Jeanine P. Wiener-Kronish

William L. Young

CHURCHILL LIVINGSTONE ELSEVIER

Volume 1

Contributors

Ted G. Abel, PhD
Professor, Department of Biology, University of Pennsylvania, Philadelphia, Pennsylvania

Olga N. Afonin, MD
Assistant Clinical Professor, Department of Anesthesia and Perioperative Care, University of California, San Francisco, School of Medicine, San Francisco, California

Paul D. Allen, BA, MS(hon), MD, PhD
Professor of Anaesthesia, Harvard Medical School; Senior Anesthesiologist, Brigham and Women's Hospital, Boston, Massachusetts

J. Jeffrey Andrews, MD
Professor and Chair, Department of Anesthesiology, University of Texas Health Sciences Center at San Antonio, San Antonio, Texas

Michael Ang-Lee, MD
Staff Anesthesiologist, Pacific Anesthesia, Bellevue, Washington

Christian C. Apfel, MD, PhD
Associate Professor, Department of Anesthesia and Perioperative Care, University of California, San Francisco, School of Medicine, San Francisco, California

William P. Arnold III, MD
Associate Professor of Anesthesiology, University of Virginia Health System, Charlottesville, Virginia

Solomon Aronson, MD, FACC, FACCP, FAHA, FASE
Professor and Executive Vice Chair, Department of Anesthesiology, Duke University Medical Center, Durham, North Carolina

Angela M. Bader, MD, MPH
Associate Professor of Anaesthesia, Harvard Medical School; Director, Weiner Center for Preoperative Evaluation, Brigham and Women's Hospital; Vice Chair, Department of Anesthesiology, Perioperative and Pain Medicine; Brigham and Women's Hospital, Boston, Massachusetts

David Baker, MPhil, DM, FRCA, FRSM
Consultant Medical Toxicologist, Chemical Hazards and Poisons Division, Health Protection Agency, London, United Kingdom; Consultant Anesthesiologist, SAMU de Paris, Hôpital Necker Enfants Malades, Paris, France

Anis Baraka, MB, BCh, DA, DM, MD, FRCA (Hon)
Professor, Department of Anesthesiology, American University of Beirut, Beirut, Lebanon

Atilio Barbeito, MD
Assistant Professor, Department of Anesthesiology, Duke University Medical Center; Staff Anesthesiologist, Veterans Affairs Medical Center, Durham, North Carolina

Steven J. Barker, MD, PhD
Professor and Chair, Department of Anesthesiology, University of Arizona College of Medicine, Tucson, Arizona

Shahar Bar-Yosef, MD
Assistant Professor, Department of Anesthesiology, Duke University Medical Center; Staff Anesthesiologist, Veterans Affairs Medical Center, Durham, North Carolina

Charles B. Berde, MD, PhD
Professor of Anaesthesia (Pediatrics), Harvard Medical School; Sara Page Mayo Chair in Pediatric Pain Medicine, and Chief, Division of Pain Medicine, Department of Anesthesiology, Perioperative and Pain Medicine, Children's Hospital Boston, Boston, Massachusetts

Darryl H. Berkowitz, MB, BCh
Assistant Professor, Department of Anesthesiology and Critical Care Medicine, University of Pennsylvania School of Medicine; Attending Anesthesiologist, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

David J. Birnbach, MD, MPH
Professor of Anesthesiology, Obstetrics and Public Health, University of Miami Miller School of Medicine; Vice Provost, University of Miami; Associate Dean and Director, UM-JMH Center for Patient Safety, Miami, Florida

David Bogod, MB, BS, FRCA, LLM
Honorary Senior Lecturer, University of Nottingham; Consultant Anaesthetist, Nottingham University Hospitals NHS Trust, Nottingham, United Kingdom

Russell C. Brockwell, MD
Attending Anesthesiologist, Anesthesia Associates of Naples, Naples, Florida

David L. Brown, MD
Chairman, Institute of Anesthesiology, The Cleveland Clinic, Cleveland, Ohio

Ingrid M. Browne, MB, BCh, MMedSci, FFARCSI
Department of Anesthesiology, National Maternity Hospital; Department of Anesthesiology, St. Vincent's University Hospital, Dublin, Ireland

Michael K. Cahalan, MD
Professor and Chair, Department of Anesthesiology, University of Utah School of Medicine, Salt Lake City, Utah

Enrico M. Camporesi, MD
Professor of Anesthesiology, Surgery, Molecular Pharmacology, and Physiology, University of South Florida, Tampa, Florida

