicate that anesthetics bind in pockets with both nonpolar and polar noncovalent chemical interactions. Binding involves weak hydrogen bond interactions with polar amino acid residues and water molecules, nonpolar van der Waals interactions, and a polarizing effect of the amphiphilic binding cavity on the relatively hydrophobic anesthetic molecules. Internal cavities are important for the conformational flexibility involved in ion channel gating and ligand-induced signal transduction of receptor proteins. Occupation of a critical volume within these cavities by anesthetics provides a plausible mechanism for alteration of receptor and ion channel function by selective stabilization of a particular confirmation (e.g., an open or inactivated state of an ion channel). Anesthetics also obtain binding energy from the entropy generated by displacing bound water from these relatively promiscuous binding sites. Studies of glycine, GABA$_A$, and NMDA receptors provide convincing evidence for the existence of anesthetic binding sites in critical neuronal signaling proteins.[108] Amino acid residues critical for volatile anesthetic actions and, by inference, binding have been identified in the α-subunit of the GABA$_A$ receptor.[108-110]

Molecular modeling based on structurally homologous proteins has also been used to identify putative anesthetic binding sites in the transmembrane domains of GABA$_A$ and glycine receptors (Fig. 20-6).[111] This model suggests that different drugs might either bind in different orientations within a single amphiphilic cavity or occupy different cavities within the protein, causing similar functional effects. Refinement of these molecular models will continue to provide new insights in the molecular basis for general anesthetic action that can be experimentally tested. Potential sites of interaction of xenon and isoflurane with the NMDA receptor have also been identified using this approach. One site, which can contain up to three xenon atoms or one molecule of isoflurane, overlaps the known binding site for the co-agonist glycine in the NR1 subunit (Fig. 20-7).[112] This suggests

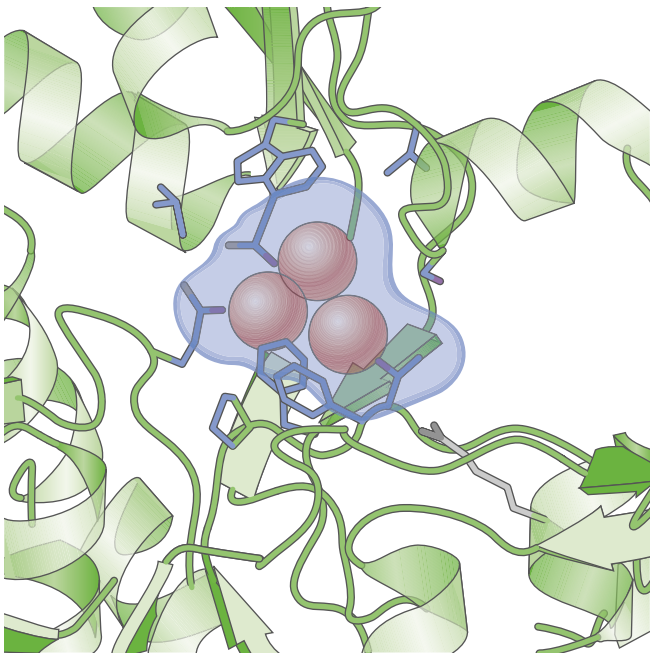

Figure 20-7 Crystal structure of the ligand binding domain of the *NMDA receptor* showing xenon binding sites predicted by molecular modeling. The *red spheres* represent xenon atoms at the center of the density clusters that comprise the binding sites. The predicted xenon binding sites occupy the site normally occupied by glycine. The same site is also large enough to accommodate isoflurane. (*Modified from Dickinson R, Peterson BK, Banks P, et al: Competitive inhibition at the glycine site of the N-methyl-D-aspartate receptor by the anesthetics xenon and isoflurane. Anesthesiology 107:756-767, 2007.*)

that two chemically dissimilar inhaled anesthetics inhibit NMDA receptors by direct competitive inhibition of agonist binding.

Molecular Targets of Inhaled Anesthetics

Ion channels have emerged as the most promising molecular targets for inhaled anesthetics. Neurotransmitter-gated ion channels, in particular $GABA_A$, glycine, and NMDA-type glutamate receptors, are leading candidates owing to their appropriate CNS distributions, essential physiologic roles in inhibitory and excitatory synaptic transmission, and sensitivities to clinically relevant concentrations of anesthetics.[16,113,114] Other ion channels that are sensitive to inhaled anesthetics include the HCN (hyperpolarization-activated cyclic nucleotide-gated) family of channels that give rise to pacemaker currents[115] and regulate dendritic excitability, two-pore domain (K_{2P}) "leak" K^+ channels that maintain resting membrane potential in many cells,[116] and voltage-gated Na^+ and Ca^{2+} channels.[117]

Inhaled anesthetics can be divided into two classes based on their distinct pharmacologic properties. The first class is the potent inhaled (volatile) anesthetics, which exhibit positive modulation of $GABA_A$ receptors, also produce significant, anesthesia-compatible effects on a number of other receptors/channels, including enhancement of inhibitory glycine receptors, inhibition of excitatory NMDA and neuronal nicotinic acetylcholine receptors, activation of K_{2P} channels, and inhibition of presynaptic Na^+ channels. Intravenous anesthetics such as propofol and etomidate represent more potent and specific positive modulators of $GABA_A$ receptors. The second class is the gaseous inhaled anesthetics, which include cyclopropane, nitrous oxide, and xenon. These anesthetics are inactive at $GABA_A$ receptors, but block NMDA receptors and activate certain K_{2P} channels at clinical concentrations. The intravenous anesthetic ketamine is a more potent and specific blocker of NMDA receptors.

Ligand-Gated Ion Channels

Potentiation of Inhibitory $GABA_A$ and Glycine Receptors

The ether anesthetics (including isoflurane, sevoflurane, and desflurane), the alkane anesthetic halothane, most intravenous anesthetics (including propofol, etomidate, barbiturates), and the neurosteroid anesthetics enhance $GABA_A$ and glycine receptor (GlyR) function. $GABA_A$ and GlyRs are members of the same Cys-loop ligand-gated ion channel superfamily that also includes the cation-permeable nicotinic acetylcholine and $5HT_3$ receptors. $GABA_A$ receptors are the principal transmitter-gated Cl^- channels in the neocortex and allocortex, whereas GlyRs fulfill this function in the spinal cord, with some overlap in the diencephalon and brainstem. Activated receptors conduct chloride ions, driving the membrane potential toward the Cl^- equilibrium potential. Both receptors are considered to be inhibitory because the Cl^- equilibrium potential is usually more negative than the normal resting potential. Channel opening also reduces membrane resistance and "shunts" excitatory responses. Most functional $GABA_A$ and GlyRs are heteropentamers, typically consisting of three different $GABA_A$ subunits (e.g., two α, two β, and one γ or δ) or two different GlyR subunits (three α and two β).[118] The subunit composition of $GABA_A$ receptors determines their physiologic and pharmacologic properties and varies between and within brain areas as well as between different compartments of individual neurons. Examples are the preferential expression of the α_5-subunit in the dendritic field of the hippocampal CA1 area (a region important for memory formation), of the α_4-subunit in the thalamus, and of the α_6-subunit in the cerebellum. Presence of a γ-subunit is required for benzodiazepine modulation of $GABA_A$ receptors and can also influence modulation by inhaled anesthetics. While the molecular mechanisms of receptor modulation by inhaled anesthetics are not definitively settled, these receptors have been key to our understanding of anesthetic-receptor interactions. Using chimeric receptor constructs between anesthetic-sensitive $GABA_A$ and insensitive GlyR subunits, specific amino acid residues in the transmembrane domains 2 and 3 critical to the action of inhaled anesthetics have been identified.[119] This laid the groundwork for the construction of anesthetic-resistant $GABA_A$ receptors and the generation of transgenic mice with altered anesthetic sensitivity (see later).

The related cation-permeable 5-hydroxytryptamine (serotonin)-3 ($5HT_3$) receptors are similarly potentiated by volatile anesthetics.[120-122] $5HT_3$ receptors are involved with autonomic reflexes and probably contribute to the emetogenic properties of volatile anesthetics (see Chapter 86).

Inhibition of Excitatory Acetylcholine and Glutamate Receptors

Neuronal nicotinic acetylcholine receptors (nnAChRs), like the other members of the Cys-loop family, are heteropentameric. They are composed of α- and β-subunits, but functional homomeric receptors can be formed by certain α-subunits. In the CNS, nnAChRs are localized primarily presynaptically.[123] Homomeric α_7-receptors have high permeability to Ca^{2+} that can exceed that of NMDA receptors.[123] In contrast to $GABA_A$ and GlyRs, nnAChRs pass cations when activated and therefore depolarize the membrane potential. Receptors containing $\alpha_4\beta_2$ subunits are very sensitive to block by isoflurane and propofol.[124,125] Relevance of nnAChR block to immobilization, sedation, and unconsciousness by inhaled anesthetics is unlikely because nnAChRs are also blocked by nonimmobilizers, although it is possible that they do contribute to amnesia.[9]

NMDA (*N*-methyl-D-aspartate) receptors are a major postsynaptic receptor subtype of ionotropic receptors for glutamate, the principal excitatory neurotransmitter in the mammalian CNS.[126] Typical NMDA receptors, defined pharmacologically by their selective activation by the exogenous agonist NMDA, are heteromers consisting of an obligatory NR1 subunit and modulatory NR2 subunits. Channel opening requires glutamate (or another agonist such as NMDA) binding to the NR2 subunit while the co-agonist glycine binds to the NR1 subunit. NMDA receptors also require membrane depolarization to relieve the voltage-dependent block by Mg^{2+}. The depolarization is typically provided by binding of glutamate to non-NMDA glutamate receptors (see later). Because of this "dual" requirement (transmitter release and postsynaptic depolarization), synaptic NMDA receptors function as coincidence detectors, and this characteristic is thought to be central to their role in learning and memory. NMDA receptors are also involved in the development of chronic pain, perhaps due to similar mechanisms underlying synaptic

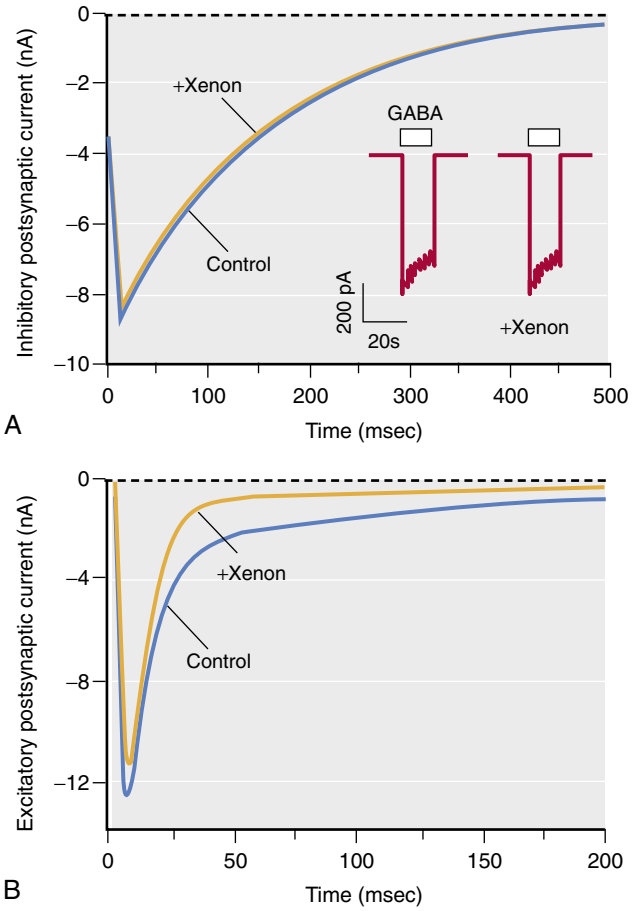

Figure 20-8 The actions of xenon on inhibitory GABAergic and excitatory glutamatergic synapses in cultured rat hippocampal neurons. Xenon (3.4 mM, ~1 MAC) has no significant effect on the inhibitory postsynaptic current (**A**) but greatly depresses the excitatory glutamatergic synaptic current, almost exclusively the slow NMDA receptor-mediated component of the current (**B**). In contrast, the principal effects of ~1 MAC isoflurane are a prolongation in the inhibitory current decay and a reduction in excitatory current peak height with little change in time course (not shown, see Fig. 20-10). (*Reprinted in modified form by permission from de Sousa SLM, et al: Contrasting synaptic activity of the inhalational general anesthetics isoflurane and xenon. Anesthesiology 92:1055-1066, 2000.*)

plasticity, and in ischemia-induced excitotoxicity by virtue of their capacity to allow entry of the ubiquitous intracellular signal Ca^{2+} on activation. The nonhalogenated inhaled anesthetics xenon, nitrous oxide, and cyclopropane, as well as the intravenous anesthetic ketamine, have minimal effects on $GABA_A$ receptors but depress excitatory glutamatergic synaptic transmission postsynaptically via NMDA glutamate receptor blockade (Figs. 20-7 and 20-8).[70,71,127] Volatile anesthetics can also inhibit isolated NMDA receptors at higher concentrations.[128] Along with presynaptic inhibition of glutamate release, this might contribute to their depression of NMDA receptor–mediated excitatory transmission.

A second class of ionotropic glutamate receptors includes the non-NMDA receptors, which are subdivided into AMPA and kainate receptors based again on their sensitivities to selective exogenous agonists.[126] Inhaled anesthetics only weakly inhibit AMPA receptors, so this action is unlikely to be important in their actions.[129] Interestingly, kainate receptors are enhanced by inhaled anesthetics, but this is unlikely to be involved in immobility because MAC is not altered in mice deficient in the GluR6 receptor subunit.[130] Most evidence suggests that the principal mechanism for depression of glutamatergic transmission by volatile anesthetics is presynaptic, with minor contributions from postsynaptic receptor blockade[117,131-133] (see "Cellular Mechanisms").

Voltage-Gated and Other Ion Channels

Na^+ Channels

Voltage-gated Na^+ channels are critical to axonal conduction, synaptic integration, and neuronal excitability. In contrast to findings in invertebrate giant axons,[134] axonal conduction in small (0.1-0.2 μm) unmyelinated hippocampal axons is depressed by volatile anesthetics[135,136] and small reductions in preterminal action potential amplitude significantly depress transmitter release and hence postsynaptic responses at a mammalian synapse.[137]

Heterologously expressed mammalian voltage-gated Na^+ channels are sensitive to clinically relevant concentrations of volatile anesthetics. The Na^+ channel family consists of nine homologous pore-forming α-subunits with distinct cellular and subcellular distributions.[138] Isoflurane and other volatile anesthetics inhibit the major mammalian Na^+ channel isoforms, including neuronal ($Na_v1.2$), skeletal muscle ($Na_v1.4$), and cardiac ($Na_v1.5$) channels, but the peripheral isoform $Na_v1.8$ is apparently resistant.[139] Volatile anesthetics, but not nonimmobilizers, also inhibit native neuronal and nerve terminal Na^+ channels,[140-143] lending support to the notion that Na^+ channel blockade contributes to the depression of synaptic neurotransmitter release.[143] In contrast, xenon has no detectable effect on Na^+, Ca^{2+}, or K^+ channels in isolated cardiomyocytes.[92] The recent demonstration that NaChBac, a prokaryotic homolog of voltage-gated Na^+ channels, is also inhibited by volatile anesthetics opens the way for structure-function studies of these channels.[141]

Ca^{2+} Channels

Multiple cellular functions depend on the tightly controlled concentration of intracellular free Ca^{2+} ($[Ca^{2+}]_i$), which is determined by the integrated activity of voltage-gated Ca^{2+} channels, capacitative Ca^{2+} channels, plasma membrane and sarco/endo-plasmic reticulum Ca^{2+}-ATPases (pumps), Na^+/Ca^{2+} exchangers, and mitochondrial Ca^{2+} sequestration. Alteration of any of these mechanisms by anesthetics could affect the many cellular processes regulated by the second messenger actions of Ca^{2+}, including synaptic transmission, gene expression, cytotoxicity, and muscle excitation-contraction coupling. Excitable cells translate their electrical activity into action by Ca^{2+} fluxes mediated primarily by voltage-gated Ca^{2+} channels in the plasma membrane. Distinct Ca^{2+} subtypes are expressed in various cells and tissues and are classified pharmacologically and functionally by the degree of depolarization required to gate the channel, such as low voltage–activated (LVA; T-type) and high voltage–activated (HVA; L-, N-, R-, and P/Q-type) channels. More recently, the molecular identity of their pore-forming α-subunits has been used for classification.[144] There is convincing evidence that volatile anesthetics inhibit certain Ca^{2+} channel isoforms but not others (for review see reference 145).

Inhibition of the presynaptic voltage-gated Ca^{2+} channels coupled to transmitter release has been proposed as a mechanism by which volatile anesthetics reduce excitatory transmission.[146]

Indeed, N-type ($Ca_v2.2$) and P-type ($Ca_v2.1$) channels, which mediate Ca^{2+} entry coupled to neurotransmitter release, are modestly sensitive to volatile anesthetics[147,148] but not in all neuron types,[149] suggesting the importance of auxiliary subunits, post-translation modification, or other potential modulators of anesthetic sensitivity. A modest contribution of R-type Ca^{2+} channels ($Ca_v2.3$) to anesthesia is suggested by its sensitivity to volatile anesthetics and a small increase in MAC produced by its genetic deletion in mice.[150] T-type Ca^{2+} channels are particularly sensitive to volatile anesthetics[151] and nitrous oxide.[152] However, mutant mice lacking a major neuronal T-type Ca^{2+} channel isoform ($Ca_v3.1$) have normal volatile anesthetic sensitivity, although the onset of anesthesia is delayed.[153] Thus, the role that inhibition of these or other Ca^{2+} channels plays in the CNS effects of inhaled anesthetics is unclear.

By contrast, a role for Ca^{2+} channel inhibition in the negative inotropic effects of volatile anesthetics, prominent at higher doses, is well established. The force of myocardial contraction is determined by the magnitude of cytosolic Ca^{2+} increase after electrical excitation, the responsiveness of the contractile proteins to Ca^{2+}, and sarcomere length. Negative inotropic effects of volatile anesthetics are mediated by reductions in Ca^{2+} availability, Ca^{2+} sensitivity of the contractile proteins, and the rate of cytosolic Ca^{2+} clearance. Volatile anesthetics reduce the Ca^{2+} transient and shorten action potential duration in cardiomyocytes primarily by inhibiting L-type ($Ca_v1.2$) Ca^{2+} currents, resulting in a negative inotropic effect and arrhythmogenicity.[90,99,154] In contrast, xenon does not depress myocardial function or inhibit L-type Ca^{2+}, Na^+, or K^+ currents in isolated cardiomyocytes.[91,92] Inhibition of transsarcolemmal Ca^{2+} influx through cardiac L-type Ca^{2+} channels plays a major role in the negative inotropic effects of volatile anesthetics, greatest for halothane, along with contributions from effects on myofilament Ca^{2+} sensitivity and sarcolemmal Ca^{2+} release.[99,155]

In contrast to voltage-gated Ca^{2+} channels that regulate the influx of extracellular Ca^{2+}, intracellular Ca^{2+} channels regulate Ca^{2+} release from intracellular stores, particularly the endoplasmic reticulum (ER) and sarcoplasmic reticulum (SR). These include 1,4,5-trisphosphate receptors (IP_3Rs), regulated by the second messenger IP_3, and ryanodine receptors (RyRs), which mediate the rapid release of intracellular Ca^{2+} critical to excitation-contraction coupling in muscle. Volatile anesthetic-induced Ca^{2+} leak occurs via both IP_3R and RyR channels, which leads to depletion of intracellular Ca^{2+} stores from the SR and ER. This blunts changes in intracellular Ca^{2+} in response to stimulation and also contributes to the smooth muscle–relaxing properties of volatile anesthetics that underlie bronchodilation and vasodilation.[156] Malignant hyperthermia susceptibility is a pharmacogenetic disorder that manifests as a potentially fatal hypermetabolic crisis triggered by volatile anesthetics, particularly halothane. It is often associated with mutations in RyR1 and the physically associated L-type Ca^{2+} channel ($Ca_v1.1$) that functions as the voltage sensor.[157] Volatile anesthetics activate the abnormal RyRs, resulting in uncontrolled intracellular Ca^{2+} release, muscle contraction, and metabolic activity[158] (see also Chapter 37.)

K^+ Channels and HCN Channels

Potassium (K^+) channels are an extremely diverse ion channel family noted for their varied modes of activation. They regulate electrical excitability, muscle contractility, and neurotransmitter release and are important in determining the input resistance and in driving repolarization and thus determine excitability and action potential duration. Given the large diversity in K^+ channel structure, function, and anesthetic sensitivity, it is not surprising that there is considerable diversity in their sensitivity and response to inhaled anesthetics[159]: from relatively insensitive (voltage-gated K^+ channels $K_v1.1$, K_v3)[160] to sensitive (some members of the two-pore domain K^+ channels [K_{2P}] family), resulting in either inhibition, activation, or no effect on K^+ currents.

Volatile anesthetic activation of certain "leak" K^+ channels was first observed in the snail *Lymnaea,*[161] although the molecular identity of the affected ion channels was unknown. Activation of K_{2P} channels by volatile and gaseous anesthetics, including xenon, nitrous oxide, and cyclopropane, was subsequently observed in mammals.[162] Increased K^+ conductance can hyperpolarize neurons, reducing responsiveness to excitatory synaptic input and altering network synchrony. Targeted deletion of the TASK-1, TASK-3, and TREK-1 K_{2P} channels in mice reduces sensitivity to immobilization by volatile anesthetics, implicating these channels as anesthetic targets in vivo.[32-34] Other members of this large family of K^+ channels are also sensitive to xenon and volatile anesthetics.[163]

The recognition that inherited channelopathies are arrhythmogenic and constitute an important contributor to sudden cardiac death,[164] particularly in young children,[165] highlights the importance of analyzing anesthetic modulation of cardiac ion channels. Recombinant HERG (human ether-a-go-go related) channels are moderately inhibited by halothane, and their depression likely contributes to arrhythmogenic effects of volatile anesthetics.[99,166] HERG channels are also involved in acquired (drug-induced) and inherited long QT syndrome. Cardiac inward-rectifying (K_{IR}), voltage-gated (K_v), and Ca^{2+}-activated K^+ channels are generally relatively insensitive to clinical concentrations of volatile anesthetics and xenon.[91,99,167] In contrast, there is considerable evidence that volatile anesthetics and xenon activate cardiac mitochondrial and sarcolemmal K_{ATP} channels,[100] an effect that plays a critical role in anesthetic preconditioning. Direct electrophysiologic effects of anesthetics with preconditioning properties have been demonstrated on both mitochondrial and sarcolemmal K_{ATP} channels, although the precise mechanisms remain to be clarified.

Volatile anesthetics also inhibit HCN "pacemaker" channels, reducing the rate of rise of pacemaker potentials and the bursting frequency of certain neurons showing autorhythmicity. They decrease I_h conductance in neurons[168] and modulate recombinant HCN1 and HCN2 channel isoforms at clinically relevant concentrations.[169] Because HCN channels contribute to resting membrane potential, control action potential firing, dendritic integration, neuronal automaticity, and temporal summation, and determine periodicity and synchronization of oscillations in many neuronal networks,[170] the anesthetic modulation of these channels could play an important role in anesthetic effects on neuronal integrative functions.

Intracellular Signaling Mechanisms

Cell signaling mechanisms are critical to all phases of organ function and have been attractive targets for the broad effects of general anesthetics. Anesthetics have poorly understood actions on intracellular cell signaling pathways, which include processes downstream from cell surface receptors and ion channels, such

as effects of second messengers, protein phosphorylation pathways, and other regulatory mechanisms.[171]

G Protein–Coupled Receptors

A variety of signals, including hormones, neurotransmitters, cytokines, pheromones, odorants, and photons, produce their intracellular actions by interactions with metabotropic receptors that activate heterotrimeric guanine nucleotide (GTP)-binding proteins (G proteins). In contrast to the ionotropic receptors that directly couple to ion-selective channels, G proteins act as indirect molecular switches to relay information from activated plasma membrane receptors to appropriate intracellular targets. Heterotrimeric G proteins consist of a large α-subunit and a smaller β/γ-subunit dimer, each expressed as multiple isoforms with distinct properties and downstream targets. G proteins regulate a plethora of downstream effectors to control the levels of cytosolic second messengers such as Ca^{2+}, cyclic adenosine monophosphate (cAMP), and inositol triphosphate (IP_3). These, in turn, regulate effector proteins such as ion channels and enzymes, either directly or via second messenger–regulated protein phosphorylation pathways. Drugs that act through G protein-coupled receptors (GPCRs), such as agonists for μ opioid and α_2-adrenergic receptors, can affect anesthetic sensitivity (reduce MAC). Inhaled anesthetics can also directly affect signaling via GPCRs.[172] For example, volatile anesthetics activate multiple rat olfactory GPCRs in vivo in a receptor- and agent-selective manner.[173] Analogous effects on related GPCRs more relevant to critical anesthetic end points are possible but remain to be demonstrated. The observation that both volatile anesthetics and nonimmobilizers inhibit mGluR5 glutamate receptors, $5\text{-}HT_{2A}$ serotonin receptors, and muscarinic acetylcholine receptors suggest that these GPCR effects do not contribute to anesthetic immobilization.[174-176]

Protein Phosphorylation

Phosphorylation of proteins on specific serine, threonine, or tyrosine hydroxyl groups, a post-translational modification involved in the regulation of many anesthetic-sensitive receptors and ion channels, is pivotal to synaptic plasticity (e.g., LTP). Phosphorylation is controlled by the balance of activity between protein kinases and phosphatases, several of which are plausible anesthetic targets. The protein kinase C (PKC) family of multifunctional protein kinases is activated by the lipid signaling molecule diacylglycerol and is involved in the regulation of many ion channels and receptors. Halothane[177] and sevoflurane[178] enhance the activity of some PKC isoforms and stimulate phosphorylation of specific PKC substrates. Structural studies have identified a potential binding site in the diacylglycerol binding domain of PKCδ, consistent with the ability of certain anesthetics to mimic this natural regulator by binding to the activating site.[179] A specific role for a direct pharmacologically relevant effect mediated by anesthetic activation of PKC or of any other kinase has yet to be demonstrated. Intrathecal injection of isoform-specific inhibitors of PKC does not affect sensitivity to halothane in vivo.[180] Knockout mice lacking the PKCγ isoform show normal sensitivity to halothane and desflurane while isoflurane MAC was increased,[181] suggesting that PKC is not critical to volatile anesthetic immobilization.

An important role for effects of volatile anesthetics and xenon on cell signaling mechanisms has been discovered for anesthetic-induced preconditioning of heart (see Chapter 23) and brain against ischemic damage.[83,87,102] Anesthetic-induced and ischemic cardiac preconditioning share critical signaling mechanisms, including activation of multiple GPCRs (e.g., adenosine, opioid, adrenergic) and protein kinases (e.g., src kinase, PKCδ, PKCε, Akt, mitogen-activated protein kinases [MAPKs]) and their downstream targets, particularly sarcolemmal and/or mitochondrial K_{ATP} channels, possibly initiated by changes in reactive oxygen species as the critical second messenger.[88] Volatile anesthetics and xenon share cardioprotective and neuroprotective effects involving these signaling pathways.[102]

The effects of anesthetics on the phosphorylation of individual residues in specific substrates can be studied using phosphorylation state-specific antibodies that are able to detect the phosphorylated form of kinase substrates. A comparison of the effects of three mechanistically diverse anesthetics (isoflurane, propofol, and ketamine) on critical intracellular protein phosphorylation signaling pathways that are known to integrate multiple second messenger systems reveals both shared and agent-specific actions in vivo.[182] All three anesthetics reduce phosphorylation of activating sites on NMDA (S897) and AMPA (S831) glutamate receptors and of the downstream extracellular signal-regulated kinase ERK2, which are involved in synaptic plasticity, consistent with depression of normal glutamatergic synaptic transmission in the anesthetized mouse cerebral cortex. This effect is somewhat selective in that several other PKA substrates examined are not affected, indicating a substrate-specific effect rather than a general inhibition of PKA activity.[183] Additional studies will be required to determine which anesthetic effects on kinase pathways represent direct effects, as occurs with PKC, and which are indirect due to anesthetic-induced alterations in signaling molecules known to regulate protein kinase and phosphatase activity such as Ca^{2+} and other second messengers.

Gene Expression

The ability of general anesthetics to alter gene expression in the brain was first observed for the highly reactive acute early genes c-*fos* and c-*jun*.[184] Anesthetic effects on gene expression have since been observed for multiple anesthetics and organs.[185] In the hippocampus of aged rats, changes in gene expression persisted for up to 2 days in rats exposed to isoflurane and nitrous oxide,[186] and changes in protein expression have been observed 3 days after exposure to desflurane.[187] The significance of these changes in gene and protein expression persisting after recovery from the classic signs of anesthesia remains to be established (see reference 78 for review).

Cellular Mechanisms

Neuronal Excitability

Neuronal excitability is determined by resting membrane potential, threshold for action potential initiation, and input resistance (an indication of overall channel activity), which can differ between compartments within an individual neuron owing to subcellular specializations (e.g., soma versus dendrite). High concentrations of volatile anesthetics hyperpolarize hippocampal pyramidal cells in slice preparations by less than 5 mV at more than five times MAC.[188,189] At relevant concentrations, neither resting membrane potential nor input resistance is significantly affected in hippocampal[190] or spinal cord neurons.[191] Anesthetic

effects on the firing properties of hippocampal neurons are complex: increased or decreased thresholds (for enflurane) have been reported.[190,192] By contrast, thalamic neurons hyperpolarize in the presence of isoflurane and are less likely to fire action potentials due to a decrease in input resistance (increased shunting), attributed to increased K^+ conductance.[193] Similar effects are observed in hypoglossal motor neurons and neurons from the locus coeruleus, where a TASK-type K_{2P} channel has been causally implicated.[115]

A role for $GABA_A$ receptors located at extrasynaptic sites has been suggested recently for volatile anesthetic effects (Fig. 20-9). Extrasynaptic $GABA_A$ receptors, which differ from synaptic receptors in their subunit composition, mediate tonic inhibition (as opposed to phasic inhibition mediated by synaptic $GABA_A$ receptors) and are remarkably sensitive to many general anesthetics. Extrasynaptic $GABA_A$ receptors have a high affinity for GABA, desensitize slowly, and are tonically exposed to low ambient GABA concentrations,[194] at which the potentiating effect of anesthetics is most significant. The effects of anesthetics on tonic inhibition have been characterized in the hippocampus, which is critically involved in learning and memory. Hippocampal neurons generate a robust tonic current via activation of α_5-subunit–containing $GABA_A$ receptors[195-199] that is highly sensitive to etomidate, propofol, midazolam, and isoflurane. $GABA_A$ receptors containing the α_5-subunit are highly sensitive to low concentrations of propofol and isoflurane that produce amnesia but not unconsciousness. Thus, these receptors provide a potential substrate for the amnesic properties of anesthetics.

Presynaptic versus Postsynaptic Effects on Synaptic Transmission

General anesthetics have potent and specific effects on synaptic transmission, including presynaptic actions (by altering transmitter release) and postsynaptic actions (by altering the responses of neurons to specific transmitters). The relative contributions of presynaptic versus postsynaptic anesthetic effects on synaptic transmission have been difficult to resolve, probably because the effects are transmitter- and synapse-specific.[117] The net effect of anesthetics on synaptic transmission is determined by the relative magnitude and direction of both their presynaptic and postsynaptic effects.

Synaptic excitation is decreased by volatile anesthetics (Fig. 20-10). Experiments in various slice preparations indicate that reduced excitation is primarily due to presynaptic mechanisms (Fig. 20-11).[131,191,200-202] A postsynaptic mechanism is also involved because neuronal excitation to directly applied glutamate is reduced to some degree.[202-204] Volatile anesthetics have inconsistent effects on cloned AMPA or NMDA glutamate receptors but potentiate kainate receptors,[112,205-207] which is consistent with a predominantly presynaptic mechanism for inhibition of glutamatergic synapses, whereas the effects of the nonhalogenated inhaled anesthetics (xenon, nitrous oxide, cyclopropane) are mediated primarily by inhibition of postsynaptic NMDA receptors (see earlier). In contrast, augmentation of GABAergic inhibition by most general anesthetics is mediated both by presynaptic and postsynaptic mechanisms. Enhancement of postsynaptic and extrasynaptic $GABA_A$ receptors is well recognized.[113] Remarkably, however, volatile anesthetics also increase spontaneous GABA release and inhibitory postsynaptic current (IPSC) frequency,[208-212] that is, their presynaptic effects at GABAergic terminals are distinct from those at glutamatergic synapses.

The mechanisms for the presynaptic effects of inhaled anesthetics, like those for their postsynaptic effects, are complex and involve multiple targets. Although a synapse-specific contribution of presynaptic Ca^{2+} channels is likely, presynaptic Na^+ channels are more sensitive than the Ca^{2+} channels coupled to glutamate release. This is consistent with observations that the predominant Ca^{2+} channel coupled to neurotransmitter release at hippocampal glutamatergic synapses (P/Q-type) is insensitive to isoflurane.[149] Other presynaptic mechanisms have been proposed, including actions on the vesicle fusion process as demonstrated in the model organism *Caenorhabditis elegans.*[213,214] However, isoflurane effects on exocytosis in rat hippocampal neurons occur primarily upstream of vesicle fusion[137,245] (see reference 117 for review).

The general effects of inhaled anesthetics are to increase inhibitory synaptic transmission and to inhibit excitatory synaptic transmission (Fig. 20-12). The relative importance of anesthetic effects on excitatory versus inhibitory synaptic transmission, and the mechanisms of these effects, are likely to differ for different anesthetics and for specific synapses and networks.[105,215] This concept extends to other putative targets and mechanisms and is incorporated in "agent-specific multiple-site" hypotheses of anesthesia.[215,216]

Simple Circuits and Complex Networks

Simple Circuit Phenomena

To reach a mechanistic understanding of phenomena involving multiple elements of a complex circuit, anatomically reduced (in vitro) or physiologically simplified (in vivo) preparations have been complemented by models with simulations (in silico). These approaches will be essential for integrating reductionist observations of the multiple molecular effects of anesthetics into functional models relevant to behavioral end points. Anatomically, simplified preparations containing native circuitry typically consist of isolated tissue slices. Anesthetic effects have been studied in acute brain slice preparations from various regions of the CNS (hippocampus, amygdala, cortex, thalamus, brainstem, spinal cord). Acute slices preserve native connections but usually lack natural inputs and outputs. Slices from developing mammalian brain can be cultured in vitro. These "organotypic slice cultures" preserve a high degree of synaptic connectivity and display spontaneous network activity, typically absent from acute slices. Physiologically, simplified preparations involve phenomena (typically evoked responses) with *relatively* well understood circuitry. Examples include paired-pulse depression (PPD), synaptic plasticity (long-term potentiation [LTP] and long-term depression [LTD]), and certain sensory-evoked responses. Computer models and simulations can assist in generating hypotheses for experimental testing and test hypotheses based on experimental data.

Synaptic Plasticity

Paired-pulse depression (PPD) and paired-pulse facilitation (PPF) are examples of short-term plasticity in response to exter-

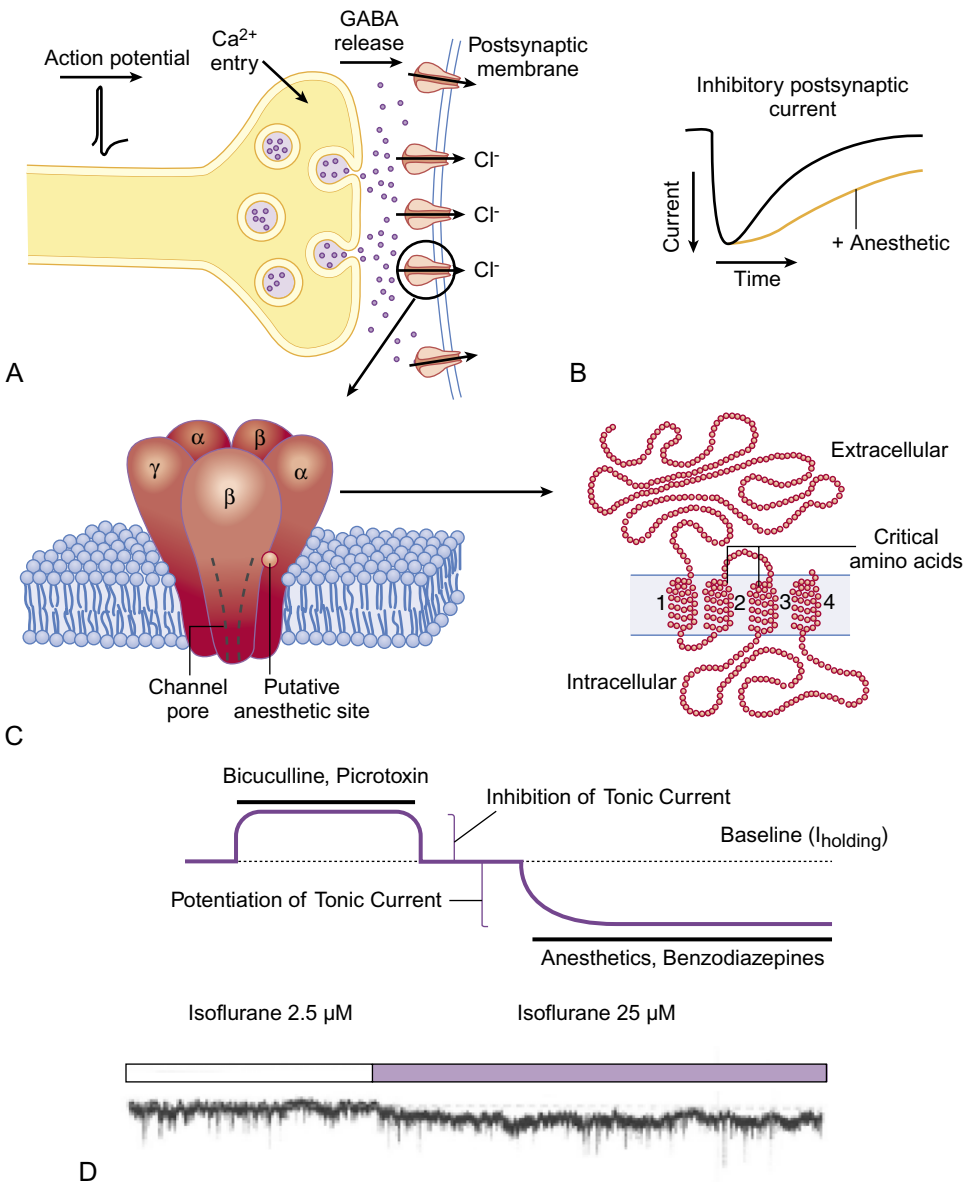

Figure 20-9 Synaptic and extrasynaptic $GABA_A$ receptors are targets for inhaled anesthetics. **A,** On binding of GABA (γ-aminobutyric acid) to the $GABA_A$ receptor, its chloride-permeable channel opens, leading to hyperpolarization. Volatile anesthetics have a relatively low potency but high efficacy at synaptic $GABA_A$ receptors and a high potency and low efficacy at extrasynaptic $GABA_A$ receptors. **B,** General anesthetics prolong channel opening and increase postsynaptic inhibition. The cartoon illustrates the prolongation of miniature inhibitory synaptic currents (mIPSCs) by the slowing of current decay. **C,** A pentameric $GABA_A$ receptor complex in the lipid bilayer membrane (*left*), with a blow-up of a single subunit showing the location of residues critical to anesthetic efficacy in the second and third transmembrane dornains (*right*). **D,** A tonic inhibitory conductance is revealed by the application of a $GABA_A$ receptor antagonist (bicuculline or picrotoxin), as shown by the upward shift in the baseline current. Anesthetics and benzodiazepines increase the tonic conductance as indicated by the inward shift in the current. (*Modified from Hemmings HC Jr, Akabas MH, Goldstein PA, et al: Emerging molecular mechanisms of general anesthetic action. Trends Pharmacol Sci 26:503-510, 2005.*)

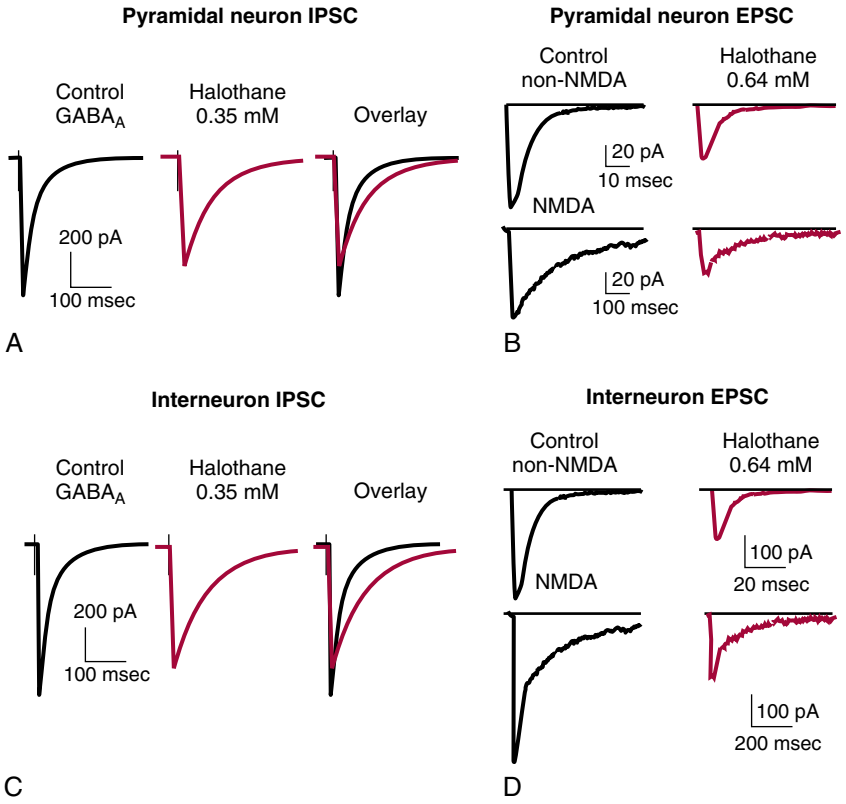

Figure 20-10 Halogenated anesthetics enhance inhibitory and depress excitatory synaptic transmission. Halothane slows the decay of $GABA_A$ receptor–mediated postsynaptic inhibitory currents (IPSCs, **A**) and depresses the amplitude of glutamatergic excitatory postsynaptic currents without affecting the decay (EPSC, **B**, **D**) in hippocampal pyramidal neurons (**A**, **B**) and interneurons (**C**, **D**). *(Panels A and C redrawn with permission from Nishikawa K, MacIver MB: Membrane and synaptic actions of halothane on rat hippocampal pyramidal neurons and inhibitory interneurons. J Neurosci 20:5915-5923, 2000. Panels B and D redrawn with permission from Perouansky M, et al: Effects of halothane on glutamate receptor-mediated excitatory postsynaptic currents: A patch-clamp study in adult mouse hippocampal slices. Anesthesiology 83:109-119, 1995.)*

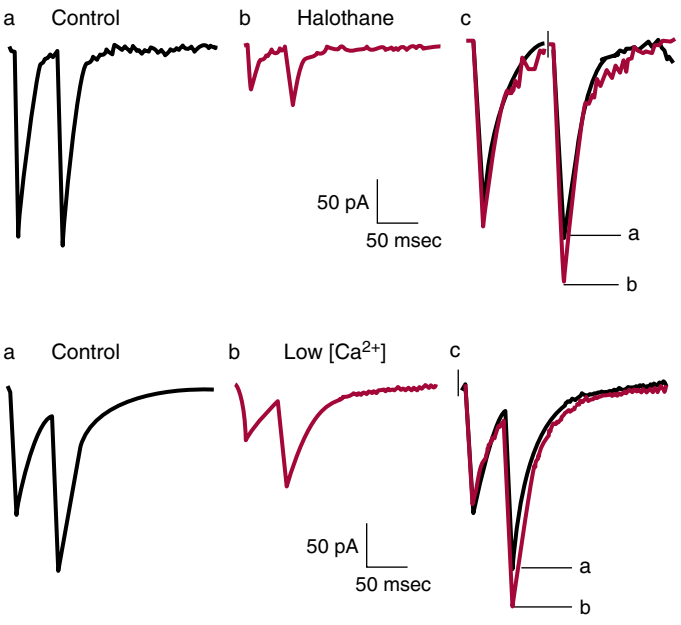

Figure 20-11 Excitatory synaptic transmission is depressed by a presynaptic action. In the paired-pulse facilitation paradigm, halothane (0.64 mM; ~2 MAC) increases the amplitude of the second paired response, an effect similar to that produced by reducing extracellular Ca^{2+} (low Ca^{2+}), indicating a presynaptic site of action. Responses to exogenous, iontophoretically applied AMPA or NMDA are much less sensitive than the presynaptic reduction in transmitter release (not shown). *(Redrawn with permission from Kirson ED, et al: Presynaptic and postsynaptic actions of halothane at glutamatergic synapses in the mouse hippocampus. Br J Pharmacol 124:1607-1614, 1998.)*

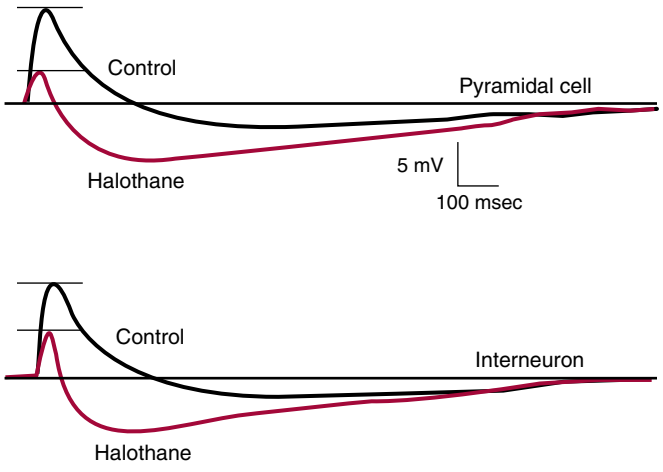

Figure 20-12 Anesthetics affect excitation and inhibition simultaneously. Halothane depresses the excitatory depolarization and augments the inhibitory hyperpolarization in both hippocampal pyramidal cells and interneurons. The net result will depend on the underlying circuitry and its function. *(Redrawn with permission form Nishikawa K, MacIver MB: Membrane and synaptic actions of halothane on rat hippocampal pyramidal neurons and inhibitory interneurons. J Neurosci 20:5915-5923, 2000.)*

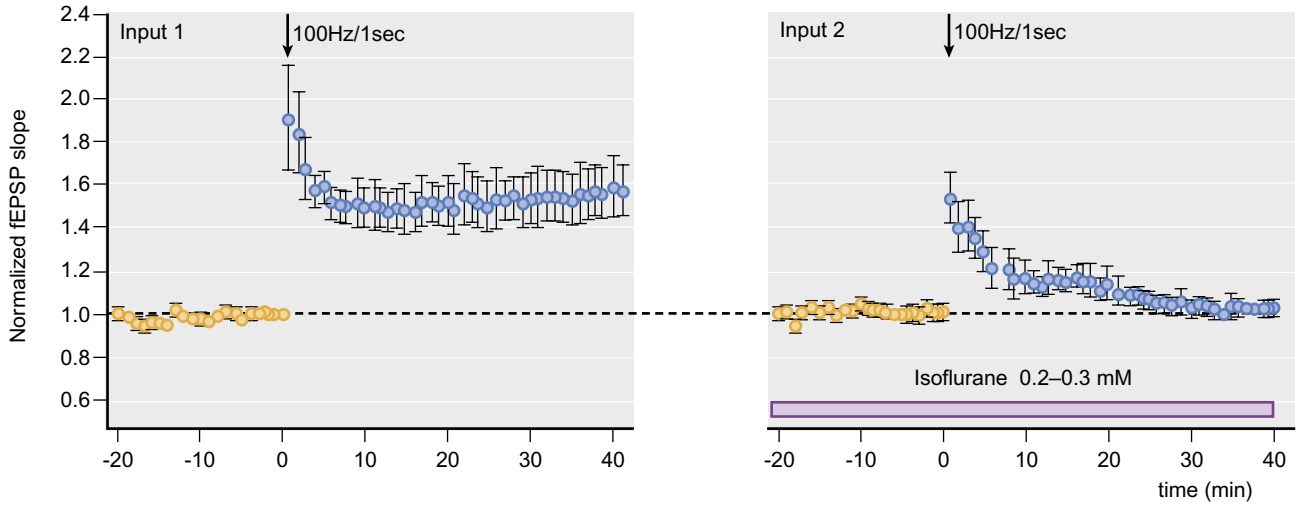

Figure 20-13 Isoflurane blocks the induction of synaptic plasticity (an in-vitro model of learning and memory). Long-term potentiation (an increase in synaptic strength) in hippocampal slices evoked by tetanic stimulation of excitatory synapses is blocked by 200-300 μM of isoflurane. (*Redrawn with permission from Simon W, et al: Isoflurane blocks synaptic plasticity in the mouse hippocampus. Anesthesiology 94:1058-1065, 2001.*)

nal stimulation. Synaptic inhibition is prolonged by volatile anesthetics in vivo[217] and in vitro[218], in general agreement with the notion that anesthetics enhance functional inhibition in the CNS. Enhancement of PPF has been attributed to the presynaptic depressant effect of volatile agents (see Fig. 20-11).[131,201]

LTP (a cellular model of learning and memory) consists of use-dependent strengthening of excitatory synaptic connections mediated by glutamate receptors (see Chapter 11).[219] The few experiments investigating volatile anesthetic effects on LTP have yielded somewhat inconsistent results: halothane, enflurane, and isoflurane do not block LTP induction in vivo, whereas ketamine does.[217] By contrast, isoflurane blocks LTP in the hippocampal slice by enhancing $GABA_A$ receptor–mediated inhibition (Fig. 20-13).[220] LTD, a use-dependent weakening of excitatory connections that is effectively a homeostatic counterpart of LTP, is also blocked by isoflurane.[220] The discrepancy between these findings in vivo and in vitro could reflect differences in the balance between excitatory and inhibitory circuitry activated by the electrical stimuli employed. Etomidate, at amnesic concentrations, blocks LTP by enhancing specific subtypes of $GABA_A$ receptors,[199] whereas ketamine blocks LTP in urethane-anesthetized animals by blocking NMDA receptors.[221,222]

Spontaneously Active Circuits

Spontaneous neuronal activity is decreased by a range of volatile anesthetics both in vivo and in cortical brain slices. This effect is largely $GABA_A$ receptor dependent and marked even at low "sedative" concentrations.[77] Because the cultured slice lacks subcortical input, these results suggest that volatile anesthetics can cause some effects (e.g., sedation) via direct cortical action. However, changes in raw neuronal firing rates might not be a precise quantitative measure of higher cognitive function. Anesthetic effects have also been tested on the circuitry underlying locomotion, a well-studied central pattern generator. Results with isoflurane in the in vitro lamprey spinal cord preparation support the spinal cord as the primary target for volatile anesthetic-induced immobility.[223]

Rhythms and Simulations

Brains perpetually generate complex electrical rhythms that range in frequency from fractions to hundreds of Hertz. Although their physiologic roles are not clear, the prevailing notion is that they reflect, subserve, or constitute fundamental higher-order processing in mammalian brains. Their modulation by anesthetics therefore deserves scrutiny. Two rhythms that have been investigated both in vitro and in vivo in the context of anesthetic mechanisms are γ-rhythms and θ-rhythms.

γ–Rhythms

Isoflurane slows the frequency of evoked γ-oscillations (30-90 Hz, also known as "40 Hz" rhythms) in humans.[224] Studies of γ-oscillations in vitro suggest that their frequency depends on the time constant of decay of $GABA_A$ receptor–mediated synaptic currents in inhibitory networks.[225] Isoflurane slows γ-rhythms in hippocampal[226] and neocortical brain slices[227] to a comparable degree as in humans,[224] providing a tentative link between receptor and circuit-level effects. However, the interaction between anesthetics and behaviorally relevant network effects is unlikely to be unitary, because flash-evoked γ-oscillations in the primary visual cortex are not affected by inhaled agents[54] whereas feedback information transfer at γ frequencies between the visual and frontal cortices is disrupted.[228]

θ-Rhythms

θ-rhythms, present in various cortical structures, are most prominent in the hippocampus where they signal its "online state." They are associated with sensorimotor and mnemonic functions in awake, behaving animals.[229] One component of the θ-rhythm (type I or atropine-resistant) can be affected by amnesic concentrations of isoflurane as well as by the amnestic nonimmobilizer F6,[56] indicating a potential network-level signature effect for anesthetic-induced amnesia. Type II θ-rhythm (atropine-sensitive) can be evoked under anesthesia and is slowed and potentiated by halothane.[230] The γ- and θ-rhythms are interlinked in complex

ways, but the nature of their modulation by anesthetics as well as its relevance are far from clear.

Models and Simulations

On the atomic scale, modeling the interaction of anesthetic molecules with target-like proteins has defined "binding motifs" that characterize the amphiphilic binding cavities for anesthetic molecules (see earlier, "Identification of Molecular Sites of Anesthetic Action").[107] Modeling anesthetic interaction with firefly luciferase using gaussian and anisotropic network modeling suggests that anesthetics act by disrupting the modes of motion essential for protein function.[231]

On the macroscopic scale, computer simulations can provide an integrated picture of the modulation of dynamic neuronal and network activity. Simulations based on two different strategies have been published in anesthesia research. A "bottom-up," neuron-by-neuron approach is based on computational models of individual neurons, known anesthetic effects on intrinsic and synaptic membrane conductances, and simple network models. Computer simulations of anesthetic effects on integrated outputs can be generated (e.g., the firing of pacemaker neurons).[232] These models obviously rely on the accuracy of the derived characteristics of real neurons and networks, and the scale of simulations is limited by the complexity of its elements. An alternative is a "top-down" approach such as mean-field modeling in which individual accuracy is sacrificed in favor of global dynamics. Global cortical phenomena, such as anesthetic-induced seizures,[233] are modeled as phase transitions based on mean interactions between populations of averaged neurons (analogous to the EEG signal that also averages the signals of neuronal populations). This approach can be extended to other global cortical phenomena such as consciousness.[234] Neuronal modeling and computer simulations will likely gain importance in the future as bridges between theoretical and experimental studies of anesthesia.

Research Strategies for the Future

The search for anesthetic mechanisms is driven by advances in the basic sciences. Some strategies that should facilitate understanding of anesthetic mechanisms include use of agonists/antagonists in vivo, nonanesthetics/nonimmobilizers, transgenic animals, and high-resolution imaging of the functioning brain.

Pharmacologic

Agonists/Antagonists and Experimental Anesthetics

Use of receptor-specific agonists and antagonists provides a pharmacologic approach to bridging in-vitro with in-vivo studies. A receptor implicated in a specific end point (e.g., immobility) is selected according to the criteria presented earlier, for example the strychnine-sensitive glycine receptor (GlyR). A contribution of spinal GlyRs to isoflurane-induced immobility is indicated if a selective GlyR antagonist applied to the spinal cord in vivo affects immobilization by isoflurane more than immobilization by an anesthetic that is inactive at GlyRs in vitro. This approach did not yield conclusive results for the roles of $GABA_A$ and GlyR for immobilization,[27,235,236] probably owing to the intricacies of drug-receptor interactions on different levels of integration in complex networks like the spinal cord. The same pharmacologic strategy did exclude an important role for NMDA receptor block in the immobilizing action of volatile anesthetics.[28] A complementary pharmacologic approach that employs experimental anesthetics, which are structurally diverse compounds that inhibit NMDA receptors in vitro with different potencies, supports the conclusion that NMDA receptor blockade does not contribute significantly to immobility by conventional volatile anesthetics.[28] A refinement of this strategy involves the anatomically discrete application of drugs to nuclei with known function. Thus, the tuberomammillary nucleus (part of the sleep pathway) has been suggested to mediate the sedative component of anesthesia for some intravenous anesthetics (e.g., propofol).[22] A discrete "general anesthesia site" for GABAergic drugs in the mesopontine tegmentum has also been proposed based on this strategy.[21,234]

Nonimmobilizers

Nonimmobilizers are compounds with physicochemical characteristics similar to those of conventional inhaled anesthetics but predicted anesthetizing concentrations (based on their lipid solubility and the Meyer-Overton correlation: MAC_{pred}) of these drugs do not induce immobility (Fig. 20-14).[8] Initially termed *nonanesthetics,* the terminology was revised when it was discovered that they cause amnesia at similar MAC_{pred} fractions as classic volatile anesthetics.[67] If a molecular or cellular process is affected in

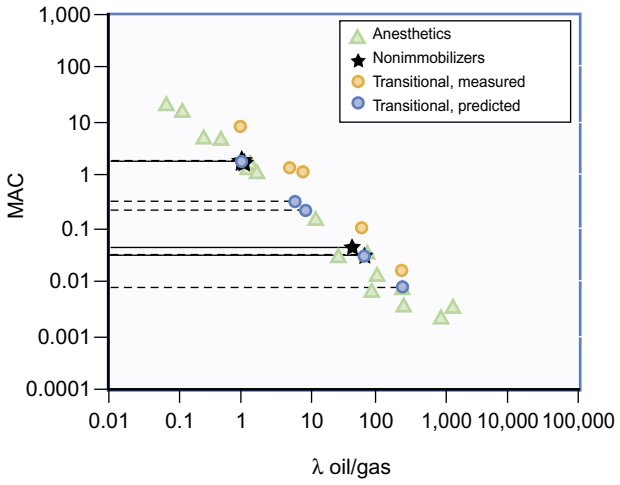

Figure 20-14 Nonimmobilizers disobey the Meyer-Overton correlation. Lipid solubility correlates well with MAC for conventional inhaled anesthetics (*green triangles*), but underestimates experimentally determined MAC for transitional compounds (*orange circles*). *Blue circles* and *dashed drop lines* show MAC values predicted based on lipid solubility for transitional compounds, and *black stars* with *solid drop lines* show predicted MAC values based on lipid solubility for nonimmobilizers. Note that predicted MAC is lower than experimentally determined MAC for transitional compounds, while it can only be calculated for nonimmobilizers, because these drugs do not immobilize at experimentally testable concentrations. MAC values (in volume %) determined in rodents. *(Data for transitional compounds and nonimmobilizers from Koblin DD, et al: Polyhalogenated and perfluorinated compounds that disobey the Meyer-Overton hypothesis. Anesth Analg 79:1043-1048, 1994.)*

similar ways by an anesthetic and a nonimmobilizer, that process is not relevant for the anesthetic state, with the notable exception of amnesia. Despite this elegant rationale, only a limited number of receptors have been excluded because, compared with volatile anesthetics, nonimmobilizers are relatively target-selective. These compounds have the potential to provide insights beyond the initially envisaged receptor-level studies by allowing the separation of sedation from amnesia for the study of underlying network activity in vivo.[56]

Genetic

Genetic strategies take two forms known as "forward" and "reverse" genetics.[238] Reverse genetics approaches focus on a particular gene, chosen because there are reasons to believe that its product might be important to anesthesia. Examples of this strategy are targeted mutations that alter the sensitivity of specific neurotransmitter receptors to anesthetics.[119] Initially, these mutations were used to identify anesthetic binding sites. Subsequently, transgenic animals rendered resistant to anesthetics, either by deletion of a putative target protein from the genome or by expressing a target receptor engineered to be insensitive to an anesthetic, were used to test behavioral relevance of the altered gene product for the anesthetic phenotype. Forward genetics, by contrast, involves the study of randomly generated mutations (either experimentally induced or naturally occurring polymorphisms) in a population that affect the phenotype of interest.

Knock-out and Knock-in Approaches

In the knock-out approach, expression of the gene encoding a protein of interest is disrupted by a specific deletion or insertion. A well-recognized problem with the global knock-out approach is that sometimes extensive compensatory changes can be induced in the proteome of the animal, from anomalies that are lethal in utero to insidious but experimentally confounding differences from wild-type. A complementary strategy is the conditional knock-out, in which the genetic deletion takes place in a restricted fashion—either anatomically (limited to certain brain regions) or temporally (that is, a gene is deleted at a known point in time). These strategies can minimize developmental anomalies and reduce the likelihood of compensatory changes. In the knock-in approach, a mutation, usually of a single amino acid residue, is targeted to produce a protein with altered sensitivity to a drug of interest. Ideally, this mutation remains completely silent in the absence of the drug, that is, it does not perturb the normal expression and function of the protein of interest or alter the expression of other genes.

$GABA_A$ Receptors

Results from transgenic animals illustrate both the utility and the difficulties of the genetic approach with respect to inhaled agents. The conditional forebrain-restricted $GABA_A$ receptor α_1-subunit knock-out mouse is less sensitive to isoflurane-induced amnesia than the wild-type, leading to the conclusion that action at these receptors contributes to its amnesic effects.[239] By contrast, a mouse harboring a mutation of the $GABA_A$ receptor α_1-subunit that renders the receptor insensitive to isoflurane in vitro did not show reduced sensitivity to either the amnesic or the immobilizing effects of isoflurane, leading to the conclusion that this subunit does not mediate the impairment of learning and memory by isoflurane.[31] Similar experiments indicate that action at the $GABA_A$ receptor β_3-subunit does not mediate immobility or amnesia by isoflurane.[30] This "bottom-up" genetic approach is a work-intensive but powerful tool that has yielded clear results with the receptor-specific intravenous anesthetics[16] but has proved more challenging to apply to the more promiscuous inhaled agents.

Two-Pore Domain K^+ Channels

Use of mice harboring knock-out mutations of several two-pore domain K^+ channel (K_{2P}) family members (TASK-1, TASK-3, TREK-1) has demonstrated a role for these channels in volatile anesthesia.[32-34] For example, TREK-1 knock-out mice are partially resistant to all volatile anesthetics tested with respect to both loss of righting reflex (a measure of consciousness) and immobility, but anesthesia can still be induced, albeit at higher anesthetic concentrations. Interestingly, responses to pentobarbital are unaffected, indicating that the mutation does not cause a generalized resistance to anesthesia.

Forward and Population Genetics

The nematode *Caenorhabditis elegans* and the fruit fly *Drosophila melanogaster,* with 300 and 100,000 neurons, respectively, have also been used as model organisms in anesthesia research. The genomes of both organisms have been sequenced and homologous genes in higher organisms can be identified for many genes. Mutations in a number of *C. elegans* genes affect sensitivity to volatile anesthetics, such as *unc64,*[214] *stomatin,*[240] and *gas1.* Mutations in the latter gene confer hypersensitivity to enflurane. Cloning of this gene revealed that it encodes the worm homolog of a subunit of NADH hydrogenase expressed in neurons.[241] Yeasts have also been used as model organisms, with even more obvious limitations with respect to identification of appropriate anesthetic end points.

Sensitivity to anesthetics is a quantitative trait (varying continuously in a population). Quantitative genetics is the study of the heritability of continuous traits. These traits are controlled by genes represented in quantitative trait loci (QTLs). A top-down population-based approach has been used to localize QTLs that govern susceptibility of individuals to anesthetics, in higher as well as lower organisms. Starting from the observation that inbred mouse strains vary in their sensitivity to isoflurane, microsatellite-based linkage analysis on one hand and single nucleotide polymorphism-based analysis of genetic variation on the other hand localized a QTL for isoflurane immobilization to the proximal part of mouse chromosome 7.[242] This type of analysis promises to assist in defining the genetic basis for variability in the susceptibility to both primary anesthetic end points and to side effects.

Imaging

Identification of the anatomic substrates for anesthetic effects on consciousness, memory, and immobility is now approachable with improved functional imaging techniques. Imaging is based on mapping of either hemodynamic or metabolic changes as surrogate measures of neuronal activity, as in positron emission tomography (PET) and functional MRI (fMRI), or on mapping the

electrical activity with high-density EEG and low-resolution brain electromagnetic tomography (LORETA). Properties of receptors can also be probed with radioactive ligands (PET). These techniques have the capacity to identify neuroanatomic substrates of drug action, with method-specific limitations. Results from functional PET imaging suggest that propofol suppresses episodic memory by targeting prefrontal and posterior parietal cortex as opposed to the medial temporal lobe[243] and that suppression of consciousness is due to anesthetic action in the thalamus, parts of the medial and posterior parietal cortex, and/or the posterior cingulate and medial parietal cortex (see reference 244 for review). Although observations of regionally specific and global suppressive effects of anesthetics on metabolic activity are unlikely to provide a definitive mechanistic understanding, such information can facilitate hypotheses and experimentally testable predictions.

Summary

The nut of "inhaled anesthetic mechanisms" has proved more difficult to crack than envisaged a generation ago, when the paradigm shifted from lipids to amphiphilic cavities in proteins as anesthetic targets. Despite a remarkable accumulation of factual knowledge, a comprehensive *theory of general anesthetic action* has not yet been formulated. Why has progress toward this goal been so difficult? Important pharmacologic characteristics of inhaled anesthetics that have impeded identification of their relevant molecular targets are their low potency (millimolar), their promiscuous activity at multiple targets, and the lack of specific antagonists. The situation is different for intravenous anesthetics that exhibit more conventional receptor pharmacology. Moreover, accumulating evidence indicates that no universal target exists to explain the actions of every general anesthetic, or even of a single anesthetic agent. It is now clear that the composite state of anesthesia and its core components (i.e., amnesia, sedation/unconsciousness, immobility) are separable behavioral states in vivo that have limited reproducibility in vitro. Resolution of these phenomena at the molecular and cellular levels represents the cutting edge of contemporary neuroscience. Of the multiple molecular and cellular anesthetic effects identified, it is unclear which are critical for the desired behavioral end points, which are harmless or beneficial side effects (e.g., preconditioning), and which, if any, could have long-lasting or delayed undesirable consequences (e.g., cell death, cognitive dysfunction). Progress in identifying the molecular targets of general anesthetics provides a foundation for identification of the network and systems level effects relevant to their behavioral and peripheral end points. As the biologic foundations of behaviors once thought to be exclusively the realm of psychology are unraveled, for which anesthetics provide a valuable investigative tool, a comprehensive theory of anesthesia will also develop.

21 Inhaled Anesthetics: Uptake and Distribution

Key Points

1. During induction and maintenance of anesthesia, ventilation, the first of five factors that govern the pulmonary inhaled anesthetic concentration, delivers anesthetic to the lung and thereby increases the alveolar concentration.
2. Uptake of anesthetic by blood passing through the lung opposes the effect of ventilation by drawing anesthetic from the lung.
3. An increased inspired concentration of anesthetic decreases the effect of uptake (the concentration effect), and at 100% inspired concentration, uptake no longer opposes the effect of ventilation.
4. Metabolism of anesthetics can increase uptake.
5. Anesthetic uptake may be enhanced by movement of anesthetic between tissues (intertissue diffusion), especially from highly perfused tissues (e.g., intestine) to poorly perfused tissues with a great capacity for anesthetic (e.g., mesenteric fat).
6. Three factors determine uptake by blood: solubility (the blood-gas partition coefficient), pulmonary blood flow (cardiac output), and the difference in anesthetic partial pressure between the lungs and venous blood returning to the lungs.
7. Solubility differentiates one anesthetic from another in that lower solubility translates to faster recovery from anesthesia.
8. Changes in ventilation and the distribution of ventilation, cardiac output (and its distribution), and inflow rate each influence anesthetic concentration in predictable ways.

The modern anesthetist expeditiously develops and then sustains anesthetic concentrations in the central nervous system that are sufficient for surgery, doing so with agents and techniques that usually permit rapid recovery from anesthesia. Producing a sufficient concentration requires delivery of anesthetic that is adequate but does not impose excessive depression. Knowledge of the factors that govern the relationship between the delivered anesthetic and brain (or heart or muscle) concentrations enhances the optimum conduct of anesthesia.

The Inspired-to-Alveolar Anesthetic Relationship

Of the steps between delivered and brain anesthetic partial pressure, none is more pivotal than that between the inspired and alveolar gases. Alveolar partial pressure governs the partial pressure of anesthetic in all body tissues: all must approach and ultimately equal alveolar partial pressure. With use of high inflow rates (and hence conversion to a non-rebreathing system), the anesthetist can precisely control the partial pressure of anesthetic that is inspired.

The Effect of Ventilation

Two factors determine how quickly the alveolar concentration of an anesthetic (F_A) rises toward the concentration being inspired (F_I): the inspired concentration itself (see "The Concentration Effect") and alveolar ventilation. Ventilation exerts a powerful effect. On induction, the unopposed effect of ventilation rapidly increases the alveolar concentration (i.e., F_A/F_I quickly approaches 1). This occurs with oxygen during the course of preoxygenation. Normally, 95% or greater washin of oxygen occurs in 2 minutes or less when a non-rebreathing (or high inflow rate) system is used (Fig. 21-1).

However, the F_A/F_I ratio for inhaled anesthetics does not mimic the F_A/F_I ratio for oxygen. In contrast to oxygen, appreci-

Table 21-1 Partition Coefficients at 37°C

Anesthetic	Blood-Gas	Brain-Blood	Liver-Blood	Kidney-Blood	Muscle-Blood	Fat-Blood
Desflurane	0.45	1.3	1.4	1.0	2.0	27
Nitrous oxide	0.47	1.1	0.8	—	1.2	2.3
Sevoflurane	0.65	1.7	1.8	1.2	3.1	48
Isoflurane	1.4	1.6	1.8	1.2	2.9	45
Enflurane	1.8	1.4	2.1	—	1.7	36
Halothane	2.5	1.9	2.1	1.2	3.4	51
Diethyl ether	12	2.0	1.9	0.9	1.3	5
Methoxyflurane	15	1.4	2.0	0.9	1.6	38

Data from references 1 through 8.

able quantities of anesthetics are taken up because the solubilities of anesthetics far exceed the solubility of oxygen (or nitrogen). At low inspired concentrations, the balance between delivery of anesthetic by ventilation and removal of anesthetic by uptake determines the FA/FI ratio. The relationship is a simple one. For example, if uptake removes a third of the inspired anesthetic molecules, FA/FI equals two thirds; if uptake removes two thirds of the inspired molecules, FA/FI equals a third.

Anesthetic Uptake Factors

Three factors determine anesthetic uptake: solubility (λ), cardiac output (Q), and alveolar-to-venous partial pressure difference ($P_A - P_v$).[1] Uptake equals the product of these factors: $\lambda \times Q \times (P_A - P_v)$ divided by barometric pressure.

Because uptake is the product of these factors rather than a sum, if any factor approaches zero, uptake must approach zero, and ventilation rapidly drives the FA/FI ratio to 1.0. Thus, if solubility is low (as in the case of oxygen), if cardiac output approaches zero (as in profound myocardial depression or death), or if the alveolar-to-venous difference becomes inconsequential (as might occur after an extraordinarily long course of anesthesia), uptake would be minimal, and FA/FI would equal 1.

Solubility

A partition coefficient describes the relative affinity of an anesthetic for two phases and hence how that anesthetic partitions itself between the two phases when equilibrium has been achieved. The blood-gas partition coefficient (λ, or "blood solubility") describes the partitioning of an anesthetic between blood and gas. For example, isoflurane has a blood-gas partition coefficient of 1.4, which means that at equilibrium, the concentration of isoflurane in blood is 1.4 times its concentration in the gas (alveolar) phase. "Equilibrium" means that no difference in partial pressure exists (i.e., a blood-gas partition coefficient of 1.4 does not indicate that the partial pressure in blood is 1.4 times that in the gas phase). The partition coefficient may be thought of in another way—it indicates the relative capacity of the two phases. Thus, a value of 1.4 means that each milliliter of blood holds 1.4 times as much isoflurane as a milliliter of alveolar gas does.

A larger blood-gas partition coefficient produces greater uptake and hence a lower FA/FI ratio. Because the partial pressure of an anesthetic in the alveoli is transmitted to arterial blood and thence to all tissues (especially the central nervous system), development of an adequate central nervous system anesthetic partial pressure may be delayed in the case of highly blood-soluble agents such as ether and methoxyflurane (Table 21-1).[1-8] Indeed, the delay in development of an anesthetizing cerebral partial pressure has contributed to the elimination of such highly blood-soluble agents from anesthetic practice. Even the moderate solubility of isoflurane could slow induction of anesthesia were it not for the use of anesthetic overpressure—that is, we compensate for the uptake of anesthetic by delivering a higher concentration than we hope to achieve in the alveoli, perhaps 2% isoflurane to produce an alveolar concentration of 1%.

Cardiac Output

The effect of altering cardiac output is intuitively obvious. If more blood passes through the lungs, more blood is available to remove anesthetic and thereby lower the FA/FI ratio. To the student of

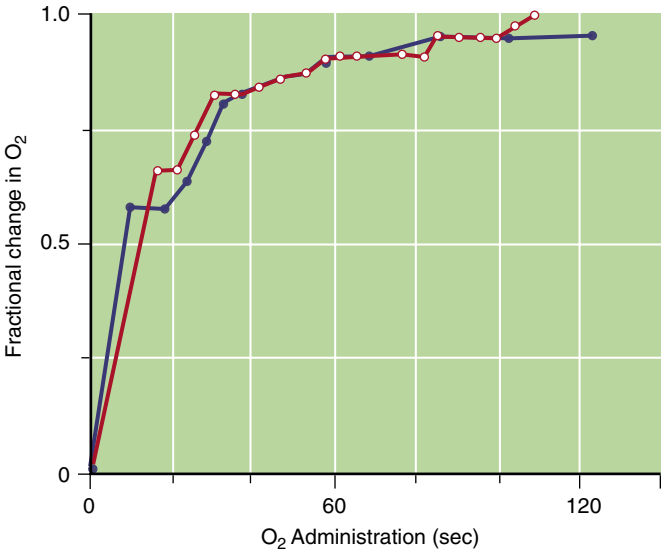

Figure 21-1 Washin of oxygen was determined in two patients breathing from a mask. A 63% change was obtained in about 30 seconds, an 86% change in about 1 minute, and a 95% to 98% change in 2 minutes. *(From Eger EI II [unpublished data].)*

uptake and distribution, this may appear to produce a conflict. It would seem that if more agent were taken up and delivered more rapidly to tissues, the tissue anesthetic partial pressure would rise more rapidly. In one sense this is true: an increase in cardiac output does hasten the equilibration of tissue anesthetic partial pressures with the partial pressure in arterial blood.[9] This reasoning, however, ignores the lower F_A/F_I ratio found with normal cardiac output. The partial pressure in the central nervous system cannot exceed that in blood, and thus a lower F_A/F_I ratio produces a lower anesthetic partial pressure in the brain—although that lower partial pressure might be achieved more rapidly.

The effect of a change in cardiac output is analogous to the effect of a change in solubility. As already noted, doubling solubility doubles the capacity of the same volume of blood to hold anesthetic. Doubling cardiac output would also double capacity, but in this case by doubling the volume of blood exposed to anesthetic.

The Alveolar-to-Venous Anesthetic Gradient

The alveolar-to-venous anesthetic partial pressure gradient, or the difference between partial pressure in the alveoli and that in venous blood, results from tissue uptake of anesthetic. Were there no tissue uptake, the venous blood returning to the lungs would contain as much anesthetic as it had when it left the lungs as arterial blood. That is, the alveolar (which equals arterial)-to-venous partial pressure difference would be zero. The presumption that alveolar and arterial anesthetic partial pressures are equal is reasonable in normal patients who have no barrier to diffusion of anesthetic from the alveoli to pulmonary capillary blood and who do not have ventilation-perfusion abnormalities. Later, we shall consider the effect of ventilation-perfusion abnormalities on anesthetic uptake.

Factors that determine the fraction of anesthetic removed from the blood traversing a given tissue parallel the factors that govern uptake at the lungs: tissue solubility, tissue blood flow, and arterial-to-tissue anesthetic partial pressure difference. Again, uptake is the product of these three factors. If any single factor approaches zero, so does uptake. The succeeding paragraphs discuss the characteristics of each of these factors and then how uptake by individual tissues can be summed to give the venous component of the alveolar-to-venous anesthetic partial pressure difference.

Blood-gas partition coefficients span values ranging from 0.45 for desflurane to 15 for methoxyflurane (see Table 21-1), a 33-fold difference. In contrast, tissue-blood partition coefficients (i.e., tissue solubility) lie between 1 and 2 for all lean tissue except muscle, for which the values for potent anesthetics lie between 2 and 3.4 (see Table 21-1)—that is, different lean tissues have similar capacity per milliliter of tissue. Put another way, a given anesthetic has roughly the same affinity for lean tissue and blood. As with blood-gas partition coefficients, tissue-blood partition coefficients define the concentration ratio of anesthetic at equilibrium between the two phases. For example, an isoflurane brain-blood partition coefficient of 1.6 means that 1 cm^3 of brain can hold 1.6 times as much isoflurane as 1 cm^3 of blood can with the same isoflurane partial pressure.

Lean tissues differ in the volume of tissue relative to the volume of blood passing that tissue. A larger volume of tissue relative to flow (as with muscle) has two implications. First, the large tissue capacity increases the transfer of anesthetic (more is lost) from blood to tissue. Second, it takes longer to fill up a tissue with a large capacity (i.e., the tissue takes longer to equilibrate with the anesthetic partial pressure being delivered in arterial blood). Thus, a large tissue volume relative to blood flow sustains the arterial-to-tissue anesthetic partial pressure difference (and hence uptake) for a longer time. In contrast, with its high perfusion per cubic centimeter of tissue, brain equilibrates rapidly with the anesthetic partial pressure. Per cubic centimeter of tissue, muscle has about a 20th the perfusion of brain, and this factor alone means that muscle takes 20 times longer than brain to equilibrate. The muscle-blood partition coefficient relative to the brain-blood partition coefficient causes a further delay. For example, the 3.1 muscle-blood partition coefficient for sevoflurane means that each 100 cm^3 of muscle has the capacity of 310 mL of blood, whereas the brain-blood partition coefficient is 1.7. Thus, equilibration is not simply 20 times longer, it is $20 \times 3.1/1.7$, or 36 times longer than with brain.

The tissue-blood coefficient for fat greatly exceeds 1 for more potent anesthetics (see Table 21-1). Fat-blood coefficients range from 2.3 (nitrous oxide) to 48 (sevoflurane). That is, each cubic centimeter of fat tissue contains 2.3 times more nitrous oxide or 48 times more sevoflurane than does a milliliter of blood with the same nitrous oxide or sevoflurane partial pressure. This enormous capacity of fat for potent inhaled anesthetics means that most of the anesthetic contained in the blood perfusing fat is transferred to the fat. Although most of the anesthetic moves from blood to fat, the anesthetic partial pressure in fat rises slowly because fat has a large capacity and low perfusion per cubic centimeter of fat.

Tissue Groups

The algebraic sum of uptake by individual tissues determines the alveolar-to-venous partial pressure difference and hence uptake at the lungs. However, we do not need to analyze the effect of individual tissues to arrive at the algebraic sum; instead, we can group tissues in terms of their perfusion and solubility characteristics (i.e., in terms of features that define the duration of a substantial arterial-to-tissue anesthetic partial pressure difference). Four tissue groups result from such an analysis (Table 21-2).[1]

The brain, heart, splanchnic bed (including the liver), kidney, and endocrine glands make up the vessel-rich group (VRG). These organs account for less than 10% of body weight but receive 75% of cardiac output. This high perfusion confers several features. The large blood flow permits the VRG to receive and remove a relatively large volume of anesthetic in the earliest moments of induction. However, the small volume of tissue relative to perfusion produces rapid equilibration of this tissue group with the anesthetic delivered in arterial blood. The time to half-equilibration (i.e., the time at which the VRG anesthetic partial pressure equals half that in arterial blood) varies from about 1 minute for nitrous oxide to 2 minutes for sevoflurane. The longer time to equilibration with sevoflurane results from its higher tissue-blood partition coefficients (see Table 21-1). Equilibration of the VRG with the anesthetic partial pressure in arterial blood is more than 90% complete in 4 to 8 minutes. Thus, after 8 minutes, uptake by the VRG is too small (i.e., the arterial-to-VRG anesthetic partial pressure difference is too small) to significantly influence the alveolar concentration. For a substantial period after 8 minutes, the muscle group (MG) determines most of uptake.

Muscle and skin, which make up the MG, have similar blood flow and solubility (lean tissue) characteristics. The lower perfusion (about 3 mL of blood per 100 cm^3 of tissue per minute)

Table 21-2 Tissue Group Characteristics

	Group			
	Vessel Rich	**Muscle**	**Fat**	**Vessel Poor**
Percentage of body mass	10	50	20	20
Perfusion as a percentage of cardiac output	75	19	6	0

Adapted from Eger EI II: Uptake of inhaled anesthetics: The alveolar to inspired anesthetic difference. *In* Eger EI II: Anesthetic Uptake and Action. Baltimore, Williams & Wilkins, 1974, pp 77-96.

distinguishes the MG from the VRG (70 mL per 100 cm^3 per minute). Although the MG represents about half of the body's bulk, it receives only 1 L/min blood flow at rest. That is, the amount of anesthetic delivered to the MG is a quarter of that delivered to the VRG, and initially the MG takes up only a quarter as much anesthetic. The large bulk relative to perfusion means two things: (1) during induction, most of the anesthetic delivered to the MG is removed from the MG blood flow, and (2) the MG continues to remove anesthetic from its blood supply for a long time. The time to half-equilibration ranges from 20 to 25 minutes (nitrous oxide) to 70 to 80 minutes (sevoflurane or isoflurane). Thus, long after equilibration of the VRG has taken place, the MG continues to take up substantial quantities of anesthetic and requires 2 to 4 hours to approach equilibration.

Once MG equilibration is complete, only fat (i.e., the fat group [FG]) serves as an effective depot for uptake. In a normal lean patient, the FG occupies a fifth of the body's bulk and receives a blood flow of about 400 mL/min (i.e., the perfusion per 100 cm^3 of fat nearly equals the perfusion per 100 cm^3 of resting muscle). Thus, during the initial delivery of anesthetic to tissues, the FG receives only 40% as much anesthetic as delivered to the MG (i.e., blood flow to the FG is 40% of that to the MG). The FG has far greater affinity than the MG for anesthetic, a property that greatly lengthens the time over which it absorbs anesthetic. The half-time to equilibration of fat ranges from 70 to 80 minutes for nitrous oxide to 30 hours for sevoflurane and isoflurane. Equilibration with fat does not occur in the course of anesthesia with any potent inhaled anesthetic.

One tissue group, the vessel-poor group (VPG), remains to be defined. The VPG consists of ligaments, tendons, bone, and cartilage (i.e., lean tissues that have little or no perfusion). The absence of significant blood flow means that the VPG does not participate in the uptake process despite the fact that it represents a fifth of the body's mass.

Synthesis of Factors Governing the Rise in FA/FI Ratio

Now consider the combined impact of ventilation, tissue volume, solubility, and blood flow distribution on the rate of rise in FA/FI. The initial rate is rapid for all agents, regardless of their solubility (Fig. 21-2).[10,11] At the start of anesthesia, this rapidity results from the absence of an alveolar-to-venous anesthetic partial pressure difference (there is no anesthetic present in the lung to create a gradient) and hence absence of uptake. Without uptake, the effect of ventilation to generate a sudden rise in FA/FI is unopposed, and the rise initially parallels that noted for oxygen (see Fig 21-1). As ventilation delivers anesthetic to the alveoli, a progressively greater alveolar-to-venous partial pressure difference develops. The resulting rise in uptake increasingly opposes the effect of ventilation to drive the alveolar concentration upward. Ultimately, a rough balance is struck between anesthetic input by ventilation and its removal by uptake. The height of the FA/FI ratio at which the balance is struck depends on the solubility factor in the uptake equation (see the earlier equation for anesthetic uptake). Greater solubility increases uptake for a given alveolar-to-venous partial pressure difference. Hence, the initial rapid rise in FA/FI is halted at a lower level with a more soluble agent. This results in the first "knee" in the curve—higher for desflurane than for sevoflurane, higher for sevoflurane than for isoflurane, and higher for isoflurane than for methoxyflurane. The position of nitrous oxide is discussed later (see "The Concentration Effect"). At 1 minute of anesthetic administration, the FA/FI ratio is approximately 0.6 for desflurane, which indicates that the FA/FI ratio still has 40% to rise (i.e., uptake is removing 40% of the desflurane delivered by ventilation). In contrast, the FA/FI ratio for methoxyflurane has risen only 6.5%, thus indicating that 93.5% of the methoxyflurane delivered by ventilation is taken up.

The balance struck between ventilation and uptake does not remain constant. FA/FI continues to rise, albeit at a slower rate than seen in the first minute. This rise results from the progressive decrease in uptake by the VRG, a decrease to an inconsequential amount after 8 minutes. Thus, by about 8 minutes, three quarters of the cardiac output returning to the lungs (i.e., the blood from the VRG) contains nearly as much anesthetic as it did when it left the lungs. The consequent rise in venous anesthetic partial pressure decreases the alveolar-to-venous partial pressure difference and hence uptake, thereby allowing ventilation to drive the alveolar concentration upward to a second knee at roughly 8 minutes.

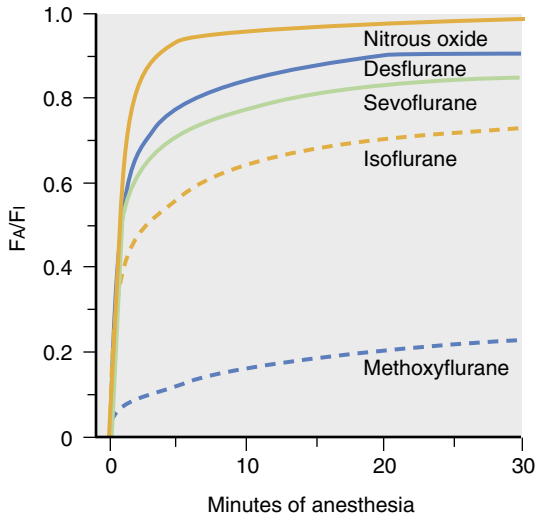

Figure 21-2 The rise in alveolar (FA) anesthetic concentration toward the inspired (FI) concentration is most rapid with the least soluble anesthetic, nitrous oxide, and slowest with the most soluble anesthetic, methoxyflurane. All data are from human studies. *(Data from Yasuda N, Lockhart SH, Eger EI II, et al: Kinetics of desflurane, isoflurane, and halothane in humans. Anesthesiology 74:489-498, 1991; and Yasuda N, Lockhart SH, Eger EI II, et al: Comparison of kinetics of sevoflurane and isoflurane in humans. Anesth Analg 72:316-324, 1991.)*

With the termination of effective uptake by the VRG, the MG and FG become the principal determinants of tissue uptake. The slow rate of change in the anesthetic partial pressure difference between arterial blood and MG or FG produces the gradual ascent of the terminal portion of the FA/FI ratio as the MG and, slower still, the FG progressively equilibrate with the arterial anesthetic partial pressure. If the graphs were extended for several hours, a third knee would be found that indicates equilibration of the MG. After that time, uptake would principally depend on the partial pressure gradient between arterial blood and fat.

The Concentration Effect

The previous analysis ignores the impact of the concentration effect on FA/FI. The inspired anesthetic concentration influences both the rate of rise and the height of the FA/FI ratio.[12] Increasing the inspired concentration accelerates the rate of rise. At an inspired concentration of 100%, the rate of rise is dictated solely by the rate at which ventilation washes gas into the lung; that is, at 100% inspired concentration, uptake no longer opposes the level to which FA/FI may rise. The cause of this extreme effect is readily perceived. At 100% inspired concentration, uptake of anesthetic creates a void that draws sufficient gas down the trachea to replace the gas taken up. Because the replacement gas concentration is 100%, uptake cannot modify the alveolar concentration. This explains why the rise in nitrous oxide shown in Figure 21-2 is more rapid than the rise in desflurane despite their nearly equal blood-gas partition coefficients: the nitrous oxide was given at an inspired concentration of 70%, whereas that of desflurane was 2%.

The concentration effect results from two factors, a concentrating effect and augmentation of inspired ventilation (Fig. 21-3).[13] The first rectangle (see Fig. 21-3A) represents a lung containing 80% (volumes per 100 volumes) nitrous oxide. If half this gas is taken up, the remaining 40 volumes exist in a total of 60 volumes, for a concentration of 67% (see Fig. 21-3B). That is, uptake of half the nitrous oxide does not halve the concentration because the remaining gases are "concentrated" in a smaller volume. If the void created by the uptake of 40 volumes is filled by drawing an equal volume of gas into the lungs (an augmentation of inspired ventilation), the final concentration equals 72% (see Fig. 21-3C).

This explanation has been criticized as being overly simplistic and ignoring the realities of some aspects of ventilation.[14] For example, if ventilation is controlled with a volume-limited respirator, an augmentation in inspired ventilation is limited to the period of the expiratory pause. Spontaneous ventilation minimizes this limitation. In any event, the reader needs to be aware that although Figure 21-3 describes the basic factors governing the concentration (and second gas effects—see the next section), the actual situation is more complex.

The impact of the concentration effect on FA/FI may be thought of as being identical to the impact of a change in solubility[15]: as the inspired concentration increases, the effective solubility decreases. Thus, at 50% inspired nitrous oxide, FA/FI rises as rapidly as the FA/FI of an anesthetic that has half the solubility of nitrous oxide and is given at a 1% inspired concentration, and 75% inspired nitrous oxide acts as an anesthetic given at 1% that has a quarter the solubility of nitrous oxide.

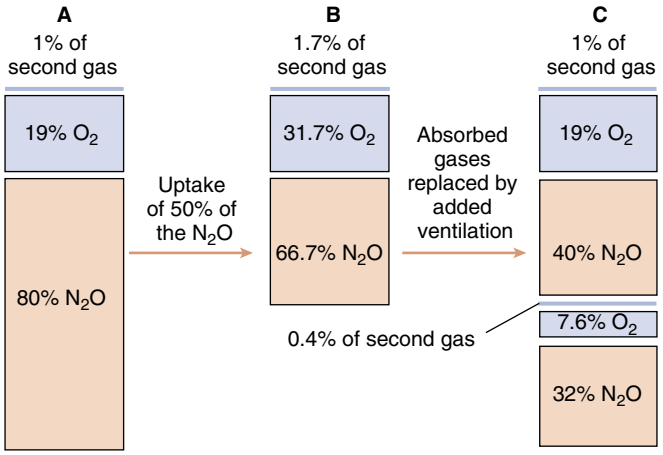

Figure 21-3 The rectangle to the left (**A**) represents a lung filled with 80% nitrous oxide plus 1% of a second gas. Uptake of 50% of the nitrous oxide does not halve the concentration of nitrous oxide (**B**) because the reduction in volume thereby increases its concentration, as well as the concentrations of all "second" gases (the oxygen and the second gas). Restoration of lung volume by the addition of gas with the same concentration as that introduced into the rectangle in **A** will increase the nitrous oxide concentration and add to the amount of second gas present in the lung (**C**). *(Modified from Stoelting RK, Eger EI II: An additional explanation for the second gas effect: A concentrating effect. Anesthesiology 30:273-277, 1969.)*

The Second Gas Effect

The factors that govern the concentration effect also influence the concentration of any potent anesthetic given concurrently.[13] The loss of volume associated with the uptake of nitrous oxide concentrates the potent anesthetic (see Fig. 21-3B). Replacement of the gas taken up by an increase in inspired ventilation augments the amount of potent anesthetic present in the lung (see Fig. 21-3C).

Experiments in dogs[16] and humans[17] demonstrate both the concentration and second gas effects. Humans given 4% desflurane with 5% or 65% nitrous oxide have a more rapid increase in FA/FI for both nitrous oxide and desflurane when 65% nitrous oxide is given (Fig. 21-4).[17]

Hendrickx and colleagues[18] confirmed the presence of the second gas effect but found, further, that the effect persists long after the majority of the uptake of nitrous oxide has ceased. They did not provide an explanation for this finding. An explanation would follow from an assumption of ventilation-perfusion abnormalities. Imagine that half the lung is poorly ventilated and the other half is well ventilated with both sides equally perfused. In the poorly ventilated half, uptake of oxygen will increase the concentration of nitrous oxide, possibly even above the inspired concentration. The increased concentration of nitrous oxide will augment its uptake and thus produce both factors that underlie the concentration and second gas effects (see Fig. 21-3). Furthermore, the half of the lung that is poorly ventilated is usually hypoventilated because of increased airway resistance. The increased airway resistance causes the poorly ventilated lung to empty last, which produces the characteristic upward sloping curve for expired carbon dioxide in patients with chronic obstructive pulmonary disease. Thus, the poorly ventilated lung would provide the increased recorded (literally the end-tidal) values for both nitrous oxide and the second gas.

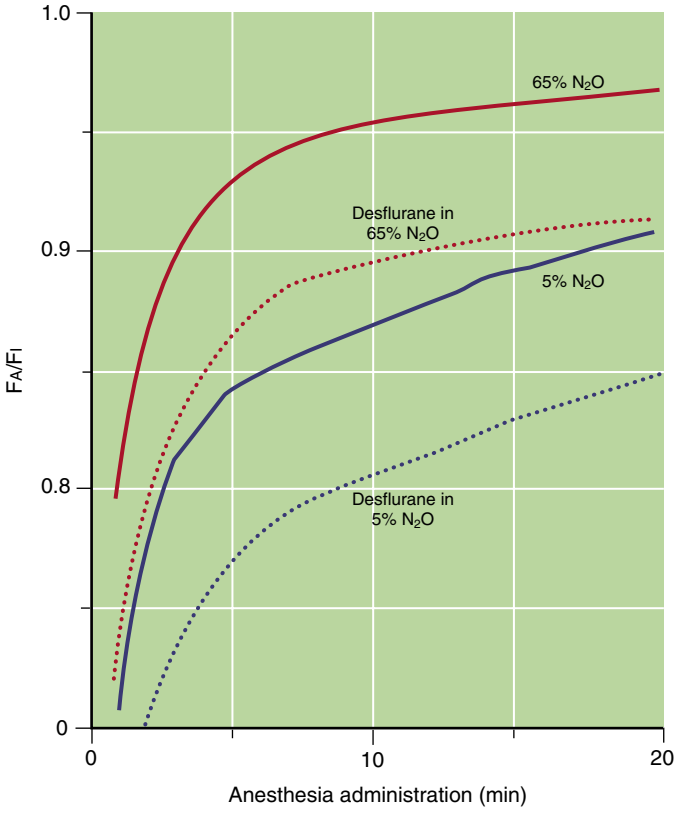

Figure 21-4 In humans, administration of 65% nitrous oxide produces a more rapid rise in the FA/FI ratio of nitrous oxide than does the administration of 5% (concentration effect, *continuous two curves*). The FA/FI ratio for 4% desflurane rises more rapidly when given with 65% nitrous oxide than when given with 5% (second gas effect, *dashed two curves*). *(Modified from Taheri S, Eger EI II: A demonstration of the concentration and second gas effects in humans anesthetized with nitrous oxide and desflurane. Anesth Analg 89:774-780, 1999.)*

Percutaneous and Visceral Anesthetic Loss

Anesthetics may be lost via three routes other than the lungs: (1) transcutaneous movement, (2) transvisceral movement, and (3) metabolism. Although transcutaneous movement does occur, such movement is small.[19-21] The greatest loss per alveolar anesthetic percent occurs with nitrous oxide. Loss of nitrous oxide might equal 5 to 10 mL/min with an alveolar concentration of 70%. Movement of anesthetic across visceral or pleural surfaces during abdominal or pulmonary surgery is greater than movement across skin, but such visceral losses are usually small relative to total uptake.[22]

Metabolism of Anesthetics

Although percutaneous loss of anesthetic may not appreciably affect anesthetic uptake, loss of anesthetic by biodegradation can significantly change uptake, particularly with agents that undergo extensive biodegradation. Carpenter and coworkers[23] found that as much as half of the halothane and three quarters of the methoxyflurane that are taken up undergo biodegradation. They speculated that such biodegradation could explain the finding that the alveolar concentration of halothane decays more rapidly on recovery from anesthesia than does the alveolar concentration of isoflurane, an anesthetic that is significantly less soluble in blood.[24,25] Two reasons suggest that agents such as isoflurane and desflurane are less likely to be affected: first, they are not metabolized as readily as halothane or methoxyflurane,[24,25] and second, anesthetizing concentrations appear to saturate the enzymes responsible for metabolism of the anesthetic.[26] Saturation of enzymes in particular may limit the impact of metabolism during the washin as opposed to the washout of anesthetic. The combined effect of these factors remains to be determined, but it appears that metabolism is not a significant determinant of FA/FI during anesthesia with isoflurane or desflurane.[10,11] A small influence on the kinetics of sevoflurane may exist and thus explain why there is a more substantial difference between the FA/FI for desflurane versus sevoflurane during induction and maintenance of anesthesia than for the parallel washout curves (F_A/F_{A_0}) during recovery.[11]

Intertissue Diffusion

Carpenter and associates[24] examined the washin and washout of isoflurane, enflurane, halothane, and methoxyflurane given simultaneously for fixed times to healthy young patients. Washout was examined for several days after discontinuation of administration of the anesthetics. Analysis suggested that a model with five compartments best explained the resulting data for all the anesthetics (i.e., the model was independent of solubility and metabolism of the anesthetics). Four of these compartments had half-times consistent with the model described earlier in this chapter: compartments related to washin and washout of the lungs, the VRG, the MG, and the FG.

The additional, fifth, compartment was more difficult to explain. This compartment had a half-time of roughly 300 minutes, which is between that for muscle and fat. This additional compartment was important because it accounted for almost a third of the anesthetic taken up. Part of the compartment could be explained by uptake by highly perfused fat, such as that found in bone marrow. However, perfusion of marrow fat alone could not account for the amount of uptake by this compartment. Carpenter and coauthors[24] speculated that this uptake resulted from diffusion of anesthetic from lean tissues to adjacent thin layers of fat tissue. Such diffusion could be from the heart to pericardial fat, from the kidney to perirenal fat, from the intestine to mesenteric and omental fat, and from the dermis to subcutaneous fat. Yasuda and coworkers[10,11] confirmed these findings and extended them to desflurane and sevoflurane.

Factors Modifying the Rate of Rise in FA/FI

Alteration of the factors that govern the rate of delivery of anesthetic to or removal from the lungs changes the alveolar concentration of anesthetic. We have seen the importance of differences in solubility (see Fig. 21-2). The succeeding sections examine the impact of differences in ventilation and circulation and the interaction of these differences with factors such as solubility.

The Effect of Ventilatory Changes

By augmenting delivery of anesthetic to the lungs, increased ventilation accelerates the rate of rise in FA/FI (Fig. 21-5).[1,27] A change in ventilation produces a greater relative change in FA/FI with a more soluble anesthetic. In Figure 21-5, a doubling of ventilation increases the methoxyflurane concentration at 10 minutes of anesthetic administration by 75%, increases the isoflurane concentration by 18%, and increases the desflurane concentration by only 6%.

The impact of solubility may be explained as follows. With a poorly soluble agent such as desflurane, FA/FI increases rapidly, even with hypoventilation. Because FA normally cannot exceed FI, there is little room for augmentation of ventilation to further increase FA/FI. With a highly soluble agent such as methoxyflurane, most of the anesthetic delivered to the lungs is taken up, so if uptake at 4-L/min ventilation equaled x, uptake at 8 L/min would approach 2x. Thus, if cardiac output is held constant, ventilation at 8 L/min produces an arterial methoxyflurane concentration that is nearly twice the concentration produced by ventilation at 4 L/min. Because arterial and alveolar concentrations are in equilibrium, our example suggests that doubling ventilation must nearly double the concentration of a highly soluble anesthetic in the alveoli or blood.

These observations imply that imposed alterations in ventilation (e.g., an increase produced by conversion from spontaneous to controlled ventilation) produce greater changes in anesthetic concentration (and thus effect) with more soluble agents. Because such effects include both anesthetic depth and depression of circulation, greater caution must be exercised when ventilation is augmented during anesthesia produced with a highly soluble agent.

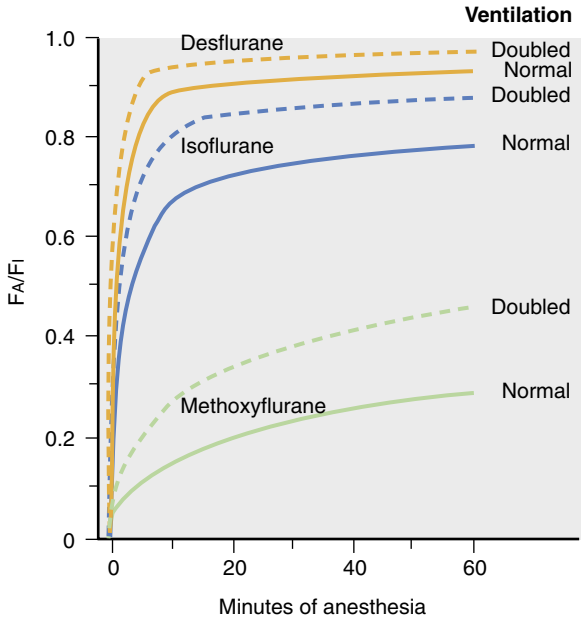

Figure 21-5 The FA/FI ratio rises more rapidly if ventilation is increased, in this case doubled. Solubility modifies this impact of ventilation: the effect on the anesthetizing partial pressure is greatest with the most soluble anesthetic (methoxyflurane) and least with the least soluble anesthetic (desflurane). *(Derived from simulations using GAS MAN from Philip JH: GAS MAN Computer Program. Chestnut Hill, MA, Med Man Simulations, Inc., 2002.)*

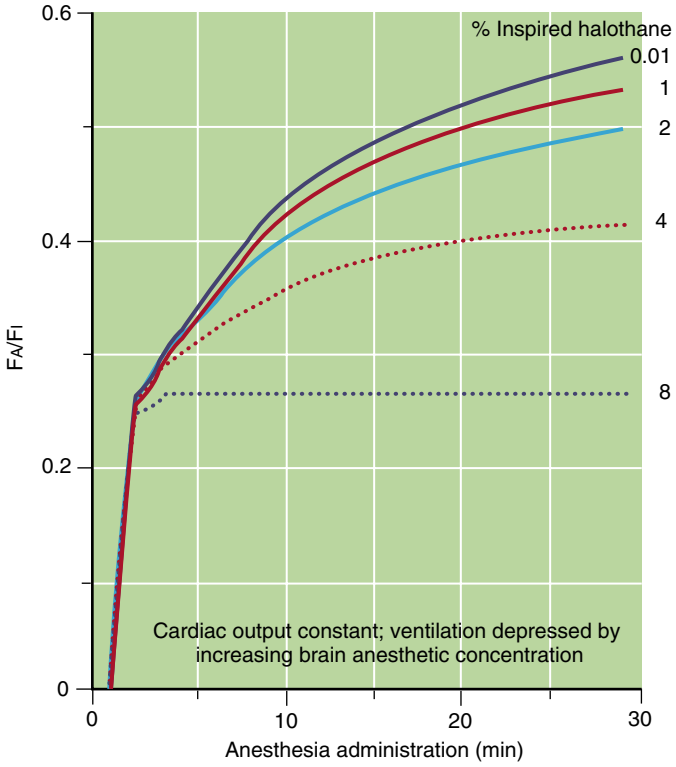

Figure 21-6 An increase in the inspired halothane concentration does not produce a proportional increase in the alveolar concentration because of the progressively greater depression of ventilation that occurs as alveolar halothane is increased. The initial "overshoot" seen with 10% to 20% inspired halothane results from the delay in transfer of alveolar halothane partial pressure to the brain (i.e., time must pass before the brain receives and is depressed by the very great concentrations attained in the lungs). *(From Munson ES, Eger EI II, Bowers DL: Effects of anesthetic-depressed ventilation and cardiac output on anesthetic uptake. Anesthesiology 38:251-259, 1973.)*

Anesthetics themselves may alter ventilation and thereby alter their own uptake.[9,28] Modern potent agents (desflurane, halothane, isoflurane, sevoflurane) are profound respiratory depressants whose capacity to depress ventilation is directly related to anesthetic dose.[29-32] At some concentration, all inhaled anesthetics probably produce apnea, a feature that must limit the maximum alveolar concentration (MAC) that can be obtained with spontaneous ventilation.

Thus, administration of an anesthetic concentration that produces significant respiratory depression decreases delivery of anesthetic to the alveoli.[9,33] As a result, doubling the inspired concentration does not double the alveolar concentration attained at a given point in time. At high inspired concentrations, further increases in inspired concentration produce little absolute change in alveolar concentration (Fig. 21-6). Anesthetics can thereby exert a negative-feedback effect on their own alveolar concentration, an effect that increases the safety of spontaneous ventilation by limiting the maximum concentration that is attained in the alveoli.

The Effect of Changes in Cardiac Output

The previous section assumed constant cardiac output and examined the effect of changes in ventilation; in this section we assume constant ventilation and examine the effect of changes in cardiac

output. An increase in cardiac output augments uptake and thereby hinders the rise in FA/FI.[1,33] As with a change in ventilation, a change in cardiac output affects the alveolar concentration of a poorly soluble agent less than it does the alveolar concentration of a highly soluble agent (Fig. 21-7). The reason for the impact of a change in solubility is similar to the reason explaining the effect of a change in ventilation. A decrease in cardiac output can do little to increase the FA/FI ratio of a poorly soluble agent because the rate of rise is rapid at any cardiac output. In contrast, nearly all of a highly soluble agent is taken up, and a halving of blood flow through the lungs must concentrate the arterial (equals alveolar) anesthetic, nearly doubling its partial pressure in the case of an extremely soluble agent.

This effect of solubility suggests that conditions that lower cardiac output (e.g., shock) will increase alveolar anesthetic concentrations more with anesthetics that have greater solubility. The higher FA/FI ratio should be anticipated and the inspired anesthetic concentration should be lowered accordingly to avoid further circulatory depression. Because shock tends to increase ventilation and decrease cardiac output, it presents a two-pronged problem: an increase in ventilation and a decrease in cardiac output accelerate the rise in FA/FI. Perhaps this is an argument for the use of nitrous oxide in patients in shock. In contrast to more soluble anesthetics (e.g., isoflurane), the alveolar concentration of nitrous oxide would be little influenced by the associated cardiorespiratory changes.

Anesthetics also affect the circulation. They can depress cardiac output.[34] In contrast to the negative feedback that results from respiratory depression, circulatory depression produces a positive feedback: depression decreases uptake, and this increases the alveolar concentration, which in turn further decreases uptake.

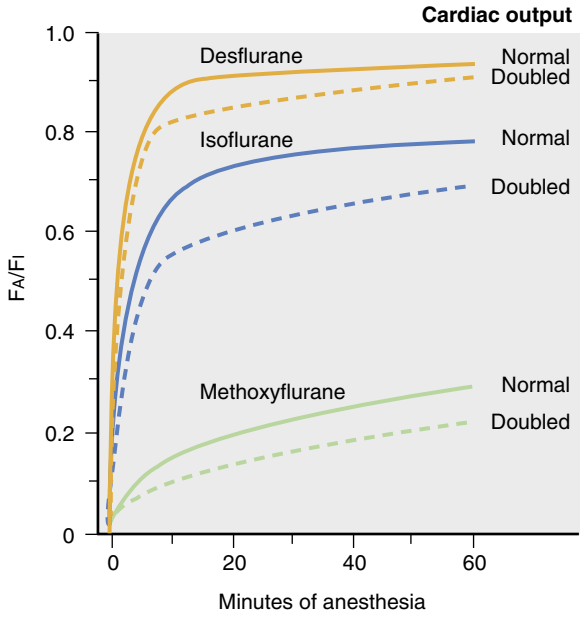

Figure 21-7 If unopposed by a concomitant increase in ventilation, an increase in cardiac output will decrease alveolar anesthetic concentration by augmenting uptake. The resulting alveolar anesthetic change is proportionately greatest (i.e., as a fraction of the "normal" curve; the "doubled" curve is least) with the most soluble anesthetic. *(Derived from simulations using GAS MAN from Philip JH: GAS MAN Computer Program. Chestnut Hill, MA, Med Man Simulations, Inc., 2002.)*

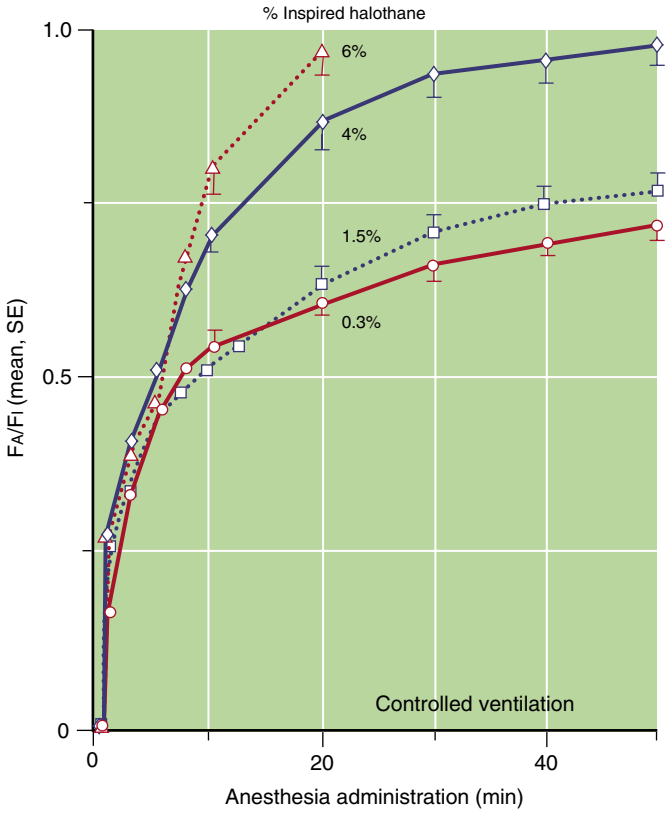

Figure 21-8 Dogs given constant ventilation demonstrate different rates of rise in FA/FI. The rates of rise depend on the inspired halothane concentration. The two greatest concentrations accelerate the rate of rise by depressing cardiac output and thereby decreasing uptake. *(Modified from Gibbons RT, Steffey EP, Eger EI II: The effect of spontaneous versus controlled ventilation on the rate of rise of alveolar halothane concentration in dogs. Anesth Analg 56:32-34, 1977.)*

A potentially lethal acceleration of the rise in FA/FI results from the depression of cardiac output (Fig. 21-8).[9,28,35] The impact of this acceleration increases in importance with increasing anesthetic solubility.

The Effect of Concomitant Changes in Ventilation and Perfusion

The preceding considerations of the effects of ventilatory and circulatory alterations presume that one variable changed while the other remained constant. In fact, both may change concomitantly. If both ventilation and cardiac output increase proportionately, an intuitive expectation might be that FA/FI would not be altered. After all, uptake equals the product of solubility, cardiac output, and the alveolar-to-venous anesthetic partial pressure difference (see the anesthetic uptake equation earlier). In the absence of other changes, doubling cardiac output doubles uptake, and this should exactly balance the influence of doubling of ventilation on FA/FI. That is, a doubling of both delivery of anesthetic to the lungs and removal of anesthetic from the lungs should produce no net change in alveolar concentration.

This reasoning ignores one other factor in the equation that defines uptake. An increase in cardiac output increases tissue blood flow and thereby accelerates the rate at which tissue equi-

libration occurs. Thus, an increase in cardiac output accelerates the narrowing of the alveolar-to-venous partial pressure difference[36] and consequently reduces the impact of the increase in cardiac output on uptake. The net result is that a proportional increase in ventilation and cardiac output increases the rate of rise in FA/FI.

The magnitude of acceleration of the rise in FA/FI depends in part on the distribution of the increase in cardiac output. If the increase is distributed proportionately to all tissues (e.g., if a doubling of output doubles flow to all tissues), the increase is fairly small (Fig. 21-9).[36,37] Thus, conditions such as hyperthermia and thyrotoxicosis only slightly influence the development of an anesthetizing anesthetic concentration through their influence on FA/FI. However, if the increase in cardiac output is diverted to the VRG, a greater effect is seen. Perfusion of the VRG is normally high and the VRG normally equilibrates rapidly. Further increases in perfusion can hasten the rate of equilibration, but the process is rapid for both normal and accelerated equilibration. Because blood returning from the VRG soon has the same partial pressure that it had leaving the lungs, it cannot remove more anesthetic from the lungs. Thus, after a few minutes, the increase in ventilation is not matched, even in part, by an increase in uptake. The result is a considerable acceleration in the rise in FA/FI. This effect may be seen in a comparison of the FA/FI curves for children and adults (Fig. 21-10). Children (especially infants) have relatively greater perfusion of the VRG and consequently show a significantly faster rise in FA/FI.[6,38,39] A clinical result of this accelerated rise is more rapid development of anesthesia in young patients. The higher perfusion of the brain further accelerates the development of anesthesia.

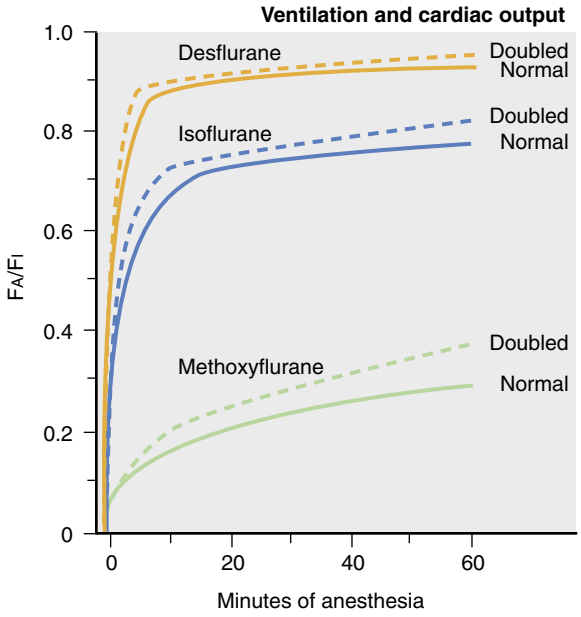

Figure 21-9 Proportional increases in alveolar ventilation (VA) and cardiac output (Q) will increase the rate at which FA/FI rises.[37] As indicated in the illustration, the effect is relatively small if the increase in cardiac output is distributed proportionately to all tissues (i.e., if cardiac output is doubled, all tissue blood flows are doubled). The greatest effect occurs with the most soluble anesthetic. *(Derived from simulations using GAS MAN from Philip JH: GAS MAN Computer Program. Chestnut Hill, MA, Med Man Simulations, Inc., 2002.)*

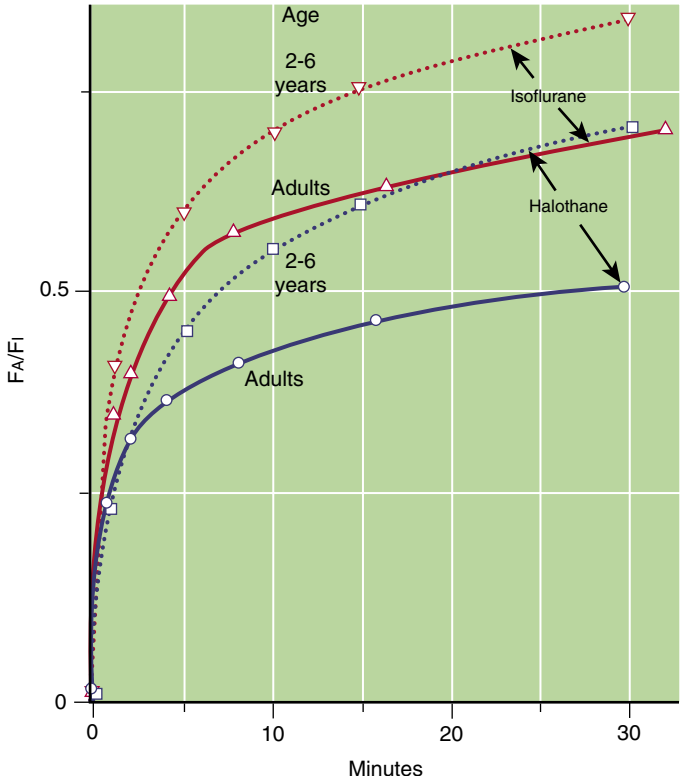

Figure 21-10 The alveolar rate of rise in halothane is more rapid in children (*upper curve*) than in adults (*lower curve*). The difference probably results from the greater ventilation and perfusion per kilogram of tissue in children and the fact that a disproportionate amount of the increased perfusion is devoted to the vessel-rich group. *(Modified from data from several sources.[6,38,39])*

Ventilation-Perfusion Abnormalities

Up to this point I have assumed that alveolar and arterial anesthetic partial pressures are equal (i.e., that the alveolar gases completely equilibrate with the blood passing through the lungs). For normal patients, this assumption is approximately correct, but diseases such as emphysema and atelectasis, as well as congenital cardiac defects, produce substantial deviations in equilibration. The associated abnormality in the ventilation-perfusion ratio does two things: (1) it increases the alveolar (end-tidal) anesthetic partial pressure and (2) it decreases the arterial anesthetic partial pressure (i.e., a partial pressure difference appears between alveolar gas and arterial blood). The relative change depends on the solubility of the anesthetic. With a poorly soluble agent, the end-tidal concentration is slightly increased, but the arterial partial pressure is significantly reduced. The opposite occurs with a highly soluble anesthetic.[40]

The considerable decrease in arterial anesthetic partial pressure that occurs with poorly soluble agents may be explained as follows. Abnormalities in the ventilation-perfusion ratio increase ventilation relative to perfusion of some alveoli, whereas in other alveoli, the reverse occurs. With a poorly soluble anesthetic, an increase in ventilation relative to perfusion does not appreciably increase the alveolar or arterial anesthetic partial pressure issuing from those alveoli (see effect for desflurane in

Fig. 21-5). However, when ventilation decreases relative to perfusion, a significant effect can occur, particularly when ventilation is absent, as in a segment of atelectatic lung. Blood emerges from that segment with no additional anesthetic. Such anesthetic-deficient blood then mixes with blood from the ventilated segments containing a normal complement of anesthetic. The mixture produces an arterial anesthetic partial pressure that is considerably below normal.

With highly soluble agents, a different situation results from similar abnormalities in the ventilation-perfusion ratio. In alveoli receiving more ventilation relative to perfusion, the anesthetic partial pressure rises to a higher level than usual (see Fig. 21-5 for effect with methoxyflurane). That is, blood issuing from these alveoli has an increased anesthetic content, the increase being nearly proportional to the increased ventilation. Assuming that overall (total) ventilation remains normal, this increase in the anesthetic contained by blood from the relatively hyperventilated alveoli compensates for the lack of uptake of anesthetic in unventilated alveoli.

These effects are illustrated in Figure 21-11 for a condition that may be iatrogenically produced, endobronchial intubation.

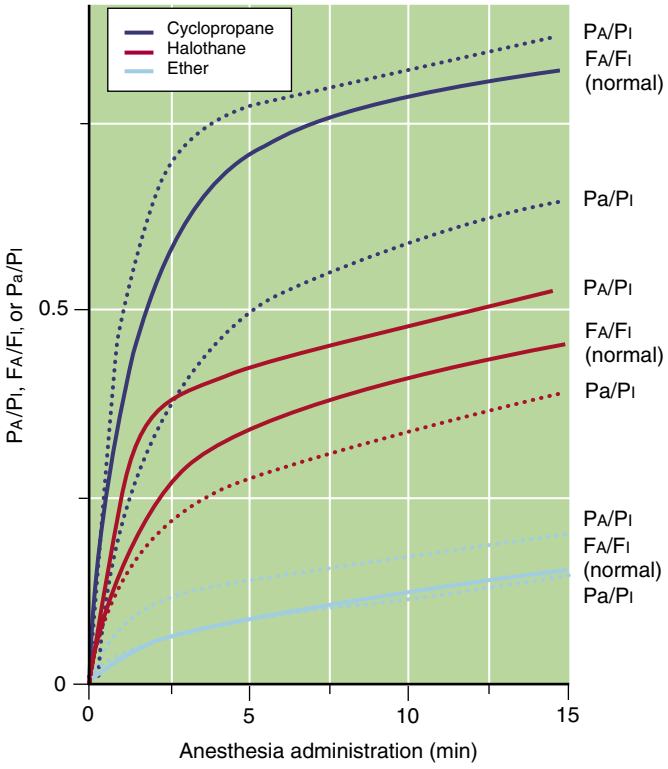

Figure 21-11 When no ventilation-perfusion abnormalities exist, the alveolar (P_A or P_{ET}) and arterial (Pa) anesthetic partial pressures rise together (*continuous lines*) toward the inspired partial pressure (P_I). Shunting of 50% of cardiac output through the lungs accelerates the rate of rise in end-tidal partial pressure (*dashed lines*) and retards the rate of rise in arterial partial pressure (*dot-dashed lines*). The greatest retardation of the rise in P_a/P_I is found with the least soluble anesthetic, cyclopropane, and the least with the very soluble anesthetic ether. *(From Eger EI II, Severinghaus JW: Effect of uneven pulmonary distribution of blood and gas on induction with inhalation anesthetics. Anesthesiology 25:620-626, 1964.)*

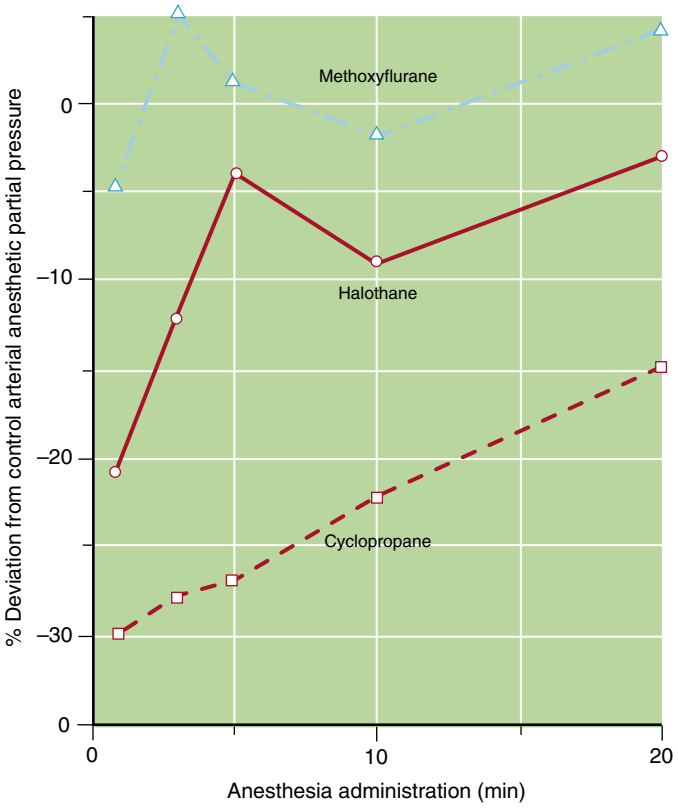

Figure 21-12 In dogs, when only the right lung was ventilated, the increase in the very soluble anesthetic methoxyflurane in arterial blood was normal (i.e., did not deviate from control), whereas the increase in the poorly soluble anesthetic cyclopropane (a blood-gas partition coefficient similar to that of sevoflurane) was significantly slowed. *(From Stoelting RK, Longnecker DE: Effect of right-to-left shunt on rate of increase in arterial anesthetic concentration. Anesthesiology 36:352-356, 1972.)*

Because all ventilation is now directed to the intubated lung, this lung is hyperventilated relative to perfusion. F_A/F_I for this lung is slightly increased (above that obtained in the absence of endobronchial intubation) with the poorly soluble cyclopropane (solubility similar to that of sevoflurane) and greatly increased with the highly soluble ether. As indicated earlier, the increase with ether compensates for the absence of uptake from the unventilated lung, a compensatory mechanism that is not available with cyclopropane. The result is that the arterial partial pressure of cyclopropane is well below normal, whereas the arterial partial pressure of ether is scarcely changed.

These concepts have been confirmed experimentally by comparing the rate of rise in arterial anesthetic with and without endobronchial intubation in dogs.[41] Endobronchial intubation significantly slowed the arterial rate of rise in cyclopropane but did not influence the rise with methoxyflurane. An intermediate result was obtained with halothane (Fig. 21-12). These data suggest that in the presence of ventilation-perfusion ratio abnormalities, the anesthetic effect of agents such as nitrous oxide, desflurane, and sevoflurane may be delayed more than the anesthetic effect of isoflurane.

The Effect of Nitrous Oxide on Closed Gas Spaces

Volume Changes in Highly Compliant Spaces

During the course of anesthetic administration, appreciable volumes of nitrous oxide can move into closed gas spaces. Although such transfer does not influence FA/FI, it may have important functional consequences. There are two types of closed gas spaces in the body, those enclosed by compliant walls and those enclosed by noncompliant walls. The former (bowel gas, pneumothorax, pneumoperitoneum, or air emboli) are subject to changes in volume secondary to transfer of nitrous oxide into these spaces.[42] These spaces normally contain nitrogen (from air), a gas whose low solubility (blood-gas partition coefficient of 0.015) limits its removal by blood. The far greater solubility of nitrous oxide in blood (blood-gas partition coefficient of 0.47) enables blood to carry more nitrous oxide to the enclosed space than it can carry away nitrogen, and the result is an increase in volume. The theoretical limit to the increase in volume is a function of the alveolar nitrous oxide concentration because this is the concentration ultimately achieved in the closed gas space. That is, at equilibrium, the concentration of nitrous oxide in the closed gas space must equal its concentration in the alveoli. An alveolar concentration of 50% might double the gas space volume, and a 75% concentration might produce a fourfold increase.

These theoretical limits may be approached if equilibrium is achieved rapidly, as with pneumothorax or gas emboli. Administration of 75% nitrous oxide in the presence of pneumothorax may double the volume of the pneumothorax by 10 minutes and may triple it by 30 minutes (Fig. 21-13).[42] Because this increase in volume may seriously impair cardiorespiratory function,[43] the use of nitrous oxide is contraindicated in the presence of a significant pneumothorax.

A still more rapid expansion of volume occurs if air inadvertently enters the bloodstream in a patient anesthetized with nitrous oxide. Expansion may be complete in seconds rather than minutes. The volume of an air embolus that is lethal decreases in animals breathing nitrous oxide as opposed to air,[44] doing so by an amount that would be predicted from the maximum theoretical expansion (Fig. 21-14). These results suggest caution in the use of nitrous oxide for procedures in which air embolization is a risk (e.g., posterior fossa craniotomies, laparoscopy). They also suggest that if air embolization is suspected, administration of nitrous oxide should be discontinued immediately. Conversely, a nitrous oxide "challenge" may be used to test whether air embolization has occurred.[45]

An endotracheal tube cuff filled with air is also susceptible to expansion by nitrous oxide[46]; 75% nitrous oxide surrounding such a cuff can double or triple the volume of the cuff. The result may be an unwanted increase in pressure exerted on the tracheal mucosa. Similarly, nitrous oxide may expand the cuffs of balloon-tipped (e.g., Swan-Ganz) catheters[47] when the balloons are inflated with air. The expansion is rapid, and a doubling of volume may occur within 10 minutes, a concern if the cuff lies within the pulmonary artery. Finally, entry of nitrous oxide into the air-filled cuff of a laryngeal mask airway can increase the volume and pressure of gas within the cuff.[48]

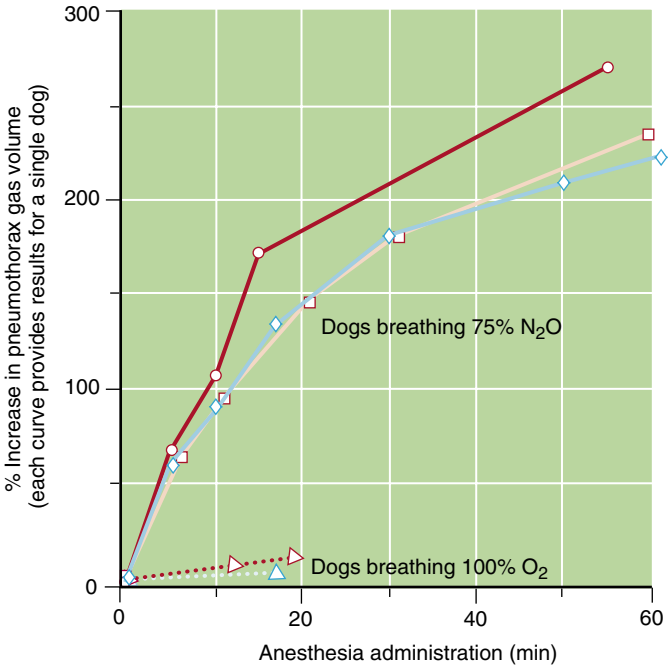

Figure 21-13 The volume of a pneumothorax created by air injection is little affected when oxygen is subsequently breathed (*filled triangle* and *circles*). However, if 75% nitrous oxide is breathed, the volume doubles in 10 minutes and triples in a half-hour (*open circles*, *squares*, and *triangles*). *(From Eger EI II, Saidman LJ: Hazards of nitrous oxide anesthesia in bowel obstruction and pneumothorax. Anesthesiology 26:61-66, 1965.)*

Pressure Changes in Poorly Compliant Spaces

Entrance of nitrous oxide into gas cavities surrounded by poorly compliant walls can increase intracavity pressure. Administration of nitrous oxide may impose untoward increases in intraocular pressure after intravitreal injection of sulfur hexafluoride.[49] Other examples include the gas space created by pneumoencephalography (now rare as a deliberate procedure) and the natural gas space in the middle ear. Pressure in the head or middle ear may rise by 20 to 50 mm Hg because of the ingress of nitrous oxide.[50,51] Recognition of this problem has decreased the use of nitrous oxide for tympanoplasty because the increased pressure may displace the graft. An increase in middle ear pressure may cause adverse postoperative effects on hearing.[52] The capacity of nitrous oxide to expand the gas in the middle ear has also been used to elevate an adherent atelectatic tympanic membrane off the promontory and ossicles.[53]

Anesthetic Circuitry

The previous discussions generally considered that the alveolar anesthetic concentration (FA) was moving toward a constant inspired anesthetic concentration (FI). In practice, the inspired concentration is not usually constant because a non-rebreathing system is not used. The rebreathing that results from the use of an anesthetic circuit causes the inspired concentration to be less than that in the gas delivered from the anesthetic machine. The

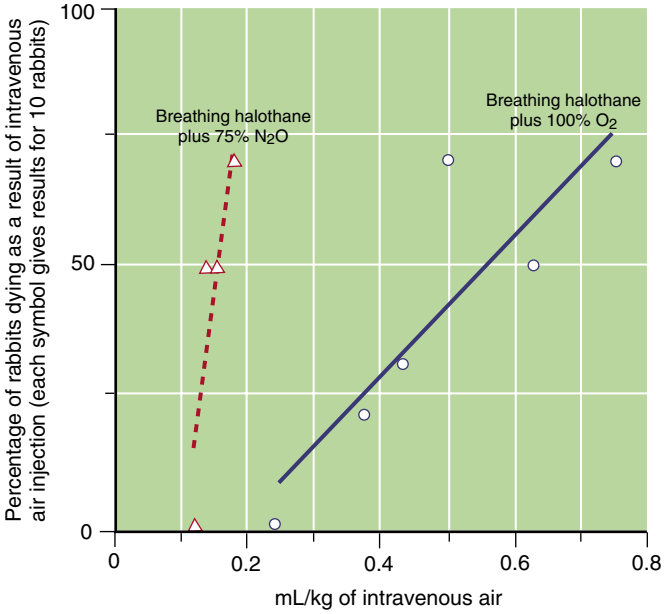

Figure 21-14 An intravenous air embolus equaling 0.55 mL/kg administered to rabbits killed half the rabbits when they breathed oxygen. If they breathed 75% nitrous oxide, only 0.16 mL/kg was required to kill half the animals. *(Modified from Munson ES, Merrick HC: Effect of nitrous oxide on venous air embolism. Anesthesiology 27:783-787, 1966.)*

inspired concentration is thus influenced by the delivered concentration, by the need to "wash in" the circuit, and by the depletion of anesthetic in rebreathed gases produced by uptake of anesthetic.

Washin of the Circuit

To begin anesthesia, anesthetic must be washed into the volume of the circuit. At inflow rates of 1 to 5 L/min and a circuit volume of 7 L (3-L bag, 1-L carbon dioxide absorber, 1 L of various fittings, and 2 L of corrugated hoses), washin of the circuit is 75% to 100% complete in 10 minutes (Fig. 21-15). Higher inflow rates accelerate the rise in inspired concentration, which suggests that induction can be accelerated and made more predictable with the use of high inflow rates.

Loss of Anesthetic to Plastic and Soda Lime

Uptake of anesthetic by several circuit components can also constitute a hindrance to the development of an adequate inspired anesthetic concentration. The rubber or plastic components of the circuit could remove significant amounts of some older anesthetics. However, uptake of nitrous oxide, desflurane, or sevoflurane by circuit components is too insignificant to materially hinder development of the inspired anesthetic concentration.[54,55]

Older normal (moist) carbon dioxide absorbents (e.g., soda lime) containing 13% to 15% water can degrade sevoflurane and thereby slightly increase requirements for sevoflurane.[56] Degradation removes hydrogen fluoride and produces an unsaturated compound (compound A). Nitrous oxide, desflurane, and isoflurane are not materially degraded. Degradation of sevoflurane has been a concern because compound A is nephrotoxic.[57] However, toxicity results only from prolonged sevoflurane administration at high concentrations and appears to require degradation by the obsolete absorbent Baralyme.[58] Some new absorbents, those lacking monovalent bases (e.g., NaOH), do not degrade sevoflurane.[59]

In contrast to normal (moist) carbon dioxide absorbents, older desiccated absorbents materially degrade all potent inhaled anesthetics.[60] Desiccated older absorbents degrade all anesthetics containing the CHF_2-O- moiety (i.e., desflurane and isoflurane) to carbon monoxide.[60] Degradation by soda lime is minimal at hydrations approximately 10% or greater than those found in normal soda lime.[60] Some new absorbents (again, those lacking monovalent bases) do not produce clinically important concentrations of carbon monoxide, even when completely dry.[61]

The Effect of Rebreathing

Inspired gas contains two gases: that delivered from the anesthetic machine and that previously exhaled by the patient and subsequently rebreathed. Because the patient removes (takes up) anesthetic from the rebreathed gas, the amount taken up and the amount rebreathed influence the inspired anesthetic concentration. An increase in uptake or rebreathing lowers the inspired concentration of a highly soluble gas more than the inspired concentration of a poorly soluble gas. This effect of uptake can be diminished by increasing the inflow rate to decrease rebreathing. An inflow rate that equals or exceeds minute ventilation eliminates rebreathing.[62]

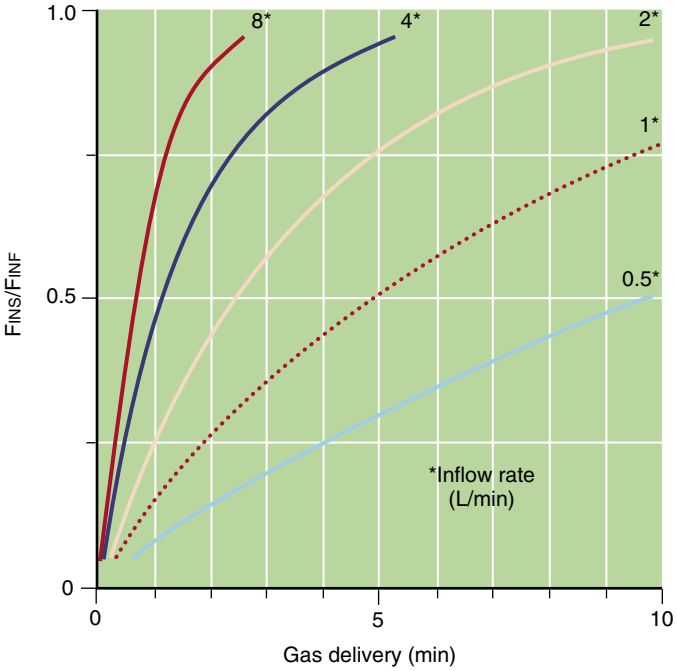

Figure 21-15 The inflow rate and circuit volume determine the rate at which the inspired anesthetic concentration (FINS) rises toward the inflowing concentration (FINF). In the case illustrated here, the circuit volume is 7 L. *(From Eger EI II: Effect of anesthetic circuit on alveolar rate of rise.* In *Eger EI [ed]: Anesthetic Uptake and Action. Baltimore, Williams & Wilkins, 1974, pp 192-205.)*

High inflow rates (i.e., ≥5 L/min) have the advantage of increasing the predictability of the inspired anesthetic concentration but the disadvantages of being wasteful and increasing atmospheric pollution. High inflow rates may be unacceptably costly because they increase consumption of expensive volatile anesthetics. High inflow rates may also dry inspired gas and make it difficult to estimate ventilation from excursions of the rebreathing bag. These several disadvantages prompt the use of low inflow rates.

Low-Flow or Closed-Circuit Delivery of Anesthesia

Much of the previous discussion assumed the use of a nonrebreathing system and a fixed inspired concentration of anesthetic. Although this approach does not invalidate the principles described earlier, it also does not reflect the variety of approaches applied in practice. Practice often deviates in two ways: (1) most anesthetists use lower inflow (fresh gas flow) rates to provide more economical delivery of anesthesia (Fig. 21-16), and (2) most anesthetists apply a constant alveolar rather than a constant inspired concentration because a constant alveolar concentration more closely reflects a constant level of anesthesia.

A low inflow rate provides several advantages and a few disadvantages, the latter particularly applying to kinetics. The advantages of low-inflow administration (defined as fresh gas flow of less than half the minute volume, usually less than 3 L/min) or closed-circuit anesthesia (defined as delivery of gases in amounts sufficient to replace only the gases—oxygen and anesthetic—removed by the patient) include lower cost, increased humidification, reduced heat loss, decreased release of anesthetic to the environment, and better capacity to assess physiologic variables such as ventilation. On the debit side, one must be more concerned about oxygen levels (especially if nitrous oxide is used because the patient also contributes nitrogen from stores in the body, and such nitrogen can slightly decrease the inspired concentration of oxygen). However, the debit of most immediate concern is the lack of control that low flow and especially closed circuits offer.

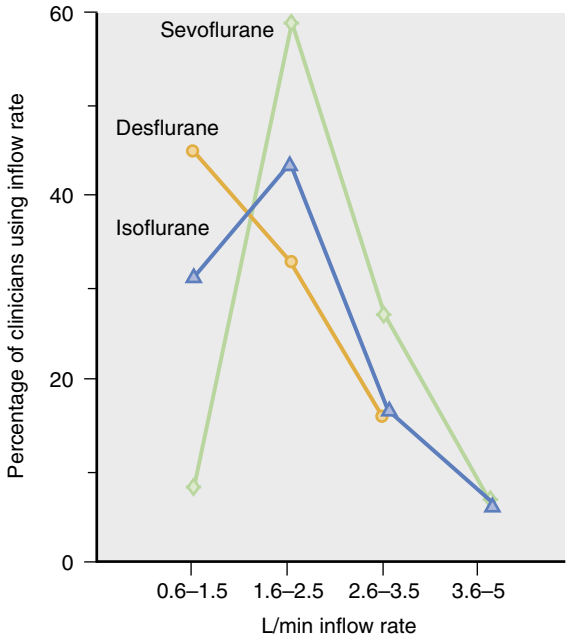

Figure 21-16 In 2005, anesthetists were surveyed regarding the inflow rates that they commonly used for maintenance of anesthesia. The responses varied broadly, but the majority used low-flow systems in which inflow rates of 2 L/min or less were applied. *(Unpublished data from Inform Research Flow Rate Tracking Study, May 2005, supplied as a personal communication by Baxter Healthcare Corp. to E. I. Eger II.)*

Closed-Circuit Anesthesia

Use of a closed circuit represents an extreme of anesthetic administration, one infrequently used because few systems completely eliminate leakage of gas from the circuit. Indeed, anesthetists often draw off approximately 200 mL/min for analysis of oxygen, carbon dioxide, and anesthetic levels.

Usually, closed-circuit anesthesia requires replacement of three gases: (1) oxygen, (2) nitrous oxide, and (3) a potent volatile anesthetic. Each replacement implies somewhat different considerations. Oxygen replacement remains constant unless metabolism changes as a result of a sympathetic response to stimulation, alteration in body temperature, or shivering. Replacement of nitrous oxide follows a fairly predictable course, in part because the concentration applied does not usually vary. Furthermore, nitrous oxide is the least soluble of anesthetics, especially in fat, and is the most prone to percutaneous loss (a constant value). Of most interest and potential variability is uptake of the potent inhaled anesthetics.

Uptake of potent anesthetics may be estimated from the values (constants) obtained by Yasuda and colleagues[10,11] in human volunteers. These values may be applied to achieve uptake at a constant alveolar concentration. To provide an appropriate level for comparison, I have assumed an alveolar concentration equal to MAC. The resulting figure (Fig. 21-17) reveals parallel shapes for each anesthetic, shapes dictated by the perfusion and solvent characteristics of the three major tissue compartments (plus intertissue diffusion). Thus, the large initial uptake rapidly decreases to a much lower level in 5 to 10 minutes as a result of the high initial uptake in the VRG (high because of its large perfusion) and the rapid decrease in uptake imposed by a short time constant (the time constant is obtained by taking the ratio of the capacity of a system to the flow through the system; it is useful in that it indicates the time for a 63% change to take place in the system). The subsequent slower decrease primarily results from the longer time constant of the MG, which dominates this period until its uptake declines below that provided by fourth compartment and the FG.

Although the curves for each anesthetic do not differ in shape, they differ in position. The height of each curve (i.e., uptake) is directly proportional to two factors: solubility and MAC. This relationship tends to minimize differences among anesthetics because solubility and MAC tend to move inversely. For example, although the MAC for desflurane is five times that for isoflurane, its uptake is less than twice that of isoflurane because of its lower solubility in blood and tissues.

Uptake may be estimated from the "square-root-of-time rule," first proposed by Severinghaus[63] and expanded greatly by

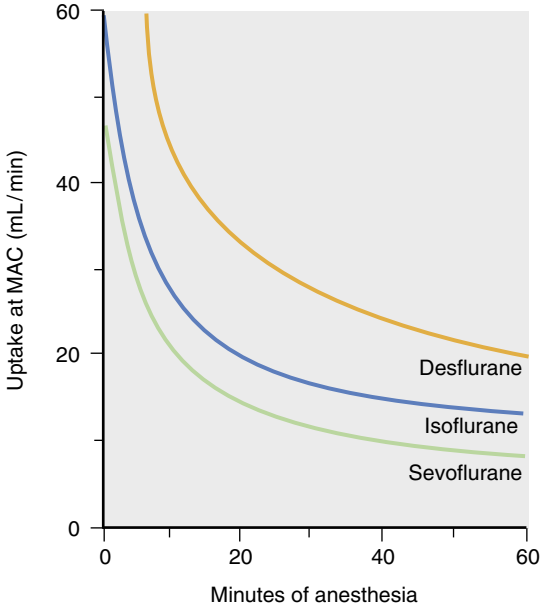

Figure 21-17 The uptake (in milliliters per minute), as illustrated in this graph, resulted from the application of constants calculated by Yasuda and coworkers[10,11] from their measurements in human volunteers. The application also assumed that alveolar concentration equals the minimum alveolar concentration (MAC) required to produce immobility in 50% of patients subjected to a surgical incision. Uptake is a function of both MAC and solubility of the anesthetic in blood and tissues. Thus, the fivefold higher MAC for desflurane than isoflurane is offset by a threefold lower solubility, which produces less than a twofold difference in uptake at any point in time. Uptake for all anesthetics initially declines rapidly as a function of the rate at which the vessel-rich group equilibrates. The further decline after 5 to 10 minutes is a function of the approach to equilibration of the muscle group. *(Data from Yasuda N, Lockhart SH, Eger EI II, et al: Kinetics of desflurane, isoflurane, and halothane in humans. Anesthesiology 74:489-498, 1991; and Yasuda N, Lockhart SH, Eger EI II, et al: Comparison of kinetics of sevoflurane and isoflurane in humans. Anesth Analg 72:316-324, 1991.)*

Lowe and Ernst[64] in their classic description of closed-circuit anesthesia. This rule states that uptake at any point in time may be estimated as uptake during the first minute of anesthesia divided by the square root of time in minutes. Making certain assumptions permits an estimate of uptake during the first minute. In general, uptake equals the product of blood solubility, cardiac output, and alveolar-to-venous anesthetic partial pressure difference. Several sources supply standard values for solubility and cardiac output, and the alveolar-to-venous anesthetic partial pressure difference may be estimated if we determine what alveolar partial pressure we wish and assume that the venous anesthetic partial pressure is inconsequential. At the start of anesthesia, an inconsequential venous partial pressure is reasonable because no anesthetic can appear in venous blood before recirculation (about 30 seconds), and even the anesthetic that appears is small in amount because tissue uptake is maximal during the first minute. Thus, we might estimate isoflurane uptake in a normal adult as $1.4 \times 5400 \times 0.0115$, or 87 mL, where 1.4 is the blood-gas partition coefficient, 5400 is cardiac output, and 0.0115 is MAC as a fraction of 1 atm. By 4 minutes, uptake would equal 87 mL/2; by 9 minutes, 87 mL/3; and by 64 minutes, 87 mL/8.

Hendrickx and associates[65] questioned the accuracy of the square-root-of-time rule and suggested that the rule overestimates the decrease in uptake with the passage of time. This author[66] considered whether the evidence provided by Hendrickx and colleagues overturned the square-root-of-time rule, and the matter continues to be debated.

Replacement of the anesthetic taken up may be accomplished by infusion of liquid anesthetic directly into the anesthetic circuit, either continuously or as boluses. Bolus injection from a syringe has an elegant simplicity but two disadvantages: (1) the circuit concentration modestly oscillates, and (2) the anesthetist is required to remember when and how much to inject. An alternative solution applies a variable bypass (Tec-type) vaporizer, one capable of accurate delivery of a range of concentrations at low inflow rates (e.g., 200 mL/min). This solution may not be applicable in the initial delivery of anesthesia because the demand for vapor may exceed the capability of presently available vaporizers. For example, the maximum output of a conventional isoflurane vaporizer is 5%, and at a 200-mL/min flow of oxygen, only approximately 10 mL of isoflurane vapor can be produced per minute, far less than the 87 mL estimated earlier. Even after 1 hour of anesthesia, an isoflurane vaporizer is barely capable of meeting the demand for anesthetic (Fig. 21-18A). This difficulty may be overcome in several ways. If a concentration less than MAC is acceptable, less delivery of vapor is required. Thus, the concurrent use of nitrous oxide decreases demand on the vaporizer. In addition, the use of nitrous oxide also increases the total fresh gas flow to compensate for the considerable uptake of nitrous oxide. If fresh gas flow increases to 1500 mL/min, 79 mL of isoflurane vapor can be produced. Another solution is to select an anesthetic with a vaporizer capability closer to demand. Such a solution tends to be available for less soluble anesthetics. For example, we calculate the uptake of desflurane in the first minute of anesthesia to be $0.45 \times 5400 \times 0.06$, or 146 mL. At a 200-mL/min flow of oxygen, the 18% maximum output of a desflurane vaporizer permits delivery of 44 mL. Although it is still inadequate to meet demand in the first minute, this figure is 2.6 times closer to meeting that demand than the isoflurane vaporizer, and within 10 minutes, the desflurane vaporizer can supply the required volume (see Fig. 21-18A).

Figure 21-18A suggests one of the major difficulties associated with the closed-circuit approach, namely, control. Clearly, there is an enormous difference between delivered (i.e., vaporizer dial) and alveolar concentrations. The differences decrease with less soluble anesthetics, but even with an anesthetic such as desflurane and even after the initial high-uptake period is passed, the dialed concentration markedly exceeds the alveolar concentration that it sustains. This means that changes in uptake (e.g., secondary to the increase in cardiac output that may result from surgical stimulation) can considerably alter alveolar anesthetic concentration unless the delivered concentration is changed. The alveolar concentration changes for two reasons: (1) assuming constant ventilation, the difference between alveolar and inspired concentrations varies directly with uptake (e.g., greater uptake increases the difference), and (2) because of rebreathing, the inspired concentration varies inversely with uptake (e.g., increased uptake lowers the inspired concentration). Thus, the sum of these effects either decreases or increases the alveolar concentration. A closed circuit has an inherent element of instability not present in an open circuit.

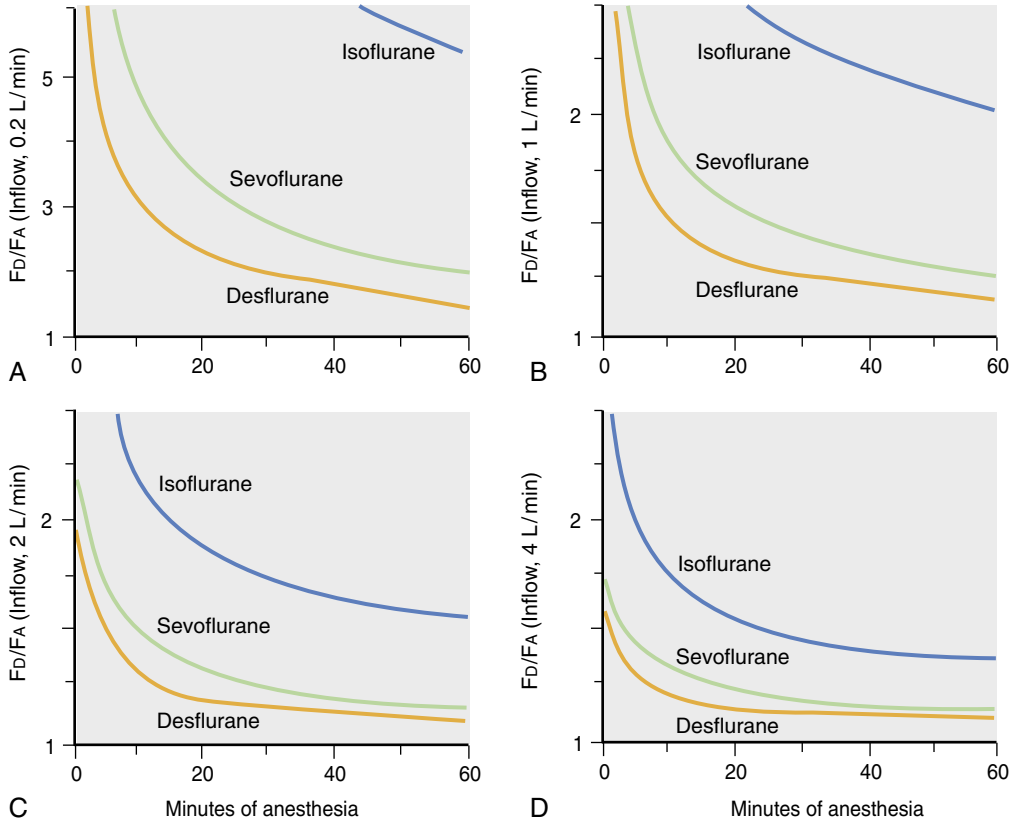

Figure 21-18 **A** to **D,** The ratio of delivered to alveolar concentrations (FD/FA) required to sustain the alveolar concentration constant at, for example, the minimum alveolar concentration (MAC) is a function of several factors. First, it is determined by uptake (see Fig. 21-17) and thus is greatest with the most soluble anesthetic, isoflurane. Second, it is determined by rebreathing and thus decreases with increasing inflow rates. Although these graphs have the same shape, the concentrations at any point in time progressively decrease as the inflow rate increases. The lowest values for any anesthetic result from a non-rebreathing system (i.e., when the inflow rate equals or exceeds minute ventilation).

Low-Flow Anesthetic Delivery

The instability of the closed circuit may be greatly mitigated by the use of low-flow (less than half minute ventilation) anesthetic delivery. Low-flow delivery may provide most of the advantages of closed systems while retaining considerable advantages over open systems in economy, maintenance of humidification and temperature, and limitation of atmospheric pollution. Low-flow delivery also diminishes the disadvantages of the closed circuit in the areas of constancy of oxygen and anesthetic levels and elimination of carbon monoxide and toxic anesthetic breakdown products.

In a low-flow delivery system, two factors control the relationship between the concentration delivered from a vaporizer (FD) and that in the alveoli (FA), a relationship that may best be described as the ratio of the two variables (FD/FA). First, we have already seen that uptake governs this ratio in a closed system (see Fig. 21-18A). Thus, FD/FA is higher for more soluble anesthetics, and regardless of solubility, the ratio is highest early in anesthetic administration and decreases rapidly in the first 5 to 10 minutes of anesthesia (as uptake by the VRG of tissues decreases to the point of near-equilibration) and more slowly thereafter (as uptake by tissue groups with longer time constants, such as muscle, the fourth compartment, and fat, decreases).

Second, the inflow rate also governs FD/FA. The relationship is inverse: the higher the inflow rate, the lower the ratio (compare Fig. 21-18B to D with Fig. 21-16A). An increase in inflow rate decreases FD/FA by decreasing rebreathing. Rebreathing is important because uptake of anesthetic depletes the concentration of anesthetic in rebreathed gases, and hence the concentration in delivered gases (FD) must be sufficient to compensate for this depletion. The higher the inflow rate, the less the compensation required because rebreathing is less.

However, increases in the inflow rate do not produce proportional decreases in FD/FA. The greatest reduction in FD/FA is achieved with modest increases in the inflow rate. Thus, a large decrease occurs when the inflow rate is changed from that needed for a closed circuit (Fig. 21-18A) to a 1-L/min inflow rate (Fig. 21-18B), whereas only a small decrease occurs when the inflow rate is increased from 2 to 4 L/min (Fig. 21-18C and D). Once the inflow rate exceeds minute ventilation (i.e., a non-rebreathing system exists), further increases in inflow rate have no effect on FD/FA, and FD/FA is the same as the ratio of inspired concentration (FI) to alveolar concentration (i.e., FD/FA = FI/FA).

I have used the term *anesthetic tether* as a metaphor for the FD/FA ratio.[67] A large ratio equates to a long tether, one permitting considerable variability in the alveolar concentration. With a long tether, changes in uptake secondary to changes in physiologic variables (e.g., an increase in cardiac output consequent to surgi-

cal stimulation) can appreciably alter the alveolar concentration and thus the level of anesthesia. In the example just cited, there is positive feedback because by increasing uptake, surgical stimulation decreases the alveolar concentration and thereby increases the perception of that stimulation. Most anesthetists prefer a short anesthetic tether because it provides tighter control over the level of anesthesia. A shorter tether is produced by the use of less soluble anesthetics or higher inflow rates, or both.

Another benefit of a short tether accrues to the rare anesthetist who does not have access to an agent-specific analyzer. In the absence of such an analyzer, some anesthetists may rely on the dial setting of the vaporizer to indicate the concentration of anesthetic in the patient's lungs (i.e., would assume that F_D equals F_A). Although the vaporizer setting may correlate with the concentration in the lungs, the correlation may be a distant one. The correlation is poor (1) early in anesthesia for all agents, (2) later in anesthesia with closed circuits or very low inflow rates, and (3) later in anesthesia for more soluble agents, such as isoflurane, even at higher inflow rates. Note that with poorly soluble anesthetics, such as sevoflurane and desflurane, by 30 to 60 minutes after the inception of anesthetic administration, the concentration delivered by the vaporizer may be less than 20% greater than that in the alveoli (i.e., the F_D/F_A ratio is 1.2), even at inflow rates of 1 to 2 L/min (Fig. 21-18B and C).

Economic concerns increasingly dictate the practice of anesthesia. The reader may wish to appreciate the differences in anesthetic consumption as a function of the choice of inflow rate, the duration of anesthesia, and the choice of anesthetic. The reports by Yasuda and coauthors[10,11] provide constants that may be used to estimate the uptake of commonly available potent inhaled anesthetics. By using the gas laws and published values for specific gravities, values for uptake of vapor may be converted to milliliters of liquid taken up. Combining this information with knowledge of the function of circuit rebreathing systems[68] allows an estimate of the amount of liquid in milliliters that must be delivered at various inflow rates to provide a constant alveolar concentration equal to MAC (Table 21-3).[68] The relative costs of anesthesia may be estimated by applying the price of the anesthetic of interest to the number of milliliters needed to sustain anesthesia.

Table 21-3 Milliliters of Liquid Anesthetic at Various Inflow Rates Needed to Sustain an Alveolar Concentration Equal to Minimum Alveolar Concentration

Anesthetic	Anesthetic Duration (min)	Inflow Rate (L/min, Not Including Anesthetic)				
		0.2	1.0	2.0	4.0	6.0
Halothane	30	3.0	4.1	5.4	8.0	10.5
	60	4.6	6.5	9.0	13.9	18.8
Isoflurane	30	4.0	5.8	8.0	12.3	16.7
	60	6.3	9.6	13.9	22.3	30.7
Sevoflurane	30	3.3	6.3	10.1	17.6	25.2
	60	4.9	10.9	18.2	33.0	47.8
Desflurane	30	6.7	14.8	25.0	45.2	65.4
	60	10.1	26.1	46.0	85.8	126

Modified from Weiskopf RB, Eger EI II: Comparing the costs of inhaled anesthetics. Anesthesiology 79:1413-1418, 1993.

If both economy and a low F_D/F_A ratio are desirable, the aforementioned considerations suggest that a good compromise is the use of a low-flow delivery system after an initial period of higher flow. Higher flow (4 to 6 L/min) might be applied early in anesthesia (i.e., at the time of highest uptake) and then be decreased progressively as uptake decreases. Flow rates of 2 to 4 L/min might be given for the period from 5 to 15 minutes after induction of anesthesia, and flow rates of 1 to 2 L/min may be given thereafter. If the average inflow rate were 2 L/min, 1 hour of anesthesia with the four potent anesthetics listed in Table 21-3 would require the administration of 9.0 to 46.0 mL of liquid. This fivefold range of values is smaller than the eightfold range of potency (MAC) values because the amount of anesthetic delivered must account for more than potency. The amount delivered must also compensate for uptake and loss of anesthetic through the overflow valve. The relatively smaller uptake and loss of the less soluble desflurane and sevoflurane are what accounts for the reduction from eightfold to fivefold. An even smaller range is found at lower inflow rates, with approximately twofold decreases for a closed circuit. However, such flows should not be used with sevoflurane because of the greater concentrations of compound A that result.

Recovery from Anesthesia

Nearly all the factors that govern the rate at which the alveolar anesthetic concentration rises on induction apply to recovery. Thus, the immediate decline is extremely rapid because the washout of functional residual capacity by ventilation is as rapid as the washin. Only 2 minutes is required to eliminate 95% to 98% of nitrogen from the lungs when pure oxygen is breathed.

Nitrogen, however, is a poorly soluble gas relative to the inhaled anesthetics. As ventilation sweeps anesthetic from the alveoli, an anesthetic partial pressure gradient develops between the partial pressure in the returning venous blood and the partial pressure in the alveoli. This gradient drives anesthetic into the alveoli, thereby opposing the tendency of ventilation to lower the alveolar concentration. The effectiveness of the venous-to-alveolar gradient in opposing the tendency of ventilation to decrease the alveolar anesthetic partial pressure is in part determined by the solubility of the anesthetic such that an agent with greater solubility, such as isoflurane, opposes the elimination produced by ventilation more than an agent with lesser solubility does, such as desflurane and sevoflurane, because a greater reserve exists in blood for the more soluble anesthetics. Thus, the fall in the alveolar partial pressure of isoflurane is slower than the fall with desflurane and sevoflurane. The rapidity of recovery largely depends on the solubility of the anesthetic.[69]

Differences Between Induction and Recovery

Recovery differs from induction in two crucial ways. First, on induction, the effect of solubility to hinder the rise in alveolar anesthetic concentration could be overcome by increasing the inspired anesthetic concentration (i.e., by applying overpressure). No such luxury is available during recovery; the inspired concen-

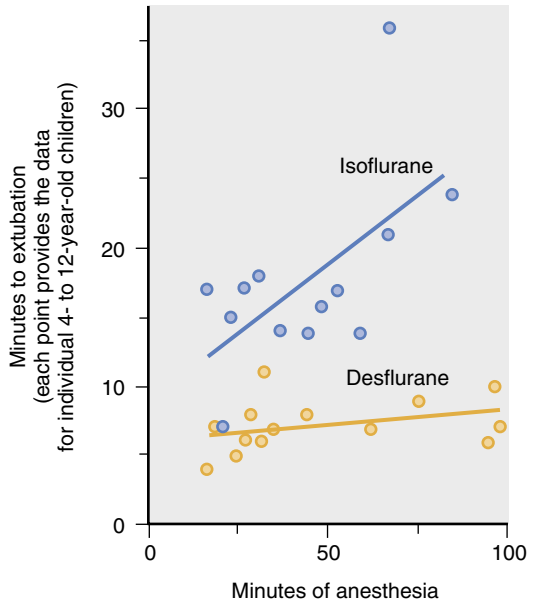

Figure 21-19 Solubility and duration of anesthesia affect the decrease in alveolar concentration on recovery and hence the time needed to recover from anesthesia. The time to tracheal extubation after anesthesia with anesthetics that have different solubilities illustrates these two aspects of recovery.[72] The time to extubation is longer after anesthesia in children anesthetized with isoflurane (the more soluble anesthetic) than in those anesthetized with desflurane. In addition, the duration of anesthesia has less impact on the time to extubation after anesthesia with the less soluble desflurane because most of the desflurane is cleared at the lung (does not recirculate to delay recovery.) *(Data from Nordmann GR, Read JA, Sale SM, et al: Emergence and recovery in children after desflurane and isoflurane anaesthesia: Effect of anaesthetic duration. Br J Anaesth 96:779-785, 2006.)*

tration cannot be reduced below zero. Second, on induction, all the tissues initially have the same anesthetic partial pressure—zero. On recovery, the tissue partial pressures are variable. The VRG has a pressure that usually equals that required for anesthesia; that is, the VRG has come to equilibrium with the alveolar anesthetic partial pressure. The MG may or may not have the same partial pressure as that found in the alveoli. A longer anesthetic course (2 to 4 hours) might permit equilibrium to be approached, but a shorter one would not. The high capacity of fat for all anesthetics except nitrous oxide precludes equilibration of the FG with the alveolar anesthetic partial pressure until hours or even days after anesthesia.

The failure of muscle and fat to equilibrate with the alveolar anesthetic partial pressure means that these tissues cannot initially contribute to the transfer of anesthetic back to the lungs. In fact, as long as an anesthetic partial pressure gradient exists between arterial blood and tissue blood, that tissue will continue to take up anesthetic. Thus, for the first several hours of recovery from anesthesia, fat continues to take up anesthetic and by so doing accelerates the rate of recovery. Only after the alveolar (equals arterial) anesthetic partial pressure falls below that in a tissue can the tissue contribute anesthetic to the alveoli.

The failure of several tissues to reach equilibration with the alveolar anesthetic partial pressure means that the rate of decrease in alveolar anesthetic on recovery is more rapid than its rate of increase on induction and that recovery depends in part on the duration of anesthesia.[70,71] A longer duration of anesthesia puts more anesthetic into the slowly filling muscle and fat depots. Obviously, these reservoirs can supply more anesthetic to the blood returning to the lungs when they are filled than when they are empty and can thereby prolong the time to recovery.[69]

Solubility influences the effect of duration of anesthesia on the rate at which the alveolar anesthetic partial pressure declines.[71] The decline in partial pressure of a poorly soluble agent is rapid in any case, and thus the acceleration imparted by a less than complete tissue equilibration cannot significantly alter the rate of recovery. The approach to equilibration becomes important with increasing solubility. With a more soluble anesthetic, recovery may be rapid after a short duration of anesthesia but may be slow after a prolonged duration. Recovery from anesthesia with desflurane and sevoflurane is more rapid and less influenced by the duration of anesthesia than with isoflurane.[69] For example, in children the time to extubation is longer after anesthesia with isoflurane than after anesthesia with desflurane (Fig. 21-19).[72] In addition, the duration of anesthesia minimally affects the time to extubation after desflurane anesthesia but has a substantial effect after isoflurane anesthesia (see Fig. 21-19).[72] Similarly, in volunteers anesthetized with 1.25 MAC desflurane versus sevoflurane, response to command and orientation occur sooner after desflurane, and duration has less of an impact on the time to respond and be oriented (Fig. 21-20).[73]

The importance of solubility and duration of anesthesia on the rate of recovery may be appreciated with the use of context-dependent times, or times to reach particular levels of washout of the alveoli or the VRG after the administration of anesthetics of specific duration.[74,75] Regardless of the duration of anesthesia, the alveolar concentrations of poorly soluble anesthetics (nitrous oxide, desflurane, sevoflurane) and a moderately soluble anesthetic (isoflurane) decrease by 60% in roughly the same period

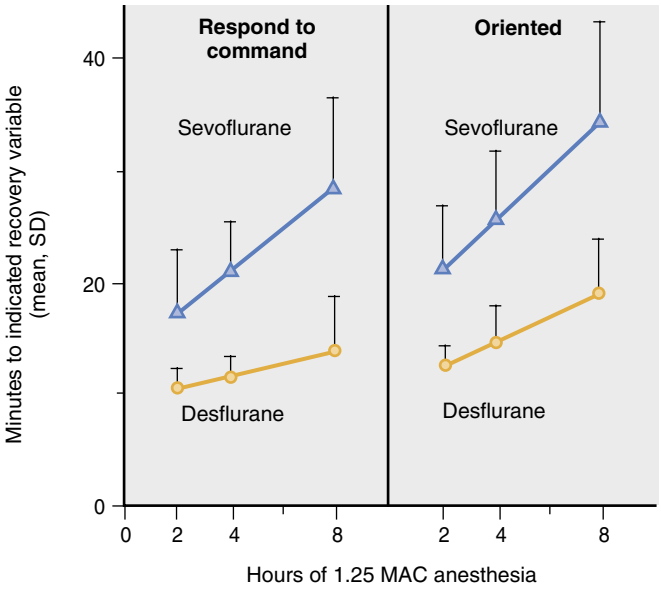

Figure 21-20 A differential time to awakening and a differential effect of anesthetic duration is shown after 2, 4, or 8 hours of anesthesia at 1.25 minimum alveolar concentration (MAC) for desflurane versus sevoflurane. Awakening to respond to a command or to orientation is more rapid after anesthesia with the less soluble desflurane, and the duration of anesthesia has less of an impact. *(From Eger EI II, Gong D, Koblin DD, et al: Effect of anesthetic duration on kinetic and recovery characteristics of desflurane vs. sevoflurane [plus compound A] in volunteers. Anesth Analg 86:414-421, 1998.)*

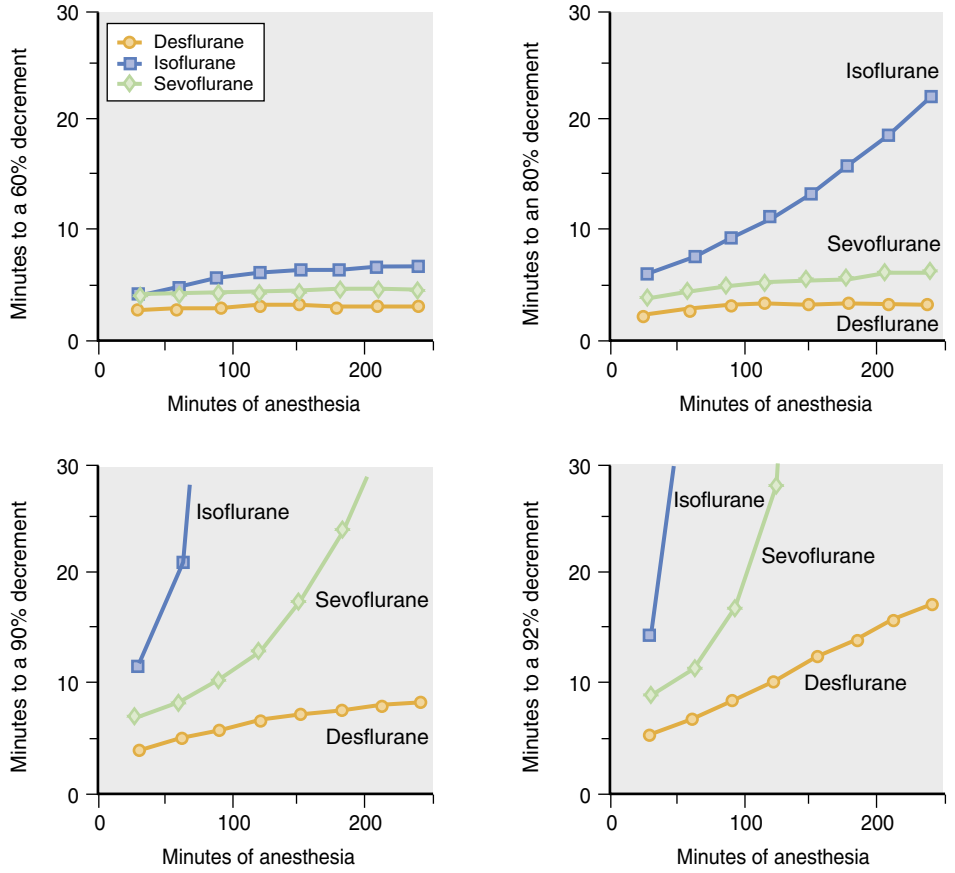

Figure 21-21 The time to decrease partial pressure in the alveoli or vessel-rich group by a certain fraction directly depends on several factors, primary among which are the solubility of the anesthetic and the duration of anesthesia. If a decrement of 60% is needed, little difference in time to recovery will be found for a comparison of isoflurane, sevoflurane, and desflurane. If an 80% decrement is needed to permit awakening, awakening from isoflurane will be delayed for progressively longer times as the duration of anesthesia is increased, but awakening from desflurane or sevoflurane will be minimally affected. If 90% of the anesthetic must be eliminated, awakening from both sevoflurane and isoflurane will be delayed more and more as the duration of anesthesia increases (isoflurane more than sevoflurane), but awakening from desflurane will be minimally affected. At a 92% decrement, the duration of anesthesia will also affect recovery from desflurane. *(Modified from Eger EI II, Shafer SL: Tutorial: Context-sensitive decrement times for inhaled anesthetics. Anesth Analg 101:688-696, 2005.)*

(Fig. 21-21).[75] If the desired recovery were attained at a 60% decrease, the choice of anesthetic would matter little on the time to recovery from anesthesia, even after prolonged anesthesia. If an 80% decrement is required, an increasing duration of anesthesia markedly affects recovery from isoflurane but minimally affects recovery from sevoflurane and desflurane (see Fig. 21-21). At a 90% decrement, the duration of anesthesia considerably affects recovery from both isoflurane and sevoflurane, and at a 92% decrement, recovery from desflurane begins to be affected (see Fig. 21-21).

More than 90% elimination of anesthetic may be required to restore pharyngeal reflexes to normal. Significant pharyngeal dysfunction may be found at 25% of MAC-awake (i.e., 5% to 8% of MAC).[76] At such small MAC values, context-sensitive decrement times become of increasing importance to recovery. McKay and associates[77] found that the capacity to drink 20 mL of water without coughing or drooling occurred sooner after desflurane than after sevoflurane (Fig. 21-22).

Pharmacodynamics adds to the determination of recovery. If immobility is accomplished with an inhaled anesthetic, the concentration exceeds MAC. Recovery sets a different goal, namely, awakening—that is, reaching MAC-awake, the concentration of anesthetic allowing appropriate response to command in 50% of subjects. MAC-awake differs among anesthetics. As a fraction of MAC, the MAC-awake of nitrous oxide (65% of MAC) exceeds that of desflurane isoflurane, and sevoflurane (approximately 33% of MAC).[78-80] The MAC-awake of propofol is still less (20%).[81] A lower MAC-awake value correlates with a greater capacity to provide amnesia: propofol is most potent and nitrous oxide least potent. However, a high MAC-awake means that awakening will occur at a higher anesthetic concentration relative to that required for anesthesia. All other factors being equal, awakening from nitrous oxide anesthesia is more rapid than awakening from anesthesia with desflurane, isoflurane, or sevoflurane.

Can I Have My Cake and Eat It Too?

The less soluble new inhaled anesthetics desflurane and sevoflurane offer more rapid recovery from anesthesia than with more soluble older anesthetics, such as isoflurane. However, this rapid recovery comes at a price: the new anesthetics are more expensive. Might it be possible to have the best of both worlds by using isoflurane for the major portion of anesthesia and reserve desflurane

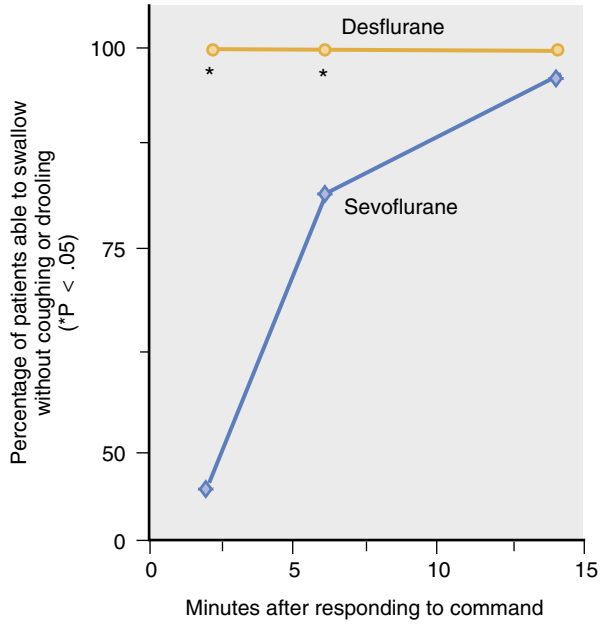

Figure 21-22 Recovery of function of pharyngeal muscles may require a decrement of 92% to 95% in anesthetic concentration.[76] At such substantial amounts of elimination, context-sensitive decrement times would suggest the possibility of more rapid recovery of airway reflexes with the less soluble desflurane, even though both anesthetics are poorly soluble. McKay and colleagues[77] measured the time from responding to command to the time that patients could swallow 20 mL of water without coughing or drooling. All patients anesthetized with desflurane could swallow 20 mL of water without coughing or drooling 2 minutes after responding to command, but fewer than 50% of patients anesthetized with sevoflurane could do so. At 6 minutes after responding to command, a significant percentage of patients given sevoflurane still could not swallow the water without coughing or drooling.

(or sevoflurane) for the final minutes? The premise would be that such an approach would provide the economy of isoflurane and the rapid recovery of desflurane. Neumann and colleagues[82] tested this premise. Volunteers were anesthetized for 2 hours on three occasions: once with 1.25 MAC isoflurane, once with 1.25 MAC desflurane, and once with 1.5 hours of 1.25 MAC isoflurane followed by 0.5 hours of a combination of desflurane and isoflurane ("crossover"). The combination provided a total of 1.25 MAC (i.e., desflurane was added as the isoflurane was eliminated, the addition being sufficient to sustain a total of 1.25 MAC). To ensure economy, all anesthetics were delivered at an inflow rate of 2 L/min. The premise was not realized. Recovery after crossover was no faster than recovery after isoflurane alone (Fig. 21-23). Recovery after desflurane alone was considerably faster than recovery after either isoflurane or the crossover from isoflurane to desflurane.

Impact of Metabolism

Saturation of the enzymes responsible for the metabolism of anesthetics may limit the ability of metabolism to significantly alter the rate at which the alveolar anesthetic partial pressure rises. This limitation does not exist on recovery, and metabolism may be an important determinant of the rate at which the alveolar anesthetic partial pressure declines. However, such metabolism applies significantly only to obsolete anesthetics such as halothane and methoxyflurane.[23] Sevoflurane is only slightly metabolized and desflurane and isoflurane undergo so little metabolism that such degradation cannot affect their kinetics.[10,11]

Diffusion Hypoxia

Uptake of large volumes of nitrous oxide on induction of anesthesia gives rise to the concentration and second gas effects. On recovery from anesthesia, the outpouring of large volumes of nitrous oxide can produce what Fink[83] called diffusion anoxia. These volumes may cause hypoxia (Fig. 21-24) in two ways. First, they may directly affect oxygenation by displacing oxygen.[83] Second, by diluting alveolar carbon dioxide, they may decrease respiratory drive and hence ventilation.[83,84] Both these effects require that large volumes of nitrous oxide be released into the alveoli. Because large volumes of nitrous oxide are released only during the first 5 to 10 minutes of recovery, this is the period of greatest concern. This concern is enhanced by the fact that the first 5 to 10 minutes of recovery may also be the time of greatest respiratory depression. For these reasons, many anesthetists administer 100% oxygen for the first 5 to 10 minutes of recovery. This procedure may be particularly indicated in patients with preexisting lung disease or in those in whom postoperative respiratory depression is anticipated (e.g., after nitrous oxide–narcotic anesthesia).

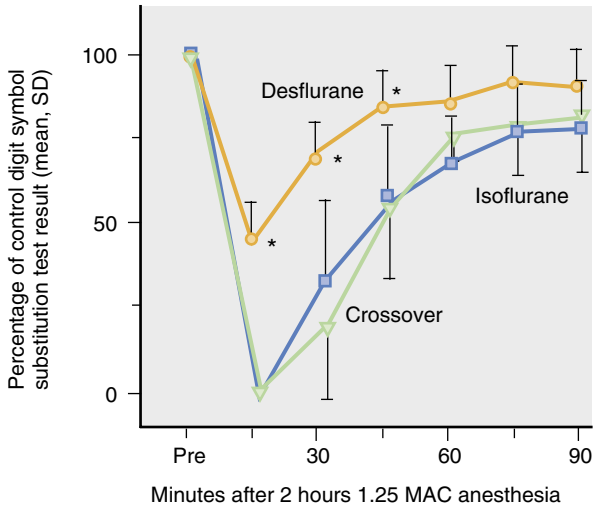

Figure 21-23 Volunteers were anesthetized for 2 hours on three occasions: once with 1.25 minimum alveolar concentration (MAC) isoflurane; once with 1.25 MAC desflurane; and once with 1.5 hours of 1.25 MAC isoflurane, followed by 0.5 hour of a combination of desflurane and isoflurane ("crossover"). The combination provided a total of 1.25 MAC (i.e., desflurane was added as the isoflurane was eliminated, the addition being sufficient to sustain a total of 1.25 MAC). All anesthetics were delivered at a 2-L/min inflow rate. At the end of 2 hours, anesthetic administration was discontinued and a non-rebreathing system was applied. The digit symbol substitution test (DSST) was applied at 15-minute intervals and the results were displayed as a percentage of the control (preanesthesia) results. Recovery of judgment and cognition as defined by the DSST was more rapid at 15, 30, and 45 minutes with desflurane given alone (*asterisks* indicate significant differences from isoflurane or crossover results), and recovery was less affected by the duration of anesthesia with desflurane. *(Data from Neumann MA, Weiskopf RB, Gong DH, et al: Changing from isoflurane to desflurane towards the end of anesthesia does not accelerate recovery in humans. Anesthesiology 88:914-921, 1998.)*

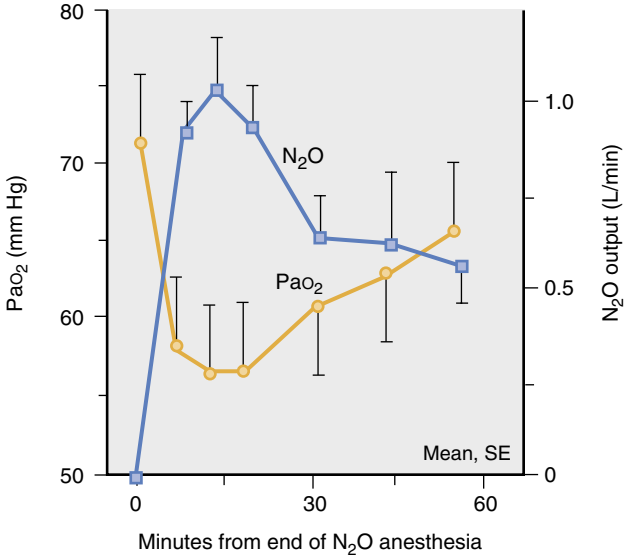

Figure 21-24 At time zero, the inspired gas was changed from 21% oxygen/79% nitrous oxide to 21% oxygen/79% nitrogen. Arterial oxygen subsequently fell in association with the outpouring of nitrous oxide. *(Modified from Sheffer L, Steffenson JL, Birch AA: Nitrous-oxide–induced diffusion hypoxia in patients breathing spontaneously. Anesthesiology 37:436-439, 1972.)*

Impact of the Anesthetic Circuit

The anesthetic circuit may limit the rate of recovery just as it limits induction. If not disconnected from the circuit on cessation of anesthetic delivery, the patient may continue to inspire anesthetic. To reduce the inspired level to zero or nearly zero, two factors must be taken into account: the anesthetic within the circuit must be washed out, and the patient's exhaled air, which contains anesthetic, must not be rebreathed. The effect of each of these factors on raising the inspired anesthetic concentration can be overcome with the use of high inflow rates of oxygen (i.e., 5 L/min or greater).

22 Pulmonary Pharmacology

Key Points

1. Inhaled anesthetics affect every facet of pulmonary physiology, from the variety of forces controlling ventilation and pulmonary blood flow to surface tension, secretion of mucus, airway smooth muscle tone, and lung inflammatory responses.
2. The bronchodilatory actions of volatile anesthetics occur through several complex mechanisms that involve both a decrease in intracellular calcium concentration and a reduction in calcium sensitivity. Volatile anesthetics increase baseline pulmonary dynamic compliance, but these agents are more effective at attenuating increases in pulmonary airway resistance caused by chemical or mechanical stimuli. Inhaled anesthetics preferentially dilate the distal airways rather than the proximal airways.
3. Inhaled anesthetics diminish the rate of mucus clearance by decreasing ciliary beat frequency, disrupting metachronism, or altering the characteristics of mucus.
4. Pulmonary surfactant decreases the work of breathing by reducing alveolar surface tension. Volatile anesthetics cause progressive, yet reversible reductions in phosphatidylcholine, the main lipid component of surfactant. The roles of depressed mucociliary function and alterations in type II alveolar cell function in postoperative pulmonary complications after the administration of a volatile agent are unknown.
5. The multiple sites of actions of inhaled anesthetics on the pulmonary parenchyma and vasculature complicate direct assessment of anesthetic-induced alterations in pulmonary vascular resistance. Volatile anesthetics cause a biphasic contraction-relaxation response in pulmonary vascular smooth muscle that is mediated at multiple sites through a Ca^{2+}-mediated signaling pathway. Overall, the net effect of inhaled anesthetic–induced changes in pulmonary vascular resistance is relatively small.
6. Hypoxic pulmonary vasoconstriction (HPV) is an important mechanism by which pulmonary blood is preferentially redistributed away from poorly ventilated lung regions to those with adequate alveolar ventilation. Most inhaled anesthetics attenuate HPV in vitro and exert relatively modest inhibitory effects on HPV, shunting, or oxygenation in vivo.
7. Inhaled anesthetics (with the exception of xenon) reduce tidal volume and minute ventilation and cause tachypnea in a dose-related fashion. The relative effect of inhaled anesthetics in increasing arterial carbon dioxide tension (as an index of respiratory depression) is enflurane > desflurane = isoflurane > sevoflurane = halothane > nitrous oxide.
8. Inhaled anesthetics affect the inspiratory and expiratory respiratory muscles to varying degrees, possibly as a result of the differential sensitivity of bulbospinal inspiratory and expiratory neurons.
9. All inhaled anesthetics depress the ventilatory responses to hypercapnia and hypoxia by altering central and peripheral chemoreceptor function in a dose-dependent fashion. The effects of subanesthetic concentrations of inhaled agents on hypercapnic responses are controversial. Inhibition of hypoxic responses by subanesthetic concentrations of volatile agents depends on the agent used and perhaps the baseline state of central nervous system arousal. These findings may have important clinical implications during the perioperative period.
10. Volatile anesthetics may exhibit proinflammatory actions and worsen acute lung injury. Alternatively, volatile anesthetics have been shown to reduce inflammation and improve both chemical and physiologic pulmonary function in acute lung injury.

This chapter describes the pulmonary pharmacology of inhaled anesthetics. The lungs are unique in their exposure to a wide variety a physical forces, including ventilation, blood flow, and surface tension, and inhaled anesthetics selectively modulate each of these properties. Specific sections of this chapter focus on airway tone, pulmonary vascular resistance (PVR), mucociliary function, surfactant production, ventilatory control, and acute lung injury. The actions of volatile anesthetics on each of these systems are discussed.

Bronchomotor Tone

Transient increases in airway resistance may be caused, at least in part, by an increase in bronchiolar smooth muscle tone. Patients without recent symptoms of asthma have a very low frequency of perioperative respiratory complications, yet perioperative bronchospasm develops in approximately 6% of patients with asthma. Prospective studies have demonstrated that 1.7% of patients with asthma experience a poor respiratory outcome[1] and that 25% wheeze after the induction of anesthesia.[2] Of the 40 cases of bronchospasm resulting in settled malpractice claims reported by the American Society of Anesthesiologists Closed Claims Project,[3] 88% involved brain damage or death, and only half of these patients had a history of asthma or chronic obstructive pulmonary disease (COPD). Because significant bronchospasm may occur in normal subjects without underlying lung disease, understanding of the physiologic effects of inhaled agents on bronchial smooth muscle is very important.

Pharmacology of Bronchial Smooth Muscle

Pinto-Pereira and colleagues[4] summarized the mechanisms by which increases in airway resistance might occur. Airway smooth muscle extends as far distally as the terminal bronchioles and is affected by autonomic nervous system activity and nonadrenergic, noncholinergic mechanisms. Parasympathetic nerves originating in vagal centers within the central nervous system mediate baseline airway tone and reflex bronchoconstriction. Changes in intracellular calcium (ICa^{2+}) levels and Ca^{2+} influx may be caused by alterations in cyclic nucleotides within bronchial smooth muscle. Agonist-induced contraction is mediated by an increase in myosin light chain kinase activity, phosphorylation of the 20-kd regulatory myosin light chain, and an increase in Ca^{2+} sensitivity.[5] Exogenous administration of acetylcholine or stimulation of the vagus nerve increases the level of cyclic guanosine monophosphate (cGMP) relative to cyclic adenosine monophosphate (cAMP) and results in bronchial smooth muscle contraction. Activation of bronchial smooth muscle cells by agonist also involves the second messenger cyclic adenosine diphosphate ribose, which indirectly releases Ca^{2+} from the sarcoplasmic reticulum (SR) by activating ryanodine channels.[6] Agonist-induced stimulation of particulate guanylyl cyclase relaxes bronchial smooth muscle by decreasing Ca^{2+} current. In contrast, stimulation of soluble guanylyl cyclase by substances such as nitric oxide (NO) reduces ICa^{2+} concentration and Ca^{2+} sensitivity.[7]

Release of histamine in the airway or various forms of mechanical or chemical stimulation may increase afferent vagal activity and produce reflex bronchoconstriction. This increase in bronchomotor tone is attenuated by the cholinergic antagonist atropine. M_2 and M_3 muscarinic receptors on airway smooth muscle mediate bronchoconstriction by increasing Ca^{2+} sensitivity.[8] Presynaptic M_2 muscarinic receptors have also been identified that inhibit release of acetylcholine, and thus drugs that preferentially inhibit M_2 receptors (e.g., ipratropium bromide) may paradoxically produce bronchoconstriction,[9] although this effect is not commonly observed in patients.

Adrenergic receptors in bronchial smooth muscle are classified into α and β_2 types. α-Receptors have been characterized in the human bronchial tree, but their activity may be clinically insignificant. In contrast, the β_2-receptor subtypes play an important role in bronchiolar smooth muscle responsiveness. Stimulation of β_2-adrenoreceptors causes cAMP-mediated relaxation via activation of protein kinase A and subsequent efflux of Ca^{2+} out of the cell and into the SR. Notably, asthma, as well as allergy- and methacholine-induced bronchospasm, does not appear to be genetically linked to a dominant β_2-adrenoceptor gene.[10]

Respiratory epithelium releases substances that modulate bronchial smooth muscle tone. Epithelial removal enhances contractile responses to acetylcholine, histamine, and serotonin in large airways and decreases relaxation responses to isoproterenol in small airways. These actions are analogous to the effect of endothelial damage on vascular smooth muscle tone. However, porcine bronchiolar epithelium–mediated bronchomotor activity is not significantly affected by cardiopulmonary bypass, in contrast with the vascular endothelium–mediated smooth muscle dysfunction seen in this situation.[11] Although endogenous epithelial factors have been identified, NO may play an important vasodilatory role in respiratory epithelium, similar to that of vascular endothelium. Endothelin-1 is also a potent endogenous bronchoconstrictor, as well as vasoconstrictor, that functions by activation of the inositol triphosphate (IP_3) pathway.[12]

Volatile Anesthetics

Volatile anesthetics are all bronchodilators, but some controversy remains about which volatile anesthetic exerts the most potent bronchodilation. In many studies using animal models, it appears that halothane has the most pronounced effect of relaxing airway smooth muscle. It is important to eliminate the indirect effects of arterial carbon dioxide tension when examining the actions of volatile agents on bronchial tone, especially during spontaneous ventilation, because hypercapnia-induced bronchodilation and hypocapnia-induced bronchoconstriction are both attenuated by isoflurane.[13] What may be interpreted as a dose-dependent effect of deepening the level of anesthesia with volatile anesthetics may actually be due to an indirect action mediated by a progressive increase in carbon dioxide tension. Isoflurane and halothane (1.5 minimum alveolar concentration [MAC]) produce similar reductions in airway resistance in a canine model of bronchospasm induced by aerosolized *Ascaris* antigen. Similar results were obtained with volatile agents during methacholine-induced airway constriction. Taken together, these data suggest that isoflurane and halothane produce direct bronchodilation and depress airway reflexes. Isoflurane appears to share significant bronchodilating properties with halothane and enflurane, but halothane increases dynamic compliance (a measure of small airway resistance) to a greater extent than isoflurane does. This finding may be particularly important in view of the fact that isoflurane

preferentially relaxes bronchioles rather than bronchi in vitro.[14] The structure of the respiratory epithelium changes from pseudostratified columnar cells of the large airways to thinner, cuboidal cells of the bronchioles, and thus a relatively large amount of histologic heterogeneity exists between these regions. Although all volatile anesthetics bronchodilate, their specific effects on bronchioles depend on the location in and structure of the respiratory tree. Park and colleagues[15] demonstrated that isoflurane and halothane dilate fourth-order bronchi at equivalent MAC values. Halothane, isoflurane, sevoflurane, and desflurane, at concentrations of up to 1 MAC, similarly attenuated methacholine-induced bronchoconstriction in open-chest, pentobarbital-anesthetized rats.[16]

Using computed tomography (CT), Brown and coworkers[17,18] showed that halothane causes greater bronchodilation than isoflurane does at low concentrations (Fig. 22-1). Halothane also had a more pronounced relaxing effect than isoflurane did at a similar MAC in intact airway smooth muscle as measured by high-resolution CT.[19] All volatile agents, including sevoflurane[20,21] and desflurane,[22,23] relax airway smooth muscle. Sevoflurane (1 MAC) reduced respiratory system resistance (determined via an isovolume technique) by 15% in patients undergoing elective surgery. In contrast, desflurane did not significantly alter resistance.[24] Halothane, desflurane, and isoflurane appear to relax the distal airways (i.e., bronchioles) to a greater extent than the proximal airways (i.e., bronchi).[22] Similarly, isoflurane and sevoflurane had greater inhibitory effects on bronchial than on tracheal smooth muscle contraction.[25] These differential effects appear to be related to the type of voltage-dependent Ca^{2+} channels (VDCs) present in these regions. Administration of volatile anesthetics to children undergoing elective imaging studies resulted in progressive reductions in the cross-sectional area of the upper airway musculature and subsequent pharyngeal airway collapse.[26] As observed with isoflurane and halothane in animal models, the effects of sevoflurane in children were not uniformly distributed along the upper airway (also see Chapter 82).

Inhalation of 1 or 2 MAC halothane, enflurane, sevoflurane, or isoflurane does not alter baseline pulmonary resistance and dynamic pulmonary compliance. However, these anesthetics significantly attenuated increases in pulmonary resistance and decreases in dynamic pulmonary compliance in response to intravenous histamine. Halothane was most effective in altering indices of bronchodilation, whereas responses to isoflurane, enflurane, and sevoflurane were nearly identical.[21] In contrast, desflurane produced bronchodilation at 1 MAC but increased airway resistance at 2 MAC.[27] Halothane, enflurane, and sevoflurane were found to be equivalent in dilating third- or fourth-generation bronchi as measured directly with a fiberoptic bronchoscope in vivo.[28]

Mechanisms of Action

Volatile anesthetics relax airway smooth muscle by directly depressing smooth muscle contractility. This action appears to result from direct effects on bronchial epithelium and airway smooth muscle cells and indirect inhibition of reflex neural pathways. The mechanisms responsible for the direct relaxation effects involve decreases in ICa^{2+}, an important regulator of smooth muscle reactivity. Several intracellular mediators responsible for mobilization of Ca^{2+} are potential sites for the action of volatile anesthetics, but the predominant mechanism appears to be inhibition of cell-membrane–associated VDCs, an action that reduces entry of Ca^{2+} into the cytosol.[29] Volatile anesthetic–induced increases in cAMP concentration cause decreases in free ICa^{2+} by stimulating efflux of Ca^{2+} and increasing uptake of Ca^{2+} into the SR. This action contributes to airway smooth muscle relaxation.[30] In addition to the decrease in ICa^{2+} levels, volatile anesthetic–induced decrease in calcium sensitivity as a result of inhibition of protein kinase C activity[31] and inhibition of G protein function are also reported mechanisms.[32] It has been suggested that volatile anesthetics differentially modify pulmonary resistance by altering the density of the gas mixture (Fig. 22-2).[31] In a laboratory lung model with fixed resistance, high concentrations of volatile agents increased the density of the gas mixture and the calculated resistance, with desflurane having the greatest increase at all MAC values studied.

The effects of volatile anesthetics on proximal versus distal airways may be related to differential effects on VDCs and the relative distribution of these channels. Long-lasting (L-type) VDCs appear to be the predominant mechanism for entry of Ca^{2+} into tracheal smooth muscle, whereas both transient (T-type) and L-type VDCs are present in bronchial smooth muscle cells.[25,33] Yamakage and associates[25] demonstrated that isoflurane and sevoflurane inhibit both types of VDCs in a dose-dependent fashion but that their effects on T-type VDCs in bronchial smooth muscle were much greater (Fig. 22-3). The differential effects of volatile anesthetics on tracheal as opposed to bronchial smooth muscle may also be related to effects on Ca^{2+}-activated chloride

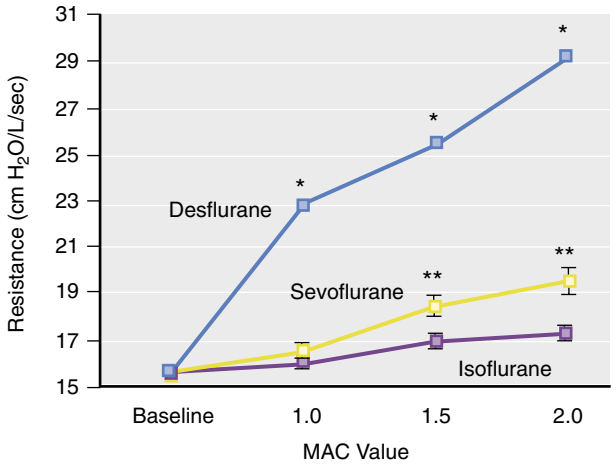

Figure 22-2 Comparison of the effect of different volatile anesthetics at equivalent concentrations on total pulmonary resistance. At 1 minimum alveolar concentration (MAC), only desflurane significantly increased pulmonary resistance when compared with isoflurane and sevoflurane. At 1.5 and 2 MAC, sevoflurane significantly increased total pulmonary resistance when compared with isoflurane, whereas desflurane caused a more pronounced increase than the other two agents did. *Increased pulmonary resistance in comparison to sevoflurane and isoflurane; **increased pulmonary resistance in comparison to isoflurane. *(Reproduced from Nyktari VG, Papaioannou AA, Prinianakis G, et al: Effect of the physical properties of isoflurane, sevoflurane and desflurane on pulmonary resistance in a laboratory lung model. Anesthesiology 104:1202, 2006, with permission.)*

channel activity[34,35] or differential sensitivity of K^+ channel subtypes.[34] Early studies proposed that volatile anesthetics relax airway smooth muscle by opening adenosine triphosphate (ATP)-sensitive potassium channels (K_{ATP}). However, halothane was found to exert minimal effects on tracheal smooth muscle K_{ATP} channels.[36]

The proposed signaling pathways underlying volatile anesthetic–induced bronchodilation are depicted in Figure 22-4. In addition to effects on VDCs, halothane reduces ICa^{2+} by depleting SR Ca^{2+}.[37,38] Halothane-induced reductions in SR Ca^{2+} appear to occur through enhancement of IP_3 and ryanodine receptor channels,[38] but whether halothane exerts direct effects on IP_3 concentrations remains controversial. Warner and coworkers[39] also demonstrated that halothane attenuates acetylcholine-induced Ca^{2+} sensitization in canine tracheal smooth muscle to a greater extent than isoflurane or sevoflurane does. These findings are analogous to the differential effects of volatile anesthetics on relaxing airway smooth muscle. Halothane may reduce free Ca^{2+} in the cytoplasm or limit influx of Ca^{2+} across the cell membrane. Alterations in Ca^{2+} sensitivity are an important mechanism by which volatile anesthetics cause smooth muscle relaxation. This effect appears to be mediated, at least in part, by an increase in smooth muscle protein phosphatase[40] and modulation of G proteins that exert actions on cGMP, specifically G_q and G_i.[32,41] Volatile anesthetics affect the function of G proteins in a variety of tissues, but halothane-induced relaxation of airway smooth muscle occurs independent of pertussis toxin–sensitive inhibitory G proteins, which are sensitive to the relaxation effects of β-adrenoceptor agonists.[42] Volatile anesthetics interact with the muscarinic receptor–heterotrimeric G protein complex to prevent agonist-promoted nucleotide exchange at the Gα subunit of the G protein.[43] It is perhaps through this mechanism that volatile anesthetics inhibit signaling proteins such as phospholipase C, protein kinase C, and ion channels. In addition to the role of volatile anesthetics as inhibitors of muscarinic agonist–induced guanine nucleotide exchange, they also appear to exert direct effects on the G protein–receptor complex.[42] The final pathway in airway smooth muscle contraction is the generation of force and shortening of smooth muscles regulated by myosin cross-bridge number and kinetics. Isoflurane modulated both cross-bridge number and the cycling rates of isolated rat airway smooth muscle.[44]

The bronchoconstricting effects of low inhaled concentrations of carbon dioxide were attenuated by inhaled but not by intravenous halothane, thus suggesting a direct action on airway musculature or local neural reflex arcs rather than centrally controlled reflex pathways. Halothane-, isoflurane-, sevoflurane-, and desflurane-induced dilatation of distal bronchial segments partially depends on the presence of bronchial epithelium.[15,45] A prostanoid (e.g., prostaglandin E_2 or I_2) or NO may mediate the bronchodilatory effects of these volatile anesthetics. For example, isoflurane-mediated bronchodilation appears to more dependent on NO than on prostanoids, but the converse is true for halothane. Focal epithelial damage or inflammation may occur in the small airways of patients with asthma or after exposure to allergen, and as a consequence, the bronchodilatory response to volatile anesthetics may be reduced.[46] The greatest bronchodilatory action of volatile agents in patients with chronic reactive airway disease occurs primarily in the proximal rather than the distal airways.

Stimulation of intrinsic airway nerves in vitro produces a cholinergic contractile response that is inhibited by atropine. In addition to the direct effects just described, volatile anesthetic–induced bronchodilation also occurs via modulation of airway cholinergic neural transmission mediated through prejunctional and postjunctional mechanisms.[47,48] The combination of atropine and halothane did not increase airway caliber over that attained with either drug alone. These findings suggest that halothane dilates airways by blocking vagal tone during unstimulated conditions.[17] Release of histamine and the nonadrenergic, noncholinergic bronchodilatory neural reflex, believed to be mediated by NO,[49] do not appear to play a significant role in low-dose halothane-induced bronchodilation. Potent tracheal constriction occurs in response to the endogenously produced polypeptide endothelin-1. Administration of isoflurane at a clinically relevant dose (2%) depressed endothelin-1–induced airway smooth muscle contraction in rat tracheal rings, thus suggesting another potential mechanism for airway smooth muscle relaxation.[50]

Effects of Inhaled Anesthetics on Bronchomotor Tone in Humans

Volatile anesthetics may be an effective method of treating status asthmaticus when other more conventional treatments have failed.[51] One percent halothane administered to 12 patients in status asthmaticus rapidly improved bronchospasm, reduced the incidence of barotrauma, and enhanced arterial blood gas ten-

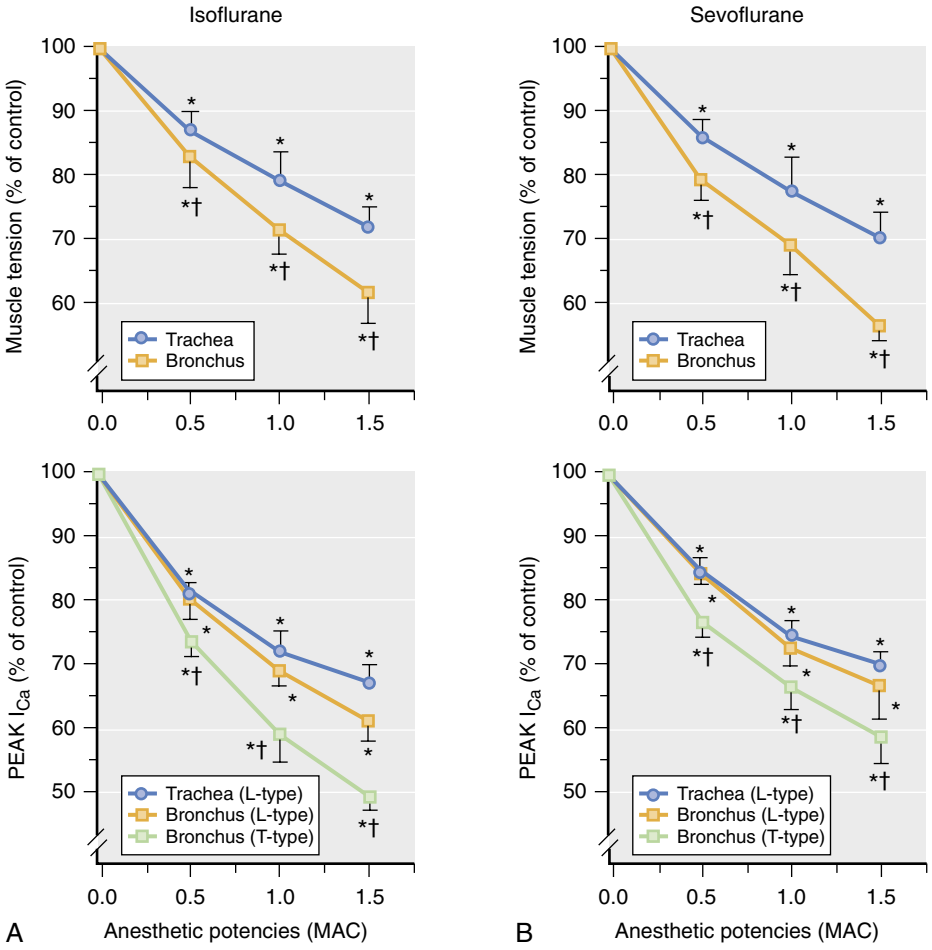

Figure 22-3 Effect of isoflurane and sevoflurane on porcine tracheal versus bronchial smooth muscle tension or inward Ca^{2+} current (I_{Ca}) through T- and L-type voltage-dependent Ca^{2+} channels (VDCs). There were no differences in the inhibition of L-type VDCs. Both anesthetics had greater inhibitory effects on T-type VDCs in bronchial smooth muscle. sions in the absence of adverse hemodynamic effects.[52] However, the possibility of cardiac arrhythmias, depression of myocardial contractility, and lack of availability in the United States suggest that other agents may be preferred in the treatment of status asthmaticus.

Rooke and associates[53] compared the bronchodilating effects of halothane, isoflurane, sevoflurane, and thiopental/nitrous oxide in 66 healthy patients undergoing induction of anesthesia and tracheal intubation (Fig. 22-5). In contrast to thiopental or nitrous oxide, all volatile anesthetics significantly reduced respiratory system resistance. At equivalent MAC, sevoflurane and halothane decreased resistance to a similar degree, whereas isoflurane produced substantially less bronchodilation in vivo. Previously described animal studies demonstrating equal potency of sevoflurane and isoflurane and relatively greater potency of halothane for bronchodilation must be extrapolated with caution because *Ascaris*- or histamine-mediated experimental bronchospasm may not precisely mimic tracheal intubation–induced bronchospasm in humans. In contrast to these findings in experimental animals, Arakawa and colleagues[51] showed that similar inspired concentrations of halothane, isoflurane, and sevoflurane produce nearly identical reductions in airway resistance in patients with status asthmaticus.

Although the use of β-adrenoceptor agonists may be beneficial for the treatment of bronchospasm in patients anesthetized with halothane,[42,54] this may not be the case with other inhaled agents. The β_2-adrenergic agonist fenoterol lowered respiratory system resistance after endotracheal intubation but did not reduce resistance further when administered in the presence of 1.3% isoflurane.[55] These data should be interpreted with caution because the technique used to determine respiratory system resistance may be partially responsible for these results inasmuch as this index incorporates alterations in lung and chest wall resistance, as well as tissue viscosity.

The actions of volatile anesthetics on bronchomotor tone are dependent on the agent eliciting contraction in vitro.[19] Relaxation of tracheal smooth muscle by halothane and isoflurane is greater in the presence of the endogenous mediator serotonin (potentially representing anaphylactoid or immunologic reactions) than in the presence of acetylcholine (representing the

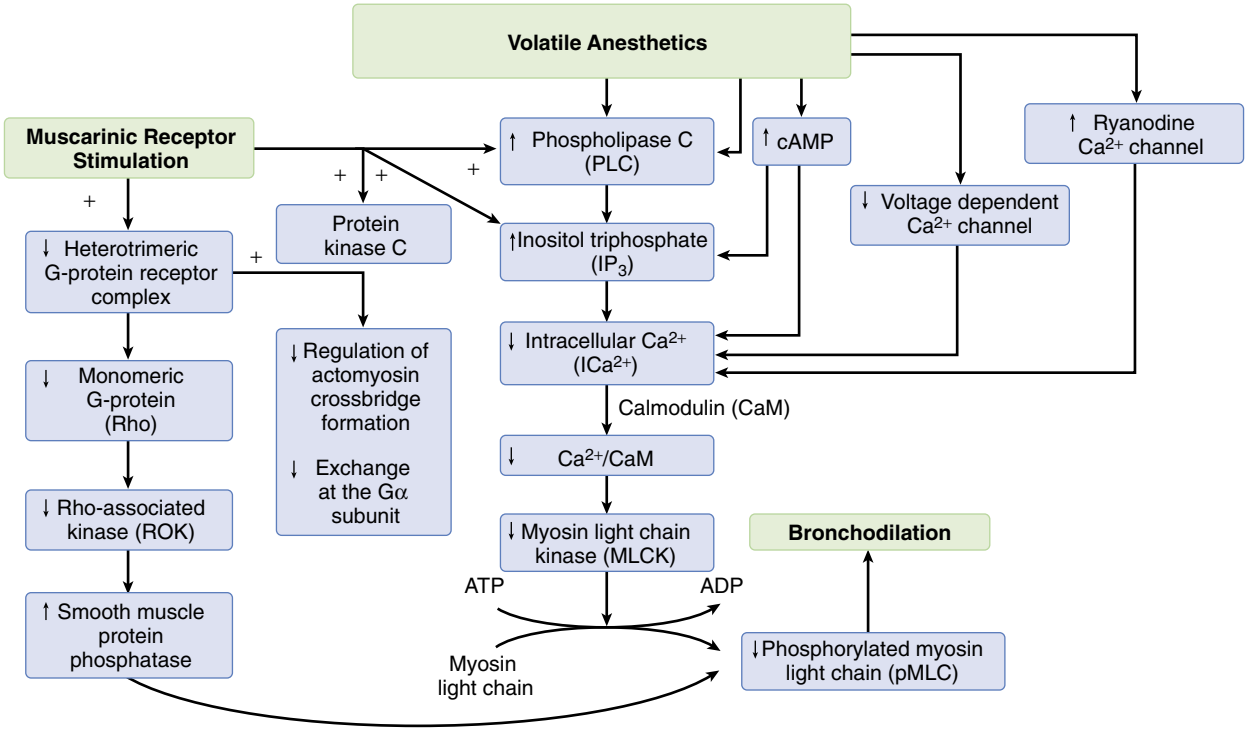

Figure 22-4 Proposed signaling pathways underlying volatile anesthetic (specifically, halothane)-induced bronchodilation or inhibition (or both) of muscarinic agonist–induced contraction of airway smooth muscle. +, excitatory action of muscarinic receptor agonist; ↑, activation or increase attributable to the volatile anesthetic; ↓, inhibition or decrease attributable to the volatile anesthetic. Signal transduction along pathway A is supported by work from Warner and coworkers on a role of halothane in decreasing Ca^{2+} sensitivity rather than a change in ICa^{2+} content. *(Adapted from Pabelick CM, Prakash YS, Kannan MS, et al: Effects of halothane on sarcoplasmic reticulum calcium release channels in porcine airway smooth muscle cells. neurally derived mediator of reflex bronchospasm). Inhaled anesthetics may remain effective bronchodilators even with severe serotonin- or histamine-induced bronchospasm that is refractory to β_2-adrenoceptor therapy.

Volatile anesthetic–induced decreases in bronchomotor tone and neurally mediated airway reflexes may be partially opposed by a simultaneous reduction in functional residual capacity (FRC) in anesthetized patients. This decrease in FRC increases airway resistance. An increased risk for morbidity and mortality during the perioperative period has been well established in patients with asthma and may be partially attributed to these FRC-mediated increases in airway resistance. Exposure of airway smooth muscle to low temperatures may abolish the inhibitory effects of volatile anesthetics on carbachol-induced contraction.[56] These findings suggest that intraoperative hypothermia also may attenuate volatile anesthetic–induced bronchodilation.

Bronchospasm may occur with respiratory diseases other than asthma. For example, healthy patients undergoing surgical stimulation of the pulmonary parenchyma or airways (including tracheal stimulation by an endotracheal tube) are at risk for bronchospasm. The choice of preoperative medication, induction agent, muscle relaxant, and type of inhaled agent are important factors in determining the development of bronchospasm in patients with known reactive airway disease. Recently, Iwasaki and coworkers[29] demonstrated that sevoflurane-induced relaxation of airway smooth muscle and VDCs was dependent on

the type of hyperreactive airway model. Sevoflurane had smaller effects in a chronic cigarette-smoking model (enlarged alveolar ducts and lesser muscarinic hyperreactivity) than in an acute ovalbumin-sensitized (antigen–acute asthmatic) model. Morphologic changes in the peripheral airways may be responsible to some degree for the decrease in bronchodilator efficacy of volatile anesthetics in cigarette smokers, but sevoflurane and isoflurane decrease respiratory system resistance in patients with COPD.[57] In contrast with an acute asthmatic model characterized by eosinophilic inflammation and airway wall changes, the inflammation in chronic asthma involves many other cell types, including mast cells, macrophages, epithelial cells, and bronchial smooth muscle cells. In addition, chronic inflammation is associated with remodeling of bronchial epithelium to produce smooth muscle hypertrophy, gland hyperplasia, and neovascularization. In a murine model of chronic asthma, administration of sevoflurane acted at the airway level and lung periphery to reduce resistive and viscoelastic pressure, as well as lung static resistance, when compared with animals anesthetized with pentobarbital.[58]

Although halothane may be a more potent bronchodilator than other inhaled anesthetics, the often-profound respiratory irritation produced in the upper airways (even though better tolerated than isoflurane and desflurane) may have outweighed the benefit of a direct bronchodilatory action. Thus, subtle differences in the bronchodilating effects of volatile anesthetics certainly exist, but avoiding or minimizing airway irritation and maintaining adequate depth of anesthesia are probably of greater clinical importance.

Advances in manufacturing technology and scavenging systems have made the use of xenon more economically feasible[59] (also see Chapter 21). Clinical use of xenon remains limited in the United States. Xenon may have important neuroprotective and cardiovascular advantages over volatile anesthetics.[60] The effects of xenon on airway resistance differ markedly from those of volatile agents because this anesthetic gas has higher density and viscosity than air.[61-63] In pentobarbital-anesthetized pigs, baseline airway resistance was significantly greater during 70% xenon-oxygen than during 70% nitrous oxide–oxygen anesthesia, although measured peak and mean airway pressure was unaffected. In contrast, airway pressure and resistance were moderately increased during xenon anesthesia and methacholine-induced bronchoconstriction.[62] In addition, pulmonary resistance during inhalation of 50% xenon was similar to that observed during inhalation of 50% nitrous oxide or 70% nitrogen in methacholine-treated dogs.[64] A randomized, double-blind comparison of xenon and nitrous oxide showed that although both agents similarly increased expiratory lung resistance, fewer patients receiving xenon experienced decreases in oxygen saturation.[65] Administration of 33% xenon to long-term mechanically ventilated patients may transiently, but significantly elevate peak airway pressure.[61] This increase in airway pressure may be attenuated by reducing the inspiratory flow rate. The higher density and viscosity of xenon lead to increases in the Reynolds number and probably cause the zone of transition from turbulent to laminar gas flow to move more distally to smaller airways. Theoretically, this action may result in exacerbation of bronchospasticity in patients with preexisting small airway disease or a decrease in arterial oxygen tension. Other studies have shown that arterial oxygen and carbon dioxide tension is unaffected during administration of xenon and nitrous oxide mixtures,[66] but caution has nevertheless been suggested when using xenon in patients with bronchospastic or obstructive pulmonary disease.

Mucociliary Function and Surfactant

Normal Mucociliary Function

Foreign particulate matter, microorganisms, and dead cells are removed by the upward clearance of mucus from the tracheobronchial tree as a primary pulmonary defense mechanism. Ciliated respiratory epithelium extends throughout the respiratory tract as far as the terminal bronchioles and decreases in density from trachea to alveoli. Ciliary motion consists of a rapid stroke in a cephalad direction, followed by a slower recovery stroke in the opposite direction. Movements of cilia are closely coordinated in a proximal-to-distal direction to move matter toward the trachea efficiently. This resulting wave of motion is known as *metachronism*. The bending of individual cilia results from ATP-dependent sliding of two parallel fibers within the ciliary filament.

Mucus is a mixture of water, electrolytes, and macromolecules (e.g., lipids, mucins, enzymes) secreted by goblet cells and mucosal glands. Thicker layers of mucus slow the removal of surface particles from the airway, whereas low-viscosity mucus promotes more rapid ciliary transport. The amount and physical properties of the mucus layer may also promote the coordination of ciliary beats.[67] Mucociliary function may be assessed by high-speed videomicroscopy to examine the ciliary beat frequency. In vivo techniques in experimental animals have used a tracheal window model. The velocity of mucus movement has been measured with radioactive markers or fiberoptic bronchoscopy in humans.