Javier H. Campos, MD
Professor of Anesthesia, University of Iowa College of Medicine; Vice Chair for Clinical Affairs, Medical Director of Operating Rooms, and Director of Cardiothoracic Anesthesia, Department of Anesthesia, University of Iowa Hospitals and Clinics, Iowa City, Iowa

Lydia Cassorla, MD, MBA
Professor, Department of Anesthesia and Perioperative Care, University of California, San Francisco, School of Medicine, San Francisco, California

Charles J. Coté, MD
Professor of Anaesthesia, Harvard Medical School; Director of Clinical Research, Division of Pediatric Anesthesia, Department of Anesthesia and Critical Care, MassGeneral Hospital for Children, Massachusetts General Hospital, Boston, Massachusetts

Bernard J. Dalens, MD, PhD
Associate Professor of Anesthesiology, Laval University; Clinical Professor, Department of Anesthesiology, Centre Hospitalier de l'Université Laval, Quebec City, Quebec, Canada

Clifford S. Deutschman, MS, MD, FCCM
Professor, Department of Anesthesiology and Critical Care, and Director, Stavropoulos Sepsis Research Program, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania

Peter Dieckmann, PhD
Department of Anaesthesiology and Intensive Care Medicine, University Hospital Tuebingen, Tuebingen, Germany; Researcher, Danish Institute for Medical Simulation, Copenhagen University Hospital Herlev, Herlev, Denmark

Sudhir Diwan, MD, MS, FIPP
Associate Professor of Clinical Anesthesiology, Weill Cornell Medical College; Director, Division of Pain Medicine, New York Presbyterian Hospital, New York, New York

John C. Drummond, MD, FRCPC
Professor of Anesthesiology, University of California, San Diego, School of Medicine; Staff Anesthesiologist, Veterans Affairs Medical Center, San Diego, California

Richard P. Dutton, MD, MBA
Associate Professor of Anesthesiology, University of Maryland School of Medicine; Director, Trauma Anesthesiology, R. Adams Cowley Shock Trauma Center, University of Maryland Medical System, Baltimore, Maryland

David M. Eckmann, PhD, MD
Horatio C. Wood Associate Professor of Anesthesiology and Critical Care and Professor of Bioengineering, University of Pennsylvania, Philadelphia, Pennsylvania

Edmond I. Eger II, MD
Professor, Department of Anesthesia and Perioperative Care, University of California, San Francisco, School of Medicine, San Francisco, California

Christoph Eich, MD, DEAA
Lecturer, Georg-August University School of Medicine; Attending Pediatric Anaesthesiologist, Department of Anaesthesiology, Emergency and Intensive Care Medicine, University Medical Centre Göttingen, Göttingen, Germany

Matthew R. Eng, BS, MD
The University of Texas Southwestern Medical Center, Dallas, Texas

Lars I. Eriksson, MD, PhD
Professor and Academic Chair, Department of Anesthesiology and Intensive Care Medicine, Karolinska University Hospital, Solna, Stockholm, Sweden

Stephen M. Eskaros, MD
Department of Anesthesia and Critical Care, University of California, Los Angeles, Ronald Reagan Medical Center, Los Angeles, California

Neil E. Farber, MD, PhD
Associate Professor of Anesthesiology, Pediatrics, Pharmacology and Toxicology, Medical College of Wisconsin; Director of Pediatric Anesthesia Research, Children's Hospital of Wisconsin, Milwaukee, Wisconsin

Marc Allan Feldman, MD, MHS
Head, Section of Anesthesia, Cole Eye Institute; Director, Cole Eye Institute Operating Rooms, Cleveland Clinic, Cleveland, Ohio

Stephen P. Fischer, BA, MS, MD
Associate Professor, Department of Anesthesia; Medical Director, Anesthesia Preoperative Evaluation Clinic, Stanford University School of Medicine, Stanford, California

Lee A. Fleisher, MD
Robert Dunning Dripps Professor and Chair, Department of Anesthesiology and Critical Care; Professor of Medicine, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania

Pamela Flood, MD
Associate Professor of Clinical Anesthesiology, Columbia University College of Physicians and Surgeons; Associate Attending Anesthesiologist, New York Presbyterian Hospital, New York, New York

Kazuhiko Fukuda, MD, PhD
Professor, Department of Anesthesiology, Kyoto University Hospital, Kyoto, Japan