Impaired mucociliary function in the upper airways correlates with low levels of nasal NO, but the clinical significance of this finding remains to be defined.[68] Maintenance of bronchial perfusion is also critically important to preservation of normal mucociliary function.[69] Although nervous control of ciliary coordination has not been demonstrated in vertebrates, mucociliary clearance is closely related to autonomic nervous system activity, most likely related to changes in the physical characteristics of respiratory secretions.[67]

Postoperative hypoxemia and atelectasis are common causes of perioperative morbidity. Many factors can affect mucociliary function in mechanically ventilated patients and potentially contribute to these complications. Poorly humidified inspired gases are known to reduce ciliary movement and desiccate mucus. The flow rate of mucus was maintained within the normal range during a 40-minute exposure to an inspired air temperature higher than 32°C in dogs. However, 3 hours of inhalation of dry air resulted in complete cessation of the flow of tracheal mucus, which was restored by the subsequent use of inspired gases with 100% relative humidity at 38°C. Several anesthesia-related factors also reduce the rate of mucus movement, including administration of a high inspired oxygen concentration, adjuvant medications (cortisone, atropine, β-receptor blockers), the presence of a cuffed endotracheal tube, and positive-pressure ventilation.[70]

Effects of Inhaled Anesthetics on Mucociliary Function

Volatile anesthetics and nitrous oxide may diminish rates of mucus clearance by decreasing ciliary beat frequency, disrupting metachronism, or altering the physical characteristics or quantity of mucus. Halothane, enflurane, isoflurane, and sevoflurane, in contrast to many intravenous anesthetics,[71,72] reduced ciliary movement and beat frequency in vitro.[73-75] Among the volatile anesthetics, sevoflurane exhibited the weakest cilia-inhibitory effects in rat cultured tracheal epithelial cells in vitro (Fig. 22-6).[75]

Gamsu and colleagues[76] compared the rate of tantalum clearance from the lungs of postoperative patients who had undergone general anesthesia for either intra-abdominal or lower extremity operations. Tantalum is a powder that adheres to airway mucus and can be used to study mucociliary transport. Retention of tantalum was demonstrated for as long as 6 days after intra-abdominal surgery, with an average retention time three times greater than that observed in the control group. Tantalum retention was closely correlated with retention of mucus (Fig. 22-7). Teflon disks placed on the tracheal mucosa and observed with fiberoptic bronchoscopy were used to study tracheal mucus velocity in young women undergoing gynecologic surgery.[77] Administration of halothane (1% to 2%) and nitrous oxide (60%) rapidly decreased the rate of mucus movement. Little or no mucus motion was observed after 90 minutes' exposure to halothane-N_2O. The inspired gases were humidified, but high-inspired concentrations of oxygen, a cuffed endotracheal tube, and positive-pressure ventilation were confounding factors in this study. Bronchial mucosal transport velocity was also determined with the use of radiolabeled albumin microspheres deposited distally in the mainstem bronchi via fiberoptic bronchoscopy in healthy patients.[78] In contrast to the findings of the study with halothane, mucus velocity was unchanged during the administration of isoflurane (1.5 MAC). Whether this relative lack of effect of isoflurane on mucus transport was specifically related to the type of volatile agent was unclear. However, mucus pooling has been observed during and after anesthesia, and impaired bronchial mucus transport velocity is associated with increased pulmonary complications.

Konrad and colleagues[79] have shown that smokers have significantly slower bronchial mucus transport velocity and more frequent pulmonary complications than do nonsmokers undergoing abdominal or thoracic surgery. The specific effects of volatile anesthetics on mucus movement in smokers has not been well studied, but one may presume that there would be a further decrement in mucus transport. Impairment of mucociliary function also occurs after lung transplantation. The mechanism for this dysfunction may be related to alterations in the surface properties of mucus and marked impairment of mucociliary transport distal to the bronchial transection and reanastomosis.[80] The effects of volatile anesthetics on mucus transport in pulmonary transplant patients have not been described; however, the baseline reductions in mucociliary movement would predispose patients to postoperative respiratory complications.

The effects of sevoflurane and remifentanil on bronchial mucus transport were compared with those of total intravenous anesthesia (consisting of propofol and remifentanil) in patients undergoing general surgery.[81] In contrast to the in vitro results,[75] bronchial mucus transport velocity was significantly reduced 30 minutes after endotracheal intubation in patients receiving sevoflurane. The data indicate that pulmonary therapy directed at enhancing clearance of secretions from the airways may be beneficial in the immediate postoperative period regardless of the type of inhaled anesthetic chosen.

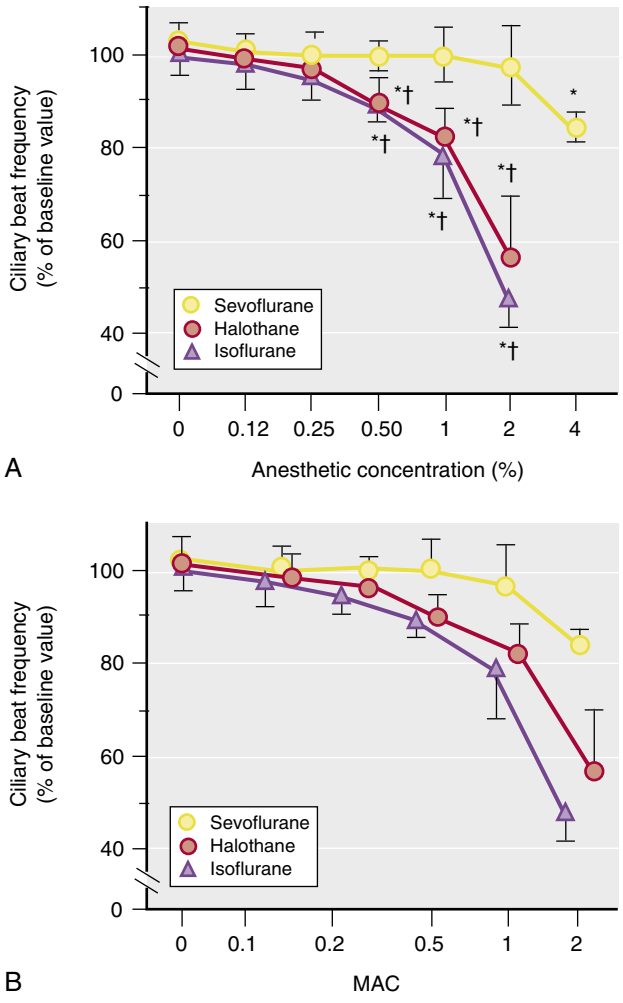

Figure 22-6 Effects of sevoflurane, halothane, and isoflurane on ciliary beat frequency (CBF) in cultured rat tracheal epithelial cells. CBF was measured at baseline and 30 minutes after exposure to various anesthetic concentrations. Values represent means ± SD. **A,** Plot of percent baseline CBF versus anesthetic concentration. *$P < .05$ versus 0% vehicle and †$P < .05$ versus sevoflurane at the same concentration. **B,** Percent baseline CBF versus minimum alveolar concentration (MAC). *(Modified from Matsuura S, Shirakami G, Iada H, et al: The effect of sevoflurane on ciliary motility in rat cultured tracheal epithelial cells: A comparison with isoflurane and halothane. Effects of Inhaled Anesthetics on Surfactant

Pulmonary surfactant decreases the work of breathing by reducing surface tension at the fluid-gas interface. Surfactant is a mixture of proteins and phospholipids synthesized by alveolar type II cells. Similar to mucus, surfactant plays a role in removing foreign particles from airways while also enhancing the bactericidal actions of alveolar macrophages. Both halothane[82] and iso-

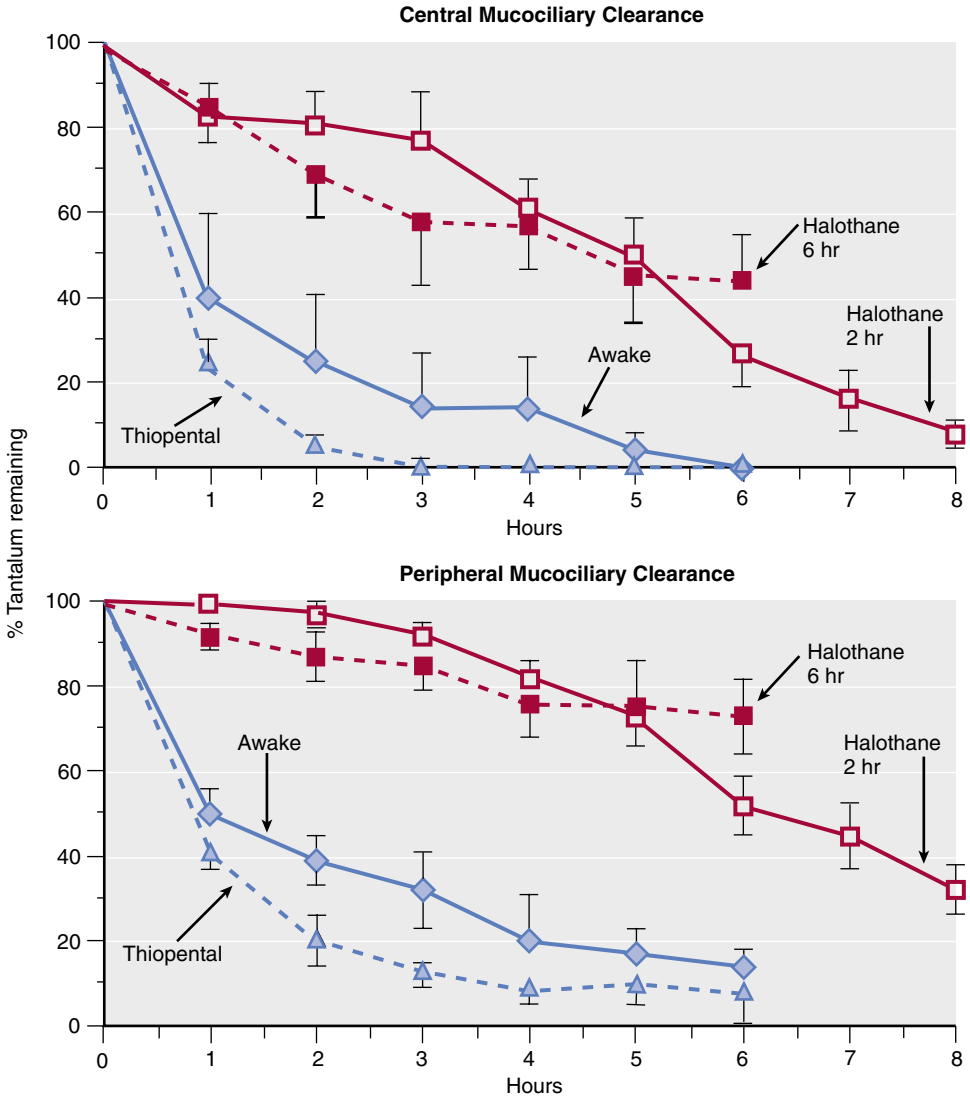

Figure 22-7 Mucociliary clearance measured as tantalum clearance in patients undergoing surgery under either general or local anesthesia (awake). Note the decrease in mucociliary clearance in both the peripheral and central airways during halothane anesthesia. *(Modified from Forbes AR, Gamsu G: Mucociliary clearance in the canine lung during and after general anesthesia. Anesthesiology 50:26, 1979, with permission.)*

flurane[83] transiently reduced phosphatidylcholine synthesis by alveolar cells in a dose-dependent manner during a 4-hour exposure. High concentrations of halothane also disrupted the energy metabolism of cultured alveolar cells as indicated by reduced ATP content and enhanced glycolytic metabolism. Halothane and isoflurane potentiated the hydrogen peroxide–mediated reduction of phosphatidylcholine in alveolar type II cells,[83,84] possibly via halothane-specific effects on cell energetics. Halothane decreased Na^+/K^+-adenosine triphosphatase (ATPase) and Na^+ channel activity in alveolar type II cells, an effect that was probably related to alterations in ICa^{2+} concentrations or ATP depletion.[85] A similar decrease in type II alveolar cell Na^+/K^+-ATPase has been shown after treatment with isoflurane.[86] Transepithelial Na^+ transport helps regulate alveolar fluid balance, and thus significant impairment in such transport may promote alveolar edema. This observation is particularly important because halothane and isoflurane decrease alveolar epithelial fluid clearance.[87] The phospholipid makeup of surfactant is critical to its functional integrity. However, the hydrophobic surfactant-associated protein C, which is synthesized exclusively by alveolar type II cells, confers the properties of rapid surface adsorption and reduction of surface tension to phospholipids, facilitates the adsorption and spreading of phospholipids to form the surfactant monolayer, and enhances lipid uptake in alveolar type II cells. In addition, exogenous surfactant that contains surfactant-associated protein C is effective in decreasing rates of barotrauma and mortality in vivo. Clinically relevant concentrations of halothane increased surfactant-associated protein C mRNA in vitro but exerted the converse effect in mechanically ventilated rats.[88] In contrast, thiopental administration increased the content of surfactant-associated protein C mRNA in both in vitro and in vivo (mechanically ventilated) models (Fig. 22-8).[88] Extrapolation of these findings to patients undergoing anesthesia should be done with caution, but these results suggest a potentially additive and deleterious role of halothane and mechanical ventilation on surfactant production and homeostasis of the alveolar space, particularly in the presence

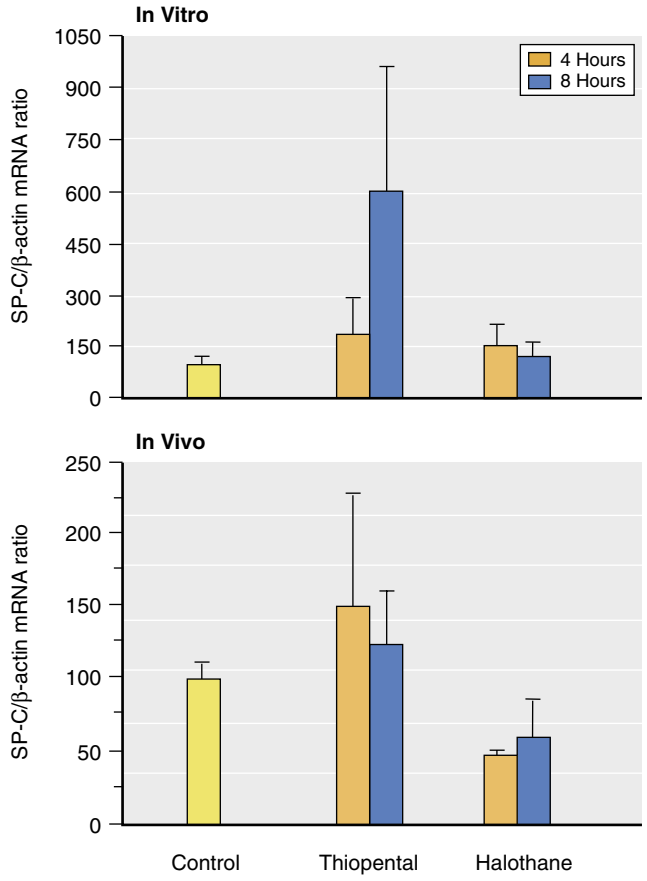

Figure 22-8 Halothane increases surfactant-associated protein C (SP-C) mRNA in vitro but exerts the opposite effects in mechanically ventilated rats. Thiopental administration increased the content of surfactant-associated protein C mRNA in both in vitro and in vivo models. *(Modified from Paugam-Burtz C, Molliex S, Lardeux B, et al: Differential effects of halothane and thiopental on surfactant protein C messenger RNA in vivo and in vitro in rats. Anesthesiology 93:805, 2000, with permission.)*

of acute lung injury. The actions of desflurane and sevoflurane on pulmonary surfactant metabolism have yet to be evaluated.

The specific roles of depressed mucociliary function and alterations in type II alveolar cells on pulmonary complications remain unclear, but impairment of ciliary motility, bronchial mucus transport, and surfactant production may play a significant role in perioperative morbidity. As discussed later, inhaled anesthetics may also play an important immunomodulatory role on type II alveolar cells during lung injury.

Prolonged administration of inhaled anesthetics may lead to mucus pooling and adversely alter alveolar cell surfactant metabolism. These actions may result in deleterious effects on pulmonary function, including atelectasis and infection. Patients at greatest risk appear to include those with excessive or abnormal mucus or surfactant production and those with acute lung injury (e.g., chronic bronchitis, asthma, cystic fibrosis, and chronic mechanical ventilation). Nevertheless, controlled studies of the effects of inhaled anesthetics on mucociliary function, surfactant metabolism, and immunomodulation in patients with or animal models of compromised pulmonary performance have yet to be performed.

Pulmonary Vascular Resistance

Determinants of Pulmonary Vascular Tone

PVR is lowest at a lung volume equivalent to FRC. Pulmonary blood vessels are compressed at high lung volumes, whereas vessels become shorter, narrower, and more tortuous because of loss of the supportive tethering of surrounding lung parenchyma at low lung volumes. Changes in pulmonary arterial pressure and PVR have significant effects on gas and fluid exchange in the lung. An increase in PVR causes a corresponding increase in pulmonary arterial pressure that promotes interstitial fluid transudation. PVR is also increased by positive end-expiratory pressure, alveolar hypoxia and hypercapnia, and critical closing pressure. Inhaled anesthetics tend to reduce lung volume and may therefore have indirect effects on PVR through this mechanism as well.

Direct changes in pulmonary vascular tone alter PVR by changing the slope of the pressure-flow relationship. Such direct changes may be produced by a rapid rise in ICa^{2+} or by alterations in sympathetic nervous system tone, arterial oxygen and carbon dioxide tension, acid-base balance, or circulating concentrations of catecholamines. Hypercapnia at constant pH (i.e., isohydria) does not alter isolated pulmonary arterial tone, but normocapnic acidosis relaxes isolated pulmonary arteries by an endothelium-independent mechanism.[89] Nevertheless, pulmonary arterial endothelial dysfunction has also been reported to potentiate hypercapnic vasoconstriction.[90]

Vasoactive substances can affect vascular tone as well. Inducible, endothelial, and neuronal NO synthases are widely distributed in the lung, are extensively involved in vascular homeostasis, and are intimately linked to the pulmonary oxygen environment (also see Chapter 31). NO synthase appears to play little role in the regulation of PVR in a healthy, normoxic lung,[91,92] but this enzyme and its metabolite NO are critical mediators of PVR during hypoxia.[93] In addition to producing vasodilation in ventilated, normoxic pulmonary regions during one-lung hypoxia, NO may also release an endogenous inhibitor of NO synthase that vasoconstricts nonventilated, hypoxic regions.[94] NO may be beneficial in the treatment of high-altitude pulmonary edema[95] and neonatal pulmonary hypertension resulting from a variety of congenital heart diseases, hypoplastic lung, and meconium aspiration. NO is also beneficial in the treatment of adult pulmonary hypertension as long as the resistance is not "fixed," such as in acute severe mitral regurgitation, congestive heart failure, and heart or lung transplantation. However, inhalation of NO during acute bronchospasm may paradoxically worsen the hypoxemia.[96] Whether this adverse action is mediated by direct bronchodilatory actions on less constricted peripheral airways or by worsening intrapulmonary shunt is unclear. The pulmonary endothelial dysfunction associated with cardiopulmonary bypass impairs endothelium-dependent vasodilation.[97] Nonetheless, use of NO in pediatric and adult cardiac surgical patients has become a common means of reducing PVR in this setting. Similar to NO, carbon monoxide (CO) stimulates guanylyl cyclase and increases cGMP levels in pulmonary arterial vascular smooth muscle cells to regulate vascular tone. Inhaled CO also attenuates the hypoxemia-induced increases in PVR through this mechanism.[98] Prostacyclin is another endogenous vasodilatory substance released from endothelium that elicits smooth muscle relaxation through stimulation of adenylyl cyclase and production of cAMP.

More recently, a role for endothelium-derived hyperpolarizing factor (EDHF) was identified as a third pathway for endothelium-mediated vasorelaxation.[99] EDHF produces relaxation by hyperpolarizing vascular smooth muscle in a process involving activation of potassium channels. Production of EDHF may be elicited by endothelial agonists or alterations in wall shear stress.[99] Although EDHF appears to be an important regulator of pulmonary blood flow, its role in modulating PVR has not been well defined.

Mechanism of Hypoxic Pulmonary Vasoconstriction

Regional alterations in PVR affect the regional distribution of blood flow within the lung, produce changes in ventilation-perfusion matching, and simultaneously affect gas exchange (also see Chapter 15). The distribution of pulmonary blood flow and ventilation in the lung, which was once thought to primarily be a gravity-mediated phenomenon, now appears to also be due to regional heterogeneity caused by asymmetric branching of the airways and blood vessels.[100] An increase in PVR occurring within an area of atelectasis causes localized tissue hypoxia but optimizes overall gas exchange (e.g., decreases the alveolar-arterial oxygen tension gradient [$P_{AO_2} - P_{aO_2}$]) by shifting blood flow away from the atelectatic segment to well-ventilated regions of the lung. This phenomenon, termed hypoxic pulmonary vasoconstriction (HPV), is unique to the pulmonary circulation in that other vascular beds (e.g., coronary, cerebral) dilate in response to hypoxia. Thus, HPV maintains oxygenation, and drugs (including anesthetics) that interfere with HPV may adversely affect gas exchange.

HPV is a locally mediated phenomenon that occurs when alveolar oxygen tension falls below 100 mm Hg and is maximal when oxygen tension is approximately 30 mm Hg. The specific mechanisms underlying HPV and the precise location of oxygen sensors remain unclear.[101,102] Mixed venous oxygen tension may influence HPV in the atelectatic lung because alveolar oxygen tension approaches venous oxygen tension under these conditions. Hypercapnia-induced acidosis increases PVR in intact animals and isolated, perfused lungs. Acidosis-induced increases in PVR are relatively minor at normal alveolar oxygen tensions but are dramatically enhanced during alveolar hypoxia. Local acidosis and increases in alveolar carbon dioxide tension may augment HPV and further improve arterial oxygenation in healthy lungs. High carbon dioxide concentrations reduce NO levels,[103] but whether this action is responsible for hypercapnia-induced improvements in the ratio of ventilation to perfusion is unknown.[104]

Inhaled Anesthetics and Hypoxic Pulmonary Vasoconstriction

All volatile anesthetics vasodilate the pulmonary vascular bed. Akata[105] presented a thorough review of the mechanisms by which inhaled anesthetics produce this vasodilation, including a reduction in free cytosolic calcium and inhibition of myofilament calcium sensitivity. Although nitrous oxide increases PVR, the pulmonary vasodilator effect of volatile agents is relatively small in normal lungs. The limited decreases in PVR produced by volatile anesthetics are frequently offset by a concomitant reduction in cardiac output in vivo. The net effect of these actions results in little if any change in pulmonary artery pressure and a small decrease in total pulmonary blood flow. In contrast with their direct vasodilatory actions, halothane, isoflurane, enflurane, and desflurane attenuate K_{ATP} channel– and endothelin-mediated pulmonary vasodilation in chronically instrumented dogs.[106-108] Inhibition of pulmonary vasodilation is not a uniform observation during administration of volatile anesthetics under all conditions. For example, isoflurane and halothane, but not enflurane, enhance isoproterenol-mediated vasodilation.[109,110] Unlike the findings with other volatile agents, K_{ATP} channel–mediated pulmonary vasodilation in response to lemakalim is preserved during sevoflurane anesthesia.[108] Indeed, there is evidence that halothane, enflurane, and isoflurane but not sevoflurane differentially modulate pulmonary vascular tension through calcium-activated or voltage-sensitive K^+ channels, at least in isolated rabbit lungs.[111] In isolated lungs, halothane- and enflurane-induced constriction of pulmonary vessels was potentiated by Kv channel inhibition. Vasoconstriction during halothane administration was also attenuated by K_{Ca} channel blockade. Isoflurane did not affect pulmonary vessels when Kv channels were inhibited. In contrast to the findings with halothane and enflurane, sevoflurane dilated pulmonary vessels and the dilation was not influenced by K^+ channel subtype inhibitors (Fig. 22-9). Isoflurane also attenuated hypotension-induced pulmonary vasoconstriction.[112]

Rather than causing pure vasodilation, volatile anesthetics produced a paradoxical initial dose-dependent increase in force in isolated pulmonary arterial strips because of release of Ca^{2+} from intracellular stores. Subsequently, a decrease in force (associated with activation of Ca^{2+}-calmodulin–dependent protein kinase II) occurs (Fig. 22-10).[113,114] Extrapolation of these results to humans in vivo must be approached with caution, but these studies suggest that vasodilatory responses may be more profound in patients with reduced SR Ca^{2+} stores (e.g., neonates) or those with depressed protein kinase activity (e.g., primary pulmonary hypertension).

Several mechanisms contribute to the diminished FRC, reduced oxygenation, and increased alveolar-arterial oxygen gradient during anesthesia. Volatile anesthetics contribute to this process by affecting HPV. The effects of volatile agents on HPV are multifactorial and involve direct actions on the pulmonary vasculature combined with indirect effects mediated by systemic hemodynamics, the autonomic nervous system, and humoral actions. In general, in vitro studies have demonstrated that all known inhaled anesthetics attenuate HPV to some degree in isolated perfused lungs or in in situ preparations with constant perfusion (Fig. 22-11), whereas most intravenous anesthetics do not. Addition of the Ca^{2+} channel blocker verapamil to a volatile anesthetic further reduces HPV by an additional 35% to 40%, thus suggesting that volatile anesthetics and Ca^{2+} channel antagonists may inhibit HPV through different sites of action. The mechanism of the direct inhibitory action of volatile anesthetics on HPV is unclear but may be related to enhancement of arachidonic acid metabolism[115] or other endothelial-derived vasodilating factors.[116] Conversely, other evidence suggests that anesthetic-induced inhibition of HPV may occur independent of the presence of pulmonary vascular endothelium, NO, or guanylate cyclase.[117-119]

Volatile anesthetics also disrupt Ca^{2+} homeostasis in vascular smooth muscle and thereby interfere with pulmonary vasoconstriction. Halothane and isoflurane attenuated

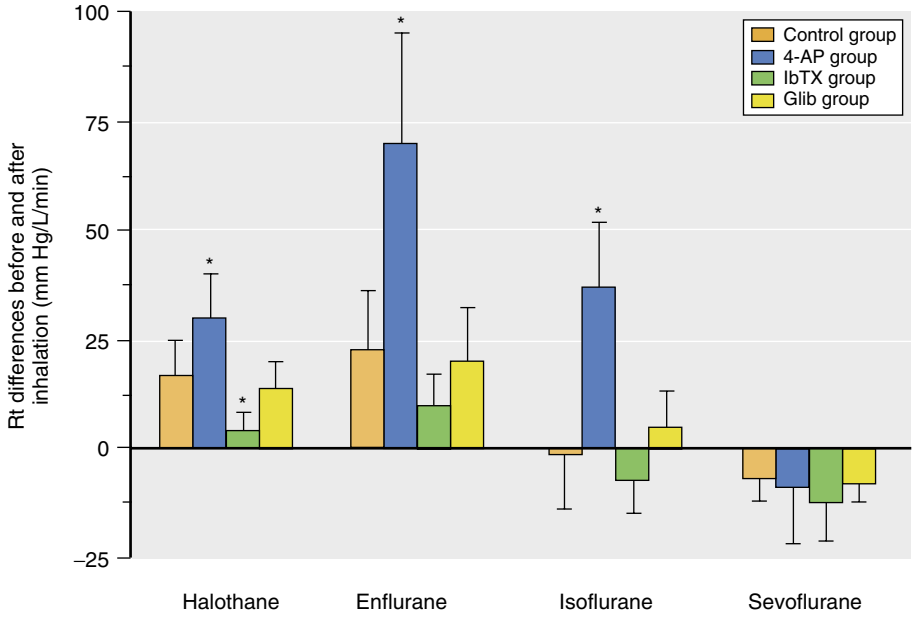

Figure 22-9 Total pulmonary vascular resistance (Rt) before and after anesthetic inhalation. Data are means ± SD. *$P < .01$ versus control group. 4AP, voltage-sensitive K^+ channel inhibitor; Glib, glibenclamide, an adenosine triphosphate–sensitive K^+ channel inhibitor; IbTX, calcium-activated K^+ channel inhibitor; Rt difference, resistance after administration of anesthetic minus resistance before administration of anesthetic. *(Modified from Liu R, Ishibe Y, Okazaki N, et al: Volatile anesthetics regulate pulmonary vascular tension through different potassium channel subtypes in isolated rabbit lungs. Can J Anaesth 50:301, 2003, with permission.)*

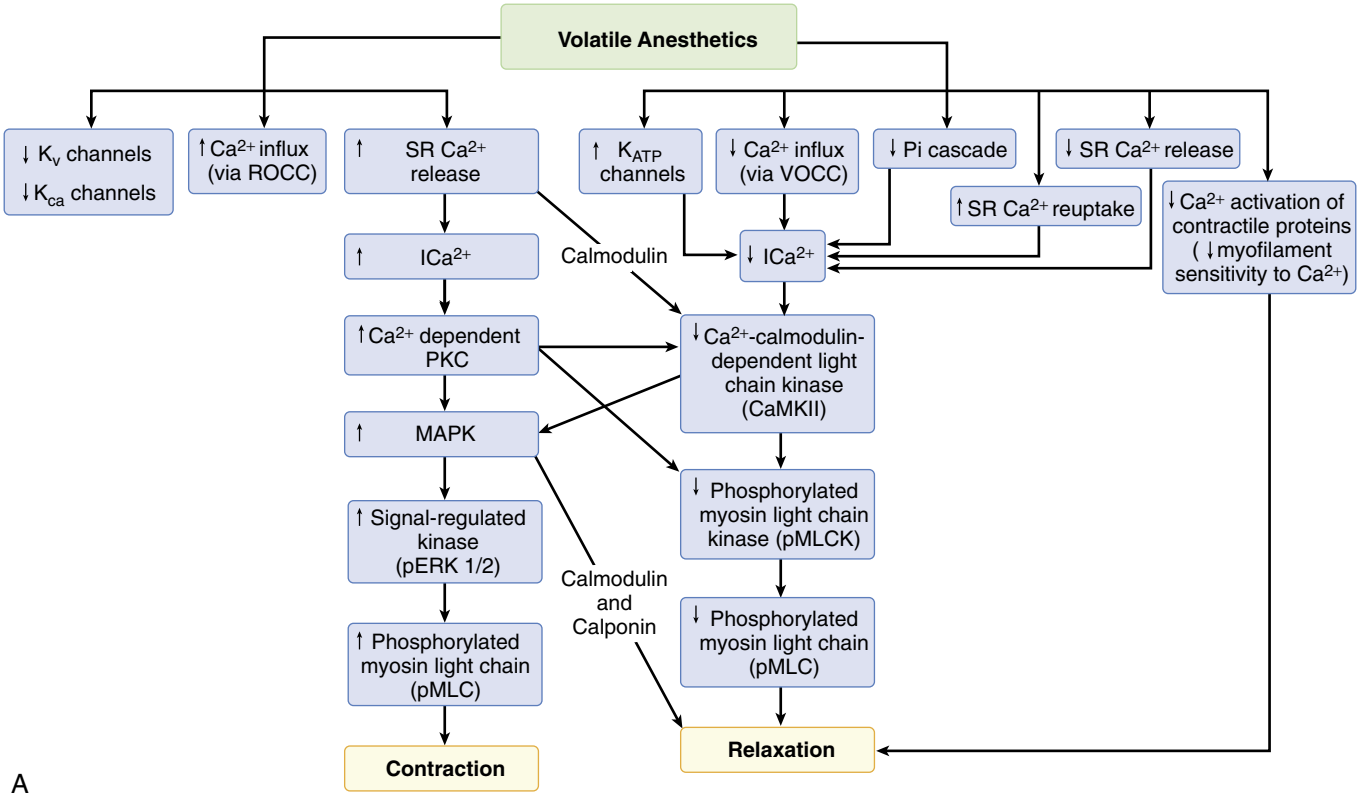
endothelium-dependent vasodilation by inhibiting accumulation of cGMP[119] and K_{ATP} channel–mediated interaction between NO and prostacyclin in isolated canine pulmonary artery rings.[120] In contrast, isoflurane modulated the HPV response, at least in part, through Ca^{2+}-activated and voltage-sensitive K^+ but not K_{ATP} channels in isolated rabbit lungs. Attenuation of HPV by sevoflurane occurred independent of K^+ channel function.[121] Rats with liver cirrhosis exhibited a blunted HPV response and arterial hypoxemia. These cirrhotic rats demonstrated increased NO and reduced endothelin concentrations, but the blunted HPV response observed in these animals did not involve these systems and was mediated instead by activation of Ca^{2+}-activated K^+ channels.[122]

The action of volatile anesthetics on HPV in vivo have been poorly delineated, in part because of several factors that are known to impair HPV, including temperature, pH, carbon dioxide tension, relative degree of hypoxia, size of the hypoxic area, surgical trauma, and concomitant medications. During one-lung ventilation, the direct inhibitory effects of volatile anesthetics on HPV may increase perfusion in the nonventilated lung. This enhanced perfusion potentially leads to an increase in shunt fraction and a reduction in arterial oxygenation. However, volatile anesthetics may also affect HPV, lung perfusion, and oxygenation by indirect actions on cardiac output and mixed venous oxygen saturation.[123] The direct effects of anesthetics on HPV, as opposed to indirect actions mediated through alterations in pulmonary perfusion, must be appreciated. The efficacy of HPV varies inversely with pulmonary arterial blood flow, and a direct inhibition of HPV by anesthetics may be opposed by a simultaneous reduction in cardiac output such that HPV may appear to be unaffected. Thus, the net HPV response to volatile anesthetics remains unchanged when cardiac output is reduced, but it may be fully intact or only minimally attenuated when pulmonary blood flow is preserved. A reduction in cardiac output also decreases mixed venous oxygenation, which leads to pulmonary vasoconstriction. These data emphasize the flow dependence of HPV during administration of a volatile anesthetic. Baseline pulmonary blood flow and pressure also modulate the effects of HPV. Elevated pulmonary artery pressure may cause passive distention of constricted vascular beds and thus reverse the HPV. Alternatively, reflex pulmonary and systemic vasoconstriction in response to hypotension may increase PVR in healthy lung segments, thereby leading to a shift of pulmonary blood flow to hypoxic areas of lung.

Early studies suggested that nitrous oxide attenuates HPV in animal models in vivo. In contrast, clinically relevant concentrations of halothane, isoflurane, enflurane, sevoflurane, and desflurane appear to have minimal effects on HPV in vivo (Fig. 22-12).[124,125] As opposed to the findings with isoflurane,[115] inhibition of HPV was not observed during sevoflurane or desflurane anesthesia[124] in chronically instrumented dogs subjected to gradual occlusion of the right main pulmonary artery. Nitrous oxide,[126] desflurane, and isoflurane,[127] but not xenon,[126] reduced mixed venous oxygen saturation, cardiac output, and arterial oxygenation during one-lung ventilation in pigs. However, nitrous oxide,[126] xenon,[126] desflurane,[127,128] and isoflurane[127,129] did not alter perfusion of the nonventilated lung or reduce the shunt fraction during one-lung ventilation. In animals with a preexisting gas exchange defect as a result of pneumoperitoneum, sevoflurane but not isoflurane caused more pronounced abnormalities in gas exchange than did propofol.[130] Thus, although reductions in HPV by inhaled anesthetics, as predicted by in vitro studies, have been relatively small in vivo, coexisting pulmonary disease may worsen anesthetic-induced gas exchange abnormalities.



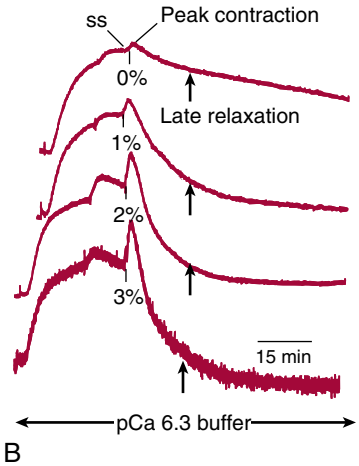


Figure 22-10 A, Proposed signaling pathways underlying volatile anesthetic–induced contraction and relaxation in pulmonary artery smooth muscle. Intracellular calcium (ICa^{2+}) may be increased by release from the sarcoplasmic reticulum (SR), by inhibition of voltage-sensitive (K_v) or calcium-activated (K_{Ca}) potassium channels, or by receptor-operated Ca^{2+} channels. Increased ICa^{2+} results in an initial dose-dependent increase in force (associated with activation of protein kinase C and increased mitogen-activated protein kinase [MAPK]). Volatile anesthetics also decrease ICa^{2+} by activating K_{ATP} channels, thereby inhibiting Ca^{2+} influx via voltage-operated Ca^{2+} channels (VOCC), decreasing SR-induced release of Ca^{2+}, inhibiting the phosphatidylinositol (Pi) cascade, and enhancing SR-mediated reuptake of Ca^{2+}. The resultant decrease in force is associated with activation of Ca^{2+}-calmodulin–dependent protein kinase II. It is important to note that there are many agent-specific effects of volatile anesthetics on each component of these pathways. **B,** Example of a biphasic (contraction/relaxation) effect of halothane on pulmonary arterial smooth muscle. 0%, 1%, 2%, and 3%, halothane concentrations; ss, control force at steady state before halothane. Halothane dose-dependently enhanced Ca^{2+}-activated peak force, as well as late relaxation. *(Modified from Akata[105], Su and Vo[113], and Zhong and Su,[114] with permission.)*

The half-maximum inhibiting effect (ED_{50}) values were within the range of 1 and 2 minimum alveolar concentration (MAC) (for rabbits) for both agents. *(Reproduced from Loer SA, Scheeren T, Tarnow J: Desflurane inhibits hypoxic pulmonary vasoconstriction in isolated rabbit lungs. Anesthesiology 83:552, 1995, with permission.)*

Effects of Inhaled Anesthetics on the Pulmonary Vasculature in Humans

Isoflurane does not alter pulmonary shunt function in healthy patients, even at concentrations that produce systemic hypotension.[131] Most clinical thoracic surgery is usually undertaken with the patient in the lateral position with an open chest, which dramatically alters the relative distribution of ventilation and perfusion. Under these circumstances, a diseased nondependent lung may substantially affect pulmonary vascular responsiveness to hypoxia, as may surgical manipulation of the lung itself. Most observations in experimental animals or patients undergoing single-lung ventilation fail to demonstrate clinically significant attenuation of HPV during administration of a volatile anesthetic. There do not appear to be significant differences in shunt fraction, PVR, or oxygenation between isoflurane and sevoflurane anesthesia in patients with lung cancer undergoing one-lung ventilation for lobectomy.[132] Two studies demonstrated that the shunt fraction is similar in patients receiving propofol or either isoflurane[133] or sevoflurane[134] during single-lung ventilation. No significant differences in shunt fraction or arterial oxygen tension were observed when pulmonary gas exchange was compared during intravenous infusion of ketamine (which does not inhibit HPV) and administration of enflurane. In contrast, isoflurane[135,136] and sevoflurane[136] impaired oxygenation and decreased shunt fraction more than intravenous infusion of propofol did during single-lung ventilation in humans. However, the differences in oxygenation observed in these studies were small and of little clinical relevance. Interpretation of the differences in findings between these intravenous and volatile anesthetics observed in studies may be complicated by the depth of anesthesia. In contrast, the doses of propofol and sevoflurane selected were based on similar depth of anesthesia (determined with a bispectral index [BIS] monitor), and comparable reductions in arterial oxygenation were observed in patients undergoing one-lung ventilation.[137] Similar and rather modest changes in shunt fraction and oxygenation were shown to occur with halothane,[138] isoflurane,[132,138,139] desflurane,[139] and sevoflurane[132] in patients undergoing thoracotomy and single-lung ventilation (Fig. 22-13).

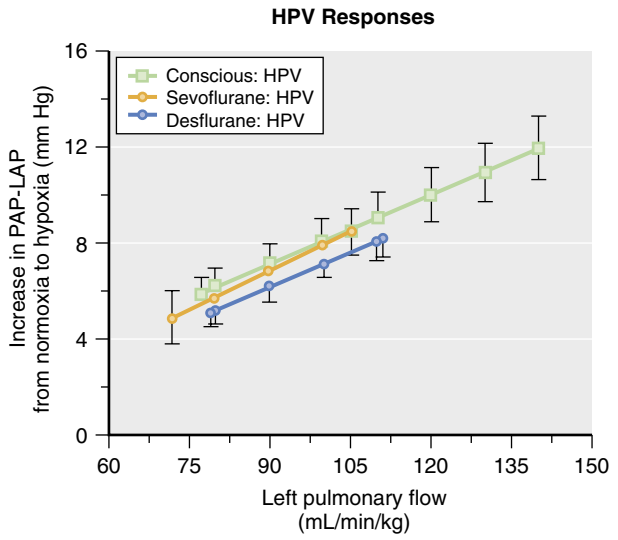

Figure 22-12 Composite hypoxic pulmonary vasoconstriction (HPV) responses (increase in pulmonary artery pressure [PAP] minus left atrial pressure [LAP]) as a function of left pulmonary flow in the same seven chronically instrumented dogs in the conscious state and during sevoflurane and desflurane anesthesia. Neither anesthetic affected the magnitude of HPV when compared with the response in the conscious state. *(From Lesitsky MA, Davis S, Murray PA: Preservation of hypoxic pulmonary vasoconstriction during sevoflurane and desflurane anesthesia compared to the conscious state in chronically instrumented dogs. Anesthesiology 89:1501, 1998, with permission.)*

There is convincing evidence that all volatile anesthetics may be used safely in patients undergoing thoracotomy and single-lung ventilation (also see Chapter 59). The increase in shunt and decrease in oxygenation caused by halothane or isoflurane[138] was consistent with an approximately 20% inhibition of

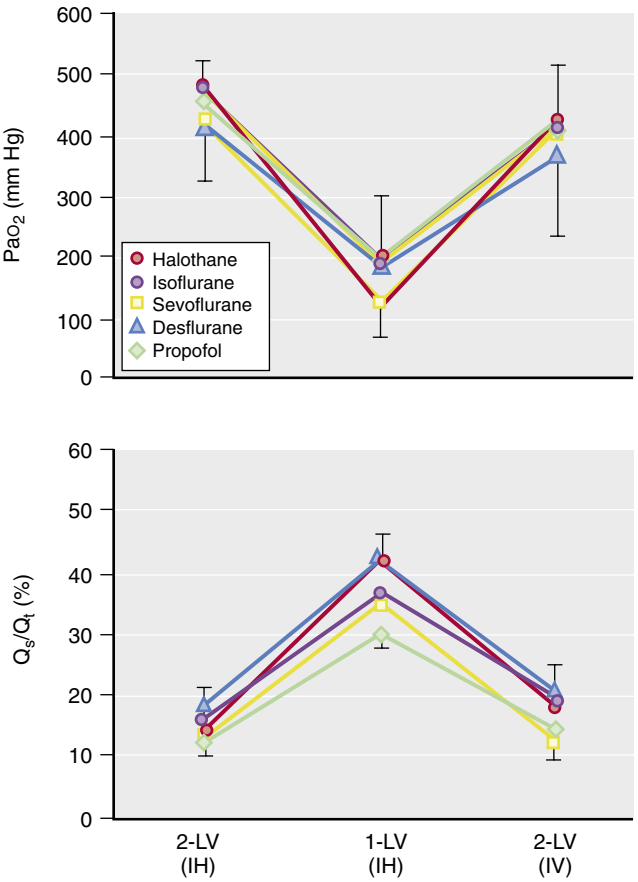

Figure 22-13 Arterial oxygenation (Pao_2) and intrapulmonary shunt (Q_s/Q_t) in patients with both lungs ventilated (2-LV) or with one lung ventilated (1-LV). Patients received an inhaled agent (IH)—halothane, isoflurane, sevoflurane, or desflurane—or the intravenous anesthetic propofol. Note the minimal effect on Pao_2 and shunt that occurs when changing from a volatile anesthetic to an intravenous agent. *(Adapted from Abe et al.,[132,136] Benumof et al.,[138] and Pagel et al.,[139] with permission.)*

HPV at 1 MAC. Instead of a 50% reduction in pulmonary blood flow in a hypoxic lung in the absence of a volatile agent, blood flow decreases by 40% during hypoxia in the presence of 1 MAC isoflurane. This change in flow corresponds to an increase in pulmonary shunt by about 4% of cardiac output. Carlsson and colleagues[140] applied multiple inert gas elimination techniques to measure the true shunt fraction in humans anesthetized with volatile agents and demonstrated a 2% to 3% increase in shunt fraction corresponding to approximately 20% HPV inhibition with 1.5% isoflurane. There were also no significant effects on arterial oxygenation with clinically relevant concentrations of isoflurane or enflurane. Indeed, the use of total intravenous anesthesia with propofol and alfentanil as opposed to a volatile anesthetic did not decrease the risk for hypoxemia during single-lung ventilation.[133] Not only does isoflurane appear to be safe to use during single-lung ventilation, but administration of isoflurane before pulmonary ischemia also protects against ischemia-reperfusion injury. Isoflurane attenuated increases in PVR and reductions in the coefficient of filtration and the wet-to-dry ratio in isolated rabbit lungs subjected to ischemia and reperfusion.[141]

Marked increases in shunting have been demonstrated by the administration of pulmonary vasodilators (e.g., sodium nitroprusside, nitroglycerin) in dogs with oleic acid–induced pulmonary edema. Theoretically, volatile anesthetics may produce a similar response in patients with adult respiratory distress syndrome or with other types of pulmonary pathology associated with large right-to-left intrapulmonary shunts, but this hypothesis has yet to be comprehensively examined. Isoflurane did not attenuate the enhanced pulmonary vasoconstrictor response to sympathetic α-adrenoreceptor activation or influence pulmonary vascular tone in the presence of increased PVR secondary to endothelin-mediated receptor activation[142] after single-lung transplantation.[143] These findings may have important implications for the intraoperative anesthetic management of patients with similar abnormalities in pulmonary vasoregulation because volatile anesthetics may produce smaller reductions in PVR than might be expected.

The precise effects of inhaled anesthetics on HPV and pulmonary shunt in patients with preexisting pulmonary disease remain to be defined, but the action of these agents on the pulmonary vasculature itself must be considered when evaluating causes of hypoxemia during anesthesia. Clinical observations suggest that volatile anesthetics exert only mild, if any inhibitory effects on HPV and oxygenation. This relatively minor inhibition of HPV by volatile anesthetics should not significantly influence clinical decision-making, especially given the efficacy of continuous positive airway pressure in improving oxygenation of the nondependent lung. Thus, the net effect of volatile anesthetics on HPV is multifactorial and not only depends on the direct effects of these agents on pulmonary vasomotor tone but is also determined by indirect actions that commonly occur during anesthesia and surgery.

Control of Ventilation

Many different stimuli interact in a complex manner to control ventilation in humans. The traditional approach to studying the effects of drugs on ventilation has been to measure ventilatory responsiveness (e.g., expired minute volume, respiratory frequency, arterial carbon dioxide tension) before and after drug administration. A complete description of ventilatory control is beyond the scope of this chapter, and several excellent reviews of this subject already exist.[144-150] However, an understanding of normal ventilatory responses and control mechanisms is necessary to appreciate the actions of anesthetics and the methods by which these effects are measured.

Control of Breathing—Central Controllers, Sensors, Effectors

A control system that modulates ventilation is required to maintain the stability of arterial blood gas tension and acid-base status, as well as to integrate the respiratory rate and tidal volume to minimize the work of breathing in response to variations in total ventilatory requirements (Fig. 22-14). The system responsible for receiving and integrating input signals and ultimately producing movement of air in and out of the lungs is composed of the following:

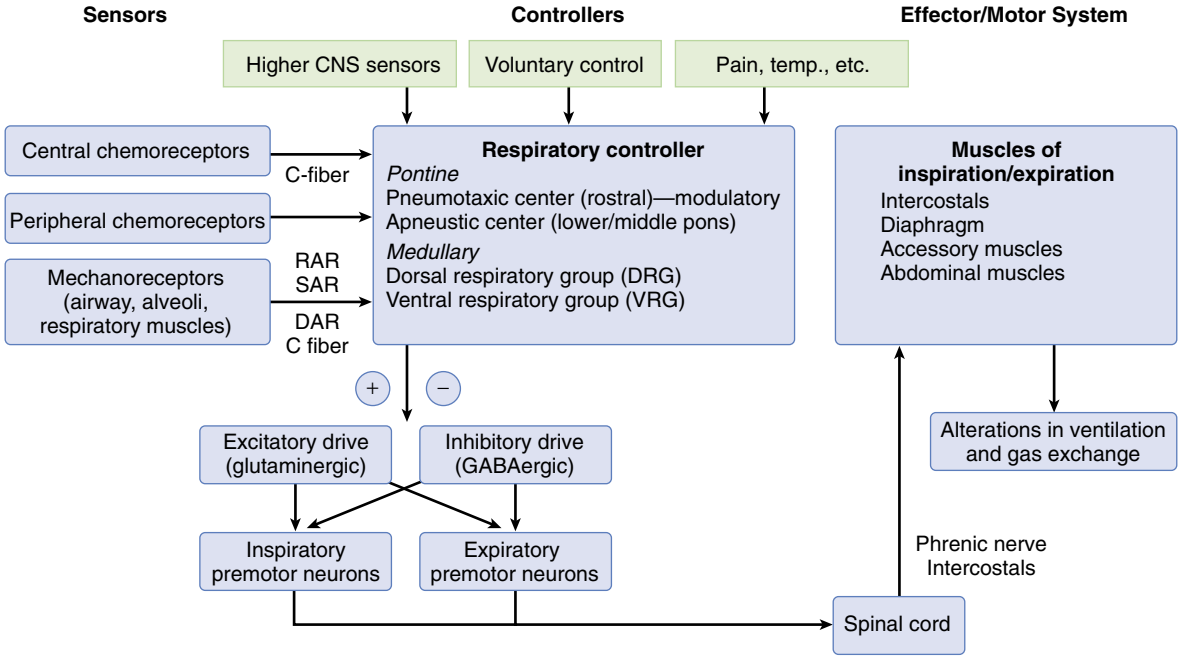

Figure 22-14 Some aspects of the reflex control of ventilation. Sensors include central and peripheral chemoreceptors, as well as a variety of mechanoreceptors. Input from these many sources interacts to alter ventilatory controller output from pontomedullary sites to muscles of respiration, thus altering ventilation and ultimately gas exchange. Central and peripheral chemoreceptors transmit information via nonmyelinated C fibers. Mechanoreceptors, such as rapidly (RAR) and slowly (SAR) adapting stretch receptors and deflation-activated receptors (DAR) are found in airway smooth muscle, alveoli, and respiratory muscle. C fibers may also transmit information from mechanoreceptors. Inspiratory bulbospinal neurons in the medulla are premotor neurons that drive phrenic and intercostal motoneurons and ultimately the diaphragm and muscles of inspiration. Excitatory drive to these motoneurons is mediated by glutaminergic neurotransmission. The neurons of timing and pattern generation, as well as premotor neurons, are also subject to tonic γ-aminobutyric acid (GABA)-mediated inhibition.

The *sensory system* may be chemical (i.e., peripheral and central chemoreceptors) or mechanical (i.e., distortion receptors located in airways, alveoli, and respiratory muscles).

The *respiratory control system* integrates the signal input from receptor sites, centers of consciousness, and other influences (e.g., pain) and subsequently produces nerve traffic to the muscles of respiration.

The *motor system* is composed of the chest wall, intercostal, diaphragmatic, and abdominal muscles, all of which respond to signals from the control center through phrenic and spinal nerves.

The respiratory rhythm generator resides within the brainstem and consists of two primary types of respiratory neurons: the dorsal respiratory group (DRG), chiefly associated with inspiration, and the ventral respiratory group (VRG), which contains inspiratory and expiratory neurons. The cortex is able to override these brainstem centers if voluntary control is desired. Other parts of the brain, such as the hypothalamus and limbic system, may modulate ventilation during certain emotional states. The precise mechanism of rhythm generation remains unknown, but regions in the ventrolateral medulla (including the rostral VRG) contain rhythm-generating, self-oscillating neurons. Central terminations of afferent airway sensory fibers are found in the caudal portion of the nucleus tractus solitarius. Second-order neurons then innervate neurons located in respiratory-related regions of the pons, medulla, and spinal cord. Medullary regions involved in the generation and modulation of respiratory and sympathetic nervous system vasomotor output, such as the retrotrapezoid nucleus, may also contain neurons functioning as central oxygen detectors.[151] The rostral pons contains the pneumotaxic center, which has inspiratory and expiratory neurons and plays a critical modulating role by fine-tuning respiratory rhythm and integrating vagal and chemoreceptive input. The apneustic center, located in the lower portion of the pons, appears to have an excitatory effect on the inspiratory area of the medulla. Whether this center plays an important role in normal respiration is unclear. Central respiratory control mechanisms regulate tidal volume and inspiratory and expiratory times to achieve adequate ventilation and gas exchange. Excitatory drive to bulbospinal inspiratory neurons of the caudal VRG is mediated by tonic input (acting through *N*-methyl-D-aspartate [NMDA] receptors) and phasic input (primarily consisting of non-NMDA glutamate receptors).[152,153] Neurotransmission in bulbospinal expiratory neurons is mediated via NMDA-type glutamate receptor input and modulated by γ-aminobutyric acid type A ($GABA_A$) receptors.[152]

Input signals originate from chemoreceptors and mechanoreceptors in the upper airways, lungs, and chest wall and are transmitted by the vagus and spinal nerves. Extensive discussion of these receptors and their physiologic consequences is beyond the scope of the current chapter. However, because volatile anesthetics may differentially affect pulmonary sensory receptors, a basic understanding of the types, function, and location of these receptors is important. Traditionally, lung sensory receptors were divided into three groups: slowly and rapidly adapting stretch receptors (SARs and RARs, respectively) and bronchopulmonary C fibers. SARs lie within airway smooth muscle, discharge regularly during sustained inflation, and demonstrate little adaptation. Stimulation of these receptors by lung inflation results in slowing

of the respiratory rate because of an increase in expiratory time. The opposite effect is observed during lung deflation, which initiates inspiratory activity. This phenomenon, known as the Hering-Breuer reflex, is largely inactive in adult humans but appears to be active and potentially important in neonates. Activation of SARs by persistent elevations in end-expiratory lung volume produced an inhibitory effect on central drive (i.e., an increase in the apneic threshold) and an attenuated ventilatory response to progressive hypercapnia.[154] RARs, also known as irritant receptors, lie between airway epithelial cells and are stimulated by dust, cold air, and other noxious airway irritants. These receptors initially discharge vigorously and cause bronchoconstriction and hyperpnea, but their responses are extinguished rapidly.[147] RARs in the bronchi are more chemosensitive than those located in the more proximal airway but will also cause coughing, mucus secretion, bronchoconstriction, and laryngospasm. In addition, RARs in the bronchi stimulate hyperventilation.[155] C fiber receptors are nonmyelinated chemosensors but may also respond to lung inflation at high thresholds. Activation of these receptors results in tachypnea, bronchoconstriction, and secretion of mucus. Several other receptor types have been described, including Aδ-nociceptors, "cough" receptors, J receptors, deflation-activated receptors (DARs), and a variety of mechanically driven receptors in the upper airways, intercostal muscles, and diaphragm.[146,148]

Changes in chest wall position produce alterations in efferent impulses from stretch receptors in intercostal muscle spindles that act to maintain relatively constant tidal volume during variations in inspiratory resistance. Increases in spindle discharge enhance motor activity to muscle fibers until muscle shortening relieves tension in the spindles. With increased inspiratory resistance, the muscle spindles detect a failure of shortening by the appropriate amount and increase afferent signals to the motor neuron pool. Accessory muscles of inspiration may also be recruited. This reflex increase in inspiratory effort sustains tidal volume and minute ventilation despite a greater inspiratory resistive load. These and other forces maintain normal ventilation with changes in body position, inspiratory resistance, and compliance. Extrapolation of these data obtained from experimental animals to humans should be approached with caution. For example, tension receptors in the diaphragm, not the muscle spindles, induce reflex inhibition of inspiratory intercostal activity associated with a decrease in inspiratory duration in dogs, but not humans. This effect appears to be mediated at the supraspinal level.[156]

Central and peripheral chemoreceptors respond to changes in the chemical composition of blood or the surrounding fluid. A complete discussion of chemical control of ventilation may be found in several excellent reviews.[157-160] Briefly, central and peripheral chemoreceptors are critical to chemical control of respiration. Central chemoreceptors are located near the ventrolateral medulla and other brainstem sites and respond to changes in the hydrogen ion (H^+) concentration in cerebrospinal fluid and not to arterial carbon dioxide tension or pH. Unlike H^+, carbon dioxide diffuses rapidly through the blood-brain barrier. Central chemoreceptors are more profoundly affected by respiratory than by metabolic alterations in arterial carbon dioxide tension. In contrast, peripheral chemoreceptors, located in the carotid bodies, are sensitive to changes in arterial carbon dioxide tension, pH, and most importantly, arterial oxygen tension. The mechanisms by which peripheral chemoreceptive cells respond to hypoxia and hypercapnia appear to be separate and synergistic because hypoxemia potentiates the chemical drive to a carbon dioxide challenge. Peripheral chemoreceptors appear to contribute about a third to total resting minute ventilation at normocapnia and normoxia as determined by respiratory functional testing. This contribution falls to 15% during hyperoxic normocapnia, thus suggesting that central chemoreceptors control 85% of the carbon dioxide drive during hyperoxia. Both stimuli cause membrane depolarization and activation of afferent nerve transmission.

Changes in ventilation secondary to alterations in arterial carbon dioxide tension are mediated principally at the level of the medulla. Patients whose peripheral chemoreceptors have been denervated by bilateral carotid endarterectomy demonstrate a modestly attenuated increase in ventilation in response to inhaled carbon dioxide. Inspiration of carbon dioxide in normal subjects increases minute ventilation by approximately 3 L/min/mm Hg of arterial carbon dioxide tension. This observation demonstrates high gain from central chemoreceptors in response to variations in arterial carbon dioxide tension. The slope of the relationship between minute ventilation and arterial carbon dioxide tension is an index of ventilatory drive, provided that hypoxic conditions are avoided to minimize peripheral chemoreceptor stimulation. NO is increased in the carotid bodies during hypoxia,[161] plays an inhibitory role in both the peripheral and central chemoreflex pathways during hypoxia,[162] and may act as a respiratory stimulant under normoxic conditions.[163] Experiments to determine the relationship between minute ventilation and arterial carbon dioxide tension require interpretation with these potential confounding variables in mind.

A biphasic response to hypoxia exists in humans. Adults and neonates display a similar initial hypoxia-induced increase in ventilation, but neonates exhibit a more pronounced ventilatory decline in response to hypoxic oxygen concentrations than adults do. This reaction may represent a balance between active inhibition of brainstem neuronal activities and augmentation of peripheral chemoreceptor function. Acute hypoxemia stimulates oxygen-sensitive (type I—glomus) cells in the carotid bodies to initiate a cascade of responses, including closure of K^+ channels and resultant membrane depolarization. Reactive oxygen species generated by reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, mitochondria, or heme oxygenase have been proposed as mediators of this response.[158] Release of ATP subsequently activates chemoafferent fibers of the carotid sinus nerve to relay the information to the brainstem respiratory control centers.[160] Similarly, release of ATP by central chemoreceptors on the ventral surface of the medulla after hypercapnic stimulation immediately precedes an increase in respiratory drive.[160]

General Ventilatory Effects of Anesthetics

In general, all volatile anesthetics decrease tidal volume in a dose-dependent manner. A concomitant increase in respiratory rate only partially offsets the depression of minute ventilation. As a result, an increase in resting arterial carbon dioxide tension takes place (Fig. 22-15). Early studies demonstrated that isoflurane produces more profound respiratory depression than halothane does, but in contrast to halothane, isoflurane did not progressively increase the respiratory rate.[164] Like halothane, enflurane reduces tidal volume and minute ventilation concomitant with compensatory tachypnea in a dose-related manner.[165] Prolonged administration (3 to 7 hours) of halothane or enflurane decreases the

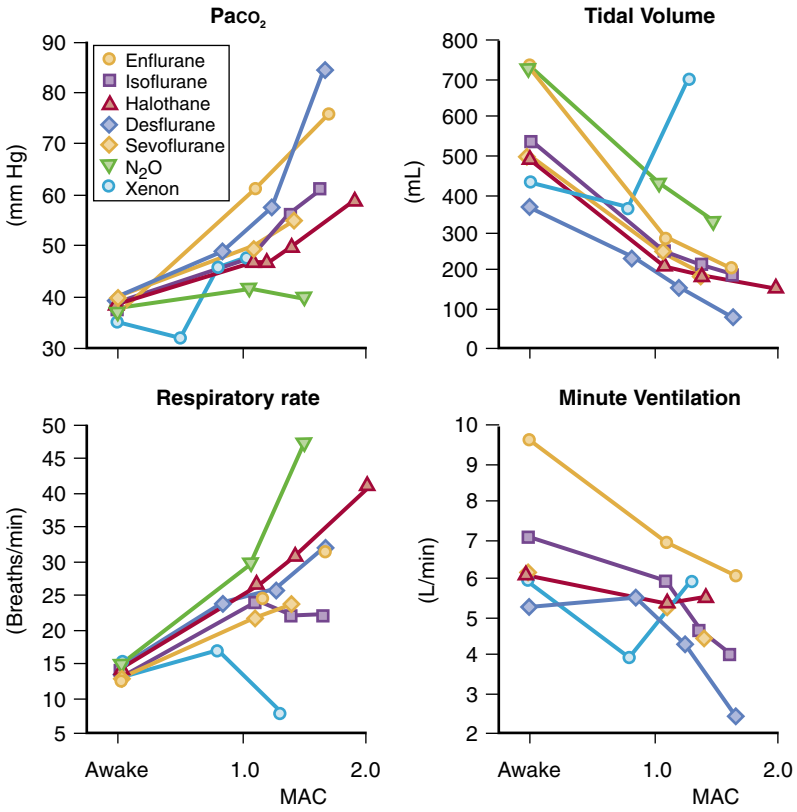

Figure 22-15 Comparison of mean changes in resting $Paco_2$, tidal volume, respiratory rate, and minute ventilation in patients anesthetized with either halothane, isoflurane, enflurane, sevoflurane, desflurane, nitrous oxide, or xenon. Anesthetic-induced tachypnea compensates in part for the ventilatory depression caused by all volatile anesthetics (decrease in minute ventilation and tidal volume and concomitant increase in $Paco_2$). Desflurane results in the greatest increase in $Paco_2$ with corresponding reductions in tidal volume and minute ventilation. Isoflurane, like all other inhaled agents, increases the respiratory rate; however, isoflurane does not result in dose-dependent tachypnea. MAC, minimum alveolar concentration. *(Data from references 164-169. Note that the data for xenon have been extrapolated from several sources[63,170,171] because there have been no well-controlled studies measuring all variables.)*

degree of respiratory depression as indicated by resting arterial carbon dioxide tension.[165,172]

Desflurane and sevoflurane also exhibit dose-related ventilatory depression, primarily by reducing tidal volume.[166,167,173] Unlike isoflurane, sevoflurane and desflurane cause dose-related increases in the respiratory rate. Thus, desflurane does not significantly reduce minute ventilation at concentrations less than 1.6 MAC. The reduction in respiratory rate produced by desflurane at higher concentrations was less than that caused by halothane. The relative effect of inhaled anesthetics (<1.24 MAC) in increasing arterial carbon dioxide tension (as an index of respiratory depression) is enflurane > desflurane = isoflurane > sevoflurane = halothane > nitrous oxide. Halothane and sevoflurane also cause similar respiratory changes in spontaneously breathing children. Nevertheless, potentially important differences between these two agents have been identified and include reduced minute ventilation and respiratory rate, a delay in the timing of peak inspiratory flow, and an earlier occurrence of peak expiratory flow during sevoflurane than during halothane anesthesia.[174] The ventilatory depression produced by higher concentrations of desflurane and sevoflurane is similar to that caused by enflurane and isoflurane, respectively. Isoflurane-induced respiratory depression is reduced by surgical stimulation (Fig. 22-16).[175] The respiratory depression observed during desflurane or sevoflurane anesthesia is reduced in the presence of nitrous oxide at equivalent MAC values.[176] This phenomenon is principally related to the reduction in volatile anesthetic required when nitrous oxide is added to the inspired gas mixture. The alteration in ventilatory pattern caused by anesthetics has been attributed to relative sensitization of pulmonary stretch receptors that subsequently produce tachypnea and low tidal volumes. The presence of a volatile anesthetic increased vagal afferent discharge at varying lung volumes in decerebrate cats (i.e., sensitization of pulmonary stretch receptors),[177] but little evidence exists of such a mechanism in humans. Halothane-induced tachypnea is primarily a suprapontine effect that may occur in cats, but the mechanism of

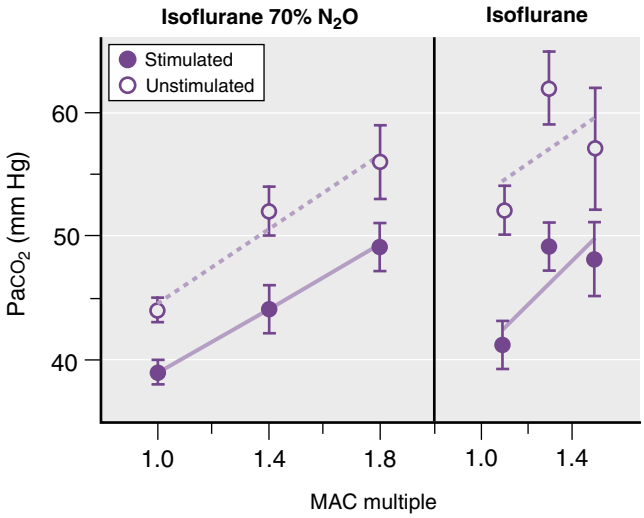

Figure 22-16 Effect of surgical stimulation on the ventilatory depression of inhaled anesthesia with isoflurane in the presence and absence of nitrous oxide. Surgical stimulation increased alveolar ventilation and decreased $Paco_2$ at all depths of anesthesia examined. MAC, minimum alveolar concentration. *(Modified from Eger EI, Dolan WM, Stevens WC, et al: Surgical stimulation antagonizes the respiratory depression produced by Forane. Anesthesiology 36:544, 1972, with permission.)*

production of tachypnea with decreased tidal volume in anesthetized humans remains unclear.

The respiratory depressant effects of xenon were first described more than 50 years ago. Xenon (1 MAC) causes a reduction in minute ventilation and a rise in arterial carbon dioxide tension. However, unlike other inhaled anesthetics, the decrease in minute ventilation is due to decreases in the respiratory rate, which are partially compensated by increases in tidal volume.[170] At lower concentrations of xenon (33% or approximately 0.5 MAC), the decrease in respiratory rate may be entirely offset by an increase in tidal volume. Depression of the pontine pneuomotaxic center may be the mechanism for this "xenon effect." Minute ventilation may actually increase and arterial carbon dioxide tension remain the same or decrease in healthy humans.[171]

Lung and Airway Receptors

The receptors responsible for eliciting protective airway reflexes are nonuniformly distributed. Sensitivity to airway irritation appears to be greater at the larynx and trachea than at the more peripheral airways in spontaneously breathing anesthetized patients in the presence of a laryngeal mask airway (LMA). Increasing concentrations of sevoflurane had little effect in altering these responses. The direct effects of halothane, isoflurane, and enflurane on pulmonary and laryngeal irritant receptors and tracheobronchial SARs have been investigated in spontaneously breathing and vagotomized, paralyzed dogs.[178,179] Volatile anesthetics increase the activity of laryngeal irritant receptors[178] and inhibit pulmonary irritant receptors.[179] Volatile anesthetics also elevate the excitation threshold and increase the sensitivity of low-threshold stretch receptors. Halothane and, to a lesser extent, sevoflurane attenuate the end-expiratory discharge frequency of SARs.[179,180] These agents may not affect or may even augment inspiratory activity. The clinical implications of these findings have yet to be precisely determined, but these anesthetic-induced changes in SAR function may play a role in the reduction of bronchomotor tone observed with volatile anesthetics. The severity of airway hyperreactivity was determined in 123 children breathing spontaneously through LMAs and undergoing either isoflurane or sevoflurane anesthesia.[181] Isoflurane was associated with greater airway hyperreactivity and more adverse airway events during LMA removal. An ongoing debate lingers in the anesthesiology literature regarding comparisons of upper airway reactivity between sevoflurane and desflurane. Sevoflurane (1 MAC) may provide greater suppression of responses to tracheal[182] and LMA[183] stimulation than desflurane does in elective surgical patients (Fig. 22-17). Higher concentrations (1.8 MAC) of these agents produce similar attenuation of coughing, tachycardia, and hypertension associated with tracheal stimulation, yet desflurane may irritate the respiratory tract at concentrations exceeding 1 MAC. Nevertheless, there were no differences in airway irritation with the use of an LMA in elective surgical patients receiving low concentrations of either desflurane or sevoflurane.[184] However, a significant increase in airway irritation was observed in smokers independent of the type of volatile agent.[185] The concomitant use of propofol and fentanyl in these patients and the relatively lower concentrations of desflurane than sevoflurane may have limited the ability to detect differences between these two anesthetic

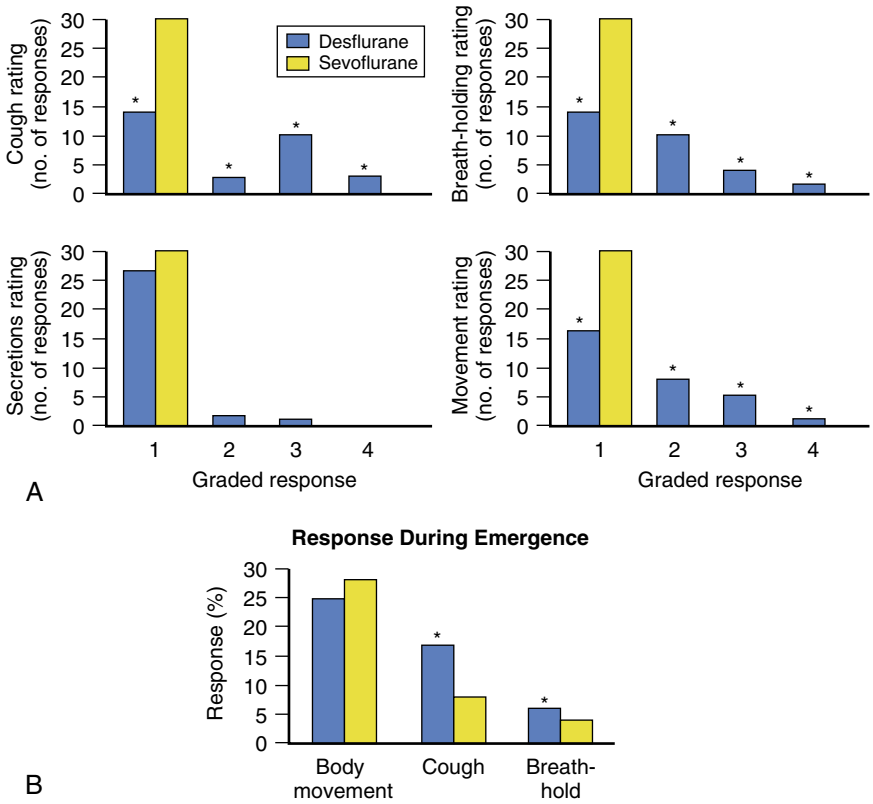

Figure 22-17 **A,** Graded responses to body movement, coughing, breath-holding, and secretions during transition to 2 minimum alveolar concentration (MAC) desflurane and sevoflurane anesthesia. **B,** Percentage of patients experiencing body movement, coughing, and breath-holding during emergence associated with sevoflurane and desflurane. *Desflurane caused more events than sevoflurane did in elective surgical patients. *(Modified from Arain S, Shankar H, Ebert TJ: Desflurane enhances reactivity during the use of the laryngeal mask airway. Anesthesiology 103:495, 2005, with permission.)*

agents in this study. The profound cardiovascular stimulation induced by rapid increases in the concentration of desflurane is due to activation of tracheopulmonary RARs.[186]

Volatile anesthetics produce a greater magnitude of depression of upper airway electromyographic[187] or nerve activity[188] than diaphragmatic activity in anesthetized, spontaneously breathing (Fig. 22-18) or paralyzed, ventilated, vagotomized cats. The extent to which this depression of upper airway motor neuron activity occurs as a result of anesthetic-induced inhibition of the reticular activating system is unknown. Upper airway caliber represents a balance between dilating and constricting forces. Outward-dilating forces are produced by neurogenic activity in the genioglossus, posterior cricoarytenoid, and hyoid muscles, whereas during inspiration, subatmospheric intraluminal pressure causes an inward collapsing force. It has been suggested that volatile anesthetics may cause relaxation of the genioglossus muscle with resultant posterior tongue displacement, a reduction in airway caliber, and consequent upper airway obstruction. Halothane, isoflurane and sevoflurane have all been shown to relax the upper airway musculature. Inhibition of upper airway muscle activity by isoflurane was independent of dose, and even subanesthetic concentrations totally abolished genioglossus activity.[189] In contrast, sevoflurane-induced changes in upper airway caliber was dose-dependent in children[26] (Fig. 22-19) and primarily occurred in an anterior-posterior dimension. In addition to these direct effects of sevoflurane on airway musculature, sevoflurane may also increase upper airway resistance by reducing lung volumes (which causes rostral tracheal displacement) or by increasing pharyngeal constrictor muscle activity.[26] Interestingly, whereas propofol predominantly caused narrowing in the hypopharynx at the level of the epiglottis,[190] sevoflurane more profoundly reduced airway caliber at the level of the soft palate. Respiratory premotor neurons are inhibited by the effects of volatile anesthetics through enhancement of GABAergic inhibitory activity and simultaneous depression of excitatory glutaminergic mechanisms.[153,191] However, hypoglossal motor neurons (which innervate all tongue muscles and are intimately involved in maintaining airway patency during inspiration) are extremely sensitive to subanesthetic concentrations of volatile anesthetics.[192] This inhibition of inspiratory hypoglossal motor neurons by volatile anesthetics is not related to actions at a K^+ leak channel but may be due to an enhancement of a tonic modulatory inhibition (Fig. 22-20).

Ventilatory Mechanics and Mechanoreceptors in the Chest Wall

Induction of general anesthesia reduces FRC. Loss of tonic parasternal intercostal muscle activity,[193,194] development of phasic expiratory activity of respiratory muscles (Fig. 22-21),[194] alteration in diaphragm position,[193] and changes in thoracic blood volume have been proposed as mechanisms responsible for anesthetic-induced decreases in FRC. In contrast to intercostal muscle function, diaphragmatic activity is relatively spared during halothane anesthesia.[194] A change in diaphragmatic shape occurs during anesthesia, with dependent regions shifting cephalad and nondependent regions shifting caudad (Fig. 22-22).[195] Anesthesia-enhanced expiratory muscle activity results in inward displacement of the rib cage, an action that contributes to the reduction in FRC. In contrast, inspiratory rib cage expansion may remain relatively well preserved because of phasic inspiratory activity of the scalene muscles despite the attenuation of parasternal intercostal muscle activity.[193] Areas of atelectasis in dependent lung regions frequently occur in anesthetized, spontaneously ventilating humans and may be related to alterations in respiratory muscle tone but not specifically to any single chest wall structure.[195] There is no direct correlation between changes in FRC and anesthesia-induced atelectasis.[196] As a result of the reduction in lung volume secondary to decreases in FRC, airway resistance increases. This action may partially counteract the direct bronchodilatory effects of volatile anesthetics.

Reasons for the differential effects of inhaled anesthetics on inspiratory and expiratory respiratory muscles are unknown but may be related to direct actions on brainstem control mechanisms or differential sensitivity of premotor and motor neurons. Stuth and coworkers[197-199] showed that bulbospinal respiratory neurons are more resistant than phrenic nerve activity to the depressant effects of volatile anesthetics in vagotomized, decerebrate dogs. The inhibition of expiratory premotor neurons by volatile agents is mediated by presynaptic reduction of glutaminergic excitation and enhancement of $GABA_A$ergic inhibitory receptor function (Fig. 22-23).[152,153,191] Sevoflurane also depressed phrenic nerve activity and enhanced the overall inhibition of inspiratory motor neurons to a greater extent than halothane did. Increases in carbon dioxide drive only partially compensated for these anesthetic-induced depressant actions. There appears to be less halothane-induced depression of expiratory than inspiratory bulbospinal premotor neurons. These findings suggest that the effects

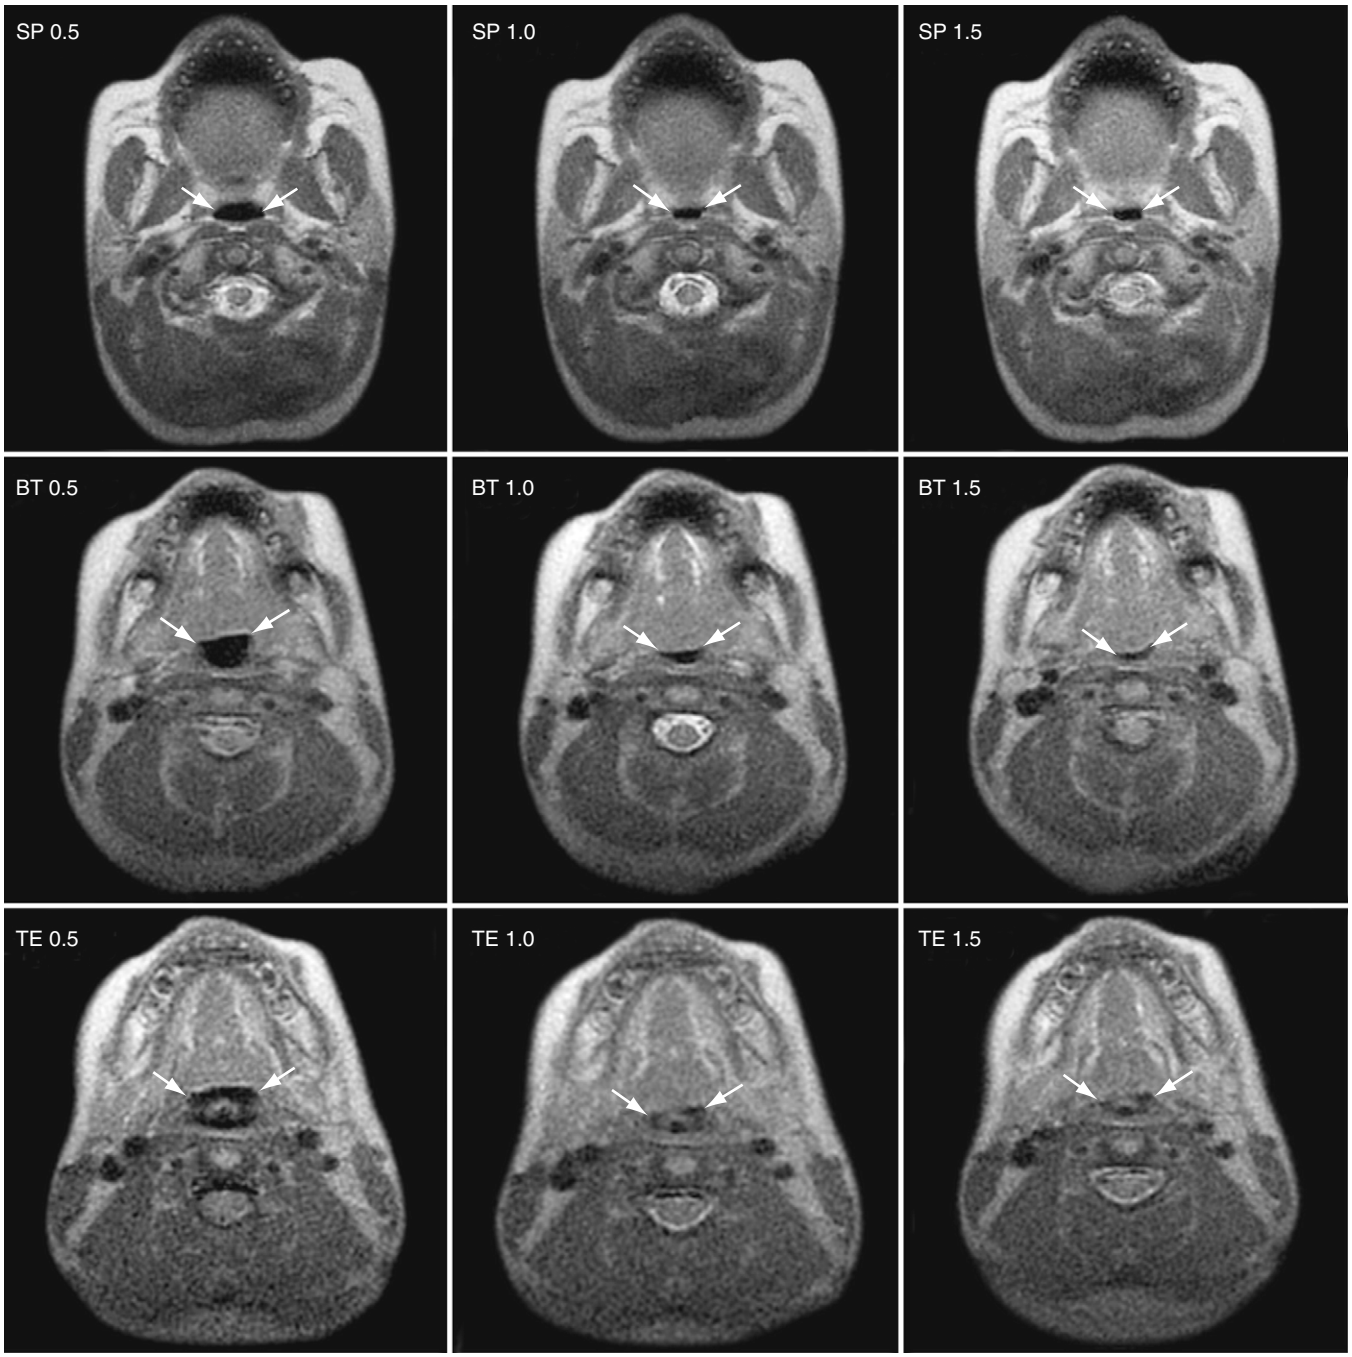

Figure 22-19 Magnetic resonance images at the level of the soft palate (SP), base of the tongue (BT), and tip of the epiglottis (TE) of a child in early expiration demonstrating a progressive reduction in cross-sectional area with increasing concentration of sevoflurane (0.5, 1, 1.5 minimum alveolar concentration). *Arrows* show the site of the collapsible pharyngeal airway. *(From Crawford MW, Arrica M, Macgowan CK, Yoo S-J: Extent and localization of changes in upper airway caliber with varying concentrations of sevoflurane in children. of volatile agents on respiratory muscle function may be due to a relatively greater influence on motor efferent pathways (including spinal respiratory motor neurons) than on brainstem-mediated mechanisms (Fig. 22-24).[198]

Volatile anesthetics differentially depress neuromuscular transmission and skeletal muscle contractility. Halothane impairs excitation-contraction coupling and neuromuscular transmission to equivalent degrees, whereas isoflurane, sevoflurane, and enflurane depress diaphragmatic contraction primarily through alterations in neuromuscular transmission.[200,201] Isoflurane, enflurane, and sevoflurane depress diaphragmatic tension in response to phrenic nerve stimulation. These results may partially explain clinical observations in humans, but a wide range of species variations also exist that make extrapolation of results obtained from experimental animals to humans difficult. Similar to volatile agents, nitrous oxide affects chest wall function and breathing by

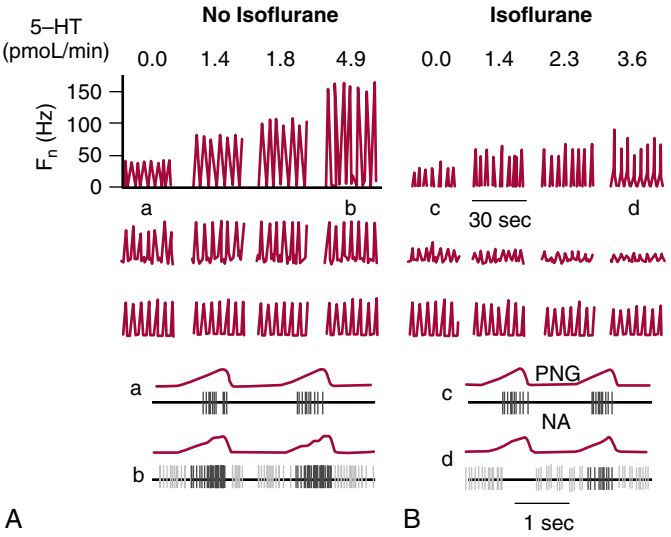

Figure 22-20 Inhibition of inspiratory hypoglossal motoneurons (XII) by a subanesthetic concentration (0.3 minimum alveolar concentration) of isoflurane in the absence and presence of graded doses of serotonin (5-HT). This inhibition in the presence of 5-HT rules out a major contribution of K^+ leak channels. Note the significant decline in hypoglossal nerve activity (≈60%) with isoflurane as opposed to phrenic nerve activity (PNG) (<10%). F_n represents the neurons' spontaneous peak discharge frequency. The letters a to d indicate the records for which time-enlarged views are shown. NA, neuronal activity. *(From Brandes IF, Zuperku EJ, Stucke AG, et al: Isoflurane depresses the response of inspiratory hypoglossal motoneurons to serotonin in vivo. Anesthesiology 106:736, 2007, with permission.)*

changing the distribution and timing of the neural drive to the respiratory muscles.[202] Nitrous oxide decreases tidal volume as a result of a reduction in rib cage motion and increased phasic expiratory activity in humans. In contrast, xenon does not affect transdiaphragmatic pressure or diaphragmatic electromyography

because this anesthetic noble gas preserves neuromuscular transmission.[63]

The work of breathing expressed in joules is defined as pressure or force multiplied by the tidal volume during inspiration. The respiratory work of the lung is further broken down into elastic work (required to overcome recoil of the lung) and resistive work (required to overcome airway flow resistance and the viscoelastic resistance of pulmonary tissue in the absence or presence of an airway apparatus). The work of breathing is usually derived from transpulmonary pressure–tidal volume curves. Volatile anesthetics increase the work of breathing in adults and children. Sevoflurane anesthesia increased viscoelastic and elastic pressure in the lung, findings indicative of a reduction in pulmonary compliance mediated at the lung periphery rather than at the airway level in normal rats.[203] This finding was supported histologically by the observation of increased areas of alveolar collapse alternating with hyperinflation. In contrast, most studies in humans demonstrate that low concentrations of volatile anesthetics significantly reduce upper and lower respiratory system resistance (Fig. 22-25).[204] In a murine model of chronic asthma, sevoflurane anesthesia significantly decreased resistance in the central and distal airways in addition to lowering resistance in the lung periphery.[58] These data suggest that sevoflurane exerts a beneficial action in the presence of chronic airway obstruction and implies that volatile agents reduce the work of breathing (Fig. 22-26).

Expiration is passively affected by the recoil characteristics of the lung during normal breathing. In anesthetized patients, the ventilatory response to expiratory resistance is reduced to a greater extent than the response to inspiratory resistance. Conscious and anesthetized humans exhibit decreases in the respiratory rate during expiratory resistive loads, but the rib cage–abdominal wall motion asynchrony that causes less effective ventilation and increases in carbon dioxide is seen only in anesthetized subjects.[205] This concept may be particularly important in spontaneously breathing, anesthetized patients who demonstrate expiratory obstruction, such as may occur with partial occlusion of a breathing circuit, asthma, emphysema, or airway secretions. Interestingly, the ventilation-perfusion inhomogeneity caused by volatile anesthetics has been proposed as a new mechanism by which nitrous oxide produces a second gas effect in the presence of sevoflurane.[206]

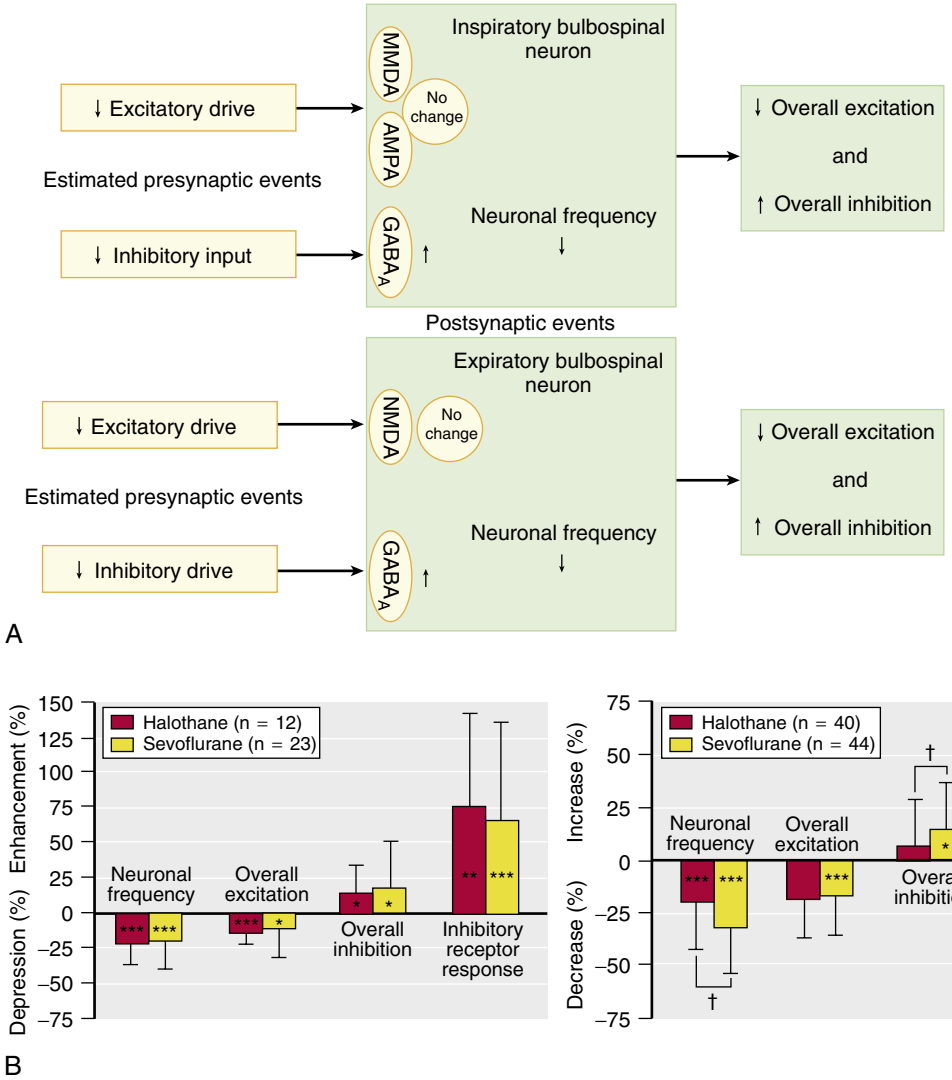

Figure 22-23 A, Schematic diagram of the effects of volatile anesthetics on synaptic transmission to expiratory and inspiratory premotor neurons in the caudal ventral respiratory group. In expiratory neurons, the overall glutaminergic excitatory drive is reduced without affecting *N*-methyl-D-aspartate (NMDA) receptor function, and overall inhibition is increased because of an increase in type A γ-aminobutyric acid ($GABA_A$) receptor function. The presynaptic inhibitory drive is also reduced and leads to a decrease in the control discharge frequency of the premotor neuron. In inspiratory neurons, there is a reduction in overall glutaminergic excitation with an increase in overall inhibitory input. Postsynaptic α-amino-3-hydroxy-5-methylisoxazole-4-propionate (AMPA) and NMDA receptor responses were not changed, thus suggesting that the presynaptic excitatory drive is diminished. **B,** Effects of halothane and sevoflurane on excitatory and inhibitory neurotransmission to canine medullary expiratory (left graph) and inspiratory (right graph) neurons. Values are mean changes ± SD for neuronal control frequency, overall excitation, overall inhibition, and inhibitory receptor response by a 1 minimum alveolar concentration of halothane and sevoflurane. There were no differences in anesthetic-induced changes between halothane and sevoflurane in expiratory neurons. †$P < 0.05$ sevoflurane enhanced overall inhibition and depressed neuronal frequency more than halothane did in inspiratory neurons. *$P < .05$, **$P < .01$, ***$P < .001$ versus no change. *(Adapted from Stucke and colleagues[152,153,189] with permission.)*

Effects of Anesthetics on Ventilatory Response to Chemical Stimuli

The effects of inhaled anesthetics on respiratory drive are typically characterized by the ventilatory response to alterations in arterial carbon dioxide tension or hypoxia. Arterial carbon dioxide tension is the most important stimulus for ventilation. The apneic threshold, defined as the highest arterial carbon dioxide tension at which a subject remains apneic, is approximately 4 or 5 mm Hg below resting arterial carbon dioxide tension. There are no significant agent-specific or depth-related effects of ether, halothane, or isoflurane on the relationship between apneic thresholds and resting arterial carbon dioxide tension in humans. Volatile anesthetic–induced ventilatory depression increases resting carbon dioxide tension and the apneic threshold to similar degrees. Thus, *assisted* ventilation, which lowers arterial carbon dioxide tension below the apneic threshold during anesthesia, ultimately becomes *controlled* ventilation. Return of spontaneous ventilation in a mechanically hyperventilated patient is dependent on return of carbon dioxide tension toward the apneic threshold after cessation of positive-pressure ventilation. The duration of apnea required before a patient will begin to breathe spontaneously is dependent on anesthetic depth. Continuation of positive-pressure ventilation (or intentional hyperventilation) to eliminate volatile agents and maintenance of relative hypercapnia during

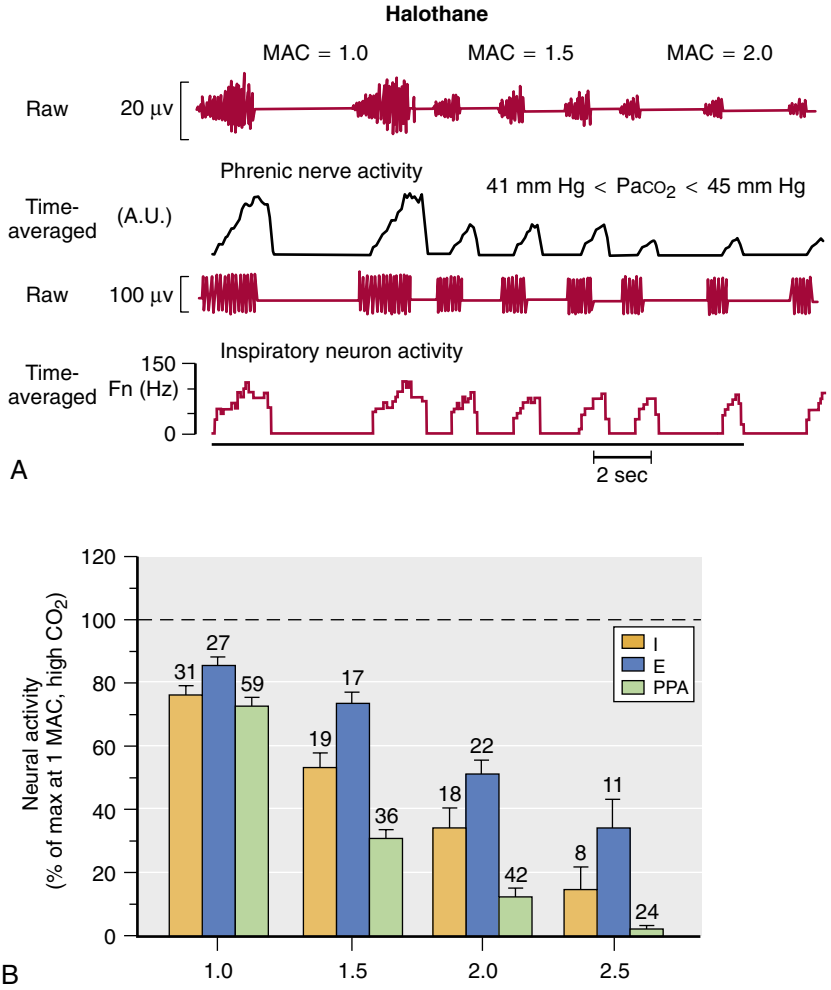

Figure 22-24 Effect of increasing halothane on phrenic nerve and neuron activity. With increasing anesthetic depth, both peak phrenic nerve (PPA) and peak neuron activities are depressed. PPA shows the greatest sensitivity to halothane. **A,** Phrenic nerve activity and the discharge frequency of an inspiratory bulbospinal neuron. Inspiratory (phrenic burst) duration decreases with increasing anesthetic depth. **B,** Peak expiratory neuron (E) activity, peak inspiratory neuron (I) activity, and PPA. Expiratory neuronal activity was most resistant to the effects of halothane. *Bars* show normalized means ± SEM, and the numbers above the *bars* indicate the numbers of neurons studied for each condition. Anesthesiology 81:1470, 1994, with permission.)*

mechanical ventilation are two commonly used clinical strategies to shorten the emergence time. Such maneuvers decrease the apneic threshold or increase resting arterial carbon dioxide tension and reduce emergence time during isoflurane, desflurane, or sevoflurane anesthesia (Fig. 22-27).[207,208] Rebreathing of carbon dioxide[209] or gradual increases in the concentration of sevoflurane[210] may reduce the incidence of apnea during induction with inhaled anesthetics. The activity of expiratory brainstem neurons may be temporarily "switched off" during rapid increases in anesthetic concentration and thereby contribute to apnea under these conditions.[210]

Carbon Dioxide Response Curves

Volatile anesthetics depress the ventilatory response to hypercapnia in a dose-dependent fashion. Moderate concentrations (<1 MAC) of volatile agents markedly attenuate or entirely eliminate hypercapnia-induced increases in ventilatory drive. Even low concentrations of nitrous oxide may substantially affect responses to hypercapnia. The slope of the minute ventilation–arterial carbon dioxide tension relationship returns toward normal after 6 hours of halothane anesthesia, but ventilatory responsiveness to carbon dioxide nevertheless remains profoundly depressed. The addition of nitrous oxide to halothane depresses ventilation less than equivalent-MAC halothane alone does, but the carbon dioxide–ventilatory response slope was unaltered when either a nitrous oxide–desflurane combination or desflurane alone was used.[166] Interestingly, the response to hypercapnia was more profoundly depressed during desflurane than during isoflurane or sevoflurane anesthesia at 0.5 MAC in C3 mice (C3 mice have a blunted response to hypercapnia and hypoxia at baseline).[211]

Subanesthetic concentrations (<0.2 MAC) of volatile anesthetics may depress the peripheral chemoreflex loop and inhibit the ventilatory response to hypercapnia.[212,213] At higher concentrations, central chemoreceptors may also be affected. In contrast, Pandit and colleagues[214] showed that subanesthetic concentrations of sevoflurane did not affect the response to acute or sustained hypercapnia. The apparent discrepancies between these results may be related to the sustained nature of the hypercapnic responses or differences in the state of central nervous system arousal under baseline conditions. A review of all published studies investigating the effect of low concentrations of volatile anesthetics on hypercapnic drive suggests a relative lack of any substantial inhibitory effect.[166]

Depression of ventilatory responsiveness to inhaled carbon dioxide is clinically important. Accumulation of carbon dioxide and concomitant acidemia may cause dysfunction in several organ systems, including the heart (e.g., arrhythmias), lungs (e.g., pulmonary hypertension), and brain (e.g., increased intracranial

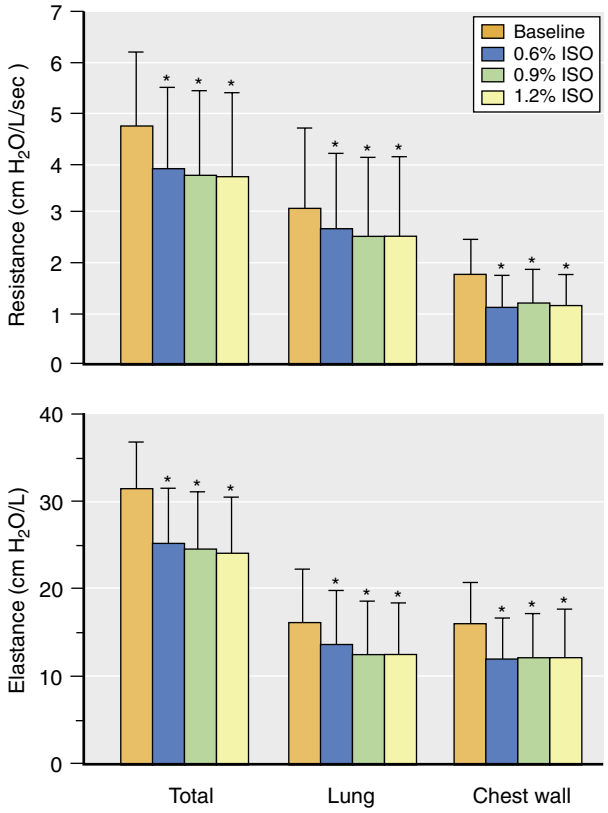

Figure 22-25 Isoflurane at 0.6% reduced respiratory system elastance (E in cm H_2O/L) and resistance (R in cm H_2O/L/sec). "Total" represents the total respiratory system (lung + chest wall). Values are means ± SD. *P < .05 versus baseline. pressure) in patients with or without coexisting disease. Inadequate respiratory system compensation for elevations in arterial carbon dioxide tension may occur in response to rebreathing of carbon dioxide from malfunctioning anesthetic circuits, from abdominal carbon dioxide insufflation during laparoscopic surgery, or as a result of increased metabolic production of the gas during anesthesia. The reduction in ventilatory drive induced by hypercapnia may also occur in the immediate postoperative period and can contribute to significant morbidity, especially in patients with chronic lung disease.

Experimental studies have shown that rebreathing carbon dioxide recruits expiratory respiratory muscles, including the internal intercostals, but is incapable of reversing the profound depression of parasternal intercostal muscle activity produced by halothane.[215] The peripheral chemoreceptor transduction (i.e., phrenic nerve response) to acute, severe carbon dioxide stimulation was also depressed by halothane in paralyzed, vagotomized dogs in a dose-related manner.[216] Carbon dioxide sensitivity was diminished, but not abolished, by concentrations of halothane usually required for surgical anesthesia. Furthermore, halothane depressed peripheral and central carbon dioxide sensitivity to similar degrees, but the peripheral chemoreceptors contributed only approximately 15% of the total carbon dioxide sensitivity.

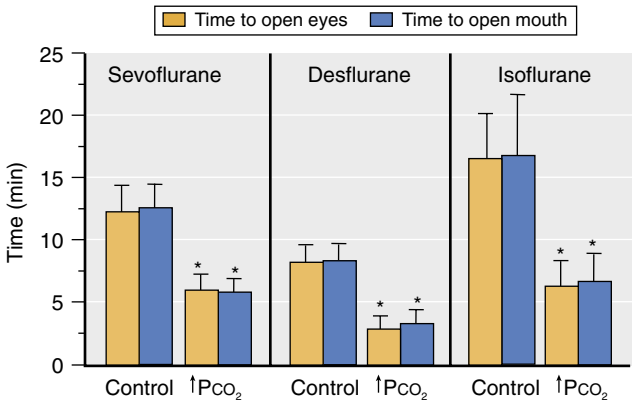

Figure 22-27 Average time between turning off the vaporizer and patients opening their eyes or mouth during the control condition (mild hypocapnia) and during hypercapnia (↑P_{CO_2}). Patients were anesthetized with either isoflurane, sevoflurane, or desflurane. Data are means ± SD. *P < .05 versus control—hypocapnia). *(Adapted from Sakata DJ, Golapakrishnan NA, Orr JA, et al: Rapid recovery from sevoflurane and desflurane with hypercapnia and hyperventilation. Anesth Analg 104:587, 2007, with permission.)*

These data suggest that the response of peripheral chemoreceptors to carbon dioxide may appear to be of minimal clinical significance. However, if the response of peripheral chemoreceptors to hypoxia is abolished by low concentrations of volatile anesthetics, marked respiratory impairment during episodes of hypercapnia and hypoxia (such as those encountered in the perioperative period) may occur.

Ventilatory Responses to Hypoxemia

Volatile anesthetics and nitrous oxide attenuate the ventilatory response to hypoxia in experimental animals and humans in a dose-dependent manner.[217,218] Peripheral chemoreceptors appear to be the major site of this inhibitory action. Rapid inhibition (30 seconds) of the hypoxic response and reductions in carotid sinus nerve discharge were observed when peripheral chemoreceptors were stimulated during the administration of halothane (0.5% to 1.0%) to decerebrate cats.[219] Alternatively, Stuth and coworkers[220] demonstrated that the phrenic nerve response to hypoxia is attenuated, but not abolished, by halothane in vagotomized dogs. The cause of these differences may be attributed to the more pronounced degree of hypoxia (arterial oxygen tension < 40 mm Hg) achieved in experimental animals than in humans (Pao_2 ~50 mm Hg). Volatile anesthetics attenuated the usual synergistic effect of hypoxia and hypercapnia on ventilation, but the ventilatory response to hypoxia depends on the degree to which arterial carbon dioxide tension exceeds the peripheral chemoreflex threshold rather than its elevation above resting partial pressure.[221] The response is also influenced by the presence of NO (and presumably fully functional pulmonary arterial endothelium).[222] This latter role of NO may be more complex because in addition to local release, NO is also released in the ventrolateral medulla after activation of peripheral chemoreceptors during hypoxia in response to sympathoexcitation.[223]

Halothane also produced a biphasic ventilatory response (similar to that observed in newborns) in kittens that have previously attained an adult-like hyperventilatory hypoxic response.[224] Whether the cause of this altered response during halothane anesthesia is mediated by peripheral chemoreceptors is unknown, but it is unlikely that activity at the level of the brainstem is solely responsible for this phenomenon.[225]

The ventilatory response to hypoxia is substantially more sensitive to the effects of volatile anesthetics than is the response to hypercapnia.[217,226] Attenuation of peripheral chemoreceptor responses occurs at concentrations of volatile anesthetics as low as 0.1 MAC. As with the hypercapnic ventilatory drive, controversy exists about the influence of subanesthetic concentrations of volatile agents on the hypoxic ventilatory drive. Administration of 0.1 MAC sevoflurane[227] or isoflurane has little to no effect on the hypoxic drive in humans.[228] Other investigators[229] have demonstrated that anesthetic-induced blunting of the ventilatory response to acute hypoxemia occurs with all volatile anesthetics except desflurane.[230] In analyzing studies on the effect of low concentrations of volatile anesthetics on hypoxic ventilatory responses (including negative studies), Pandit[231] proposed the following order of sensitivity: halothane (most depressant, 42%) > enflurane (52%) > isoflurane (71%) > sevoflurane (72%) > desflurane (96%) (Fig. 22-28). Notably, subanesthetic concentrations of desflurane decrease hypoxic sensitivity during hypercapnia, thus suggesting that this agent exerts an effect at the peripheral chemoreceptors.[230] The reasons for inconsistencies between many of these studies may be related to differences in the state of patient arousal during administration of the subanesthetic concentrations of volatile agent, the specific agent administered, the rate of application of the hypoxic stimulus, and the presence or absence of simultaneous hypercapnia. Attenuation of the acute hypoxic ventilatory response appears to be agent specific inasmuch as the effects of isoflurane, but not halothane or sevoflurane, were blunted in the presence of audiovisual stimulation.[217] The mechanisms by which low concentrations of volatile anesthetics attenuate the hypoxic ventilatory drive is unknown despite extensive study. Interestingly, administration of antioxidants to healthy volunteers reversed the attenuation of the hypoxic ventilatory response to halothane and isoflurane.[218] These results suggest that volatile anesthetics may depress the hypoxic response by influencing the oxidation-reduction state of oxygen-sensing elements in the carotid bodies (Fig. 22-29). How antioxidants mediate this response is unclear but may be related to actions on the mitochondrial electron transport chain, volatile anesthetic binding sites, or potassium channel function.

The profound depression of hypoxic responsiveness produced by volatile anesthetics (with the exception of desflurane as noted earlier) suggests that patients may manifest a diminished ventilatory response to hypoxemia in the recovery room for some time after use of the agent has been discontinued. Audiovisual stimulation may attenuate the effects of low residual concentra-

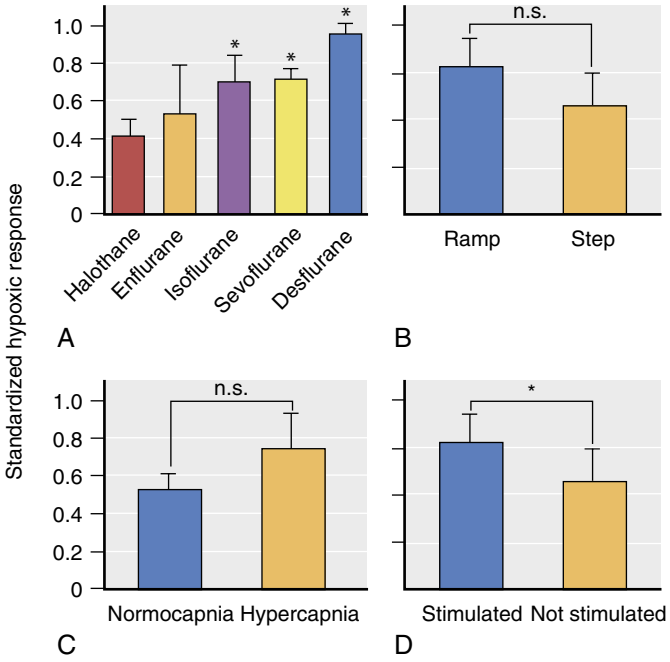

Figure 22-28 Analysis of data groups from 37 separate studies investigating the effect of low-dose volatile anesthetics on the acute ventilatory response to hypoxia in humans. **A,** Anesthetics depress the hypoxic ventilatory response in the order halothane > enflurane > isoflurane > sevoflurane > desflurane. *P < 0.05 versus halothane. **B,** Data grouped according to the speed of the hypoxic stimulus. **C,** Data grouped according to background carbon dioxide. **D,** Data grouped according to whether the hypoxic challenge occurred in the presence or absence of subject stimulation. *P < .05. *Error bars* represent 95% confidence intervals. *(Adapted from Pandit JJ: The variable effect of low-dose volatile anaesthetics on the acute ventilatory response to hypoxia in humans: A quantitative review. tions of anesthetics in postoperative patients. In contrast, pain appears to be a poor stimulus to blunt the hypoxic ventilatory response to volatile agents. This phenomenon may be especially important in patients who depend to some degree on a hypoxic drive to establish their level of ventilation (e.g., those with chronic respiratory failure). In these circumstances, the ability of these patients to maintain adequate spontaneous ventilation in the presence of a volatile anesthetic may be severely impaired. Although there appear to be few clinically relevant differences between volatile anesthetics in hypoxia-induced depression of the ventilatory response in normal subjects, the effects in patients with pulmonary disease have not been studied extensively.

Hypoxia may occur postoperatively for several reasons. Diffusion hypoxia is well known and may occur during recovery from nitrous oxide anesthesia. Rapid elimination of nitrous oxide from blood to the alveoli combined with slower nitrogen diffusion reduces the alveolar oxygen concentration. In contrast, diffusion hypoxia may not occur during xenon anesthesia because the blood-gas partition coefficient of the noble gas (0.12) is similar to that of nitrogen and thus diffusion into alveoli may be slower.[66] The specific actions of xenon on the hypoxic ventilatory drive have not been clearly defined.

Acute Lung Injury

Mechanisms of Acute Lung Injury

Acute lung injury and acute respiratory distress syndrome are inflammatory disorders characterized by excessive infiltration of neutrophils, release of inflammatory mediators, and destruction of the alveolar-capillary membrane (also see Chapters 91 and 93). This series of events results in compromised gas exchange and pulmonary edema. There are a variety of causes of acute lung injury, including sepsis and positive-pressure ventilation. Endotoxin-induced lung injury is typified by hypoxemia resulting from a ventilation-perfusion mismatch with shunting through collapsed alveoli. This clinical condition associated with sepsis may be modeled in the laboratory by injection or inhalation of lipopolysaccharide, a component of the outer membrane of gram-negative bacteria. Lipopolysaccharides bind to Toll-like receptor 4 to activate nuclear factor κB, upregulate adhesion molecules, and stimulate cytokine-induced neutrophil migration into the pulmonary parenchyma. The alveolar epithelium, which may be injured by endotoxin, plays a critical role in maintaining alveolar homeostasis by the production of specific proteins, including surfactant and a variety of cytokines, and by clearing excess alveolar liquid. Notably, failure of the alveolar epithelium is even associated with increased mortality.[232]

Acute ventilator-induced lung injury is manifested as severe distention of and damage to bronchoalveolar structures, lung overinflation, and bronchiectasis.[233] Caveolae are flask-shaped invaginations of the plasma membrane that are involved in endocytosis, signal transduction, and transendothelial albumin transport. Caveolin-1, an integral membrane protein and component of endothelial caveolae, regulates the endothelial uptake and transport of albumin.[234] Inflammatory cytokines, including tumor necrosis factor-α, interleukin-1β, and macrophage inflammatory protein 2, may be released from alveolar epithelial cells, neutrophils, and macrophages. Cytokines are important mediators of leukocyte recruitment and activation. In general, attenuation of the cytokine response is considered beneficial in terms of reducing potential lung injury. Alternatively, in certain clinical situations such as immunocompromised patients, blunting of the release of inflammatory mediators and failure of neutrophil migration into the inflamed lung may predispose to a greater risk for pulmonary infections. Unfortunately, release of cytokines is highly variable and depends on experimental conditions. For example, altering the ventilation strategy alone may modify lung cytokine responses to lipopolysaccharide,[231] and positive-pressure ventilation in the absence of anesthesia may exacerbate the inflammatory responses.[235] The molecular mechanisms mediating acute lung injury have not been well defined. Nitric oxide, derived from inducible nitric oxide synthase (iNOS) in response to inflammation and endotoxin, appears to play an important role in acute lung injury inasmuch as inhibition of iNOS substantially reduced pulmonary lymph filtration and improved oxygenation during endotoxemia in conscious sheep.[236]

The presence of preexisting pulmonary disease, such as chronic bronchitis, pneumonia, or COPD, or smoking may exacerbate the pulmonary damage that occurs in response to an acute lung injury.[185] As with acute lung injury, smoking induces an inflammatory state. In contrast to acute lung injury, tobacco abuse increases the number but decreases the response of macrophages and neutrophils. Thus, these cells are less capable of releasing cytokines during infection. In addition, goblet cell hyperplasia, decreased mucociliary clearance, and increased airway reactivity occur and also contribute to potential infection, bronchospasm, and acute lung injury.[237]

Effects of Inhaled Anesthetics on Acute Lung Injury

Previous studies suggested that volatile anesthetics may augment the inflammatory response during mechanical ventilation,[238-240] but results of another investigation indicated that short-term positive-pressure ventilation with high tidal volumes does not affect systemic proinflammatory or anti-inflammatory cytokines in the lungs of healthy, isoflurane-anesthetized patients.[241] Volatile anesthetics have been shown to promote macrophage aggregation, enhance gene expression of proinflammatory cytokines,[238,242] (Fig. 22-30) exacerbate the extent of lung injury, and increase mortality after experimental aspiration.[240] Halothane also caused DNA and cell damage, nuclear fragmentation, and apoptotic-like changes in isolated pulmonary epithelial cells.[243] One mechanism by which volatile anesthetics may worsen acute lung injury is through an increase in alveolar membrane permeability. Halothane and isoflurane were found to transiently increase pulmonary vascular endothelial damage on radionuclide scanning.[244] Isoflurane also enhanced alveolar epithelial permeability in patients undergoing surgery.[245] Desflurane increased lipid peroxidation as measured in bronchoalveolar lavage samples from healthy surgical patients.[246] These data suggest that desflurane may promote pulmonary alveolar membrane injury. In contrast, sevoflurane caused less pronounced effects in this model, thus suggesting that this agent may exert a protective effect. Furthermore, isoflurane but not sevoflurane increased albumin permeability and transport in isolated rat lungs.[234] This deleterious action appeared to be related to enhancement of caveolin-1–mediated albumin uptake. Similarly, pretreatment with isoflurane but not sevoflurane enhanced neurogenic pulmonary edema in rats.[247] The proinflammatory response and enhanced cytokine levels in patients were also more pronounced after desflurane than after sevoflurane anesthesia.[242] In contrast to the transient effects of halothane and isoflurane, there were no significant effects on alveolar integrity or ultrastructure after high concentrations of sevoflurane were administered to pigs.[248] However, administration of sevoflurane to pigs[238] and healthy surgical patients[242] moderately enhanced inflammatory mediators such as leukotriene C_4, nitrate, nitrite, tumor necrosis factor-α, interleukin-1β, and interleukin-6. Inhalation of volatile anesthetics, including sevoflurane, was associated with an increase in proinflammatory cytokine protein from and gene expression in macrophages obtained from mechanically ventilated rats.[239] As with previous studies, sevoflurane appeared to produce relatively less pronounced effects than other volatile agents did. Oleic acid–induced lung injury was associated with impaired pulmonary gas exchange because of a ventilation-perfusion mismatch and shunting in mechanically ventilated dogs. Low concentrations of isoflurane exacerbated this impairment and worsened oxygen delivery.[249]

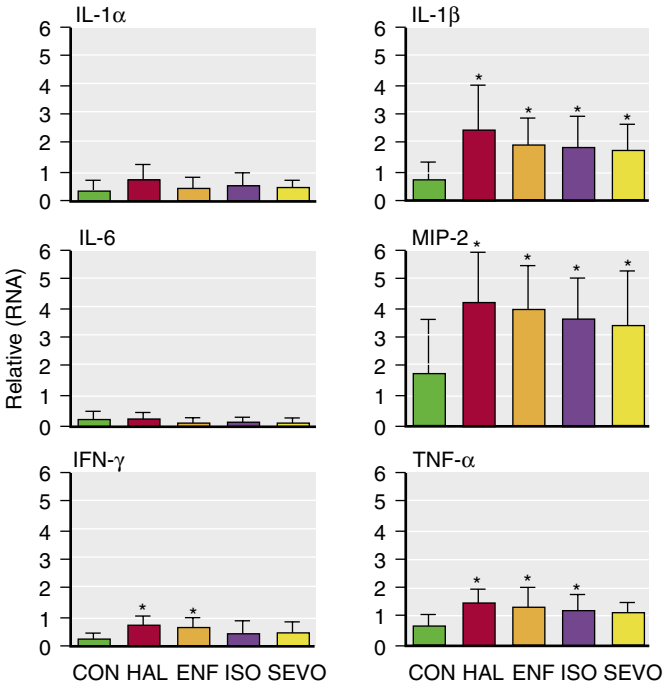

Figure 22-30 Changes in expression of proinflammatory cytokines from macrophages during mechanical ventilation without (CON, control) and with volatile anesthetics (HAL, halothane, ENF, enflurane, ISO, isoflurane, SEVO, sevoflurane). Values are the ratio of cytokine mRNA to β-actin mRNA and are presented as means ± SD. *$P < .05$ versus the control group (mechanical ventilation without volatile anesthetics). Gene expression for interleukin-1β (IL-1β), macrophage inflammatory protein 2 (MIP-2), interferon-γ (IFN-γ), and tumor necrosis factor-α (TNF-α) all increased significantly in comparison to mechanical ventilation alone. *(Adapted from Kotani N, Takahashi S, Sessler DI, et al: Volatile anesthetics augment expression of proinflammatory cytokines in rat alveolar macrophages by mechanical ventilation. Anesthesiology 91:187, 1999, with permission.)*

The actions of volatile anesthetics on lung inflammatory reactions are not clear. Under certain conditions, volatile anesthetics appear to play an anti-inflammatory and protective role in lung injury. One determinant of whether volatile anesthetics reduce or exacerbate pulmonary cytokine formation appears to be the cell types studied and the conditions under which the cytokine expression is measured. Volatile anesthetics increase the secretion and gene expression of some cytokines in alveolar macrophages but decrease the formation of proinflammatory cytokines in alveolar type II cells.[235,250,251] When compared with thiopental anesthesia, pigs anesthetized with sevoflurane exhibited reduced expression of tumor necrosis factor and interleukin-1β in lung tissue.[252] Pretreatment with 1.1% sevoflurane also significantly reduced the inflammatory response by alveolar type II cells exposed to lipopolysaccharide and attenuated the endotoxin-induced chemotaxis of neutrophils.[253] The latter data suggested another potential role of volatile agents in mediating inflammatory responses.

Under controlled conditions, volatile anesthetics tend to increase cytokine formation and appear to enhance inflammatory responses. In contrast, in models of lung acutely injured by stimulation with lipopolysaccharide, *Escherichia coli* endotoxin, or

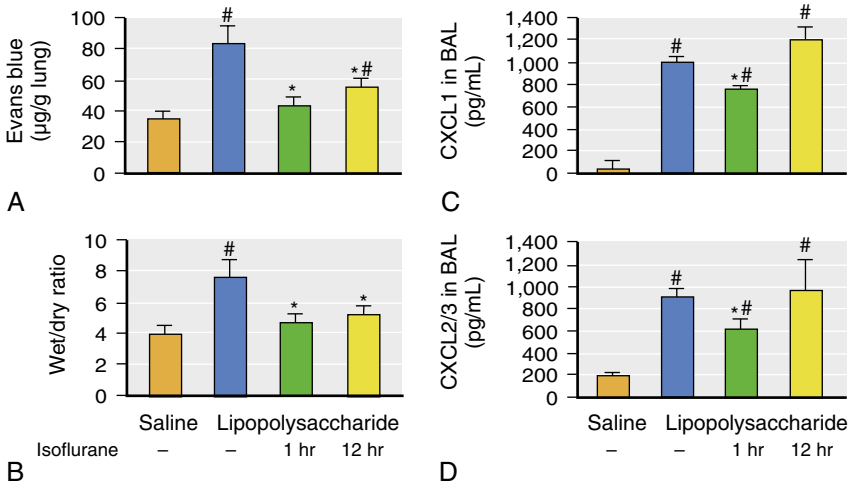

Figure 22-31 Capillary protein leakage measured by extravasation of Evans blue dye (**A**) and formation of lung edema measured by the ratio of wet to dry lung weight (**B**) in mice receiving saline, lipopolysaccharide, or isoflurane 1 or 12 hours before lipopolysaccharide. Endotoxin aerosol induced a significant increase in both capillary protein leakage and edema formation, which was reduced by pretreatment with isoflurane. **C** and **D,** Alveolar release of the two most important neutrophil-attracting chemokines CXCL1 and CXCL2/3 measured with an enzyme-linked immunosorbent assay 2 hours after receipt of lipopolysaccharide. Early, but not late (12 hour) isoflurane pretreatment reduced chemokine secretion significantly. Data are means ± SD. #Significant change between control and endotoxin-treated mice. *Significant difference between animals with and without isoflurane treatment. *(Adapted from Reutershan J, Chang D, Hayes JK, Ley K: Protective effects of isoflurane pretreatment in endotoxin-induced lung injury. Anesthesiology 104:511, 2006, with permission.)*

interleukin-1β, volatile anesthetics appear to exert anti-inflammatory effects, including inhibition of cytokine formation, reduction of neutrophil migration into the lung interstitium and alveolar space, and attenuation of protein leakage and pulmonary edema (Fig. 22-31).[235,250,251] Peri-ischemic inhalation of low concentrations of sevoflurane appears to provide endothelial protection in humans subjected to forearm ischemia-reperfusion injury.[254] Inhibition of leukocyte adhesion has been postulated as a mechanism for this protection. Isoflurane, given after the initiation of ischemia, also protects against warm ischemia-reperfusion injury in an isolated, perfused rat lung model.[255] This protective effect may be related to modulation of potassium channels and prevention of excessive intracellular calcium overload. Hypoxia induces a series of responses, including erythropoiesis, angiogenesis, and glycolysis, to maintain homeostasis. Under hypoxic conditions, hypoxia inducible factor is responsible for the activation of hypoxia-responsive genes, such as iNOS, heme oxygenase, and vascular endothelial growth factor, in the lung. Exposure of isolated cells to isoflurane resulted in significant increases in hypoxia inducible factor 1α, and enhanced gene expression for hypoxia-responsive genes.[256] Whether these actions are involved in the protective effects of volatile anesthetics in acute lung injury remains unknown. The specific effects of nitrous oxide or xenon on pulmonary inflammatory reactions or acute lung injury remain to be examined.

Summary

Inhaled anesthetics have potent and clinically significant effects on respiratory function. Volatile anesthetics reduce bronchial smooth muscle tone, adversely affect mucociliary function, and dilate the pulmonary vasculature. Volatile anesthetics also alter the activity of respiratory sensors, the central nervous system, and muscles of respiration. These actions are mediated by direct effects on pulmonary parenchyma and indirect actions on afferent, central, and efferent neural pathways. The depressant effects of these volatile anesthetics are further enhanced in patients with pulmonary disorders. The inhaled anesthetics nitrous oxide and xenon also affect the respiratory system. Although many actions of xenon have not been as well described, this agent is unusual in that it increases tidal breathing and decreases the respiratory rate, an action opposite that of other anesthetics. The effects of volatile anesthetics on acute lung injury have been described as both proinflammatory and anti-inflammatory. Further investigations are needed to determine the precise role of these agents as friend or foe. An understanding of the multifactorial actions of inhaled anesthetics on the respiratory system is critical to the safe delivery of anesthesia.

23 Cardiovascular Pharmacology

Key Points

1. In a normal heart, volatile anesthetics produce dose-related depression in left ventricular, right ventricular, and left atrial myocardial contractility; left ventricular diastolic function; and left ventricular–arterial coupling.
2. The negative inotropic effects of volatile anesthetics are related to alterations in intracellular Ca^{2+} homeostasis within the cardiac myocyte.
3. Volatile anesthetics affect the determinants of left ventricular afterload to varying degrees in the presence of normal and dysfunctional myocardium.
4. The systemic hemodynamic effects of volatile anesthetics are complex and determined by the interaction of myocardial effects, direct actions on the arterial and venous vasculature, and alterations in autonomic nervous system activity.
5. Volatile anesthetics sensitize myocardium to the arrhythmogenic effects of epinephrine to varying degrees and may prevent or facilitate the development of atrial or ventricular arrhythmias during myocardial ischemia or infarction, depending on the concentration of the agent, the extent of the injury, and the location affected within the conduction pathway.
6. Volatile anesthetics are relatively weak coronary vasodilators that are not capable of producing coronary steal at typically used clinical concentrations, even in patients with steal-prone coronary artery anatomy.
7. Volatile anesthetics exert important cardioprotective effects against reversible and irreversible myocardial ischemia in experimental animals and humans when administered before, during, or immediately after the onset of coronary artery occlusion and reperfusion.
8. Volatile anesthetics depress baroreceptor reflex control of arterial pressure to varying degrees.
9. Nitrous oxide causes direct negative inotropic effects, does not substantially affect left ventricular diastolic function, and produces modest increases in pulmonary and systemic arterial pressure via a sympathomimetic effect. These actions are dependent to some degree on the baseline anesthetic.
10. Xenon is essentially devoid of cardiovascular effects but has been shown to protect myocardium against infarction in experimental animals.

This chapter comprehensively describes the cardiovascular pharmacology of modern volatile anesthetics (including isoflurane, desflurane, and sevoflurane), nitrous oxide, and xenon. Comparison to older volatile anesthetics (halothane and enflurane) will be made only when necessary because these drugs are no longer clinically available. The actions of inhaled anesthetics on cardiovascular function, cardiac electrophysiology, the coronary circulation, and autonomic nervous system control of the circulation will be examined in detail.

Volatile Anesthetics and Cardiovascular Function

Myocardial Contractility

Isoflurane, desflurane, and sevoflurane depress myocardial contractility in vitro and in vivo. Investigations conducted in the

1960s demonstrated that the older volatile anesthetics halothane and enflurane produce dose-related depression of force-velocity relationships and Frank-Starling curves in isolated cardiac muscle preparations and intact, closed-chest dogs, respectively. These findings supported clinical observations of circulatory depression during halothane and enflurane anesthesia in humans. Isoflurane produces direct negative inotropic effects as indicated by decreases in the maximal velocity of shortening, peak developed force, and maximal rate of force development during isotonic contraction in isolated feline papillary muscles. These reductions in myocardial contractility by isoflurane also contribute to the cardiovascular depression observed with this anesthetic in humans. Similarly, desflurane and sevoflurane depress the intrinsic inotropic state in isolated myocardium, and these actions play an important role in determining the hemodynamic effects of these volatile anesthetics in humans with or without heart disease.

The relative degree of myocardial depression produced by volatile anesthetics in vivo has been more difficult to establish because simultaneous alterations in systemic and pulmonary hemodynamics and autonomic nervous system activity complicate assessment of left ventricular (LV) systolic function. Isovolumic and ejection-phase measures of myocardial contractility demonstrated that halothane and enflurane cause very similar negative inotropic effects in experimental animals and humans. These findings were subsequently confirmed by using the slope (E_{es}) of the LV end-systolic pressure–midaxis diameter relationship as a relatively heart rate– and load-independent index of the inotropic state in chronically instrumented dogs. In contrast, isoflurane produces less myocardial depression in vivo than the older anesthetics do. For example, isoflurane caused smaller reductions in the maximum rate of LV pressure development (dP/dt) than halothane did when identical minimum alveolar concentrations (MACs) were directly compared in the presence and absence of autonomic nervous system function, which suggested that the differences in myocardial depression caused by these anesthetics occur independent of autonomic nervous system activity. Differences in the negative inotropic effects of halothane and isoflurane have been quantified by using the slope (M_w) of the regional preload recruitable stroke work relationship derived from differentially loaded LV pressure–segment length diagrams. In these studies, conducted in chronically instrumented dogs, isoflurane maintained contractility an average of 20% higher than halothane did at identical MAC. Differences in the relative degree of myocardial depression produced by isoflurane and the older volatile anesthetics halothane and enflurane were also inferred in humans by using isovolumic and ejection-phase measures of the contractile state. The negative inotropic actions of all volatile anesthetics are exacerbated by hypocalcemia, calcium (Ca^{2+}) channel blockers, and β_1-adrenoceptor antagonists and may be reversed by the administration of exogenous Ca^{2+}, cardiac phosphodiesterase fraction III inhibitors, β_1-adrenoceptor agonists, Ca^{2+} channel agonists, and myofilament Ca^{2+} sensitizers. The differential effects of isoflurane and the older volatile anesthetics halothane and enflurane on myocardial contractility are maintained during the depression or augmentation of the inotropic state produced by these vasoactive drugs.

Desflurane causes systemic and coronary hemodynamic effects that are remarkably similar to those produced by isoflurane. Desflurane and isoflurane have been shown by isovolumic and ejection-phase measures of contractility to depress myocardial function to equivalent degrees in experimental animals and humans. These observations have been verified by using both end-systolic pressure-volume relationships and preload recruitable stroke work (Fig. 23-1) in the presence and absence of autonomic nervous system activity.[1] However, the unique cardiovascular stimulation associated with rapid increases in inspired desflurane concentration in humans may lead to transient increases in myocardial contractility as a result of augmentation of sympathetic nervous system tone. The effects of sevoflurane on myocardial contractility have also been shown to be virtually indistinguishable from those produced by isoflurane in dogs. Sevoflurane caused less myocardial depression than an equivalent halothane MAC in pigs did and produced less myocardial depression than enflurane did in humans as evaluated by echocardiography. Sevoflurane decreased contractile function to approximately 40% to 45% of control values at 1.75 MAC in the presence and absence of autonomic nervous system tone as determined by regional preload recruitable stroke work in dogs. This magnitude of myocardial depression agreed with previous data for isoflurane and desflurane in an identical experimental model. Thus, the vast

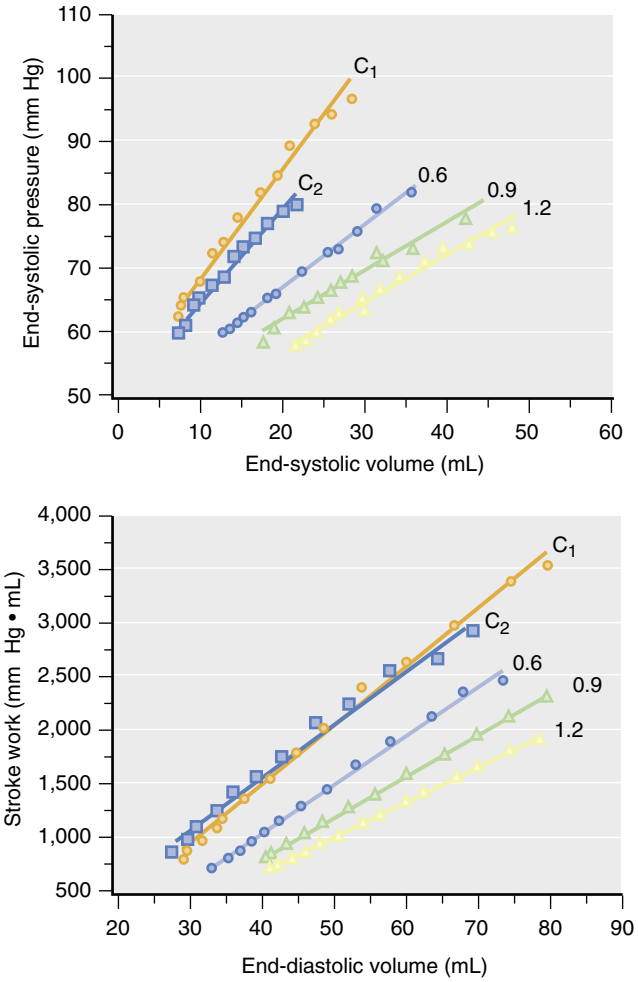

Figure 23-1 End-systolic pressure-volume (*top panel*) and stroke work–end-diastolic volume relationships (*bottom panel*) before (control 1; C_1), during 0.6, 0.9, and 1.2 minimum alveolar concentration, and after isoflurane (control 2; C_2) in an experiment in an open-chest dog. *(Adapted from Hettrick DA, Pagel PS, Warltier DC: Desflurane, sevoflurane, and isoflurane impair canine left ventricular–arterial coupling and mechanical efficiency. Anesthesiology 85:403-413, 1996.)*

majority of evidence collected to date indicates that isoflurane, desflurane, and sevoflurane depress the contractile state to similar degrees in normal ventricular myocardium.

The effects of volatile anesthetics on myocardial contractility in animal models or patients with LV dysfunction have been less extensively studied. An early in vitro study demonstrated that isoflurane causes greater reductions in maximum shortening velocity and the peak rate of force development in feline papillary muscles from failing hearts subjected to chronic pressure overload than in muscles from normal hearts. The older volatile anesthetic halothane also produced more pronounced myocardial depression in ischemic than in normal myocardium. Isoflurane and halothane were shown to cause relatively greater negative inotropic effects in ventricular myocardium obtained from cardiomyopathic hamsters than from normal hamsters (Fig. 23-2).[2] Isoflurane and sevoflurane also produced greater depression of contractility in right ventricular (RV) papillary muscles obtained from ferrets with experimental pressure-overload hypertrophy than from ferrets with normal myocardium.[3] These findings suggested that the myocardial depression caused by volatile anesthetics in failing or hypertrophied myocardium was accentuated and provided indirect evidence that patients with underlying contractile dysfunction may be more sensitive to the negative inotropic effects of volatile anesthetics. This hypothesis has not been comprehensively examined in vivo, however. In contrast, isoflurane, sevoflurane, and desflurane caused similar declines in contractility in ventricular myocytes obtained from rats with and without chemically induced chronic hyperglycemia.[4] These data suggested that volatile anesthetics do not cause a more exaggerated negative inotropic effect in myocardium obtained from this model of diabetes mellitus.

Volatile anesthetic–induced declines in contractile function were well tolerated and did not precipitate frank systolic dysfunction in experimental models of myocardial ischemia or infarction. In fact, volatile anesthetics have been shown to exert important beneficial effects on mechanical function during myocardial ischemia and reperfusion injury. Volatile anesthetics reduced experimental myocardial infarct size,[5] preserved metabolic and structural integrity during regional ischemia and reperfusion, enhanced the functional recovery of stunned myocardium, and improved indices of LV diastolic performance during brief coronary artery occlusion. Isoflurane was also shown to produce beneficial decreases in LV preload and afterload in patients with ischemic heart disease. These improvements in loading conditions in patients with compromised LV function may serve to offset the direct negative inotropic effects of anesthetics and contribute to relative maintenance of cardiac performance by optimizing the Starling operating range of the heart or by improving LV diastolic function. Isoflurane produced dose-related depression of myocardial contractility in a canine model of moderate LV dysfunction induced by chronic rapid LV pacing, but isoflurane anesthesia was well tolerated and did not precipitate frank LV failure in this model.[6] These findings with isoflurane were attributed to simultaneous improvements in LV loading conditions and filling dynamics that contributed to relative maintenance of cardiac output in the setting of moderate LV dysfunction despite concomitant reductions in contractility.

Cellular Mechanisms of Myocardial Depression

Volatile anesthetics depress myocardial contractility via alterations in intracellular Ca^{2+} homeostasis at several subcellular targets in the normal cardiac myocyte. Volatile anesthetics caused dose-related inhibition of the transsarcolemmal Ca^{2+} transient by affecting both L- and T-type Ca^{2+} channels. Isoflurane produced less pronounced reductions in the intracellular Ca^{2+} transient than the older volatile anesthetics did. The structural conformation and functional integrity of voltage-dependent Ca^{2+} channels were directly altered by volatile anesthetics as indicated by the attenuated binding of Ca^{2+} channel blockers. The partial inhibition of Ca^{2+} influx via sarcolemmal Ca^{2+} channels has several important consequences, including declines in the availability of Ca^{2+} for contractile activation, depression of Ca^{2+}-dependent release of Ca^{2+} from the sarcoplasmic reticulum (SR), and reduction of the amount of Ca^{2+} that can subsequently be stored in the SR. In contrast to the older volatile anesthetics halothane and enflurane, isoflurane did not stimulate release of Ca^{2+} from the SR nor directly activate ryanodine-sensitive SR Ca^{2+} release channels, thereby reducing SR Ca^{2+} storage. Unlike halothane, isoflurane also did not appear to provoke nonspecific leakage of Ca^{2+} from the SR, an action that contributes to further decreases in accumulation of the Ca^{2+} available for release during contraction in the presence of the older volatile agent. When combined with decreases in transsarcolemmal Ca^{2+} flux, these alterations in SR function represent important mechanisms by which older volatile anesthetics depress the intracellular Ca^{2+} transient and reduce myocardial contractility to a greater extent than with identical MAC concentrations of isoflurane, desflurane, or sevoflurane. In addition, isoflurane and sevoflurane have been shown to inhibit Ca^{2+} transport from the cell through sarcolemmal Ca^{2+}-adenosine triphosphatase (ATPase), an action that partially offsets reductions in SR Ca^{2+} stores. The partial preservation of the myocardial

positive frequency staircase effect observed with newer volatile anesthetics at physiologic excitation rates in vitro may also be attributed to this relative maintenance of SR function, in contrast to the findings with halothane or enflurane.

Volatile anesthetics also depress contractile function by inhibiting Na^+-Ca^{2+} exchange and reducing the intracellular Ca^{2+} concentration independent of the voltage-dependent Ca^{2+} channel in vitro. This effect may be particularly important in neonatal myocardium because it is more sensitive to the negative inotropic actions of volatile anesthetics than adult myocardium is. The relative contribution of inhibition of the Na^+-Ca^{2+} exchanger to anesthetic-induced depression of myocardial contractility in the intact heart remains controversial, but a role for inhibition of Na^+-Ca^{2+} exchange in anesthetic preconditioning was demonstrated recently.[7] Volatile anesthetics may also exert direct effects on the contractile apparatus and reduce myofilament Ca^{2+} sensitivity. Volatile anesthetics decreased tension development in skinned cardiac myofibrils and reduced myofibrillar ATPase activity. These actions may contribute to declines in actin-myosin cross-bridge kinetics during contraction, but not through a direct interaction with cardiac cross-bridge mechanics.[8] In addition, volatile anesthetics may modestly reduce myofilament Ca^{2+} sensitivity, but this mechanism probably plays a relatively minor role in the negative inotropic effects of these anesthetics at clinically relevant concentrations in vivo.

The cellular mechanisms responsible for volatile anesthetic–induced depression of myocardial contractility in failing myocardium have not been studied in detail. The most comprehensive investigation published to date examined the effects of isoflurane and sevoflurane on intracellular Ca^{2+} homeostasis in a ferret model of RV pressure-overload hypertrophy.[3] Isoflurane and sevoflurane produced more pronounced reductions in peak intracellular Ca^{2+} concentration and exaggerated decreases in myofilament Ca^{2+} sensitivity in ventricular myocytes obtained from hypertrophied hearts than in normal myocytes.[3] Whether similar alterations in intracellular Ca^{2+} regulation are produced by volatile anesthetics in other forms of heart failure remains to be determined. Profound abnormalities in Ca^{2+} homeostasis are characteristic features of failing myocardium, and it appears highly likely that volatile anesthetics will cause further reductions in contractile function by producing additive or synergistic effects on Ca^{2+} metabolism under these conditions.

Diastolic Function

Definitions of heart failure based solely on contractile dysfunction are inadequate because LV function during diastole significantly influences overall cardiac performance. The heart serves dual roles: it propels blood into the high-pressure arterial vasculature during systole and collects blood from the low-pressure venous circulation during diastole. Thus, heart failure may occur not only as a result of impaired contractility but also as a result of altered LV diastolic function. The timing, rate, and extent of LV filling are determined by several major factors, including the rate and degree of myocardial relaxation, the intrinsic mechanical properties of the left ventricle itself and those imposed by external constraints, and the structure and function of the left atrium, the pulmonary venous circulation, and the mitral valve. Although abnormalities in LV diastolic function may be linked to decreases in myocardial contractility, heart failure may result from primary diastolic dysfunction in the absence of or before the appearance of alterations in LV systolic function in a variety of pathologic conditions, including ischemic heart disease, pressure- or volume-overload hypertrophy, hypertrophic obstructive cardiomyopathy, and restrictive disease processes.

Volatile anesthetics produce dose-related prolongation of LV isovolumic relaxation in vivo. This delay in isovolumic relaxation is associated with declines in early LV filling but is not of sufficient magnitude to affect LV chamber stiffness. Coronary blood flow is highest during isovolumic relaxation, and the delays in relaxation produced by volatile anesthetics contribute to impairment of coronary flow during early diastole. Prolongation of LV relaxation probably occurs as a result of simultaneous depression of myocardial contractility and not because of a direct negative lusitropic effect. In fact, volatile anesthetics modestly enhanced relaxation of isolated ferret myocardium in vitro. Volatile anesthetics cause concentration-related decreases in the rate and extent of early LV filling concomitant with negative inotropic effects. They also reduce LV filling associated with atrial systole.[9] Isoflurane, desflurane, and sevoflurane did not alter invasively derived indices of regional myocardial or chamber stiffness, thus indicating that LV distensibility was unaffected by these volatile anesthetics. The older volatile anesthetic halothane also did not directly alter the intrinsic viscoelastic properties of myocardium despite producing relatively greater negative inotropic effects.

The effects of isoflurane and halothane on LV diastolic function in a canine model of dilated cardiomyopathy were described.[6] In contrast to the findings in dogs with normal LV function, isoflurane improved several indices of LV relaxation and filling in cardiomyopathic dogs despite producing simultaneous negative inotropic effects. In addition, halothane did not exacerbate the preexisting diastolic dysfunction inherent in this experimental model. The findings with isoflurane and halothane were most likely related to favorable reductions in LV preload produced by these volatile anesthetics and were not due to direct positive lusitropic effects. These data further suggested that isoflurane-induced improvements in LV isovolumic relaxation and filling dynamics may contribute to relative maintenance of cardiac output in the presence of LV dysfunction despite simultaneous reductions in contractility. The findings in cardiomyopathic dogs supported earlier clinical observations that patients with severe ischemic heart disease or congestive heart failure tolerate isoflurane or halothane anesthesia without acute hemodynamic decompensation.

The dependence of LV relaxation on afterload is markedly enhanced in failing myocardium. Thus, a reduction in afterload may increase not only LV systolic performance by decreasing impedance to LV ejection but also the rate of LV relaxation and contribute to improvements in LV diastolic filling and compliance. The effects of isoflurane and halothane on the dependence of LV relaxation on afterload were explored in dogs before and after the development of rapid LV pacing–induced cardiomyopathy.[10] The dependence of LV relaxation on afterload was unaffected by isoflurane and halothane anesthesia in dogs with dilated cardiomyopathy (Fig. 23-3), thus further suggesting that these volatile anesthetics do not exert direct actions on LV isovolumic relaxation in failing myocardium independent of negative inotropic effects.

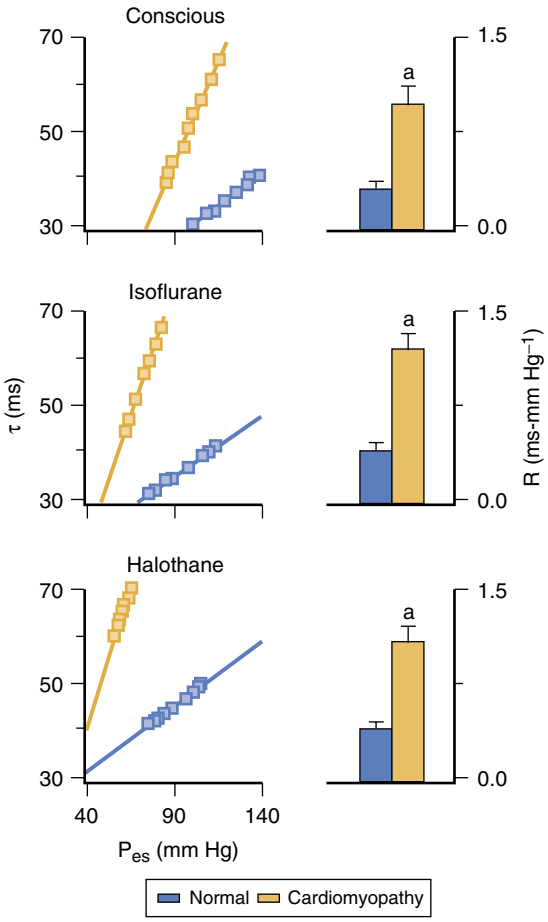

Figure 23-3 Linear relationship between the time constant of isovolumic relaxation (τ) and left ventricular end-systolic pressure (P_{es}) during inferior vena cava occlusion (*left panels*) in a typical dog before (*yellow squares*) and after (*blue squares*) the development of pacing-induced cardiomyopathy in the conscious state and during isoflurane and halothane anesthesia. The histograms on the *right* illustrate the slope (R) of the τ-versus-P_{es} relationship in the conscious state (*top right panel*) and during isoflurane (*middle right panel*) and halothane (*bottom right panel*) anesthesia before (*yellow bars*) and after (*blue bars*) pacing. a, Significantly ($P < .05$) different from normal myocardium. *(Adapted from Pagel PS, Hettrick DA, Kersten JR, et al: Isoflurane and halothane do not alter the enhanced afterload sensitivity of left ventricular relaxation in dogs with pacing-induced cardiomyopathy. Anesthesiology 87:952-962, 1997.)*

Left Ventricular–Arterial Coupling and Mechanical Efficiency

Optimum transfer of stroke volume from the left ventricle to the arterial circulation requires appropriate matching of these mechanical systems. LV-arterial coupling has most often been described by using a series elastic chamber model of the cardiovascular system. The elastances of the contracting left ventricle (E_{es}) and the arterial vasculature (E_a) are determined from LV end-systolic pressure-volume and end-systolic arterial pressure–stroke volume relationships, respectively. The ratio of E_{es} to E_a defines coupling between the left ventricle and the arterial circulation and provides a useful technique for assessment of the actions of drugs, including volatile anesthetics, on LV-arterial matching in vivo. Analysis of the pressure-volume relationship also creates a framework for the study of LV mechanical efficiency as defined by the ratio of stroke work to pressure-volume area. LV-arterial coupling may theoretically be maintained during anesthesia because declines in LV afterload may balance simultaneous reductions in myocardial contractility. Low concentrations of isoflurane (1 MAC), but not halothane, maintained E_{es}/E_a in barbiturate-anesthetized, acutely instrumented dogs, consistent with preservation of mechanical coupling between the left ventricle and the arterial circulation. However, isoflurane decreased E_{es}/E_a at 2 MAC, thus suggesting that the vasodilating effects of this anesthetic were unable to compensate for the relatively greater declines in contractility. Desflurane, sevoflurane, and isoflurane maintained optimum LV-arterial coupling and mechanical efficiency as evaluated by E_{es}/E_a and stroke work–pressure-volume area ratios at low anesthetic concentrations (<0.9 MAC) by producing simultaneous declines in myocardial contractility and LV afterload.[1] However, mechanical matching between the left ventricle and the arterial vasculature and the efficiency of total LV energy transfer to external stroke work degenerate at higher anesthetic concentrations, thus indicating that anesthetic-induced reductions in contractility are not appropriately balanced by declines in afterload. Halothane (<1.0 MAC) but not isoflurane also reduced the ratio of oscillatory to mean hydraulic power in vivo, which indicates that this anesthetic decreases LV mechanical efficiency as well. The detrimental alterations in LV-arterial coupling produced by volatile anesthetics contribute to the reductions in overall cardiac performance observed with higher concentrations of these anesthetics in vivo.

Left Ventricular Afterload

A definition of LV afterload that describes the mechanical properties of the arterial vasculature opposing LV ejection is clear, but quantitative evaluation of afterload in vivo remains a difficult problem whose solution often confuses this clinically intuitive concept. Systemic vascular resistance, calculated as the ratio of mean arterial pressure to cardiac output, is the most commonly used estimate of LV afterload. However, systemic vascular resistance inadequately describes LV afterload because this index ignores the mechanical characteristics of the blood and arterial walls, fails to account for the frequency-dependent, phasic nature of arterial blood pressure and blood flow, and does not consider the potential effects of arterial wave reflection. As a result, systemic vascular resistance cannot be used reliably to quantify changes in LV afterload produced by drugs, including volatile anesthetics, or cardiovascular disease. Aortic input impedance ($Z_{in}[\omega]$) obtained from power spectral or Fourier series analysis of aortic pressure and blood flow waveforms provides a comprehensive description of LV afterload because $Z_{in}(\omega)$ incorporates arterial viscoelasticity, frequency dependence, and wave reflection. However, analysis of $Z_{in}(\omega)$ is conducted in the frequency domain and not as a function of time, and as a result, $Z_{in}(\omega)$ is very difficult to apply in a clinical setting. $Z_{in}(\omega)$ is most often interpreted by using an electrical three-element Windkessel model of the arterial circulation that describes characteristic aortic impedance (Z_c), total arterial compliance (C), and total arterial resistance (R). Z_c represents aortic resistance to LV ejection, C is determined primarily by the compliance of the aorta

and represents the energy storage component of the arterial circulation, and R equals the combined resistance of the remaining arterial vasculature. The three-element Windkessel model has been shown to closely approximate $Z_{in}(\omega)$ in a variety of physiologic conditions.

Volatile anesthetics alter $Z_{in}(\omega)$ by affecting the mechanical properties of the arterial vascular tree. In contrast to the results obtained with the older agent halothane, isoflurane produced dose-related decreases in R in a canine model, consistent with the known effects of this drug on systemic vascular resistance. Isoflurane and halothane also caused similar increases in C and Z_c concomitant with reductions in mean arterial pressure. Thus, the major difference between the effects of isoflurane and halothane on LV afterload derived from the Windkessel model of $Z_{in}(\omega)$ was related to R, a property of arteriolar resistance vessels, and not to C or Z_c, the mechanical characteristics of the aorta. In contrast to the findings with sevoflurane, desflurane also reduced R in dogs, thus suggesting that this agent is a more potent peripheral vasodilator. Importantly, the inverse relationship between C and mean arterial pressure remains unchanged by volatile anesthetics, unlike the findings with the arterial vasodilator sodium nitroprusside or the intravenous anesthetic propofol. These data emphasize that volatile anesthetics do not fundamentally affect aortic mechanical characteristics.

Isoflurane and halothane produced alterations in $Z_{in}(\omega)$ in an experimental model of heart failure that are somewhat different from those observed in the normal cardiovascular system. These volatile anesthetics decreased arterial pressure but did not affect C and Z_c in the presence of LV dysfunction. Isoflurane also did not reduce R in the presence of dilated cardiomyopathy, in contrast to the actions of this volatile anesthetic in the presence of normal LV performance. Thus, neither isoflurane nor the older agent halothane reduced arterial hydraulic resistance or favorably improved the rectifying properties of the aorta in the presence of pacing-induced cardiomyopathy. The findings suggest that volatile anesthetics do not exert beneficial actions on LV afterload in the presence of heart failure.

Right Ventricular Function

The crescent-shaped right ventricle is composed of embryologically distinct inflow and outflow tracts that differ in their structure and response to autonomic nervous system activity. Sequential contraction of the RV inflow and outflow tracts establishes regional pressure gradients within the right ventricle during systole and accounts for the peristaltic mechanical action of this pump. True isovolumic relaxation does not occur in the right ventricle. Instead, ejection of blood from the outflow tract into the pulmonary artery continues after the inflow tract has begun to relax. The effects of volatile anesthetics on the function and contraction sequence of the RV inflow and outflow tracts have been incompletely studied. Halothane produced similar depression of contractile function in the RV inflow and outflow tracts when a uniform definition of end-systole and end-diastole was used for both regions of the RV. Halothane also caused dose-related decreases in RV contractility as evaluated by using regional preload recruitable stroke work derived from RV pressure–segment length diagrams in the RV inflow and outflow tracts in the presence and absence of autonomic nervous system reflexes.[11] Importantly, halothane also abolished the normal RV sequential contraction pattern without exerting differential negative inotropic effects on different regions of the right ventricle, thus suggesting that volatile anesthetics may alter RV contraction dynamics by adversely affecting cardiac autonomic nervous system activity. Isoflurane also exerted qualitatively different effects on RV and LV afterload and hydraulic power generation that were also partially mediated by the autonomic nervous system.[12] Hence, isoflurane probably produces fundamentally different actions on RV and LV contraction dynamics in vivo.

Left Atrial Function

The left atrium serves three major roles that exert a profound effect on LV filling and overall cardiovascular performance. The left atrium is a contractile chamber that actively empties immediately before the onset of LV systole and establishes the final LV end-diastolic volume. The left atrium is a reservoir that stores pulmonary venous return during LV contraction and isovolumic relaxation after closure and before opening of the mitral valve. The left atrium is also a conduit that empties its contents into the left ventricle down a pressure gradient after the mitral valve opens and continues to passively transfer pulmonary venous blood flow during LV diastasis. These contraction, reservoir, and conduit functions of the left atrium mechanically facilitate the transition between the almost continuous flow through the pulmonary venous circulation and the intermittent filling of the left ventricle. Advances in the understanding and clinical significance of left atrial (LA) mechanical function were recently reviewed.[9]

The negative inotropic effects of the older volatile anesthetics halothane and methoxyflurane were initially described in rat atrial myocardium in vitro. Volatile anesthetics also depressed the contractile function of atrial human myocardium.[13] These actions have been attributed to reductions in transsarcolemmal Ca^{2+} influx through voltage-dependent Ca^{2+} channels and decreases in Ca^{2+} availability from the SR, mechanisms that are very similar to those responsible for anesthetic-induced depression of LV myocardium. The negative inotropic effects of volatile anesthetics in the intact left atrium were quantified by pressure-volume analysis (Fig. 23-4).[14] Desflurane, sevoflurane, and isoflurane reduced LA contractility (i.e., E_{es}) by approximately 50% at an end-tidal concentration of 1.2 MAC. The magnitude of this effect on LA myocardium was similar to the degree of LV contractile depression produced by these anesthetics as quantified by LV end-systolic pressure-volume relationships.[1] Desflurane, sevoflurane, and isoflurane also impaired LA and LV relaxation to similar degrees. These data indicate that volatile anesthetics produce equivalent alterations in contractility and relaxation in LA and LV myocardium.[14] The magnitude of reductions in the LA inotropic and lusitropic state produced by volatile anesthetics was also similar in the intact left atrium, thus supporting the results obtained in isolated human atrial myocardium.[13]

Desflurane, sevoflurane, and isoflurane altered the passive mechanical behavior of the left atrium.[14] LA reservoir function (V loop area and reservoir volume) was maintained during the administration of anesthetic at concentrations of less than 1.0 MAC. Such preservation of reservoir function contributed to the relative maintenance of LV stroke volume[1] by compensating for decreases in LV filling associated with a reduced contribution of LA contraction. The volatile anesthetics also reduced dynamic LA chamber stiffness, an action that most likely contributed to

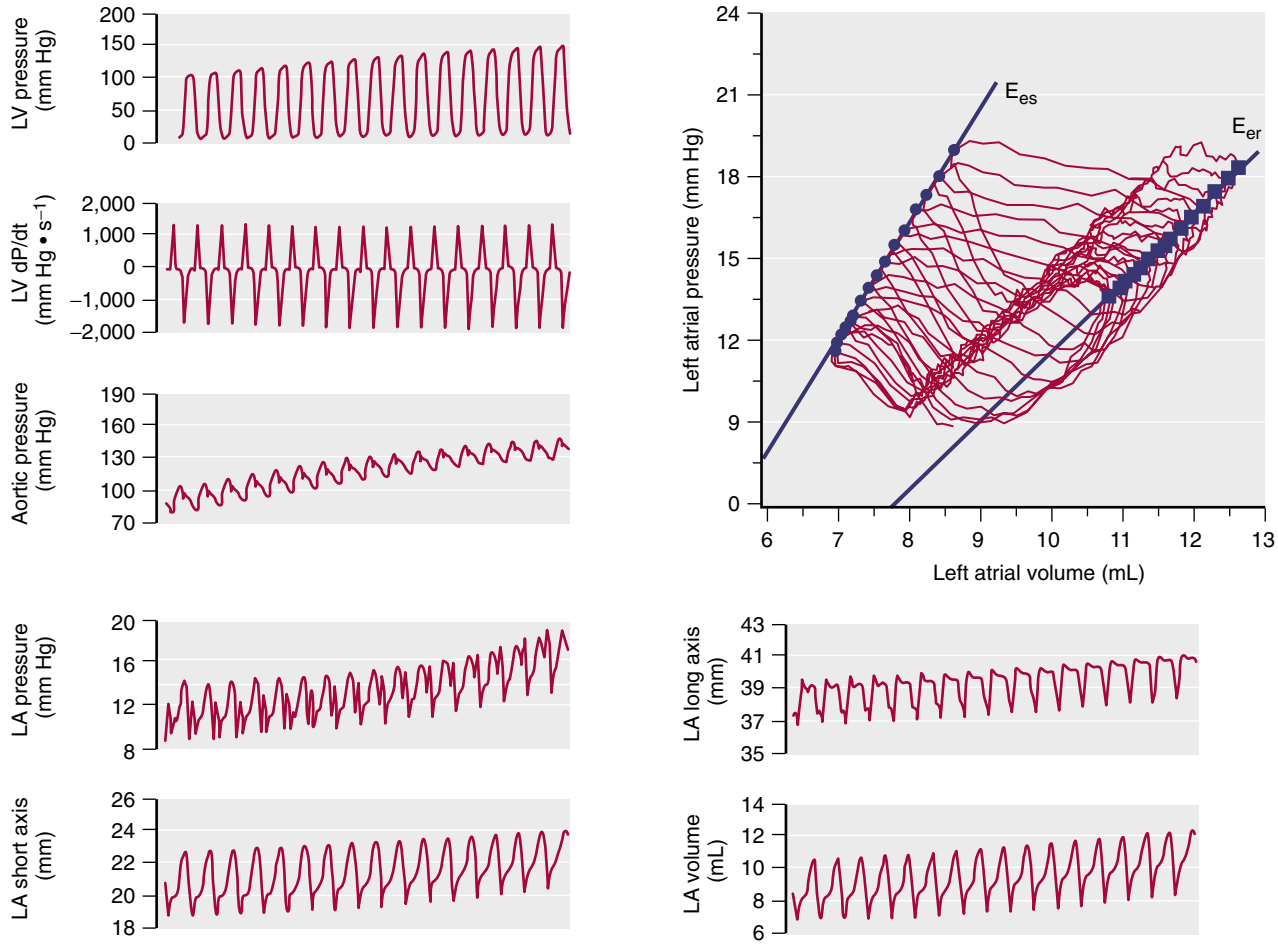

Figure 23-4 Continuous left ventricular (LV) pressure, LV dP/dt, aortic pressure, left atrial (LA) pressure, LA short- and long-axis dimensions, and LA volume waveforms (*left*) and corresponding LA pressure-volume diagrams (*right*) resulting from the intravenous administration of phenylephrine (200 µg) observed in a typical experiment. The maximum LA elastance (*solid dots*) and end-reservoir pressure and volume (*solid squares*) for each pressure-volume diagram were used to obtain the slopes (E_{es} and E_{er}) and extrapolated volume intercepts of the LA end-systolic and end-reservoir pressure-volume relationships to quantify myocardial contractility and dynamic chamber stiffness, respectively. *(Adapted from Gare M, Schwabe DA, Hettrick DA, et al: Desflurane, sevoflurane, and isoflurane affect left atrial active and passive mechanical properties and impair left atrial–left ventricular coupling in vivo. Analysis using pressure-volume relations. Anesthesiology 95:689-698, 2001.)*

the preservation of reservoir function because the delays in LA relaxation and declines in LV systolic function that also occurred would be expected to decrease reservoir function.[15] However, LA reservoir function was reduced during the administration of higher concentrations of volatile anesthetics because further impairment of LA relaxation and LV contractility occurred. Decreases in the ratio of LA stroke work to total pressure-volume diagram area and increases in the ratio of LA conduit to total reservoir volume were also produced by desflurane, sevoflurane, and isoflurane. These data indicate that the LA contribution to LV filling becomes less active and more passive during the administration of volatile anesthetics.

Desflurane, sevoflurane, and isoflurane decreased the ratio of LA to LV elastance (E_{es}/E_{LV}), consistent with impaired mechanical matching between these chambers. As described earlier, volatile anesthetics have been shown to produce LV diastolic dysfunction by delaying LV isovolumic relaxation and impairing early LV filling in association with direct negative inotropic effects. Thus, the attenuation of transfer of kinetic energy from the left atrium to the left ventricle probably resulted from the combination of LA contractile depression and LV systolic and diastolic dysfunction. Volatile anesthetic–induced abnormalities in LA-LV matching were greater than the analogous impairment in LV-arterial coupling evaluated via a similar series elastic chamber model in a previous investigation[1] because these anesthetics produced beneficial alterations in the determinants of LV afterload that partially compensate for simultaneous depression of LV myocardial contractility.

The influence of isoflurane on LA function in the presence of preexisting LV dysfunction has also been examined.[16] Isoflurane depressed LA contractility, impaired LA-LV coupling, and reduced the active LA contribution to LV filling in dogs with pacing-induced cardiomyopathy, findings that were similar in magnitude to those observed in healthy canine hearts.[14] In contrast to the findings in normal dogs,[14] LA reservoir function was reduced in dogs with LV dysfunction at lower isoflurane concentrations (0.6 and 0.9 MAC).[16] These findings indicate that the ability of the left atrium to act as a reservoir for pulmonary venous return is attenuated during isoflurane anesthesia. Such an isoflurane-induced reduction in LA storage ability suggested that the quantity of blood transferred from the left atrium to the left ventricle when the mitral valve opens may be reduced, thereby

providing another potential mechanism by which volatile anesthetics can reduce early LV filling in the presence of preexisting LV dysfunction.

Systemic Hemodynamics

Volatile anesthetics cause direct negative chronotropic actions in vitro by depressing sinoatrial node activity, but alterations in heart rate in vivo are primarily determined by the interaction of volatile anesthetics and baroreceptor reflex activity. Halothane does not appreciably change the heart rate in humans because this anesthetic attenuates baroreceptor reflex responses. In contrast, isoflurane increases the heart rate in response to simultaneous decreases in arterial pressure. These findings occur with this volatile agent because baroreceptor reflexes are relatively preserved when compared with older anesthetics. Desflurane also causes dose-related increases in heart rate in humans. Desflurane- and isoflurane-induced tachycardia may be more pronounced in pediatric patients or in the presence of vagolytic drugs and, conversely, may be attenuated in neonates and geriatric patients or by the concomitant administration of opioids (see Chapters 71 and 82). Rapid increases in the inspired desflurane concentration above 1 MAC may be associated with further transient increases in heart rate and arterial pressure as a result of activation of the sympathetic nervous system. Interestingly, similar increases in heart rate also occur when the inspired isoflurane concentration is increased rapidly. The cardiovascular stimulation induced by rapid increases in desflurane or isoflurane concentration in humans resulted from activation of tracheopulmonary and systemic receptors and was attenuated by pretreatment with β_1-adrenoceptor antagonists, α_2-adrenoceptor agonists, or opioids. In contrast to the findings with isoflurane and desflurane, sevoflurane did not alter heart rate or cause cardiovascular stimulation during rapid increases in anesthetic concentration in humans.

All modern volatile anesthetics cause concentration-related decreases in arterial pressure. The mechanism by which these anesthetics reduce arterial pressure differs between anesthetics. The decreases in arterial pressure produced by halothane and enflurane were attributed to reductions in myocardial contractility and cardiac output, whereas isoflurane, desflurane, and sevoflurane decrease arterial blood pressure primarily as a result of reductions in LV afterload. Thus, isoflurane, desflurane, and sevoflurane maintain cardiac output because these anesthetics produce less pronounced reductions in myocardial contractility and greater decreases in systemic vascular resistance in humans than halothane or enflurane does. Isoflurane and desflurane may also preserve autonomic nervous system regulation of the circulation to a greater degree than other volatile anesthetics do. The baroreceptor reflex–mediated tachycardia that occurs during isoflurane and desflurane anesthesia serves to maintain cardiac output despite modest declines in contractility and stroke volume. The declines in arterial pressure produced by volatile anesthetics may be attenuated by surgical stimulation or concomitant administration of nitrous oxide. Volatile anesthetics also cause modest, dose-related increases in right atrial pressure in humans. These effects probably occur as a result of direct negative inotropic actions. The cardiovascular effects of volatile anesthetics are altered by the duration of anesthesia. Increases in myocardial contractility and cardiac output and decreases in LV preload and afterload occur after several hours of constant MAC anesthesia. Recovery from circulatory depression is greatest during halothane anesthesia but is somewhat less pronounced during prolonged administration of isoflurane and desflurane.

The systemic hemodynamic effects of volatile anesthetics in the presence of LV dysfunction are similar but not identical to those observed in the normal heart. Volatile anesthetics, including isoflurane, modestly increase or do not affect the heart rate in experimental animals with pacing- or doxorubicin-induced dilated cardiomyopathy and patients with coronary artery disease and LV dysfunction. These findings may be attributed to altered baroreceptor reflex activity, β_1-adrenoceptor downregulation, increases in central sympathetic nervous system activity, and withdrawal of parasympathetic nervous system tone associated with heart failure. Isoflurane and halothane caused pronounced reductions in LV end-diastolic pressure and chamber dimension in cardiomyopathic dogs concomitant with decreases in mean arterial pressure.[6] These findings supported previously observed declines in pulmonary artery pressure during isoflurane anesthesia in patients with coronary artery disease and heart failure and suggested that venodilation represents a major hemodynamic consequence of this volatile agent in experimental and clinical heart failure. In contrast to the findings in normal dogs, isoflurane did not beneficially influence, and the older agent halothane detrimentally affected, the determinants of LV afterload in cardiomyopathic dogs. As a result of these actions and the simultaneous declines in LV preload and myocardial contractility, cardiac output may be more profoundly reduced during isoflurane or halothane anesthesia in the presence of preexisting LV dysfunction.

Volatile Anesthetics and Cardiac Electrophysiology

Cardiac Conduction

Volatile anesthetics slow the rate of sinoatrial node discharge by direct and indirect effects on sinoatrial node automaticity. These actions may be altered in vivo by vasoactive drugs or autonomic nervous system activity. Older volatile anesthetics and, to a lesser extent, isoflurane shorten the cardiac action potential and the effective duration of the refractory period in normal Purkinje fibers, but volatile anesthetics also prolong His-Purkinje and ventricular conduction times. Halothane, enflurane, and isoflurane also prolong atrioventricular conduction time and refractoriness. When combined with the direct actions of volatile anesthetics on sinoatrial node discharge, these data suggest that volatile anesthetics have the potential to produce bradycardia and atrioventricular conduction abnormalities. However, primary disturbances in atrioventricular conduction leading to second- or third-degree atrioventricular block in humans probably do not occur with volatile anesthetics in the absence of conduction disease or drugs that directly prolong the atrioventricular conduction time.

Volatile anesthetics may have proarrhythmogenic or antiarrhythmogenic actions against the abnormal cardiac electrophysiologic mechanisms produced by myocardial ischemia or infarction. Halothane, enflurane, and isoflurane have been shown to be cardioprotective against ventricular fibrillation produced by coronary artery occlusion and reperfusion. Protective effects against ouabain-induced arrhythmias have also been demonstrated with the older volatile agent halothane. Volatile anesthetics

may exert antiarrhythmic effects by opposing subsidiary pacemaker activity in infarcted myocardium. Conversely, halothane and, to a lesser extent, isoflurane may be arrhythmogenic in Purkinje fibers in experimental myocardial infarction by facilitating reentrant activity or increasing temporal dispersion of refractory period recovery. These actions may be related to inhibition of the slow Na^+ current in false tendon fibers and induction of reentry of premature impulses into more refractory Purkinje fibers in the border zone of an ischemic area. Halothane, enflurane, and isoflurane prolong the QT_c interval in humans. These data suggest that patients with idiopathic or acquired long QT syndrome may be at greater risk for the development of torsades de pointes ventricular tachycardia during anesthesia with these agents.

Epinephrine-Induced Arrhythmias

Halothane and, to a lesser extent, other volatile anesthetics sensitize myocardium to the arrhythmogenic effects of epinephrine. Sensitization is the interaction between volatile anesthetics and catecholamines that leads to reductions in the threshold for both atrial and ventricular arrhythmias. Sequentially escalating doses of epinephrine produce premature ventricular contractions and sustained ventricular tachyarrhythmias during halothane anesthesia. Halothane-epinephrine–induced arrhythmias are attenuated by pretreatment with sodium thiopental, presumably via effects on the atrioventricular node or the upper His bundle. A synergistic interaction between α_1- and β-adrenoceptors has been strongly implicated in the pathogenesis of halothane-epinephrine–induced ventricular arrhythmias. Stimulation of the α_{1A}-adrenoceptor in the His-Purkinje system by epinephrine during halothane anesthesia transiently slows Purkinje fiber conduction. This proarrhythmogenic effect is mediated by phospholipase C and the intracellular second messenger inositol triphosphate. Enhanced conduction in the Purkinje–ventricular muscle junction accompanied by simultaneous α_1-adrenoceptor–mediated depression of Purkinje conduction also plays an important role in halothane-epinephrine–induced arrhythmias. The doses of epinephrine required to produce ventricular arrhythmias during desflurane or sevoflurane anesthesia are similar to but significantly less than those observed during administration of isoflurane and halothane. Halothane-catecholamine sensitization also promotes abnormal automaticity of the dominant and latent atrial pacemakers. These effects may produce premature ventricular contractions and arrhythmias originating from the His bundle. Intact sinoatrial node function reduces the incidence of epinephrine-induced ventricular escape during halothane anesthesia and is protective against His bundle arrhythmias.

Volatile Anesthetics and the Coronary Circulation

Coronary Vascular Effects in Vitro

Volatile anesthetics cause direct coronary artery vasodilation in vitro; however, the simultaneous reductions in determinants of myocardial oxygen consumption (MVo_2), including heart rate, preload, afterload, and inotropic state, produced by these anesthetics cause coronary vasoconstriction in vivo via metabolic autoregulation. Volatile anesthetic–induced alterations in coronary blood flow are also affected by the reductions in coronary perfusion pressure produced by these anesthetics. Thus, the combination of direct and indirect actions determines the net effect of volatile anesthetics on coronary vascular tone. Isoflurane and halothane caused vasodilation of isolated coronary arteries. Halothane produced more profound coronary artery dilation than isoflurane did at similar MAC in isolated coronary arteries larger than 2000 μm. In contrast, isoflurane caused vasodilation of predominantly small (<900 μm) canine epicardial coronary arteries. Halothane may produce greater vasodilatory effects in large coronary arteries than isoflurane does because halothane causes more pronounced suppression of the voltage-dependent Ca^{2+} current.

The direct negative inotropic effects of volatile anesthetics caused a reduction in coronary blood flow in isolated, contracting hearts during precise control of ventricular loading conditions via flow-metabolism coupling. Thus, a decrease in myocardial O_2 demand was accompanied by an increase in coronary vascular resistance, findings that may be incorrectly interpreted as suggesting that volatile anesthetics produce coronary vasoconstriction. However, examination of the actions of volatile anesthetics on myocardial O_2 extraction and the ratio of myocardial O_2 delivery to MVo_2 revealed that these drugs are coronary vasodilators. Halothane and isoflurane decreased myocardial O_2 extraction and increased the ratio of O_2 delivery to consumption in isolated, beating hearts.[17] These findings indicate that volatile anesthetics produce direct coronary vasodilation in isolated hearts because myocardial O_2 delivery exceeds MVo_2 and coronary sinus O_2 tension increases. Halothane, isoflurane, and sevoflurane also caused similar reductions in adenosine-induced coronary flow reserve in tetrodotoxin-arrested, isolated hearts. Because mechanical work was not performed in this preparation, these findings supported the hypothesis that volatile anesthetics cause direct coronary vasodilation of similar magnitude.

Coronary Vascular Effects in Vivo

Halothane has variable effects on coronary blood flow and coronary vascular resistance in vivo that occur concomitant with changes in MVo_2. Decreases in MVo_2 caused declines in coronary blood flow with relative maintenance of or modest increases in coronary vascular resistance during halothane anesthesia. Despite the decreases in coronary blood flow, halothane increased coronary sinus O_2 tension and decreased O_2 extraction, thus indicating that halothane is a relatively weak coronary vasodilator. Like halothane, isoflurane variably altered coronary blood flow in vivo.[18,19] Isoflurane reduced MVo_2 and simultaneously decreased O_2 extraction, findings indicative of direct coronary vasodilation.[18] Isoflurane produced mild, transient increases in blood flow independent of changes in MVo_2 and autonomic nervous system activity during induction of anesthesia with inhaled anesthetics. Perfusion of the left anterior descending coronary artery with blood previously equilibrated with isoflurane dramatically increased coronary blood flow,[20] but only mild coronary vasodilation occurred after a period of anesthetic equilibration in a similar experimental model.[19] Isoflurane-induced increases in coronary blood flow were not accompanied by epicardial coronary artery dilation, thus verifying that isoflurane dilates predominantly

small coronary arteries. However, adenosine, a potent coronary vasodilator, caused considerably greater vasodilation in coronary microvessels than isoflurane did. The more profound decreases in myocardial O_2 extraction produced by isoflurane than by enflurane indicate that isoflurane is a more potent coronary vasodilator than its structural isomer is.

The influence of desflurane and sevoflurane on coronary blood flow in the intact cardiovascular system has been incompletely examined. Desflurane and isoflurane caused similar increases in the ratio of O_2 delivery to consumption and decreased O_2 extraction, consistent with coronary vasodilation. However, the increases in coronary blood flow produced by desflurane, but not by isoflurane, were attenuated by pharmacologic blockade of the autonomic nervous system, which suggests that isoflurane causes relatively greater direct coronary vasodilation in vivo than desflurane does. Sevoflurane did not produce any significant degree of coronary vasodilation, in contrast to the findings with other volatile anesthetics.

Coronary Vasodilator Reserve and Autoregulation

Volatile anesthetics alter coronary vasodilator reserve, defined as the ratio of peak coronary blood flow after brief coronary artery occlusion (reactive hyperemia) to baseline flow. Coronary vasodilator reserve was greater during isoflurane than during halothane anesthesia. This observation suggested that the older agent halothane may be a more potent coronary vasodilator than isoflurane because greater baseline coronary vasodilation should be accompanied by a reduced ability to further increase coronary blood flow in response to a brief ischemic episode. However, halothane also reduced the determinants of MVo_2 to a greater degree in vivo than isoflurane did. Peak coronary blood flow during reactive hyperemia and percent flow debt repayment are directly related to the intensity of the ischemic stimulus and the magnitude of the O_2 debt accumulated during coronary artery occlusion. Thus, the differences in coronary vasodilator reserve produced by isoflurane and halothane may reflect differences in the intensity of ischemia during coronary occlusion and not the relative vasodilator efficacy of these volatile anesthetics.

Dilation of coronary arteriolar resistance vessels by volatile anesthetics altered pressure autoregulation in the coronary vasculature.[21] The changes in autoregulation produced by vasoactive drugs, including volatile anesthetics, are typically determined by the slope of the pressure-flow curve generated by progressive constriction of a coronary artery. Changes in these pressure-flow curves demonstrated that autoregulation is disrupted during anesthesia as opposed to the conscious state (Fig. 23-5). Isoflurane produced more profound alterations in autoregulation than the older volatile anesthetics did, as indicated by greater increases in the slope of the pressure-flow relationship. Coronary perfusion pressure also played a more important role in the determination of coronary blood flow during anesthesia. Volatile anesthetics impaired coronary autoregulation to some degree, but these anesthetics did not produce the profound degree of coronary vasodilation and inhibition of autoregulation seen with adenosine or dipyridamole.[21] In contrast to volatile anesthetics, these drugs cause maximal coronary vasodilation and inhibit pressure autoregulation to such a degree that coronary blood flow becomes directly dependent on coronary perfusion pressure. Thus, volatile anesthetics are weak coronary vasodilators.

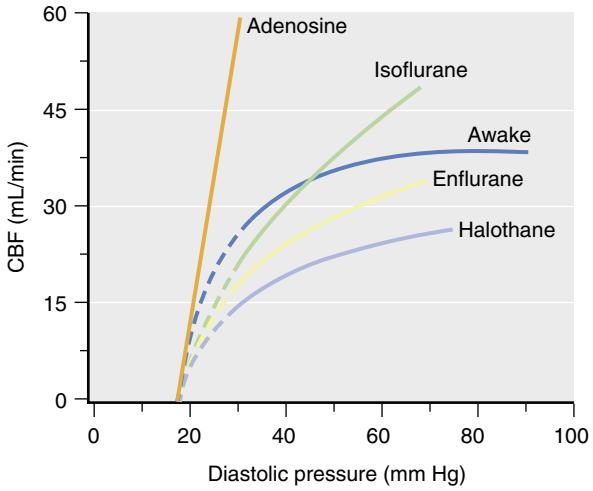

Figure 23-5 Qualitative description of the effects of volatile anesthetics on the coronary blood flow (CBF)–diastolic pressure relationship as compared with the effect of adenosine-induced maximal coronary vasodilation in awake and anesthetized dogs. *Solid lines* are drawn from mean slopes determined by linear regression analysis. *Dashed lines* represent the nonlinear portion of the curve and are estimates. When compared with the findings obtained in awake dogs, the anesthetics affect absolute CBF variably but do not increase the slope of the CBF-pressure plots. *(Adapted from Hickey RF, Sybert PE, Verrier ED, Cason BA: Effects of halothane, enflurane, and isoflurane on coronary blood flow autoregulation and coronary vascular reserve in the canine heart. Anesthesiology 68:21-30, 1988.)*

Mechanisms of Volatile Anesthetic–Induced Coronary Vasodilation

Volatile anesthetics produce direct coronary artery relaxation by affecting intracellular Ca^{2+} regulation at several locations in the vascular smooth muscle cell. Volatile anesthetics inhibited influx of Ca^{2+} through voltage- and receptor-operated Ca^{2+} channels in coronary vascular smooth muscle. Volatile anesthetics also reduced accumulation of Ca^{2+} in and release by the coronary vascular smooth muscle SR, inhibited G proteins linked to phospholipase C, and decreased formation of the second messenger inositol triphosphate. The coronary vasodilating actions of volatile anesthetics are probably not related to the production or release of nitric oxide (NO). Investigations conducted in isolated coronary and aortic vascular preparations and in the intact canine coronary circulation[20] demonstrated that volatile anesthetic–induced coronary vasodilation occurs independent of NO. Some experimental evidence suggested that the direct coronary vasodilator effects of isoflurane may be mediated by the vascular endothelium, but other data indicated that volatile anesthetics, including isoflurane, may adversely affect the release or action of NO.[22] The results of one investigation demonstrated that NO-induced formation of cyclic guanylate monophosphate is partially attenuated by the older agent halothane,[23] whereas other studies have indicated that volatile anesthetics do not affect vasodilation produced by the NO donors sodium nitroprusside or nitroglycerin.[24] Volatile anesthetics may also reduce the stability of NO

by generating oxygen-derived free radicals[24] while leaving NO release and its action on vascular smooth muscle unaffected.[22] Whether the results of these later studies conducted in isolated aortic preparations are applicable to the coronary circulation requires further evaluation, but these investigations have provided important information about the potential interactions between NO metabolism and volatile anesthetics in the coronary circulation.

Isoflurane and halothane cause coronary vasodilation by activation of adenosine triphosphate (ATP)-sensitive potassium (K_{ATP}) channels.[25,26] Increases in coronary blood flow in response to halothane and isoflurane were attenuated by the nonselective K_{ATP} channel antagonist glyburide in isolated rat hearts and anesthetized pigs, respectively.[25,26] Glyburide also partially blocked increases in coronary blood flow during intracoronary administration of volatile anesthetic–equilibrated blood in canine hearts in situ.[27] Isoflurane-induced reductions in coronary vascular resistance were attenuated by the selective adenosine$_1$ (A_1) receptor antagonist 8-cyclopentyl-1,3,dipropylxanthine (DPCPX).[28] These data suggest that the coronary vasodilation produced by isoflurane may occur partially as a result of stimulation of A_1 receptors coupled to K_{ATP} channels.[28]

Volatile Anesthetics and Ischemic Myocardium

Isoflurane and halothane decreased subendocardial blood flow and myocardial lactate extraction, produced contractile dysfunction, and caused electrocardiographic changes in the presence of coronary stenosis concomitant with declines in coronary perfusion pressure. Regional ischemia during isoflurane- or halothane-induced reductions in perfusion pressure was functionally indicated by the appearance of paradoxical systolic lengthening and postsystolic shortening.[29] Contractile dysfunction in the region distal to a critical coronary stenosis was more severe during isoflurane than during halothane anesthesia coincident with higher flow in the normal zone and lower flow in the ischemic zone. These findings suggest that the coronary vasodilation produced by isoflurane may cause a detrimental redistribution of coronary blood flow away from ischemic myocardium if hypotension is allowed to occur ("coronary steal"). However, these potentially adverse effects of volatile anesthetics on ischemic myocardium were avoided if coronary perfusion pressure was restored. Subendocardial blood flow in the perfusion bed distal to a critical coronary stenosis was reduced during isoflurane-induced declines in arterial pressure, but treatment of hypotension with phenylephrine restored subendocardial blood flow to values observed before the administration of isoflurane. The transmural distribution of coronary blood flow between the subendocardium and subepicardium (endo/epi ratio) decreased during isoflurane anesthesia despite control of arterial pressure. Administration of phenylephrine to maintain arterial pressure constant increased subepicardial blood flow more than subendocardial flow. This increase in subepicardial perfusion accounted for the decline in the endo/epi ratio in the absence of an absolute reduction in subendocardial flow. Restoration of coronary perfusion pressure to baseline levels during isoflurane anesthesia also increased coronary collateral blood flow and normalized myocardial oxygen tension in the ischemic zone.[21]

Investigations in dogs with steal-prone anatomy (complete occlusion of a coronary artery with collateral flow from an adjacent vessel with a critical stenosis) have repeatedly demonstrated that isoflurane and halothane do not alter collateral-dependent or ischemic-zone myocardial blood flow, endocardial-to-epicardial coronary blood flow distribution, or electrocardiographic findings when diastolic arterial pressure is held constant. Coronary collateral perfusion was unchanged during isoflurane or halothane anesthesia in dogs at a mean arterial pressure of 50 mm Hg. Coronary steal did not occur in a chronically instrumented canine model of coronary artery disease with the administration of isoflurane,[30] halothane,[31] desflurane,[32] or sevoflurane[33] independent of severe coronary stenosis or the development of coronary collaterals. These findings refuted earlier evidence in dogs with amaroid constrictor–induced augmentation of the coronary collateral circulation in which it was suggested that isoflurane reduces collateral blood flow and causes coronary steal in vivo. These effects of volatile anesthetics were in stark contrast to those obtained with adenosine, a potent coronary vasodilator that produces coronary steal when arterial pressure is maintained at control levels in models of multivessel coronary artery disease (Fig. 23-6).

Volatile Anesthetic–Induced Myocardial Protection

Acute Preconditioning by Volatile Anesthetics

The controversy about volatile anesthetic–induced coronary vasodilation and coronary steal has detracted from substantial experimental evidence indicating that volatile anesthetics exert important protective effects during myocardial ischemia and reperfusion injury. The older anesthetic halothane attenuated ST-segment changes caused by brief coronary artery occlusion and decreased ST-segment elevation to a greater extent than propranolol and sodium nitroprusside did despite producing similar hemodynamic effects. Isoflurane and desflurane produced beneficial actions on LV diastolic mechanics during acute regional myocardial ischemia.[29] Isoflurane and sevoflurane decreased myocardial reperfusion injury and improved functional recovery after global ischemia in isolated hearts.[34,35] Volatile anesthetics also enhanced systolic functional recovery of postischemic-reperfused ("stunned") myocardium when these anesthetics were administered before brief periods of myocardial ischemia in vivo. These salutary effects were accompanied by preservation of high-energy phosphate levels.[36] Volatile anesthetics have been shown to attenuate the effect of oxygen-derived free radicals on development of LV pressure in isolated hearts. Halothane also preserved contractile function and ultrastructural integrity during reperfusion after normothermic cardioplegic arrest.[37] In 1997, three research groups independently reported that administration of halothane or isoflurane before prolonged coronary artery occlusion and reperfusion reduces myocardial infarct size in vivo (Fig. 23-7).[5,38,39] Termed "anesthetic preconditioning," this beneficial effect was found to persist despite discontinuation of the volatile anesthetic before coronary artery occlusion.[5] This short-term memory phase was similar to that observed during ischemic preconditioning.

Anesthetic preconditioning has been shown to be dose related in experimental animals[40,41] independent of alterations in

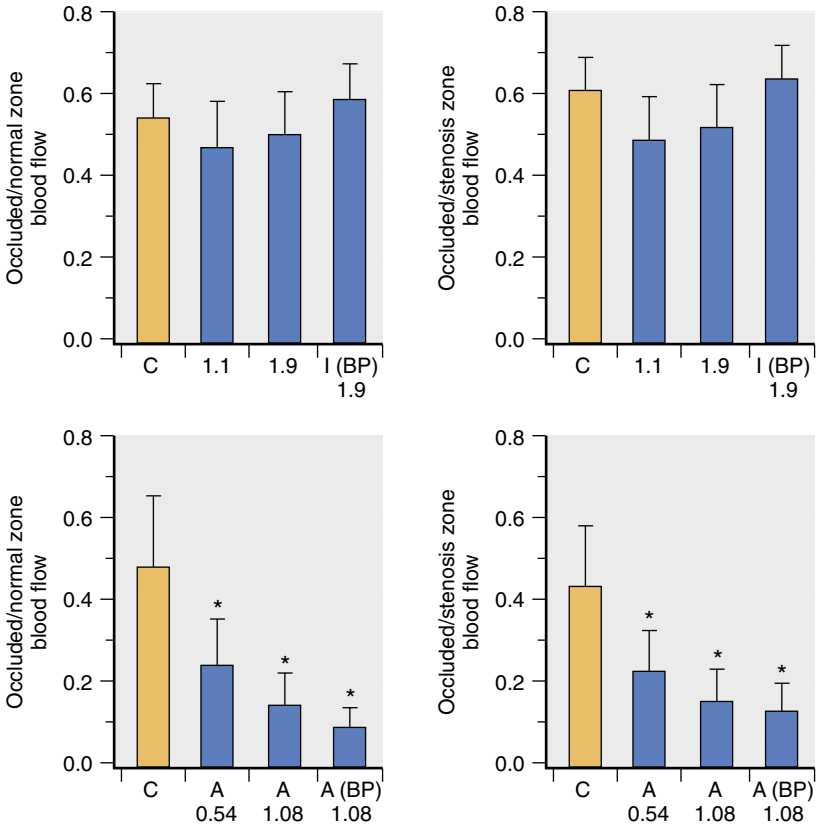

Figure 23-6 Comparison of occluded to normal and occluded to stenotic-zone myocardial blood flow in dogs with steal-prone coronary artery anatomy in the conscious state (C), during administration of isoflurane at 1.1 and 1.9 minimum alveolar concentration (I), during adenosine (A) infusions (0.54 and 1.08 mg/min), and during maintenance of heart rate and arterial pressure at conscious values during the highest doses (BP). Isoflurane does not cause coronary steal, in contrast to the significant (*$P < .05$) reductions in blood flow to collateral-dependent myocardium produced by adenosine. *(Adapted from Hartman JC, Kampine JP, Schmeling WT, Warltier DC: Actions of isoflurane on myocardial perfusion in chronically instrumented dogs with poor, moderate, or well-developed coronary collaterals. J Cardiothorac Anesth 4:715-725, 1990.)*

systemic hemodynamics or coronary collateral blood flow. Isoflurane and sevoflurane also produced dose-dependent preservation of isolated ventricular myocyte viability during ischemia in vitro.[42] Isoflurane elicited cardioprotection when the volatile agent was discontinued 15 or 30 minutes before prolonged coronary artery occlusion and reperfusion in rabbits[43] and dogs,[5] respectively. In contrast, sevoflurane failed to reduce the extent of myocardial infarction if the anesthetic was discontinued 30 minutes before the onset of prolonged ischemia.[44] These data suggest that the memory period of anesthetic preconditioning may differ between volatile anesthetics on the basis of species and pharmacokinetics. Dual as opposed to single exposure to sevoflurane improved anesthetic preconditioning in guinea pig hearts, thus indicating that repetitive administration of a volatile agent appears to confer an additional benefit.[45] The cardioprotection resulting from anesthetic preconditioning was shown to be restricted to a range of ischemia durations between 25 and 40 minutes in Langendorff perfused isolated guinea pig hearts.[46] Accordingly, anesthetic preconditioning may be especially beneficial in patients with ongoing myocardial ischemia of intermediate duration. Interestingly, the mechanism of sevoflurane-induced cardioprotection was independent of the type of ischemic stimulus (hypoxia versus metabolic inhibition) in isolated rat ventricular trabeculae.[47] These results indirectly suggested that anesthetic

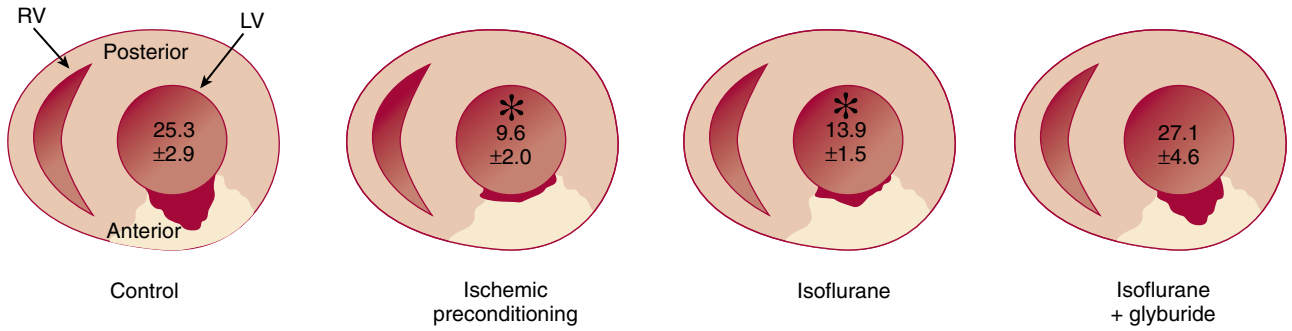

Figure 23-7 Schematic illustration of canine myocardium subjected to 60-minute coronary artery occlusion and reperfusion and then stained to identify the region of myocardial infarction (*dark red area*) within the area of myocardium at risk for infarction (*light yellow area*). Isoflurane decreased the extent of myocardial infarction. The protective effect of isoflurane was equivalent to that produced by ischemic preconditioning and was abolished by pretreatment with glyburide. *Significantly ($P < .05$) different from control. *(Adapted from Kersten JR, Schmeling TJ, Pagel PS, et al: Isoflurane mimics ischemic preconditioning via activation of K_{ATP} channels. Reduction of myocardial infarct size with acute memory phase. Anesthesiology 87:361-370, 1997.)*

preconditioning may be equally effective at preserving myocardial integrity during supply or demand myocardial ischemia in patients with coronary artery disease, but this intriguing hypothesis remains to be formally tested. Advanced age and increased heart size attenuated the efficacy of sevoflurane preconditioning in rats[48] and guinea pigs.[49] These experimental observations may also have important clinical ramifications in elderly patients at risk for the development of myocardial ischemia. In contrast, sevoflurane was capable of exerting cardioprotective effects in ischemic newborn rabbit myocardium.[50]

Volatile anesthetics may also produce beneficial effects on blood flow to and neutrophil interaction with ischemic myocardium. Volatile anesthetics produce coronary vasodilation by activating K_{ATP} channels or by favorably affecting intracellular Ca^{2+} homeostasis in vascular smooth muscle. Decreases in collateral blood flow after coronary artery occlusion have been shown to be less pronounced than declines in flow to normal myocardium in the presence of the older agent halothane. The ratio of myocardial O_2 delivery to MVo_2 was also increased in collateral-dependent myocardium during halothane anesthesia. Halothane inhibited platelet thrombi formation via increases in platelet cyclic adenosine monophosphate concentration and thereby decreased cyclic variations in coronary blood flow associated with a critical coronary artery stenosis. Sevoflurane increased blood flow to collateral-dependent myocardium when arterial pressure was maintained at conscious values mediated by Ca^{2+}-activated potassium (BK_{Ca}) channels.[51] Sevoflurane also improved recovery of coronary vascular reactivity and enhanced endothelial NO release in isolated hearts subjected to global ischemia and reperfusion. Volatile anesthetics attenuated adhesion of neutrophils and platelets in the coronary vasculature after ischemia and reperfusion. Isoflurane pretreatment also inhibited cytokine-induced cell death after ischemia-reperfusion injury in vitro.[52] Furthermore, isoflurane and sevoflurane preconditioned against neutrophil-induced contractile dysfunction in isolated rat hearts through activation of adenosine receptors.[53] Taken together, the results of these investigations suggest that the salutary actions of volatile anesthetics on coronary perfusion and neutrophil function may, to some degree, be responsible for the protection against ischemia-reperfusion injury afforded by these drugs.

The mechanisms responsible for volatile anesthetic–induced protection during myocardial ischemia and reperfusion have been intensively investigated in recent years and are the subject of several major reviews.[54-57] The beneficial effects of volatile anesthetics may be attributed to a favorable reduction in the myocardial oxygen demand required for active contraction along with concomitant preservation of energy-dependent vital cellular processes because these anesthetics cause direct negative inotropic, lusitropic, and chronotropic effects and decrease LV afterload. However, the older agent halothane exerted protective effects during complete functional arrest induced by cardioplegia.[37] Isoflurane, desflurane, and sevoflurane also produced cardioprotection when administered solely during reperfusion.[58] These data indicate that preferential alterations in myocardial oxygen supply-demand relationships are not solely responsible for the anti-ischemic actions of volatile anesthetics. Isoflurane and halothane may significantly lower excessive intracellular Ca^{2+} during reperfusion via a direct decline in the net transsarcolemmal Ca^{2+} transient resulting from partially inhibited Ca^{2+} channel activity or an indirect reduction of oxygen-derived free radical formation. In contrast to this rather nonspecific intracellular Ca^{2+} reduction hypothesis, a large body of very compelling evidence has convincingly demonstrated that cardioprotection by volatile anesthetics occurs as a consequence of the activation of endogenous signal transduction pathways. To date, K_{ATP} channels,[5] G protein–coupled receptor ligands (e.g., adenosine, opioid),[39,59] isoforms of protein kinase C (PKC),[60] protein tyrosine kinase (PTK),[60] reactive oxygen and nitrogen species, nuclear factor κB (NF-κB),[61] and several components of the prosurvival reperfusion injury salvage kinase cascade[62] have all been shown to mediate acute preconditioning by volatile anesthetics. These elements will now be discussed in detail.

Mitochondrial and Sarcolemmal K_{ATP} Channels

The K_{ATP} channel plays a central role in ischemic and anesthetic preconditioning. The K_{ATP} channel is a heteromultimeric complex consisting of an inwardly rectifying K^+ channel (K_{ir}) and a sulfonylurea receptor (SUR).[63] Pharmacologically distinct K_{ATP} channels have been identified in cardiac sarcolemmal and mitochondrial membranes. It was originally proposed that opening of sarcolemmal K_{ATP} channels protects ischemic myocardium by shortening the duration of the action potential and preventing intracellular Ca^{2+} overload. However, subsequent studies performed after discovery of the mitochondrial K_{ATP} channel indicated that the beneficial actions of K_{ATP} channel opening occur independent of the action potential duration. Nevertheless, ischemic preconditioning was not observed in the absence of the sarcolemmal K_{ir} channel in transgenic mice.[64] These data suggest that protection against ischemic injury requires contribution of the sarcolemmal K_{ATP} channel. In contrast, mitochondrial K_{ATP} channels appear to be the primary mediators of ischemic preconditioning.[65] Preservation of mitochondrial bioenergetic function appears to be vital for cellular protection against myocardial ischemia.[66] Mitochondrial K_{ATP} channel openers maintained intracellular Ca^{2+} homeostasis and inhibited mitochondrial Ca^{2+} overload.[67] These actions enhanced myocyte survival by preventing tissue necrosis or apoptosis (programmed cell death).[68] In contrast to the well-known generalized cellular destruction and profound inflammatory response that typify necrosis, the highly regulated, ATP-dependent phenomenon of apoptosis is characterized by selective DNA lysis associated with the formation of apoptotic bodies, appearance of condensed chromatin, absence of inflammation, and preservation of cell membrane structure.[69] Activation of mitochondrial K_{ATP} channels inhibited apoptosis in rat ventricular myocytes by attenuating oxidant stress during reperfusion.[70] Alteration of the mitochondrial oxidation-reduction state by activation of K_{ATP} channels may also promote cellular protection.[71] Experiments conducted in isolated cardiac mitochondria indicated that membrane depolarization, matrix swelling, and uncoupling of ATP synthesis occur as a result of increased oxygen consumption, are associated with opening of mitochondrial K_{ATP} channels, and may mediate cellular viability during ischemic preconditioning.[71] Opening of mitochondrial K_{ATP} channels depolarized the inner mitochondrial membrane and caused transient swelling of the mitochondrial matrix[72] because of a shift in ionic balance.[73] Mitochondrial K_{ATP} channel opening initially reduced ATP production as a result of membrane depolarization[74] but subsequently stimulated a compensatory increase in respiration that optimized the efficiency of oxidative phosphorylation, in part by regulating energy-dependent matrix volume. Influx of potassium into mitochondria occurred as a consequence of the balance between K^+ influx through the mitochondrial K_{ATP}

channel and K^+ efflux produced by the mitochondrial K^+-H^+ antiporter. The mitochondrial K_{ATP} channel agonist diazoxide promoted K^+ influx and caused matrix alkalinization in isolated rat ventricular myocardium.[75] These actions were abolished by 5-hydroxydecanoate (5-HD) and ATP. Thus, a moderate disturbance in mitochondrial homeostasis caused by opening of mitochondrial K_{ATP} channels may promote myocardial tolerance to ischemic stress by altering energetic systems to reduce Ca^{2+} overload, prevent the activation of necrotic or apoptotic pathways, or attenuate oxidant stress.

The endogenous mechanisms involved in anesthetic preconditioning are strikingly similar to those implicated in ischemic preconditioning, although differences between these phenomena have been suggested by microarray gene chip analysis.[76] It is hypothesized that a "trigger" (e.g., a brief ischemic episode, exposure to a volatile anesthetic) initiates a cascade of signaling events leading to activation of an "end-effector" that is responsible for resistance to injury. K_{ATP} channel activation has been implicated as the end-effector in this protective scheme during anesthetic preconditioning. Administration of isoflurane and sevoflurane preserved myocyte viability in a cellular model of ischemia, in contrast to cells that were not exposed to a volatile agent.[42] The selective mitochondrial K_{ATP} channel antagonist 5-HD but not the selective sarcolemmal K_{ATP} channel antagonist HMR-1098 abolished this protective effect.[42] The nonselective K_{ATP} channel blocker glyburide (also known as glibenclamide) attenuated the recovery of contractile function produced by isoflurane in stunned myocardium (Fig. 23-8). Isoflurane-induced reductions in canine myocardial infarct size[5] and the ATP-sparing effects of this agent were also abolished by glyburide. 5-HD inhibited preconditioning by isoflurane in rats,[40] rabbits,[77] and isolated human myocardium.[78] Both HMR-1098 and 5-HD abolished the protective effects of desflurane in dogs,[79] thus supporting a role for both sarcolemmal and mitochondrial K_{ATP} channels in anesthetic acute preconditioning. However, HMR-1098 did not affect desflurane preconditioning of isolated human right atrial myocardium.[80] Thus, controversy continues to exist about the relative importance of sarcolemmal versus mitochondrial K_{ATP} channels in anesthetic preconditioning.

Results from in vitro experiments also strongly suggest that volatile anesthetics produce profound effects on sarcolemmal K_{ATP} channel function. Isoflurane stimulated outward K^+ current through sarcolemmal K_{ATP} channels in isolated ventricular myocytes during patch-clamping.[81] Volatile anesthetics also reduced sarcolemmal K_{ATP} channel sensitivity to inhibition by ATP, thereby increasing the probability of being in the open state.[82] However, other patch-clamp experiments failed to confirm these results and suggested that volatile anesthetics do not open sarcolemmal K_{ATP} channels. For example, isoflurane did not alter sarcolemmal K_{ATP} channel current in human atrial cells[78] and, furthermore, inhibited sarcolemmal K_{ATP} channel activity in rabbit ventricular myocytes.[82] Nevertheless, volatile anesthetics have been shown to enhance sarcolemmal K_{ATP} channel current by facilitating channel opening after initial activation. The ε-isoform of PKC (PKC-ε) was shown to prime the sarcolemmal K_{ATP} channel to open in the presence of isoflurane.[83] Facilitation of sarcolemmal K_{ATP} channel current by isoflurane during reduced intracellular ATP concentrations was also dependent on PKC-dependent signaling.[84] In addition, reactive oxygen species (ROS) contributed to isoflurane-induced sensitization of the sarcolemmal K_{ATP} channel to the opener pinacidil.[85] Isoflurane also directly

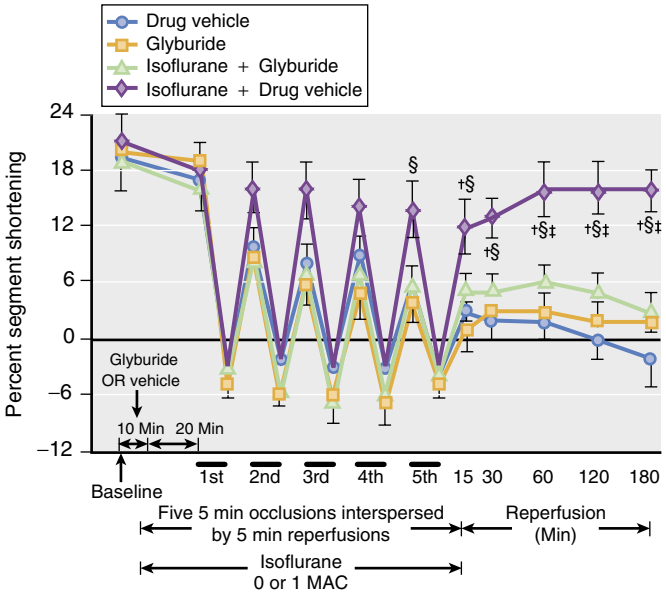

Figure 23-8 Percent segment shortening (%SS) in the intermittently ischemic and reperfused left anterior descending coronary artery (LAD) region. %SS decreases significantly ($P < .05$) from baseline during each 5-minute LAD occlusion and reperfusion in all groups. Significant decreases in %SS during each 5-minute reperfusion and throughout 180 minutes of final reperfusion are observed in dogs pretreated with glyburide, a nonselective K_{ATP} channel antagonist, in the presence or absence of isoflurane. %SS recovers to baseline values after reperfusion in dogs receiving isoflurane alone. †Significantly ($P < .05$) different from dogs pretreated with drug vehicle. ‡Significantly ($P < .05$) different from dogs receiving glyburide and isoflurane. §Significantly ($P < .05$) different from dogs pretreated with glyburide. *(From Kersten JR, Schmeling TJ, Hettrick DA, et al: Mechanism of cardioprotection by isoflurane: Role of adenosine triphosphate–regulated potassium [K_{ATP}] channels. Anesthesiology 85:794-807, 1996.)*

opened sarcolemmal K_{ATP} channels during intracellular acidosis of a magnitude similar to that observed during ischemia.[86] The sarcolemmal K_{ATP} channel acted as an effector during isoflurane preconditioning against oxidative stress in adult ventricular myocytes.[87] The effects of volatile anesthetics on sarcolemmal K_{ATP} channel function may persist beyond the duration of administration,[84] suggesting a cellular basis for the early "memory" phase of anesthetic preconditioning in vivo. Isoflurane preconditioning produced prolonged sensitization of the sarcolemmal K_{ATP} channel to opening by a PKC δ-isoform (PKC-δ)-mediated mechanism[88] or by enhancing induction of sarcolemmal K_{ATP} channel current via a diacylglycerol PKC activator.[84] Isoflurane preconditioning caused persistent reductions in the sensitivity of the sarcolemmal K_{ATP} channel to inhibition by ATP and adenosine 5′-diphosphate.[89] The nucleotide binding domains of the regulatory sulfonylurea receptor SUR2A were shown to play important roles in isoflurane-induced facilitation of sarcolemmal K_{ATP} channel activity during moderate intracellular acidosis, similar to that encountered during early ischemia.[90] These data support the contention that isoflurane directly interacts with subunits of the cardiac sarcolemmal K_{ATP} channel.[90]

It is also clear, based on several experimental studies, that volatile anesthetics directly or indirectly open mitochondrial K_{ATP} channels in vitro. Isoflurane and sevoflurane increased mitochondrial flavoprotein oxidation, an index of mitochondrial K_{ATP} channel activity, in guinea pig cardiac myocytes, and this increase in fluorescence was inhibited by the selective mitochondrial K_{ATP} channel inhibitor 5-HD.[91] Isoflurane also directly activated the

mitochondrial K_{ATP} channels reconstituted in lipid bilayers.[92] Isoflurane-induced increases in mitochondrial flavoprotein fluorescence were not inhibited by pretreatment with adenosine, PKC, PTK, or p38 mitogen-activated protein kinase (MAPK) inhibitors, suggesting that isoflurane may directly activate mitochondrial K_{ATP} channels.[93] In contrast, isoflurane and sevoflurane failed to directly enhance flavoprotein fluorescence in rat ventricular myocytes, but these anesthetics did enhance fluorescence induced by the mitochondrial K_{ATP} channel agonist diazoxide.[42] These data suggest that volatile anesthetics may not directly open but, instead, indirectly prime mitochondrial K_{ATP} channels by acting on other intracellular signaling elements that modulate the activity of the channel. Sarcolemmal K_{ATP} channels may also be linked to the function of the inner mitochondrial membrane. The ROS generated by mitochondria may act to open sarcolemmal K_{ATP} channels. An uncoupler of mitochondrial oxidative phosphorylation (2,4-dinitrophenol) reversibly activated sarcolemmal K_{ATP} channel current concomitant with nicotinamide adenine dinucleotide oxidation. These and other data led to the contention that crosstalk may occur between sarcolemmal and mitochondrial K_{ATP} channels during preconditioning phenomena.[94] However, such crosstalk has yet to be specifically demonstrated during anesthetic preconditioning. To summarize, the experimental results collected to date provide somewhat conflicting results about a possible direct action of volatile anesthetics on sarcolemmal and mitochondrial K_{ATP} channel activity. Nevertheless, volatile anesthetics clearly prime the activation of these channels in both sarcolemmal and mitochondrial membranes.

K_{ATP} channels in vascular smooth muscle cells are essential regulators of coronary vascular tone when ATP production is reduced. Volatile anesthetic–induced coronary vasodilation[95] was attenuated by glyburide, thus indicating an important role for K_{ATP} channels in this process. The beneficial actions of anesthetic preconditioning may therefore be partially attributed to increases in myocardial oxygen supply mediated by K_{ATP} channel–dependent coronary vasodilation. However, the fact that sevoflurane caused an increase in coronary collateral blood flow in vivo in the presence of glyburide indicates that this volatile anesthetic may enhance coronary collateral blood flow independent of activation of K_{ATP} channels. Sevoflurane-induced increases in collateral perfusion occur as a result of Ca^{2+}-regulated potassium (BK_{Ca}) and not K_{ATP} channel activation.[51] Thus, the cardioprotection provided by volatile anesthetics is unlikely to be solely related to favorable alterations in coronary vascular tone mediated by K_{ATP} channels.

G Proteins and Their Coupled Receptor Ligands

The sequential activation of several intracellular elements in a transduction pathway may facilitate amplification of the initial signal between other redundant systems. This concept was clearly illustrated by the observation that the direct K_{ATP} channel opener nicorandil enhances the cardioprotective effects of isoflurane.[96] G protein–coupled receptor ligands and their downstream signaling elements have been shown to converge on the K_{ATP} channel during anesthetic preconditioning. Pertussis toxin abolished the reductions in infarct size produced by isoflurane, thus indicating that inhibitory guanine (G_i) nucleotide–binding proteins are linked to the signal transduction pathways that mediate anesthetic preconditioning.[97] In contrast, pertussis toxin did not prevent the beneficial effects of direct K_{ATP} channel opening produced by nicorandil. These data strongly support the contention that volatile anesthetics modulate K_{ATP} channel activity through a second messenger. Halothane-induced protection against infarction was completely abolished by blockade of the adenosine A_1 receptor,[39] and the selective A_1 receptor antagonist DPCPX also partially attenuated the beneficial effects of isoflurane on stunned myocardium.[98] Isoflurane eliminated increases in interstitial adenosine during repetitive periods of coronary artery occlusion and reperfusion as demonstrated via a myocardial microdialysis technique.[98] These findings suggest that ATP preservation and a subsequent reduction in adenosine released into the interstitium occur during isoflurane anesthesia. The results were also very similar to those obtained during ischemic preconditioning and pharmacologic preconditioning with bimakalim. Thus, volatile anesthetics may either directly activate A_1 receptors or indirectly enhance A_1 receptor sensitivity to diminished endogenous adenosine concentrations.[98] The preservation of cardiac myocyte viability during ischemia produced by volatile anesthetics was also sensitive to adenosine receptor– and G_i protein–mediated signaling blockade.[42] Adenosine also enhanced isoflurane preconditioning through both mitochondrial K_{ATP} channel–dependent and channel-independent mechanisms in isolated, buffer-perfused rat hearts.[99]

The nonselective opioid antagonist naloxone also abolished isoflurane-induced preconditioning in the rat.[40] These data indicate an important link between volatile anesthetics and another family of G_i protein–coupled receptors. Volatile anesthetics competitively inhibited the ligand binding site of G_i protein–coupled receptors.[100] Thus, anesthetic preconditioning appears to be associated with the activation of at least two separate receptor-mediated pathways (A_1 and opioid) that are linked to G_i proteins. Interestingly, the combination of isoflurane and a selective δ_1-opioid receptor agonist amplified the preconditioning response in the rat.[59] This effect was synergistic and sensitive to inhibition by glyburide.[59] The combined administration of isoflurane and morphine also markedly reduced infarct size in vivo, and this protective effect was abolished by 5-HD.[40] Hence, combined administration of a volatile anesthetic and an opioid capable of agonist action at the δ_1-opioid receptor may stimulate similar or cooperative signaling cascades that amplify K_{ATP} channel activation to profoundly augment myocardial protection beyond that produced by either drug alone. A G_s protein–coupled receptor ligand system, the β_1-adrenoceptor and its downstream target protein kinase A, was also recently shown to mediate desflurane and sevoflurane but not ischemic preconditioning in rabbits.[101] These data suggest that both G_i and G_s may play important roles in anesthetic preconditioning in vivo.

Protein Kinases

Ischemic preconditioning has been shown to produce translocation and phosphorylation of several protein kinases, most importantly PKC, involved in cardioprotective signal transduction. PKC is an essential component of the signaling pathway involved in protecting myocardium against cell death during ischemia and reperfusion.[102] The diverse PKC isoform family is a large group of serine-threonine protein kinases that are distinguished by variable regulatory domains and cofactors and also display diverse tissue and species distributions. G protein–coupled receptor ligands, including A_1, δ_1-opioid, and bradykinin, have been shown to activate PKC during ischemic preconditioning. Volatile anesthetics stimulated PKC translocation and activity, possibly by interacting with regulatory domain of the enzyme. Inhibition of

PKC partially attenuated isoflurane-induced augmentation of the functional recovery of stunned myocardium in dogs.[103] The beneficial actions of the older agent halothane were entirely blocked by selective inhibition of PKC in rabbits.[39] Colchicine, a drug that depolymerizes microtubule assemblies, prevented isoflurane-induced reductions in myocardial infarct size in rabbits. This interesting result suggests that an intact cytoskeleton is essential for translocation of the PKC to occur. In fact, volatile anesthetic–induced PKC translocation and activation appear to be required to open K_{ATP} channels and produce cardioprotection. For example, the nonselective PKC antagonist chelerythrine abolished sevoflurane-induced increases in mitochondrial K_{ATP} channel activity in rat ventricular myocyte and prevented protection from ischemic damage.[42] Patch-clamp experiments demonstrated that isoflurane does not facilitate K_{ATP} channel opening in excised membranes but enhances K_{ATP} channel current in a whole-cell configuration concomitant with PKC stimulation.[104] These observations were supported by findings that both adenosine and PKC enhance K_{ATP} channel activity during ischemic preconditioning. Specific PKC consensus sites were demonstrated on K_{ATP} channels, thereby suggesting a molecular basis for phosphorylation and activation of the channel by this critical enzyme.[105] Translocation of PKC-δ but not PKC-ε plays an important role in isoflurane preconditioning in isolated perfused rat hearts.[106] Phosphorylation of the serine 643 residue of PKC-δ appeared to mediate transfer of the preconditioning stimulus (exposure to 1.5 MAC isoflurane) to mitochondrial K_{ATP} channels.[106] Both PKC-δ and PKC-ε translocation was implicated in isoflurane (1.0 MAC) preconditioning in rats in vivo, and opening of mitochondrial K_{ATP} channels and generation of ROS were shown to be upstream events that accompanied PKC activation in this model (Fig. 23-9).[60] Another study implicated PKC-ε alone during sevoflurane preconditioning in isolated perfused guinea pig hearts.[107] A role for PKC-ε was also demonstrated in isoflurane preconditioning in rats by another research group,[108] but only at lower concentrations (<0.5 MAC) of the volatile agent. Desflurane preconditioning produced time-dependent translocation of PKC-ε through activation of extracellular signal–regulated kinases 1 and 2 (ERK1/2).[109] In contrast, PKC-δ mediated sevoflurane preconditioning through ROS production independent of mitochondrial K_{ATP} channels in isolated rat trabeculae.[110] Taken as a whole, these experimental data strongly suggest that at least two different isoforms of PKC (ε and δ) appear to be important mediators of anesthetic preconditioning.