David M. Gaba, MD
Professor of Anesthesia and Associate Dean for Immersive and Simulation-Based Learning, Stanford University; Staff Anesthesiologist and Director, Patient Simulation Center of Innovation, VA Palo Alto Health Care System, Palo Alto, California

Michael T. Ganter, MD
Consultant, University Hospital Zurich, Zurich, Switzerland

Adrian W. Gelb, MB, ChB, DA, FRCPC
Professor, Department of Anesthesia and Perioperative Care, University of California, San Francisco, School of Medicine, San Francisco, California

Simon Gelman, MD, PhD, FANZCA
Leroy D. Vandam/Benjamin G. Covino Distinguished Professor of Anaesthesia, Harvard Medical School; Chairman Emeritus, Department of Anesthesiology, Perioperative and Pain Medicine, Brigham and Women's Hospital, Boston, Massachusetts

Peter S. A. Glass, MB, ChB, FFA (SA)
Professor and Chair, Department of Anesthesiology, Stony Brook University Medical Center, Stony Brook, New York

David B. Glick, MD, MBA
Associate Professor, Department of Anesthesiology, University of Chicago; Medical Director, Post-Anesthesia Care Unit, University of Chicago Hospitals, Chicago, Illinois

Lawrence T. Goodnough, MD
Professor of Medicine and Pathology, Stanford University School of Medicine; Director, Transfusion Service, Stanford University Medical Center, Stanford, California

Sumeet Goswami MB, BS
Assistant Professor, Department of Anesthesia and Critical Care, Columbia University College of Physicians and Surgeons, Columbia University Medical Center, New York, New York

Salvatore Grasso, MD
Assistant Professor, Department of Anaesthesia and Intensive Care Medicine, University of Bari, Bari, Italy

Andrew T. Gray, MD, PhD
Professor of Clinical Anesthesia, Department of Anesthesia and Perioperative Care, University of California, San Francisco, School of Medicine; Staff Anesthesiologist, San Francisco General Hospital, San Francisco, California

William J. Greeley, MD, MBA
Chair and Anesthesiologist-in-Chief, Department of Anesthesiology and Critical Care Medicine, The Children's Hospital of Philadelphia; Professor of Anesthesia and Pediatrics, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania

George A. Gregory, MD
Professor of Anesthesia and Pediatrics, University of California, San Francisco, School of Medicine, San Francisco, California

Alina M. Grigore, MD
Associate Professor of Anesthesiology, Mayo Clinic College of Medicine; Senior Associate Consultant, Mayo Clinic Hospital, Phoenix, Arizona

Thomas E. Grissom, MD, FCCM
Associate Professor, Department of Anesthesiology, University of Maryland School of Medicine, Baltimore, Maryland

Michael A. Gropper, MD, PhD
Professor and Vice Chair, Department of Anesthesia and Perioperative Care, University of California, San Francisco, School of Medicine; Director of Critical Care Medicine, UCSF Medical Center, San Francisco, California

Fouad Salim Haddad, MD, FACA, DABA
Department of Anesthesiology, American University of Beirut, Beirut, Lebanon

C. William Hanson, MD
Professor of Anesthesiology and Critical Care, Surgery and Internal Medicine, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania

Michael C. Hauser, MD
Associate Professor, Department of Anesthesiology, Cleveland Clinic Lerner College of Medicine, Cleveland, Ohio

Göran Hedenstierna, MD, PhD
Professor of Clinical Physiology, Department of Medical Science, Uppsala University; Head of Nuclear Medicine, Uppsala University Hospital, Uppsala, Sweden

Eugenie S. Heitmiller, MD
Associate Professor, Department of Anesthesiology and Critical Care Medicine and Department of Pediatrics; Vice Chairman for Clinical Affairs, Johns Hopkins University School of Medicine, Baltimore, Maryland

Hugh C. Hemmings Jr., MD, PhD
Professor of Anesthesiology, Vice Chair for Research in Anesthesiology, and Professor of Pharmacology, Weill Cornell Medical College; Attending Anesthesiologist, New York Presbyterian Hospital–Weill Cornell Medical Center, New York, New York

John Henderson, MB, ChB, FRCA
Consultant Anaesthetist, Gartnavel General Hospital, Glasgow, Scotland, United Kingdom

Zak Hillel, PhD, MD
Professor of Clinical Anesthesiology, Columbia University College of Physicians and Surgeons; Director of Cardiac Anesthesia, St. Luke's–Roosevelt Hospital, New York, New York