PKC has been shown to stimulate PTK[111] and several MAPK moieties[112] during ischemic preconditioning, and some evidence also indicates a role for these proteins in anesthetic-induced cardioprotection independent of receptor activation. The PTK inhibitor lavendustin A and the Src-selective inhibitor PP1 abolished isoflurane preconditioning in rats.[60] In contrast, lavendustin A and another nonselective PTK inhibitor (genistein) did not alter desflurane preconditioning in rabbits.[113] These data suggest that the role of PTK in anesthetic preconditioning may be dependent on the species. The MAPK family of proteins plays important roles in signal transduction from the cell surface to the nucleus and in the initiation and progression of apoptosis. ERK1 and ERK2 are MAPKs that mediate cell division, proliferation, and survival.[62] They were previously implicated in ischemia and opioid-induced preconditioning in rats. The reductions in infarct size and ERK1/2 phosphorylation produced by administration of desflurane before ischemia and reperfusion were abolished by a selective ERK1/2 inhibitor,[109] thereby providing the first evidence suggesting that ERK1/2 mediates anesthetic preconditioning. ERK1/2 was also shown to trigger isoflurane preconditioning in rabbits.[114] In addition, ERK1/2-related signaling proteins control the expression of several genes concerned with cell survival, including hypoxia-inducible factor-1α (HIF-1α), an important DNA-binding complex whose activity is influenced by intracellular oxygen tension. Myocardial hypoxia is a potent inducer of HIF-1α protein expression, and the combination of reduced oxygen tension and activation of ERK1/2 signaling is known to potentiate HIF-1α expression and activity.[115] Furthermore, HIF-1α upregulates transcription of vascular endothelial growth factor (VEGF).[116] This important angiogenic protein plays a central role in coronary collateral development in response to chronic myocardial ischemia,[117] and enhanced expression of both HIF-1α and VEGF occurs during myocardial ischemia in rats.[118] ERK1/2-dependent upregulation of HIF-1α and VEGF has also been shown during ischemic and hypoxic preconditioning.[119] Administration of isoflurane likewise produced temporal upregulation of HIF-1α and VEGF expression by activating ERK1/2 in rabbit myocardium (Figs. 23-10 and 23-11).[114] Another MAPK (p38) strongly implicated in ischemic preconditioning also appeared to mediate anesthetic preconditioning in isolated rat hearts.[120] p38 MAPK has been shown to interact with the actin cytoskeleton through MAPK-activated protein kinase 2 (MAPKAPK-2) and heat shock protein 27 (HSP-27). Isoflurane and xenon preconditioning were recently demonstrated to activate both MAPKAPK-2 and HSP-27 downstream of PKC and p38 MAPK.[121] These exciting data provide another potential link between anesthetic preconditioning and the cytoskeleton, thereby suggesting another mechanism by which signaling elements involved in cardioprotection may be transported to appropriate locations within the cell. Activated protein kinase G (PKG) has been shown to open mitochondrial K_{ATP} channels during ischemic and pharmacologic preconditioning. PKG was recently demonstrated to transmit G_i protein-receptor ligand coupled from the cytosol to the inner mitochondrial membrane by a pathway that includes PKC-ε to produce cardioprotection.[122] Whether PKG also mediates anesthetic preconditioning has yet to be determined.

The prosurvival protein phosphatidylinositol-3′-kinase (PI3K) has been shown to be responsible for the phosphorylation of a variety of subcellular targets implicated in cell survival, protein synthesis, and metabolism. Activation of this kinase pathway not only reduces cell necrosis but also contributes to the preservation of viable myocardium by inhibiting apoptosis and maintaining mitochondrial integrity.[62] PI3K converts phosphatidylinositol 4,5-bisphosphate (PIP_2) to phosphatidylinositol 3,4,5-triphosphate (PIP_3),[123] and PIP_3-stimulated phosphorylation of the serine-threonine kinase Akt by phosphoinositide-dependent kinase 1 (PDK1) subsequently inhibits the formation of several proapoptotic proteins (e.g., Bad, Bax, caspases). PDK1 is a also potent activator of other protein kinases,[123] including PKC and PTK, implicated in anesthetic preconditioning.[56] A role for PI3K signaling in isoflurane preconditioning was recently demonstrated. A selective inhibitor of PI3K (wortmannin) abolished reductions in infarct size and also blocked phosphorylation of the downstream enzyme target Akt that were produced by administration of isoflurane before prolonged coronary artery occlusion in rabbits.[124] Isoflurane preconditioning increased Akt phosphorylation and expression of the antiapoptotic B-cell lymphoma-2 (Bcl-2) protein and reduced expression of the apoptotic protein

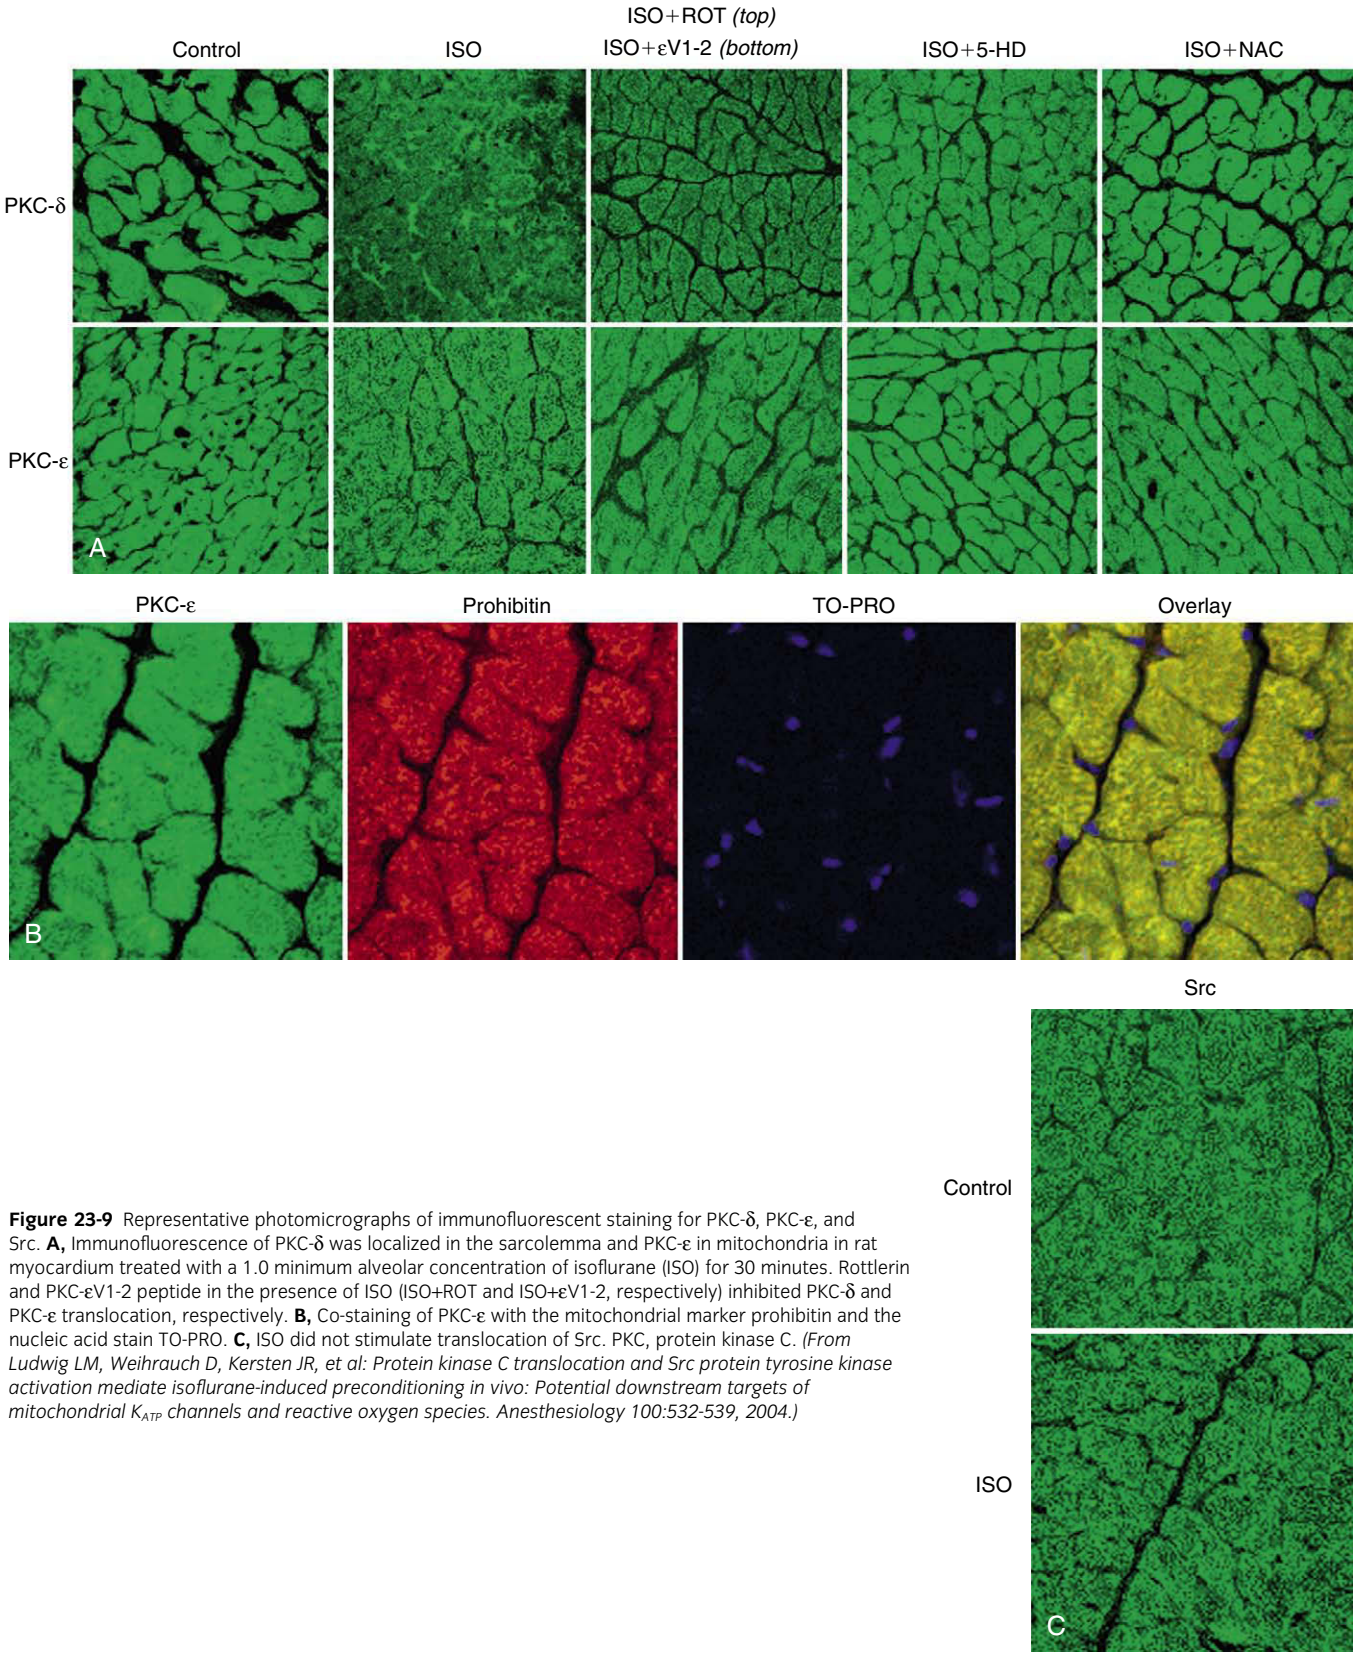

Figure 23-9 Representative photomicrographs of immunofluorescent staining for PKC-δ, PKC-ε, and Src. **A,** Immunofluorescence of PKC-δ was localized in the sarcolemma and PKC-ε in mitochondria in rat myocardium treated with a 1.0 minimum alveolar concentration of isoflurane (ISO) for 30 minutes. Rottlerin and PKC-εV1-2 peptide in the presence of ISO (ISO+ROT and ISO+εV1-2, respectively) inhibited PKC-δ and PKC-ε translocation, respectively. **B,** Co-staining of PKC-ε with the mitochondrial marker prohibitin and the nucleic acid stain TO-PRO. **C,** ISO did not stimulate translocation of Src. Bax in rabbits concomitant with decreases in infarct size and the number of apoptotic myocytes.[125] Wortmannin and another selective PI3K antagonist (LY294002) abolished these actions, thus indicating that PI3K-induced modulation of proapoptotic and antiapoptotic protein balance plays a role in isoflurane cardioprotection.[125] Activation of Akt by isoflurane was also shown to protect rat atrial and ventricular myocytes against apoptosis in vitro produced by exposure to hypoxia, hydrogen peroxide, or activated neutrophils concomitant with increased expression of Bcl-2.[126] Collectively, these data suggest that prosurvival PI3K signaling plays a central role in anesthetic preconditioning.

A transition in mitochondrial permeability caused by opening of the mitochondrial permeability transition pore (mPTP) may be a critical end-effector in the myocardial necrosis and apoptosis resulting from ischemia-reperfusion injury. This event has been shown to be modulated by PI3K-mediated signaling pathways.[127] The mPTP is located on the inner mitochondrial membrane, and opening of the pore abolishes the mitochondrial membrane potential ($\Delta\Psi_m$), inhibits oxidative phosphorylation, and facilitates the release or activation of several proapoptotic proteins, including cytochrome *c*. These actions rapidly produce cell death. Opening of the mPTP appears to occur specifically at the onset of reperfusion,[128] in part as a consequence of intracellular Ca^{2+} overload and the presence of large quantities of cytotoxic oxygen-derived free radicals. The protective effects of classic[127] and delayed[129] ischemic preconditioning were mediated by inhibition of mitochondrial permeability transition. A role for mPTP inhibition was also suggested in the preconditioning produced by the selective mitochondrial K_{ATP} channel agonist diazoxide.[127] Similar to the findings with ischemic preconditioning, desflurane preconditioning improved mPTP resistance to Ca^{2+}-induced opening in isolated mitochondria obtained from pretreated rabbits.[130] The selective mitochondrial K_{ATP} channel antagonist 5-HD abolished this effect.[130] Isoflurane preconditioning also elicited partial mitochondrial uncoupling and reduced mitochondrial Ca^{2+} uptake in intact ventricular myocytes,[131] presumably mediated through mPTP or mitochondrial K_{ATP} channels.

Reactive Oxygen Species

Reperfusion of ischemic myocardium is associated with the release of large quantities of ROS that disrupt intracellular Ca^{2+} homeostasis, cause lipid peroxidation, damage cell membranes, depress contractility, and produce reversible and irreversible tissue injury.[132] Isoflurane and the older volatile anesthetics have been shown to attenuate the toxic effects of oxygen-derived free radicals on LV pressure development in isolated hearts. Isoflurane decreased hydroxyl radical generation in the ischemic rat heart, and halothane had a similar effect in dogs.[133] The protective effects of sevoflurane were associated with reduced dityrosine formation, an indirect marker of reactive oxygen and nitrogen species.[134] These results supported the contention that volatile anesthetics may reduce the release of deleterious quantities of ROS immediately after coronary artery occlusion and reperfusion.

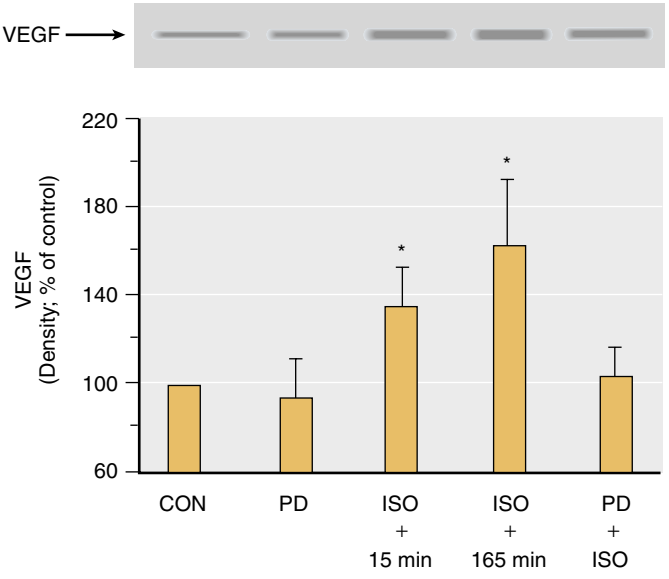

Figure 23-11 Representative immunoblots (*top panel*) of vascular endothelial growth factor (VEGF) in rats receiving 0.9% saline (CON), PD 098059 (PD, 1.0 mg/kg), 1.0 minimum alveolar concentration of isoflurane (ISO) administered for 30 minutes, and PD 098059 (1.0 mg/kg) administered before ISO. Left ventricular tissue samples were obtained 15 or 165 minutes after the administration of ISO or at a corresponding time point in rats that did not receive the volatile anesthetic. Histograms illustrating VEGF expression in each experimental group are depicted in the *lower panel*. All data are means ± SD. *Significantly ($P < .05$) different from CON. *(From Wang C, Weihrauch D, Schwabe DA, et al: Extracellular signal–regulated kinases trigger isoflurane preconditioning concomitant with upregulation of hypoxia-inducible factor-1α and vascular endothelial growth factor in rats. In contrast to these data implicating a pathologic role of large amounts of ROS, a variety of preconditioning stimuli, including brief ischemia, mitochondrial K_{ATP} channel openers, opioids, and volatile anesthetics, stimulate a small burst of ROS that paradoxically appears to initiate downstream signaling events and produce protection from subsequent ischemic injury. Pretreatment with low concentrations of ROS mimicked the beneficial effects of ischemic preconditioning,[135] and free radical scavengers administered before or during ischemia attenuated this cardioprotection.[136] These findings suggest that ischemic preconditioning is mediated by small quantities of ROS released during the preconditioning stimulus. Scavengers of superoxide anion and inhibition of nitric oxide synthase (NOS) abolished the beneficial actions of sevoflurane against ischemic damage.[134] Similarly, desflurane preconditioning was mediated by NO.[137] These results indicate that that superoxide anion may act to trigger anesthetic preconditioning and also suggest that NO may scavenge superoxide anion upon reperfusion to reduce injury. Scavengers of ROS attenuated isoflurane-induced reductions in myocardial infarct size in rabbits[138] (Fig. 23-12) and also inhibited the salutary actions of opening of mitochondrial K_{ATP} channels.[139] Isoflurane was shown with the fluorescent probe dihydroethidium and laser confocal microscopy to directly increase superoxide anion formation in vivo independent of ischemia and reperfusion.[43] Thus, volatile anesthetics may be capable of producing small amounts of superoxide anion that exert protective effects during subsequent ischemia. These data provide compelling evidence that small quantities of ROS play a critical role in anesthetic preconditioning.

ROS act as critical regulatory mediators in many signaling processes that protect the cardiac myocyte from oxidative stress. Activation of PKC[135] and MAPKs[140] by ROS was implicated in ischemic and pharmacologic preconditioning. Hydrogen peroxide activated several MAPK subtypes in neonatal rat ventricular myocytes, but stimulation of p38 MAPK and subsequent phosphorylation of HSP-25/27 appeared to be particularly important in producing cardioprotection. ROS also activated G proteins ($G_i\alpha$ and $G_o\alpha$) that may likewise play a role in preconditioning.[141] Furthermore, there is indirect evidence linking ROS production by volatile anesthetics to activation of protein kinases implicated in the signaling pathways responsible for anesthetic preconditioning. For example, ROS scavengers inhibited isoflurane-induced PKC translocation.[60]

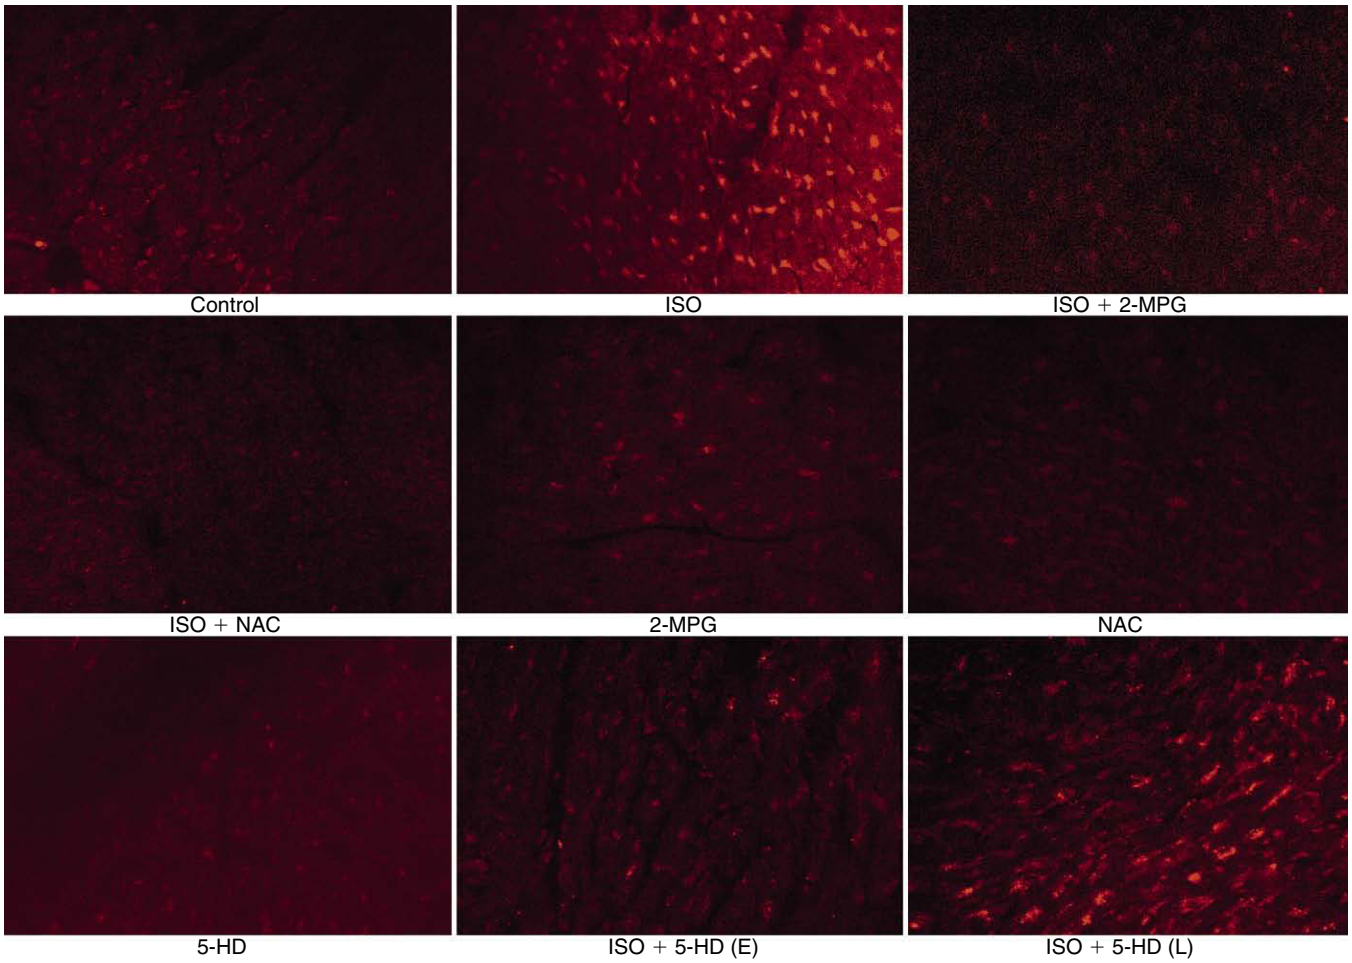

Figure 23-12 Superoxide anion production measured by dihydroethidium fluorescence in control rabbits (CON) and rabbits receiving *N*-acetylcysteine (NAC), *N*-2-mercaptopropionyl glycine (2-MPG), or 5-hydroxydecanoate (5-HD) in the presence and absence of a 1.0 minimum alveolar concentration of isoflurane (ISO). *Significantly ($P < .05$) different from isoflurane. *(From Tanaka K, Weihrauch D, Ludwig LM, et al: Mitochondrial adenosine triphosphate–regulated potassium channel opening acts as a trigger for isoflurane-induced preconditioning by generating reactive oxygen species. Anesthesiology 98:935-943, 2003.)*

The temporal relationship between mitochondrial K_{ATP} channel opening and ROS production during ischemic or pharmacologic preconditioning remains somewhat controversial. Mitochondrial K_{ATP} channels triggered preconditioning by generating ROS.[139] Opening of mitochondrial K_{ATP} channels by selective agonists generated ROS that appeared to be essential for activation of MAPK and the subsequent beneficial effects against ischemic injury. For example, the selective mitochondrial K_{ATP} channel agonist diazoxide enhanced cell viability after hypoxia and reoxygenation in vitro concomitant with the generation of oxygen-derived free radicals.[142] These beneficial actions were attenuated in cells pretreated with 5-HD or ROS scavengers, thus suggesting that the cardioprotection produced by mitochondrial K_{ATP} channel agonists occurs as a result of triggering by ROS. Morphine increased the fluorescence intensity of the hydrogen peroxide–sensitive probe 2′,7′-dichlorofluorescein, an action that was blocked by 5-HD.[143] These data also demonstrated a link between activation of mitochondrial K_{ATP} channels by opioids and ROS production. Diazoxide and another mitochondrial K_{ATP} channel opener (cromakalim) directly caused release of superoxide anion from complex I of the electron transport chain in isolated rat heart mitochondria concomitant with matrix alkalinization.[144] In contrast, other investigations suggested that ROS modulated activity of the mitochondrial K_{ATP} channels. For example, xanthine oxidase–derived superoxide anion–activated mitochondrial K_{ATP} channels from bovine ventricular myocardium reconstituted in lipid bilayers.[145] In addition, ROS triggered opening of mitochondrial K_{ATP} channels, and this event subsequently generated additional quantities of both ROS and NO.[146] Thus, whether mitochondrial K_{ATP} channel opening acts as a trigger or end-effector of ischemic or pharmacologic preconditioning remains unclear.[147] However, a complementary interaction between ROS and mitochondrial K_{ATP} channels appears to exist that may create a positive-feedback interaction between these elements and thereby contribute to cardioprotection.

Whether opening of mitochondrial K_{ATP} channels by volatile anesthetics precedes or follows ROS production during anesthetic preconditioning also remains unclear. Pretreatment with 5-HD or a ROS scavenger (e.g., *N*-acetylcysteine, *N*-2-mercaptoproprionyl glycine) before exposure to isoflurane abolished ROS production in rabbits.[77] However, 5-HD administered after discontinuation of isoflurane but before prolonged coronary artery occlusion only partially attenuated this effect, thus suggesting that mitochondrial K_{ATP} channel opening acted as a trigger for anesthetic preconditioning by producing ROS (Fig. 23-13). In contrast, sevoflurane-induced ROS production was not inhibited by 5-HD pretreatment in isolated guinea pig hearts.[148] Despite the rather equivocal nature of these two studies,[77,148] it is quite evident that ROS play a major role in anesthetic preconditioning in conjunction with mitochondrial K_{ATP} channels. Interestingly, a quantity of ROS that exceeds a critical threshold produced opening of the mPTP and a subsequent burst of ROS[149] that stimulated further release of additional ROS from other mitochondria.[150] This "ROS-induced ROS release" contributed to mPTP-dependent cell death in adult rat myocytes after ischemia-reperfusion.[151] Thus, volatile anesthetics or other mitochondrial K_{ATP} channel openers may prevent opening of the mPTP in an oxidant-sensitive fashion to produce cardioprotection. Desflurane preconditioning increased resistance of Ca^{2+}-induced mPTP opening,[130] but the dependence of this process on ROS has not been examined. Further investigation will be required

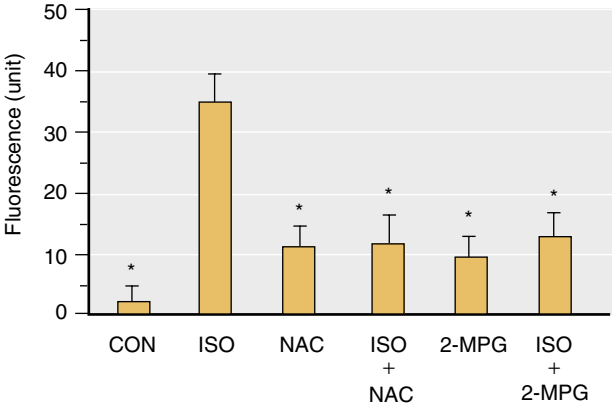

Figure 23-13 Superoxide anion production measured using dihydroethidium fluorescence in rabbits receiving (CON), *N*-acetylcysteine (NAC), or *N*-2-mercaptopropionyl glycine (2-MPG) in the presence and absence of 1.0 minimum alveolar concentration isoflurane (ISO). *Significantly ($P < 0.05$) different from isoflurane. *(From Tanaka K, Weihrauch D, Kehl F, et al: Mechanism of preconditioning by isoflurane in rabbits: a direct role for reactive oxygen species. to more clearly define the precise relationship between ROS, mitochondrial K_{ATP} channels, and mPTP during anesthetic preconditioning.

NF-κB is an important transcription factor activated during ischemia-reperfusion injury that is involved in the inflammatory response to oxidative stress. The regulatory protein IκB-α maintains NF-κB in its inactive form under normal conditions, but activation of IκB-α kinase by ROS or inflammatory cytokines during ischemia removes this passive inhibition of NF-κB. Dissociated NF-κB translocates to the nucleus, binds to promoter gene regions, and initiates transcription. Ischemic preconditioning reduces NF-κB activation and blunts the production of inflammatory cytokines, chemokines, and adhesion molecules, thereby contributing to a reduction in myocardial necrosis. Sevoflurane preconditioning also attenuated activation of NF-κB and reduced NF-κB–dependent inflammatory gene expression in isolated rat hearts.[61] These data suggest that inhibition of NF-κB also mediates anesthetic preconditioning. The role of ROS in this process is currently unknown.

ROS derived from mitochondrial oxidative phosphorylation have been shown to mediate ischemic[152] and pharmacologic preconditioning.[143] The complex III inhibitor myxothiazol inhibited hypoxia-[152] and acetylcholine-induced[153] ROS production and abolished preconditioning in vitro. Volatile anesthetics inhibited electron transport chain complexes I and II in isolated cardiac mitochondria.[154,155] Sevoflurane-induced complex I inhibition was attenuated by a superoxide dismutase mimetic[155] and an NOS inhibitor,[156] thus suggesting that ROS, NO, or their reaction products may inhibit mitochondrial respiration through a positive-feedback mechanism to amplify free radical signals for triggering anesthetic preconditioning. Conversely, because myxothiazol, but not a complex I inhibitor, abolished isoflurane cardioprotection and ROS generation,[157] it was thought that complex III may be the source of ROS during anesthetic preconditioning. These data suggested the possibility that volatile anesthetics may modulate multiple sites of the electron transport chain either directly or indirectly through a ROS-mediated feedback mechanism. An

inhibitor of cyclooxygenase-2 (COX-2) (celecoxib) but not COX-1 (aspirin) or COX-3 (acetaminophen) blocked isoflurane-induced cardioprotection in rabbits,[158] so selective modulation of arachidonic acid metabolism by volatile anesthetics may represent another potential source of ROS during anesthetic preconditioning. Hence, at least three sources of oxygen- or nitrogen-derived free radicals (mitochondrial electron transport, NOS, and COX-2) have been identified to date, but whether other enzymes (e.g., nicotinamide adenine dinucleotide oxidase, lipoxygenase, xanthine oxidase, cytochrome P450) known to generate such reactive intermediates are involved in anesthetic preconditioning remains unknown.

The precise identity of the ROS involved in anesthetic preconditioning has also not been defined. Superoxide anion directly opened mitochondrial K_{ATP} channels in vitro,[145] thus implicating this reactive intermediate in ischemic preconditioning. Isoflurane directly enhanced ethidium fluorescence in rabbit myocardium independent of subsequent ischemia and reperfusion.[43,77] Dihydroethidium is oxidized by intracellular superoxide anion to produce ethidium, which subsequently binds to DNA, thereby further amplifying its fluorescence. These data strongly suggest that superoxide anion mediates anesthetic preconditioning. Sevoflurane also generated superoxide anion before ischemia and reperfusion in isolated hearts.[148] In contrast to these findings with superoxide anion, another ROS (hydrogen peroxide) stimulated PTK-dependent activation of phospholipase C in mouse embryonic fibroblasts and rendered these cells resistant to stress. Hydrogen peroxide activates G_i and G_o proteins,[141] as well as protein kinases involved in reducing cellular injury.[159] Hydrogen peroxide may also be converted to more reactive species that subsequently modify cysteine residues specific to G proteins and selectively activate these proteins.[160] Thus, hydrogen peroxide or its immediate free radical metabolites represent another group of ROS known to affect many of the signaling molecules implicated in anesthetic preconditioning. Dismutation of superoxide anion leads to the production of hydrogen peroxide, hydroxyl radical, and peroxynitrite, and these radicals may differentially alter channel or protein kinase activity. For example, superoxide anion and hydrogen peroxide enhanced, but peroxynitrite reduced Ca^{2+}-regulated K^+ channel function.[161] Whether anesthetic preconditioning also produces other ROS that activate mitochondrial K_{ATP} channels or inhibit the formation of intermediates that adversely affect these channels, such as peroxynitrite, remains to be elucidated.

Delayed Preconditioning by Volatile Anesthetics

Ischemic preconditioning is characterized by an early phase (limited to 1 to 3 hours after the brief ischemic stimulus) and a late, "delayed," or "second-window" phase of preconditioning that occurs after 24 hours and persists for as long as 72 hours after the ischemic episode.[162] Several protein kinases,[163,164] COX-2,[165] NOS,[166] and NF-κB[167] have been implicated in the signaling responsible for delayed preconditioning. NO donors, G protein–coupled receptor ligands (e.g., δ-opioid, adenosine), and mitochondrial K_{ATP} channel openers mimic the protective effects of delayed preconditioning. Experimental evidence indicates that volatile anesthetics may also be capable of producing late pharmacologic preconditioning. Tonkovic-Capin and colleagues first described delayed preconditioning by isoflurane in isolated perfused neonatal rabbit hearts subjected to a 2-hour exposure to 1% of the volatile agent 24 hours before the onset of ischemia.[168] Remote administration of isoflurane reduced myocardial infarct size and enhanced the recovery of LV pressure development in pretreated rabbit hearts as compared with those that had not previously been exposed to the volatile agent.[168] The magnitude of the delayed cardioprotective effect was similar to that observed during isoflurane preconditioning. The second window of cardioprotection produced by isoflurane was abolished by the mitochondrial K_{ATP} channel antagonist 5-HD and was also partially attenuated by the selective sarcolemmal K_{ATP} channel antagonist HMR-1098.[168] Sevoflurane-delayed preconditioning was also inhibited by pretreatment with 5-HD.[169] These findings established a central role for K_{ATP} channels in anesthetic late preconditioning. Remote exposure to 2.5% sevoflurane for 1 hour decreased infarct size, reduced release of creatine kinase, improved LV function, maintained intracellular ATP concentrations, and preserved intracellular Na^+ and Ca^{2+} homeostasis in isolated rat hearts but not in those not receiving sevoflurane pretreatment.[170] The salutary actions of sevoflurane were more pronounced at 48 than at 24 hours after exposure to the volatile agent.[170] Acute preconditioning with sevoflurane also conferred additional cardioprotection after ischemic late preconditioning in rabbits through activation of mitochondrial K_{ATP} channels.[171]

In contrast to the findings in rabbits and rats, exposure to 1.0 MAC isoflurane for 6 hours did not produce late preconditioning against myocardial infarction in dogs when the volatile agent was administered 24 hours before prolonged coronary artery occlusion and reperfusion in vivo.[172] The results occurred independent of alterations in systemic hemodynamics or coronary collateral perfusion and suggested that delayed cardioprotection by volatile anesthetics may be species specific.[172] Intravenous emulsified sevoflurane produced delayed preconditioning against myocardial infarction in rabbits.[173] The blood concentration of sevoflurane required for this beneficial effect was equivalent to a MAC value of approximately 0.17, suggesting that only a small amount of the volatile agent is required to produce cardioprotection. Similarly, inhalation of subanesthetic (0.5% or 1.0%) concentrations of sevoflurane by healthy volunteers produced time-dependent alterations in gene expression in white blood cells, including several transcripts that have been strongly implicated in late ischemic preconditioning.[174] Sevoflurane also reduced expression of the proinflammatory L-selectin (CD62L) in granulocytes concomitant with increased resistance to inflammatory activation 24 and 48 hours after exposure to the volatile agent.[174] These exciting data provided the first evidence that volatile anesthetics have the potential to produce a second window of cardioprotection in humans.

Several investigations have begun to explore the mechanisms responsible for delayed anesthetic preconditioning in experimental animals. COX-2 mediated late ischemic and δ-opioid–induced pharmacologic preconditioning in rabbits. Delayed ischemic and δ-opioid–induced pharmacologic preconditioning was also shown to increase COX-2 transcription and translation and enhance myocardial concentrations of prostaglandin E_2 (PGE_2) and 6-keto-$PGF_2\alpha$ 24 hours after the initial ischemic stimulus.[165] A role for COX-2 has been demonstrated in the second window of isoflurane preconditioning. Administration of the selective COX-2 antagonist celecoxib after but not before remote isoflurane exposure abolished reductions in myocardial infarct size associated with the volatile agent.[175] These data indicate that COX-2 functions as a mediator but not as a trigger of delayed isoflurane cardioprotection.[175] In contrast to the

findings with late ischemic and δ-opioid–induced preconditioning,[165] COX-2 protein expression was unaffected by remote isoflurane administration, suggesting that an increase in COX-2 activity may instead mediate the cardioprotective effect of volatile anesthetics in this setting.[175] Inducible NOS (iNOS) regulates COX-2 activity during the late phase of ischemic preconditioning.[176] NO functions as a trigger and mediator of this second window of ischemic preconditioning.[177] Neuronal NOS (nNOS) may also mediate the late phase of ischemic preconditioning in concert with COX-2.[178] A central role for NO metabolism was described during isoflurane-induced delayed preconditioning in rabbits.[179] Administration of the nonselective NOS antagonist L-arginine methyl ester (L-NAME), but not selective iNOS or nNOS inhibitors, before remote isoflurane exposure or coronary artery occlusion and reperfusion abolished reductions in infarct size produced by the volatile agent.[179] Increases in endothelial NOS (eNOS) but not iNOS transcription and translation were also observed during the second window of isoflurane preconditioning.[179] These data demonstrated that the NO produced by eNOS triggers and mediates late isoflurane preconditioning in rabbits. Administration of isoflurane 24 to 72 hours before global ischemia and reperfusion also reduced infarct size and preserved LV function in isolated rat hearts.[180] In contrast to the findings in rabbits, upregulation and activation of iNOS mediated isoflurane delayed preconditioning in rats.[180] Interestingly, a second window of isoflurane preconditioning did not occur in female rabbits.[181] This gender specificity may be related to an estrogen-related upregulation of eNOS in female rabbits that confers substantial protection against infarction independent of subsequent remote administration of a volatile anesthetic.[181]

A role for reactive oxygen and nitrogen species in isoflurane delayed preconditioning has also been demonstrated in rats.[182] Reductions in infarct size occurred after remote 2-hour inhalation of isoflurane concentrations as low as 0.8%, which confirmed that subanesthetic concentrations of a volatile anesthetic are capable of providing a second window of cardioprotection.[173,174] Pretreatment with a superoxide anion scavenger or a nonselective NOS antagonist abolished the protection produced by remote isoflurane exposure. As observed in isoflurane acute preconditioning,[77] remote administration of the volatile agent increased ethidium fluorescence consistent with the generation of superoxide anion, and pretreatment with an inhibitor of the mitochondrial electron transport chain inhibited this response.[182] Delayed cardioprotection mediated by 12-lipoxygenase expression and activity has been linked to opioid receptor activation.[183] 12-Lipoxygenase was also demonstrated to mediate isoflurane delayed preconditioning in mice.[184] A selective inhibitor of 12-lipoxygenase abolished reductions in infarct size produced by the administration of isoflurane 24 hours before prolonged coronary occlusion and reperfusion. These cardioprotective effects were accompanied by enhanced expression of 12-lipoxygenase localized to the intercalated disk regions adjoining adjacent ventricular myocytes.[184]

Postconditioning by Volatile Anesthetics

The first minutes of reperfusion are critical for salvaging ischemic myocardium, but reperfusion also paradoxically exacerbates the initial damage caused by the ischemic insult.[185] Modulation of conditions during reperfusion favorably affects the extent of ischemic injury. Studies of controlled reperfusion after ischemia have indicated that gradual reperfusion at low intracoronary pressure reduces myocardial damage.[186,187] Such control over coronary hemodynamics during early reperfusion reduced myocardial infarct size, preserved postischemic contractile function, limited endothelial injury, and attenuated myocardial edema. Despite these data, most of the experimental and clinical research examining the adverse consequences of ischemia-reperfusion injury and how they may be minimized has instead focused on interventions performed before the onset of ischemia. Clearly, coronary artery occlusion cannot be temporally predicted in most patients with acute myocardial infarction with any degree of certainty, and as a result, application of preconditioning strategies may be primarily limited to clinical situations in which the precise onset of ischemia is well defined (e.g., inflation of an angioplasty balloon, application of an aortic cross-clamp during cardiopulmonary bypass).

In 2003, Zhao and Vinten-Johansen reported that brief episodes of coronary artery occlusion conducted during early reperfusion after prolonged ischemia reduced myocardial infarct size, attenuated neutrophil accumulation, partially inhibited the generation of cytotoxic reactive oxygen species, decreased endothelial dysfunction, and diminished apoptosis.[187-189] This phenomenon was initially termed "ischemic postconditioning" and later shortened to simply "postconditioning." The reductions in myocardial infarct size caused by postconditioning were shown to be remarkably similar to those produced by ischemic preconditioning.[189] Activation of ERK1/2 and formation of NO were initially shown to mediate this form of cardioprotection.[189,190] Subsequently, the prosurvival PI3K-Akt signaling cascade, including the downstream enzymes eNOS and target of rapamycin (TOR)/70-kd ribosomal protein s6 kinase (p70s6K), was shown to play a central role in postconditioning.[191] These signaling elements are critical mediators of cellular necrosis and apoptosis via their actions on the balance of proapoptotic and antiapoptotic proteins, the activity of the regulatory enzyme glycogen synthase kinase-3β (GSK-3β), and the transition state of the mPTP (Fig. 23-14).[192,193] Postconditioning has also been shown to occur in the human heart.[194] Administration of a diverse variety of drugs (e.g., G protein–coupled receptor ligands [adenosine, bradykinin, opioids], insulin, statins, urocortin, growth factors [basic fibroblast growth factor, insulin-like growth factor I]) immediately before or during early reperfusion mimics the beneficial actions of postconditioning. Many elements of prosurvival signaling mediate this "pharmacologic postconditioning."[195]

Although anesthetic preconditioning has been studied extensively and many of the mechanisms responsible for this phenomenon have been characterized in detail, substantially less attention has been directed toward exploration of the possible beneficial effects of volatile anesthetics when administered immediately before or during reperfusion (termed "anesthetic postconditioning"). Nevertheless, some experimental evidence indicates that volatile anesthetics are capable of exerting cardioprotective effects under these conditions. The older volatile agent halothane prevented reoxygenation-induced hypercontracture of cardiac myocytes in vitro, a potential cause of myocyte necrosis during early reperfusion.[196] Halothane also reduced reperfusion injury after regional ischemia in rabbit hearts.[197] Desflurane and sevoflurane reduced infarction size when administered during the first 15 minutes of reperfusion in rabbits.[198] Isoflurane enhanced the functional recovery of isolated rat hearts when administered solely during reperfusion.[58] The salutary actions of sevoflurane during reperfusion were shown to be dose dependent in rats.[199]

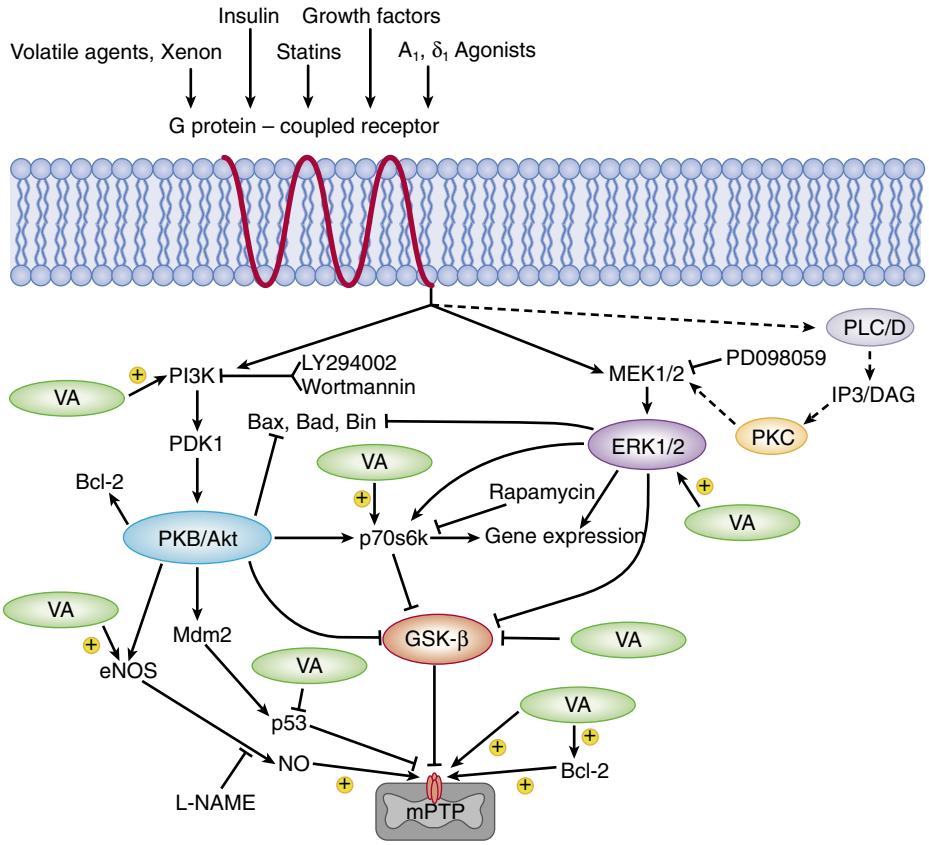

Figure 23-14 Schematic illustration depicting the potential sites of action of volatile anesthetics (VA) on cardioprotective signaling during early reperfusion. G protein–coupled receptor ligands (e.g., adenosine A_1, opioid δ_1), VA, insulin, statins, and growth factors activate parallel phosphoinositol 3-kinase (PI3K) or extracellular signal–regulated kinase (ERK1/2) cascades to produce protection. G protein–coupled activation of protein kinase C (PKC) by phospholipases (PLC/D) through the second messengers diacylglycerol (DAG) and inositol triphosphate (IP3) also contributes to activation of PI3K and ERK1/2. PI3K phosphorylates phosphoinositide-dependent kinase (PDK1), which activates Akt (also known as protein kinase B [PKB]). This moiety stimulates the activity of antiapoptotic proteins (e.g., B-cell lymphoma-2 [Bcl-2]) and simultaneously inhibits the activity of proapoptotic proteins (e.g., Bax, Bad, Bim, caspases). Akt/PKB also inhibits the β-isoform of glycogen synthase kinase (GSK-β) and activates endothelial nitric oxide synthase (eNOS), 70-kd ribosomal protein s6 kinase (p70s6K), and murine double-minute-2 (Mdm2) protein. p70s6K also inhibits GSK-β activity. Nitric oxide (NO) produced by eNOS inhibits whereas Mdm2-induced phosphorylation of the proapoptotic protein p53 opens the mitochondrial permeability transition pore (mPTP). Inhibition of GSK-β and activation of mitochondrial K_{ATP} channels also act to close the mPTP. The transition state of the mitochondrial pore is critical for preservation of mitochondrial integrity and cell viability during ischemia and reperfusion. Activation of ERK1/2 also inhibits GSK-β and blocks the formation of proapoptotic proteins. LY294002 and wortmannin, rapamycin, PD 098059, and L-arginine methyl ester (L-NAME) block the activity of PI3K, p70s6K, ERK1/2, and eNOS, respectively. Volatile anesthetics have been proposed to enhance the activity of PI3K-Akt, p70s6k, ERK1/2, and eNOS. Volatile anesthetics have also been suggested to directly inhibit GSK-β and mPTP concomitant with enhanced expression of Bcl-2 and inhibition of p53. Volatile anesthetic–induced activation of mitochondrial K_{ATP} channels also inhibits mPTP. These actions of volatile anesthetics may contribute to the cardioprotective effects during early reperfusion.

Administration of sevoflurane after ischemia also improved contractile and metabolic function concomitant with reduced myoplasmic Ca^{2+} loading in isolated guinea pig hearts.[200]

The mechanisms by which volatile anesthetics produce cardioprotection during reperfusion have yet to be firmly established. Halothane abolished reoxygenation-induced attenuation of SR-dependent oscillations of intramyoplasmic Ca^{2+} concentration in isolated cardiac myocytes.[196] These[196] and other findings[200] suggested that volatile anesthetics may prevent intracellular Ca^{2+} overload during early reperfusion. Isoflurane and sevoflurane also reduced postischemic adhesion of polymorphonuclear leukocytes.[201] However, the precise mechanisms by which volatile anesthetics act to reduce intracellular Ca^{2+} overload or attenuate the adverse consequences of large quantities of reactive oxygen intermediates during early reperfusion were not elucidated by these previous studies. Although it is certainly tempting to propose that similar signaling pathways mediate anesthetic preconditioning and postconditioning, substantial differences between the genomic responses associated with these phenomena have been demonstrated.[202] These findings suggest that the mechanisms responsible for anesthetic preconditioning and postconditioning may not be identical.

Chiari and coworkers demonstrated that brief exposure to 1.0 MAC isoflurane administered during the final 3 minutes of coronary artery occlusion and the first 2 minutes of reperfusion reduces myocardial infarct size in rabbits.[203] The degree of myocardial preservation observed with isoflurane postconditioning was similar in magnitude to the cardioprotection afforded by isoflurane preconditioning in an identical experimental preparation.[77] Postconditioning with 0.5 MAC isoflurane (a concentration that did not produce cardioprotection alone) also reduced the time threshold required for ischemic postconditioning. The beneficial actions of isoflurane before and during early reperfusion with or without subthreshold ischemic postconditioning

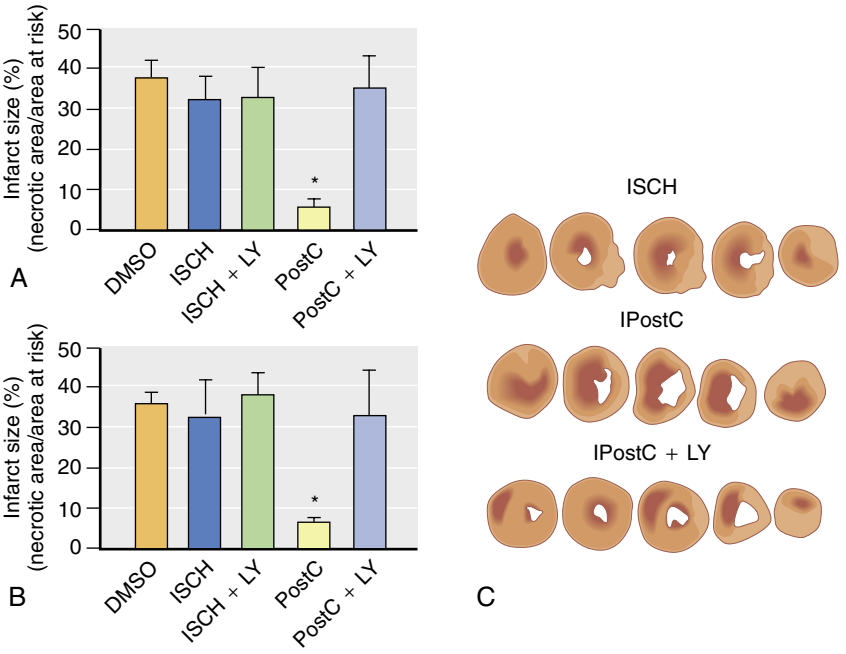

Figure 23-15 Infarct size was determined by 1% triphenyltetrazolium chloride staining. Areas infarcted in vivo by coronary artery ligation were excluded from determination of infarct size (**A**). The scarred chronic infarct resulting from coronary ligation was distinguished from fresh infarcts (*salmon pink*). Release of lactate dehydrogenase during reperfusion (**B**) served as an independent method to estimate infarct size. **C,** Transverse sections of representative experiments. DMSO, dimethyl sulfoxide (<0.1%; used to dissolve the phosphatidylinositol-3′-kinase antagonist LY294002); PostC, ischemic postconditioning; ISCH, unprotected remodeled hearts exposed to ischemia-reperfusion alone; LY, LY294002 (15 μM); PostC, anesthetic postconditioning. Data are given as means ± SD ($n = 5$ in each group). *$P < 0.05$ versus ISCH. *(From Feng J, Fischer G, Lucchinetti E, et al: Infarct-remodeled myocardium is receptive to protection by isoflurane postconditioning. Role of protein kinase B/Akt signaling. Anesthesiology 104:1004-1014, 2006.)*

were blocked by pretreatment with the selective PI3K antagonist wortmannin. Isoflurane also increased phosphorylation of the PI3K downstream target protein Akt, and this effect was also inhibited by wortmannin pretreatment. These data demonstrated for the first time that activation of the PI3K signaling pathway directly mediates the protective effects of isoflurane postconditioning in vivo.[203] A central role for PI3K-Akt signaling in isoflurane postconditioning was subsequently demonstrated in infarct-remodeled myocardium as well (Fig. 23-15), thus suggesting that postconditioning by volatile anesthetics may also be maintained in diseased myocardium.[204]

Reperfusion after a prolonged ischemic insult initiates or hastens apoptosis.[205] Isoflurane postconditioning reduced cytochrome *c* translocation from mitochondria (an important early marker of apoptosis mediated by PI3K-Akt) and decreased the number of terminal deoxynucleotidyl transferase–mediated dUTP nick end labeling (TUNEL; another indicator of apoptosis)-positive ventricular myocytes in situ.[206] These data provided the first direct evidence indicating that isoflurane postconditioning preserves myocardial integrity, in part by attenuating apoptotic cell death. Volatile anesthetics were previously shown to abolish norepinephrine-induced apoptosis in rat ventricular myocytes as indicated by reductions in TUNEL-positive cell staining, attenuation of increases in annexin V staining (an index of DNA laddering), and inhibition of elevated caspase-9 activity.[207]

When administered in a dose that did not alter infarct size alone, morphine enhanced isoflurane postconditioning against myocardial infarction.[206] The protective effects of the combination of subthreshold doses of morphine and isoflurane during early reperfusion were abolished by pretreatment with wortmannin, thus indicating that the cardioprotection observed was mediated by activation of PI3K. The nonselective opioid antagonist naloxone also inhibited the protective effects of morphine, isoflurane, and their combination during early reperfusion, thus suggesting that opioid receptor activation also mediates isoflurane postconditioning and its augmentation by morphine. Cardioprotection by opioids during reperfusion occurs as a result of activation of δ_1-opioid receptors,[208] and postconditioning against infarction by isoflurane and its potentiation by the clinically relevant opioid morphine may also be mediated by the δ_1-opioid receptor. This hypothesis remains to be tested, but a role for the δ_1-opioid receptor in anesthetic preconditioning was described previously.[59]

Activation of ERK1/2 is a redundant mechanism by which downstream elements of the PI3K cascade may be stimulated to favorably modulate reperfusion injury.[62] ERK1/2 mediates ischemic[209] and pharmacologic[210] postconditioning and also plays an important role in the preconditioning produced by volatile anesthetics.[109,114] Selective inhibition of ERK1/2 abolished the reductions in infarct size produced by isoflurane postconditioning.[211] Both PI3K-Akt and ERK1/2 phosphorylate TOR/p70s6K, an important regulator of protein translation.[62] A selective inhibitor of this enzyme (rapamycin) abolished cardioprotection during ischemic[191] and pharmacologic[208] postconditioning. Isoflurane postconditioning was also inhibited by rapamycin in normal and infarct-remodeled myocardium, thus implicating a role for p70s6K in this phenomenon as well.[211,212]

PI3K-Akt activates eNOS and increases the formation of NO,[191] and a central role for NO has been demonstrated in postconditioning by ischemia[191] or G protein–coupled receptor ligands.[210] A nonselective NOS inhibitor, but not selective iNOS or nNOS inhibitors, abolished reductions in infarct size produced by the administration of isoflurane before and during early reperfusion in rabbits, a finding suggesting that eNOS mediates isoflurane postconditioning.[211] Furthermore, isoflurane inhaled at the onset of reperfusion enhanced the cardioprotective effect of ischemic postconditioning through a NO-dependent mechanism in rabbits.[213] Isoflurane postconditioning also enhanced expression of eNOS in infarct-remodeled rat myocardium, and a selective PI3K antagonist inhibited this isoflurane-induced phosphorylation of eNOS.[204] These data suggest that NO derived from

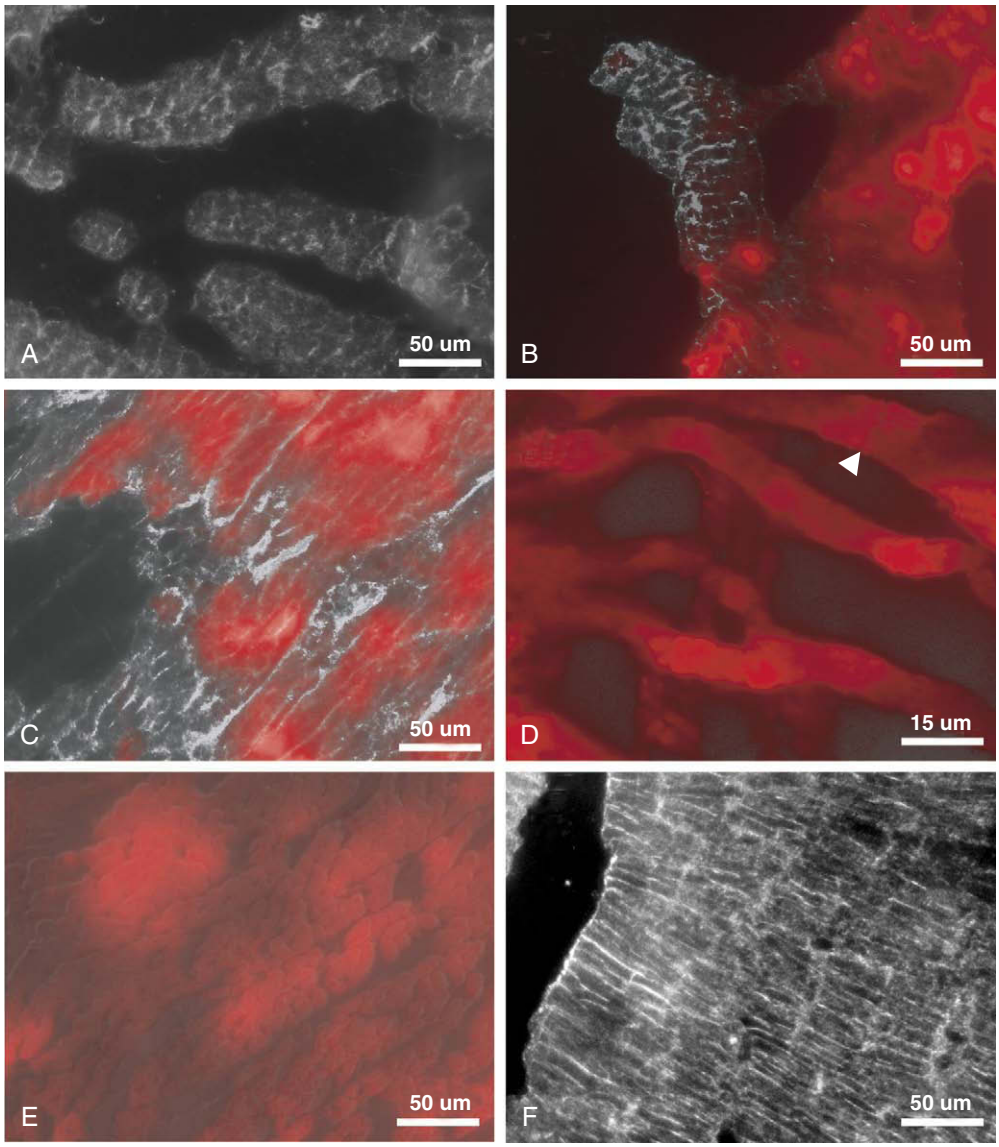

Figure 23-16 Postischemic uptake of MitoTracker Red 580 in the mitochondria of isolated perfused rat hearts. Unprotected hearts show no staining (**A**) except for superficial epicardial layers of the myocardium (**B**). In contrast, postconditioned protected hearts exhibit marked accumulation of MitoTracker Red 580 in tissue (**C** and **D**), similar to control hearts not subjected to ischemia-reperfusion (time-matched perfusion) (**E**). Atractyloside, a direct opener of the mitochondrial permeability transition pore, completely abolished the isoflurane effects (**F**). **A** through **F** are epifluorescence micrographs (*red channel*) merged with phase-contrast images. **D** shows at higher magnification the syncytial net of postconditioned myocytes containing brightly staining mitochondria (*red channel*). The *arrow* indicates intercalated disks. *(From Feng J, Lucchinetti E, Ahuja P, et al: Isoflurane postconditioning prevents opening of the mitochondrial permeability transition pore through inhibition of glycogen synthase kinase 3β. Anesthesiology 103:987-995, 2005.)*

eNOS plays an important role in anesthetic postconditioning in healthy and infarct-remodeled myocardium.

Inhibition of mPTP has been shown to mediate ischemic postconditioning.[214] Isoflurane postconditioning was abolished by the mPTP opener atractyloside and enhanced by the mPTP inhibitor cyclosporine in rabbits.[215] Similarly, atractyloside and a selective PI3K antagonist (LY294002) abolished isoflurane postconditioning in rats.[212] LY294002 also inhibited phosphorylation of the regulatory enzyme GSK-3β and opened the mPTP as determined by nicotinamide adenine dinucleotide measurements (Fig. 23-16).[212] Taken together, these data[212,215] indicate that administration of isoflurane during early reperfusion protects against reperfusion injury by preventing mPTP opening via a PI3K-dependent mechanism through inhibition of GSK-3β.

Experimental evidence has strongly suggested that mitochondrial K_{ATP} channel activation is an end-effector during anesthetic preconditioning.[56] Opening of mitochondrial K_{ATP} channels during ischemic or pharmacologic preconditioning may produce small alterations in intramitochondrial homeostasis that promote protection against subsequent ischemic damage through energy-dependent regulation of mitochondrial matrix volume. Opening of mitochondrial K^+ influx pathways favorably regulated matrix volume and improved function during simulated ischemia and reperfusion.[216] A selective mitochondrial K_{ATP} channel antagonist (5-HD) inhibited isoflurane postconditioning,[215] suggesting that mitochondrial K_{ATP} channel opening by brief administration of isoflurane during early reperfusion may be responsible for cardioprotection in rabbits. Mitochondrial K_{ATP} channels mediate

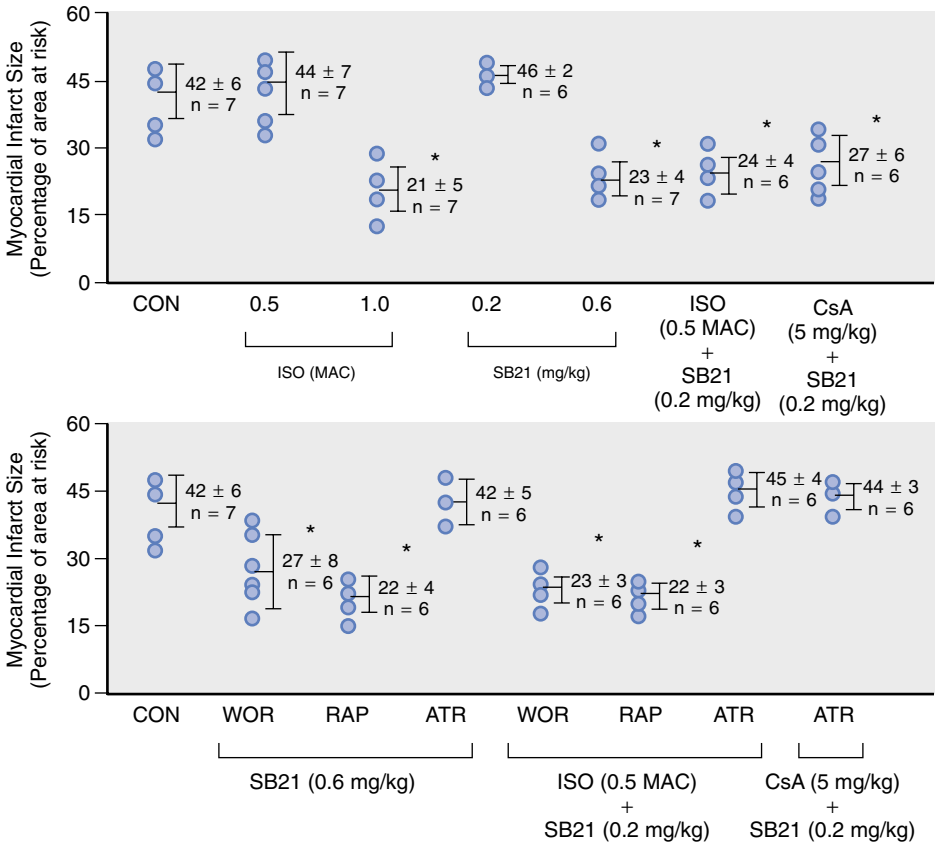

Figure 23-17 Myocardial infarct size depicted as a percentage of the left ventricular area at risk in rabbits receiving 0.9% saline (control, CON), isoflurane (ISO, 0.5 or 1.0 minimum alveolar concentration [MAC]), SB 216763 (SB21, 0.2 or 0.6 mg/kg), 0.5 MAC ISO plus 0.2 mg/kg SB21, or cyclosporine (CsA, 5 mg/kg) plus 0.2 mg/kg SB21 (*top panel*). Infarct sizes in rabbits receiving 0.6 mg/kg SB21 or 0.5 MAC ISO plus 0.2 mg/kg SB21 in the presence of wortmannin (WOR, 0.6 mg/kg), rapamycin (RAP, 0.25 mg/kg), or atractyloside (ATR, 5 mg/kg) are depicted in the *bottom panel*. Infarct sizes in rabbits receiving A (CsA, 5 mg/kg) plus 0.2 mg/kg SB21 in the presence of atractyloside pretreatment are also illustrated in the *bottom panel*. Each point represents a single experiment. All data are means ± SD. *Significantly ($P < .05$) different from CON. *(From Pagel PS, Krolikowski JG, Neff DA, et al: Inhibition of glycogen synthase kinase potentiates isoflurane-induced protection against myocardial infarction during early reperfusion in vivo. Anesth Analg 102:1348-1354, 2006.)*

sevoflurane postconditioning in rats.[217] However, a close interaction between mitochondrial K_{ATP} channels and mPTP was previously identified during diazoxide and desflurane preconditioning.[127,130] Hence, isoflurane postconditioning may not be solely attributable to the actions of the volatile agent on mitochondrial K_{ATP} channels alone but, instead, may be dependent on the interaction between mitochondrial K_{ATP} channel opening and mPTP inhibition.

GSK-3β is an important mediator of cellular function whose activation has been implicated in the pathogenesis of diabetes mellitus and Alzheimer's disease. Inhibition of GSK-3β may play a critical role in protection against myocardial ischemia-reperfusion injury inasmuch as selective blockade of the enzyme mimics the beneficial actions of ischemic preconditioning[218] and opioid postconditioning.[208] GSK-3β was shown to be a central regulator of several prosurvival signaling enzymes (e.g., PI3K, p70s6K, PKC, protein kinase A) during cardioprotection against hypoxia-reoxygenation injury in isolated ventricular myocytes.[192] Selective inhibition of GSK-3β also limited mPTP opening.[192] Thus, many endogenous signaling pathways appear to converge on and regulate the activity of GSK-3β, thereby favorably modulating mitochondrial permeability transition and producing protection against ischemia-reperfusion injury. Administration of isoflurane during early reperfusion phosphorylated and inactivated GSK-3β in a PI3K- and mPTP-dependent fashion concomitant with cardioprotection in isolated perfused rats.[212] A selective inhibitor of GSK-3β (SB 216763) was also shown to lower the threshold of isoflurane postconditioning against infarction in rabbits.[219] The salutary actions of the effects of GSK-3β inhibition were abolished by the mPTP opener atractyloside but not the PI3K or p70s6K antagonists wortmannin or rapamycin.[219] These data suggest that isoflurane postconditioning is mediated by the combined actions of SB 216763 and volatile anesthetic on the mPTP and provide pharmacologic evidence suggesting that isoflurane produces a direct inhibitory effect on GSK-3β independent of its actions on PI3K and p70s6K activity (Fig. 23-17).

Mitochondria are the putative target of several apoptotic proteins that either directly damage mitochondrial membranes or indirectly open the mPTP and lead to release of cytochrome *c*. Phosphorylation of Bad by PI3K results in its sequestration from mitochondria and inhibits apoptosis.[220] Similarly, activation of PI3K prevents Bax-induced apoptosis by inhibiting the critical conformational change required for its translocation to mitochondrial membranes.[221] Activation of PI3K has also been shown to phosphorylate and inactivate procaspase-9 and thereby inhibit this important mediator of apoptotic cell death.[222] The mechanisms by which inhibition of GSK-3β favorably affects the mPTP to cause protection against ischemia-reperfusion injury have not been clearly elucidated. Activated GSK-3β binds to and promotes the actions of p53,[223] a tumor suppressor protein known to interact with and stimulate the disruption of mitochondria during apoptosis.[224] p53 translocates to mitochondria, increases mitochondrial membrane permeability by directly interacting with Bax, abolishes $\Delta\Psi_m$, and causes the release of cytochrome *c*.[225]

A central role for inhibition of p53 in myocardial and neuronal protection against cellular injury has been characterized. Activation of p53 by hypoxia or ROS[226] produces immediate or delayed programmed cell death by stimulating mitochondrial apoptotic pathways and enhancing the transcription of other proapoptotic proteins (e.g., Bax, apoptosis-inducing factor

[AIF]).[227] Enhanced p53 expression was observed after ischemia and reperfusion in isolated rat ventricular myocytes, and ischemic preconditioning substantially reduced this effect.[228] Ischemic preconditioning also attenuated p53 transcription and translation in hippocampal pyramidal neurons in a rat model of global forebrain ischemia and reperfusion.[229] Inhibition of p53 with the selective antagonist pifithrin-α or stimulated degradation of the protein by PI3K-mediated phosphorylation of murine double-minute-2 protein (Mdm2), an oncogenic factor known to facilitate p53 degradation, has previously been shown to protect against ischemic injury in isolated rat hearts.[230] Phosphorylated Mdm2 associates with p53 and inactivates the latter protein by blocking its active site and promoting subsequent degradation of it through ubiquitin complex formation.[231] Thus, ischemic preconditioning may have abrogated the deleterious actions of p53 by PI3K-mediated phosphorylation of the downstream moiety Mdm2.[230] Direct inhibition of p53 with pifithrin-α protected against neuronal cell death produced by ischemia, excitotoxins, or amyloid β-peptide.[232] Targeted deletion of p53 prevented cardiac rupture after infarction in transgenic mice, presumably by simulating the protective actions of ischemic preconditioning via inhibition of apoptotic cell death, thereby preserving myocardial integrity.[233] Inhibition of p53 by pifithrin-α was recently demonstrated to lower the threshold of isoflurane postconditioning in vivo.[234] Blockade of this action by atractyloside indicated that the cardioprotection observed was mediated by actions of the selective p53 inhibitor and the volatile anesthetic on the mPTP. Thus, experimental evidence suggests that administration of isoflurane during early reperfusion may affect the interaction between GSK-3β and p53 to modulate the transition state of the mPTP.

Bcl-2 protein has been identified in the outer mitochondrial membrane, regulates the mPTP, and inhibits apoptosis.[235] Overexpression of Bcl-2 attenuated apoptosis and protected against ischemia-reperfusion injury in transgenic mice.[236] A key interaction between Bcl-2 and mPTP inhibition was previously implicated during delayed ischemic preconditioning.[129] A selective inhibitor (HA14-1) of Bcl-2 abolished isoflurane-induced Bcl-2 expression and attenuated reductions in apoptosis (e.g., cytochrome *c* release, TUNEL staining) in isolated atrial and ventricular myocytes subjected to hypoxia-reoxygenation injury, hydrogen peroxide, or activated neutrophils.[126] HA14-1 also inhibited isoflurane and ischemic postconditioning in vivo but did not affect cardioprotection produced by the direct mPTP inhibitor cyclosporine.[237] Thus, the salutary actions of isoflurane on transient, repetitive ischemia during early reperfusion may also occur as a result of indirect modulation of the mPTP mediated "upstream" by Bcl-2.[237] In fact, PI3K has been shown to phosphorylate and activate Bcl-2 concomitant with inactivation of proapoptotic proteins, including Bad, Bax, and p53.[238] As a result, activation of PI3K signaling by isoflurane postconditioning appears to produce cardioprotection by several redundant mechanisms that affect apoptotic protein homeostasis.

Coronary Vascular Effects of Volatile Anesthetics in Humans

Evaluation of the actions of volatile anesthetics on the human coronary circulation is difficult not only because the methods used to determine coronary blood flow in humans are limited but also because interpretation of clinical findings during anesthesia is complicated by changes in hemodynamics, the impact of surgery, and the use of adjuvant anesthetics or vasoactive drugs. Halothane decreases MVo_2 and variably alters coronary blood flow in patients with coronary artery disease, but metabolic or electrocardiographic evidence of ischemia has not been observed during halothane anesthesia. A report published in 1983[239] described the occurrence of myocardial ischemia, as indicated by new electrocardiographic changes and abnormal myocardial lactate extraction, in 10 of 21 patients anesthetized with isoflurane who were undergoing major vascular surgery. Five patients were treated with phenylephrine and pacing to return arterial pressure and heart rate to control values, and after these interventions, the electrocardiographic and metabolic derangements resolved in two of the five patients. Despite the apparent dependence of these new episodes of myocardial ischemia on alterations in systemic hemodynamics, the author[239] proposed that isoflurane had caused coronary steal in these patients, even though no specific evidence of redistribution of blood flow between normal and collateral-dependent zones was presented. The data have not been uniformly supported by subsequent studies. Coronary blood flow remained unchanged during isoflurane anesthesia in patients undergoing coronary artery bypass graft (CABG) surgery, but coronary sinus O_2 content increased consistent with modest coronary vasodilation. Isoflurane alone did not produce electrocardiographic or metabolic evidence of ischemia. Instead, myocardial ischemia occurring during isoflurane anesthesia was most often associated with tachycardia or hypotension. In addition, isoflurane actually increases the tolerance to pacing-induced ischemia in patients with coronary artery disease. Comparison of studies examining the effects of isoflurane on the incidence of intraoperative myocardial ischemia was also complicated by differences in patient age, surgical procedure, operative time, and preoperative LV ejection fraction. Importantly, compelling evidence demonstrating redistribution of coronary blood flow away from ischemic to normal myocardium in humans anesthetized with isoflurane has yet to be reported.

The incidence of intraoperative myocardial ischemia in susceptible patients has been difficult to define. Less than 50% of intraoperative ischemic episodes have been linked to alterations in systemic hemodynamics.[240] The strongest predictor of intraoperative ischemia remains preexisting ischemia on arrival at the operating room and not anesthetic technique.[241] The only hemodynamic event definitively related to intraoperative ischemia in patients undergoing CABG surgery is tachycardia.[241] Perioperative use of β_1-adrenoceptor antagonists to prevent myocardial ischemia strongly supports this contention.[242] Sternotomy caused greater increases in calculated indices of MVo_2, myocardial lactate production, and the incidence of hypertension requiring treatment with vasoactive drugs during morphine than during halothane anesthesia. In contrast, induction of anesthesia with desflurane in patients undergoing CABG surgery may be associated with tachycardia, hypertension, and a greater incidence of ischemia than during induction with sufentanil.[243] Steal-prone anatomy was identified in 23% of patients with coronary artery disease enrolled in the Coronary Artery Surgery Study.[244] However, patients with steal-prone coronary anatomy did not have a greater incidence of ischemia during desflurane anesthesia than did patients with other forms of coronary artery disease.[243] The incidence of myocardial ischemia and adverse cardiac outcomes in cardiac patients undergoing noncardiac surgery has been shown

to be similar during sevoflurane and isoflurane anesthesia. New electrocardiographic changes, the incidence of postoperative myocardial infarction, and mortality were similar in patients undergoing CABG surgery independent of anesthetic technique or the presence of steal-prone anatomy.[245] In summary, despite the findings that volatile anesthetics are mild coronary vasodilators, these anesthetics did not cause abnormal redistribution of myocardial perfusion resulting in ischemia when tachycardia and hypotension were avoided in patients with coronary artery disease.

Cardioprotection by Volatile Anesthetics in Humans

Anesthetic preconditioning most likely occurs in human myocardium, but evaluation of this process in patients at risk for myocardial ischemia is complicated by simultaneous alterations in systemic and coronary hemodynamics; the use of other anesthetics, analgesics, or vasoactive drugs; preexisting disease states; and the influence of surgery on cardiovascular homeostasis. Isoflurane[78] and desflurane[80] enhanced the recovery of contractile function in human atrial trabeculae by stimulation of adenosine receptors and activation of K_{ATP} channels. A role for adenosine receptors, MAPKs, and ROS has previously been demonstrated in other forms of preconditioning in human atrial myocytes concomitant with mitochondrial K_{ATP} channel opening. Isoflurane decreased postoperative release of troponin I and the myocardial form of creatine kinase in patients undergoing CABG surgery, thus suggesting a reduction in the severity of myocardial necrosis.[246] Administration of the older agent enflurane before cardioplegic arrest also enhanced postischemic recovery of contractile function in patients undergoing CABG surgery.[247] Sevoflurane, but not the intravenous anesthetic propofol, was shown to preserve myocardial function in patients undergoing CABG surgery or aortic valve replacement concomitant with a reduction in the release of troponin I (Fig. 23-18).[248,249] Desflurane or sevoflurane, but not propofol, maintained contractile function and caused less pronounced release of troponin I after cardiopulmonary bypass in elderly patients with three-vessel coronary artery disease and preexisting LV dysfunction who were undergoing CABG surgery.[250] The beneficial effects of sevoflurane were most apparent when the volatile anesthetic was administered throughout CABG surgery versus before the initiation of cardiopulmonary bypass or after construction of the coronary anastomoses alone.[251] The incidence of atrial fibrillation early after CABG surgery may also be reduced by the intraoperative administration of sevoflurane instead of intravenous anesthetics.[252]

In a double-blind, placebo-controlled study of 72 patients undergoing CABG surgery with cardiopulmonary bypass, sevoflurane preconditioning (inhalation of 4% sevoflurane during the first 10 minutes of cardiopulmonary bypass), but not placebo, reduced postoperative release of brain natriuretic peptide (BNP), a biochemical marker of LV dysfunction, and cystatin C, an indicator of renal dysfunction, concomitant with translocation of PKC-δ and PKC-ε (Fig. 23-19).[253] Postoperative biochemical markers of hepatic injury were also lower with a sevoflurane-based anesthetic technique than with intravenous propofol anesthesia in patients undergoing CABG surgery with cardio-

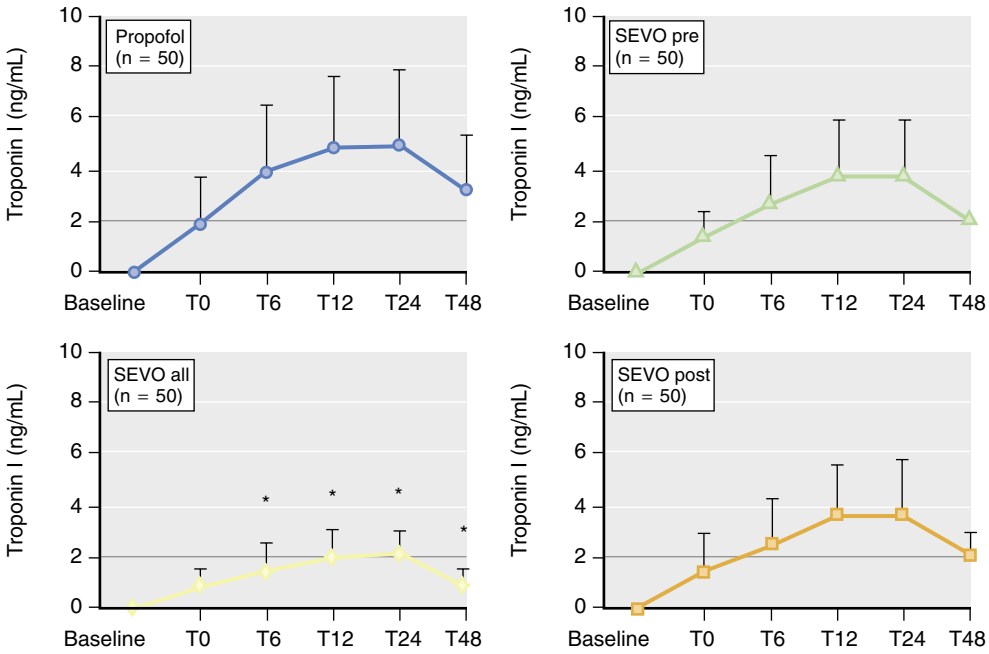

Figure 23-18 Cardiac troponin I concentrations in the four groups before surgery (baseline), at arrival in the intensive care unit (T0), and after 6 (T6), 12 (T12), 24 (T24), and 48 (T48) hours. Data are presented as means ± SD. *Statistically significant difference with the propofol group ($P < .05$). In all groups, a transient increase in troponin I concentrations was observed. Only in the SEVO all group was this increase significantly less than in the propofol group. For the sake of clarity, the SD bars are represented in only one direction. SEVO, sevoflurane. *(From De Hert SG, ten Broecke PW, Mertens E, et al: Sevoflurane but not propofol preserves myocardial function in coronary surgery patients. Anesthesiology 97:42-49, 2002.)*

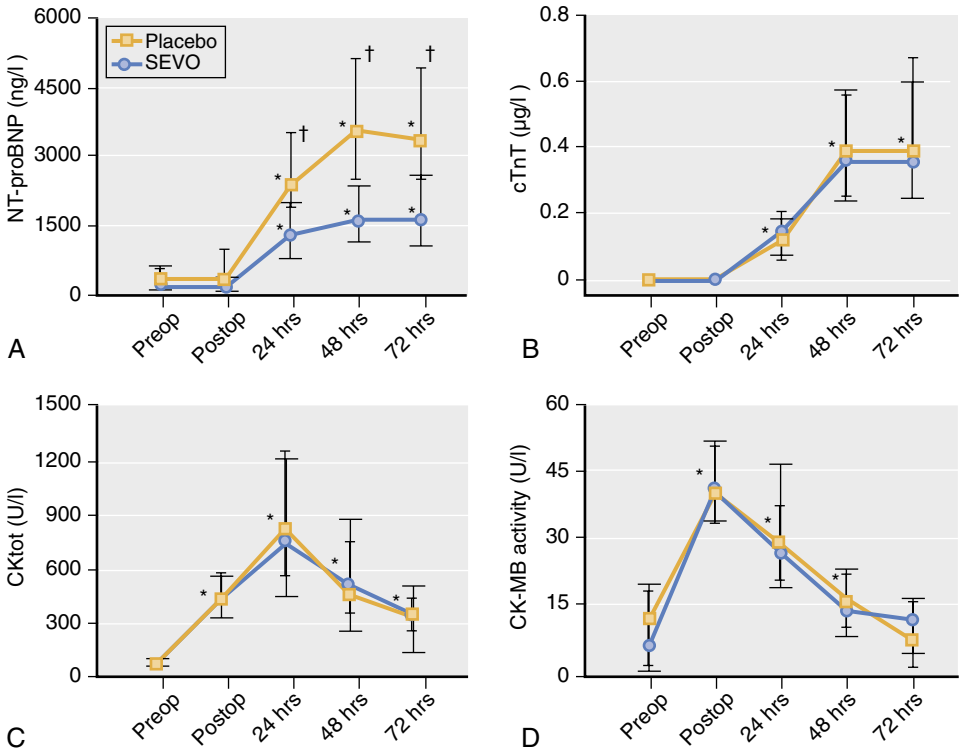

Figure 23-19 Biomarkers of myocardial injury at various time points for the placebo (PLACEBO)- and sevoflurane (SEVO)-treated groups: N-terminal pro–brain natriuretic peptide (NT-proBNP) (**A**), cardiac troponin T (cTnT) (**B**), total creatine kinase (CKtot) (**C**), and creatine kinase-MB (CK-MB) isoenzyme activity (**D**). Two-factor repeated-measures analysis of variance indicated that the groups differed significantly in plasma NT-proBNP concentrations (time effect, $P < .001$; group effect, $P < .001$; group-time interaction, $P = .003$). There was no difference in cTnT, CKtot, and CK-MB concentrations. Multiple *t*-tests with the Bonferroni correction for multiple comparisons were used to compare plasma concentrations of the different biomarkers at each time point with the respective preoperative baseline value within groups and to compare plasma concentrations at each time point between groups. *Significantly increased in comparison to baseline values ($P < 0.05$). †Significant difference between groups ($P < 0.05$). PLACEBO, group with a narrow cap; SEVO, group with a wide cap. The plot shows medians and lower and upper quartiles. *(From Julier K, da Silva R, Garcia C, et al: Preconditioning by sevoflurane decreases biochemical markers for myocardial and renal dysfunction in coronary artery bypass graft surgery: A double-blinded, placebo-controlled multicenter study. Anesthesiology 98:1315-1327, 2003.)*

pulmonary bypass.[254] When compared with placebo, brief (10-minute) administration of 4% sevoflurane reduced platelet–endothelial cell adhesion molecule-1 (PECAM-1/CD31) and increased catalase expression in atrial biopsy specimens concomitant with a reduction in the indices of myocardial injury (e.g., cardiac troponin T, N-terminal pro-BNP) in patients undergoing CABG surgery and cardiopulmonary bypass.[255] The membrane protein PECAM-1 has been shown to play important roles in atherosclerotic plaque instability and migration of leukocytes through the vascular endothelium. Notably, an improvement in 1-year cardiovascular outcome was also observed in sevoflurane-preconditioned patients in this study.[255] These compelling data suggest that volatile anesthetics may exert long-term beneficial effects against ischemic injury in patients with coronary artery disease, in part by favorably modulating transcription of protective and antiprotective proteins.

More recently, low end-tidal concentrations (0.5% to 1.0%) of sevoflurane were shown to protect against endothelial damage in human volunteers undergoing 15-minute forearm ischemia followed by reperfusion.[256] A marked reduction in reactive hyperemic response (an indicator of ischemic injury and endothelial function) and attenuation of leukocyte activation (as measured by CD11a expression) were observed in volunteers pretreated with sevoflurane but not in those who were not.[256] Sevoflurane-induced alterations in genetic regulatory control of myocardial energy metabolism were also recently suggested to predict postoperative cardiac function in patients undergoing off-pump CABG surgery.[257] These data confirmed and extended previous findings indicating that desflurane decreases troponin I release, reduces inotropic drug use, and decreases the number of patients requiring prolonged hospitalization when compared with a propofol-opioid–based intravenous anesthetic technique in patients undergoing off-pump CABG surgery.[258] A meta-analysis of 22 previous studies incorporating more than 2800 patients undergoing CABG surgery suggested that sevoflurane and desflurane anesthesia was associated with reductions in postoperative troponin I release, but whether this decrease in a major index of myocardial necrosis translated into improved long-term outcome was unclear.[259] Thus, clinical investigations conducted to date provide tantalizing evidence suggesting that volatile anesthetics may represent an important therapeutic modality to reduce the risk for perioperative myocardial ischemia and infarction, but this contention will require a large-scale, randomized clinical trial for confirmation.

Volatile Anesthetics and Neural Control of the Circulation

Volatile anesthetics have been shown to depress baroreceptor reflex control of arterial pressure in experimental animals to varying degrees. This inhibition of baroreceptor reflex activity occurs as a result of depression of central nervous system integration of afferent baroreceptor input, attenuation of efferent autonomic nervous system activity, and reductions in ganglionic transmission and end-organ response. Volatile anesthetics increase resting afferent nerve traffic and enhance the sensitivity of arterial baroreceptors by a Ca^{2+}-dependent mechanism. These anesthetic-induced increases in baroreceptor sensitivity and discharge frequency tonically reduce overall sympathetic nervous system activity and attenuate sympathetic responses to declines in arterial pressure.[260] Isoflurane and the older volatile anesthetics halothane and enflurane inhibited preganglionic sympathetic efferent activity at clinically relevant concentrations in vivo. Volatile anesthetics reduced postganglionic sympathetic nerve activity, suggesting that attenuation of ganglionic transmission represents a major mechanism by which volatile anesthetics depress sympathetic nerve traffic. Depression of the sympathetic outflow caused by volatile anesthetics has also been suggested by examination of endogenous plasma norepinephrine kinetics. Isoflurane and halothane decreased plasma concentrations of norepinephrine to varying degrees by causing more pronounced reductions in norepinephrine spillover than clearance. Volatile anesthetics may also attenuate parasympathetic nervous system function. The older agent halothane was shown to depress vagal nerve efferent activity by direct measurement of parasympathetic nerve activity. These findings were supported by the results of several other studies demonstrating that volatile anesthetics inhibit reflex bradycardia in response to increases in arterial pressure. Parasympathetic and sympathetic nervous system outflow appears to be depressed to an equivalent degree during halothane or isoflurane anesthesia.

The effects of volatile anesthetics on neural control of the cardiovascular system have been incompletely examined in healthy humans and have not been described in patients with autonomic nervous system dysfunction. Halothane and enflurane produced greater attenuation of baroreceptor reflex regulation of the heart rate than equivalent MAC concentrations of isoflurane did. Depression of baroreceptor function by these volatile anesthetics may be more profound than with fentanyl, diazepam, and nitrous oxide anesthesia. Baroreceptor-mediated control of peripheral arteriolar tone was also attenuated in young volunteers during halothane anesthesia. Steady-state anesthetic concentrations of sevoflurane were shown to cause greater depression of sympathetic nerve activity measured directly by microneurography than desflurane did at equivalent levels of hypotension.[261] These findings paralleled results demonstrating pronounced sympathetic hyperactivity during rapid increases in inspired desflurane concentration in humans.[262] Importantly, the actions of volatile anesthetics on baroreceptor reflex control of the circulation may be profoundly altered during autonomic dysfunction in elderly patients or in those with essential hypertension, diabetes mellitus, or heart failure.

Nitrous Oxide and Cardiovascular Function

Myocardial Contractility and Left Ventricular Diastolic Function

Experiments in papillary muscle and isolated heart preparations have consistently demonstrated that nitrous oxide produces a direct negative inotropic effect. Conflicting results about the influence of nitrous oxide on contractility have been observed in experimental animals and healthy volunteers. Several problems have contributed to the apparently contradictory results in vivo. The changes in contractile function observed may be influenced by the actions of nitrous oxide on the systemic circulation or by autonomic nervous system reflex effects because nitrous oxide may increase sympathetic nervous system tone.[263] Studies using nitrous oxide alone are difficult to perform and interpret because this gas does not produce total anesthesia at partial pressures of less than 1 atm. The effects of nitrous oxide on contractile function may be influenced by different baseline anesthetics. Finally, lack of use of load-insensitive measures of myocardial contractility has allowed only qualitative assessment of the effects of nitrous oxide on the intrinsic inotropic state in the intact heart.

The regional preload recruitable stroke work relationship demonstrated that nitrous oxide depresses myocardial contractility in dogs anesthetized with isoflurane or sufentanil in the absence of autonomic nervous system activity.[264] Seventy percent nitrous oxide decreased M_w by 28% and 41% during sufentanil and isoflurane anesthesia, respectively. These results indicated that 70% nitrous oxide decreases contractility to approximately the same extent as 1 MAC isoflurane does. Similar findings were reported with the use of LV end-systolic pressure-dimension relationships in acutely instrumented dogs. These nitrous oxide–induced myocardial depressant effects may be offset by concomitant increases in sympathetic nervous system tone. The negative inotropic actions of nitrous oxide may be more pronounced in the presence of preexisting LV dysfunction.[265] In addition, nitrous oxide–induced depression of contractile function appeared to overcome the mild sympathomimetic effect of this anesthetic gas in patients with coronary artery or valvular heart disease and LV dysfunction because increases in baseline sympathetic nervous system activity were not further augmented by nitrous oxide in these clinical conditions.

The actions of nitrous oxide on LV diastolic function have been incompletely studied. Modest increases in maximal lengthening velocity and maximal rate of decline in force were observed in ferret papillary muscle concomitant with decreases in the contractile state.[266] No changes in the rate of isometric or isotonic relaxation were observed, indicating that nitrous oxide does not substantially modify myocardial relaxation. Nitrous oxide modestly increased segmental indices of LV chamber stiffness and reduced early LV filling in acutely instrumented dogs. These findings were supported by evidence indicating that nitrous oxide may produce LV diastolic dysfunction after cardiopulmonary bypass in patients undergoing CABG surgery.[267] Nitrous oxide caused dose-related reductions in the intracellular Ca^{2+} transient in vitro.[268] This finding indicated that nitrous oxide–induced depression of myocardial contractility was related to

decreases in the availability of Ca^{2+} for contractile activation. Nitrous oxide did not affect myofibrillar sensitivity to Ca^{2+} or Ca^{2+} uptake and release from the SR. In addition, the diastolic Ca^{2+} transient was unaffected by nitrous oxide, suggesting that this anesthetic gas does not alter myocardial relaxation kinetics.[266,268]

Hemodynamics

Assessment of the hemodynamic effects of nitrous oxide in humans is often complicated by concomitant administration of volatile anesthetics, opioids, or other anesthetic adjuvants in the presence or absence of cardiovascular disease. Typical clinical concentrations of nitrous oxide (e.g., 40% to 70%) caused modest increases in heart rate in healthy volunteers. Small increases in heart rate also occurred when hyperbaric concentrations of nitrous oxide were administered or when this anesthetic gas was added to volatile anesthetics. Declines in heart rate were observed with nitrous oxide in patients with coronary artery disease who were anesthetized with isoflurane. Modest reductions in heart rate have also been reported in patients anesthetized with morphine or fentanyl who were undergoing cardiac surgery. Sixty percent nitrous oxide caused small increases in arterial pressure in humans. Increases in arterial pressure also occurred under hyperbaric conditions or during volatile anesthesia in volunteers, consistent with a mild sympathomimetic effect. Other studies have also indicated that partial substitution of nitrous oxide for a volatile anesthetic either did not affect or modestly increased arterial pressure during isoflurane or desflurane anesthesia in experiments conducted at constant MAC. In contrast, reductions in arterial pressure have been observed in patients with coronary artery disease who received nitrous oxide in the presence and absence of opioids.

Small increases in cardiac output and stroke volume have been observed during the administration of 60% nitrous oxide in oxygen to volunteers, but cardiac output remained unchanged in the presence of hyperbaric nitrous oxide. Cardiac output has been shown to be greater in volunteers anesthetized with nitrous oxide and the older agent halothane than in those receiving halothane alone concomitant with increases in sympathetic nervous system tone. The addition of nitrous oxide to isoflurane or desflurane anesthesia also modestly increased cardiac output. In contrast, nitrous oxide reduced cardiac output and stroke volume in healthy volunteers and patients with cardiac disease receiving opioids. Hyperbaric nitrous oxide (1.5 MAC) caused a modest reduction in systemic vascular resistance. In contrast, systemic vascular resistance was higher during volatile anesthesia in the presence of nitrous oxide than in its absence. Pretreatment with the ganglionic blocker hexamethonium attenuated the relative increase in systemic vascular resistance observed during the administration of halothane and nitrous oxide, findings that may be consistent with a reduction in sympathetic nervous system tone. Nitrous oxide–induced increases in systemic vascular resistance have also been reported in volunteers and patients with cardiac disease who were anesthetized with opioids.

Nitrous oxide increases venous tone and decreases venous capacitance in conscious volunteers. This anesthetic gas has also been shown to modestly increase pulmonary artery pressure and pulmonary vascular resistance in patients with coronary artery disease who are anesthetized with morphine and diazepam or a volatile anesthetic. Thus, the combined effects of enhanced venous return, elevated pulmonary vascular resistance, and depressed contractile function probably contributed to the increases in central venous pressure observed with nitrous oxide in humans. Hyperbaric nitrous oxide also enhanced central venous pressure in association with increases in pulmonary vascular resistance. Nitrous oxide inhibited uptake of norepinephrine by the lung, and subsequent increases in plasma norepinephrine levels detected in the pulmonary vasculature may be partially responsible for the characteristic increases in pulmonary vascular resistance observed during administration of this agent. Nitrous oxide–induced increases in pulmonary vascular resistance may be more pronounced in adults with pulmonary hypertension and children with increased pulmonary blood flow. Increases in pulmonary artery pressure and vascular resistance have also been described during the administration of nitrous oxide to neonatal lambs. Such increases in pulmonary vascular resistance may potentially enhance right-to-left atrial or ventricular shunts and thereby compromise arterial oxygenation in patients with congenital heart disease.

Nitrous Oxide and Cardiac Electrophysiology

Reversible atrioventricular dissociation occurs in humans anesthetized with nitrous oxide and volatile or opioid-based anesthetics. The addition of nitrous oxide to halothane anesthesia lowered the threshold at which arrhythmias occur. This observation may result from a combination of stimulation of the sympathetic nervous system by nitrous oxide and myocardial sensitization by halothane. The incidence of arrhythmias was lower during combined nitrous oxide–opioid anesthesia than during halothane anesthesia alone.

Nitrous Oxide and the Coronary Circulation

Nitrous oxide did not produce direct effects on the coronary vasculature in vitro.[269] This anesthetic gas altered coronary blood flow concomitant with changes in MVo_2 in dogs. Nitrous oxide decreased myocardial segment shortening,[270] increased postsystolic shortening, and redistributed transmural coronary blood flow preferentially to the subepicardium (decreased endo/epi ratio) in experimental models of coronary artery disease. Nitrous oxide decreased the recovery of contractile function of canine stunned myocardium[271] and, in contrast to the findings with isoflurane, did not reduce myocardial infarct size in rats.[272] These data suggested that administration of nitrous oxide before or during transient or prolonged coronary artery occlusion and reperfusion is not associated with a cardioprotective effect. Nitrous oxide–induced sympathetic nervous system activation and imbalances in myocardial O_2 supply and MVo_2 are potential mechanisms for the absence of any beneficial effect during reversible or irreversible ischemic injury. In the presence of a volatile

anesthetic, nitrous oxide decreased MVo_2 and myocardial O_2 extraction and may exacerbate myocardial ischemia during concomitant reductions in arterial pressure in patients with coronary artery disease. However, the addition of nitrous oxide to volatile or opioid anesthetics did not increase the incidence of new regional wall motion abnormalities as assessed by transesophageal echocardiography in this patient population.

Nitrous Oxide and Neural Control of the Circulation

Nitrous oxide caused pupillary dilation, diaphoresis, and increases in systemic vascular resistance, central blood volume, and forearm vascular resistance in volunteers during volatile anesthesia, suggesting that nitrous oxide activates the sympathetic nervous system. A subsequent study demonstrated that nitrous oxide increases sympathetic nerve traffic measured via sympathetic microneurography in human volunteers, especially during the first 15 to 30 minutes of exposure to this anesthetic gas. Baroreceptor reflex–mediated control of heart rate was impaired during the administration of nitrous oxide, but regulation of sympathetic outflow to peripheral blood vessels was preserved.[263] This finding suggested that nitrous oxide does not alter sympathetic vasoconstrictor–induced maintenance of arterial pressure, which may be partially responsible for the relative stability of hemodynamics during nitrous oxide anesthesia.

Xenon

The anesthetic properties of the noble gas xenon were first described more than 50 years ago. Xenon has a blood-gas partition coefficient less than that of nitrous oxide, does not undergo biotransformation, provides rapid induction and emergence from anesthesia,[273] and exerts analgesic effects[274] independent of α_2-adrenergic and opioid receptors.[275] Despite these advantageous properties, xenon has not been routinely used for clinical anesthesia in the United States because it is more expensive than nitrous oxide and volatile anesthetics. In recent years, more efficient manufacturing techniques and the development of low-flow administration and recycling systems have reduced the cost of xenon and rekindled interest in its clinical use. Many of these issues are succinctly summarized in two excellent reviews.[276,277]

Xenon causes minimal systemic and pulmonary hemodynamic effects in vivo,[278] preserves or very modestly reduces myocardial contractility,[279,280] and attenuates alterations in hemodynamics and increases in plasma epinephrine and cortisol concentrations associated with surgical stimulation.[281,282] Xenon did not alter cardiac function or major ion currents in isolated guinea pig hearts and ventricular myocytes.[283] Similar findings were observed in isolated human atrial myocytes.[284] Several studies have recently identified the cardiac and neural protective effects of Xe.[277] The cellular mechanisms responsible for these salutary actions were initially unclear based on data indicating that xenon does not affect the amplitudes of Na^+, L-type Ca^{2+}, and inwardly rectifying K^+ channels in whole-cell patch-clamped myocytes.[283] Xe was initially shown to produce cardioprotection when the anesthetic noble gas was administered early during reperfusion in rabbits.[285] Subsequently, pretreatment with 70% Xe before ischemia was demonstrated to reduce infarct size in rats (from 51% to 28% of the LV area at risk) by activating PKC-ε and its downstream targets p38 MAPK,[286] MAPKAPK-2,[121] and HSP-27.[121] Roles for mitochondrial K_{ATP} channels, PDK1, and ERK1/2 were also implicated in Xe preconditioning,[287,288] suggesting that prosurvival signaling may play an important role in cardioprotection by Xe. Whether Xe preserves myocardial integrity by favorably modulating proteins responsible for the regulation of apoptosis through the mPTP remains unclear. Because Xe and volatile anesthetics exert similar actions on endogenous cardioprotective signal transduction, the reductions in infarct size produced by this noble gas have been assumed to be related to its anesthetic actions.[277] However, other noble gases without anesthetic properties (e.g., helium, neon) also produce cardioprotection by activating prosurvival signaling and inhibiting the mPTP.[289]

The effects of xenon in experimental models of or patients with congestive heart failure have not been studied extensively. Systemic hemodynamics, LV systolic and diastolic function, and the determinants of LV afterload were examined in chronically instrumented dogs before and after the development of rapid LV pacing–induced cardiomyopathy.[279] Xenon was remarkably devoid of hemodynamic effects in normal and cardiomyopathic dogs anesthetized with isoflurane. Xenon did not alter isoflurane-induced reductions in the preload recruitable stroke work slope (M_w) in the presence and absence of pacing-induced LV dysfunction. Xenon caused greater increases in the time constant of isovolumic relaxation in isoflurane-anesthetized, cardiomyopathic dogs than in normal dogs, but indices of early LV filling and chamber compliance remained unchanged, which suggested that xenon does not appreciably influence LV diastolic function during isoflurane anesthesia. Xenon also produced relatively minor alterations in the determinants of LV afterload in dogs before and after pacing. Taken together, these data indicate that xenon produces very subtle cardiovascular effects during isoflurane anesthesia in dogs with and without experimental dilated cardiomyopathy.[1] Finally, 56% xenon (end-tidal concentration) depressed sympathetic and parasympathetic nervous system transmission to a greater extent than did 0.8 MAC isoflurane in healthy patients undergoing elective surgery.

Summary

Volatile anesthetics exert profound effects on the cardiovascular system by altering the inotropic, chronotropic, dromotropic, and lusitropic state of the heart. These anesthetics also have significant actions on both the preload and afterload systems. These pharmacologic effects cause dramatic changes in hemodynamics that may be accentuated in patients with underlying cardiovascular disease. Less profound but equally important effects are observed with nitrous oxide and xenon. Volatile anesthetics and xenon but not nitrous oxide are cardioprotective and directly reduce the sequelae of ischemia and reperfusion injury. The use of inhaled anesthetics requires a clear understanding of their complex cardiovascular pharmacology.

24 Inhaled Anesthetics: Metabolism and Toxicity

Key Points

1. The liver is the major site of endogenous and exogenous drug metabolism. The primary result of drug metabolism is the production of more water-soluble and therefore more easily excreted drug metabolites. Drugs are sometimes biotransformed into more reactive metabolites that may lead to toxicity.
2. Most drug metabolism is catalyzed by phase 1 or phase 2 enzymes. The predominant phase 1 enzymes are the cytochrome P450 (CYP) monooxygenases. Approximately 50 of the more than 1000 CYP isoforms are functionally active in humans. The predominant isoform catalyzing the metabolism of inhaled anesthetics is CYP2E1. The major phase 2 enzyme is uridine diphosphate glucuronosyltransferase.
3. Many factors affect drug metabolism. Perhaps the most important are pharmacogenetic factors. Genetics ultimately determines absorption, distribution, metabolism, and excretion. Other important determinants are environmental factors, age, gender, disease states, and other drugs or medications. Induction and inhibition of CYP enzymes because of concurrent medications can have an important impact on therapeutic drug levels and pharmacologic effects.
4. Pharmacogenomics, or the influence of DNA sequence variation on the effect of a drug, provides a basis for understanding the interindividual variation observed in drug responses.
5. Nitrous oxide and xenon are both nonhalogenated anesthetics. Xenon is not currently approved for clinical use; however, aside from the expense associated with its use, it may be the most ideal and environmentally friendly anesthetic agent.
6. The combination of drug-related antibodies, the apparent need for prior sensitization, and the association of fever and eosinophilia all support an immune basis for anesthetic-induced hepatitis.
7. Halothane, enflurane, isoflurane, and desflurane are all metabolized to trifluoroacylated hepatic protein adducts that have been reported to induce liver injury in susceptible patients. The propensity to produce liver injury appears to parallel metabolism of the parent drug; thus, halothane (20%) ⋙ enflurane (2.5%) ≫ isoflurane (0.2%) > desflurane (0.02%). The incidence of halothane hepatitis in the adult population is roughly 1 in 10,000. Sevoflurane does not produce acylated protein adducts.
8. Halothane hepatitis has been reported in the pediatric population. The incidence appears to be approximately 1 in 200,000.
9. Toxicity and liver injury have been reported after repeat exposure on subsequent occasions to different fluorinated anesthetics. This phenomenon of cross-sensitization has also been reported with hydrochlorofluorocarbons, the chlorofluorocarbon replacement agents.
10. Sevoflurane is metabolized to hexafluoroisopropanol, formaldehyde, inorganic fluoride, and carbon dioxide. Although very high fluoride levels have been reported after sevoflurane anesthesia, fluoride-associated renal injury has not been reported.
11. The major base-catalyzed breakdown product of sevoflurane is compound A. Compound A is a nephrotoxic vinyl ether that induces both dose- and time-dependent renal injury. The threshold for renal injury in rats and humans appears to be approximately 150 ppm-hours of exposure to compound A (i.e., 50 ppm for 3 hours). The toxic threshold appears to be reached only under clinical conditions of prolonged sevoflurane anesthesia, and changes in glucosuria and enzymuria are observed. Blood urea nitrogen and creatinine levels remain unchanged. To date, no significant clinical renal toxicity has been associated with the use of sevoflurane.
12. Desiccated carbon dioxide absorbent and inhaled anesthetic interactions can lead to the production of carbon monoxide in the anesthesia circuit (desflurane ⋙ enflurane > isoflurane). Negligible amounts of carbon monoxide are formed from halothane and sevoflurane.
13. New calcium hydroxide–based CO_2 absorbents, such as Amsorb and DragerSorb Free, contain neither NaOH or KOH and thus are chemically inert and do not degrade inhaled anesthetics to carbon monoxide or degrade sevoflurane to compound A.

14. The interaction of inhaled anesthetics with CO_2 absorbents is an exothermic reaction resulting in the production of heat. The temperature of CO_2 canisters during routine clinical use averages 25°C to 45°C but increases inversely with decreased fresh gas flow, and sevoflurane is associated with the greatest production of heat. Hydrogen is an important by-product of this reaction. The high yield of hydrogen, ease of ignition, and low tissue solubility make hydrogen the most likely fuel in anesthesia machine fires because of its reactions with desiccated CO_2 absorbents and sevoflurane. This reaction can be significant and result in fire, toxic gas, and patient injury.
15. There appears to be no risk associated with brief periods of low-level occupational exposure to waste anesthetic gases (operating room, postanesthesia care unit, intensive care unit). Occupational exposure to high concentrations (10^3 ppm) may be correlated with an increased incidence of abortions and decreased fertility. Individuals with vitamin B_{12} deficiency may be at risk for neurologic injury from nitrous oxide.
16. Fluorinated inhaled anesthetics containing bromine and chlorine deplete ozone (halothane ⋙ enflurane > isoflurane) and contribute to the greenhouse gas effect and global warming. N_2O does not deplete ozone, but it does contribute to the greenhouse gas effect and global warming.

Once a drug is administered, it undergoes the processes of absorption, distribution, target interaction, metabolism, and excretion. Unlike most drugs, the inhaled anesthetics are administered in great excess of the amount metabolized, and thus biotransformation has little effect on the pharmacologic activity of anesthetics but may have a significant effect on anesthetic toxicities. It was once thought that the inhaled anesthetics were chemically inert. We now know that many of these anesthetic agents undergo significant metabolism and in many cases biotransform and chemically breakdown to reactive and potentially toxic intermediates. The metabolic processes are affected by many factors, including age, disease, drug-drug interactions, and perhaps most important, genetics. This chapter focuses on the current understanding of mechanisms of anesthetic-associated toxicities, particularly liver injury and the role of drug metabolism in many of these processes. The mechanisms and risks resulting from the interaction of carbon dioxide absorbents with inhaled anesthetics, as well as other side effects of inhaled anesthetics, are also reviewed.

Drug Metabolism and Biotransformation

The Liver and Drug Metabolism

The lipophilic characteristics of drugs that promote their passage through biologic membranes hinder their excretion from the body. Drug metabolism is therefore essential for elimination and termination of the biologic activity of lipophilic drugs because it usually results in the formation of more hydrophilic products that are less pharmacologically active and more readily excreted from the body (Fig. 24-1). Drug metabolism sometimes results in the formation of intermediates whose pharmacologic or toxicologic activity is equal to, greater than, or different from that of the parent drug.[1] Unlike most drugs, the inhaled anesthetics are administered in great excess of the amount metabolized and are excreted mainly by exhalation. Thus, biotransformation has little effect on the pharmacologic activity of anesthetics, but it may have a significant effect on the toxicity of these agents.[2] The inhaled anesthetics are absorbed through the epithelium and mucous membranes of the respiratory tract. Because of the large pulmonary surface area, access to the circulation is rapid, with

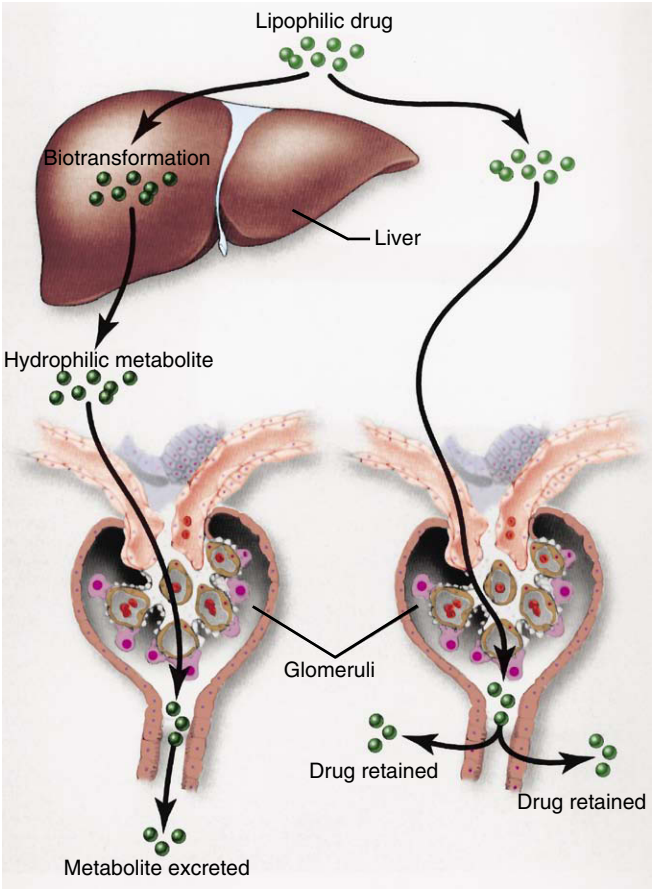

Figure 24-1 Effect of drug metabolism on excretion. Lipophilic (fat-soluble) drugs are metabolized to form relatively more hydrophilic (water-soluble) metabolites than the parent drug, and these metabolites are thus more easily excreted. *(From Weinshilboum R: Inheritance and drug response. N Engl J Med 348:529-557, 2003.)*

almost instantaneous absorption of these agents into blood and avoidance of hepatic first-pass metabolism. Thus, the pharmacologic effects of inhaled anesthetics are quite rapid and less dependent on factors governing the activities of other drugs, such as the amount of drug administered, the extent and rate of absorption, protein binding, excretion, secretion, and metabolism.[3]

The liver is the primary organ of drug metabolism because of its large size, rich concentration of drug-metabolizing enzymes, and unique double blood supply consisting of 70% of flow from the portal vein and 30% from the hepatic artery. Blood in the portal vein comes from the alimentary tract, pancreas, and spleen. Toxic materials absorbed from the alimentary tract are processed by the liver before they enter the systemic circulation. Blood flows through the hepatic sinusoids from the periphery of the hepatic lobule, fed by portal veins and hepatic arteries, to the centrally located hepatic venule or central vein. Hepatocytes, which are bathed by the sinusoidal blood supply, are the major drug-metabolizing cells in the liver and body. Several drug-metabolizing enzyme systems are located within the smooth endoplasmic reticulum of hepatocytes, whereas others are found in the cytosol of these cells. Organs with significant drug-metabolizing activity in addition to the liver are the gastrointestinal tract, kidneys, and lungs.[4,5]

The major enzymatic reactions biotransforming drugs into metabolites are oxidation, hydrolysis, and conjugation. It is very common for a drug to be metabolized into several metabolites. The ratios of various metabolites of a drug depend on enzymatic reaction rates, drug concentration near the enzymes, physicochemical reactions between metabolites and enzymes, competition of multiple drugs or endogenous substrates for the same enzyme, and many other factors.[5] Drug biotransformation reactions are broadly classified into phase 1 functionalization reactions or phase 2 biosynthetic conjugation reactions. Phase 1 reactions are catalyzed by enzymes that introduce or expose a polar functional group such as a hydroxyl or amino moiety in a drug by oxidation and hydrolytic reactions, respectively, whereas phase 2 reactions often lead to enzymatic conjugation of these polar functional groups to very polar molecules. The net effect of these reactions is the formation of molecules that are more easily excreted into urine through the kidneys or into the gastrointestinal tract by biliary excretion. *N*-Acetylation is the exception because it leads to the formation of less water-soluble metabolites.

The phase 1 enzymes most relevant to the metabolism of inhaled anesthetics are the cytochrome P450 (CYP) isoforms. These enzymes are capable of catalyzing several different types of oxidation reactions, including dehalogenation, *N*- and *O*-dealkylation, *N*- and S-oxidation, and deamination reactions. All these reactions require CYP, O_2, and reduced nicotinamide adenine dinucleotide phosphate (NADPH)-dependent cytochrome P450 reductase for activity and occur in the endoplasmic reticulum of cells, particularly hepatocytes. Under conditions of low oxygen tension, these enzymes may catalyze reductive reactions. Approximately 50 of the more than 1000 CYP isoforms are functionally active in humans and are categorized into 17 families and subfamilies. Sequences that are greater than 40% homologous belong to the same family and are identified by an Arabic number. The sequences of subfamily members are at least 55% identical and are distinguished by a capital letter. An Arabic number is used to distinguish individual isoforms within a subfamily. CYP2E1, for example, is a member of the CYP2 family, a large group of isozymes that metabolize many diverse drugs and endogenous compounds.[6] Approximately 10 isoforms in the CYP1, CYP2, and CYP3 families are responsible for the majority of drug metabolism in humans (Fig. 24-2). Most CYP isoforms metabolize multiple drugs, and some overlap in substrate specificity can be seen between the various isoforms. Thus, two or more CYP isoforms may be involved in the overall metabolism of a drug. In human liver, the CYP3A4 and CYP3A5 subfamilies account for as much as 60% of the total CYP present. CYP2E1 is particularly important in the oxidative metabolism of halogenated inhaled anesthetics, and like many CYP isozymes, it is concentrated in perivenular hepatocytes.

In phase 2 reactions, a polar molecule such as glucuronic acid, sulfate, or glycine is conjugated to a drug or its metabolites to produce highly hydrophilic products that are readily excreted into urine or in some cases into bile and the gastrointestinal tract. Glucuronidation is perhaps the most important conjugation reaction, and uridine 5′-diphosphate glucuronosyltransferase (UGT) catalyzes the transfer of glucuronic acid to aromatic and aliphatic alcohols, carboxylic acids, amines, and free sulfhydryl groups to form *O*-, *N*-, and *S*-glucuronides, respectively. UGTs, like CYPs, exist as multiple isoforms with differing substrate specificities and are localized in the endoplasmic reticulum, whereas most other phase 2 enzymes are concentrated in the cytosol. Glucuronidation is also important in the elimination of endogenous steroids, bilirubin, bile acids, and fat-soluble vitamins. Cytosolic sulfation is another important conjugation reaction that involves the catalytic transfer, by various sulfotransferase members, of inorganic sulfate from activated 3′-phosphoadenosine-5′ phosphosulfate to the hydroxyl group of phenols and aliphatic alcohols. Thus, drugs and primary metabolites with a hydroxyl group often form both glucuronide and sulfate conjugates. Two *N*-acetyltransferases, NAT1 and NAT2, are involved in the acylation of amines, hydrazines, and sulfonamides (see Fig. 24-2).

Factors Affecting Drug Metabolism

Various factors may affect drug metabolism, including environmental determinants, disease, age, gender, and genetics. The activity of many drug-metabolizing enzymes may be increased (*induced*) or decreased (*inhibited*) by concomitantly administered substances or drugs. Enzyme induction is due to enhanced gene transcription after prolonged exposure to an induction agent or, in some instances, is due to a decreased rate of enzyme degradation. Induction of CYP isozymes by numerous drugs and environmental agents has been studied extensively.[7] Enzyme inducers are often highly lipophilic drugs and environmental chemicals that are metabolized by the CYP isozymes that they induce. The inducing properties of a drug are unrelated to the nature of its pharmacologic or toxicologic activity and may differ markedly from those of other drugs in the same class. Induction by drugs such as phenobarbital results in proliferation of the smooth endoplasmic reticulum and an increase in liver weight. With this type of inducer, NADPH–cytochrome P450 reductase and specific CYP isozymes are preferentially increased. Although other inducers increase the synthesis of specific CYP isozymes, they do not affect cytochrome P450 reductase or liver weight. The mechanism by which CYP3A4 is induced is shown in Figure 24-3A, and the effect on plasma felodipine concentrations in healthy subjects is shown in Figure 24-3B.[8] Importantly, CYP3A4 induction is the result of de novo protein synthesis, and thus several weeks is needed before steady-state levels are reached. Likewise, once use

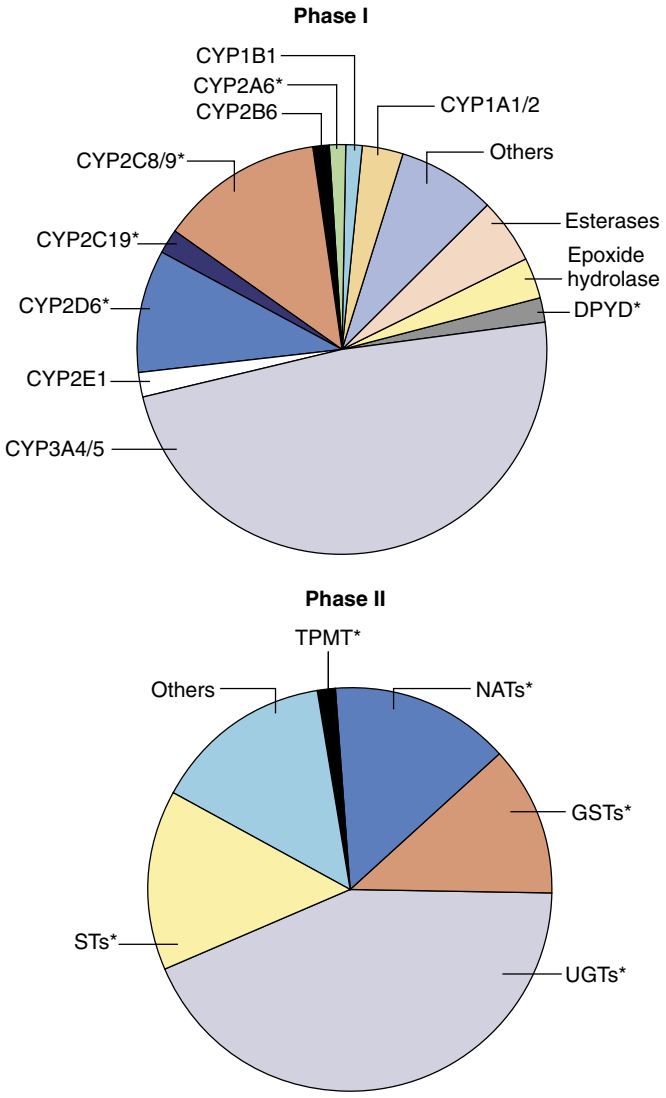

Figure 24-2 Proportion of drugs metabolized by major phase 1 or phase 2 enzymes. The relative size of each pie section indicates the estimated percentage of phase 1 (*top panel*) or phase 2 (*bottom panel*) metabolism that each enzyme contributes to the metabolism of drugs based on literature reports. Enzymes that have functional allelic variants are indicated by an *asterisk*. In many cases, more than one enzyme is involved in a particular drug's metabolism. CYP, cytochrome P450; DPYD, dihydropyridine dehydrogenase; GST, glutathione-*S*-transferase; NAT, *N*-acetyltransferase; STs, sulfotransferases; TPMT, thiopurine methyltransferase; UGT, uridine diphosphate glucuronosyltransferases. *(Adapted from Wilkinson G: Pharmacokinetics: The dynamics of drug absorption, distribution and elimination.* In *Hardman JG, Limbird LE, Goodman GA [eds]: Goodman and Gilman's The Pharmacological Basis of Therapeutics, 10th ed. New York, McGraw-Hill, 2001.)*

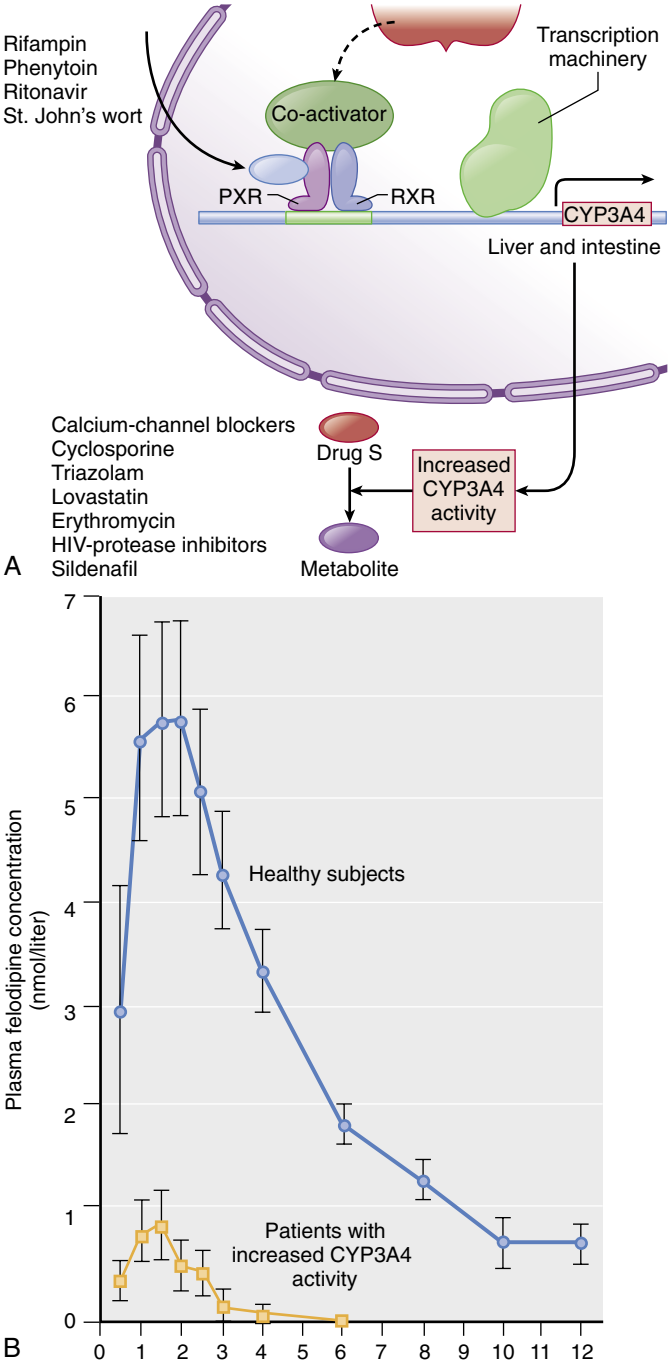

Figure 24-3 Mechanism of induction of CYP3A4-mediated metabolism of drug substrates (**A**) and the resulting reduced plasma drug concentration (**B**). In **A**, an inducing agent (Drug) interacts with the nuclear pregnane X receptor (PXR) to form a heterodimer with the retinoid X receptor (RXR); in turn, the heterodimer binds to cognate recognition sites in the 5′ regulatory region of the CYP3A4 gene. As a result, transcription of DNA is upregulated, which leads to increased synthesis of CYP3A4 enzyme and enhanced oxidative metabolism of its substrates (Drug S). This causes a reduction in the plasma drug concentration as exemplified by felodipine (**B**) and, subsequently, decreased drug effects. The same molecular mechanism is also responsible for the induction of other metabolizing enzymes and membrane transporters important in drug disposition. Comparison of the plasma felodipine concentration-time profiles in **B** with those in **A** indicates the wide range of CYP3A activity that is possible. *I bars* denote standard errors. *(From Wilkinson GR: Drug metabolism and variability among patients in drug response. N Engl J Med 352:2211-2221, 2005.)*

of the inducing drug is discontinued, it may be several weeks before baseline levels of CYP3A4 are established. Many classes of drugs and environmental chemicals, including anesthetics, anticonvulsants, insecticides, sedatives, steroids, tranquilizers, and the anti–human immunodeficiency virus (HIV) agents efavirenz and nevirapine contain one or more compounds thought to be enzyme inducers.[7] St. John's wort is also a known inducer of CYP3A. If the parent compound is toxic, enhanced metabolism may decrease its toxicity. In contrast, when metabolites are more toxic than the parent compound, metabolism increases toxicity. In many cases

involving induction, the dosage of an affected drug must be increased to maintain the therapeutic effect. Enzyme-inducing agents have the potential to modify acute and chronic toxicities of anesthetics. In view of the current practice of polypharmacy, enzyme induction may be more common in patients who are undergoing surgery than previously appreciated.

Enzyme inhibition can have as great an effect on therapeutic activity and toxicity as enzyme induction. Enzyme inhibition can lead to an increase in the plasma concentration of the parent drug and a reduction in drug metabolites, as well as exaggerated and prolonged pharmacologic effects and increased potential for toxicity. Many compounds inhibit the activity of drug-metabolizing enzymes and thereby alter the duration and intensity of pharmacologic action and the severity of toxic effects. There are several mechanisms of inhibition. Inhibitors of protein synthesis such as cycloheximide decrease enzyme synthesis and thereby reduce enzyme concentrations. Other agents are reversible inhibitors that compete for the active site of the same enzyme responsible for metabolism of the drug of interest. Still others are irreversible inhibitors that degrade the heme in cytochrome P450. Inhibition of CYP3A is common and important because of the high expression of CYP3A in intestinal epithelium and the fact that oral ingestion is the most common route of entry for drugs. After oral ingestion, bioavailability is potentially increased because of a reduction in first-pass metabolism. Inhibition of CYP3A4, for example, is noted with the ingestion of grapefruit juice. Regular consumption of 250 mL of grapefruit juice will inhibit intestinal CYP3A4 activity. A patient taking oral felodipine with grapefruit juice will experience side effects associated with an overdose of this calcium channel antagonist, such as hypotension and tachycardia, as a result of decreased levels of CYP3A4 (Fig. 24-4).[8] Potent CYP3A inhibitors include ritonavir, diltiazem, nicardipine, verapamil, and several anti-HIV agents (delavirdine, indinavir, ritonavir, and saquinavir). More general CYP inhibitors include amiodarone, cimetidine, and the macrolide antibiotics erythromycin, clarithromycin, and troleandomycin.

Some sex-related differences in drug-metabolizing activity have been observed, particularly for CYP3A, but such differences are minor relative to previously described factors. An exception is the treatment of seizure patients with phenytoin during pregnancy. Because the liver is the major site of drug metabolism, intrinsic liver disease leading to hepatic dysfunction can result in impaired drug metabolism. Diseases such as hepatitis, primary biliary cirrhosis, alcoholic liver disease, cirrhosis, and hepatocarcinoma can lead to a 50% impairment of enzymatic activity. Severe cardiac failure with decreased hepatic perfusion and impaired metabolism can also occur, as evidenced by the twofold difference in loading and maintenance doses of lidocaine for treatment of dysrhythmia in heart failure patients. Moreover, viral infections can lead to the inhibition of CYP-mediated reactions.

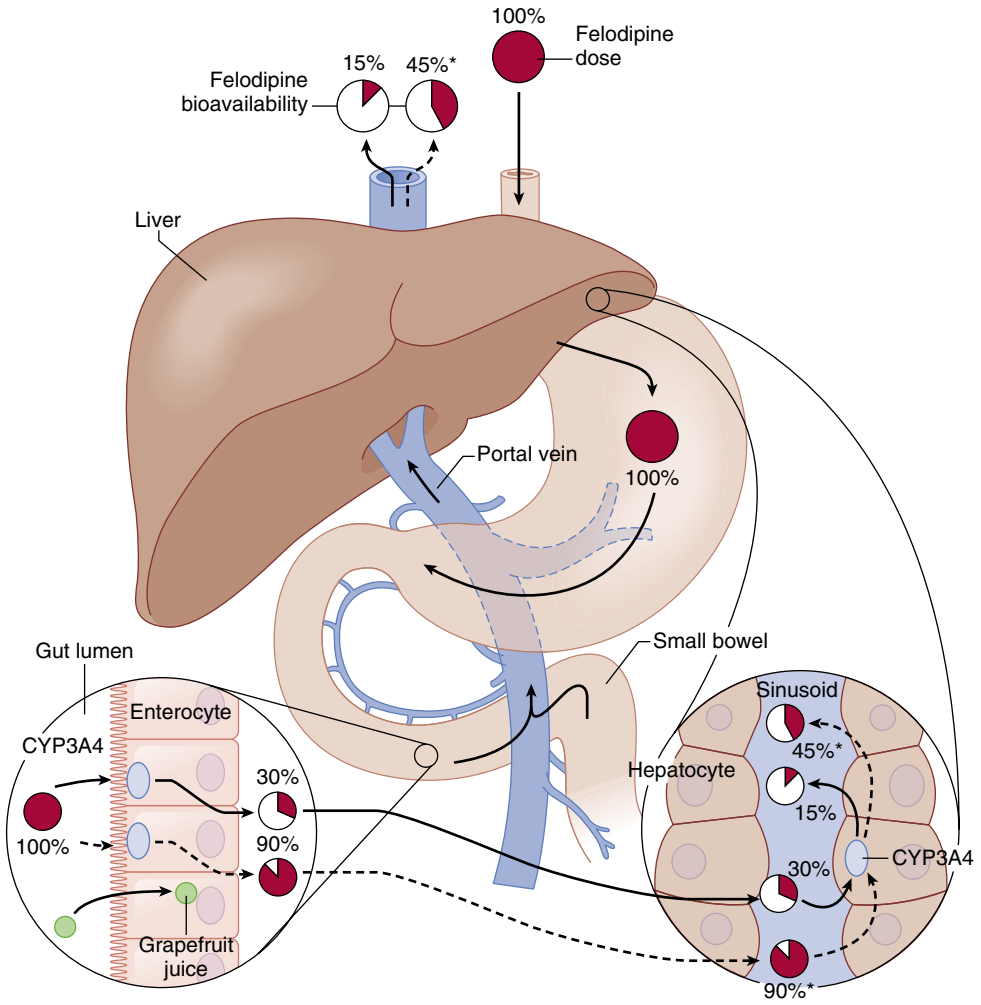

Figure 24-4 First-pass metabolism after the oral administration of a drug, as exemplified by felodipine and its interaction with grapefruit juice. The CYP3A enzymes (e.g., CYP3A4) present in enterocytes of the intestinal epithelium extensively metabolize felodipine during its absorption, and on average only 30% of the dose administered enters the portal vein (*solid line*). Subsequently, CYP3A enzymes in the liver further metabolize the drug so that only 15% of the dose is bioavailable and finally reaches the systemic circulation, where it is able to exert its effects. Grapefruit juice selectively inhibits CYP3A in the enterocyte, with the net result being an increase in the oral bioavailability of felodipine by a factor of 3, denoted by the *asterisks* and the *dashed lines*. *(From Wilkinson GR: Drug metabolism and variability among patients in drug response. N Engl J Med 352:2211-2221, 2005.)*

Developmental Differences in Infants and Children

Both phase 1 and phase 2 enzymes begin to mature during the postnatal period (also see Chapter 82), but the levels may be low enough in some cases to result in toxicity if drug therapy is not carefully monitored. For example, impairment of bilirubin glucuronidation at birth can lead to hyperbilirubinemia of the newborn and the "gray baby" syndrome as a result of high levels of the antibiotic chloramphenicol.[9,10] As children age, phase 1 enzymes appear to be affected to a greater degree than phase 2 enzymes. The predominant isoform expressed in fetal liver is CYP3A7, which peaks shortly after birth and then declines rapidly to levels that are undetectable in most adults.[11] Within hours of birth, CYP2E1 activity increases, followed by CYP2D6, CYP3A4, CYP2C9, and CYP2C19. CYP1A2 is the last isoform to appear at about 2 months of age. CYP2C9 and CYP2C19 are responsible for the biotransformation of phenytoin. The apparent half-life of phenytoin is prolonged to about 75 hours in preterm neonates but decreases to about 20 hours in term neonates during the first week of life and to 8 hours by the second week.[12]

Pharmacogenetics of Drug Metabolism

Advances in the field of genetics have had a major impact on drug metabolism and have provided the experimental tools to probe the genetic basis of intersubject variability in human drug pharmacokinetics, metabolism, and toxicity.[13] Although CYPs are most often thought of as being responsible for the deactivation of toxic compounds, they are in fact also responsible for the metabolic activation of drugs and chemicals to toxic forms. Any factor that can influence metabolism has the potential to affect toxicity. As previously discussed, drug biotransformation may be affected by many factors, including route of administration, frequency of administration, exposure to other chemicals, sex, age, diet, and genetics. The concept of pharmacogenetics originated from the clinical observation that there were patients with very low or very high plasma or urinary drug levels, followed by the realization that the biochemical traits leading to this variation were inherited. Soon thereafter, drug-metabolizing enzymes were identified, followed by discovery of the genes encoding the proteins and the DNA sequences within the genes. Most of the early pharmacogenetic traits were monogenic, involving a single gene, and most were due to genetic polymorphism.

The early discovery that impairment in the phase 1 hydrolysis of succinylcholine by butyrylcholinesterase was inherited served as an early stimulus to the development of pharmacogenetics. About 1 in 3500 white individuals is homozygous for a gene encoding an atypical form of butyrylcholinesterase. These individuals have less ability to hydrolyze succinylcholine, and thus the neuromuscular blocking effects of this drug are prolonged.[14,15] More recent studies have demonstrated that CYP2D6 represents one of the best understood examples of pharmacogenetic variation in drug metabolism. Substrates for CYP2D6 include codeine, metoprolol, nortriptyline, dextromethorphan, debrisoquin, and sparteine.[16] Approximately 5% to 10% of white subjects were found to be deficient in the ability to metabolize the antihypertensive drug debrisoquin[16] and the antiarrhythmic drug sparteine,[17] which resulted in low levels of urinary metabolites and high plasma concentrations of the parent compounds. These deficiencies were found to be inherited as an autosomal recessive trait.[17,18] The cDNA for the gene encoding CYP2D6 has been cloned, and a number of genetic variants responsible for the deficient activity of CYP2D6 have been identified. Other subjects have multiple copies of active forms of CYP2D6 that result in rapid elimination of drugs leading to subtherapeutic levels. Such is the case with the antidepressant nortriptyline (Fig. 24-5). Many other examples of poor metabolizers of drugs who have genetic variants of other CYP isoforms have been described. For example, CYP2C9 variants can lead to poor metabolism of warfarin and phenytoin and subsequent toxic levels of these compounds. Similarly, polymorphisms in the phase 2 metabolizing enzyme NAT can lead to bimodal differences in *N*-acetylation and inactivation of the antituberculosis drug isoniazid (Fig. 24-6). More recent molecular cloning studies have shown that there are two NAT genes in humans, *NAT1* and *NAT2*, and that the common genotypic polymorphism responsible for the pharmacogenetic variation in isoniazid metabolism involves the *NAT2* gene.[19] The frequency of each acetylation phenotype is dependent on race but not on sex or age. Fast acetylation is found in the Inuit and Japanese, whereas slow acetylation predominates among Scandinavians and North African white individuals.[20] Another example of the role of genetics in phase 2 metabolism concerns the antineoplastic drug azathioprine, a prodrug that is converted to the active drug 6-mercaptopurine. Thiopurines such as 6-mercaptopurine are metabolized by thiopurine-*S*-methyltransferase (TPMT).[21] This enzymatic activity is inherited in an autosomal codominant fashion. Individuals homozygous for alleles encoding inactive TPMT and receiving standard doses of azathioprine are at risk for the development of severe pancytopenia.

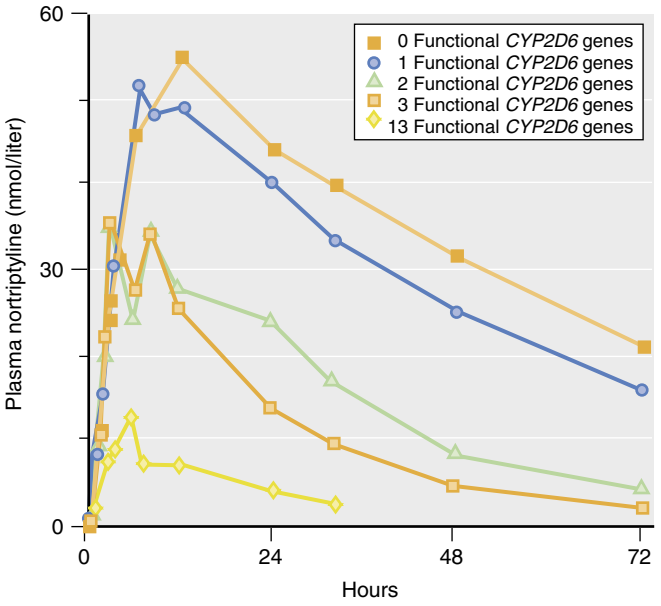

Figure 24-5 Pharmacogenetics of nortriptyline. Mean plasma concentrations of nortriptyline after a single 25-mg oral dose are shown in subjects with 0, 1, 2, 3, or 13 functional CYP2D6 genes. *(Adapted from Weinshilboum R: Inheritance and drug response. N Engl J Med 348:529-537, 2003.)*

Pharmacogenomics of Drug Metabolism

The convergence of pharmacogenetics and human genomics has resulted in the field of *pharmacogenomics*, a term used to describe

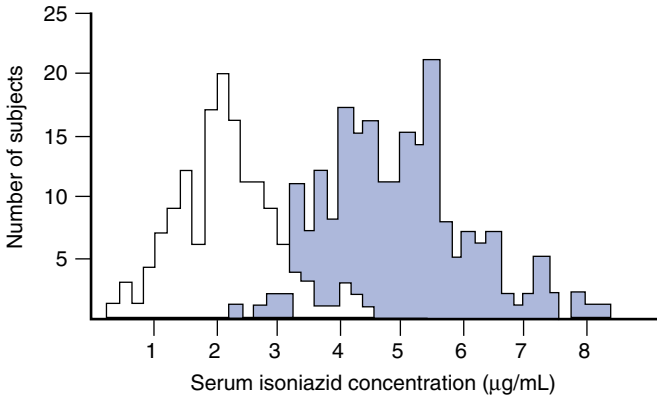

Figure 24-6 Bimodal distribution of serum isoniazid concentrations in a large group of Finnish patients. More than 300 patients were given intravenous injections of 5 mg/kg of isoniazid. Serum drug concentrations were assayed at multiple times after injection. The distribution of serum concentrations of isoniazid is shown 180 minutes after injection. The *blue* histogram represents rapid inactivators and the *black* histogram, slow inactivators. *(From Petri WA Jr: Antimicrobial Mycobacterium complex disease and leprosy. In Hardman JG, Limbird LE, Goodman GA [eds]: Goodman and Gillman's The Pharmacological Basis of Therapeutics, 10th ed. New York, McGraw-Hill, 2001.)*

the influence of variations in DNA sequence on drug responses. Pharmacogenomics holds the promise of personalized medicine: offering patients a precisely targeted drug at a precisely calibrated dose to address a specific condition. The field of pharmacogenomics began with a focus on drug metabolism but has been extended to include the full spectrum of drug disposition, including absorption, transporters, excretion, drug targets, and signal transduction. With completion of the Human Genome Project, the time is rapidly approaching when the sequences of virtually all genes encoding enzymes that catalyze both phase 1 and phase 2 reactions will be known. More than 1.4 million single-nucleotide polymorphisms were identified in the initial screening of the human genome, with over 60,000 in the coding region for genes. Some of these single-nucleotide polymorphisms have already been associated with substantial changes in the metabolism or effects of medications, and some are currently being used to predict clinical response. The potential exists for pharmacogenomics to yield a powerful set of molecular diagnostic tools with which clinicians will select medications and drug doses for individual patients. For example, a growing understanding of pharmacogenomics has led to the implementation of clinical genotyping of certain narrow–therapeutic index drugs such as the thiopurine derivatives azathioprine and 6-mercaptopurine for acute lymphoblastic lymphoma[22] and the colorectal agent irinotecan.[23] The anticoagulant warfarin, which has a narrow therapeutic range and large variations in individual patient dosage requirements, has been studied, and it has been found that mean maintenance doses depend on the CYP2C9 genotype.[24] In reports investigating the genes encoding CYP2C9 and vitamin K epoxide reductase (VKORC1), researchers demonstrated that patients with CYP2C9*2 and CYP2C9*3 allelic variants and the VKORC1 haplotype A/A require lower dosages of warfarin to achieve adequate levels of warfarin with minimal risk of bleeding.[25,26] A more recent report showed that the initial variability in the international normalized ratio (INR) response to warfarin was more strongly associated with genetic variability related to VKORC1 than to CYP2C9.[27] Both the CYP2C9 genotype and the VKORC1 haplotype had a significant influence on the warfarin dose required after the first 2 weeks of therapy. In effect, the maintenance dose of warfarin in persons heterozygous for CYP2C9*2/*3 is lower than the dose in patients who are homozygous for the normal enzyme or in compound heterozygotes. For the homozygous CYP3C9*3 genotype, even smaller doses are required to achieve the desired INR levels for anticoagulation. In the summer of 2007, the Food and Drug Administration found the accumulated evidence related to warfarin dosing compelling enough to warrant a change in the package labeling of warfarin "to highlight the potential relevance of genetic information to prescribing decisions." Predictably, drugs that inhibit CYP2C9, such as amiodarone and fluconazole, when taken with warfarin will result in an enhanced anticoagulant effect and increased risk of bleeding. In contrast, drugs that impair the metabolism of warfarin, such as cimetidine and omeprazole, have only slight potentiating effects on anticoagulation.

Metabolism of Inhaled Anesthetics

Nonhalogenated Inhaled Anesthetics

Nitrous Oxide

Nitrous oxide (N_2O) is the only nonhalogenated anesthetic that currently remains in routine clinical use. This agent is not metabolized in human tissue. However, by means of a physicochemical reaction of N_2O with vitamin B_{12}, N_2O is reductively metabolized by rat and human intestinal bacteria to molecular nitrogen (N_2). Reduction of N_2O in bacteria may occur via a single electron transfer process that results in the formation of nitrogen gas (N_2) and free radicals. N_2O can oxidize vitamin B_{12} and inhibit its coenzyme function. For example, this could affect the activity of methionine synthase, which catalyzes the transmethylation from methyltetrahydrofolate and homocysteine to produce tetrahydrofolate and methionine. Inhibition of methionine synthase has the potential to lead to decreased levels of tetrahydrofolate and methionine and subsequent impairment of DNA synthesis and "carbon 1" metabolic reactions, including methylation. However, such an effect on the activity of vitamin B_{12} would probably be inconsequential with the short courses of exposure to N_2O during anesthesia.

Xenon

The inert noble gases helium, neon, argon, krypton, xenon, and radon have found diverse and expanding applications in clinical medicine.[28] Xenon, krypton, and argon are all chemically inert in most circumstances, and all have anesthetic properties. Xenon is of particular interest because it is the only inert gas that is an anesthetic under normobaric conditions. Xenon was first identified as an anesthetic agent in 1951.[29] Although not approved for clinical use, xenon has been submitted for regulatory medical approval in Europe. Xenon is a normal constituent in atmospheric air at a concentration no greater than 0.086 ppm and thus, unlike all other inhaled anesthetics, it is not an environmental pollutant. The gas cannot be manufactured but is

Table 24-1 Anesthetic Properties of Xenon versus Other Anesthetics

	Xenon	Nitrous Oxide	Isoflurane	Desflurane	Sevoflurane
Oil-gas partition coefficient	1.9	1.4	90	18.7	53.4
Blood-gas partition coefficient	0.14	0.47	1.4	0.42	0.6
Minimum alveolar concentration (%)	71	≈105	1.15	6.0	1.71

recovered in the process of fractional distillation of liquefied air, and after several separation steps, a purity of greater than 99.99% can be obtained. The cost of xenon is presently about $10.00 (U.S.) per liter (100 times more expensive than nitrous oxide), and it may be unlikely to enjoy widespread use because of the expense associated with its extraction from air. If this problem could be overcome, xenon would be the most ideal inhaled anesthetic agent because xenon (minimum alveolar concentration [MAC] of 71%) is more potent than nitrous oxide, can provide surgical anesthesia in 30% oxygen, is very insoluble (blood-gas partition coefficient of 0.14), and has positive medical and environmental effects (Table 24-1). Xenon exhibits minimal cardiovascular and hemodynamic side effects, is not known to be metabolized in the liver or kidney, is not teratogenic, and does not trigger malignant hyperthermia in susceptible swine.[30] Recent evidence suggests both a neuroprotective[31] and a cardioprotective effect after exposure to xenon.[32] Environmental positives are that xenon does not deplete stratospheric ozone or contribute to global warming and the greenhouse effect. The unique combination of analgesia, hypnosis, and lack of cardiovascular depression in this one agent makes xenon a very attractive choice for patients with limited cardiovascular reserve. Xenon has a density of 5.887 g/L, with nitrous oxide and air having densities of 1.53 and 1.00 g/L, respectively. Because of its greater density, xenon does lead to an increase in pulmonary resistance, which results in an increase in the work of breathing.[33] Thus, xenon should be used with caution in patients with moderate to severe chronic obstructive pulmonary disease, the morbidly obese, premature infants, and any other patient in whom an increase in the work of breathing might have adverse effects.

Xenon was first used successfully for general anesthesia in human volunteers and patients in the 1950s,[29,34] was largely forgotten for 40 years, and then was rediscovered in 1990.[35] Over the past 20 years, xenon has been studied intensively in Europe and Japan in a number of clinical trials with very promising results.[36-38] Lachmann and colleagues showed that patients anesthetized with 70% xenon and 30% oxygen required 80% less supplemental fentanyl than did a similar group anesthetized with 70% nitrous oxide and 30% oxygen.[35] In a comparison of 30 American Society of Anesthesiologists (ASA) class I and II patients undergoing total abdominal hysterectomy and receiving either 60% xenon, 60% nitrous oxide with 0.5% isoflurane, or 60% nitrous oxide with 0.7% sevoflurane (all patients had epidurals and received mepivacaine to control the heart rate and blood pressure to within 20% of baseline), Goto and associates found that emergence from xenon anesthesia was two to three times faster than either comparison group.[39] In a randomized controlled multicenter trial, a total of 224 patients from six centers received either 60% xenon in 40% oxygen or 60% nitrous oxide in 0.5% isoflurane, with 1 µg sufentanil administered if indicated by defined criteria.[40] This study demonstrated significantly faster recovery from xenon anesthesia than from isoflurane–nitrous oxide anesthesia. Goto and coworkers showed that hemodynamic stability was better with xenon than with nitrous oxide with respect to maintenance of left ventricular systolic function.[41] More recently, a randomized multicenter trial was undertaken to compare left ventricular function in patients without cardiac disease who were undergoing elective surgery under either xenon or isoflurane anesthesia.[42] Xenon did not reduce contractility, whereas isoflurane decreased the contractile index, suggesting that xenon provides favorable cardiovascular stability in patients without cardiovascular disease. Although it is clear that emergence from xenon anesthesia is more rapid than emergence from desflurane or propofol anesthesia, studies have not found any significant differences in postoperative cognitive measures in patients exposed to these two agents.[43] In a recent study involving ASA III patients undergoing aortic surgery and receiving xenon ($n = 20$) or remifentanil ($n = 19$), no advantage of total intravenous anesthesia over xenon was demonstrated.[44] A recent study that included 40 ASA III and IV patients with known coronary artery disease randomized to either xenon ($n = 20$) or propofol ($n = 20$) anesthesia, both supplemented with remifentanil, showed higher arterial pressure and better left ventricular function, as assessed by echocardiograph indices, with xenon than with propofol.[45] It is certainly too early to know whether xenon anesthesia improves clinical outcomes, particularly in high-risk patients, and thus justifies the additional cost associated with its use in clinical anesthesia.

During xenon anesthesia, nitrogen released from the patient's body accumulates in the anesthesia circuit. Consequently, it is necessary to perform prolonged denitrogenation before starting xenon administration to reduce the risk for hypoxia. Another technical challenge lies in the transition from denitrogenation to closed-circuit xenon anesthesia. One could simply increase fresh gas flow (too expensive) or add xenon to the circuit as oxygen is consumed by the patient. This second method is too slow because patients typically consume only 200 to 250 mL of oxygen per minute. Several investigators use a second anesthesia machine already primed with 4 L of xenon. Thus, xenon must be given with a rebreathing system, low fresh gas flow, or a closed-circuit system. A closed-circuit system is the most economical technique for the clinical use of xenon. In the 2-hour study from Japan by Goto and colleagues, the estimated cost of providing anesthesia per patient was $170.00 for xenon ($17.00/L), $57.00 for isoflurane, and $60.00 for sevoflurane.[39] These differences in cost would be different in the United States, where xenon is $10.00/L, and would become progressively smaller with a longer duration of anesthesia because the rate of xenon consumption declines exponentially as body tissues become saturated in a closed rebreathing system. The total yearly production of xenon is approximately 6 million L, or enough for about 400,000 anesthetic procedures. If delivery systems become available that allow recycling of anesthetic gases, xenon anesthesia may become more economical and accessible to selected patients who might benefit from its lack of adverse systemic effects.

Halogenated Inhaled Anesthetics

Halothane

Approximately 25% of the halothane ($CF_3CHBrCl$) administered is metabolized to trifluoroacetic acid, chloride (Cl^-), and bromide (Br^-) (Fig. 24-7). The major metabolite in humans is trifluoroacetic acid (CF_3COOH), formed from oxidative metabolism primarily by CYP2E1 and to a lesser extent by CYP2A6.[46] The rate-limiting step in oxidative metabolism is breakage of the carbon-hydrogen bond. The first intermediate formed is probably 1,1,1-trifluoro-2-chloro-2-bromoethanol, which would be expected to rapidly decompose and produce hydrogen bromide and the reactive metabolite trifluoroacetyl chloride (TFA-Cl). This latter metabolite reacts with water to produce HCl and trifluoroacetic acid and with phosphatidylethanolamine, a membrane phospholipid, to form *N*-trifluoroacetyl-2-aminoethanol, which has been identified in urine. The TFA-Cl metabolite of halothane also reacts with tissue proteins to form trifluoroacetylated (TFA)-protein adducts, which will be discussed in the section on hepatotoxicity. Although trifluoroethanol has been identified in the urine of experimental animals, this metabolite and its glucuronide conjugate have not been found in human urine. Likewise, trifluoroacetaldehyde, another possible metabolite, has not been isolated from human urine.

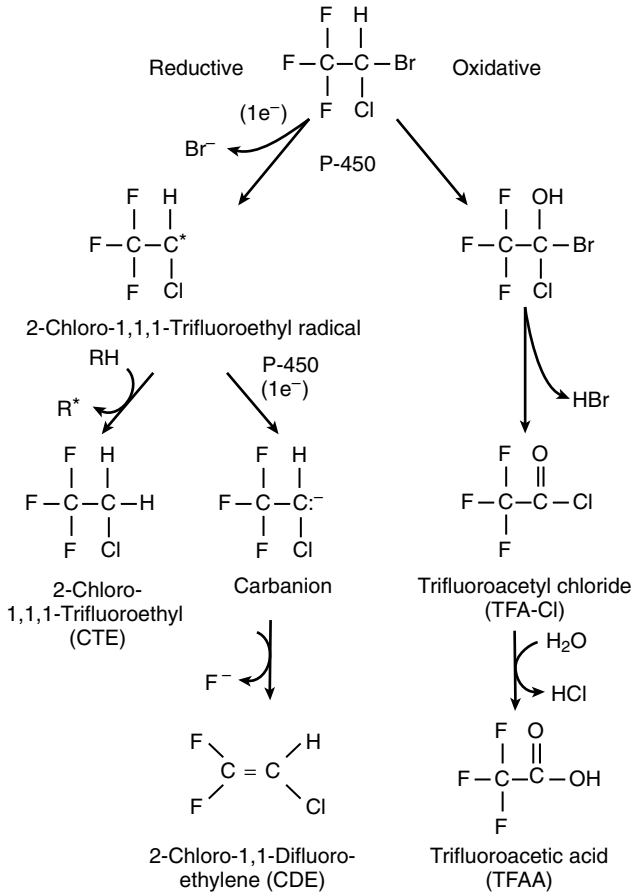

Figure 24-7 Major by-products of oxidative and reductive CYP4502E1-catalyzed halothane metabolism.

An alternative and minor route of halothane metabolism (i.e., <1% of the halothane absorbed) is via a reductive pathway that requires low oxygen tension and can be catalyzed by CYP2A6 and CYP3A4 (see Fig. 24-7).[46] Inorganic Br^- and F^- are end products of this pathway. Two volatile metabolites (2-chloro-1,1-difluoro-ethylene [CDE] and 2-chloro-1,1,1-trifluorethane [CTE]) and a volatile decomposition product of halothane (2-bromo-2-chloro-1,1-difluoroethylene [DBE]) were first identified in the exhaled gases of patients anesthetized with halothane. The formation of CDE and release of F^- probably result from a CYP-mediated two-electron reduction of halothane, whereas the formation of CTE and production of tissue free radicals result from a CYP-mediated one-electron reduction. The suicidal inactivation of CYP observed under hypoxic conditions (<40 torr O_2) is presumably the result of covalent binding of a reactive intermediate of CTE to CYP formed during the metabolism of CTE by CYP. A major pathway of formation of DBE is via the base-catalyzed dehydrofluorination of halothane as a result of its interaction with soda lime. CYP2E1 is inducible by both ethanol and isoniazid and is inhibited by disulfiram.[47] Prolonged exposure to subanesthetic concentrations of halothane results in increased drug metabolism in humans.

Enflurane

Enflurane (CHF_2-O-CF_2-CHClF) is essentially no longer used in the United States, but examination of its metabolism serves to illustrate how relatively minor changes in chemical structure can dramatically affect the extent of metabolism. Approximately 2.5% of the enflurane absorbed is metabolized (Fig. 24-8). Initial oxidation and breaking of the carbon-hydrogen bond may occur at either the chlorofluoromethyl carbon or the difluoromethyl carbon. Studies of the metabolism of enflurane with human hepatic microsomes[48] and isolation of difluoromethoxydifluoroacetic acid from rat liver, human urine, human hepatic microsomes, and cDNA-expressed CYP2E1[48] suggest that primary metabolism occurs at the chlorofluoromethyl carbon. Detection of insignificant amounts of chlorofluoroacetic acid further suggests that there is very little metabolism at the difluorormethyl carbon. The reactive intermediate formed from oxidation at the chlorofluoromethyl carbon can either hydrolyze to produce difluoromethoxydifluoroacetic acid or acetylate tissue protein to produce an adduct with immunogenic potential.[49] In either case, inorganic F^- is a product of these chemical reactions.

Surgical patients treated on a long-term basis with phenobarbital, phenytoin, or diazepam or who consumed ethanol before anesthesia with enflurane did not have elevated serum F^- concentrations when compared with untreated patients. In contrast, about 50% of surgical patients maintained on chronic isoniazid therapy demonstrated significantly elevated serum F^- concentrations.[50] Studies with purified CYP2E1 from humans[51] demonstrate that this CYP isoform is predominantly, if not exclusively, responsible for the defluorination of enflurane in human liver. Isoniazid treatment seems to significantly enhance enflurane metabolism in humans.[51]

Isoflurane

Isoflurane (CHF_2-O-CHCl-CF_3), an isomer of enflurane, is metabolized even more slowly than halothane or enflurane is (≈0.2%) (see Fig. 24-8). The metabolism of isoflurane results from oxidation of the α-carbon by hepatic CYP2E1.[52,53] The initial hydroxylated intermediate can decompose to produce a reactive

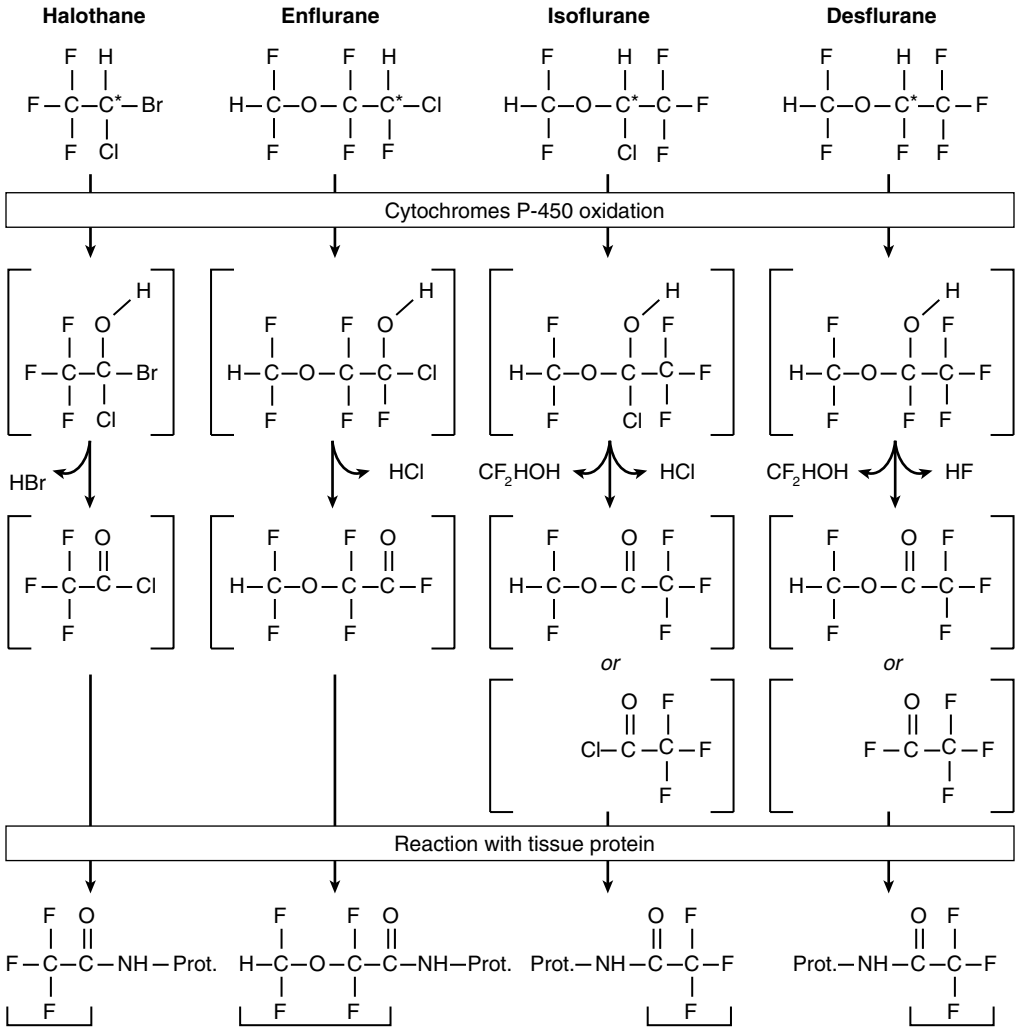

Figure 24-8 Proposed pathways for the CYP4502E1-catalyzed metabolism of halothane, enflurane, isoflurane, and desflurane to acylated hepatic proteins. For halothane, isoflurane, and desflurane, the trifluoracetylated protein adducts are identical in structure, whereas for enflurane the adduct is immunologically similar.

TFA-Cl metabolite identical to halothane or a reactive trifluoroacetyl ester intermediate. Both these products would be expected to react with water to form trifluoroacetic acid or with protein to produce TFA-protein adducts. Very small amounts of inorganic fluoride would be expected to be formed during this metabolism.

Desflurane

Desflurane (CHF_2-O-CHF-CF_3) is thought to be metabolized in a manner similar to isoflurane because these two molecules differ by only one atom at the α-carbon position, with desflurane having a fluorine atom and isoflurane having a chlorine atom (see Fig. 24-8). However, the fluorine atom substitution decreases metabolism at the α-carbon position significantly so that the F^- and nonvolatile organic fluorine compounds formed from the metabolism of desflurane are considerably less than with isoflurane. Peak serum F^- concentrations are seen immediately after exposure to desflurane.[54]

Sevoflurane

The rate of sevoflurane (CH_2F-O-CH-$[CF_3]_2$) defluorination in vitro is approximately the same as that of methoxyflurane. However, serum F^- concentrations after sevoflurane administration are significantly less than those after methoxyflurane,[55-57] presumably the result of large differences in the blood-gas partition coefficients of the two agents (0.69 for sevoflurane versus 10.2 for methoxyflurane). Approximately 5% of the sevoflurane absorbed is biotransformed.[57,58] The fluoromethoxy C-H bond is the site of oxidative metabolism of sevoflurane, which leads to the formation of hexafluoroisopropanol (HFIP) and inorganic F^- (Fig. 24-9).[59,60] Experiments using CYP2E1 purified from humans have confirmed the results of in vitro studies with liver microsomes that this isozyme is the predominant, if not the only CYP participating in sevoflurane oxidation and F^- formation.

In a study of human volunteers, HFIP accounted for 80% of the nonvolatile organic fluorine-containing compounds detected in the blood and urine of volunteers anesthetized with sevoflurane. HFIP is not subject to further degradation, but it is conjugated to form a glucuronide conjugate.[58,61] Studies in patients and volunteers have shown that much of the metabolism of sevoflurane to F^- occurs during anesthetic exposure, presumably because of the low tissue solubility of sevoflurane and the stability of its metabolites.[62,63] Peak serum F^- concentrations are reached within a few hours of the end of anesthesia.

Stereoselective Metabolism of Inhaled Anesthetics

Until recently, drug stereochemistry has been an area of relative neglect with regard to the preparation of therapeutic agents. Many drugs, including the fluorinated anesthetics, are commercially prepared and used therapeutically as racemic mixtures. A racemic mixture contains an equal amount of the two enantiomers. Enantiomers are simply nonsuperimposable mirror images, such as your left and right hands. Clinical experience has made it increasingly clear that enantiomeric forms of drugs may differ in their potency, toxicity, and pharmacologic, pharmacokinetic, and pharmacodynamic properties and actions.[64-67] Such nonsuperimposable objects are said to be chiral. The most common chiral origin is the presence of an asymmetric center, a carbon atom attached to four different substitute groups. Enantiomers are optically active; that is, a single enantiomeric form rotates the plane of polarized light passing through an aqueous solution of the enantiomer in a clockwise or counterclockwise direction. The preferred method of the International Union of Pure and Applied Chemistry (IUPAC) for the classification of enantiomers is the Cahn-Perlog-Ingold convention or (*R*/*S*) classification. In this system the four substitutions around the chiral center are assigned priorities that depend on atomic number and atomic mass. When looking down the carbon bond to the substituent with the lowest priority, if the other substituents are ordered from higher to lower in a clockwise direction, the assignment is the (*R*)-configuration; if counterclockwise, the (*S*)-configuration is designated.

The reduced cost of production of purified enantiomeric solutions has made these compounds increasingly available for clinical use. Whether the clinical use of a single stereoisomer provides significant advantages depends on both the pharmacokinetic and the pharmacodynamic properties of the respective enantiomers. For example, (*S*)-penicillamine is used to treat Wilson's disease, cystinuria, and rheumatoid arthritis because of toxicities associated with the racemic drug.[68] The calcium channel blocker (*S*)-verapamil is 10 to 20 times more potent than (*R*)-verapamil and thus appears to be a better antiarrhythmic, antianginal, and antihypertensive agent.[69] The cardiovascular drug (*S*)-propranolol is clinically useful as an antihypertensive and antianginal agent, whereas (*R*)-propranolol, which lacks cardiovascular effects, is useful in the treatment of hypothyroidism.[70,71] Ketamine is provided for clinical use as a racemic mixture, although (*S*)-ketamine has superior efficacy, faster elimination and recovery characteristics, and fewer side effects ranging from restlessness and agitation to emergence reactions than racemic ketamine does.[72] (*S*)-Ketamine is also three times more potent than (*R*)-ketamine as an anesthetic and analgesic agent, and enantiomeric stereoselectivity of the hepatic metabolism of ketamine by microsomal enzymes has been demonstrated.[73] Ropivacaine, the (*S*)-enantiomer of a bupivacaine homolog, and levobupivacaine ([*S*]-bupivacaine) were developed as alternatives to racemic bupivacaine because of its known central nervous system and cardiovascular toxicity. Ropivacaine is less potent than (*S*)-bupivacaine or racemic bupivacaine in blocking sodium channels, although the anesthetic and analgesic effects of the two drugs are similar.[74] Even though both bupivacaine and ropivacaine demonstrate similar plasma protein binding, ropivacaine has lower lipid solubility, higher plasma clearance, and a shorter elimination half-life $\left(t_{1/2\beta}\right)$ than racemic bupivacaine does.[75] Like ropivacaine, levobupivacaine has been shown to have a reduced incidence of toxicity in comparison to its (*R*)-isomer.[76] (*R*)-Cisatracurium offers clinical advantages over racemic atracurium because of its lack of histamine-releasing properties and its higher neuromuscular blocking potency. Ethanol is widely used as a pharmaceutical solvent and has recently been shown to decrease the unbound fraction of (*S*)-warfarin while increasing the unbound portion of (*R*)-warfarin. Perhaps the most infamous example of enantiomeric differences between optical isomers was observed with the drug thalidomide. The (*R*)- and (*S*)-isomers of thalidomide, as well as the racemic mixture, are equally active hypnotics; however, (*S*)-thalidomide is transformed into metabolites that proved to be embryogenic and teratogenic.[77]

Commercial halothane is a racemic mixture of (*R*)- and (*S*)-enantiomers (Fig. 24-10). As discussed previously, metabolic studies have shown that racemic halothane undergoes oxidative metabolism catalyzed by CYP2E1 to TFA-Cl, which covalently binds to several hepatic proteins that are believed to be involved in the immune response leading to halothane hepatotoxicity. To investigate whether CYP2E1 catalyzes the metabolism of halothane in a stereoselective fashion, the enantiomers of halothane were prepared and tested in vivo for their ability to form covalently bound TFA-protein adducts in the liver of mice. It was found that halothane does undergo stereoselective metabolism, with the (*R*)-isomer producing significantly greater amounts of TFA-protein adducts in liver than the (*S*)-isomer does (Fig. 24-11).[78] Because the anesthetic potency of the isomers appears to be equal,[79] these findings suggest that the (*S*)-isomer of halothane might be a safer inhaled anesthetic agent than the (*R*)-isomer or the racemic mixture. This idea is supported by the observation that the hepatotoxicity caused by halothane, enflurane, isoflurane, and desflurane is related to their relative degree

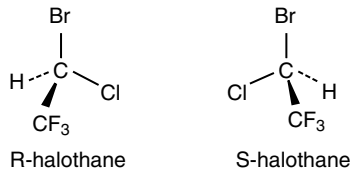

Figure 24-10 (*R*)- and (*S*)-enantiomers of halothane

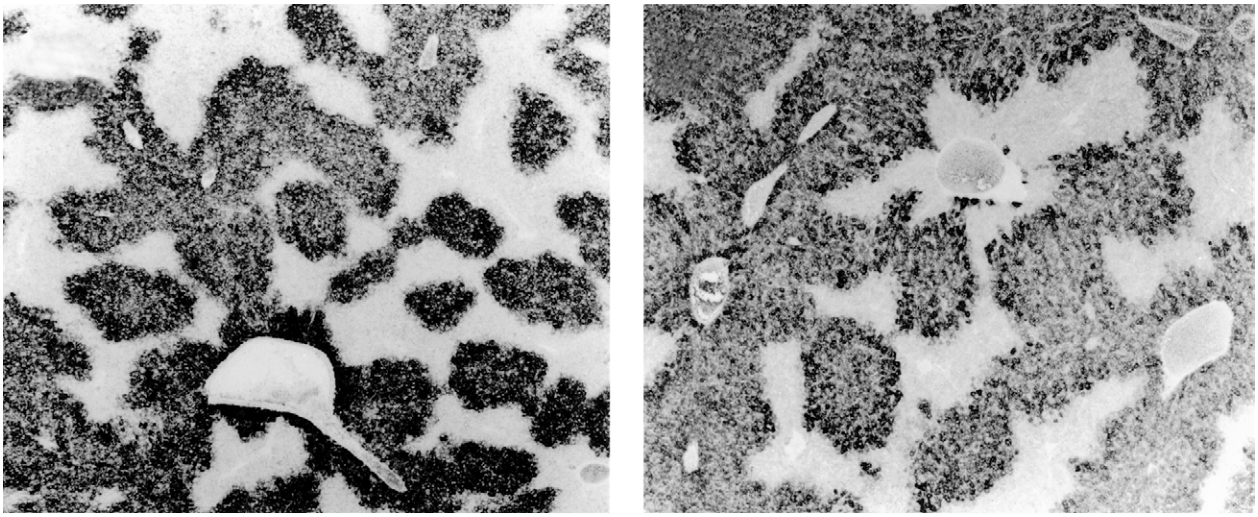

Figure 24-11 Immunochemical detection of trifluoracylated proteins in the livers of mice 24 hours after treatment with (*R*)- or (*S*)-halothane. **A**, From a mouse treated with (*R*)-halothane. **B**, From a mouse treated with (*S*)-halothane (original magnification ×50). *(From Njoku D, Laster MJ, Gong DH, et al: Biotransformation of halothane, enflurane, isoflurane and desflurane to trifluoroacetylated liver proteins: Association between protein acylation and liver injury. Anesth Analg 84:173-178, 1997.)*

of oxidative metabolism in vivo to reactive acyl halide metabolites (see Fig. 24-8). Because enflurane, isoflurane, and desflurane also contain an asymmetric carbon atom, the potential for stereoselective metabolism also exists with these agents. Indeed, other researchers have found that the ratio of (*R*)-enflurane metabolism to (*S*)-enflurane metabolism in human liver microsomes was 1.9:1.[48] It has also been demonstrated that optical isomers of isoflurane exhibit a significant difference in anesthetic potency,[80] differentially increase sleep time in mice,[81] and exhibit modest but significant stereoselectivity at the type A γ-aminobutyric acid ($GABA_A$) receptor.[82-84] Investigations with stereoisomers of anesthetic agents such as etomidate[85] also help provide a better understanding of the mechanisms of action of anesthetic agents. The clinical use of chiral anesthetic drugs as equal mixtures of their enantiomers has been accepted practice in medicine and anesthesia. With increased knowledge and awareness regarding drug toxicities, future anesthetic drugs may be developed and marketed as single, more potent and potentially less toxic optically active isomers.

Toxicity of Inhaled Anesthetics

Hepatitis

Volatile halogenated inhaled anesthetics have been associated with hepatotoxicity since the introduction of chloroform in 1847. Chloroform, as well as carbon tetrachloride and trichloroethylene, were all abandoned as anesthetic agents because of the often observed hepatotoxicity associated with their use. With the introduction of halothane into clinical practice in 1956, this compound quickly gained widespread acceptance and use. Halothane was the first of the fluorinated alkane anesthetics and represented a major advance in general anesthetics because it was safe, nonflammable, nonexplosive, and well tolerated by patients. However within 2 years of its introduction, numerous reports of hepatotoxicity and massive and often fatal hepatic necrosis associated with its use appeared in the medical literature. As a result of continuing reports, a large retrospective analysis was undertaken, "The National Halothane Study," under the auspices of the Committee on Anesthesia of the National Academy of Sciences National Research Council.[86] The purpose of this study was to compare the mortality and incidence of postoperative hepatic necrosis associated with halothane with that of other general anesthetics (ether, cyclopropane, and balanced anesthesia). The study reviewed 865,515 general anesthetics from 1959 to 1962 at 34 medical institutions and identified 82 cases of fatal hepatic necrosis. Drug-induced hepatic injury was suggested in nine of these cases, and seven of the nine patients had received halothane. Furthermore, four of the seven patients had received halothane on more than one occasion during the preceding 6 weeks. The study concluded that the mortality associated with the use of halothane compared favorably with that of other general anesthetics in use at the time and estimated the incidence of fatal hepatic necrosis associated with halothane to be 1 in 10,000 halothane anesthetics. It was further concluded that "unexplained fever and jaundice in a specific patient following the use of halothane should serve as a warning sign to avoid its subsequent use in that patient."[86] These findings provided the impetus for much of the work done over the past 50 years on the etiology of inhaled anesthetic hepatotoxicity, which is now accepted as a distinct clinical entity. Indeed, several hundred cases of hepatotoxicity have been attributed to halothane and approximately 50 cases to enflurane, but the incidence appears to be even lower with isoflurane and desflurane.[87]

Drug-induced liver injury may be caused by intrinsic or idiosyncratic mechanisms. Liver injury that is intrinsic to a particular pharmacologic agent is predictable and largely independent of host influences. Acetaminophen and chloroform are examples of pharmacologic agents that cause an intrinsic form of

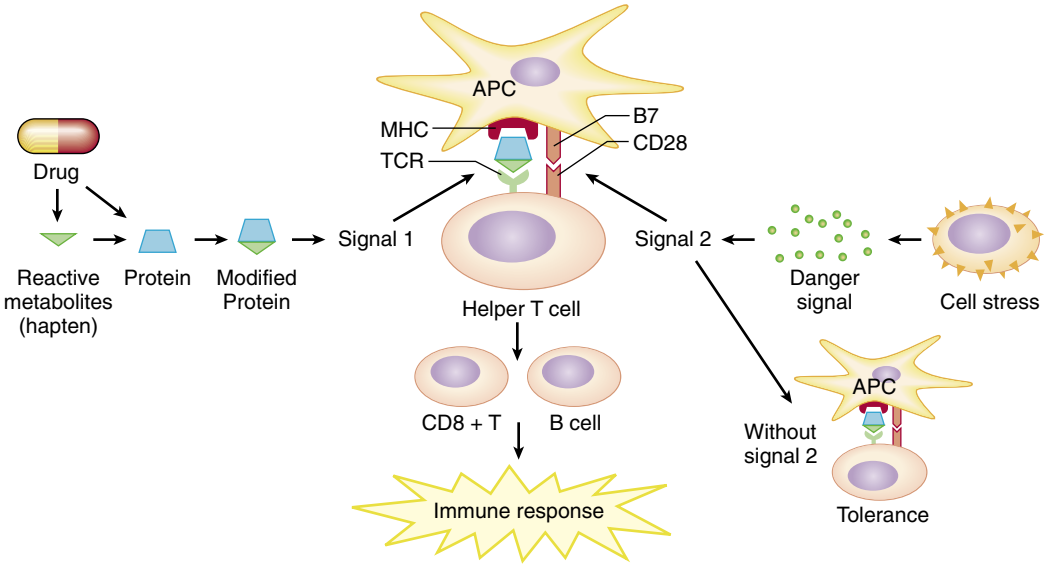

Figure 24-12 Hapten and danger hypotheses. The hapten hypothesis involves a chemically reactive drug or reactive metabolite acting as a hapten by binding to protein, which is then taken up by an antigen-presenting cell (APC) and processed. The processed antigen is presented in the context of the major histocompatibility complex (MHC) to a helper T cell; this represents signal 1. The danger hypothesis involves cell damage or stress (possibly caused by the drug or reactive metabolite) leading to the release of danger signals that result in upregulation of costimulatory factors; this is signal 2. Without signal 2, the result is immune tolerance. *(Redrawn from Uetrecht J: Idiosyncratic drug reactions: Past, present, and future. Chem Res Toxicol 21:84-92, 2008.)*

liver injury. The dose threshold for intrinsic toxicity may be achieved as a result of increased production, altered tissue sequestration, or decreased elimination of toxic metabolites. Moreover, other pharmacologic agents or chemicals, altered physiologic states, or pathologic states may affect the dose threshold for these toxicities. Nonetheless, when the dose threshold is surpassed, tissue injury may be caused by direct actions of the metabolite, which may result in inhibition or modification of the enzymatic and structural systems necessary for maintaining cellular integrity. In contrast to the intrinsic mechanisms of toxicity, many pharmacologic agents produce adverse reactions through an idiosyncratic pathway. These reactions are generally host dependent, relatively rare, and difficult to produce in animals in which the mechanisms can be systematically studied. Many idiosyncratic reactions, including liver injury caused by inhaled anesthetics, may have an immune basis. The injury is not due to the prodrug itself because small molecules are not immunogenic. Instead, reactive metabolites bind irreversibly to tissue proteins and produce a drug-protein adduct (or hapten-carrier conjugate) that can induce an immune response. The hapten hypothesis involves a chemically reactive drug or reactive metabolite acting as a hapten by binding to protein, which is then taken up by an antigen-presenting cell and processed. The processed antigen is presented in the context of the major histocompatibility complex to a helper T cell (signal 1). The danger hypothesis involves cell damage or stress (possibly caused by the drug or reactive metabolite) leading to the release of danger signals that result in the upregulation of costimulatory factors (signal 2). Without signal 2, the result is immune tolerance (Fig. 24-12).[88] In addition to the inhaled anesthetics halothane, enflurane, isoflurane, and desflurane, other examples of well-studied immune-mediated idiosyncratic drug reactions include penicillin and acetaminophen.[89]

Immune-Mediated Halothane Hepatotoxicity

Two distinct types of hepatic injury have been associated with the clinical use of halothane (Table 24-2). Mild injury occurs in 20% of adults who receive halothane, and laboratory tests show mild elevations in alanine aminotransferase (ALT) and aspartate aminotransferase (AST). The second type of injury is the fulminant form, commonly known as halothane hepatitis, which is characterized by elevated ALT, AST, bilirubin, and alkaline phosphatase levels; massive hepatic necrosis; and a fatality rate ranging from 50% to 75%. Because of the potential for halothane-induced hepatitis, halothane is not generally recommended for use in adults. In several medical malpractice cases, injury or death as a result of the use of halothane has been successfully litigated against anesthesia health care providers. Although there are some indications for the use of halothane in adults, they must be clearly evaluated and written in the medical record before each such use.

Table 24-2 Clinical Features of Halothane Hepatitis

Mild Form	Fulminant Form
Incidence, 1 : 5	Incidence, 1 : 10,000
Repeat exposure not necessary	Multiple exposures
Mild elevation of ALT, AST	Marked elevation of ALT, AST, bilirubin, alkaline phosphatase
Focal necrosis	Massive hepatic necrosis
Self-limited	Mortality rate, 50%
	Antibodies to halothane-altered protein antigens

ALT, alanine aminotransferase; AST, aspartate aminotransferase.

Table 24-3 Halothane Antigens

Molecular Mass (kd)	Protein
100	Endoplasmin
82	GRP-78
80	ERP-72
63	Calreticulin
59	Carboxylesterase
58	Protein disulfide isomerase (isoform)
57	Protein disulfide isomerase
54	Cytochrome P450

Halothane hepatotoxicity appears to link reactive metabolite formation and the hapten hypothesis. Halothane is oxidized by CYP2E1 to the reactive TFA-Cl metabolite (see Fig. 24-12). Although the incidence of liver failure is low, most patients in whom halothane hepatitis develops have antibodies against TFA-modified proteins. This implies that modification of protein by the reactive metabolite has led to an immune response. In addition, many patients have antibodies against native proteins. Patients often have a clinical history of multiple anesthetic exposure to halothane and one or more symptoms suggestive of ongoing immune processes, including fever, rash, arthralgia, and eosinophilia.[90-98] There is no evidence that the antibodies observed in halothane hepatitis actually mediate liver damage; it is entirely possible that they are just markers of an immune response. It appears that the TFA-protein adducts (Table 24-3) produced by the oxidative metabolism of halothane induce a cytotoxic T-cell response in sensitized individuals that on subsequent exposure leads to halothane hepatitis (Fig. 24-13).[99,100]

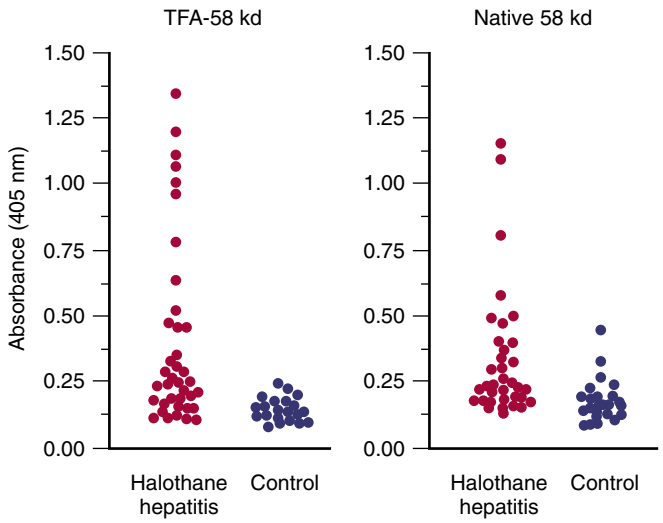

Figure 24-13 Enzyme-linked immunosorbent assay for the sera screening of patients with halothane hepatitis for antibodies that react with trifluoroacetylated 58-kd and native 58-kd proteins. All sera from 40 halothane hepatitis patients and 32 control patients were assayed at a 1 : 100 dilution. *(Adapted from Martin JL, Reed GF, Pohl LR: Association of anti-58 kDa endoplasmic reticulum antibodies with halothane hepatitis. Biochem Pharmacol 46:1247-1250, 1993.)*

Halothane Hepatitis in the Pediatric Population

The first case of halothane hepatitis in a child was reported in 1959.[101] Since that time there have been numerous reports of hepatotoxicity and massive hepatic necrosis after halothane anesthesia in children (also see Chapter 82). Two retrospective studies have examined the incidence of halothane-associated hepatotoxicity in children. The first explored 165,400 halothane anesthetics in a children's hospital in the United Kingdom over the 23-year period from 1957 to 1979 and determined the incidence of halothane hepatitis in children to be 1 in 82,000.[102] The second study examined 200,311 cases from 1958 to 1983 in a children's hospital in the United States. Only one patient in this study was concluded to have halothane hepatitis.[103] In 1987, data were reported describing halothane hepatitis in seven children aged 11 months to 15 years, all of whom had received multiple halothane anesthetics.[104] The diagnosis in this study was confirmed in all but one child by the presence of serum antibodies that reacted with halothane-altered hepatocyte antigens. There was one fatality in this group, and other causes of liver disease were excluded by the investigators. These findings indicate that the clinical syndrome of halothane hepatitis does exist in prepubertal children, although it is much rarer than in adults. The reason for the difference in incidence of halothane hepatitis observed between adults and children is not clear at present because halothane has been found to be metabolized to a similar degree in both adults and children and immune competence is known to exist from birth.

Enflurane, Isoflurane, Desflurane, and Sevoflurane

The incidence of liver injury caused by the fluorinated inhaled anesthetics follows the order of halothane > enflurane > isoflurane > desflurane and correlates with the extent of their oxidative metabolism (see Fig. 24-8), which is halothane (≈20%), enflurane (≈2.5%), isoflurane (≈0.2%), and desflurane (≈0.01%).[105] Because all of these inhaled anesthetics appear to form protein adducts that are identical or related in structure to those of halothane, it seems possible that they may cause liver injury by a mechanism similar to that of halothane, though at an appreciably lower incidence (Fig. 24-14). This lower incidence would be due to the lower levels of potentially immunogenic protein adducts formed from these drugs than from halothane when they are oxidatively metabolized by CYP2E1 (Fig. 24-15).

Enflurane was first used in North America in 1966. Although it is used much less commonly today, during the period of its highest use there were relatively few case reports of liver damage associated with it. In 1986, Eger and coauthors reviewed 10 published reports and several unpublished reports of liver damage after enflurane. Many of the cases were missing critical information on the duration of anesthetic exposure, histologic confirmation of hepatic lesions, and previous exposure to hepatic disease and hepatotoxic agents. In addition, several patients had been hypotensive or severely ill or demonstrated signs of shock and underwent operations with known potential for hepatic dysfunction. Obviously, these investigators had no choice but to conclude that the evidence did not support the existence of enflurane-associated hepatic dysfunction similar to that seen with halothane. Nevertheless, several case reports suggest that enflurane anesthesia given to patients previously anesthetized with or sensitized to halothane can result in hepatotoxicity. For example, it was found that protein adducts of halothane and enflurane, formed in the liver of rats treated separately with these drugs,

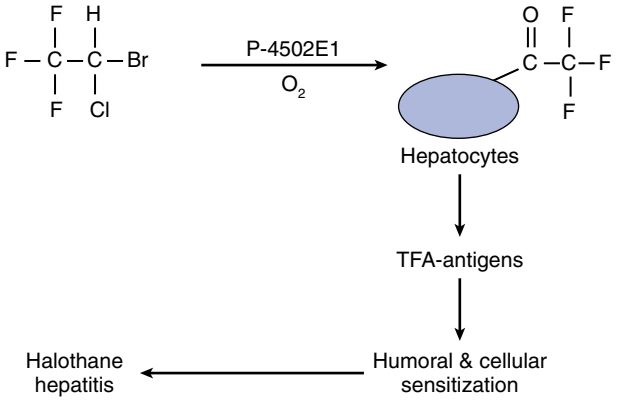

Figure 24-14 Pathway for generation of the immune response after exposure to anesthetic by susceptible patients. Halothane is metabolized to a trifluoroacetylated (TFA) adduct that binds to liver proteins. The altered protein is seen as nonself and generates an immune response, which on subsequent exposure leads to toxicity and cell death. A similar process may occur after exposure to other fluorinated drugs that generate a TFA or similar adduct. *(Adapted from Njoku D, Laster MJ, Gong DH, et al: Biotransformation of halothane, enflurane, isoflurane and desflurane to trifluoroacetylated liver proteins: Association between protein acylation and liver injury. Anesth Analg 84:173-178, 1997.)*

reacted with serum antibodies from patients in whom halothane hepatitis was diagnosed.[106] This apparent cross-reactivity could be explained by the similarity in structure of the protein adducts of halothane and enflurane (see Fig. 24-8).

Isoflurane, the structural isomer of enflurane, became available clinically in 1981. The combination of its minimal oxidative metabolism and low blood-gas solubility contributed to the popularity of this anesthetic agent. Moreover, for several years after its introduction there were no published reports of hepatic injury after the administration of this anesthetic. In 1991, a case report of fulminant hepatic failure after repeated isoflurane exposure was published.[107] In the same patient, the second isoflurane anesthetic for pyloroplasty was administered for a 2-hour period, and the third anesthetic for gastrojejunostomy was isoflurane for 30 minutes, followed by enflurane for 150 minutes. This patient had a far greater serum transaminase and alkaline phosphatase concentration after the second anesthetic than after the third exposure to anesthesia. In 2000, a case of fatal hepatotoxicity after re-exposure to isoflurane was reported in which histologic evidence of centrilobular injury and microvesicular fatty changes were found.[108] Similar histopathologic changes were observed in another case of isoflurane liver injury.[109] In addition, TFA-protein

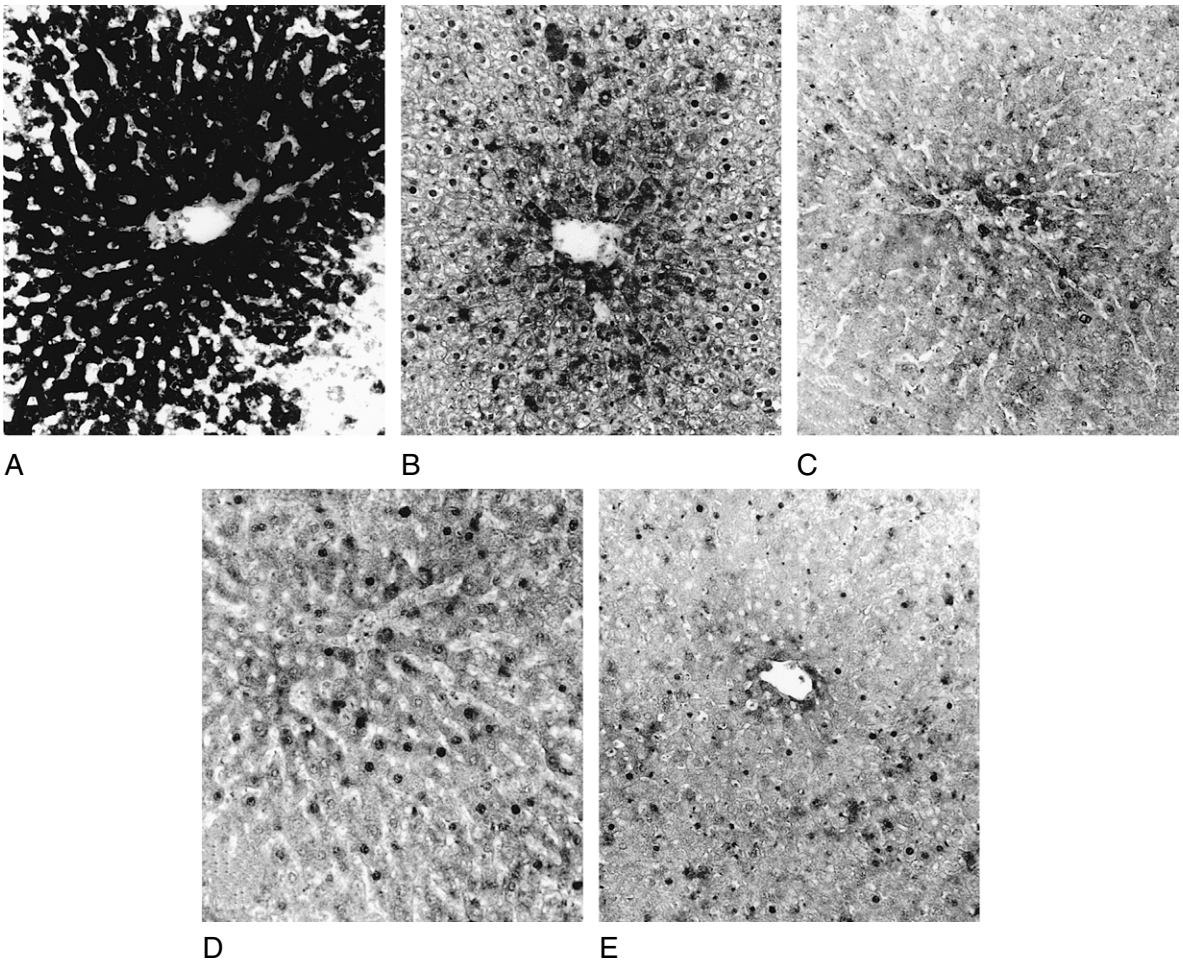

Figure 24-15 Livers from rats exposed to either halothane (**A**), enflurane (**B**), isoflurane (**C**), desflurane (**D**), or oxygen (**E**) were incubated with antitrifluoroacetylated rabbit serum to detect the presence of trifluoroacetylated liver proteins after exposure to anesthetic. Evidence of an immune response to trifluoroacetylated liver proteins can be seen in **A**, **B**, and **C**. No immunoreactivity is evident in **D** or **E**.

adducts were detected in the damaged mitochondria by electron microscopy. This finding suggests that the TFA-protein adducts may have contributed to the mitochondrial injury by a mechanism that was unrelated to an immunopathologic reaction induced by the TFA-protein adducts.

Although earlier studies of patients and volunteers did not suggest that desflurane is associated with hepatotoxicity in humans,[110,111] there are a handful of reports describing postoperative hepatotoxicity after exposure to desflurane. The first was a patient in whom fulminate hepatitis developed 12 days after receiving a desflurane anesthetic.[87] Because this patient had been exposed to halothane 10 and 18 years previously for periods of less than 1 hour, it is possible that the patient may have been sensitized to halothane. After exposure to desflurane, a cross-sensitization reaction may have occurred because both halothane and desflurane can form TFA-protein adducts. A second case has been reported in which a weak association between desflurane exposure and hepatotoxicity was described.[112] More recently, two additional cases were reported; the first was in an adult patient,[113] and the other is the first report of desflurane toxicity in a pediatric patient.[114]

There are several early case reports in the Japanese literature of sevoflurane being associated with postoperative hepatic dysfunction in patients ranging in age from 11 months to 63 years.[115,116] However, in all these reports, the association between sevoflurane exposure and liver injury as manifested by elevations in liver transaminases is extremely weak. In a single recent report from this country, postoperative liver injury was seen after sevoflurane anesthesia for appendectomy. However, this 3-year-old girl was suffering from iatrogenic acetaminophen intoxication, and it may be more likely that her injury was the result of acetaminophen rather than sevoflurane.[117] There has been a single case of fulminant hepatic failure and death attributed to sevoflurane anesthesia.[118] This patient died of multiple organ failure triggered by acute hepatic failure 2 days after open heart surgery with sevoflurane, sufentanil, and propofol anesthesia. Other possible causes of liver failure were excluded. It is worth noting again that sevoflurane is not metabolized to antigenic TFA-adducts, so the mechanism of injury in this case remains unexplained. However, it does reinforce the point that any patient sensitized to any of the fluorinated inhaled anesthetics should not be exposed to any of these agents. Several clinical considerations for the safe and reasonable use of fluorinated anesthetic agents are outlined in Box 24-1.

Box 24-1 Clinical Considerations

Halothane should not be used in adult patients without a specific, well-documented indication.

In patients experiencing postoperative hepatotoxicity after fluorinated inhaled anesthetics, these anesthetics should be avoided in the future.

Despite reports of halothane hepatitis in children, halothane remains an acceptable anesthetic choice for use in children.

Enflurane, isoflurane, and desflurane remain safer inhaled anesthetics.

Anesthetic-induced hepatitis remains a diagnosis of exclusion.

Hydrochlorofluorocarbons

Until the year 2000, the chlorofluorocarbons (CFCs) were widely used as industrial refrigerants, foam-blowing agents in the manufacture of plastics, aerosol propellants, food preservatives, and cleaning and sterilizing agents. The major source of CFC environmental contamination was the venting of automobile and truck air conditioning units into the atmosphere. CFCs are extremely stable, nontoxic, and nonflammable and were first identified as the compounds responsible for stratospheric ozone depletion in 1985. CFC molecules emitted into the lower atmosphere may take up to 7 years to diffuse upward into the stratosphere, where intense ultraviolet radiation liberates chlorine atoms, which catalyze reactions that destroy ozone molecules. The ozone-depleting potential of all halogenated hydrocarbons is a function of their molecular stability, stratospheric lifetime, and breakdown products (bromide being the most destructive and fluoride the least). Once in place, these compounds may exist for 100 or more years. Depletion of stratospheric ozone may have adverse health effects worldwide, such as increases in the incidence of skin cancer and cataract formation. As a result, recommendations put forth by The Montreal Protocol on Substances That Deplete the Ozone Layer were adopted by the Environmental Protection Agency in the United States and by several other countries. These recommendations called for total elimination of CFCs by the year 2000.

The addition of hydrogen atoms to CFC molecules to form hydrochlorofluorocarbon (HCFC) molecules (Fig. 24-16) allows degradation of these compounds in the lower atmosphere with little effect on stratospheric ozone. HCFC-123 and HCFC-124 are currently used as a CFC replacement. Because of the striking structural similarity between HCFCs and halothane, it seemed possible that the HCFCs would also form TFA-protein adducts similar to halothane (Fig. 25-17) and possibly cause liver injury. In studies in rats, the relative concentrations of TFA-protein adducts formed in the liver after the administration of these compounds were similar between halothane and HCFC-123, much lower for HCFC-124, and nearly undetectable for HCFC-125.[119] Acute exposure to HCFC-123 has been shown to produce severe hepatotoxicity in guinea pigs, which was enhanced by prior glutathione depletion.[120] In subchronic studies performed in rats and dogs, increased liver weight, slight focal liver necrosis, induction of peroxisomal activity, and hepatocellular and testicular adenomas have been found.[121,122]

Human liver microsomes in vitro show a much higher capacity than rat liver microsomes to bioactivate HCFC-123 to reactive metabolites, suggesting that HCFCs might be hepatotoxic to humans. In this regard, HCFC-123 and HCFC-124 have been implicated in liver injury in humans.[123] In this report, nine workers were accidentally exposed to a mixture of HCFC-123 and HCFC-124 repeatedly. All nine exposed workers were affected to varying degrees. For one severely affected worker, liver biopsy and immu-

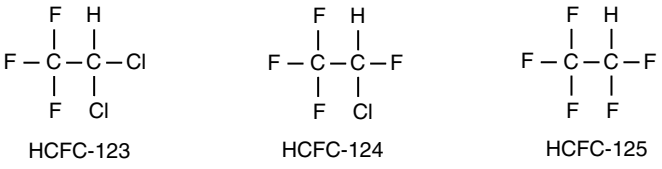

Figure 24-16 Chemical structures of the hydrochlorofluorocarbon analogs of halothane, HCFC-123, HCFC-124, and HCFC-125.

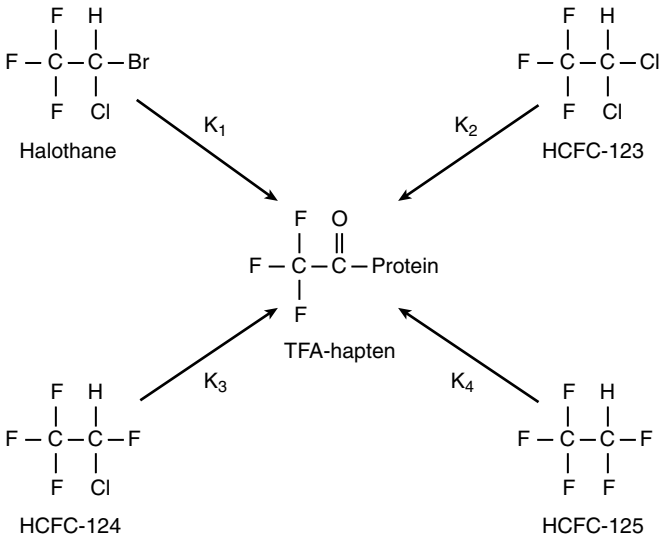

Figure 24-17 Metabolism of halothane and the hydrochlorofluorocarbon replacements HCFC-123, HCFC-124, and HCFC-125 to an identical trifluoroacetyl (TFA) metabolite.

nohistochemical staining for the presence of TFA-protein adducts were performed. The liver biopsy sample showed hepatocellular necrosis that was prominent in perivenular zone 3 and extended focally from portal tracts to portal tracts. TFA-adducted proteins were detected in the surviving hepatocytes. Autoantibodies against CYP2E1 or P58 were found in the sera of five of the nine affected workers. This report demonstrates that repeated exposure of human beings to HCFC-123 and HCFC-124 can result in serious liver injury in a high proportion of the exposed population. By contrast, halothane hepatitis occurs in only a small fraction of individuals repeatedly anesthetized with this compound. A possible explanation for this difference is that halothane is administered acutely to patients, whereas the injured workers were subchronically exposed to the HCFCs. It is possible that protracted formation of TFA-adducted proteins may result in direct toxicity. Alternatively, on the basis of in vitro metabolic studies with human liver CYP2E1, exposure of human beings to HCFC-123 might result in higher concentrations of TFA-adducted liver proteins than produced by halothane.[119] The presence of P58 and CYP2E1 autoantibodies in the serum of the exposed workers indicates that an immune component may have a role in the pathogenesis of HCFC-induced hepatotoxicity.

Presently, HFC-134a is used in virtually all automobile air conditioning units. In 2006, the European Union (EU) agreed to ban any fluorinated gas with global-warming potential (GWP) 150 times greater than an equivalent amount of CO_2 (the GWP of CO_2 is 1). Effectively, HFC-134a will be eliminated in EU countries by 2011. The best replacement candidate to date is a hydrofluoroolefin with a GWP of 4, HFO-1234yf, although unlike HFC-134a, this compound is mildly flammable. Interestingly, beginning in 2011, the German Association for Automotive Industry, which includes Audi, BMW, Daimler, Porsche, and Volkswagen, will begin replacing HFC-134a with CO_2 known in the industry as R-744. The atmospheric burden of CFCs is decreasing as a result of implementation of the Montreal Protocol. The importance of volatile anesthetics on the environment, particularly bromine-containing halothane, continues to be of some concern.

Methoxyflurane

No discussion of immune-mediated hepatotoxicity after inhaled halogenated anesthetics is complete without a brief discussion of methoxyflurane. From a historical perspective, methoxyflurane was introduced into clinical practice in the United States in 1960. There have been a number of reports of hepatic dysfunction and death from hepatic coma after exposure to methoxyflurane. A review of 24 cases of methoxyflurane-associated hepatitis revealed that a syndrome similar to halothane hepatitis may occur.[124] The authors suggested that a rare and indirect immunologic hepatic injury may occur that may have a direct effect on the liver by interfering with the splanchnic circulation. Fortunately, in humans the adverse minor changes in liver function appear to be reversible and may be related to dose, and it is still unclear whether hepatic dysfunction, as measured by bromsulphalein retention and serum hepatic enzyme elevation, was the result of the depth and duration of the anesthetic exposure, the type of operation, the extent of preexisting hepatic disease, or methoxyflurane itself.

Risk Factors for Anesthetic-Induced Hepatitis

The physiologic effects of inhaled halogenated anesthetics on the liver may affect the susceptibility to hepatic dysfunction after their administration. It is well known that inhaled anesthetics can reduce hepatic blood flow to some degree and may in this way contribute to postoperative hepatic dysfunction. However, studies of healthy volunteers found no evidence of hypoxia or anaerobic metabolism in the liver, but hypoxia or abnormalities in hepatic synthetic function may be present in patients with preexisting liver damage or other illnesses. In general, surgical manipulation or disturbance of the surgical site appears to be a more important factor in decreasing hepatic blood flow than the anesthetic agent or technique. In addition, preexisting conditions such as chronic liver disease secondary to alcoholism, viral infection (e.g., viral hepatitis and cytomegalovirus), septicemia, severe burns, nutritional deficiency, and previous or concomitant drug treatment may predispose patients to postoperative hepatic dysfunction. Unfortunately, a patient demonstrating clinical evidence of hepatic dysfunction after exposure to inhaled halogenated anesthetics presents a challenge to the anesthesia care provider because clinical tests to assess hepatic function can be nonspecific and reflect only severe hepatic dysfunction. Even so, traditional measures of hepatic function, such as serum enzymes, aminotransferases, proteins, bilirubin, and alkaline phosphatase, are still used to assess liver damage.

The mortality associated with halothane hepatitis has been reported to range from 40% to 75%. A variety of risk factors have been identified that are commonly associated with this clinical syndrome[125] (Box 24-2). Numerous studies have demonstrated that the risk for halothane hepatitis is greatly increased with use of an increasing number of anesthetics over a short period. Although the basis of this observation is not known, it is possible that increased exposure to TFA-protein adducts as a result of multiple treatments with halothane promotes the chance of a hypersensitivity reaction.

Halothane hepatitis may have a hereditary basis. The low incidence of the disease and the decreasing use of halothane make study of the genetic effects difficult and emphasize the

importance of developing an animal model of this disease. Several other associations exist for development of this disease. There is a clear sex difference observed in patients with halothane hepatitis. The disease develops in approximately twice as many females as males, the reason for which is unclear at present. In addition, the vast majority of cases of halothane hepatitis have occurred in middle-aged adults, with relatively few cases reported in prepubertal children,[102,103] and the disease is more common in obese than in nonobese patients. There is currently no evidence to suggest that the incidence of halothane hepatitis is increased in patients with liver disease unrelated to previous halothane exposure. However, because halothane can cause direct hepatotoxicity and other alternatives exist for the provision of general anesthesia, it is prudent to avoid halothane, as well as the other related fluorocarbon inhaled anesthetics, in patients with preexisting hepatic dysfunction.

Assays to Detect Patients Sensitized to Fluorinated Anesthetics

The diagnosis of halothane hepatitis has always been one of exclusion, whereas other potential causes of liver injury, such as hepatitis A, hepatitis B, hepatitis C, cytomegalovirus, Epstein-Barr virus, hepatotoxic drugs, hypotension, and hypoxia, are systematically ruled out as precipitating causes. One of the important goals of halothane hepatitis research is the development of an assay capable of detecting sensitized patients who may be at risk for the development of a hypersensitivity response on re-exposure to halothane or other fluorinated anesthetics, as well as detecting patients with the disease (Box 24-3). The assays that have been developed measure serum antibodies in halothane hepatitis patients. Two general types of immunochemical assays have been reported for detection of these antibodies. The first is immunoblotting. In this procedure, test antigens are microsomal proteins from halothane-treated rats or rabbits that have been separated into constituent polypeptides by sodium dodecyl sulfate–polyacrylamide gel electrophoresis and transferred electrophoretically to the surface of nitrocellulose membranes. With this technique, 42 of 68 (62%) patients with a clinical diagnosis of halothane hepatitis have been found to test positive for the halothane-induced antibodies.[92] Although this approach provides important information about the apparent molecular mass of the neoantigens reacting with the patients' antibodies, it is laborious and time consuming. It also has the potential disadvantage of being inherently less sensitive than other methods because it involves the protein-denaturing conditions of sodium dodecyl sulfate–polyacrylamide gel electrophoresis. This could lead to a decreased level of response if a patient's antibodies were directed against, at least in part, conformational epitopes of the TFA neoantigens.

The second immunochemical assay that has been used for detection of antibodies in the sera of patients with a clinical diagnosis of halothane hepatitis is based on the more rapid, facile, and potentially more sensitive enzyme-linked immunosorbent assay methodology, in which test antigen is applied directly to the wells of a microtiter plate. One reported enzyme-linked immunosorbent assay procedure uses microsomes from halothane-treated rabbits as test antigen. With this approach, investigators have demonstrated the presence of the antibodies in the sera of 16 of 24 (67%)[126] and 28 of 39 (72%)[126] patients with a clinical diagnosis of halothane hepatitis. In another enzyme-linked immunosorbent assay that uses the TFA hapten as test antigen in the form of TFA–rabbit serum, albumin-positive responses in patients with a clinical diagnosis of halothane hepatitis were found in two of six (33%) patients[127] and five of six patients (83%).[128] More recently, purified proteins from rat liver have been used as test antigens in the enzyme-linked immunosorbent assay. In a study using three of the purified TFA-protein neoantigens (100, 80, and 57 kd), 79% of a group of 24 halothane hepatitis patients tested positive with this assay.[129]

Fluoride-Associated Nephrotoxicity

Evidence suggests that inhaled anesthetics may induce differential effects on renal physiology. For example, halothane and enflurane decrease the glomerular filtration rate and renal blood flow, whereas isoflurane may also decrease the glomerular filtration rate but has minimal effects on renal blood flow. Conversely, the newest inhaled halogenated anesthetics have minimal effects on renal physiology. Nevertheless, despite these physiologic effects, renal autoregulation protects the kidney from decreases in blood flow that may be caused by the inhaled anesthetic. Moreover, it has been suggested that decreases in the glomerular filtration rate caused by decreases in arterial pressure will return to baseline when arterial pressure normalizes. The metabolism of certain inhaled halogenated anesthetics can produce inorganic fluoride, which may be directly nephrotoxic. The potential for fluoride-associated nephrotoxicity after the administration of inhaled halogenated anesthetics is reviewed subsequently.

Methoxyflurane

Methoxyflurane is no longer used in clinical practice; however, nephrotoxicity from inorganic fluoride released after the metabolism of methoxyflurane is discussed as a basis for understanding the nephrotoxic potential of all current and future fluorinated anesthetics. Studies investigating methoxyflurane demonstrated an association with polyuric renal failure as a result of high levels of inorganic fluoride. Patients with inorganic fluoride levels of less

than 50 µmol/L had no evidence of renal injury. Levels of 50 to 80 µmol/L were associated with moderate injury and 80 to 120 µmol/L with severe injury. Several patients who had inorganic fluoride levels higher than 120 µmol/L died.

Various mechanisms have been proposed to explain the renal injury from inorganic fluoride after the administration of methoxyflurane. One mechanism involves an inorganic fluoride–induced reduction in adenyl cyclase activity and subsequent effect on antidiuretic hormone.[130] Another mechanism involves effects on the renal countercurrent concentrating system by fluoride-induced increases in renal medullary blood flow. Nonetheless, the mechanism involving intrarenal metabolism of methoxyflurane and subsequent intrarenal production of fluoride ion is believed to be a significant cause of the renal toxicity of methoxyflurane.[131]

Despite the overall correlation between nephrotoxicity and peak serum fluoride concentrations, there is individual variability in the level of nephrotoxicity after methoxyflurane. Genetic heterogeneity, drug interactions, preexisting renal disease, and a host of other factors could account for the differences observed among patients.

Enflurane

In contrast to the renal effects of methoxyflurane, enflurane has been associated with only transient decreases in renal concentrating ability. When compared with methoxyflurane, serum fluoride concentrations after enflurane anesthesia peak earlier and fall more rapidly, thus emphasizing the important role of lipid solubility in determining total fluoride exposure (Fig. 24-18). Some clinicians have speculated that enflurane administered to patients with significant preexisting renal disease could produce additional renal dysfunction. Such fears have not been borne out, however.

Isoflurane

Isoflurane, an isomer of enflurane, is defluorinated much less than enflurane is. Because of the resistance to defluorination and the decreased likelihood of other toxicities, prolonged isoflurane administration has been investigated for use outside the operating room. Isoflurane was investigated for its effectiveness in long-term sedation of patients maintained on mechanical ventilation.[132,133] In the first study, the highest serum fluoride concentration was measured in a 2-year-old child who received 73 MAC-hours of isoflurane and had a serum fluoride level of 37.4 µmol/L.[134] In the second study, pediatric patients undergoing mechanical ventilation received isoflurane for 13 to 497 MAC-hours. The highest serum F^- concentration was 26.1 µmol/L, with no alterations in serum creatinine or osmolality.[133] From these studies we can safely conclude that isoflurane can be administered for very long periods without producing clinically significant serum fluoride concentrations; however, influences on metabolism and renal and hepatic function should be carefully considered.