Christoph K. Hofer, MD, DEAA
Senior Consultant, Institute of Anesthesiology and Intensive Care Medicine, Triemli City Hospital, Zurich, Switzerland

Terese T. Horlocker, MD
Professor of Anesthesiology and Orthopaedics, Mayo Clinic College of Medicine, Rochester, Minnesota

Steven K. Howard, MD
Associate Professor of Anesthesia, Stanford University School of Medicine; Staff Anesthesiologist, VA Palo Alto Health Care System, Palo Alto, California

Yuguang Huang, MD
Professor and Chairman, Department of Anesthesiology, Peking Union Medical College Hospital, Beijing, China

Michael Hüpfl, MD
Department of Anesthesiology and General Intensive Care, Medical University of Vienna; Medical Director, St. John's Ambulance Service, Vienna, Austria

Robert W. Hurley, MD, PhD
Assistant Professor, Department of Anesthesiology and Critical Care, Johns Hopkins University School of Medicine; Medical Director, Blaustein Pain Treatment Center and Center for Neuromodulation at Johns Hopkins University, Baltimore, Maryland

Fumito Ichinose, MD, PhD
Associate Professor of Anaesthesia, Harvard Medical School; Associate Anesthetist, Department of Anesthesia and Critical Care, Massachusetts General Hospital, Boston, Massachusetts

Samuel A. Irefin, MD, FCCM
Associate Professor, Department of General Anesthesia and the Transplant Center, Cleveland Clinic Lerner College of Medicine, Cleveland, Ohio

Ken B. Johnson, MD
Associate Professor, Carter M. Ballinger MD Presidential Chair in Anesthesiology, Department of Anesthesiology, University of Utah School of Medicine, Salt Lake City, Utah

Jean L. Joris, MD, PhD
Professor of Anesthesia, University of Liège; Associate Chief of the Service of Anesthesia and Intensive Care Medicine, CHU de Liège, Liège, Belgium

Alan D. Kaye, MD, PhD, DABPM
Professor and Chairman, Department of Anesthesiology, and Professor of Pharmacology, Louisiana State University Health Sciences Center, New Orleans, Louisiana

Max B. Kelz, MD, PhD
Assistant Professor, Department of Anesthesiology and Critical Care, Mahoney Institute for Neurological Sciences, Center for Sleep and Respiratory Neurobiology, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania

James D. Kindscher, MD
Professor and Chair, Department of Anesthesiology, Kansas University Medical Center, Kansas City, Kansas

Benjamin A. Kohl, MD
Assistant Professor, Department of Anesthesiology and Critical Care; Director, Critical Care Fellowship, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania

Andreas Kopf, MD
Instructor, Department of Anesthesiology and Critical Care Medicine, Freie Universität Berlin, Charité Campus Benjamin Franklin, Berlin, Germany

Burkhard Lachmann, MD, PhD
Professor of Anesthesiology, University of Berlin, Berlin, Germany

Arthur M. Lam, MD, FRCPC
Professor of Anesthesiology and Neurological Surgery, University of Washington School of Medicine; Anesthesiologist-in-Chief and Attending Neurointensivist, Harborview Medical Center, Seattle, Washington

Giora Landesberg, MD, DSc, MBA
Associate Professor, Hebrew University Hadassah Medical School; Director of Cardiothoracic and Vascular Anesthesia, Department of Anesthesiology and Critical Care Medicine, Hadassah University Hospital, Jerusalem, Israel

Merlin D. Larson, MD
Professor, Department of Anesthesia and Perioperative Care, University of California, San Francisco, School of Medicine, San Francisco, California

Jae-Woo Lee, MD
Assistant Professor in Residence, Department of Anesthesia and Perioperative Care, University of California, San Francisco, School of Medicine, San Francisco, California

Guillermo Lema, MD
Professor, Department of Anesthesiology, Pontificia Universidad Católica de Chile; Chief of Cardiovascular Anesthesia, Hospital Clinico, Santiago, Chile

Kate Leslie, MBBS, MD, M Epi, FANZCA
Honorary Associate Professor, Department of Pharmacology, University of Melbourne; Staff Anaesthetist, Department of Anaesthesia and Pain Management, Royal Melbourne Hospital, Melbourne, Australia

Cynthia A. Lien, MD
Professor, Department of Anesthesiology, Weill Medical College of Cornell University; Attending Anesthesiologist, New York Presbyterian Hospital, New York, New York

Lawrence Litt, PhD, MD
Professor, Department of Anesthesia and Perioperative Care and Department of Radiology, University of California, San Francisco, School of Medicine; Attending Anesthesiologist, UCSF Hospitals, San Francisco, California

Linda Liu, MD
Associate Professor of Clinical Anesthesia, Department of Anesthesia and Perioperative Care, University of California, San Francisco, School of Medicine, San Francisco, California

David A. Lubarsky, MD, MBA
Emanuel M. Papper Professor and Chair, Department of Anesthesiology, Perioperative Medicine and Pain Management; Senior Associate Dean for Quality, Safety and Risk Prevention, and Assistant Vice-President for Medical Administration, University of Miami Miller School of Medicine; Professor, Department of Management, University of Miami School of Business, Miami, Florida

Michael E. Mahla, MD
Professor of Anesthesiology and Neurosurgery; Associate Chair, Department of Anesthesiology; Assistant Dean for Graduate Medical Education, University of Florida College of Medicine, Gainesville, Florida

Vinod Malhotra, MD
Professor of Clinical Anesthesiology, Weill Medical College of Cornell University; Vice Chair for Clinical Affairs, Department of Anesthesiology and Clinical Director of Operating Rooms, New York Presbyterian Hospital–Weill Cornell Medical Center, New York, New York

Jonathan B. Mark, MD
Professor and Vice Chair, Department of Anesthesiology, Duke University Medical Center; Chief, Anesthesiology Service, Veterans Affairs Medical Center, Durham, North Carolina

Jackie L. Martin, MD
Professor, Department of Anesthesiology and Critical Care Medicine, Johns Hopkins University School of Medicine, Baltimore, Maryland

Elizabeth A. Martinez, MD, MHS
Associate Professor, Department of Anesthesiology and Critical Care Medicine and Department of Surgery, Johns Hopkins University School of Medicine; Medical Director, Adult PACU, Johns Hopkins Hospital, Baltimore, Maryland

Ricardo Martinez-Ruiz, MD
Assistant Professor of Anesthesiology and Surgery, University of Miami Miller School of Medicine; Director, Critical Care Division, and Chief, Surgical Intensive Care Unit, Department of Anesthesiology, Veterans Affairs Medical Center, Miami, Florida

J. A. Jeevendra Martyn, MD, FRCA, FCCM
Professor of Anaesthesia, Harvard Medical School; Anesthetist, Massachusetts General Hospital; Anesthetist-in-Chief, Shriners Burns Hospital; Director, Clinical and Biochemical Pharmacology Laboratory, Massachusetts General Hospital, Boston, Massachusetts

Luciana Mascia, MD, PhD
Assistant Professor, Department of Anesthesiology and Critical Care, Ospedale S. Giovanni Battista, University of Torino, Torino, Italy

George A. Mashour, MD, PhD
Assistant Professor of Anesthesiology, Assistant Professor of Neurosurgery, and Faculty, Neuroscience Graduate Program, University of Michigan Medical School; Director of Neurosurgical Anesthesia, University of Michigan Health System, Ann Arbor, Michigan

Mervyn Maze, FRCA, FRCP, FMedSci, PhD
Professor and Chair, Magill Department of Anaesthetics and Intensive Care, Chelsea and Westminster Hospital, Imperial College, London, United Kingdom

Maureen McCunn, MD, MIPP, FCCM
Associate Professor, Department of Anesthesiology and Critical Care, University of Maryland School of Medicine, Baltimore, Maryland

Matthew D. McEvoy, MD
Assistant Professor of Anesthesiology, Director of Simulation, Associate Dean for Curriculum Reform, College of Medicine, Medical University of South Carolina, Charleston, South Carolina

Brian P. McGlinch, MD
Assistant Professor, Department of Anesthesiology, Mayo Clinic College of Medicine, Rochester, Minnesota

Berend Mets, MB, ChB, PhD, FRCA, FFA(SA)
Eric A. Walker Professor and Chair, Department of Anesthesiology, Pennsylvania State University College of Medicine, Penn State Milton S. Hershey Medical Center, Hershey, Pennsylvania

Ronald D. Miller, MD
Professor and Chair, Department of Anesthesia and Perioperative Care, and Professor of Cellular and Molecular Pharmacology, University of California, San Francisco, School of Medicine, San Francisco, California

Terri G. Monk, MD
Professor, Department of Anesthesiology, Duke University Medical Center, Durham, North Carolina