Sevoflurane

Sevoflurane is defluorinated through oxidative metabolism (see Fig. 24-9) to approximately the same extent as enflurane.[135] Clinical studies show that serum fluoride concentrations often peak above 50 µmol/L even when sevoflurane is administered during surgery of average duration.[134] Because of sevoflurane's low blood-gas solubility and its rapid elimination, fluoride concentrations

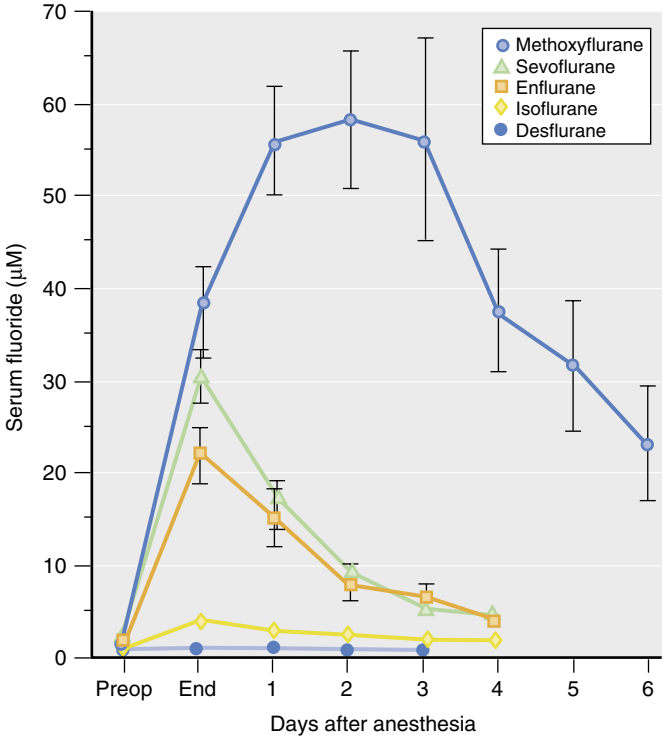

Figure 24-18 Serum inorganic fluoride (F^-) concentration before and after the administration of methoxyflurane, sevoflurane, enflurane, isoflurane, and desflurane anesthesia. After 2 to 3 minimum alveolar concentration (MAC)-hours of methoxyflurane, the mean peak F^- concentration was 61 ± 8 mol/L, which slowly declined. Sevoflurane anesthesia of 3.7 MAC-hours resulted in a mean peak F^- concentration of 30.6 ± 2 mol/L, which declined more rapidly than methoxyflurane but remained elevated for several days. After 2.7 MAC-hours of enflurane, mean peak F^- concentrations were 22.2 ± 2.8 mol/L, which also declined over a period of several days. There was no increase and almost no increase in F^- concentrations after desflurane and isoflurane administration, respectively.

fall very quickly after surgery, and renal toxicity is not expected from sevoflurane administration. In vivo studies have shown that although peak fluoride levels are comparable to those with enflurane, sevoflurane has less nephrotoxic potential, as measured by maximum urine-concentrating ability and the production of *N*-acetyl-β-glucosaminidase (NAG), an indicator of renal tubular damage.[136-138]

In a 1994 study, inorganic fluoride levels were also compared after sevoflurane and isoflurane anesthesia.[138] The elimination half-life of fluoride was 8 hours. Mean fluoride levels after sevoflurane were 30 µmol/L, although five of the patients had levels higher than 50 µmol/L. The mean for isoflurane was significantly lower at 3.9 µmol/L. However, despite the high levels in five patients, there was no evidence of renal injury as detected by blood urea nitrogen (BUN) or creatinine in this study. A similar study comparing isoflurane and sevoflurane with longer MAC-hour exposure (13.5 hours) resulted in a longer fluoride elimination half-life of about 58 hours in the sevoflurane patients and dramatically higher mean levels of inorganic fluoride (42.5 µmol/L).[134] Half of all sevoflurane-exposed patients had fluoride levels higher than 50 µmol/L, but again no renal injury was apparent as evidenced by BUN and creatinine measurements. Higuchi and coworkers measured renal concentrating ability after 10.6 MAC-hour sevoflurane or 8.5 MAC-hour isoflurane in surgical patients. Mean peak fluoride levels were 41.9 ± 2.5 µM in the sevoflurane

and 5.8 ± 0.4 μM in the isoflurane group.[139] There was no difference in the response to vasopressin between the groups. In a large multinational open-label comparative study, patients received either low-flow (1 L/min) sevoflurane ($n = 98$) or isoflurane ($n = 90$) anesthesia for at least 2 hours. BUN, creatinine, urine glucose, protein pH, and specific gravity were used to assess renal function up to 3 days after exposure. Peak fluoride levels were higher with sevoflurane (40 ±16 μM) than with isoflurane (3 ± 2 μM). BUN and creatinine decreased in both groups, and no clinically significant differences were found with respect to any measured parameter.[140]

To accurately assess the potential for injury from inorganic fluoride with sevoflurane, more sensitive measures may have to be used, including creatinine clearance (CCr), maximal urinary osmolality, urinary excretion of NAG, β_2-microglobulin, and alanine aminopeptidase. One study used several of these parameters and found evidence of transient subclinical nephrotoxicity with sevoflurane anesthesia.[141] In this study, patients underwent peripheral orthopedic procedures lasting longer than 5 hours and were exposed to either isoflurane or sevoflurane. Results were reported for two groups of sevoflurane patients, those with inorganic fluoride levels lower than 50 μM/L ($sevo_{low}$) and those with levels higher than 50 μM/L ($sevo_{high}$). This categorization was based on levels of inorganic fluoride determined 1 hour postoperatively: 4.8 μM/L for isoflurane, 36.8 μM/L for the $sevo_{low}$ group, and 55.8 μM/L for the $sevo_{high}$ group. BUN, creatinine, and CCr were normal in all groups throughout the study. Maximal urine osmolality showed a tendency toward the development of injury in the $sevo_{high}$ group. NAG levels were twice as high as isoflurane levels in the $sevo_{low}$ group and three times higher in the $sevo_{high}$ group, the latter showing evidence of subclinical renal injury. Clinically, transient loss of renal concentrating ability occurred in half the patients in the $sevo_{high}$ group. The dysfunction resolved within 6 days. An accompanying editorial suggested that this study raises the possibility of renal injury with sevoflurane in patients with impaired renal function and cautioned against its use in this patient group.[142] A second report of fluoride-induced renal injury in patients after sevoflurane anesthesia has recently been published.[143] However, a number of clinical reports have demonstrated very high levels of inorganic fluoride in some patients after sevoflurane anesthesia without obvious adverse effects. A report in 1996 described two such patients with refractory status asthmaticus, both treated with prolonged sevoflurane exposure under non-rebreathing conditions.[144] Despite very high inorganic fluoride levels, no obvious injury followed. It appears that the potential for significant renal impairment or injury after sevoflurane anesthesia in healthy patients solely as a result of inorganic fluoride is not an important clinical problem.

However, whether sevoflurane further affects renal tubular function in patients with impaired renal function is a question investigated by several groups. Cozen and associates compared sevoflurane ($n = 21$) with enflurane ($n = 20$) at 4-L/min fresh gas flow rates in patients with chronically impaired renal function (creatinine >1.5 mg/dL). Although peak fluoride levels were significantly higher in the sevoflurane group (25 ± 2.2 μM) than in the enflurane group (13.3 ± 1.1 μM), no difference was found in postoperative renal impairment.[145] Tsukamoto and colleagues compared sevoflurane ($n = 7$) with isoflurane ($n = 7$) in patients with moderately impaired renal function (CCr between 10 and 55 mM/min). Fluoride, urine NAG, γ-glutamyl transpeptidase (γ-GTP), and β_2-microglobulin were measured up to 2 weeks after surgery. With the exception of fluoride levels (sevoflurane group ⋙ isoflurane group), no differences in renal parameters were noted between the groups.[146] In a more recent study, Morita and colleagues[147] evaluated the effect of sevoflurane ($n = 15$) and propofol ($n = 15$) anesthesia on urine concentration and aquaporin-2 (AQP2) levels. AQP2 is an arginine vasopressin (AVP)-regulated water channel protein localized in the apical region of renal collecting duct cells. In both groups, plasma and urinary concentrations of AVP increased, although plasma osmolality remained unchanged. Urinary AQP2 excretion increased in the propofol group along with changes in urinary and plasma AVP. Urinary AQP2 was significantly lower at 90 minutes in the sevoflurane group, and urine osmolality showed a transient but significant decrease in parallel with AQP2 suppression, thus suggesting that sevoflurane may have produced a transient impairment of the APQ2 response to an increase in intrinsic AVP. However, because other inhaled anesthetics were not tested, it is not clear whether this observation applies to sevoflurane alone or is also a characteristic effect of other fluorinated inhaled anesthetic agents.

Desflurane

Clinical studies performed with desflurane thus far show no evidence of nephrotoxicity. Desflurane is extremely resistant to defluorination, and serum fluoride concentrations in surgical patients after exposure to desflurane are not increased above background concentrations.[148] From these findings, desflurane does not appear to be nephrotoxic.

Halothane

Halothane is not significantly defluorinated under normal clinical conditions and is not nephrotoxic. In patients who received about 19 MAC-hours of halothane, peak plasma fluoride levels were much higher in the isoflurane group than in the halothane group.[136]

In summary, fluoride-induced nephrotoxicity is a well-known entity historically associated with methoxyflurane administration and prolonged exposure to enflurane. During the administration of sevoflurane, serum inorganic fluoride levels can exceed 50 μmol/L, the level known to produce nephrotoxicity; however, no correlation with sevoflurane and polyuric renal failure has been documented. Two factors may help explain the differences seen with methoxyflurane and sevoflurane. First, it is not the peak serum fluoride concentration that determines injury but rather the duration of the systemic increase in fluoride (the area under the curve for serum fluoride). In addition, sevoflurane is an order of magnitude less soluble than methoxyflurane and thus is eliminated much more rapidly from the body. Second, the liver is the primary organ of sevoflurane metabolism, whereas both the liver and kidney metabolize methoxyflurane, and it is thought that the high intrarenal fluoride production from methoxyflurane contributes to its nephrotoxicity.

Anesthetic Degradation by Carbon Dioxide Absorbents

Sevoflurane and Compound A

Several decomposition products are formed during the interaction of sevoflurane with carbon dioxide absorbents, and

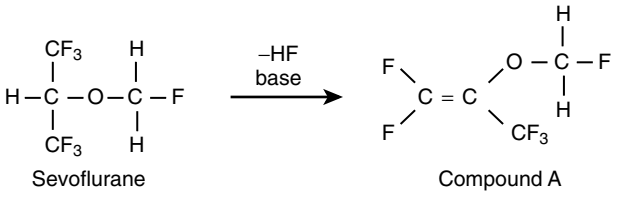

Figure 24-19 Sevoflurane degradation in the presence of base.

fluoromethyl-2-2-difluoro-1-(trifluoromethyl) vinyl ether (compound A) is the major degradation product detected (Fig. 24-19).[149-151] The dehydrofluorination of sevoflurane to form compound A is initiated by soda lime abstraction of a proton from the isopropyl group of sevoflurane in a manner that is similar to the base-catalyzed deprotonation of halothane by soda lime to yield bromochlorodifluoroethane (BCDFE, F_2C = CBrCl).

Compound A has been the subject of intense research and debate since the introduction of sevoflurane into clinical practice in the United States in 1995. Morio and coworkers found that high concentrations of compound A could cause renal injury and death in rats.[142] Other investigators have confirmed the findings of Morio and coworkers and have shown further that kidney injury occurs when levels of compound A reach 25 to 50 ppm or greater.[152] Necrosis is found primarily in the proximal tubular cells within the outer strip of the medulla, and the percentage of injured cells was lower 4 days after exposure than 1 day after exposure, consistent with repair after renal injury.[153] These and other studies suggest a threshold for renal injury of 150 to 300 ppm-hours of exposure to compound A, (e.g., 50 ppm of compound A administered for 3 hours).[153,154] Keller and coauthors reported that inspired concentrations of compound A greater than 114 ppm were associated with concentration-dependent increases in BUN, creatinine, and the urinary NAG/creatinine ratio.[153] Moderately severe histopathologic changes were noted at 202 ppm, and all chemical and histopathologic changes reversed within 14 days of exposure. This renal toxicity is both dose and time dependent: the higher the exposures over time, the greater the observed injury. During sevoflurane anesthesia in a closed or semiclosed system at low fresh gas inflow, patients are routinely exposed to compound A.

Several studies in surgical patients and human volunteers have been undertaken to investigate the possible association between sevoflurane anesthesia and renal injury as a result of exposure to compound A during sevoflurane anesthesia. In an early study, Bito and Ikeda exposed 10 patients to sevoflurane for longer than 5 hours under closed-circuit conditions with soda lime used as the absorbent.[149] Peak compound A concentrations were 19.5 ± 5.4 ppm, and serum BUN, creatinine, and electrolytes were essentially unchanged. In a follow-up study by the same investigators, 10 patients were exposed to sevoflurane at 1-L/min fresh gas flow for 10 hours. Mean compound A levels were 24.3 ± 2.4 ppm, and routine tests of renal function showed no change from preoperative values.[155] Frink and associates measured compound A levels in 16 surgical patients during low-flow sevoflurane anesthesia of 3 hours' duration with either soda lime ($n = 8$) or Baralyme ($n = 8$) used as the absorbent.[156] Maximum compound A concentrations averaged 8.16 ± 2.67 ppm with soda lime and 20.28 ± 8.6 ppm with Baralyme. A compound A concentration of 60.8 ppm was found in the breathing circuit of one of eight subjects to whom sevoflurane was administered with Baralyme absorption. In the same study, no compound A level exceeding 50 ppm was found in the eight volunteers in whom soda lime was used to scrub the carbon dioxide.

In a more comprehensive investigation, Bito and Ikeda studied 100 surgical patients undergoing resection of head and neck tumors in which surgery was expected to last longer than 10 hours. Patients received either sevoflurane ($n = 50$) or isoflurane ($n = 50$) anesthesia at low fresh gas inflow (1 L/min).[157] Mean peak compound A concentrations in the sevoflurane group were 24.6 ± 7.2 ppm. Although bilirubin, AST, and ALT levels increased postoperatively in both the sevoflurane and isoflurane groups, there were no significant differences in these parameters between the groups. Preoperative and postoperative BUN and creatinine levels remained unchanged. A number of other reports have used BUN and serum creatinine as markers of renal damage to evaluate renal function after closed-circuit or low-flow sevoflurane anesthesia,[158] and none of these studies demonstrated any change in either of these markers preoperatively and postoperatively.[157-159]

It has been argued that BUN and creatinine are not sensitive enough tests for detecting renal damage after exposure to compound A.[157-160] In an early attempt to address this issue, Kumano and colleagues measured urinary excretion of several renal tubular enzymes as measures of renal injury. Renal excretion of alanine aminopeptidase and NAG (enzymatic markers of renal integrity) increased 7 days after exposure to 7.6 MAC-hours of enflurane, but no increase was observed in patients receiving 9.6 MAC-hours of sevoflurane. Renal excretion of γ-GTP, β_2-microglobulin, BUN, and creatinine was unchanged.[161] Bito and associates studied 48 patients undergoing gastrectomy under both low-flow (1 L/min) ($n = 16$) and high-flow (6 to 10 L/min) ($n = 16$) sevoflurane anesthesia and low-flow isoflurane (1 L/min) ($n = 16$) anesthesia and looked not only at BUN and creatinine but also at CCr, NAG, and alanine aminopeptidase.[162] The average inspired compound A levels were 20 ppm in the $sevo_{low}$ group, and the average duration of exposure to this concentration was 6.11 hours. The only difference noted between the $sevo_{low}$ and the $sevo_{high}$ groups was the degree of compound A formation. Postanesthesia laboratory data showed no significant effects of compound A during sevoflurane anesthesia on any markers of renal function. Postanesthesia BUN and creatinine levels decreased, CCr increased, and urinary excretion of NAG and alanine aminopeptidase increased in all groups in comparison to preanesthesia values, but there was no significant differences observed between any of the groups. Kharasch and colleagues[163] completed a similar study in which 73 surgical patients received either sevoflurane or isoflurane anesthesia at a 1-L/min fresh gas flow. The duration of anesthesia was 3.7 or 3.9 hours, and the maximum inspired concentration of compound A was 27 ppm (range, 10 to 67 ppm). Areas under the inspired and expired compound A concentration-versus-time curves were 79 ppm-hours (range, 10 to 223 ppm-hours) and 53 ppm-hours (range, 6 to 159 ppm-hours), respectively. There were no significant differences between anesthetic groups in postoperative BUN, creatinine or urinary excretion of protein, or glucose (markers of proximal tubular resorptive function) or in NAG, proximal tubular α-glutathione-*S*-transferase (α-GST), or distal tubular π-GST (markers of tubular cell necrosis). The authors concluded that a moderate duration of low-flow sevoflurane anesthesia during which compound A formation occurs was as safe as low-flow isoflurane

Table 24-4 Percentage of Volunteers with Abnormal Renal Test Results after 8 Hours of 1.25 MAC Sevoflurane Anesthesia

	Eger Study[165]			Ebert Study[166]		
Determination	**Day 1 (%)**	**Day 2 (%)**	**Day 3 (%)**	**Day 1 (%)**	**Day 2 (%)**	**Day 3 (%)**
Glucose	75	50	80	15

α-GST	43	70	70	54	54	
π-GST	25	38	38	*		
MAC-hr exposure	328 ppm/hr			240 ppm/hr		

*The group mean was significantly increased above baseline. No individual data were reported. Blood urea nitrogen and creatinine levels were normal in all patients at all time points.
GST, glutathione-*S*-transferase; MAC, minimum alveolar concentration.

anesthesia. Nishiyama and associates studied the effect of repeat sevoflurane exposure within 30 to 90 days in neurosurgical patients.[164] Ten patients received sevoflurane at 6-L/min fresh gas flow rates on two occasions. Serum inorganic fluoride was measured 1 day after surgery, and BUN, creatinine, serum and urine β_2-microglobulin, urine NAG, and serum AST, ALT, and total bilirubin were measured 7 days postoperatively. Urine β_2-microglobulin, AST, and ALT all increased to abnormal levels after both anesthetics, with no differences observed between the anesthetics. Thus, the second sevoflurane exposure did not change the hepatic or renal metabolism of sevoflurane. These changes were indicative of mild hepatic and renal injury. The duration of anesthesia for the first and second anesthetics was 4.3 ± 0.6 hours and 4.0 ± 0.6 hours, respectively.

More recent studies in humans that have reported renal changes after the administration of sevoflurane have all occurred under conditions of prolonged sevoflurane exposure. Both Eger and colleagues[165] and Ebert and colleagues[166] exposed human volunteers to 8 hours of 1.25 MAC sevoflurane or desflurane anesthesia at a 2-L/min fresh gas flow rate and investigated pre-exposure and postexposure BUN, creatinine, and enzymatic markers of urinary function for up to 3 days or 5 to 7 days after exposure (Table 24-4). Both investigators found no difference in pre-exposure and postexposure BUN or creatinine levels in either group, but they found significant differences in enzymatic markers of renal integrity (α-GST and π-GST), albuminuria, and glucosuria in the sevoflurane-exposed group. All renal changes were transient, with normal return of renal function by 4 days after exposure in all but one volunteer, whose renal function was normal 2 weeks after exposure. In Eger's volunteers, rebreathing of sevoflurane produced an average inspired compound A concentration of 41 ppm and total exposure to compound A of 328 ppm-hours. In the Ebert study, volunteers were exposed to an average inspired compound A concentration of 27 ppm and a total exposure of 216 ppm-hours. With the exception or BUN and creatinine, both studies showed significant changes in urinary markers, the Ebert volunteers being lower on the compound A toxicity threshold curve and exhibiting less drastic changes in all markers of injury. When Goldberg and coworkers replicated Eger and colleagues' study, they obtained lower average compound A levels (253 ppm-hours) and found similar qualitative renal results.[167] Higuchi and associates[168] found increased excretion of urinary enzymes after average compound A concentrations of 215 ppm-hours. In another study, Higuchi and associates also found proteinuria in patients who were given low-flow (1 L/min) ($n = 14$) sevoflurane anesthesia and were undergoing orthopedic or dental surgeries, but not in those given high-flow (6 L/min) ($n = 14$) sevoflurane or low-flow isoflurane ($n = 14$).[169] Increased urinary NAG excretion was seen in the low-flow and high-flow sevoflurane groups, whereas BUN, creatinine, and CCr were unchanged in all groups. In human volunteers exposed to 1.25 MAC sevoflurane or desflurane for 4 hours ($n = 9$) or 2 hours ($n = 7$) at 2-L/min fresh gas flow, Eger and colleagues found average inspired compound A levels of 40 ppm. Relative to desflurane, sevoflurane given for 4 hours resulted in slightly increased urinary albumin and serum creatinine and increased urinary α-GST.[170] In a later study, Ebert and coworkers found that 5 MAC-hours of sevoflurane exposure at 1-L/min fresh gas flow, in which mean peak compound A levels were 39 ppm and total exposure to compound A was 152 ppm-hours, produced no changes in BUN, creatinine, or enzymatic markers of renal or hepatic (AST, ALT, and alkaline phosphatase) injury.[171]

Several studies have examined the use of sevoflurane in the pediatric population (also see Chapter 82). In a recent report, sevoflurane was compared with halothane anesthesia in children with a mean age of 6 years.[172] With comparable exposure, the sevoflurane group had significantly higher inorganic fluoride levels. There were no significant differences in BUN and creatinine levels, and there have been no reports of fluoride-associated renal toxicity in pediatric patients after sevoflurane anesthesia. Other tests of renal integrity were not performed. In another study, ASA class I and II children ranging in age from 3 months to 7 years received 1 MAC sevoflurane exposure at a fresh gas flow rate of 2 L/min.[173] The mean anesthetic exposure was 240 minutes, and fresh carbon dioxide absorbent was used for each patient. The soda lime temperature varied from 23°C to almost 41°C, and the inspired and expired compound A concentrations were 5.4 and 3.7 ppm, respectively. There were no differences in clinical chemical parameters, as reflected by AST, ALT, alkaline phosphatase, bilirubin, BUN, and creatinine. The maximum soda lime temperature correlated with both maximum compound A concentrations and the body surface area of the child. Therefore, to date, there have been no reports of markedly abnormal renal chemical findings in pediatric patients after exposure to sevoflurane.

There is some potential concern in pediatric patients related to HFIP, the major metabolite of sevoflurane, because levels of this metabolite may become relatively high as a result of a deficiency in UGTs that conjugate glucuronic acid to HFIP (see Fig. 24-9). For example, in one study neonatal rats were found to have

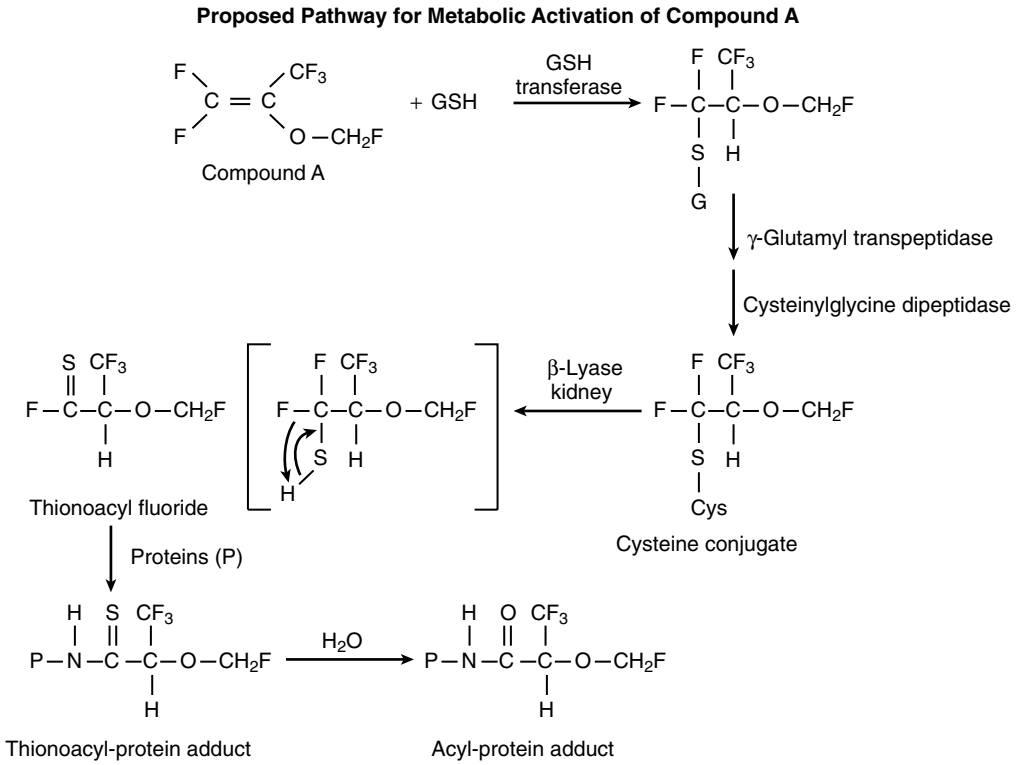

Figure 24-20 Proposed pathway for the metabolic activation of compound A showing the formation of an intrahepatic glutathione (GSH) conjugate of compound A that is translocated to the kidney, where γ-glutamyl transpeptidase, cysteinyl glycine dipeptidase, and the renal cysteine conjugate β-lyase catalyze the formation of a nephrotoxic thiol that can acylate kidney proteins. *(Adapted from Martin JL, Kandel L, Laster, MJ, et al: Studies of the mechanism of nephrotoxicity of compound A in rats. J Anesth 11:32-37, 1997.)*

high levels of free HFIP for as long as 21 postnatal days after sevoflurane exposure.[174]

It has been hypothesized that the reason that compound A causes serious injury to kidneys in rats but not humans is because of differences in levels of renal cysteine conjugate β-lyase enzymes,[175] which have been hypothesized to catalyze the conversion of compound A to a reactive thionoacyl fluoride metabolite that can acylate kidney proteins and cause toxicity (Fig. 24-20). Indeed, renal cytosolic and mitochondrial β-lyase enzyme levels in rats are approximately 20 to 30 times higher than those found in humans.[176-178] There is evidence to support the β-lyase theory of compound A–induced nephrotoxicity. Renal β-lyase appears to mediate the renal toxicity produced by several fluorinated alkenes that are structurally similar to compound A,[179-181] and metabolic intermediates of the β-lyase pathway have been identified in the bile and urine of rats and human tissues exposed to compound A.[158,163,177,178,182] Moreover, the glutathione-*S*-conjugate of compound A is nephrotoxic,[183] and the administration of aminooxyacetic acid (AOAA), an inhibitor of β-lyase (Fig. 24-21), protects against the nephrotoxicity of compound A in rats.[184] However, there is some controversy surrounding the relevance of the β-lyase pathway in compound A–induced renal injury.[182,185,186] More recently, Altuntas and coauthors reported an additional pathway of compound A metabolism, sulfoxidation.[187] The investigators showed that compound A cysteine and mercapturic acid conjugates are metabolized both enzymatically and nonenzymatically to sulfoxide metabolites. The enzymatic process was catalyzed by CYP3A1/2 and CYP3A4/5, and there exists a species difference in rat and human liver and kidney microsomes (rat > human and liver > kidney). Sulfoxide conjugates have recently been shown to be more toxic than the corresponding parent cysteine or mercapturic acid compound A conjugate. However, the toxicologic significance of *S*-conjugate sulfoxidation of compound A remains unknown. It represents an alternative route of metabolism to the deacetylation or the β-lyase pathways. Whether sulfoxidation occurs in vivo is uncertain, as is its toxicologic significance.

Investigators have reported that pretreatment of rats with AOAA and acivicin (AT-125), inhibitors of the β-lyase pathway (see Fig. 24-19),[185] did not attenuate the nephrotoxicity produced by compound A but rather was associated with nearly a threefold increase in renal injury, from 19% to 53%. These findings suggest that the β-lyase pathway may actually be a detoxification pathway. In this regard, a report by Kharasch and coworkers[186] showed that pretreatment of rats with AOAA partially protected against compound A–induced diuresis and proteinuria but failed to protect against glucosuria. In another report, AOAA again failed to decrease histologic renal injury, and pretreatment with acivicin significantly increased renal injury.[185] Moreover, using an immunochemical approach, other investigators were unable to detect protein adducts of a thionoacyl fluoride metabolite of compound A in the kidneys of rats after compound A treatment, suggesting that the β-lyase pathway of compound A metabolism in rats either does not occur or is a minor pathway of metabolism. Therefore, these findings suggest that another pathway of metabolism of compound A may be responsible for the nephrotoxicity of compound A.

Higuchi and colleagues studied the effect of low-flow sevoflurane or isoflurane anesthesia (1 L/min) on 17 patients with

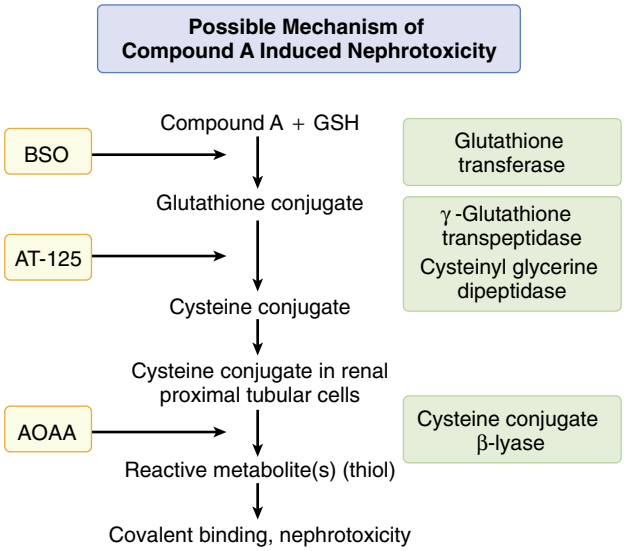

Figure 24-21 Crucial steps in the β-lyase pathway: first, conjugation of compound A with glutathione in the liver mediated by glutathione-*S*-transferase; this conjugate is then transported to the kidney. Second, the glutathione-*S*-conjugate is converted to a cysteine-*S*-conjugate, a process mediated by γ-glutamyl transpeptidase. Finally, the cysteine-*S*-conjugate of compound A is then converted to a reactive thiol, mediated by the renal cysteine conjugate β-lyase; DL-buthionine-(*S*,*R*)-sulfoximine (BSO) depletes endogenous stores of glutathione in the body, acivicin (AT-125) inhibits the activity of γ-glutamyl transpeptidase, and aminooxyacetic acid (AOAA) inhibits the activity of β-lyase. Compound A, its conjugates, and the reactive thiol have all been postulated to cause the renal necrosis that can occur in rats after the administration of compound A and the glucosuria and enzymuria that can result in rats and humans from the administration of compound A.

stable moderate renal failure (serum creatinine >1.5 mg/dL). They found no difference in BUN or creatinine up to 14 days after exposure or in CCr at 7 days after exposure in either group for patient exposures less than 130 ppm-hours of compound A.[188] In a recent multicenter randomized controlled trial, Conzen and coworkers studied 116 patients with stable renal insufficiency (CCr >1.5 mg/dL) who were administered either low-flow (1 L/min) sevoflurane (n = 59) or isoflurane (n = 57) anesthesia.[189] Total exposure to sevoflurane was 201.3 ± 98 minutes, with an average total compound A exposure of 18.9 ± 7.6 ppm. Isoflurane exposure averaged 213.6 ± 83.4 minutes, and Baralyme was used as the carbon dioxide absorbent. No significant changes above baseline values for serum creatinine, BUN, CCr, urine protein, or glucose were found at 24 or 72 hours after exposure to either anesthetic.

So what does this all mean and how does it translate into clinical care of patients? In a rebreathing system with a carbon dioxide absorber in lime (soda lime or Baralyme), patients exposed to sevoflurane will breathe compound A. The typical levels seen in clinical conditions will vary and are dependent on several factors, the most important being the inspired fresh gas flow rate. The key factor in determining potential toxicity from sevoflurane is total exposure rather than the absolute concentration, with exposure being expressed as the product of concentration and time. It appears from the many studies published to date that the lower threshold for renal changes associated with sevoflurane exposure and compound A is approximately 150 ppm-hours. At a fresh gas inflow of 2 L/min, these levels would be expected to be seen only in conditions of prolonged sevoflurane exposure and are not of concern to the vast majority of patients undergoing anesthesia and surgery. With prolonged sevoflurane exposure, when renal changes have been observed, they have been transient. It appears that compound A is of theoretical concern and academic interest, but to date no significant clinical renal toxicity has been associated with the use of sevoflurane. It is recommended that patients with preexisting renal disease not be exposed to sevoflurane and that sevoflurane be administered according to approved package labeling guidelines.

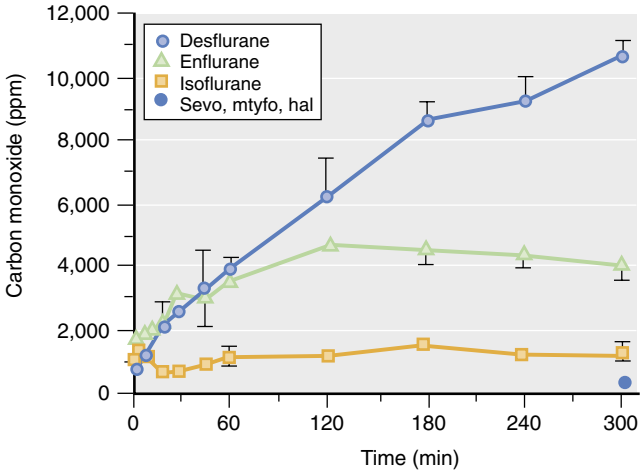
Halothane and Bromochlorodifluoroethane

Carbon dioxide absorbents also degrade halothane by a dehydrofluorination reaction to form BCDFE (F_2C = CBrCl). The potential nephrotoxicity of BCDFE was compared with that of compound A in a study by Eger and coworkers,[190] who found that (1) BCDFE was 80% less reactive than compound A; (2) halothane degraded to BCDFE 20- to 40-fold less than sevoflurane did to compound A in a standard circle system; (3) BCDFE was 75% less nephrotoxic to rats than compound A was; and (4) compounds that blocked the renal β-lyase pathway either did not change or decreased renal injury from BCDFE, whereas the same blockers either did not change or increased renal injury from compound A (see Fig. 24-21), suggesting that BCDFE and compound A may cause kidney injury by different mechanisms. These studies clearly indicate that the chance of BCDFE causing nephrotoxicity when halothane is being used as an anesthetic is negligible.

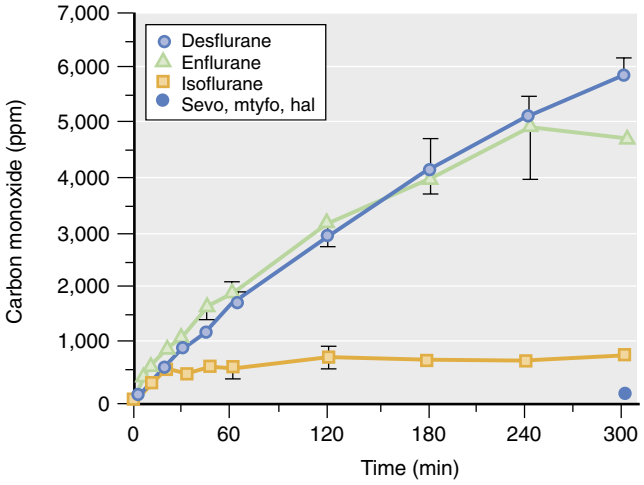
Carbon Monoxide and Heat

Carbon monoxide (CO) is an odorless, colorless, gas that is poisonous because it displaces oxygen from hemoglobin in blood and thereby leads to the formation of carboxyhemoglobin. Its affinity for binding hemoglobin is 250 times greater than that of oxygen. All humans have some CO bound to hemoglobin in their blood, on average 1% for nonsmokers and as much as 10% for those who smoke. High levels of CO can produce neuropsychiatric problems in patients, and when levels of carboxyhemoglobin reach 50%, death can occur. The problem of CO poisoning has been reported during clinical anesthesia.[191-196] The difficulty in monitoring CO levels clinically arises from the fact that pulse oximeters have not distinguished between carboxyhemoglobin and oxyhemoglobin. Masimo has just developed such a pulse oximeter that should correct this problem.

All inhaled anesthetics produce some CO as a result of their interaction with the strong bases in relatively dry carbon dioxide (CO_2) absorbents (water content <5%).[197] Several factors influence the level of CO production, including the choice of anesthetic agent, the inspired anesthetic concentration, and the type, temperature, and most important, the degree of dryness of the CO_2 absorbent.[198] Of the inhaled anesthetics, desflurane produces the most CO, followed by enflurane, isoflurane, and negligible amounts from sevoflurane and halothane (Fig. 24-22).[198,199] Intraoperative formation of CO has been reported with desflurane, enflurane, and isoflurane, with CO levels exceeding those established as safe by the U.S. Environmental Protection Agency. Desflurane, enflurane, and isoflurane are all difluoromethyl-ethyl ethers, whereas sevoflurane is a monofluoromethyl ether and halothane is an alkane. The specific mechanism appears to be abstraction of a base-catalyzed difluoromethoxy proton from the anesthetic agent (Fig. 24-23).[199] Furthermore, it has been shown



A



B

Figure 24-22 Anesthetic degradation to carbon monoxide at equivalent minimum alveolar concentrations (1.5 MAC) by barium hydroxide lime (**A**) and soda lime (**B**). Each data point is the mean ± SD ($n = 3$). The single data point at 300 minutes reflects undetectable carbon monoxide from sevoflurane (sevo), methoxyflurane (mtyfo), or halothane (hal). *(Adapted from Baxter PJ, Garton K, Kharasch ED: Mechanistic aspects of carbon monoxide formation from volatile anesthetics. Anesthesiology 89:929-941, 1998.)*

that abstraction of a proton from the difluoromethoxy group is greater with potassium (KOH) than with sodium hydroxide (NaOH).[199,200] Barium hydroxide ($Ba[OH]_2$) contains 4.6% KOH, whereas soda lime contains only 2.5% KOH and 1.5% NaOH. Unlike KOH and NaOH, $Ba(OH)_2$ does not abstract a proton from the difluoromethoxy moiety and catalyze the formation of CO from inhaled anesthetics. Because the divalent $Ca(OH)_2$ and $Ba(OH)_2$ bases are the major active components of the absorbents, the capacity to produce CO is rapidly exhausted, whereas the absorbents retain their capacity to remove CO_2.

New calcium hydroxide–based CO_2 absorbents such as Amsorb and DragerSorb Free contain neither NaOH or KOH and are chemically inert and do not degrade inhaled anesthetics to CO or degrade sevoflurane to compound A.[201] Fully hydrated or rehydrated absorbents do not degrade inhaled anesthetics to CO. Soda lime contains 15% water by weight, and only after this level of hydration has been decreased to about 1.4% will appreciable amounts of CO be formed. In contrast, Baralyme contains 13% water by weight and the threshold of hydration before CO is formed is 4.8%. However, even at these threshold levels, very little CO is actually produced. Production of large amounts of CO requires complete or nearly complete desiccation of the absorbent, a process that requires high flow of dry gas (10 L) for prolonged periods (1 to 2 days). Certain patients had high levels of CO, particularly prevalent in the first case on Mondays.[191] This appeared to be related to the practice of flushing the anesthesia machine with high fresh gas flow over the weekend, which dries out the CO_2 absorbent. Higher temperatures are also associated with increased CO production.

In general, CO toxicity has little clinical significance, regardless of the anesthetic used, as long as simple guidelines to minimize or eliminate CO are observed, including the use of fresh absorbent, the use of soda lime instead of Baralyme, or perhaps better yet, the use of a calcium hydroxide–based CO_2 absorbent. Avoidance of techniques that dehydrate the CO_2 absorbent in the anesthetic circuit is also helpful, such as low fresh gas flow, which is more economical and limits desiccation of the absorbent. Finally, as a last resort the absorbent can be rehydrated simply by adding approximately one cup of water (230 mL) per 1.2 kg of absorbent (standard canister).

The interaction of inhaled anesthetics with CO_2 absorbents is an exothermic reaction that results in the production of heat. The temperature of CO_2 canisters during routine clinical use averages 25°C to 45°C but increases inversely with decreased fresh gas flow; sevoflurane is associated with the greatest production of heat. By-products of this reaction also include HFIP, formaldehyde, methanol, sodium formate, and importantly, hydrogen. The high yield of hydrogen, up to 3 mol of hydrogen per mole of sevoflurane, ease of ignition, and low tissue solubility make it the most likely fuel in anesthesia machine fires because of reactions with desiccated CO_2 absorbents and sevoflurane.[202] These reactions can be significant and result in fires, toxic gases, and patient injury.[203,204] In laboratory settings, prolonged exposure of 1 MAC

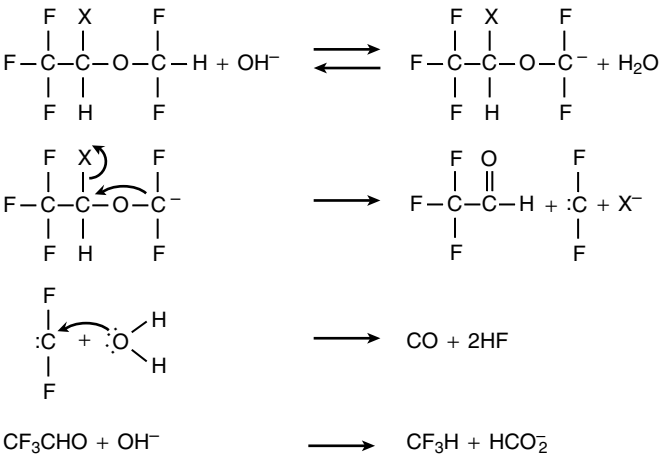


Figure 24-23 Proposed mechanism of carbon monoxide formation from difluoromethyl-ethyl ether anesthetics. Shown is the backbone structure for isoflurane (X = Cl) and desflurane (X = F). Also shown is a putative mechanism for the concomitant formation of trifluoromethane. Water in line 3 may also react as OH^-. *(Adapted from Baxter PJ, Garton K, Kharasch ED: Mechanistic aspects of carbon monoxide formation from volatile anesthetics. Anesthesiology 89:929-941, 1998.)*

sevoflurane to desiccated CO_2 absorbents resulted in canister temperatures in excess of 300°C.[205] At these high temperatures, patient injuries as a result of explosions, fires, and smoldering and melting of the plastic components of anesthesia equipment are all real possibilities. Two recent studies have documented lower concentrations of toxic sevoflurane breakdown products with use of the new-generation CO_2 absorbents.[206,207] Perhaps at some time in the near future the sodium hydroxide– and barium hydroxide –based CO_2 absorbents will be replaced by the nondestructive newer, less reactive calcium hydroxide–based CO_2 absorbents.

Other Toxicities

Nitrous Oxide and Inhaled Anesthetics

Nitrous oxide has been used and abused since its introduction into clinical practice in 1845. It is unique in its ability to oxidize vitamin B_{12} and inactivate methionine synthase and is the only anesthetic known to produce hematologic toxicity and neurotoxicity with long-term administration. Both these toxicities are the result of disruption of several pathways involved in one-carbon chemistry. After several hours of routine anesthesia with N_2O, methionine synthase activity is very low. Methionine synthase catalyzes the conversion of methyltetrahydrofolate and homocysteine to tetrahydrofolate and methionine. Failure to produce these products has a number of biochemical consequences, including reduced synthesis of thymidine, which is an essential DNA base. The reduction in thymidine synthesis takes somewhat longer to develop but lasts several days. The clinical syndrome associated with oxidation of vitamin B_{12} is essentially the same as that seen in pernicious anemia: megaloblastic hematopoiesis and subacute combined degeneration of the spinal cord. The time required to produce megaloblastic hematopoiesis with exposure to N_2O varies among patients. In healthy patients undergoing routine surgery, mild megaloblastic bone marrow changes are not seen after 6 hours, but they are seen after about 12 hours of exposure to 50% N_2O; after 24 hours of exposure, the changes are marked. Complete bone marrow failure can be expected after several days of continuous exposure. Limited evidence suggests that N_2O produces bone marrow changes earlier in seriously ill patients, and evidence also suggests that the bone marrow changes are preventable by pretreating patients with large doses of folinic acid. This drug is converted to the 5,10-methylene tetrahydrofolate needed for the synthesis of thymidine (Fig. 24-24). The neurologic disease, subacute combined degeneration of the spinal cord, develops only after several months of daily exposure to N_2O. Symptoms and signs include numbness and paresthesia in the extremities, loss of balance and unsteady gait, impairment of touch, and muscle weakness. Earlier, the disease was recognized to be similar to vitamin B_{12} deficiency, but treatment with vitamin B_{12} did not alleviate the symptoms or enhance recovery; thus, it occurs in those who abuse N_2O on a long-term basis.[208,209] Sporadic reports of postoperative neurologic disorders in patients exposed to N_2O continue to appear.[210-212] For all of the reasons just described and other environmental concerns that will be discussed later, there are serious discussions in the European Union and Japan regarding the possible elimination of nitrous oxide from modern clinical anesthesia.

Effects on Reproduction and Development

Thousands of pregnant women undergo anesthesia and surgery during gestation for indications unrelated to pregnancy. The incidence of unexpected abortion or premature labor is clearly higher after anesthesia. What is not immediately obvious is whether the patient's disease, surgery, anesthesia, or a combination of these factors is the precipitating cause. Perhaps an even greater concern is that anesthesia during pregnancy may lead to an increased incidence of congenital abnormalities in the offspring of the

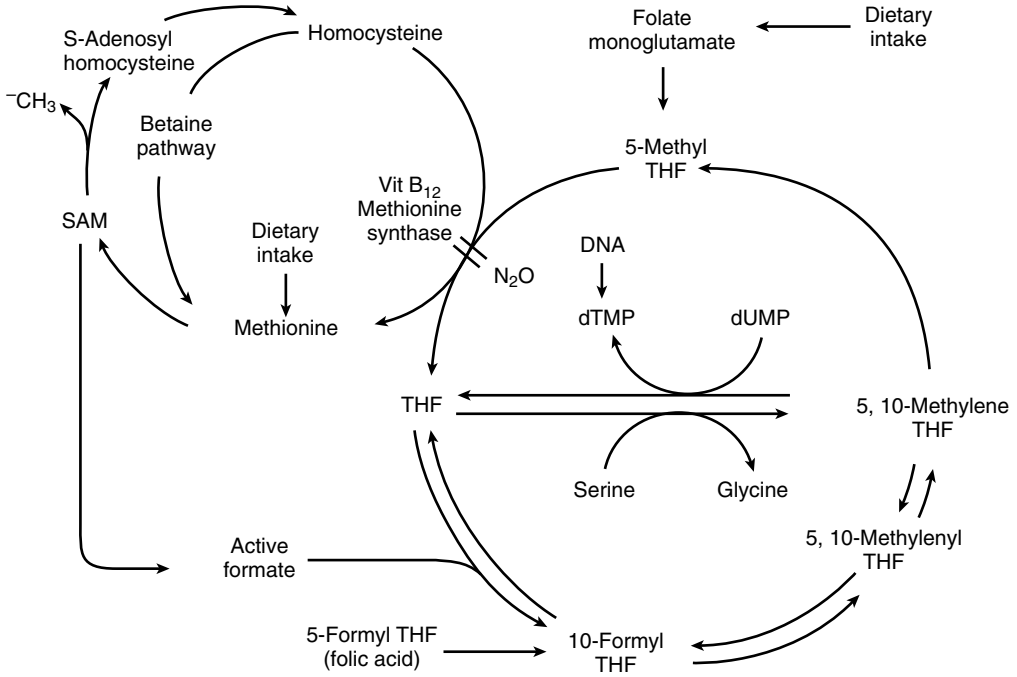

Figure 24-24 Conversion of methyltetrahydrofolate (5-Methyl THF) and homocysteine to tetrahydrofolate and methionine. dTMP, d-thymidine monophosphate; dUMP, d-uridine monophosphate; SAM, s-adenosyl methionine.

patient. A number of studies have been undertaken over the past 40 years to assess the incidence of various anesthesia- and surgery-related hazards occurring during pregnancy. In short, these studies have found that women who underwent surgery did not have an increased incidence of stillbirths or congenital anomalies among offspring. In contrast, the incidence of postnatal death within 7 days of delivery was increased when an operation occurred during the second or third trimester but not during the first trimester. The incidence of low birth weight and premature delivery was increased regardless of the trimester in which an operation occurred. The cause of these hazards was not determined, although the finding that no particular type of operation or anesthesia was associated with a higher incidence of adverse outcomes suggests that the patient's disease played the major role in determining the outcome.

In recent years, the increasing popularity of in vitro fertilization has afforded some opportunity to study the effects of anesthetics on ova. Various anesthetic regimens have been examined for their effects on rates of fertilization and cleavage of oocytes, pregnancy, and carriage to term. The results with general anesthetics have been variable, although there is some consensus that regimens that include inhaled anesthetics produce adverse effects.[213,214] In a well-controlled study of in vitro fertilization, no difference in fertilization or pregnancy rates was found in patients undergoing isoflurane anesthesia with or without N_2O, a finding implying that short exposure to N_2O is not harmful.[215] A publication on transvaginal oocyte retrieval and reproductive outcome[216] reported that general anesthesia with N_2O in combination with opiates, barbiturates, and halothane resulted in significantly lower clinical pregnancy rates (14.5%) than in patients receiving local anesthesia (23.7%) or an epidural block (25.8%). There were no adverse effects reported for oocyte collection, embryo yield, or embryo transfer. Several reports of epidemiologic surveys have been published in which the reproductive performance of operating room and dental personnel exposed to waste gases was examined. Interested readers are referred to a review of these studies.[217] One of the acknowledged shortcomings of many of the earlier published studies was the lack of a quantitative measure of anesthetic exposure, which was addressed in two more recent retrospective analyses[217,218] that attempted to quantitate N_2O exposure in female dental assistants. These investigators reported that in unscavenged dental suites, exposure to more than 5 and 3 hours of N_2O per day, respectively, was associated with reduced fertility and increased spontaneous abortion rates.

In general, N_2O is the only inhaled anesthetic that has been convincingly shown to be directly teratogenic in experimental animals, but only under experimental conditions that are considered extreme. High concentrations (50% to 75%) delivered to rats for 24-hour periods during organogenesis and low concentrations (0.1%) delivered to rats continuously throughout pregnancy result in an increased incidence of fetal resorption and visceral and skeletal abnormalities. A particularly interesting abnormality produced by high N_2O exposure is situs inversus, in which there is a disturbance in the left/right body axis so that organs such as the heart are on the wrong side of the body.[219] Although effects in rodents are seen only after extended periods of continuous exposure, it is not known whether humans are more sensitive than rodents and would show effects after shorter periods of exposure. It appears that lack of methionine rather than lack of thymidine plays the critical role in all the adverse reproductive effects other than situs inversus.[220] With situs inversus, stimulation of α_1-adrenergic receptors by N_2O appears to be the mechanism.[221] The effect is mediated by activation of calmodulin kinase 11.[222] N_2O teratogenesis is actively being investigated, not only because of its relevance to patient and occupational safety but also because N_2O can be used to determine the importance of vitamin B_{12}, folates, one-carbon chemistry, and the adrenergic system in developmental processes. The consensus is that the teratogenic effects observed in animals exposed to inhaled anesthetics are caused by physiologic changes associated with anesthesia rather than by inherent teratologic properties of the anesthetics themselves. Nonetheless, all findings emphasize the potential for anesthetics to interfere with developmental processes regardless of the mechanism.

Human studies have generally focused on the long-term behavioral effects of maternal obstetric medication, including epidural anesthesia. Claims have been made that the medication given at delivery to the mother produces depressed motor skills and impaired language ability in the infant and child for several years. Such claims, however, are controversial. Behavioral abnormalities in offspring whose mothers received inhaled anesthetics at any time during delivery have not been well studied. Furthermore, studies have not been done to assess the neurobehavioral function of children of operating room personnel who have been exposed to waste anesthetic gases. Firm conclusions about the risk for behavioral teratogenesis in the offspring of exposed personnel or in exposed patients therefore await further investigation. Finally, there is no evidence that the modern fluorinated inhaled anesthetics are mutagenic or carcinogenic.

General Anesthetics and Neurotoxicity

The issue of general anesthetics and neurotoxicity is an area of growing concern in the anesthesia community.[223] An increasing body of experimental evidence from animal studies suggests that general anesthetics can be neurotoxic in the developing and senescent brain through a process of accelerated apoptotic neurodegeneration.[224] The present nonclinical data implicate both *N*-methyl-D-aspartate receptor antagonists and drugs that potentiate GABA signal transduction as being potentially damaging to the developing brain.[225] The potential exists for combinations of anesthetic agents that have activity at both receptors to induce greater toxicity. Importantly, recent data suggest that even low nonapoptotic concentrations of anesthetics can perturb neuronal dendritic development and thereby lead to impairment of developing neuronal networks.[226] Moreover, in the rodent, this neurodegeneration is associated with cognitive impairment characterized by learning and memory deficits manifested in adulthood.[227] Several human cohort studies have shown an association between surgery in the neonatal period and poor neurodevelopmental outcomes[228,229] (also see Chapter 82). A large cohort study found a clear association between poor sensineural outcomes and surgery in preterm infants,[230] and more recently, neonates undergoing repair of patent ductus arteriosus were reported to have poorer outcomes.[231] These studies are interesting but are not conclusive evidence of a positive association. Epidemiologic observations suggest that the onset of Alzheimer's disease is related to cumulative anesthetic exposure before the age of 50 years,[232] and both halothane and isoflurane have been shown to increase the generation and toxicity of β-amyloid, a protein strongly implicated in the pathogenesis of Alzheimer's disease. Studies have further confirmed that inhaled anesthetics enhance the production, aggregation, and neurotoxicity of β-amyloid peptides,[233] the

appearance of brain plaques, and deficits characteristic of Alzheimer's disease.[234]

The central nervous system seems to be susceptible to anesthetic neurotoxicity at the extremes of ages, and general anesthetics produce neurotoxicity and enduring cognitive impairment in young animals. Extrapolating neurodevelopmental data from animals to humans to examine their clinical applicability is a challenge, and the implications of these findings to clinicians remain unclear. Current evidence is insufficient to recommend substantial changes in current clinical practice. Future animal studies are needed at comparable neurodevelopmental stages and with clinically relevant anesthetic doses and durations in animals exposed to a surgical stimulus and followed with appropriate physiologic monitoring. Further human clinical study is required, and comparison of outcomes in a large cohort study of neonates undergoing surgery under either general or regional anesthesia seems indicated. A study of this type would prove useful in helping to answer this important question, provide data to help guide clinical decisions, and further develop strategies for assessing the safety of anesthetics in neonates and children.

Exposure to Waste Anesthetic Gases

Inhaled anesthetics present a potential for adverse effects in patients administered inhaled anesthetics and in health care personnel exposed to waste anesthetic gases both in and out of the operating room environment. Recognition of postoperative exposure to exhaled waste anesthetic gases in postanesthesia care units (PACUs), intensive care units, and other patient care areas represents a new challenge. The recommended thresholds for trace inhaled anesthetic concentrations are less than 2 ppm for a volatile anesthetic when used alone and less than 0.5 ppm when used with N_2O. The recommended time-weighted average for N_2O is less than 25 ppm, which is much lower than the level of N_2O (1000 ppm) known to produce detectable inactivation of methionine synthase. To control occupational exposure to waste anesthetic gases, it is not sufficient to merely adopt scavenging systems in operating rooms; appropriate work practices, engineering controls, and occupational management protocols are also required throughout the perioperative process in all patient care areas. Many factors affect waste anesthetic gas concentrations, including the efficiency of air handling, room type and size, number of patients in a room or ward, and time spent in a particular patient care area.

Several studies have documented excessive levels of waste anesthetic gases in poorly ventilated PACU areas.[235-239] However, to date, none of these studies have documented any significant long-term adverse health effects.[235,236] An increased incidence of sister chromatid exchange has been found in operating room personnel in three of four recent studies, but the long-term implications of this finding are unknown at present.[240-243] In the only long-term prospective study with or without scavenging of waste anesthetic gases, Spence[244] found no causal relationship between exposure to waste anesthetic gases and adverse health effects.

Environmental Toxicities

The Greenhouse Effect. Solar radiation loads heat energy on the Earth, and to maintain a stable temperature, the Earth returns this load to space via infrared radiation. The primary constituents of the atmosphere, nitrogen and oxygen, are transparent to these rays. In the absence of other gases, the Earth's temperature would be −20°C. Naturally occurring gases such as methane, carbon dioxide, and N_2O absorb the infrared radiation. To overcome this absorption, the Earth has increased its temperature to approximately 15°C—the greenhouse effect. The contribution of major gases to the greenhouse effect is estimated to be 60% for carbon dioxide, 20% for methane, 14% for chlorofluorocarbons, and 6% for N_2O.[245] It is estimated that since the industrial revolution, the number of molecules of CO_2 per million molecules of air has increased from 280 to 385 ppm. *Global warming* is the increase in the average temperature of the Earth's near surface air and oceans since the mid-20th century and its projected continuation. The global air temperature rose 0.74°C during the 100 years ending in 2005. The Intergovernmental Panel on Climate Change (IPCC) concluded that "most of the observed increases in globally averaged temperatures since the mid-twentieth century is very likely due to the observed increase in anthrogenic greenhouse gas concentrations" via the greenhouse effect. The IPCC has predicted an average global rise in temperature of 1.4°C to 5.8°C between 1990 and 2100. Increasing global temperatures will decrease polar ice and thereby cause sea levels to rise and are expected to change precipitation patterns and increase the intensity of severe weather events. As a result, the Kyoto Protocol was negotiated and ratified by 175 countries and came into force on February 16, 2005. The United States is the only major industrialized country that is not a party to this agree-

Table 24-5 Summary of Atmospheric Lifetimes, Relative Input into the Stratosphere, Ozone-Depleting Potential (ODP), and Global-Warming Potential (GWP) Values for CFC-11, CFC-12, and Halogenated Volatile Anesthetics

Compound	M (g/mol)	$T_{½}$ (yr)	Input into Stratosphere (%)	ODP	S (cm^2/atm)	GWP
CFC-11	137.5	50	100	1.00	2500	0.033
CFC-12	121.0	102	100	1.55	3300	1.00
Halothane	197.4	6.6	13.2	1.56	1400	0.02
Enflurane	184.5	8.2	16.2	0.04	4800	0.08
Isoflurane	184.5	5.9	14.6	0.03	3900	0.05
Desflurane	168.0	21.4	21.4	0.00	3000	0.14
Sevoflurane	200.0	4.0	12.6	0.00	2550	0.02

ment. The United States is a signatory but has not ratified or withdrawn from the protocol. Essentially, this is an agreement under which industrialized countries will reduce their collective emissions of greenhouse gases by 5.2% relative to the year 1990 via a "cap and trade" system (effectively a 29% decrease over expected emission levels without the cuts). The goal is to lower overall emission of six greenhouse gases: carbon dioxide, methane, nitrous oxide, sulfur hexafluoride, hydrofluorocarbons, and perfluorocarbons, averaged over the period 2008 to 2112. National limitations range from reduction of 8% for the European Union, 7% for the United States, and 6% for Japan. The global-warming and ozone-depleting potential of several halocarbons, including the common fluorinated anesthetics and N_2O, is summarized in Tables 24-5[246] and 24-6.[247] N_2O is extremely stable with an atmospheric lifetime of 100 to 150 years. Its only sink is degradation by ultraviolet radiation outside the ozone layer. N_2O contributes about 5% of the greenhouse gas effect, and medical use of N_2O contributes approximately 0.35% to 2% of this total.[248,249] Like N_2O, in addition to contributing to the greenhouse effect, chlorine-containing compounds such as halothane, enflurane, isoflurane, and desflurane also deplete stratospheric ozone.[246] Present protocols call for elimination of these compounds by 2030. In addition, there is an ongoing movement in Japan[250] and the European Union to reduce and eventually eliminate N_2O from anesthesia. The contribution of anesthetic-released N_2O and chlorinated volatile agents to global warming, the greenhouse effect, and ozone depletion is minor in comparison to that generated by the combustion of fossil fuels and nitrogen-containing fertilizers. N_2O contributes 1% to ozone depletion and 0.05% to the greenhouse effect, whereas the anesthetics contribute 0.01% to ozone depletion and 0.1% to the greenhouse effect. We have reduced the toxicity of anesthetics to patients and health care workers since the inception of modern anesthesia; however, environmental toxicities may prove to be the Achilles heel of these valuable agents. Until such time as these agents are eliminated from practice or better, more stable substitutes become available, we as anesthesia providers can reduce the adverse environmental consequences of these agents by using low-flow anesthesia systems whenever possible and thus can have a small but important positive impact on the environment.

Summary

Volatile anesthetic agents, like most drugs, undergo metabolism in the body and are sometimes associated with toxic reactions. Scientific investigations and industry research have led to the development of more stable anesthetics with more desirable clinical properties. Inhaled agents that are more heavily metabolized are associated with the greatest numbers of reported toxicities. As with most drugs, these toxicities occur when the anesthetics are given as "standard-dose medications"; that is, the appropriate medication and dose are given at the proper time, in the correct manner, to the right patient. Thus, these associated toxicities under most circumstances meet the definition of adverse drug reactions (ADRs). More than 2 million ADRs are reported each year in the United States and result in more than 100,000 deaths. It should be noted that 51% of approved drugs have serious ADRs not detected before approval and that ADRs are responsible for 6% of all hospital admissions, occur in 10% to 20% of hospitalized patients, and are the cause of death in 0.1% of medical and 0.01% of surgical patients. They are the fourth leading cause of death in hospitalized patients (0.32% of hospitalized patients). When compared with most therapeutic agents, the safety of fluorinated inhaled anesthetics is remarkable. Future developments in the field of personalized medicine, in which both the selection of a specific therapeutic agent and its associated dosing are tailored to an individual patient on the basis of individual genetic profiles, will have ramifications for increased efficacy and patient safety. Idiosyncratic toxicities that involve the human immune system continue to present some of the greatest challenges to anesthesia and medicine, but new insight into the structure-toxicity relationships of drugs at the molecular level may provide the necessary tools to solve this puzzle.

The use of any anesthetic agent must be based on specific knowledge of its benefits and risks, how it may produce toxicity, and in which patients it may be most safely administered. Clearly, the perfect anesthetic agent does not exist yet, and individual patient circumstances will continue to dictate the choice and use of inhaled anesthetics in clinical practice. As ongoing research attempts to uncover emerging toxicities, the clinician is challenged to balance new information with current clinical practices and choose the safest, most effective agents for each patient.

25 Inhaled Anesthetic Delivery Systems

Key Points

1. The low-pressure circuit (LPC) is the "vulnerable area" of anesthesia machines because it is most subject to breakage and leaks. The LPC is located downstream from all safety features of anesthesia machines except the oxygen analyzer, and it is the portion of the machine that is missed if an inappropriate LPC leak test is performed.
2. It is mandatory that the LPC be checked for leaks before administering an anesthetic because leaks in the LPC can cause delivery of a hypoxic mixture or patient awareness during anesthesia (or both).
3. Because many GE/Datex-Ohmeda anesthesia machines have a one-way check valve in the LPC, a negative-pressure leak test is required to detect leaks in the LPC. A positive-pressure leak test will not detect leaks in the LPC of most GE/Datex-Ohmeda products.
4. Internal vaporizer leaks can be detected only with the vaporizer turned on.
5. Before administering an anesthetic, the circle system must be checked for leaks and for flow. To test for leaks, the circle system is pressurized to 30 cm H_2O, and the circle system airway pressure gauge is observed (static test). To check for appropriate flow to rule out obstruction and faulty valves, the ventilator and a test lung (breathing bag) are used (dynamic test).
6. Some new anesthesia workstation self-tests do not detect internal vaporizer leaks unless each vaporizer is individually turned on during the self-test.
7. In the event of pipeline crossover, two actions must be taken. The backup oxygen cylinder must be turned "on," and the wall supply sources must be disconnected.
8. Fail-safe valves and proportioning systems help minimize delivery of a hypoxic mixture, but they are not foolproof. Delivery of a hypoxic mixture can result from (1) the wrong supply gas, (2) a defective or broken safety device, (3) leaks downstream from the safety devices, (4) administration of an inert gas, and (5) dilution of the inspired oxygen concentration by high concentrations of inhaled anesthetics.
9. Because of desflurane's low boiling point and high vapor pressure, controlled vaporization of desflurane requires special sophisticated vaporizers such as the Datex-Ohmeda Tec 6 and the Aladin cassette vaporizer.
10. Misfilling a conventional variable-bypass vaporizer with desflurane could theoretically be catastrophic and result in delivery of a hypoxic mixture and a massive overdose of inhaled desflurane anesthetic.
11. Inhaled anesthetics can interact with carbon dioxide absorbents and produce toxic compounds. During sevoflurane anesthesia, compound A can be formed, particularly at low fresh gas flow rates, and during desflurane anesthesia, carbon monoxide can be produced, particularly with desiccated absorbents.
12. Desiccated strong-base absorbents (particularly Baralyme) can react with sevoflurane and produce extremely high absorber temperatures and combustible decomposition products. In combination with the oxygen- or nitrous oxide–enriched environment of the circle system, these effects can produce fires within the breathing system.
13. Anesthesia ventilators with ascending bellows (bellows that ascend during the expiratory phase) are safer than descending bellows because disconnections will be readily manifested by failure ascending bellows to refill.
14. With ascending bellows anesthesia ventilators, fresh gas flow and oxygen flushing during the inspiratory phase contribute to the patient's tidal volume because the ventilator relief valve is closed. Oxygen flushing during the inspiratory phase can cause volutrama and/or barotrauma, (particularly in pediatric patients). Therefore, the oxygen flush should never be activated during the inspiratory phase of mechanical ventilation.

15. New ventilators that use fresh gas decoupling technology virtually eliminate the possibility of barotrauma from oxygen flushing during the inspiratory phase because fresh gas flow and oxygen flush flow are diverted to the reservoir breathing bag. However, if the breathing bag has a leak or is absent, patient awareness under anesthesia and delivery of a lower than expected oxygen concentration could occur because of entrainment of room air.

16. With newer GE/Datex-Ohmeda anesthetic ventilators such as the 7100 and 7900 SmartVent, scavenging of both the patient gas and the drive gas results in substantially increased volumes of scavenged gas. Thus, the scavenging systems must be set appropriately to accommodate the increased volume or pollution of the operating room environment could result.

Over the years, the anesthesia delivery system has evolved from a simple pneumatic device to a complex multisystem workstation, and new technologies continue to advance its development at a rapid pace (Figs. 25-1 and 25-2). These continuing changes to one of the most important pieces of equipment used by anesthesia care providers can make maintaining a current knowledge base (sufficient for their safe use) difficult for many to achieve. To prevent mishaps, providers must be aware of the functional anatomy of the anesthesia workstation. Furthermore, this knowledge base must even include the newer systems as they become available, to the extent that they are represented in an individual's practice. Fortunately, the most basic workstation components are generally fairly consistent from one platform to another. These basic component systems include what was formerly referred to as the anesthesia machine proper (i.e., the pressure-regulating and gas-mixing components), the vaporizers, the anesthesia breathing circuit, the ventilator, the scavenging system, and respiratory and physiologic monitoring systems.

For anesthesia care providers to safely use the many features of today's anesthesia workstation, a thorough understanding of its operation is essential. Because of large-scale education efforts, in addition to improvements in engineering and design of the anesthesia workstation, malpractice claims associated with gas delivery equipment are becoming less frequent. On the other hand, because of the continual development of new volatile anesthetics, aftermarket add-on devices, and even new anesthesia workstation features, equipment-related mishaps are not likely to disappear completely. In fact, in a review of the anesthesia closed-claims literature, Caplan and coworkers found that although claims related to the medical gas delivery system were rare, when they did occur, they were usually severe and death or permanent brain injury frequently resulted.[1]

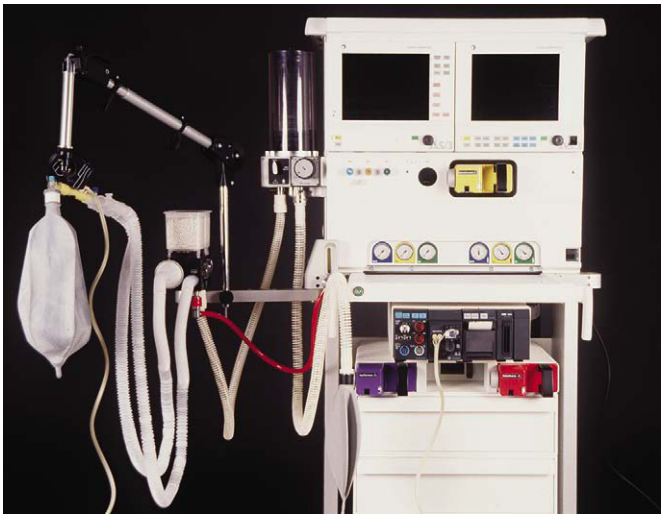

Figure 25-1 GE/Datex-Ohmeda S/5 Anesthesia Delivery Unit (ADU) workstation. *(Courtesy of GE Medical.)*

Figure 25-2 Dräger Narkomed 6000 anesthesia workstation.

In this chapter we examine the anesthesia workstation piece by piece. We will describe the normal operation, function, and integration of major anesthesia workstation subsystems. More important, we illustrate potential problems and hazards associated with the various components of the anesthesia delivery system and the appropriate preoperative checks that may help detect and prevent such problems.

Anesthesia Workstation Standards and Pre-use Procedures

A few years ago, fundamental knowledge of basic anesthesia machine pneumatics would suffice for most anesthesia care pro-

viders. Today, a detailed understanding of pneumatics, electronics, and even computer science is helpful to fully understand the capabilities and complexities of the anesthesia workstation. Along with changes in the composition of the anesthesia workstation, including more complex ventilation systems and integrated monitoring, recently there has also been increasing divergence between anesthesia workstation designs from different manufacturers. In 1993, a joint effort between the American Society of Anesthesiologists (ASA) and the U.S. Food and Drug Administration (FDA) produced the 1993 FDA Anesthesia Apparatus Checkout Recommendations (Appendix 1). This pre-use checklist was versatile in that it could be applied to most commonly available anesthesia machines equally well, and it did not require users to vary the pre-use procedure significantly from machine to machine.

Today, because of increasing fundamental anesthesia workstation design variations, the 1993 FDA pre-use checklist may no longer be applicable to certain anesthesia workstations. In such cases, anesthesia care providers must be aware of this and follow the original equipment manufacturer's recommended pre-use checklist. Some of the latest workstations even have computer-assisted self-tests that automatically perform all or a part of the pre-use machine checkout procedure. The availability of such automated checkout features further adds to the complexity of constructing a standardized pre-use anesthesia machine checklist such as the one that the anesthesia community has enjoyed in the recent past. Ultimately, the responsibility for performing adequate pre-use testing of the anesthesia workstation falls to the anesthesia care provider. It will be the anesthesia care provider of record who must be aware of which anesthesia workstation components are tested by these automated self-tests and which ones are not. Because of the number of machines available and the variability among their self-testing procedures, we will limit their discussion to general topics related to these systems.

Standards for Anesthesia Machines and Workstations

Standards for anesthesia machines and workstations provide guidelines for manufacturers regarding their minimum performance, design characteristics, and safety requirements. During the past 2 decades, the progression of anesthesia machine standards has been as follows:

1979: American National Standards Institute (ANSI) Z79.8-1979[2]
1988: American Society for Testing and Materials (ASTM) F1161-88[3]
1994: ASTM F1161-94[4] (reapproved in 1994 and discontinued in 2000)
2000: ASTM F1850-00[5]

To comply with the 2000 ASTM F1850-00 standard, newly manufactured workstations must have monitors that measure the following parameters: continuous breathing system pressure, exhaled tidal volume, ventilatory carbon dioxide concentration, anesthetic vapor concentration, inspired oxygen concentration, oxygen supply pressure, arterial oxygen saturation of hemoglobin, arterial blood pressure, and continuous electrocardiogram. The anesthesia workstation must have a prioritized alarm system that groups the alarms into three categories: high, medium, and low priority. These monitors and alarms may be automatically enabled and made to function by turning on the anesthesia workstation, or the monitors and alarms can be manually enabled and made functional by following a pre-use checklist.[5]

Checking Your Anesthesia Workstation

A complete anesthesia apparatus checkout procedure must be performed each day before the anesthesia workstation is first used. An abbreviated version should be performed before each subsequent case. Several checkout procedures exist, but the 1993 FDA Anesthesia Apparatus Checkout Recommendations reproduced in Appendix 1 are the most popular and remain applicable to the majority of anesthesia machines in use worldwide.[6-10] Anesthesia care providers should also be aware that many machines have been modified in the field. The addition of aftermarket products may mandate modification of the pre-use checklist. The user must always refer to the original equipment manufacturer's operator's manual for special procedures or precautions related to particular workstations.

Because of the divergent nature of many contemporary anesthesia workstation designs, the philosophy of "one pre-use machine checkout procedure fits all machines" has had to be changed to a philosophy of "not all workstations are created equally." As a result, in 2005 the ASA's Committee on Equipment and Facilities began to develop a revised pre-use checklist that was designed to be more workstation specific and, indeed, was intended to eventually replace the 1993 FDA Anesthesia Apparatus Checkout Recommendations. Instead of the 1993 checklist, which elaborated specific checks and how they should be performed, the new pre-use guideline elaborates only specific systems and subsystems that must be evaluated. It is ultimately up to the user, in conjunction with workstation manufacturers, and local policy to determine the actual mechanisms/specific tests that will be used to accomplish these subsystem evaluations. Appendix 2 contains the most current version of these recommendations. Although the new recommendations also now address who (personnel-wise) may be responsible for performing such machine pre-use evaluations, every anesthesia care provider must be aware that the ultimate responsibility for proper machine pre-use safety checks rests on the provider using the machine to deliver anesthetic care. The current guidelines for developing institution-specific checkout procedures before anesthesia delivery can also be found on the ASA website at www.asahq.org/clinical/fda.htm. Also located at the same website are sample workstation-specific pre-use checklists developed by other institutions that can be adapted/modified for use in other practice settings.

Testing Specific Components of the Anesthesia Delivery System

The three most important preoperative checks are (1) calibration of the oxygen analyzer, (2) the low-pressure circuit leak test, and (3) the circle system tests. Each is discussed in the following paragraphs. Additional details regarding these systems will be presented in subsequent sections describing the anatomy of the anesthesia workstation. For a simplified diagram of a two-gas

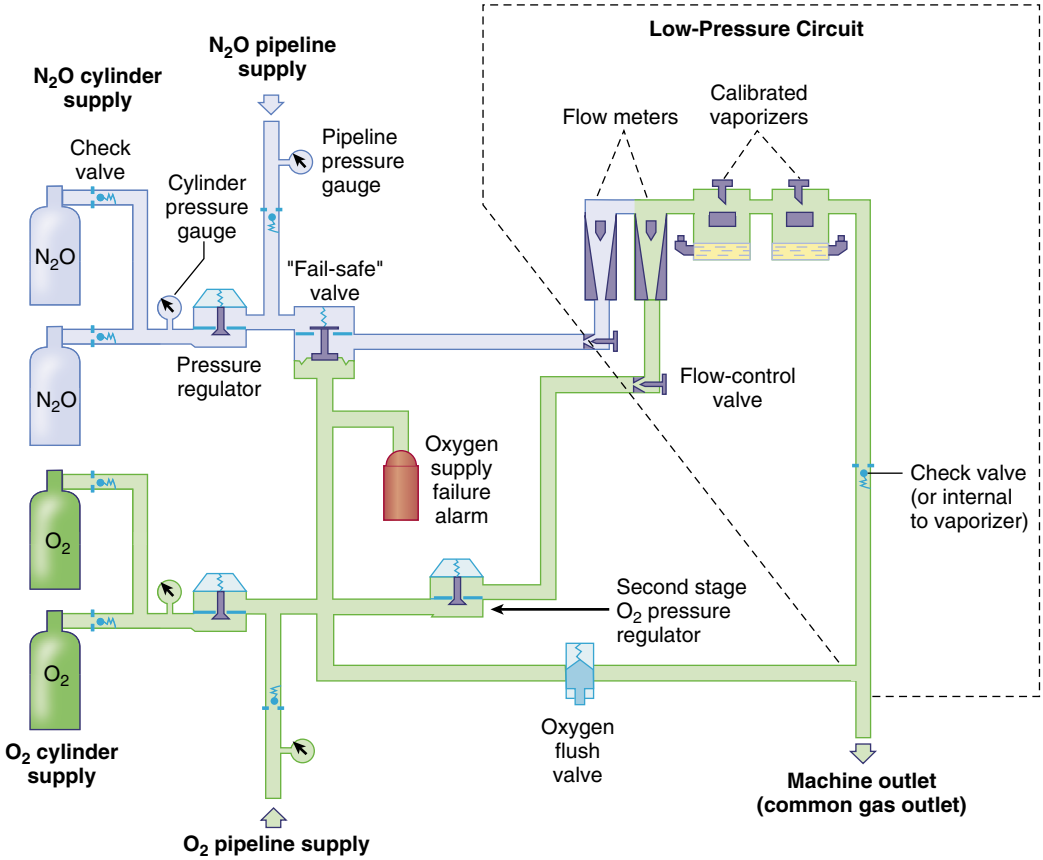

Figure 25-3 Diagram of a generic two-gas anesthesia machine. *(Modified with permission from Check-Out, a Guide for Preoperative Inspection of an Anesthesia Machine. Park Ridge, IL, American Society of Anesthesiologists, 1987.)*

anesthesia machine and the components described in the following discussion, please refer to Figure 25-3. A comprehensive discussion of Figure 25-3 can also be found in the section "Anesthesia Workstation Pneumatics."

Calibration of the Oxygen Analyzer

The oxygen analyzer is one of the most important monitors on the anesthesia workstation. It is the only machine safety device that evaluates the integrity of the low-pressure circuit in an ongoing fashion. Other machine safety devices, such as the fail-safe valve, the oxygen supply failure alarm, and the proportioning system, are all upstream from the flow control valves. The only machine monitor that detects problems downstream from the flow control valves is the oxygen analyzer. Calibration of this monitor is described in Appendix 1 (Anesthesia Apparatus Checkout Recommendations, 1993, No. 9). The actual procedure for calibrating the oxygen analyzer has remained reasonably similar over the recent generations of anesthesia workstations. Generally, the oxygen concentration–sensing element must be exposed to room air for calibration to 21%. This may require manually setting a dial on older machines, but on newer ones, it usually involves only temporary removal of the sensor, selecting and then confirming that the oxygen calibration is to be performed from a set of menus on the workstation's display screen, and finally reinstalling the sensor.

Low-Pressure Circuit Leak Test

The low-pressure leak test checks the integrity of the anesthesia machine from the flow control valves to the common gas outlet. It evaluates the portion of the machine that is downstream from all safety devices except the oxygen analyzer. The components located within this area are *precisely* the ones most subject to breakage and leaks. Leaks in the low-pressure circuit can cause hypoxia and/or patient awareness.[11,12] Flow tubes, the most delicate pneumatic component of the machine, can crack or break. A typical three-gas anesthesia machine has 16 O-rings in the low-pressure circuit. Leaks can occur at the interface between the glass flow tubes and the manifold and at the O-ring junctions between the vaporizer and its manifold. Loose filler caps on vaporizers are a common source of leaks, and these leaks can cause patient awareness under anesthesia.[11,13]

Several different methods have been used to check the low-pressure circuit for leaks, including the oxygen flush test, the common gas outlet occlusion test, the traditional positive-pressure leak test, the North American Dräger positive-pressure leak test, the Ohmeda 8000 internal positive-pressure leak test, the Ohmeda negative-pressure leak test, the 1993 FDA universal negative-pressure leak test, and others. One reason for the large number of methods is that the internal design of various machines differs considerably. The most notable example is that most GE Healthcare/Datex-Ohmeda (hereafter referred to as Datex-

Table 25-1 Check Valves and Manufacturer-Recommended Leak Test

Data from Ohio Medical Products, Ohmeda, Datex-Ohmeda, North American Dräger, Dräger Medical.

Ohmeda) workstations have a check valve near the common gas outlet whereas Dräger Medical workstations do not. The presence or absence of the check valve profoundly influences which preoperative check is indicated.

Several mishaps have resulted from application of the wrong leak test to the wrong machine.[14-17] It is therefore mandatory that the appropriate low-pressure leak test be performed each day. To do so, it is essential that the exact location and operating principles of the Datex-Ohmeda check valve be understood. Many Datex-Ohmeda anesthesia workstations have a machine outlet check valve located in the low-pressure circuit (see Table 25-1). The check valve is located downstream from the vaporizers and upstream from the oxygen flush valve (Fig. 25-3). It is open (Fig. 25-4, left) in the absence of backpressure. Gas flow from the manifold moves the rubber flapper valve off its seat and allows gas to proceed freely to the common outlet. The valve closes (Fig. 25-4, right) when backpressure is exerted on it.[8] Backpressure sufficient to close the check valve may occur with the following conditions: oxygen flushing, peak breathing circuit pressures generated during positive-pressure ventilation, or use of a positive-pressure leak test.

Generally speaking, the low-pressure circuit of anesthesia workstations without an outlet check valve can be tested with a positive-pressure leak test, and machines with check valves must

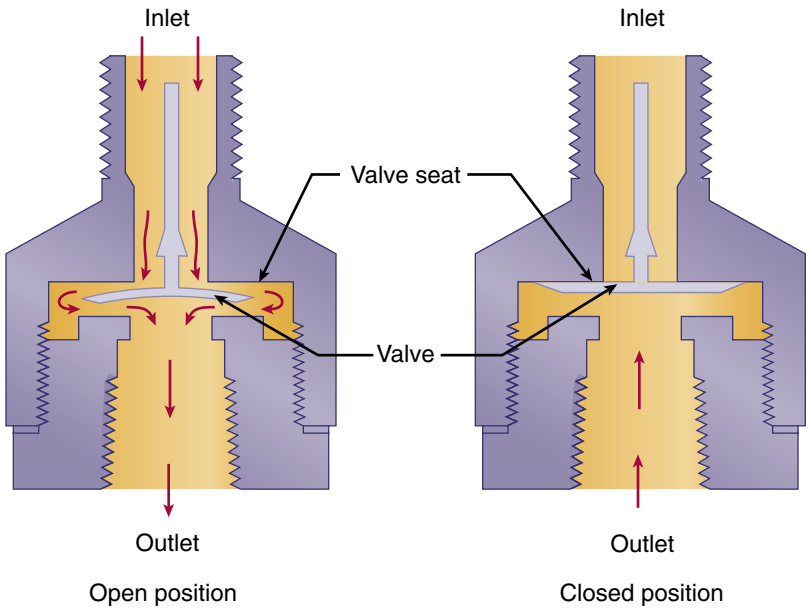

Figure 25-4 Machine outlet check valve. See text for details. *(Reproduced with permission from Bowie E, Huffman LM: The Anesthesia Machine: Essentials for Understanding. Madison, WI, Ohmeda, a Division of BOC Health Care, Inc., 1985.)*

be tested with a negative-pressure leak test. When performing a positive-pressure leak test, the operator generates positive pressure in the low-pressure circuit by using flow from the anesthesia machine or from a positive-pressure bulb to detect a leak. When performing a negative-pressure leak test, the operator creates negative pressure in the low-pressure circuit by using a suction bulb to detect leaks. Two different low-pressure circuit leak tests are described in the following paragraphs.

Oxygen Flush Positive-Pressure Leak Test Historically, older anesthesia machines did not have check valves in the low-pressure circuit. Therefore, it was common practice to pressurize the breathing circuit and the low-pressure circuit with the oxygen flush valve to test for internal anesthesia machine leaks. Because many modern Datex-Ohmeda machines now have check valves in the low-pressure circuit, however, application of a positive-pressure leak test to these machines can be misleading or even dangerous (Fig. 25-5). Inappropriate use of the oxygen flush valve or the presence of a leaking flush valve may lead to inadequate evaluation of the low-pressure circuit for leaks. In turn, this can lull the anesthesia care provider into a false sense of security despite the presence of large leaks.[15-19] Positive pressure from the breathing circuit results in closure of the outlet check valve, and the value on the airway pressure gauge will fail to decline. The system appears to be tight, but in actuality, only the circuitry downstream from the check valve is leak free.[20] Thus, a vulnerable area exists from the check valve back to the flow control valves because this area is not tested by a positive-pressure leak test.

1993 FDA Negative-Pressure Leak Test The 1993 FDA universal negative-pressure leak test[10] (Appendix 1, No. 5) was named "universal" because at that time it could be used to check all contemporary anesthesia machines, regardless of the presence or absence of check valves in the low-pressure circuit. It remains effective for many anesthesia workstations and can be applied to many Datex-Ohmeda machines, Dräger Medical machines, and others. Unfortunately, some newer machines are no longer compatible with this test. The ASA's Committee on Equipment and Facilities in conjunction with the FDA is expected to update the 1993 Anesthesia Apparatus Checkout Recommendations as this chapter comes to press. Until the new recommendations become available, the 1993 guidelines should continue to be followed as closely as possible because they remain applicable to the vast majority of anesthesia workstations in use worldwide.

The 1993 FDA checklist is based upon the Datex-Ohmeda negative-pressure leak test (Fig. 25-6). It is performed with a negative-pressure leak-testing device, which is a simple suction bulb. The machine's master switch, flow control valves, and vaporizers are turned off. The suction bulb is attached to the common fresh gas outlet and squeezed repeatedly until it is fully collapsed. This action creates a vacuum in the low-pressure circuitry. The machine is free of leaks if the hand bulb remains collapsed for at least 10 seconds. A leak is present if the bulb reinflates during this period. The test is repeated with each vaporizer individually turned to the "on" position because internal vaporizer leaks can be detected only with the vaporizer turned on.

The FDA "universal" negative-pressure low-pressure circuit leak test has several advantages.[21] It is quick and simple to perform,

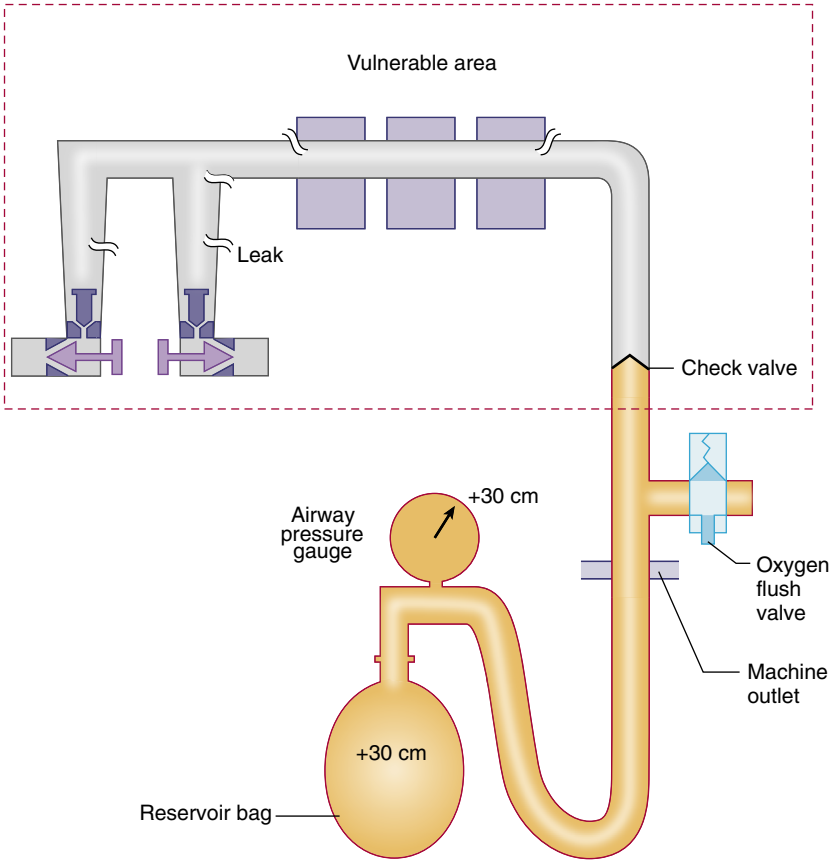

Figure 25-5 Inappropriate use of the oxygen flush valve to check the low-pressure circuit of an Ohmeda machine equipped with a check valve. The area within the *rectangle* is not checked by inappropriate use of the oxygen flush valve. The components located within this area are *precisely* the ones most subject to breakage and leaks. Positive pressure within the patient circuit closes the check valve, and the value on the airway pressure gauge does not decline despite leaks in the low-pressure circuit.

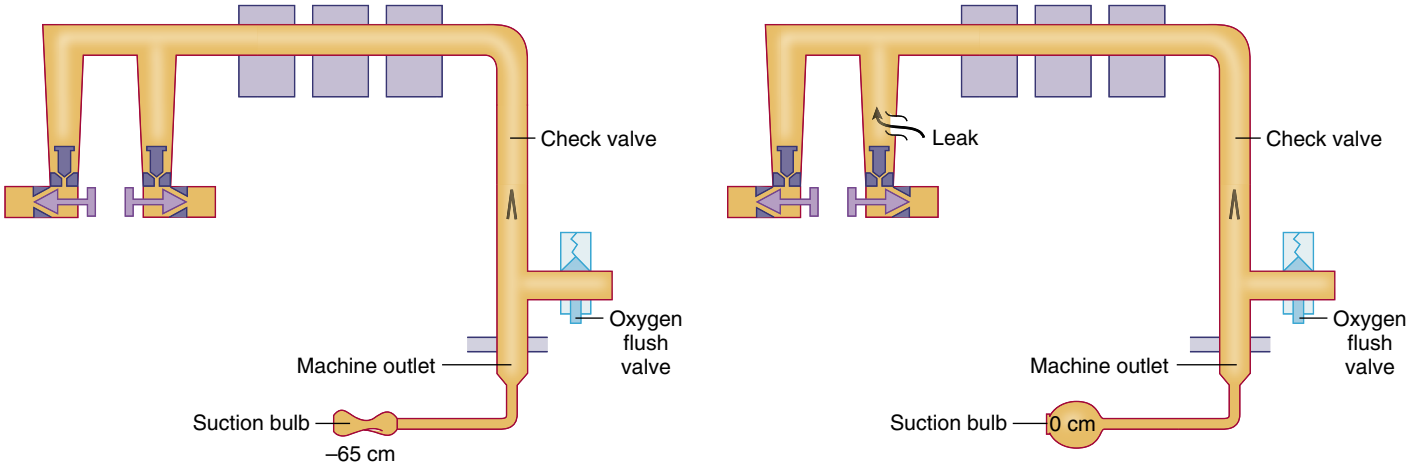

Figure 25-6 Food and Drug Administration negative-pressure leak test. **Left,** A negative-pressure leak-testing device is attached directly to the machine outlet. Squeezing the bulb creates a vacuum in the low-pressure circuit and opens the check valve. **Right,** When a leak is present in the low-pressure circuit, room air is entrained through the leak and the suction bulb inflates. *(Reprinted with permission from Andrews JJ: Understanding anesthesia machines.* In *1988 Review Course Lectures. Cleveland, OH, International Anesthesia Research Society, 1988, p 78.)*

has an obvious end point, and may help isolate the problem. For example, if the bulb reinflates in less than 10 seconds, a leak is present somewhere in the low-pressure circuit. Therefore, it differentiates between breathing circuit leaks and leaks in the low-pressure circuit. The "universal" negative-pressure leak test is the most sensitive of all contemporary leak tests because it is not dependent on volume. That is, it does not involve the use of a breathing bag or corrugated hoses whose compliance could mask a significant leak. It can detect leaks as small as 30 mL/min. Finally, the operator does not need detailed or in-depth knowledge of proprietary design differences. If the operator performs the universal test correctly, the leak will be detected.

Circle System Tests

The circle system tests (Appendix 1, Nos. 11 and 12) evaluate the integrity of the circle breathing system, which spans from the common gas outlet to the Y-piece (Fig. 25-7). It has two parts—the *leak test* and the *flow test*. To thoroughly check the circle system for leaks, valve integrity, and obstruction, both tests must be performed preoperatively. The *leak test* is performed by closing the pop-off valve, occluding the Y-piece, and pressurizing the circuit to 30 cm H_2O with the oxygen flush valve. The value on the pressure gauge will not decline if the circle system is leak free, but this does not ensure valve integrity. The value on the gauge will read 30 cm H_2O even if the unidirectional valves are stuck shut or the valves are incompetent.

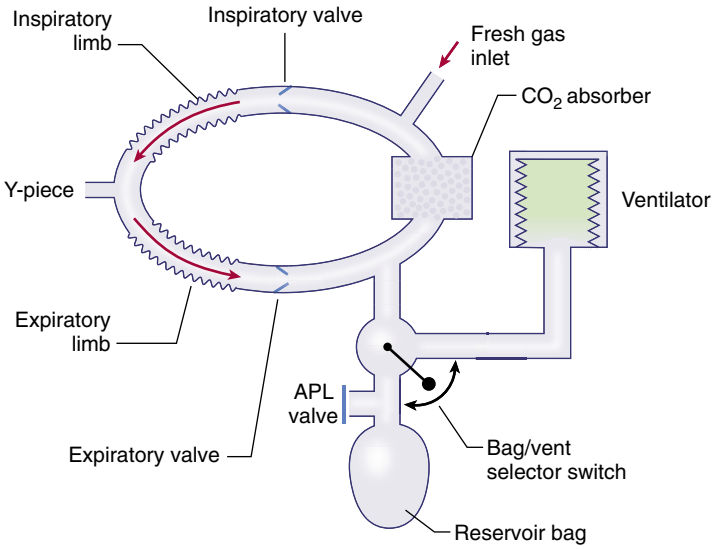

Figure 25-7 Components of the circle system. APL, adjustable pressure-limiting; B, reservoir bag; V, ventilator. *(Reproduced with permission from Brockwell RC: Delivery systems for inhaled anesthesia.* In *Barash PG [ed]: Clinical Anesthesia, 5th ed. Philadelphia, Lippincott Williams & Wilkins, 2006, p 562.)*

The *flow test* checks the integrity of the unidirectional valves, and it detects obstruction in the circle system. It can be performed by removing the Y-piece from the circle system and breathing through the two corrugated hoses individually. The valves should be present, and they should move appropriately. The operator should be able to inhale but not exhale through the inspiratory limb and able to exhale but not inhale through the expiratory limb. The flow test can also be performed by using the ventilator and a breathing bag attached to the "Y"-piece as described in the 1993 FDA Anesthesia Apparatus Checkout Recommendations (Appendix 1, No. 12).[10]

Workstation Self-Tests

As mentioned previously, many new anesthesia workstations now incorporate technology that allows the machine to either automatically or manually walk the user through a series of self-tests to check for functionality of the electronic, mechanical, and pneumatic components. Tested components commonly include the gas supply system, flow control valves, circle system, ventilator, and, in the case of the Datex-Ohmeda Anesthesia Delivery Unit (ADU), even the Aladin cassette vaporizer. The comprehensiveness of these self-diagnostic tests varies from one model and manufacturer to another. If these tests are to be used, all manufacturer recommendations must be read and strictly followed. Although a thorough understanding of what the particular workstation's self-tests include is very helpful, this information is often difficult to obtain and may vary greatly between devices.

One particularly important point of caution with self-tests should be noted on systems with manifold-mounted vaporizers such as the Dräger Medical Fabius GS and the Narkomed 6000 series. A manifold-mounted vaporizer does not become part of an anesthesia workstation's gas flow stream until its concentration control dial is turned to the "on" position. Therefore, to detect internal vaporizer leaks on this type of system, the "leak test" portion of the self-diagnostic must be repeated separately with each individual vaporizer turned to the "on" position. If this precaution is not taken, large leaks that could potentially result in patient awareness, such as from a loose filler cap or cracked fill indicator, could go undetected.

Anesthesia Workstation Pneumatics

Anatomy of an Anesthesia Workstation

A simplified diagram of a generic two-gas anesthesia machine is presented in Figure 25-3. The pressures within the anesthesia workstation can be divided into three circuits: a high-pressure, an intermediate-pressure, and a low-pressure circuit (see Fig. 25-3). The *high-pressure circuit* is confined to the cylinders and the cylinder primary pressure regulators. For oxygen, the pressure range of the high-pressure circuit extends from a high of 2200 pounds per square inch gauge (psig) to 45 psig, which is the regulated cylinder pressure. For nitrous oxide in the high-pressure circuit, pressures ranges from a high of 750 psig in the cylinder to a low of 45 psig. The *intermediate-pressure circuit* begins at the regulated cylinder supply sources at 45 psig, includes the pipeline sources at 50 to 55 psig, and extends to the flow control valves. Depending on the manufacturer and specific machine design, second-stage pressure regulators may be used to decrease pipeline supply pressure to the flow control valves to an even lower pressure such as 14 or 26 psig within the intermediate-pressure circuit.[22,23] Finally, the *low-pressure circuit* extends from the flow control valves to the common gas outlet. Therefore, the low-pressure circuit includes the flow tubes, vaporizer manifold, vaporizers, and the one-way check valve on most Datex-Ohmeda machines.[22]

Both oxygen and nitrous oxide have two supply sources: a pipeline supply source and a cylinder supply source. The pipeline supply source is the primary gas source for the anesthesia machine. The hospital pipeline supply system provides gas to the machine at approximately 50 psig, which is the normal working pressure of most machines. The cylinder supply source serves as a backup if the pipeline supply fails or as the primary supply if the anesthesia workstation is being used in a location without the availability of pipeline-supplied gases. As previously described, the oxygen cylinder source is regulated from 2200 to approximately 45 psig, and the nitrous oxide cylinder source is regulated from 745 to approximately 45 psig.[22-24]

A safety device traditionally referred to as the *fail-safe* valve is located downstream from the nitrous oxide supply source. It serves as an interface between the oxygen and nitrous oxide supply sources. This valve shuts off or proportionally decreases the supply of nitrous oxide (and other gases) if the oxygen supply pressure declines. To meet ASTM standards, contemporary machines have an alarm device to monitor the oxygen supply pressure. A high-priority alarm is actuated as the declining oxygen supply pressure reaches a predetermined threshold such as 30 psig.[22-24]

Many Datex-Ohmeda machines have a second-stage oxygen regulator located downstream from the oxygen supply source in the intermediate-pressure circuit. It is adjusted to a precise pressure level, such as 14 psig.[23] This regulator supplies a constant pressure to the oxygen flow control valve regardless of fluctuating oxygen pipeline pressures. For example, flow from the oxygen flow control valve will be constant if the oxygen supply pressure is greater than 14 psig.

The flow control valves represent an important anatomic landmark within the anesthesia workstation because they separate the intermediate-pressure circuit from the low-pressure circuit. The low-pressure circuit is the part of the machine that lies downstream from the flow control valves. The operator regulates flow entering the low-pressure circuit by adjusting the flow control valves. The oxygen and nitrous oxide flow control valves are linked mechanically or pneumatically by a proportioning system to help prevent inadvertent delivery of a hypoxic mixture. After leaving the flow tubes, the mixture of gases travels through a common manifold and may be directed to a calibrated vaporizer. Precise amounts of inhaled anesthetic can be added, depending on the vaporizer control dial setting. The total fresh gas flow plus the anesthetic vapor then travel toward the common gas outlet.[22,23]

Many Datex-Ohmeda anesthesia machines have a one-way check valve located between the vaporizer and the common gas outlet in the mixed-gas pipeline. Its purpose is to prevent backflow into the vaporizer during positive-pressure ventilation, thereby minimizing the effects of intermittent fluctuations in downstream pressure on the concentration of inhaled anesthetic (see "Intermittent Backpressure" in the section "Vaporizers"). The

presence or absence of this check valve *profoundly* influences which preoperative leak test is indicated (see "Checking Your Anesthesia Workstation"). The oxygen flush connection joins the mixed-gas pipeline between the one-way check valve (when present) and the machine outlet. Thus, when the oxygen flush valve is activated, the pipeline oxygen pressure has a "straight shot" to the common gas outlet.[22,23]

Pipeline Supply Source

Under normal conditions, the pipeline supply serves as the primary gas source for the anesthesia machine. Most hospitals today have a central piping system to deliver medical gases such as oxygen, nitrous oxide, and air to the operating room. The central piping system must supply the correct gases at the appropriate pressure for the anesthesia workstation to function properly. Unfortunately, this does not always occur. Proven as recently as 2002, even large medical centers with huge cryogenic bulk oxygen storage systems are not immune to component failures that may contribute to critical oxygen pipeline supply failures.[25] In this case, rupture of a faulty joint at the bottom of the primary cryogenic oxygen storage tank released 8000 gallons of liquid oxygen to flood the streets in the surrounding area. This mishap suddenly compromised oxygen delivery in a major medical center.

In a survey of approximately 200 hospitals in 1976, 31% reported difficulties with pipeline systems.[26] The most common problem was inadequate oxygen pressure, followed by excessive pipeline pressure. The most devastating reported hazard, however, was accidental crossing of oxygen and nitrous oxide pipelines, which has led to many deaths. This problem caused 23 deaths in a newly constructed wing of a general hospital in Sudbury, Ontario, during a 5-month period.[26,27] More recently, in 2002 two additional hypoxic deaths were reported in New Haven, Connecticut. These deaths resulted from a medical gas system failure in which an altered oxygen flow meter was inadvertently connected to a wall supply source for nitrous oxide.[28]

In the event that a pipeline crossover is ever suspected, the anesthesia care provider must immediately make *two* corrective actions. First, the backup oxygen cylinder should be turned on. Then the pipeline supply must be disconnected. This second step is mandatory because the machine will preferentially use the inappropriate 50-psig pipeline supply source instead of the lower pressure (45 psig) oxygen cylinder source if the wall supply is not disconnected.

Gas enters the anesthesia machine through the pipeline inlet connections (arrows in Fig. 25-3). The pipeline inlet fittings are gas-specific Diameter Index Safety System (DISS) threaded body fittings. The DISS provides threaded noninterchangeable connections for medical gas lines to minimize the risk of misconnection. A check valve located downstream from the inlet prevents reverse flow of gases from the machine to the pipeline or the atmosphere.

Cylinder Supply Source

Anesthesia workstations have E-cylinders for use when a pipeline supply source is not available or the pipeline system fails. As has been shown again in the recent literature, anesthesia care providers can easily become complacent in assuming that backup gas cylinders are in fact present on the back of the anesthesia workstation and, furthermore, if present, that they contain an adequate supply of compressed gas. Any pre-use checklist should contain steps that confirm both.[29]

Medical gases supplied in E-cylinders are attached to the anesthesia machine via the hanger yoke assembly. The hanger yoke assembly orients and supports the cylinder, provides a gas-tight seal, and ensures unidirectional flow of gases into the machine.[22] Each hanger yoke is equipped with the Pin Index Safety System (PISS). The PISS is a safeguard introduced to eliminate cylinder interchanging and the possibility of accidentally placing the incorrect gas on a yoke designed to accommodate another gas. Two metal pins on the yoke assembly are arranged so that that they project into corresponding holes on the cylinder valve. Each gas or combination of gases has a specific pin arrangement.[30]

Once the cylinders are turned on, compressed gases may pass from their respective high-pressure cylinder sources into the anesthesia machine (see Fig. 25-3). A check valve is located downstream from each cylinder if a double-yoke assembly is used. This check valve serves several functions. First, it minimizes transfer of gas from a cylinder at high pressure to one with lower pressure. Second, it allows an empty cylinder to be exchanged for a full one while gas flow continues from the other cylinder into the machine with minimal loss of gas or supply pressure. Third, it minimizes leakage from an open cylinder to the atmosphere if one cylinder is absent.[22,23] A cylinder supply pressure gauge is located downstream from the check valves. The gauge will indicate the pressure in the cylinder with the higher pressure when two reserve cylinders of the same gas are opened at the same time.

Each cylinder supply source has a pressure-reducing valve known as the cylinder pressure regulator. It reduces the high and variable storage pressure present in a cylinder to a lower, more constant pressure suitable for use in the anesthesia machine. The oxygen cylinder pressure regulator reduces the oxygen cylinder pressure from a high of 2200 psig to approximately 45 psig. The nitrous oxide cylinder pressure regulator receives pressure of up to 745 psig and reduces it to approximately 45 psig.[22,23]

The gas supply cylinder valves should be turned off when not in use, except during the preoperative machine checkout period. If the cylinder supply valves are left on, the reserve cylinder supply can be silently depleted whenever the pressure inside the machine decreases to a value lower than the regulated cylinder pressure. For example, oxygen pressure within the machine can decrease below 45 psig with oxygen flushing or possibly even during use of a pneumatically driven ventilator, particularly at high inspiratory flow rates. Additionally, the pipeline supply pressures of all gases can fall to less than 45 psig if problems exist in the central piping system. If the cylinders are left on when this occurs, they will eventually become depleted and no reserve supply may be available if a pipeline failure occurs.[20,23]

The amount of time that an anesthesia machine can operate from E-cylinder supplies is commonly of concern. This is becoming particularly important to anesthesia care providers now that anesthesia machines are being used more frequently in the setting of office-based and remote (outside the operating room) anesthesia care within hospitals. For oxygen, the volume of gas remaining in the cylinder is proportional to cylinder pressure. One author has proposed the following equation to help estimate the time remaining[31]:

$$\text{Approximate remaining time (hr)} \approx \frac{\text{Oxygen cylinder pressure (psig)}}{200 \times \text{Oxygen flow rate (L/min)}}$$

It should be noted that this calculation will provide a gross estimate of the time remaining and may not be exact. Furthermore, users should be cautioned that use of a pneumatically driven mechanical ventilator will dramatically increase oxygen utilization rates, thus decreasing the time remaining until depletion of the cylinder. Hand ventilation at low fresh gas flow rates may consume less than 5% of the amount of oxygen consumed by intermediate flow meter settings coupled with the use of pneumatically powered mechanical ventilation.[25] Because piston-type anesthesia ventilators such as found in the Dräger Medical Fabius GS and Narkomed 6000 series do not affect oxygen consumption rates, they may be preferable to conventional gas-driven ventilators in practice settings that are dependent on the use of compressed gas cylinders as the primary gas source.

Oxygen Supply Pressure Failure Safety Devices

Oxygen and nitrous oxide supply sources existed as independent entities in older models of anesthesia machines, and they were not pneumatically or mechanically interfaced. Therefore, abrupt or insidious oxygen pressure failure had the potential to lead to the delivery of a hypoxic mixture. The 2000 ASTM F1850-00 standard states that "The anesthesia gas supply device shall be designed so that whenever oxygen supply pressure is reduced to below the manufacturer specified minimum, the delivered oxygen concentration shall not decrease below 19% at the common gas outlet."[5] Contemporary anesthesia machines have a number of safety devices that act together in a cascade manner to minimize the risk of delivery of a hypoxic gas mixture as oxygen pressure decreases. Several of these devices are described in the following sections.

Pneumatic and Electronic Alarm Devices

Many older anesthesia machines have a pneumatic alarm device that sounds a warning when the oxygen supply pressure decreases to a predetermined threshold value, such as 30 psig. The 2000 ASTM F1850-00 standard mandates that a medium-priority alarm be activated within 5 seconds when oxygen pressure decreases below a manufacturer-specific pressure threshold.[5] Electronic alarm devices are now used to meet this guideline.

Fail-Safe Valves

A fail-safe valve is present in the gas line supplying each of the flow meters except oxygen. Controlled by oxygen supply pressure, the valve shuts off or proportionally decreases the supply pressure of all other gases (nitrous oxide, air, carbon dioxide, helium, nitrogen) as the oxygen supply pressure decreases. Unfortunately, the misnomer "fail safe" has led to the misconception that the valve prevents administration of a hypoxic mixture. Such is not the case. Machines that either are not equipped with a flow proportioning system (see "Proportioning Systems") or whose system may be disabled by the user can deliver a hypoxic mixture under normal working conditions. On such a system, the oxygen flow control valve can be closed intentionally or accidentally. Normal oxygen pressure will keep the other gas lines open so that a hypoxic mixture can result.[22,23]

Many Datex-Ohmeda machines are equipped with a fail-safe valve known as the pressure sensor shut-off valve (Fig. 25-8). This valve operates in a threshold manner and is either open or closed. Oxygen supply pressure opens the valve, and the valve return spring closes the valve. Figure 25-8 shows a nitrous oxide pressure sensor shut-off valve with a threshold pressure of 20 psig. In Figure 25-8A, an oxygen supply pressure greater than 20 psig is exerted on the mobile diaphragm. This pressure moves the piston and pin upward and the valve opens. Nitrous oxide flows freely to the nitrous oxide flow control valve. In Figure 25-8B, the oxygen supply pressure is less than 20 psig, and the force of the valve return spring completely closes the valve.[23] Nitrous oxide flow stops at the closed fail-safe valve, and it does not advance to the nitrous oxide flow control valve.

North American Dräger uses a different fail-safe valve known as the oxygen failure protection device (OFPD) to interface the oxygen pressure with that of other gases, such as nitrous oxide or other inert gases. In contrast to Datex-Ohmeda's oxygen pressure sensor shut-off valve, the OFPD is based on a proportioning principle rather than a threshold principle. The pressure of all gases controlled by the OFPD will decrease proportionally with the oxygen pressure. The OFPD consists of a seat nozzle

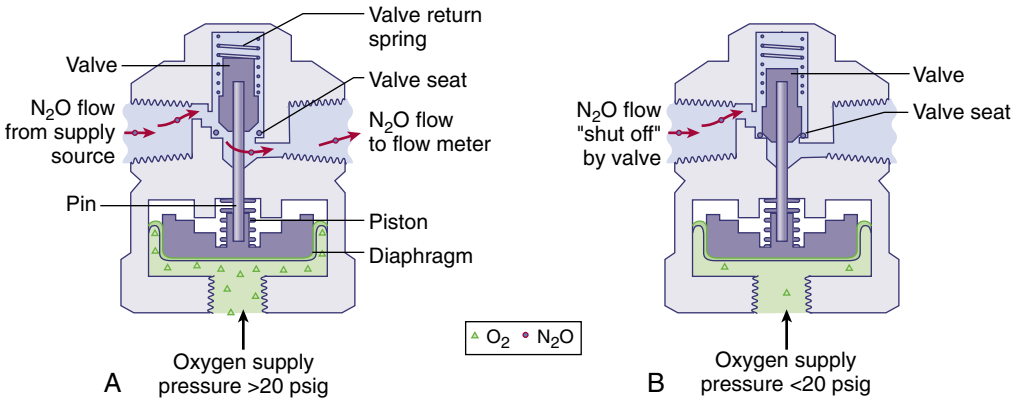

Figure 25-8 Pressure sensor shut-off valve. The valve is open in **A** because the oxygen supply pressure is greater than the threshold value of 20 psig. The valve is closed in **B** because of inadequate oxygen pressure. *(Redrawn with permission from Bowie E, Huffman LM: The Anesthesia Machine: Essentials for Understanding. Madison, WI, Ohmeda, A Division of BOC Health Care, Inc., 1985.)*

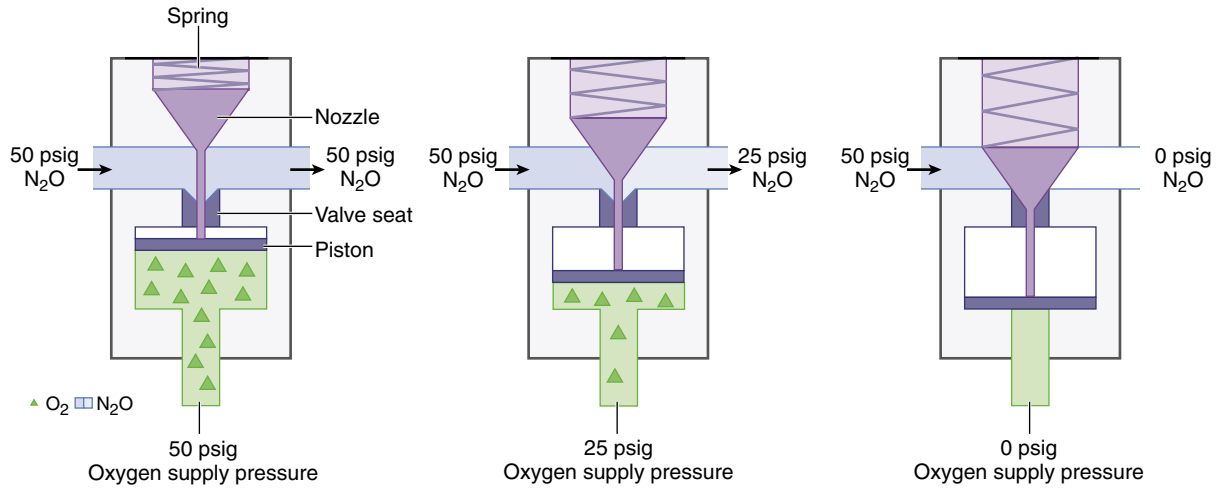

Figure 25-9 An oxygen failure protection device that responds proportionally to changes in oxygen supply pressure. See text for details. *(Redrawn with permission from Narkomed 2A Anesthesia System. Technical Service Manual, 6th ed. Telford, PA, North American Dräger, June 1985.)*

assembly connected to a spring-loaded piston (Fig. 25-9). The oxygen supply pressure in the left panel of Figure 25-9 is 50 psig. This pressure pushes the piston upward, which forces the nozzle away from the valve seat. Nitrous oxide alone or combined with other gases advances toward the flow control valve at 50 psig. The oxygen pressure in the right panel is 0 psig. The spring is expanded and forces the nozzle against the seat, thereby preventing flow through the device. Finally, the center panel shows an intermediate oxygen pressure of 25 psig. The force of the spring partially closes the valve. The nitrous oxide pressure delivered to the flow control valve is 25 psig. There is a continuum of intermediate configurations between the extremes (0 to 50 psig) of oxygen supply pressure. These intermediate valve configurations are responsible for the proportional nature of the OFPD. An important concept to be understood with these particular fail-safe devices is that the Datex-Ohmeda pressure sensor shut-off valve is threshold in nature (all or nothing) whereas the Dräger OFPD is a variable-flow type proportioning system.

Second-Stage Oxygen Pressure Regulator

Most contemporary Datex-Ohmeda workstations have a second-stage oxygen pressure regulator set at a specific value ranging from 12 to 19 psig. Output from the oxygen flow meter is constant when the oxygen supply pressure exceeds the threshold (minimal) value. The pressure sensor shut-off valve of Datex-Ohmeda is set at a higher threshold value (20 to 30 psig) to ensure that oxygen is the last gas flowing if oxygen pressure failure occurs.

Flow Meter Assemblies

The flow meter assembly (Fig. 25-10) precisely controls and measures gas flow to the common gas outlet. With traditional glass flow meter assemblies, the flow control valve regulates the amount of flow that enters a tapered, transparent flow tube known as a Thorpe tube. A mobile indicator float inside the flow tube indicates the amount of flow passing through the associated flow control valve. The quantity of flow is indicated on a scale associated with the flow tube.[22,23] Some newer anesthesia workstations

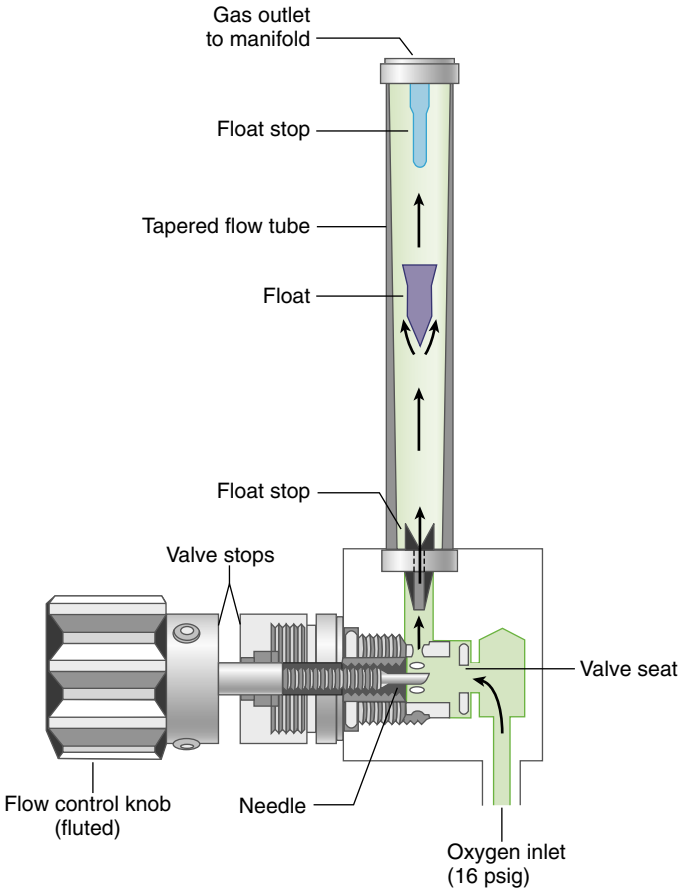

Figure 25-10 Oxygen flow meter assembly. The oxygen flow meter assembly is composed of the flow control valve assembly plus the flow meter subassembly. *(Reproduced with permission from Bowie E, Huffman LM: The Anesthesia Machine: Essentials for Understanding. Madison, WI, Ohmeda, A Division of BOC Health Care, Inc., 1985.)*

have now replaced the conventional glass flow tubes with electronic flow sensors that measure the flow of the individual gases. These flow rate data are then presented to the anesthesia care provider in either numerical format, graphic format, or a combination of the two. Integration of these "electronic flow meters" is an essential step in the evolution of the anesthesia workstation if it is to become fully integrated with anesthesia data-capturing systems such as computerized anesthesia record-keeping systems.

Operating Principles of Conventional Flow Meters

Opening the flow control valve allows gas to travel through the space between the float and the flow tube. This space is known as the annular space (Fig. 25-11). The indicator float hovers freely in an equilibrium position where the upward force resulting from gas flow equals the downward force on the float resulting from gravity at a given flow rate. The float moves to a new equilibrium position in the tube when flow is changed. These flow meters are commonly referred to as *constant-pressure* flow meters because the decrease in pressure across the float remains constant for all positions in the tube.[22,30,32]

Flow tubes are tapered, with the smallest diameter at the bottom of the tube and the largest diameter at the top. The term *variable orifice* designates this type of unit because the annular space between the float and the inner wall of the flow tube varies with the position of the float. Flow through the constriction created by the float can be laminar or turbulent, depending on the flow rate (Fig. 25-12). The characteristics of a gas that influence its flow rate through a given constriction are viscosity (laminar flow) and density (turbulent flow). Because the annular space is tubular at low flow rates, laminar flow is present and *viscosity* determines the gas flow rate. The annular space simulates an orifice at high flow rates, and turbulent gas flow then depends predominantly on the *density* of the gas.[22,32]

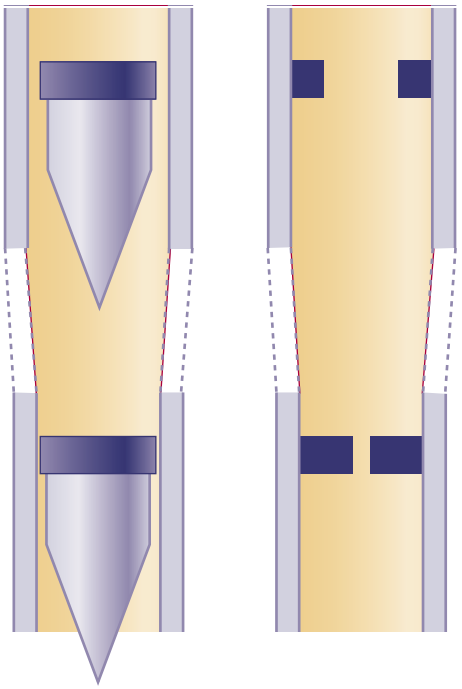

Figure 25-12 Flow tube constriction. The *lower* pair of illustrations represents the lower portion of a flow tube. The clearance between the head of the float and the flow tube is narrow. The equivalent channel is tubular because its diameter is less than its length. Viscosity is dominant in determining the gas flow rate through this tubular constriction. The *upper* pair of illustrations represents the upper portion of a flow tube. The equivalent channel is orificial because its length is less than its width. Density is dominant in determining the gas flow rate through this orificial constriction. *(Redrawn with permission from Macintosh R, Mushin WW, Epstein HG: Physics for the Anaesthetist, 3rd ed. Oxford, Blackwell Scientific, 1963.)*

Components of the Flow Meter Assembly

Flow Control Valve Assembly The flow control valve (see Fig. 25-10) assembly is composed of a flow control knob, a needle valve, a valve seat, and a pair of valve stops.[22] The assembly can receive its pneumatic input either directly from the pipeline source (50 psig) or from a second-stage pressure regulator. The location of the needle valve in the valve seat changes to establish different orifices when the flow control valve is adjusted. Gas flow increases when the flow control valve is turned counterclockwise, and it decreases when the valve is turned clockwise. Extreme clockwise rotation may result in damage to the needle valve and valve seat. Therefore, flow control valves are equipped with valve "stops" to prevent such occurrence.[23]

Safety Features. Contemporary flow control valve assemblies have numerous safety features. The oxygen flow control knob is physically distinguishable from other gas knobs. It is distinctively fluted, projects beyond the control knobs of the other gases, and is larger in diameter than the flow control knobs of other gases. All knobs are color-coded for the appropriate gas, and the chemical formula or name of the gas is permanently marked on each. Flow control knobs are recessed or protected with a shield or barrier to minimize inadvertent change from a preset position. If a single gas has two flow tubes, the tubes are arranged in series and controlled by a single flow control valve.[5]

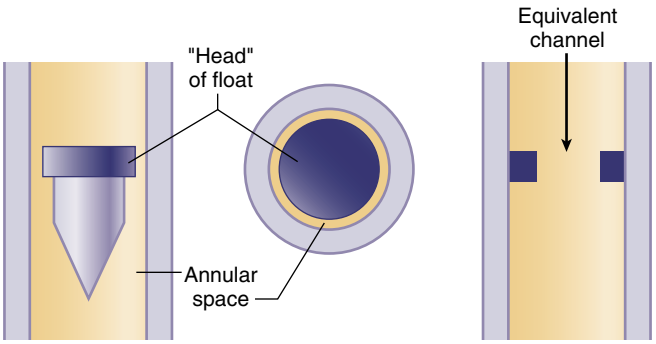

Figure 25-11 The annular space. The clearance between the head of the float and the flow tube is known as the annular space. It can be considered an equivalent to a circular channel of the same cross-sectional area. *(Redrawn with permission from Macintosh R, Mushin WW, Epstein HG: Physics for the Anaesthetist, 3rd ed. Oxford, Blackwell Scientific, 1963.)*

Flow Meter Subassembly The flow meter subassembly (see Fig. 25-10) consists of the flow tube, the indicator float with float stops, and the indicator scale.[22]

Flow Tubes. Contemporary flow tubes are made of glass. Most have a single taper in which the inner diameter of the flow tube increases uniformly from bottom to top. Manufacturers

provide double flow tubes for oxygen and nitrous oxide to provide better visual discrimination at low flow rates. A fine flow tube indicates flow from approximately 200 to 1 L/min, and a coarse flow tube indicates flow from approximately 1 to 10 to 12 L/min. The two tubes are connected in series and supplied by a single flow control valve. The total gas flow is that shown on the higher flow meter.

Indicator Floats and Float Stops. Contemporary anesthesia machines use several different types of bobbins or floats, including plumb-bob floats, rotating skirted floats, and ball floats. Flow is read at the top of plumb-bob and skirted floats and at the center of the ball on ball-type floats.[22] Flow tubes are equipped with float stops at the top and bottom of the tube. The upper stop prevents the float from ascending to the top of the tube and plugging the outlet. It also ensures that the float will be visible at maximum flows instead of being hidden in the manifold. The bottom float stop provides a central foundation for the indicator when the flow control valve is turned off.[22,23]

Scale. The flow meter scale can be marked directly on the flow tube or to the right of the tube.[5] Gradations corresponding to equal increments in flow rate are closer together at the top of the scale because the annular space increases more rapidly than the internal diameter from bottom to top of the tube. Rib guides are used in some flow tubes with ball-type indicators to minimize this compression effect. They are tapered glass ridges that run the length of the tube. There are usually three rib guides spaced equally around the inner circumference of the tube. In the presence of rib guides, the annular space from the bottom to the top of the tube increases almost proportionally with the internal diameter. This results in a nearly linear scale.[22] Rib guides are used on many Dräger Medical flow tubes.

Safety Features. The flow meter subassemblies for each gas on the Datex-Ohmeda Modulus I, Modulus II, Modulus II Plus, CD, and Aestiva are housed in independent, color-coded, pin-specific modules. The flow tubes are adjacent to a gas-specific, color-coded backing. The flow scale and the chemical formula (or name of the gas) are permanently etched on the backing to the right of the flow tube. Flow meter scales are individually hand-calibrated to the specific float to provide a high degree of accuracy. The tube, float, and scale make an inseparable unit. The entire set must be replaced if any component is damaged.

Dräger Medical does not use a modular system for its flow meter subassembly. The flow scale, the chemical symbol, and the gas-specific color codes are etched directly onto the flow tube. The scale in use is obvious when two flow tubes for the same gas are used.

Problems with Flow Meters

Leaks Flow meter leaks are a substantial hazard because the flow meters are located downstream from all machine safety devices except the oxygen analyzer.[33] Leaks can occur at the O-ring junctions between the glass flow tubes and the metal manifold or in cracked or broken glass flow tubes, the most fragile pneumatic component of the anesthesia machine. Even though gross damage to conventional glass flow tubes is usually apparent, subtle cracks and chips may be overlooked and result in errors in delivered flow.[34] The use of electronic flow meters and removal of conventional glass flow tubes from some newer anesthesia workstations (Datex-Ohmeda S/5 ADU and the Dräger Fabius) may help eliminate this potential source of leaks (see "Electronic Flow Meters").

Eger and colleagues in 1963[35] demonstrated that in the presence of a flow meter leak, a hypoxic mixture is less likely to occur if the oxygen flow meter is located downstream from all other flow meters.[32] Figure 25-13 is a more contemporary version of the figure in Eger's original publication. The unused airflow tube has a large leak. Nitrous oxide and oxygen flow rates are set at a ratio of 3:1. A potentially dangerous arrangement is shown in Figure 25-13A and B because the nitrous oxide flow meter is located in the downstream position. A hypoxic mixture can result because a substantial portion of the oxygen flow passes through the leak and all nitrous oxide is directed to the common gas outlet. A safer configuration is shown in Figure 25-13C and D. The oxygen flow meter is located in the downstream position. A portion of the nitrous oxide flow escapes through the leak, and the remainder goes toward the common gas outlet. A hypoxic mixture is less likely because all the oxygen flow is advanced by the nitrous oxide.[35] North American Dräger flow meters are arranged as in Figure 25-13C, and Datex-Ohmeda flow meters are arranged as in Figure 25-13D.

A leak in the oxygen flow tube may result in creation of a hypoxic mixture even when oxygen is located in the downstream position (Fig. 25-14).[33,34] Oxygen escapes through the leak and nitrous oxide continues to flow toward the common outlet, particularly at high ratios of nitrous oxide to oxygen flow.

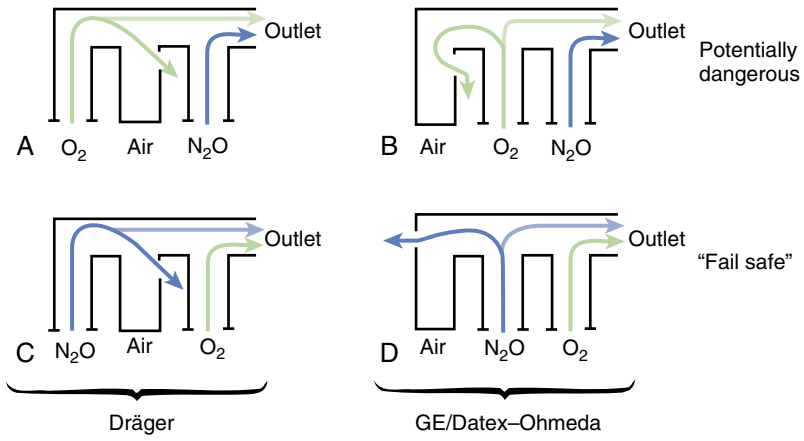

Figure 25-13 The flow meter sequence is a potential cause of hypoxia. In the event of a flow meter leak, a potentially dangerous arrangement exists when nitrous oxide is located in the downstream position (**A** and **B**). The safest configuration exists when oxygen is located in the downstream position (**C** and **D**). See text for details. *(Modified with permission from Eger EI II, Hylton RR, Irwin RH, et al: Anesthetic flow meter sequence—a cause for hypoxia. Anesthesiology 24:396, 1963.)*

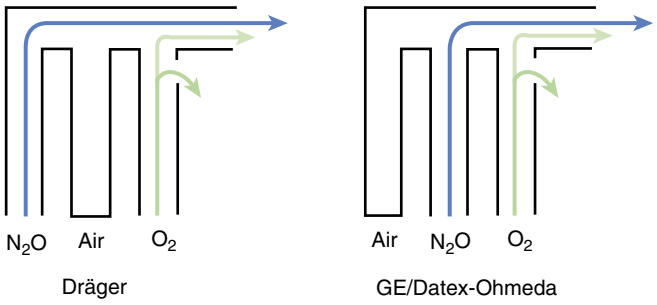

Figure 25-14 An oxygen leak from the flow tube can produce a hypoxic mixture regardless of the arrangement of the flow tubes.

Inaccuracy Flow measurement error can occur even when flow meters are assembled properly with appropriate components. Dirt or static electricity can cause a float to stick, and the actual flow may be higher or lower than that indicated. Sticking of the indicator float is more common in the low flow ranges because the annular space is smaller. A damaged float can cause inaccurate readings because the precise relationship between the float and the flow tube is altered. Backpressure from the breathing circuit can cause a float to drop so that it reads less than the actual flow. Finally, if flow meters are not aligned properly in the vertical position (plumb), readings can be inaccurate because tilting distorts the annular space.[17,22,34]

Ambiguous Scale Before the standardization of flow meter scales and the widespread use of oxygen analyzers, at least two deaths resulted from confusion created by ambiguous scales.[17,34,36] The operator read the float position beside an adjacent, but erroneous scale in both cases. Today, this error is less likely to occur because contemporary flow meter scales are marked either directly on the flow tube or immediately to the right of it.[5] The possibility of confusion is minimized when the scale is etched directly onto the tube.

Electronic Flow Meters

As mentioned earlier, some newer anesthesia workstations such as the Datex-Ohmeda S/5 ADU and the North American Dräger Fabius GS, among others, have conventional control knobs and flow control valves but have electronic flow sensors and digital displays rather than glass flow tubes. The output from the flow control valve is represented graphically, numerically, or by both means in liters per minute on the workstation's integrated user interface. These systems are dependent on electrical power to provide a precise display of gas flow. However, even when electrical power is totally interrupted, because the flow control valves themselves are nonelectronic, oxygen should continue to flow. Because these machines do not have individual flow tubes that physically quantitate the flow of each gas, electronic flow sensors and often a small conventional pneumatic "fresh gas" or "total flow" indicator are provided to give the user an estimate of the total quantity of fresh gas flowing from all flow control valves. This miniature flow tube indicator serves to inform the user of the approximate quantity of gas that is leaving the anesthesia workstation's common gas outlet, and it is functional even in the event of total power failure.

Proportioning Systems

Manufacturers equip anesthesia workstations with proportioning systems in an attempt to prevent the creation and delivery of a hypoxic mixture. Nitrous oxide and oxygen are interfaced mechanically or pneumatically (or both ways) so that the minimum oxygen concentration at the common gas outlet is between 23% and 25%, depending on the manufacturer.

Datex-Ohmeda Link-25 Proportion-Limiting Control System

Conventional Datex-Ohmeda machines use the Link-25 system. The heart of the system is mechanical integration of the nitrous oxide and oxygen flow control valves. It allows independent adjustment of either valve, yet automatically intercedes to maintain a minimum 25% oxygen concentration with a maximum nitrous oxide–oxygen flow ratio of 3:1. The Link-25 automatically increases oxygen flow to prevent delivery of a hypoxic mixture.

Figure 25-15 illustrates the Datex-Ohmeda Link-25 system. The nitrous oxide and oxygen flow control valves are identical. A 14-tooth sprocket is attached to the nitrous oxide flow control valve and a 28-tooth sprocket to the oxygen flow control valve. A chain physically links the sprockets. When the nitrous oxide flow control valve is turned through two revolutions, or 28 teeth, the oxygen flow control valve will revolve once because of the 2:1 gear ratio. The final 3:1 flow ratio results because the nitrous oxide flow control valve is supplied by approximately 26 psig whereas the oxygen flow control valve is supplied by 14 psig. Thus, the combination of the mechanical and pneumatic aspects of the system yields the final oxygen concentration. The Datex-Ohmeda Link-25 proportioning system can be thought of as a system that *increases oxygen flow* when necessary to prevent delivery of a fresh gas mixture with an oxygen concentration of less than 25%.

Recently, a few reports related to failures of the Datex-Ohmeda Link-25 system have been published. The authors of these reports describe failures that either resulted in an inability to administer oxygen without nitrous oxide or allowed creation of a hypoxic mixture. These reported failures of the Link-25 on the Datex-Ohmeda Excel series anesthesia machines should cer-

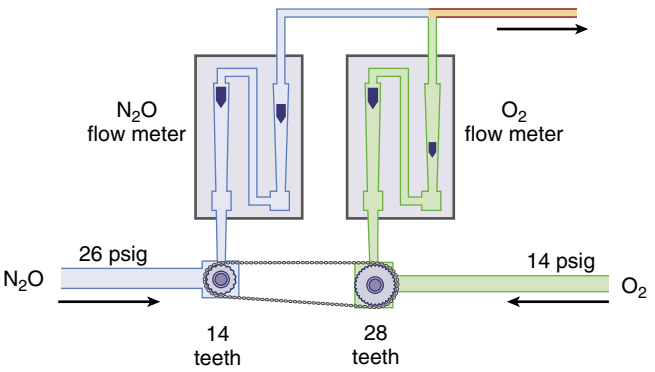

Figure 25-15 Ohmeda Link-25 Proportion-Limiting Control system. See text for details.

tainly raise the awareness of clinicians to the possibility of failure of this type of proportioning system.[36-40]

North American Dräger Oxygen Ratio Monitor Controller/Sensitive Oxygen Ratio Controller System

North American Dräger's proportioning system, the Oxygen Ratio Monitor Controller (ORMC), is used on the North American Dräger Narkomed 2A, 2B, 3, and 4 series. An equivalent system known as the Sensitive Oxygen Ratio Controller (S-ORC) is used on some newer Dräger anesthesia workstations such as the Dräger Fabius GS and Narkomed 6000 series. The ORMC and the S-ORC are pneumatic oxygen–nitrous oxide interlock systems designed to maintain a fresh gas oxygen concentration of at least 25% ± 3%. They maintain the fresh gas oxygen concentration at levels substantially higher than 25% at oxygen flow rates of less than 1 L/min. The ORMC and S-ORC limit nitrous oxide flow to prevent delivery of a hypoxic mixture. This is unlike the Datex-Ohmeda Link-25, which actively increases oxygen flow.

A schematic of the ORMC is shown in Figure 25-16. It is composed of an oxygen chamber, a nitrous oxide chamber, and a nitrous oxide slave control valve. All are interconnected by a mobile horizontal shaft. Pneumatic input into the device is from the oxygen and nitrous oxide flow meters. These flow meters are unique in that they have specific resistors located downstream from the flow control valves. These resistors create backpressure directed to the oxygen and nitrous oxide chambers. The value of the oxygen flow tube resistor is three to four times that of the nitrous oxide flow tube resistor, and the relative value of these resistors determines the value of the controlled fresh gas oxygen concentration. Backpressure in the oxygen and nitrous oxide chambers pushes against rubber diaphragms attached to the mobile horizontal shaft. Movement of the shaft regulates the nitrous oxide slave control valve, which feeds the nitrous oxide flow control valve.

If the oxygen pressure is proportionally higher than the nitrous oxide pressure, the nitrous oxide slave control valve opens wider to allow more nitrous oxide to flow. As the nitrous oxide flow is increased manually, the nitrous oxide pressure forces the shaft toward the oxygen chamber. The valve opening becomes more restrictive and limits flow of nitrous oxide to the flow meter.

Figure 25-16 illustrates the action of a single ORMC/S-ORC under different sets of circumstances. The backpressure exerted on the oxygen diaphragm, in the upper configuration, is greater than that exerted on the nitrous oxide diaphragm. This causes the horizontal shaft to move to the left, thereby opening the nitrous oxide slave control valve. Nitrous oxide is then able to proceed to its flow control valve and out through the flow meter. In the bottom configuration, the nitrous oxide slave control valve is closed because of inadequate oxygen backpressure.[24]

To summarize, in contrast to the Datex-Ohmeda Link-25 system, which actively increases oxygen flow to maintain a fresh gas oxygen concentration greater than 25%, the Dräger ORMC and S-ORC are systems that limit nitrous oxide flow to prevent delivery of a fresh gas mixture with an oxygen concentration of less than 25%.

Limitations

Proportioning systems are not foolproof. Workstations equipped with proportioning systems can still deliver a hypoxic mixture under certain conditions. In the following sections we briefly present some situations in which this can occur.

Wrong Supply Gas Both the Datex-Ohmeda Link-25 and the Dräger ORMC/S-ORC will be fooled if a gas other than oxygen is present in the oxygen pipeline. In the Link-25 system, the nitrous oxide and oxygen flow control valves will continue to be mechanically linked. Nevertheless, a hypoxic mixture can proceed to the common gas outlet. In the case of the Drager ORMC or S-ORC, the rubber diaphragm for oxygen will reflect adequate supply pressure on the oxygen side even though the incorrect gas is present, and flow of both the wrong gas plus nitrous oxide will result. The oxygen analyzer is the only workstation monitor besides an integrated multigas analyzer that would detect this condition in either system.

Defective Pneumatics or Mechanics Normal operation of the Datex-Ohmeda Link-25 and the North American Dräger ORMC/S-ORC is contingent on pneumatic and mechanical integrity.[41] Pneumatic integrity in the Datex-Ohmeda system requires properly functioning second-stage regulators. A nitrous oxide–oxygen ratio other than 3:1 will result if the regulators are not precise. The chain connecting the two sprockets must be intact. A 97% nitrous oxide concentration can occur if the chain is cut or broken.[42] In the North American Dräger system, a functional OFPD is necessary to supply appropriate pressure to the ORMC. The mechanical aspects of the ORMC/S-ORC, such as the rubber diaphragms, the flow tube resistors, and the nitrous oxide slave control valve, must likewise be intact.

Leaks Downstream The ORMC/S-ORC and the Link-25 function at the level of the flow control valves. A leak downstream from these devices, such as a broken oxygen flow tube (see Fig. 25-14), can result in delivery of a hypoxic mixture to the common gas outlet. In this situation, oxygen escapes through the leak, and the predominant gas delivered is nitrous oxide. The oxygen monitor and the integrated multigas analyzer are the only machine safety devices that can detect this problem.[33] For the majority of its products, Dräger Medical recommends a preoperative positive-pressure leak test to detect such a leak. However, in addition to this test, for many North American Dräger products, application of the negative-pressure leak test as well may provide a more sensitive way to detect such a leak. Datex-Ohmeda almost universally recommends a preoperative negative-pressure leak test for its workstations because of the frequently present check valve located at the common gas outlet (see "Checking Your Anesthesia Workstation").

Inert Gas Administration Administration of a third inert gas, such as helium, nitrogen, or carbon dioxide, can cause a hypoxic mixture because contemporary proportioning systems link only nitrous oxide and oxygen.[43] Use of an oxygen analyzer is mandatory (or preferentially a multigas analyzer when available) if the operator uses a third inert gas.

Dilution of Inspired Oxygen Concentration by Volatile Inhaled Anesthetics Volatile inhaled anesthetics are added to the mixed gases downstream from both the flow meters and the proportioning system. Concentrations of less potent inhaled anesthetics such as desflurane may account for a larger percentage of the total fresh gas composition than is the case with more potent agents. This can be seen when the maximum vaporizer dial settings of the various volatile agents are examined (e.g., a desflurane maximum dial setting of 18% versus an isoflurane maximum dial setting of 5%). Because significant percentages of these inhaled anesthetics may be added downstream of the proportioning system, the resulting gas-vapor mixture may contain an inspired oxygen concentration less than 21% despite a functional proportioning system. The anesthesia care provider must be aware of this possibility, particularly when high concentrations of less potent volatile inhaled anesthetics are used.

Oxygen Flush Valve

The oxygen flush valve allows direct communication between the oxygen high-pressure circuit and the low-pressure circuit (see Fig. 25-3). Flow from the oxygen flush valve enters the low-pressure circuit downstream from the vaporizers and most importantly downstream from the Datex-Ohmeda machine outlet check valve. The spring-loaded oxygen flush valve stays closed until the operator opens it by depressing the oxygen flush button. Actuation of the valve delivers 100% oxygen at 35 to 75 L/min to the breathing circuit.[23]

The oxygen flush valve can provide a high-pressure oxygen source suitable for jet ventilation under the following circumstances: (1) the anesthesia machine is equipped with a one-way check valve positioned between the vaporizers and the oxygen flush valve, and (2) when a positive-pressure relief valve exists downstream of the vaporizers, this pressure relief valve must be upstream of the outlet check valve. Because the Ohmeda Modulus II has such a one-way check valve and its positive-pressure relief valve is upstream from the check valve, the entire oxygen flow of 35 to 75 L/min is delivered to the common gas outlet at a high pressure of 50 psig. On the other hand, the Ohmeda Modulus II Plus and some Ohmeda Excel machines are not capable of functioning as an appropriate oxygen source for jet ventilation. The Ohmeda Modulus II Plus, which does not have the check valve, provides only 7 psig at the common gas outlet because some oxygen flow travels retrogradely through an internal relief valve located upstream from the oxygen flush valve. The Ohmeda Excel 210, which does have a one-way check valve, also has a positive-pressure relief valve downstream from the check valve and therefore is unsuitable for jet ventilation. Older North American Dräger machines such as the Narkomed 2A (which also does not have an outlet check valve) provide an intermediate pressure of 18 psig to the common gas outlet because some pressure is vented retrogradely through a pressure relief valve located in the vaporizers.[44]

Several hazards have been reported with the oxygen flush valve. A defective or damaged valve can stick in the fully open position and result in barotrauma.[45] A valve sticking in a partially open position can result in patient awareness because oxygen flow from the incompetent valve dilutes the inhaled anesthetic.[19,46] Improper use of normally functioning oxygen flush valves also can result in problems. Overzealous intraoperative oxygen flushing can dilute inhaled anesthetics. Oxygen flushing during the inspiratory phase of positive-pressure ventilation can produce barotrauma if the anesthesia machine does not incorporate fresh

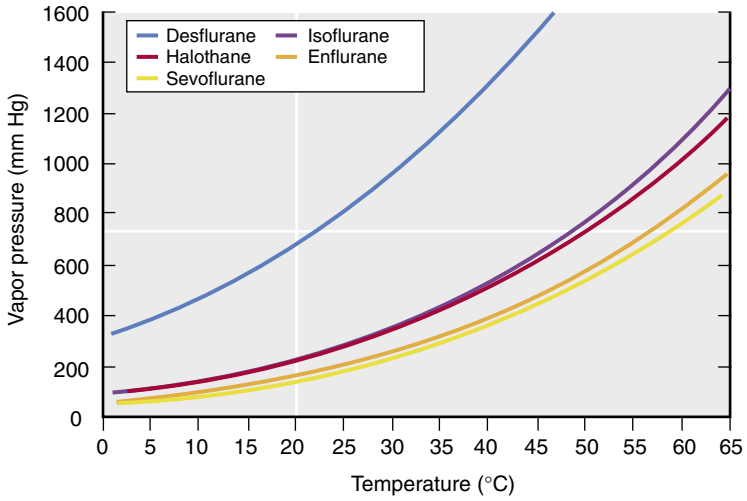

Figure 25-17 Vapor pressure–versus-temperature curves for desflurane, isoflurane, halothane, enflurane, and sevoflurane. The vapor pressure curve for desflurane is both steeper and shifted to higher vapor pressures than the curves for other contemporary inhaled anesthetics are. *(From inhaled anesthetic package insert equations and Susay SR, Smith MA, Lockwood GG: The saturated vapor pressure of desflurane at various temperatures. Anesth Analg 83:864-866, 1996.)*

gas decoupling or an appropriately adjusted inspiratory pressure limiter. Anesthesia systems (Dräger Narkomed 6000 series, Julian, Fabius GS, and Datascope Anestar) with fresh gas decoupling are inherently safer from the standpoint of minimizing the chance of producing barotrauma as a result of inappropriate oxygen flush valve use. These systems physically divorce the fresh gas inflow from either the flow meters or the oxygen flush valve from the delivered tidal volume presented to the patient's lungs (see "Fresh Gas Decoupling"). With traditional anesthesia breathing circuits, excess volume cannot be vented during the inspiratory phase of mechanical ventilation because the ventilator relief valve is closed and the APL valve is either out of circuit or closed.[47] An alternative way to manage this problem can be seen with the Datex-Ohmeda S/5 ADU and Aestiva. These circle systems use an integrated adjustable pressure limiter. If this device is properly adjusted, it functions like the APL valve to limit the maximum airway pressure to a safe level, thereby reducing the possibility of barotrauma.

Some very old anesthesia systems made use of a freestanding vaporizer downstream from the common gas outlet, and with these systems oxygen flushing could rapidly deliver large quantities of inhaled anesthetic to the patient. Finally, inappropriate preoperative use of the oxygen flush to evaluate the low-pressure circuit for leaks can be misleading, particularly on Datex-Ohmeda machines with a one-way check valve at the common outlet.[18] Because backpressure from the breathing circuit closes the one-way check valve air-tight, major low-pressure circuit leaks can go undetected with this leak test (see "Checking Your Anesthesia Workstation").

Vaporizers

As dramatic as the evolution of the anesthesia workstation has been over recent years, vaporizers have also changed from rudimentary ether inhalers and copper kettles to the present temperature-compensated, computer-controlled, and flow-sensing devices that we use today. In 1993, with the introduction of desflurane to the clinical setting, an even more sophisticated vaporizer was introduced to handle the unique physical properties of this agent. Now, a new generation of anesthesia vaporizers blending both "old" copper kettle–like technology and "new" computerized control technology has emerged in the Datex-Ohmeda Aladin cassette vaporizer system. Before discussion of variable-bypass vaporizers, the Datex-Ohmeda Tec 6 desflurane vaporizer and the Datex-Ohmeda Aladin cassette vaporizer, certain physical principles will be reviewed briefly to facilitate understanding of the operating principles, construction, and design of contemporary volatile anesthetic vaporizers.

Physics

Vapor Pressure

Contemporary inhaled volatile anesthetics exist in the liquid state at temperatures below 20°C. When a volatile liquid is in a closed container, molecules escape from the liquid phase to the vapor phase until the number of molecules in the vapor phase is constant. These molecules in the vapor phase bombard the wall of the container and create a pressure known as the *saturated vapor pressure*. As the temperature increases, more molecules enter the vapor phase, and the vapor pressure increases (Fig. 25-17). Vapor pressure is independent of atmospheric pressure and is contingent only on the temperature and physical characteristics of the liquid. The *boiling point* of a liquid is defined as the temperature at which vapor pressure equals atmospheric pressure.[48-50] At 760 mm Hg, the boiling points for desflurane, isoflurane, halothane, enflurane, and sevoflurane are approximately 22.8°C, 48.5°C, 50.2°C, 56.5°C, and 58.5°C, respectively. Unlike other contemporary inhaled anesthetics, desflurane boils at temperatures that may be encountered in clinical settings such as operating rooms for pediatric and burn patients. This unique physical characteristic alone mandates a special vaporizer design to control the delivery of desflurane. If agent-specific vaporizers are inadvertently misfilled with incorrect liquid anesthetic agents, the resulting mixtures of volatile agents may demonstrate properties uniquely different from those of the individual component agents. The altered vapor pressure and other physical properties of the resulting azeotropic mixtures caused by the mixing of various agents may change the output of the anesthetic vaporizer (see "Misfilling" in the section "Variable-Bypass Vaporizers").[51]

Latent Heat of Vaporization

When a molecule is converted from a liquid to the gaseous phase, energy is consumed because the molecules of a liquid tend to cohere. The amount of energy that is consumed for a given liquid to be converted to a vapor is referred to as the *latent heat of vaporization*. It is more precisely defined as the number of calories required to change 1 g of liquid into vapor without a change in temperature. The energy for vaporization must come from either the liquid itself or an outside source. The temperature of the liquid itself will decrease during vaporization in the absence of an outside energy source. This energy loss can lead to significant decreases in temperature of the remaining liquid and greatly diminish subsequent vaporization.[48,50,52]

Specific Heat

The *specific heat* of a substance is the number of calories required to increase the temperature of 1 g of a substance by 1°C.[21,48,50] The substance can be a solid, liquid, or gas. The concept of specific heat is important to the design, operation, and construction of vaporizers because it is applicable in two ways. First, the specific heat for an inhaled anesthetic is important because it indicates how much heat must be supplied to the liquid to maintain a constant temperature when heat is being lost during vaporization. Second, manufacturers select vaporizer component materials that have high specific heat to minimize the temperature changes associated with vaporization.

Thermal Conductivity

Thermal conductivity is a measure of the speed at which heat flows through a substance. The higher the thermal conductivity, the better the substance conducts heat.[48] Vaporizers are constructed of metals that have relatively high thermal conductivity, which helps maintain a uniform internal temperature.

Variable-Bypass Vaporizers

The Datex-Ohmeda Tec 4, Tec 5, and Tec 7, as well as the North American Dräger Vapor 19.n and 20.n vaporizers, are classified as variable-bypass, flow-over, temperature-compensated, agent-specific, out-of-breathing-circuit vaporizers.[48] *Variable bypass* refers to the method of regulating the concentration of anesthetic agent output from the vaporizer. The concentration control dial setting determines the ratio of flow that goes through the bypass chamber and the vaporizing chamber as fresh gas from the flow meters enters the vaporizer inlet. The gas channeled through the vaporizing chamber flows over a wick system saturated with the liquid anesthetic and subsequently also becomes saturated with vapor. Thus, *flow-over* refers to the method of vaporization and is in contrast to the bubble-through system that may be seen in some copper kettle–type vaporizers of old. The Tec 4, Tec 5, Tec 7, and Dräger Vapor 19.n and 20.n are further classified as *temperature compensated*. Each of these vaporizers is equipped with an automatic temperature-compensating device that helps maintain constant vaporizer output over a wide range of operating temperatures. These vaporizers are *agent specific* and *out of circuit* because each is designed to accommodate a single anesthetic agent and to be physically located outside the breathing circuit. Variable-bypass vaporizers are used to deliver halothane, enflurane, isoflurane, and sevoflurane, but not desflurane.

Basic Operating Principles

A diagram of a generic, variable-bypass vaporizer is shown in Figure 25-18. Vaporizer components include the concentration control dial, the bypass chamber, the vaporizing chamber, the filler port, and the filler cap. The operator fills the vaporizing chamber with liquid anesthetic through the filler port. The

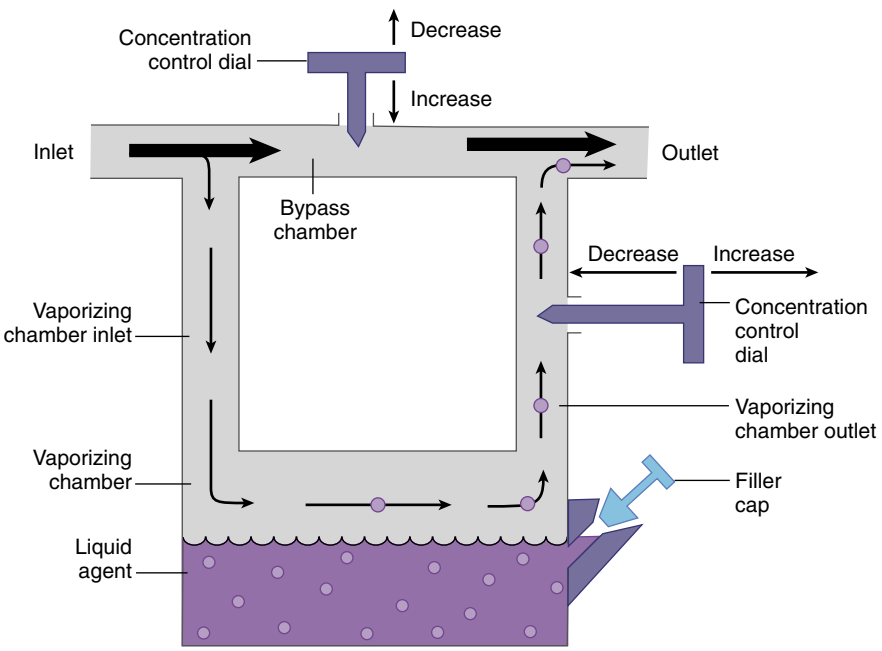

Figure 25-18 Generic variable-bypass vaporizer. See text for details.

maximum safe fill level is predetermined by the position of the filler port, which is situated to minimize the chance of overfilling. If a vaporizer is overfilled or tilted, liquid anesthetic can spill into the bypass chamber. If this were to happen, both the vaporizing chamber flow and the bypass chamber flow could potentially be carrying saturated anesthetic vapor, and an overdose would result. The concentration control dial is a variable restrictor, and it can be located either in the bypass chamber or in the outlet of the vaporizing chamber. The function of the concentration control dial is to regulate the relative flow rates through the bypass and vaporizing chambers.

Flow from the flow meters enters the inlet of the vaporizer. More than 80% of the flow passes straight through the bypass chamber to the vaporizer outlet, and this accounts for the name "bypass chamber." Less than 20% of the flow from the flow meters is diverted through the vaporizing chamber. Depending on the temperature and vapor pressure of the particular inhaled anesthetic, the fresh gases entering the vaporizing chamber entrain a specific flow of the inhaled anesthetic agent. The mixture that exits the vaporizer is the combination of flow through the bypass chamber, flow through the vaporizing chamber, and flow of entrained anesthetic vapor. The final concentration of inhaled anesthetic is the ratio of the flow of the inhaled anesthetic to the total gas flow.[48,53]

The vapor pressure of an inhaled anesthetic depends on the ambient temperature (see Fig. 25-17). For example, at 20°C the vapor pressure of isoflurane is 238 mm Hg, whereas at 35°C the vapor pressure almost doubles (450 mm Hg). Variable-bypass vaporizers have an internal mechanism to compensate for variations in ambient temperature. The temperature-compensating valve of the Datex-Ohmeda Tec 4 is shown in Figure 25-19. At relatively high ambient temperatures, such as those commonly seen in operating rooms designated for the care of pediatric or burn patients, the vapor pressure inside the vaporizing chamber is high. To compensate for this increased vapor pressure, the bimetallic strip of the temperature-compensating valve leans to the right, thereby decreasing resistance to flow through the bypass chamber and allowing more flow to pass through the bypass chamber and less flow to pass through the vaporizing chamber. In contrast, in a cold operating room environment, the vapor pressure inside the vaporizing chamber is reduced. To compensate for this decrease in vapor pressure, the bimetallic strip leans to the left, which increases resistance to flow through the bypass chamber and causes more flow to pass through the vaporizing chamber and less to pass through the bypass chamber. The net effect in both situations is maintenance of relatively constant vaporizer output.

Factors That Influence Vaporizer Output

If an ideal vaporizer existed, with a fixed dial setting its output would be constant regardless of varied flow rates, temperature, backpressure, and carrier gases. Designing such a vaporizer is difficult because as ambient conditions change, the physical properties of gases and vaporizers themselves can change.[53] Contemporary vaporizers approach ideal but still have some limitations. Even though some of the most sophisticated vaporizer systems now available use computer-controlled components and multiple sensors, they have yet to become significantly more accurate than conventional vaporizers. Several factors that affect vaporizer performance in general are described in the following paragraphs.

Flow Rate With a fixed dial setting, vaporizer output can vary with the rate of gas flowing through the vaporizer. This variation is particularly notable at the extremes of flow rates. The output of all variable-bypass vaporizers is less than the dial setting at low flow rates (<250 mL/min) because of the relatively high density of volatile inhaled anesthetics. Insufficient turbulence is generated in the vaporizing chamber at low flow rates to upwardly advance the vapor molecules. At extremely high flow rates, such as 15 L/min, the output of most variable-bypass vaporizers is less than the dial setting. This discrepancy is attributed to incomplete mixing and failure to saturate the carrier gas in the vaporizing chamber.

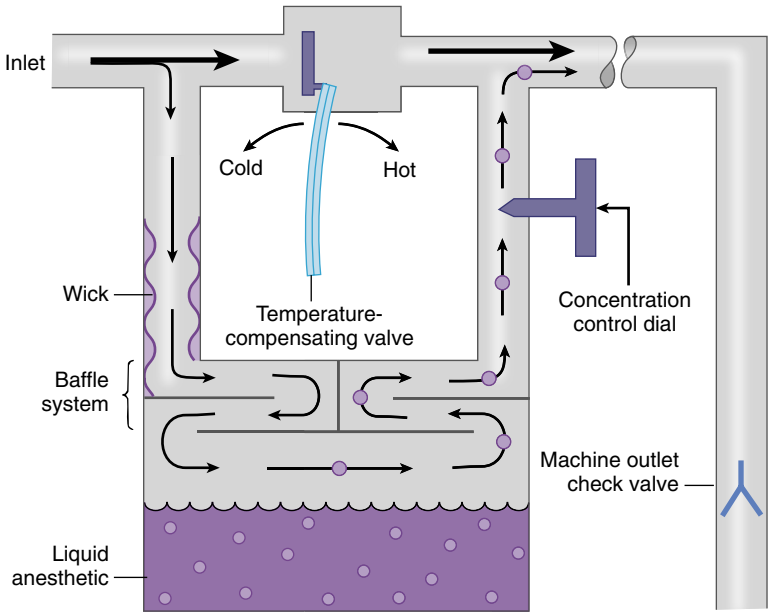

Figure 25-19 Simplified schematic of the Ohmeda Tec–type vaporizer. See text for details

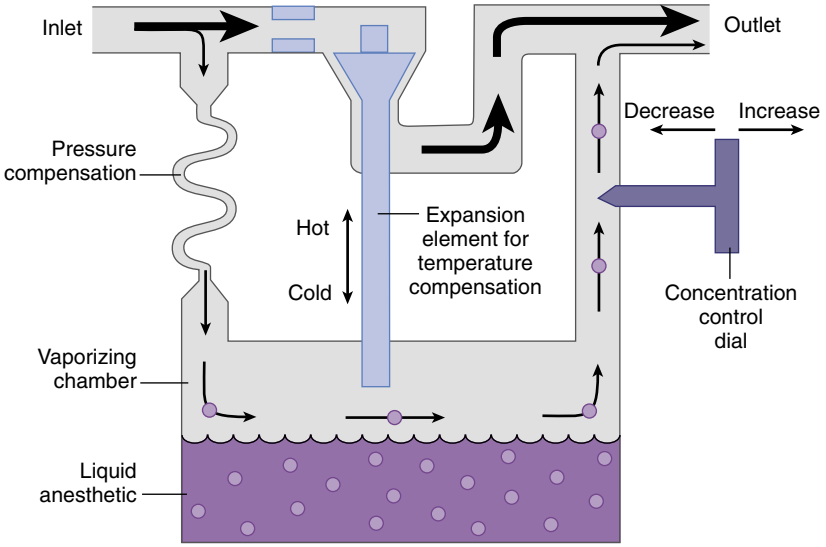

Figure 25-20 Simplified schematic of the North American Dräger Vapor 19.n and 20.n vaporizers. See text for details.

In addition, the resistance characteristics of the bypass chamber and the vaporizing chamber can vary as flow increases. These variations can result in decreased vapor output concentration.[53]

Temperature Because of improvements in design, the output of contemporary temperature-compensated vaporizers is almost linear over a wide range of temperatures. Automatic temperature-compensating mechanisms in the bypass chamber maintain constant vaporizer output with varying temperatures.[23] As previously described, a bimetallic strip (Fig. 25-19) or an expansion element (Fig. 25-20) directs a greater proportion of gas flow through the bypass chamber as temperatures increase.[53] Additionally, the wick systems are placed in direct contact with the metal wall of the vaporizer to help replace energy (heat) consumed during vaporization. The materials that vaporizers are constructed of are chosen because they have a relatively high specific heat and high thermal conductivity. These factors help minimize the effect of cooling during vaporization.

Intermittent Backpressure The intermittent backpressure that results from either positive-pressure ventilation or use of the oxygen flush valve may lead to higher than expected vaporizer output. This phenomenon, known as the *pumping effect*, is more pronounced at low flow rates, low dial settings, and low levels of liquid anesthetic in the vaporizing chamber.[48,53-56] Additionally, the pumping effect is increased by rapid respiratory rates, high peak inspired pressures, and rapid drops in pressure during expiration.[46-50] Newer variable-bypass vaporizers such as the Datex-Ohmeda Tec 4, Tec 5, and Tec 7 and the North American Dräger Vapor 19.n and 20.n are relatively immune from the pumping effect. One proposed mechanism for the pumping effect is dependent on retrograde transmission of pressure from the patient circuit to the vaporizer during the inspiratory phase of positive-pressure ventilation. Gas molecules are compressed in both the bypass and vaporizing chambers. When the backpressure is suddenly released during the expiratory phase of positive-pressure ventilation, vapor exits the vaporizing chamber both through the vaporizing chamber outlet and retrogradely through the vaporizing chamber inlet because the output resistance of the bypass chamber is lower than that of the vaporizing chamber, particularly at low dial settings. The enhanced output concentration results from the increment of vapor that travels in the retrograde direction to the bypass chamber.[53-56]

To decrease the pumping effect, the vaporizing chambers of newer systems are smaller than those of early variable-bypass vaporizers such as the Fluotec Mark II (750 mL).[55] Therefore, no substantial volumes of vapor can be discharged from the vaporizing chamber into the bypass chamber during the expiratory phase. The North American Dräger Vapor 19.n and 20.n vaporizers (see Fig. 25-20) have a long spiral tube that serves as the inlet to the vaporizing chamber.[55] When the pressure in the vaporizing chamber is released, some of the vapor enters this tube but does not enter the bypass chamber because of tube length.[49] The Tec 4 (see Fig. 25-19) has an extensive baffle system in the vaporizing chamber, and a one-way check valve has been inserted at the common gas outlet to minimize the pumping effect. This check valve attenuates but does not eliminate the increase in pressure because gas still flows from the flow meters to the vaporizer during the inspiratory phase of positive-pressure ventilation.[48,57]

Carrier Gas Composition Vaporizer output is influenced by the composition of the carrier gas that flows through the vaporizer.[58-65] During experimental conditions, when the carrier gas is changed rapidly from 100% oxygen to 100% nitrous oxide, a sudden transient decrease in vaporizer output occurs, followed by a slow increase to a new steady-state value (B in Fig. 25-21).[63,64] Because nitrous oxide is more soluble than oxygen in the halogenated liquid within the vaporizer sump, when this switch occurs, the output from the vaporizing chamber is transiently reduced.[63] Once the anesthetic liquid is totally saturated with nitrous oxide, vaporizing chamber output increases somewhat, and a new steady state is established.

The explanation for the new steady-state output value is less well understood.[65] With contemporary vaporizers such as the North American Dräger Vapor 19.n and 20.n and the Ohmeda Tec–type conventional vaporizers, the steady-state output value is less when nitrous oxide is the carrier gas instead of oxygen (see B in Fig. 25-21). Conversely, the output of some older vaporizers is enhanced when nitrous oxide is the carrier gas instead of oxygen.[58,60] The steady-state plateau is achieved more rapidly with

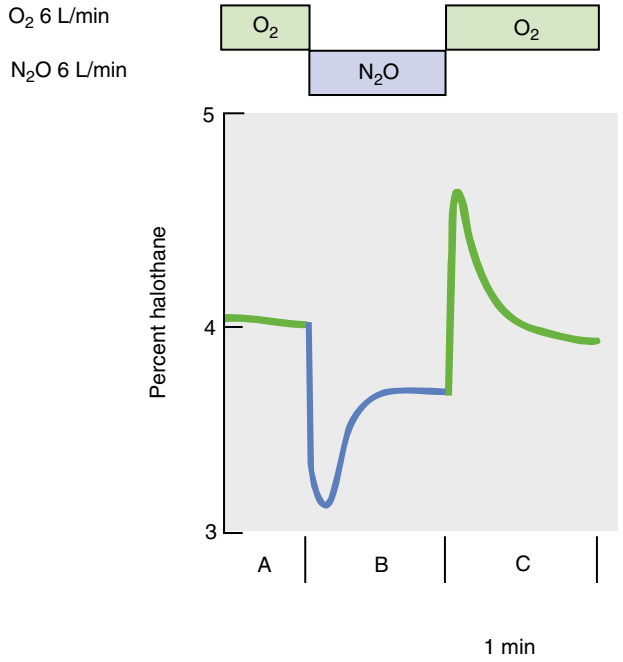

Figure 25-21 Halothane output of a North American Dräger Vapor 19.n vaporizer with different carrier gases. The initial output concentration is approximately 4% halothane when oxygen is the carrier gas at flows of 6 L/min (A). When the carrier gas is quickly switched to 100% nitrous oxide (B), the halothane concentration decreases to 3% within 8 to 10 seconds. A new steady-state concentration of approximately 3.5% is then attained within 1 minute. See text for details. *(Modified with permission from Gould DB, Lampert BA, MacKrell TN: Effect of nitrous oxide solubility on vaporizer aberrance. Anesth Analg 61:939, 1982.)*

increased flow rates, regardless of the ultimate output value.[64] Factors that contribute to the characteristic steady-state response resulting when various carrier gases are used include the viscosity and density of the carrier gas, the relative solubility of the carrier gas in the anesthetic liquid, the flow-splitting characteristics of the specific vaporizer, and the concentration control dial setting.[60,63-65]

Safety Features

Newer generations of anesthesia vaporizers, including the North American Dräger 19.n and 20.n and the Datex-Ohmeda Tec 4, Tec 5, and Tec 7, now have built-in safety features that have minimized or eliminated many hazards once associated with variable-bypass vaporizers. Agent-specific, keyed filling devices help prevent filling a vaporizer with the wrong agent. Overfilling of these vaporizers is minimized because the filler port is located at the maximum safe liquid level. Finally, today's vaporizers are firmly secured to a vaporizer manifold on the anesthesia workstation. Thus, problems associated with vaporizer tipping have become much less frequent. Contemporary interlock systems prevent the administration of more than one inhaled anesthetic.

Hazards

Despite many safety features, some hazards are still associated with contemporary variable-bypass vaporizers.

Misfilling Vaporizers not equipped with keyed fillers have occasionally been misfilled with the wrong anesthetic liquid.[66] A potential for misfilling exists even on contemporary vaporizers equipped with keyed fillers.[67-69] When vaporizer misfilling occurs, either an anesthetic overdose or underdose will result if the anesthesia care provider is depending on the concentration control dial markings to determine the anesthetic dose. The use of supplemental monitoring such as a multigas analyzer may alert the user to such a problem.

Contamination Contamination of anesthetic vaporizer contents has occurred as a result of filling an isoflurane vaporizer with a contaminated bottle of isoflurane. A potentially serious incident was avoided because the operator did not use the contaminated vaporizer after detecting an abnormal acrid odor.[70]

Tipping Tipping of a vaporizer can occur when it is incorrectly "switched out" or moved. However, short of the entire machine being turned over, tipping is unlikely when a vaporizer is attached to the anesthesia workstation manifold. Excessive tipping can allow the liquid agent to enter the bypass chamber and cause an output with an extremely high concentration of agent.[71] The Tec 4 is slightly more immune to tipping than the North American Dräger Vapor 19.n because of its extensive baffle system. However, if either vaporizer is tipped, it should not be used until it has been flushed for 20 to 30 minutes at high fresh gas flow rates. During this procedure, having the vaporizer concentration control dial set at a low concentration maximizes bypass chamber flow and will aid in removal of any residual liquid anesthetic in that area.[48] After this procedure, use of a multigas analyzer is strongly recommended. The Dräger Vapor 20.n series vaporizers now have a transport ("T") dial setting that helps prevent tipping-related problems. When the dial is placed in this position, the vaporizer sump is isolated from the bypass chamber, thereby reducing the likelihood of tipping and resulting in an accidental overdose. Therefore, any time that one of these vaporizers is moved separate from the anesthesia workstation, the control dial should be placed in the "T" position.

The design of the Tec 6 and the Aladin cassette vaporizer systems, both from Datex-Ohmeda, has practically eliminated the possibility of tipping with these products. Because the Aladin cassette vaporizer's bypass chamber is physically separated from the "cassette" and permanently resides in the anesthesia workstation, the possibility of tipping is virtually eliminated, sparing overturning the entire anesthesia workstation. Tipping of the Aladin cassettes themselves when they are not installed in the vaporizer is not problematic.

Overfilling Improper filling procedures combined with failure of the vaporizer sight glass can cause overfilling and patient overdose. Liquid anesthetic enters the bypass chamber, and up to 10 times the intended vapor concentration can be delivered to the common gas outlet.[72] Most modern vaporizers are now relatively immune to overfilling because of side-fill rather than top-fill designs. Side-fill systems largely prevent overfilling.

Underfilling Just as with overfilling, underfilling of anesthetic vaporizers may be problematic. When a Tec 5 sevoflurane vaporizer is in a low fill state and used under conditions of high fresh gas flow rates (>7.5 L/min) and high dial settings (such as seen during inhalational induction), output from the vaporizer may abruptly decrease to less than 2%. The cause of this problem is most likely multifactorial. However, the combination of a low

vaporizer fill state (<25% full) and a high vaporizing chamber flow rate can result in a clinically significant and reproducible fall in vaporizer output.[73] Because sevoflurane has become a particularly popular agent for use during inhalational induction, all anesthesia care providers should be aware of this particular hazard.

Simultaneous Administration of Inhaled Anesthetics On some older anesthesia machines from Datex-Ohmeda (equipped with the Select-a-Tec three-vaporizer manifold) that did not use a vapor interlock system, two inhaled anesthetics could be administered simultaneously when the center vaporizer was removed. On such machines, the left or right vaporizer needed to be moved to the central position if the central vaporizer was removed (as indicated by the manifold warning label). Once this was done, the vaporizer's interlock system would operate properly and allow only one agent to be administered at a time. More contemporary Select-a-Tec–type vaporizer manifolds from GE and Dräger Medical have a built-in vapor interlock or vapor exclusion devices that prevent this problem. On these newer two- or three-vaporizer systems, the vaporizers do not necessarily have to be in adjacent positions on the manifold for the vapor exclusion systems to work properly. In one basic type of system used on early GE workstations, a U-shaped plastic device linked the vaporizer extension rods even when the vaporizers were not adjacent to one another on the manifold to prevent simultaneously turning on two vaporizers. On such a system, the manifold and the vaporizers themselves comprise the vapor interlock or vapor exclusion system. This type of system reduced the chance of accidental simultaneous administration of two volatile anesthetic agents.

Leaks Vaporizer leaks occur frequently and can result in patient awareness during anesthesia.[11,15,54,74] A loose filler cap is the most common source of vaporizer leaks. With some key-filled Penlon and Dräger vaporizers, a loose filler screw clamp allows saturated anesthetic vapor to escape.[11] Leaks can occur at the O-ring junctions between the vaporizer and its manifold. To detect a leak within a vaporizer, the concentration control dial must be in the "on" position. Even though vaporizer leaks in Dräger systems can potentially be detected with a conventional positive-pressure leak test (because of the absence of an outlet check valve), a negative-pressure leak test is more sensitive and allows the user to detect even small leaks. Datex-Ohmeda recommends a negative-pressure leak-testing device (suction bulb) to detect vaporizer leaks in the Modulus I, Modulus II, Excel, and Aestiva workstations because of the check valve located just upstream of each machine's fresh gas outlet (see "Checking Your Anesthesia Workstation").

Many newer anesthesia workstations are capable of performing self-testing procedures, which in some cases may eliminate the need for the conventional negative-pressure leak testing. However, it is of vital importance that anesthesia care providers understand that these self-tests may not detect internal vaporizer leaks on systems with add-on vaporizers. For the self-tests to determine whether an internal vaporizer leak is present, the leak test must be repeated with each vaporizer sequentially while its concentration control dial is turned to the "on" position. Recall that when a vaporizer's concentration control dial is set in the "off" position, it may not be possible to detect even major internal leaks such as an absent or loose filler cap.

Anesthesia Vaporizers and Environmental Considerations Today more than ever, anesthesia care providers are being asked to provide anesthesia to patients outside the operating room. One such location that has sometimes proved difficult to work in is the magnetic resonance imaging (MRI) suite. The presence of a powerful magnet field, significant noise pollution, and limited access to the patient during the procedure all complicate care in this setting. Essential to the anesthesia care provider is an understanding of the extremely powerful magnetic fields used in these devices. It is imperative that only nonferrous (MRI-compatible) equipment be used in these settings. Some anesthesia vaporizers, although they may appear nonferrous by testing with a horseshoe magnet, may indeed contain substantial internal ferrous components. Inappropriate use of such devices in an MRI suite may potentially turn them into a dangerous missile if left unsecured.[75]

The Datex-Ohmeda Tec 6 Vaporizer for Desflurane

Because of its unique physical characteristics, controlled vaporization of desflurane required a novel approach to vaporizer design. Datex-Ohmeda developed the Tec 6 vaporizer, the first such system, and released it into clinical use in the early 1990s. The Tec 6 vaporizer is an electrically heated, pressurized device specifically designed to deliver desflurane.[76,77] The vapor pressure of desflurane is three to four times that of other contemporary inhaled anesthetics, and it boils at 22.8°C,[78] which is near room temperature (see Fig. 25-17). Desflurane has minimum alveolar anesthetic concentration (MAC) values of 6% to 7%.[78] Desflurane is valuable because it has a low blood-gas solubility coefficient of 0.45 at 37°C, and recovery from anesthesia is more rapid than with many other potent inhaled anesthetics.[78] In 2004, Dräger Medical received FDA approval for its own version of the Tec 6 desflurane vaporizer. The operating principles described in the following discussion are applicable to either system, even though we refer to the Tec 6 specifically.

Unsuitability of Contemporary Variable-Bypass Vaporizers for Controlled Vaporization of Desflurane

Desflurane's high volatility and moderate potency preclude its use with contemporary variable-bypass vaporizers such as Datex-Ohmeda Tec 4, Tec 5, and Tec 7 or the North American Dräger Vapor 19.n or 20.n for two primary reasons[76]:

1. At 20°C the vapor pressure of desflurane is near 1 atm. The vapor pressures of enflurane, isoflurane, halothane, and desflurane at 20°C are 172, 240, 244, and 669 mm Hg, respectively (see Fig. 25-17).[78] Equal amounts of flow through a traditional vaporizer would vaporize many more volumes of desflurane than any other of these agents. For example, at 1 atm and 20°C, 100 mL/min passing through the vaporizing chamber would entrain 735 mL/min of desflurane versus 29, 46, and 47 mL/min of enflurane, isoflurane, and halothane, respectively.[76] Under these same conditions, to produce a 1% desflurane output, the amount of bypass flow necessary to achieve sufficient dilution of the large volume of desflurane-saturated anesthetic vapor would be approximately 73 L/min versus 5 L/min or less

for the other three anesthetics. Additionally, above 22.8°C at 1 atm, desflurane will boil. The amount of vapor produced would be limited only by the heat energy available from the vaporizer because of its specific heat.[76]

2. Contemporary vaporizers lack an external heat source. The latent heat of vaporization for desflurane is approximately equal to that of enflurane, isoflurane, and halothane; however its MAC is four to nine times higher than those of the other three inhaled anesthetics. Thus, the absolute amount of desflurane vaporized over a given period is considerably greater than that of the other anesthetic drugs. Supplying desflurane via a conventional vaporizer in higher (equivalent MAC) concentrations would lead to excessive cooling of the vaporizer and significantly reduce its output. In the absence of an external heat source, temperature compensation with the traditional mechanical devices would be almost impossible. Because of the broad range of temperatures seen in the clinical setting and because of desflurane's steep vapor pressure–versus-temperature curve (see Fig. 25-17), delivery of desflurane in a conventional anesthetic vaporizer would be at best unpredictable.[767]

Operating Principles of the Tec 6 and Tec 6 Plus

To achieve controlled vaporization of desflurane, Datex-Ohmeda introduced the Tec 6 vaporizer to widespread clinical practice in 1993. This was the first clinically available vaporizer ever to be electrically heated and pressurized. The physical appearance and operation of the Tec 6 and contemporary vaporizers are similar, but some aspects of the internal design and operating principles are radically different. The Tec 6 Plus represents a later version of the original Tec 6. The Tec 6 Plus has the same basic Tec 6 design, but it also incorporates an enhanced audible alarm system not previously available on the Tec 6.

Functionally, operation of the Tec 6 is more accurately described as a dual-gas blender than as a vaporizer. A simplified schematic of the Tec 6 is shown in Figure 25-22. The vaporizer has two independent gas circuits arranged in parallel. The fresh gas circuit is shown in orange, and the vapor circuit is shown in blue. Fresh gas from the flow meters enters at the fresh gas inlet, passes through a fixed restrictor (R1), and exits at the vaporizer gas outlet. The vapor circuit originates at the desflurane sump, which is electrically heated and thermostatically controlled to 39°C, a temperature well above desflurane's boiling point. The heated sump assembly serves as a reservoir of desflurane *vapor*. At 39°C, the vapor pressure in the sump is approximately 1300 mm Hg absolute,[79] or approximately 2 atm absolute (see Fig. 25-17). Just downstream from the sump is the shut-off valve. After the vaporizer warms up, the shut-off valve fully opens when the concentration control valve is turned to the "on" position. A pressure-regulating valve located downstream from the shut-off valve downregulates the pressure to approximately 1.1 atm absolute (74 mm Hg gauge) at a fresh gas flow rate of 10 L/min. The operator controls the output of desflurane by adjusting the concentration control valve (R2), which is a variable restrictor.[76]

The vapor flow through R2 joins the fresh gas flow through R1 at a point downstream from the restrictors. Until this

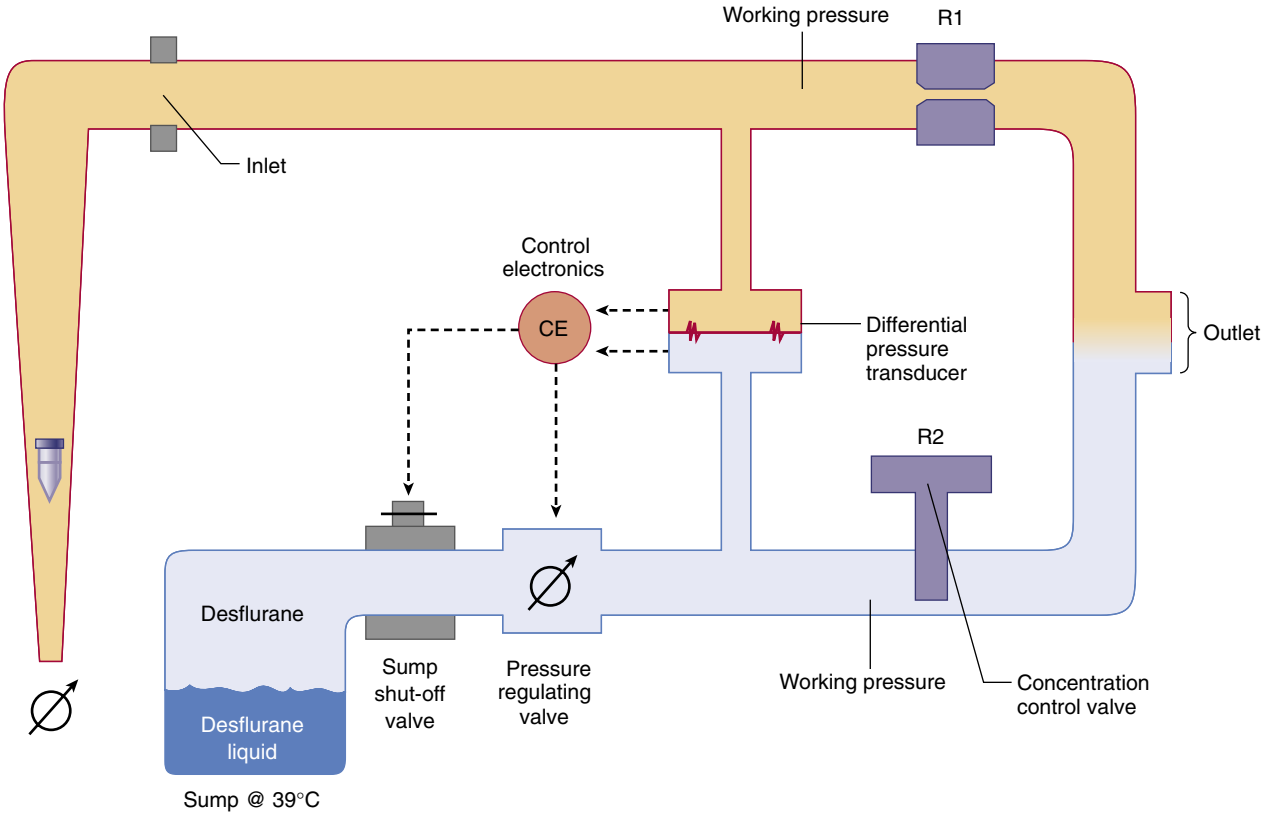

Figure 25-22 Simplified schematic of the Tec 6 desflurane vaporizer. *(From Andrews JJ: Operating Principles of the Ohmeda Tec 6 Desflurane Vaporizer: A Collection of Twelve Color Illustrations. Washington, DC, Library of Congress, 1996, with permission.)*

point, the two circuits are physically divorced. They are interfaced pneumatically and electronically, however, through differential pressure transducers, a control electronics system, and a pressure-regulating valve. When a constant fresh gas flow rate encounters the fixed restrictor R1, a specific backpressure proportional to the fresh gas flow rate pushes against the diaphragm of the control differential pressure transducer. The differential pressure transducer conveys the pressure difference between the fresh gas circuit and the vapor circuit to the control electronics system. The control electronics system regulates the pressure-regulating valve so that the pressure in the vapor circuit equals the pressure in the fresh gas circuit. This equalized pressure supplying R1 and R2 is the working pressure, and the working pressure is constant at a fixed fresh gas flow rate. If the operator increases the fresh gas flow rate, more backpressure is exerted on the diaphragm of the control pressure transducer, and the working pressure of the vaporizer increases.[76]

Table 25-2 shows the approximate correlation between the fresh gas flow rate and working pressure for a typical vaporizer. At a fresh gas flow rate of 1 L/min, the working pressure is 10 millibars, or 7.4 mm Hg gauge. At a fresh gas flow rate of 10 L/min, the working pressure is 100 millibars, or 74 mm Hg gauge. Therefore, there is a linear relationship between the fresh gas flow rate and working pressure. When the fresh gas flow rate is increased 10-fold, the working pressure increases 10-fold.[76]

Listed below are two specific examples to demonstrate the operating principles of the Tec 6.[76]

Example A: *Constant fresh gas flow rate of 1 L/min with an increase in the dial setting.* With a fresh gas flow rate of 1 L/min, the working pressure of the vaporizer is 7.4 mm Hg. That is, the pressure supplying R1 and R2 is 7.4 mm Hg. As the operator increases the dial setting, the opening at R2 becomes larger, thereby allowing more vapor to pass through R2. Specific vapor flow values at different dial settings are shown in Table 25-3.

Example B: *Constant dial setting with an increase in fresh gas flow from 1 to 10 L/min.* At a fresh gas flow rate of 1 L/min, the working pressure is 7.4 mm Hg, and at a dial setting of 6%, the vapor flow rate through R2 is 64 mL/min (see Tables 25-2 and 25-3). With a 10-fold increase in the fresh gas flow rate, there is a concomitant 10-fold increase in the working pressure to 74 mm Hg. The ratio of R2 to R1 resistance is constant at a fixed dial setting of 6%. Because R2 is supplied by 10 times more pressure, the vapor flow rate through R2 increases 10-fold to 640 mL/min. Vaporizer output is constant because both fresh gas flow and vapor flow increase proportionally.

Table 25-2 Fresh Gas Flow Rate Versus Working Pressure

Factors That Influence Vaporizer Output

Varied altitude and carrier gas composition influence Tec 6 output. Each is discussed in the following paragraphs.

Varied Altitudes Although ambient pressure changes affect conventional vaporizer output significantly in terms of volume percent (%vol/vol; i.e., concentration), their effect on anesthetic potency (partial pressure) is minimal. This effect is illustrated with the example of isoflurane in Table 25-4. With a constant dial setting of 0.89%, at 1 atm, if perfectly calibrated, the %vol/vol delivered would be 0.89%, and the partial pressure of isoflurane would be 6.8 mm Hg. Maintaining the same dial setting and lowering the atmospheric pressure to 0.66 atm or 502 mm Hg (roughly equivalent to an elevation of 10,000 ft) would result in an increase in the concentration output to 1.75% (almost double), but the partial pressure increases to only 8.77 mm Hg (just a 29% increase) because of the proportional decline in ambient pressure.

In general, it is thought that the partial pressure of the volatile anesthetic agent in the central nervous system, not its concentration, is responsible for the anesthetic effect. Therefore, to maintain a constant depth of anesthesia when a gross change in barometric pressure occurs, %vol/vol must be changed in inverse proportion to atmospheric pressure. For the most part, traditional variable-bypass vaporizers automatically compensate for this change, and for practical purposes the effect of barometric pressure can generally be ignored.

This should be considered in stark contrast to the response of the Tec 6 desflurane vaporizer at varied altitudes (Table 25-4). One must remember this device is more accurately described as a dual-gas blender than a vaporizer. Regardless of ambient pressure, the Tec 6 will maintain a constant concentration of vapor output (%vol/vol), not a constant partial pressure. This means that at high altitudes, the partial pressure of desflurane will decrease in proportion to the reduction in atmospheric pressure divided by the calibration pressure (normally 760 mm Hg) per the following formula:

$$\text{Required dial setting} = \text{Normal dial setting (vol\%)} \cdot \frac{760 \text{ mm Hg}}{\text{Ambient pressure (mm Hg)}}$$

For example, at an altitude of 2000 m or 6564 feet, where the ambient pressure is 608 mm Hg, the operator must advance the concentration control dial from 10% to 12.5% to maintain the required anesthetic partial pressure. In hyperbaric settings, the

operator must decrease the dial setting to prevent delivery of an overdose.

Carrier Gas Composition Vaporizer output approximates the dial setting when oxygen is the carrier gas because the Tec 6 vaporizer is calibrated with 100% oxygen. At low flow rates when a carrier gas other than 100% oxygen is used, however, a clear trend toward reduction in vaporizer output emerges. This reduction parallels the proportional decrease in viscosity of the carrier gas. Nitrous oxide has lower viscosity than oxygen does, so the backpressure generated by resistor R1 (see Fig. 25-22) is less when nitrous oxide is the carrier gas, and the working pressure is reduced. At low flow rates and with nitrous oxide used as the carrier gas, vaporizer output is approximately 20% less than the dial setting. This suggests that at clinically useful fresh gas flow rates, gas flow across resistor R1 is laminar, and the working pressure is proportional to both the fresh gas flow rate and the viscosity of the carrier gas.[80]

Safety Features

Because desflurane's vapor pressure is near 1 atm, misfilling contemporary vaporizers with desflurane could theoretically result in both desflurane overdose and creation of a hypoxic gas mixture.[81] Datex-Ohmeda has introduced a unique, anesthetic-specific filling system to minimize occurrence of this potential hazard. The agent-specific filler of the desflurane bottle, known as the "Saf-T-Fill" adapter, is intended to prevent its use with traditional vaporizers. The filling system also minimizes spillage of liquid or vapor anesthetic by maintaining a "closed system" during the filling process. Each desflurane bottle has a spring-loaded filler cap with an O-ring on the tip. The spring seals the bottle until it is engaged in the filler port of the vaporizer. Thus, this anesthetic-specific filling system interlocks the vaporizer and the dispensing bottle and thereby prevents loss of anesthetic to the atmosphere. One recent case report described misfilling of a Tec 6 desflurane vaporizer with sevoflurane. This error was possible because of similarities between a new type of keyed filler for sevoflurane and the desflurane Saf-T-fill adapter. In this case, the desflurane vaporizer detected this error and automatically shut itself off.[69]

Major vaporizer faults cause the shut-off valve located just downstream from the desflurane sump (see Fig. 25-22) to close and produce a no-output situation. The valve is closed and a "no-output" alarm is activated immediately if any of the following conditions occur: (1) the anesthetic level decreases to below 20 mL, (2) the vaporizer is tilted, (3) a power failure occurs, or (4) there is a disparity between the pressure in the vapor circuit and the pressure in the fresh gas circuit that exceeds a specified tolerance.

Summary

The Tec 6 vaporizer is an electrically heated, thermostatically controlled, constant-temperature, pressurized, electromechanically coupled dual-circuit, gas-vapor blender. The pressure in the vapor circuit is electronically regulated to equal the pressure in the fresh gas circuit. At a constant fresh gas flow rate, the operator regulates vapor flow with a conventional concentration control dial. When the fresh gas flow rate increases, the working pressure increases proportionally. For a given concentration setting even when varying the fresh gas flow rate, the vaporizer output is constant because the amount of flow through each circuit remains proportional.[76]

The Datex-Ohmeda Aladin Cassette Vaporizer

The vaporizer system used in the Datex-Ohmeda S/5 ADU is unique in that the single electronically controlled vaporizer is designed to deliver five different inhaled anesthetics, including halothane, isoflurane, enflurane, sevoflurane, and desflurane. The vaporizer consists of a permanent internal control unit housed within the ADU and an interchangeable Aladin agent cassette that contains anesthetic liquid. The Aladin agent cassettes are color-coded for each anesthetic agent, and they are also magnetically coded so that the Datex-Ohmeda ADU can identify which anesthetic cassette has been inserted. The cassettes are filled using agent-specific fillers.[48,82]

Though very different in external appearance, the functional anatomy of the S/5 ADU cassette vaporizer (Fig. 25-23) is very similar to that of the Dräger Vapor 19.n and 20.n and the Datex-Ohmeda Tec 4, Tec 5, and Tec 7 vaporizers. The Aladin

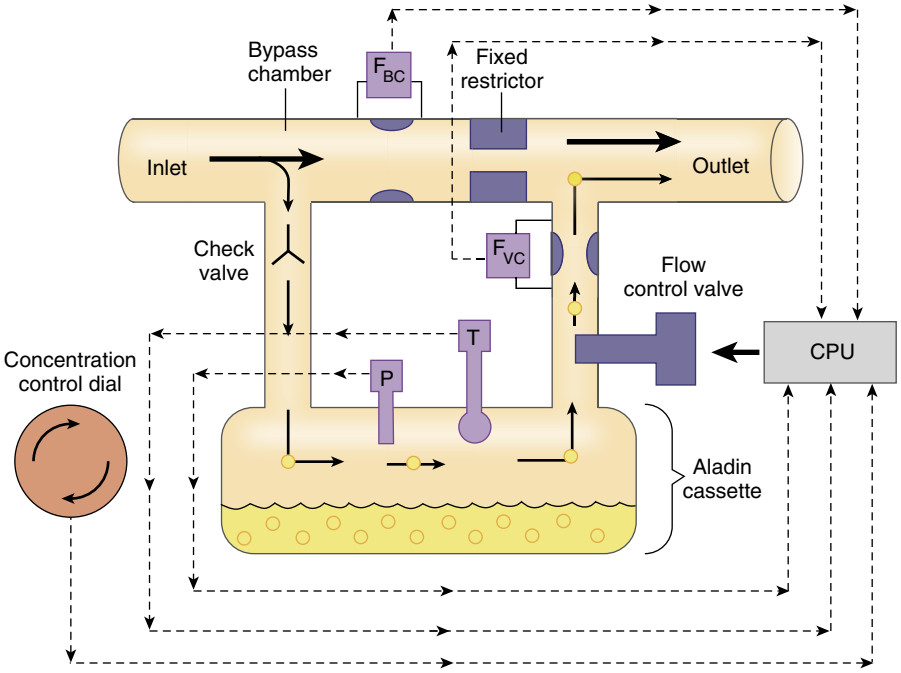

Figure 25-23 Simplified schematic of Datex-Ohmeda Aladin Cassette Vaporizer. The *black arrows* inside the vaporizer represent flow from the flow meters, and the *yellow circles* represent anesthetic vapor. The heart of the vaporizer is the electronically controlled flow control valve located in the outlet of the vaporizing chamber. CPU, central processing unit; F_{BC}, flow measurement unit that measures flow through the bypass chamber; F_{VC}, flow measurement unit that measures flow through the vaporizing chamber; P, pressure sensor; T, temperature sensor. *(Modified from Andrews JJ: Operating Principles of the Datex-Ohmeda Aladin Cassette Vaporizer: A Collection of Color Illustrations. Washington, DC, Library of Congress, 2000.)*

system is functionally similar to these conventional vaporizers because it is also made up of a bypass chamber and vaporizing chamber. A fixed restrictor is located in the bypass chamber, and flow measurement sensors are located both in the bypass chamber and in the outlet of the vaporizing chamber. The heart of the S/5 ADU cassette vaporizer is the electronically regulated flow control valve located in the vaporizing chamber outlet. This valve is controlled by a central processing unit (CPU). The CPU receives input from multiple sources, including the concentration control dial, a pressure sensor located inside the vaporizing chamber, a temperature sensor located inside the vaporizing chamber, a flow measurement unit located in the bypass chamber, and a flow measurement unit located in the outlet of the vaporizing chamber. The CPU also receives input from the flow meters regarding the composition of the carrier gas. By using data from these multiple sources, the CPU is able to precisely regulate the flow control valve to obtain the desired vapor concentration output. Appropriate electronic control of the flow control valve is essential to proper functioning of this vaporizer.[48,83]

A fixed restrictor is located in the bypass chamber, and it causes flow from the vaporizer inlet to split into two flow streams (see Fig. 25-23). One stream passes through the bypass chamber, and the other portion enters the inlet of the vaporizing chamber and passes through a one-way check valve. The presence of this check valve is unique to the Aladin system. This one-way valve prevents retrograde flow of the anesthetic vapor back into the bypass chamber, and its presence is crucial when delivering desflurane if room temperature is higher than the boiling point of desflurane (22.8°C).[48] A precise amount of vapor-saturated carrier gas passes through the flow control valve, which is regulated by the CPU. This flow then joins the bypass flow and is directed to the outlet of the vaporizer.[48]

As mentioned during discussion of the Tec 6, controlled vaporization of desflurane presents a unique challenge, particularly when room temperature is greater than the boiling point of desflurane (22.8°C). At higher temperatures, the pressure inside the vaporizer sump increases, and the sump becomes pressurized. When sump pressure exceeds pressure in the bypass chamber, the one-way check valve located in the vaporizing chamber inlet closes to prevent carrier gas from entering the vaporizing chamber. At this point the carrier gas passes straight through the bypass chamber and its flow sensor. Under these conditions, the electronically regulated flow control valve simply meters in the appropriate flow of pure desflurane vapor needed to achieve the desired final concentration selected by the user. At least one case report has described failure of the vaporizing chamber inlet check valve to function as designed. In this case, an anesthetic overdose occurred as a result of regurgitation of desflurane from the vaporizing chamber in a retrograde fashion back into the bypass chamber. Because of this report, ADU users should be cautious of this potential problem, especially when desflurane is used.[83]

During operating conditions in which high fresh gas flow rates or high dial settings (or both) are used, large quantities of anesthetic liquid are vaporized rapidly. As a result, the temperature of the remaining liquid anesthetic and the vaporizer itself decreases because of energy consumption, or the latent heat of vaporization. To offset this cooling effect, the S/5 ADU is equipped with a fan that forces warmed air from an "agent heating resistor" across the cassette (vaporizer sump) to raise its temperature when necessary. The fan is activated during two common clinical scenarios: (1) desflurane induction and maintenance and (2) sevoflurane induction.

Anesthetic Breathing Circuits

As the prescribed mixture of gases from the flow meters and vaporizer exits the anesthesia workstation at the common gas outlet, it then enters an anesthetic breathing circuit. The function of the anesthesia breathing circuit is not only to deliver oxygen and anesthetic gases to the patient but also to eliminate carbon

dioxide. Carbon dioxide can be removed either by washout with adequate fresh gas inflow or by the use of carbon dioxide absorbent media (e.g., soda lime absorption). The following discussion focuses on semiclosed rebreathing circuits and the circle system.

Mapleson Systems

In 1954 Mapleson described and analyzed five different semiclosed anesthetic systems, and they are now classically referred to as the Mapleson systems and are designated with letters A through E (Fig. 25-24).[84] Subsequently, in 1975 Willis and coauthors described the F system that was added to the original five.[85] The Mapleson systems consist of several common components, including a facemask, a spring-loaded pop-off valve, reservoir tubing, fresh gas inflow tubing, and a reservoir bag. Within the Mapleson systems, three distinct functional groups can be seen: A, BC, and DEF groups. The Mapleson A, also known as the Magill circuit, has a spring-loaded pop-off valve located near the facemask, and fresh gas flow enters the opposite end of the circuit near the reservoir bag. In the B and C systems, the spring-loaded pop-off valve is located near the facemask, but the fresh gas inlet tubing is located near the patient. The reservoir tubing and breathing bag serve as a blind limb where fresh gas, dead space gas, and alveolar gas can collect. Finally, in the Mapleson D, E, and F or "T-piece" group, fresh gas enters near the patient, and excess gas is popped off at the opposite end of the circuit.

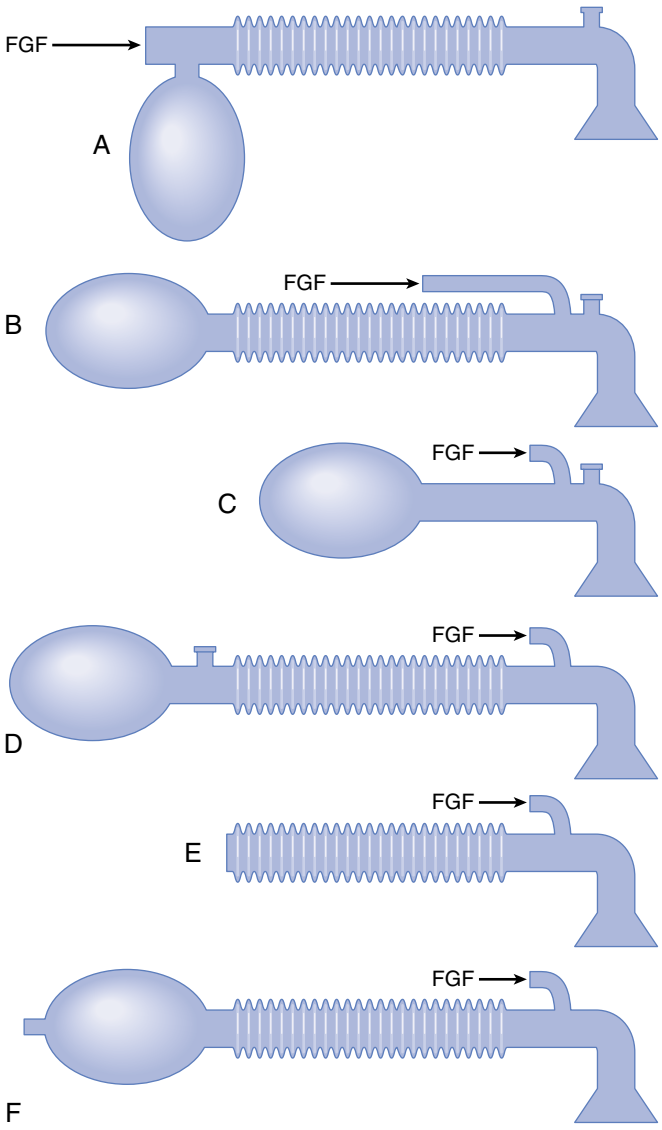

Figure 25-24 Mapleson breathing systems A-F. *(Redrawn with permission from Willis BA, Pender JW, Mapleson WW: Rebreathing in a T-piece: Volunteer and theoretical studies of the Jackson-Rees Modification of Ayer's T-piece during spontaneous respiration. Br J Anesth 47:1239, 1975.)*

Even though the components and their arrangement are simple, functional analysis of the Mapleson systems can be complex.[86,87] The amount of carbon dioxide rebreathing associated with each system is multifactorial, and variables that dictate the ultimate carbon dioxide concentration include the following: (1) the fresh gas inflow rate, (2) minute ventilation, (3) the mode of ventilation (spontaneous or controlled), (4) tidal volume, (5) the respiratory rate, (6) the inspiratory-to-expiratory ratio, (7) the duration of the expiratory pause, (8) the peak inspiratory flow rate, (9) the volume of the reservoir tube, (10) the volume of the breathing bag, (11) ventilation by mask, (12) ventilation through an endotracheal tube, and (13) the CO_2 sampling site.

The performance of the Mapleson systems is best understood by studying the expiratory phase of the respiratory cycle.[88] Illustrations of the various arrangements of Mapleson system component may be found in Figure 25-24. During spontaneous ventilation, the Mapleson A has the best efficiency of the six systems in that it requires a fresh gas inflow rate of only 1 times minute ventilation to prevent rebreathing of carbon dioxide.[89] However, it has the worst efficiency during controlled ventilation because a minute ventilation as high as 20 L/min is needed to prevent rebreathing. Systems DEF are slightly more efficient than systems BC. To prevent rebreathing CO_2, the DEF systems require a fresh gas inflow rate of approximately 2.5 times minute ventilation, whereas the fresh gas inflow rates required for BC systems are somewhat higher.[87]

The following summarizes the relative efficiency of different Mapleson systems with respect to prevention of rebreathing during spontaneous ventilation: A > DFE > CB. During controlled ventilation, DFE > BC > A.[84,87] The Mapleson A, B, and C systems are rarely used today, but the D, E, and F systems are commonly used. In the United States, the most popular representative from the DEF group is the Bain circuit.

Bain Circuit

The Bain circuit is a coaxial circuit and a modification of the Mapleson D system. Fresh gas flows through a narrow inner tube within the outer corrugated tubing.[90] The central fresh gas tubing enters the outer corrugated hose near the reservoir bag, but the fresh gas actually empties into the circuit at the patient end (Fig. 25-25). Exhaled gases enter the corrugated tubing and are vented through the expiratory valve near the reservoir bag. The Bain circuit may be used for both spontaneous and controlled ventilation. The fresh gas inflow rate necessary to prevent rebreathing is 2.5 times minute ventilation.

The Bain circuit has many advantages over other systems. It is lightweight, convenient, easily sterilized, and potentially reusable. Scavenging of gases from the expiratory valve is facilitated because the valve is located away from the patient. Exhaled gases in the outer reservoir tubing add warmth to the inspired fresh

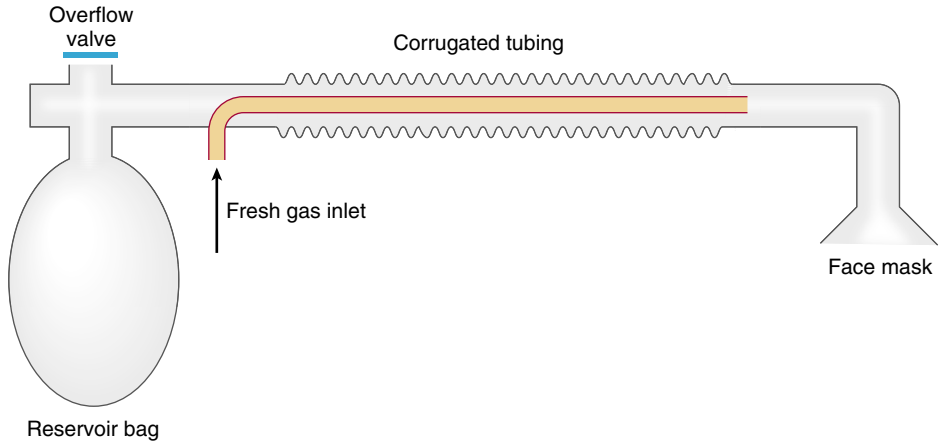

Figure 25-25 The Bain circuit. *(Redrawn with permission from Bain JA, Spoerel WE: A streamlined anaesthetic system. Can Anaesth Soc J 19:426, 1972.)*

gases by countercurrent heat exchange. The main hazards related to use of the Bain circuit are either an unrecognized disconnection or kinking of the inner fresh gas hose. These problems can cause hypercapnia as a result of inadequate gas flow or increased respiratory resistance. As with other circuits, an obstructed antimicrobial filter positioned between the Bain circuit and the endotracheal tube can result in increased resistance in the circuit. This may produce hypoventilation and hypoxemia and may even mimic the signs and symptoms of severe bronchospasm.[91]

The outer corrugated tube should be transparent to allow ongoing inspection of the inner tube. The integrity of the inner tube can be assessed as described by Pethick.[92] With his technique, high-flow oxygen is fed into the circuit while the patient end is occluded until the reservoir bag is filled. The patient end is opened, and oxygen is flushed into the circuit. If the inner tube is intact, the venturi effect occurs at the patient end. This causes a decrease in pressure within the circuit, and as a result, the reservoir bag deflates. Conversely, a leak in the inner tube allows fresh gas to escape into the expiratory limb, and the reservoir bag will remain inflated. This test is recommended as part of the preanesthesia check if a Bain circuit is used.

Circle Breathing Systems

For many years, the overall design of the circle breathing system has changed very little from one anesthesia workstation manufacturer to the next. Both the individual components and the order in which they appeared in the circle system were consistent across major platforms. In recent years, however, with the increasing technologic complexity of the anesthesia workstation, the circle system has undergone some major changes as well. These changes have resulted in part from an effort to improve patient safety (as in the integration of fresh gas decoupling and inspiratory pressure limiters) but have also allowed the deployment of new technologic advances. Two such major new technologies used in some new workstations have been (1) a return to the application of single-circuit piston-type ventilators and (2) the use of new spirometry devices that are located at the Y-connector instead of at the traditional location on the expiratory circuit limb. The following discussion focuses first on the traditional circle breathing system and is then followed by a brief discussion of some variations in the design of newer circle systems.

The Traditional Circle Breathing System

The circle system remains the most popular breathing system in the United States. It is so named because its components are arranged in a circular manner (see Fig. 25-7). One version of the traditional circle system, referred to as either a "universal F" or a "single-limb circuit," has increased in popularity in recent years. Although these systems appear very different externally, they have the same overall functional layout as the traditional circle system, and the following discussion is applicable to both the traditional circle system and the "universal F" system.

The circle system prevents rebreathing of carbon dioxide by use of carbon dioxide absorbents but allows partial rebreathing of other exhaled gases. The extent of rebreathing of the other exhaled gases depends on the arrangement of the breathing circuit components and the fresh gas flow rate. A circle system can be semiopen, semiclosed, or closed, depending on the amount of fresh gas inflow.[93] A semiopen system has no rebreathing and requires a very high flow of fresh gas. A semiclosed system is associated with some rebreathing of exhaled gases and is the most commonly used application in the United States. A closed system is one in which the inflow gas exactly matches that being taken up, or consumed, by the patient. In a closed system there is complete rebreathing of exhaled gases after absorption of carbon dioxide, and the overflow (pop-off or APL) valve or ventilator relief valve remains closed.

The circle system (see Fig. 25-7) consists of seven primary components, including (1) a fresh gas inflow source, (2) inspiratory and expiratory unidirectional valves, (3) inspiratory and expiratory corrugated tubes, (4) a Y-piece connector, (5) an overflow or pop-off valve referred to as the APL valve, (6) a reservoir bag, and (7) a canister containing a carbon dioxide absorbent. The inspiratory and expiratory valves are placed in the system to ensure that gas flow through the corrugated hoses remains unidirectional. The fresh gas inflow enters the circle by a connection from the common gas outlet of the anesthesia machine.

Numerous variations of the circle arrangement are possible, depending on the relative positions of the unidirectional valves, the pop-off valve, the reservoir bag, the carbon dioxide

absorber, and the site of fresh gas entry. However, to prevent rebreathing of carbon dioxide *in a traditional circle system*, three rules must be followed: (1) a unidirectional valve must be located between the patient and the reservoir bag on both the inspiratory and expiratory limbs of the circuit, (2) the fresh gas inflow cannot enter the circuit between the expiratory valve and the patient, and (3) the overflow (pop-off) valve cannot be located between the patient and the inspiratory valve. If these rules are followed, any arrangement of the other components will prevent rebreathing of carbon dioxide.[89] Some newer anesthesia workstations now use less traditional circle breathing systems. Two of these systems are discussed in detail later (see "Anesthesia Workstation Variations").

The most efficient circle system arrangement with the highest conservation of fresh gases is one in which the unidirectional valves are near the patient and the pop-off valve is located just downstream from the expiratory valve. This arrangement minimizes dead space gas and preferentially eliminates exhaled alveolar gases. A more practical arrangement, the one used on most conventional anesthesia machines (see Fig. 25-7), is somewhat less efficient because it allows alveolar and dead space gases to mix before they are vented.[94,95]

The main advantages of the circle system over other breathing systems include (1) maintenance of relatively stable inspired gas concentrations, (2) conservation of respiratory moisture and heat, and (3) prevention of operating room pollution. Additionally, the circle system can be used for closed-system anesthesia or semiclosed with very low fresh gas flows. The major disadvantage of the circle system stems from its complex design. Commonly, the circle system may have 10 or more different connections. These multiple connection sites set the stage for misconnections, disconnections, obstructions, and leaks. In a recent closed-claim analysis of adverse anesthetic outcomes arising from gas delivery equipment, more than a third (25/72) of malpractice claims resulted from breathing circuit misconnections or disconnections.[1] Malfunction of the circle system's unidirectional valves can result in life-threatening problems. Rebreathing can occur if the valves stick in the open position, and total occlusion of the circuit can occur if they are stuck shut. If the expiratory valve is stuck in the closed position, breath stacking and barotrauma or volutrauma can result. Obstructed filters located in the expiratory limb of the circle breathing system have caused increased airway pressure, hemodynamic collapse, and bilateral tension pneumothorax. Causes of circle system obstruction and failure include manufacturing defects, debris, patient secretions, and particulate obstruction from other odd sources such as albuterol nebulization.[96-99] Some systems, such as the Datex-Ohmeda 7900 SmartVent, use flow transducers located on both the inspiratory and expiratory limbs of the circle system. In one report, cracks in the flow transducer tubing used by this system produced a leak in the circle system that was difficult to detect.[100]

Carbon Dioxide Absorbents

Much has appeared in the literature lately regarding the issue of adverse chemical reactions between carbon dioxide absorbent materials and anesthetic agents. Some of these undesirable interactions are quite dramatic, such as sevoflurane interacting with desiccated Baralyme and resulting in fires within the breathing system and severe patient injury.[101,102] Although other sources of ignition and fire in the breathing system continue to be described,[103] the Baralyme-sevoflurane problem is somewhat unique in that nothing "unusual" is added to or removed from the breathing system for this to occur. Other reactions such as desflurane or sevoflurane with desiccated strong-base absorbents can produce more insidious patient morbidity and even death from the release of by-products such as carbon monoxide (CO) or compound A.[104] Although absorbent materials may be problematic, they still represent an important component of the circle breathing system. Different anesthesia breathing systems eliminate carbon dioxide with varying degrees of efficiency. The closed and semiclosed circle systems both *require* that carbon dioxide be absorbed from the exhaled gases to avoid hypercapnia. If one could design an ideal carbon dioxide absorbent, its characteristics would include lack of reactivity with common anesthetics, absence of toxicity, low resistance to airflow, low cost, ease of handling, and efficiency in carbon dioxide absorption.

The Absorber Canister

On modern anesthesia machines, the absorber canister (see Fig. 25-7) is composed of one or two clear plastic canisters alone or arranged in series. The canisters can be filled either with loose bulk absorbent or with absorbent supplied by the factory in prefilled plastic disposable cartridges called *prepacks*. Free granules from bulk absorbent can create a clinically significant leak if they lodge between the clear plastic canister and the O-ring gasket of the absorber. Leaks have also been caused by defective prepacks that were larger than factory specifications.[105] Prepacks can also cause total obstruction of the circle system if the clear plastic shipping wrapper is not removed before use.[106]

Chemistry of Absorbents

Two formulations of carbon dioxide absorbents are commonly available today: soda lime and calcium hydroxide lime (Amsorb). Of these agents, the most commonly used is soda lime. All serve to eliminate carbon dioxide from the breathing circuit with varying degrees of efficiency. Formerly, a product known as Baralyme, or barium hydroxide lime, was frequently used. This compound had significant interaction with contemporary volatile anesthetic drugs and was voluntarily removed from the market after several mishaps were reported in the literature (see later).

By weight, the approximate composition of "high-moisture" soda lime is 80% calcium hydroxide, 15% water, 4% sodium hydroxide, and 1% potassium hydroxide (an activator). Small amounts of silica are added to produce calcium and sodium silicate. This addition produces a harder, more stable pellet and thereby reduces dust formation. The efficiency of soda lime absorption varies inversely with its hardness; therefore, little silicate is used in contemporary soda lime. Sodium hydroxide is the catalyst for the carbon dioxide absorptive properties of soda lime.[107,108] Baralyme is a mixture of approximately 20% barium hydroxide and 80% calcium hydroxide. It may also contain some potassium hydroxide. Baralyme is the primary carbon dioxide

absorbent implicated as an agent that may produce fires in the breathing system when used with sevoflurane. Calcium hydroxide lime is one of the newest clinically available carbon dioxide absorbents. It consists primarily of calcium hydroxide and calcium chloride and contains two setting agents: calcium sulfate and polyvinylpyrrolidine. The latter two agents serve to enhance the hardness and porosity of the agent.[109] The most significant advantage of calcium hydroxide lime over other agents is its lack of the strong bases sodium and potassium hydroxide. Absence of these chemicals eliminates the undesirable production of CO and the nephrotoxic substance known as compound A, and it may reduce or eliminate the possibility of a fire in the breathing circuit.[110] The most significant disadvantages of calcium hydroxide lime are (1) less absorptive capacity—about 50% less than absorbents containing strong bases—and (2) generally higher cost per unit than other absorbents.[111,112]

The size of the actual absorptive granules has been determined over time by trial and error. The current particle sizes represent a compromise between resistance to airflow and absorptive efficiency.[113] The smaller the granule size, the greater the surface area that is available for absorption. However, as particle size decreases, airflow resistance increases. The granular size of soda lime and Baralyme used in clinical practice is between 4 and 8 mesh, a size at which absorptive surface area and resistance to flow are optimized. Mesh size refers to the number of openings per linear inch in a sieve through which the granular particles can pass. A 4-mesh screen means that there are four quarter-inch openings per linear inch. Likewise, an 8-mesh screen has eight per linear inch.[107]

Absorption of carbon dioxide by absorbents such as soda lime occurs via a series of chemical reactions; it is not a physical process like water soaking into a sponge. Carbon dioxide combines with water to form carbonic acid. Carbonic acid reacts with the hydroxides to form sodium (or potassium) carbonate and water. Calcium hydroxide accepts the carbonate to form calcium carbonate and sodium (or potassium) hydroxide. The equations are as follows:

1. $CO_2 + H_2O \rightleftharpoons H_2CO_3$
2. $H_2CO_3 + 2NaOH\ (KOH) \rightleftharpoons Na_2CO_3\ (K_2CO_3) + 2H_2O +$ Heat
3. $Na_2CO_3\ (K_2CO_3) + Ca(OH)_2 \rightleftharpoons CaCO_3 + 2NaOH\ (KOH)$

Some carbon dioxide may react directly with $Ca(OH)_2$, but this reaction is much slower.

Absorptive Capacity

The maximum amount of carbon dioxide that can be absorbed by soda lime is 26 L of CO_2 per 100 g of absorbent. The absorptive capacity of calcium hydroxide lime is significantly less and has been reported to be 10.2 L per 100 g of absorbent.[109,112] However, as mentioned previously, absorptive capacity is the product of both available chemical reactivity and physical (granule) availability. As the absorbent granules stack up in the absorber canisters, small passageways inevitably form. These small passages channel gases preferentially through low-resistance areas. Because of this phenomenon, the functional absorptive capacity of either soda lime or calcium hydroxide lime may be substantially decreased. In practice, as a result of channeling, the efficiency of soda lime may be reduced such that only 10 to 20 L or less of carbon dioxide can actually be absorbed per 100 g of absorbent.[114]

Indicators

Ethyl violet is the pH indicator added to both soda lime and calcium hydroxide lime to help assess the functional integrity of the absorbent. This compound is a substituted triphenylmethane dye with a critical pH of 10.3.[108] Ethyl violet changes from colorless to violet when the pH of the absorbent decreases as a result of carbon dioxide absorption. When the absorbent is fresh, the pH exceeds the critical pH of the indicator dye, and it exists in its colorless form (Fig. 25-26A). However, as absorbent becomes exhausted, the pH decreases below 10.3, and ethyl violet changes to its violet form (Fig. 25-26B) because of alcohol dehydration. This change in color indicates that the absorptive capacity of the material has been consumed. Unfortunately, in some circumstances ethyl violet may not always be a reliable indicator of the functional status of absorbent. For example, prolonged exposure of ethyl violet to fluorescent light can produce photodeactivation of this dye. When this occurs, the absorbent appears white even though it may have a reduced pH and its absorptive capacity has been exhausted.[115]

Some newer absorbent materials may also include indicators that reveal whether the material has become desiccated. Users should refer to the product manufacturers' literature to determine whether their absorbent material uses this type of indicator.