Richard E. Moon, MD, CM
Professor of Anesthesiology and Medicine, Duke University School of Medicine; Chief, Division of General, Vascular and Transplant Anesthesia; Medical Director, Center for Hyperbaric Medicine and Environmental Physiology, Duke University Medical Center, Durham, North Carolina

Kenjiro Mori, MD, PhD, FRCA
Professor Emeritus, Department of Anesthesia, Kyoto University Hospital, Kyoto, Japan

Jonathan Moss, MD, PhD
Professor, Department of Anesthesia and Critical Care, University of Chicago, Chicago, Illinois

Phillip S. Mushlin, MD, PhD
Associate Professor of Anaesthesia, Harvard Medical School, and Brigham and Women's Hospital, Boston, Massachusetts

Peter Nagele, MD
Assistant Professor, Department of Anesthesiology, Washington University School of Medicine, St. Louis, Missouri; Associate Professor, Department of Anesthesiology and General Critical Care, Medical University of Vienna, Vienna, Austria

Mohamed Naguib, MB BCh, MSc, FFARCSI, MD
Professor, Department of Anesthesiology and Pain Management, The University of Texas MD Anderson Cancer Center, Houston, Texas

Shinichi Nakao, MD, PhD
Associate Professor of Anesthesiology, Kansai Medical University, Moriguchi, Osaka, Japan

Akiyoshi Namiki, MD, PhD
Professor and Chair, Department of Anesthesiology, Sapporo Medical University School of Medicine, Sapporo, Hokkaido, Japan

Aruna T. Nathan, MBBS, FRCA
Attending Anesthesiologist, Department of Anesthesiology and Critical Care Medicine, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

Patrick J. Neligan, MA, MB, FFARCSI
Honorary Senior Lecturer in Anaesthesia, University College Galway, National University of Ireland; Consultant in Anaesthesia and Intensive Care Medicine, University College Hospitals, Galway, Ireland

Stanton P. Newman, PhD
Professor of Health Psychology and Director, Centre for Behavioural and Social Sciences in Medicine, Division of Medicine, University College London, London, United Kingdom

Dorre Nicholau, MD, PhD
Clinical Professor, Department of Anesthesia and Perioperative Care, University of California, San Francisco, School of Medicine, San Francisco, California

Claus U. Niemann, MD
Associate Professor of Anesthesia and Surgery, Department of Anesthesia and Perioperative Care, Department of Surgery, Division of Transplantation, University of California, San Francisco, School of Medicine, San Francisco, California

Ervant Nishanian, PhD, MD
Assistant Professor, Department of Anesthesiology and Critical Care, Division of Cardiothoracic Anesthesiology, Columbia University College of Physicians and Surgeons, New York, New York

Edward J. Norris, MD, MBA, FAHA
Associate Professor, Department of Anesthesia and Critical Care, The Johns Hopkins University School of Medicine; Director, Vascular and Endovascular Anesthesia, The Johns Hopkins Hospital and Medical Institutions, Baltimore, Maryland

Florian R. Nuevo, MD
Department of Anesthesiology, University of Santo Tomas Hospital, Manila, Philippines

Nancy A. Nussmeier, MD
Professor and Chair, Department of Anesthesiology, SUNY Upstate Medical University, Syracuse, New York

Christopher J. O'Connor, MD
Professor, Department of Anesthesiology, Rush University Medical Center, Rush Medical College, Chicago, Illinois

Jerome O'Hara, MD
Associate Professor, Cleveland Clinic Lerner College of Medicine; Section Head of Anesthesia, Glickman Urological Institute, Cleveland Clinic, Cleveland, Ohio

Paul S. Pagel, MD, PhD
Professor of Anesthesiology, Medical College of Wisconsin; Staff Anesthesiologist, Clement J. Zablocki Veterans Affairs Medical Center, Milwaukee, Wisconsin

Peter J. Papadakos, MD
Professor of Anesthesiology, Surgery and Neurosurgery, University of Rochester School of Medicine; Director of Critical Care Medicine, University of Rochester Medical Center, Rochester, New York

Anil Patel, MBBS, FRCA
Honorary Senior Lecturer, Institute of Otolaryngology, University College London; Consultant, Royal National Throat, Nose and Ear Hospital and University College Hospital, London, United Kingdom

Piyush M. Patel, MD, FRCPC
Professor of Anesthesiology, University of California, San Diego; Staff Anesthesiologist, Veterans Affairs Medical Center; San Diego, California

Ronald Pauldine, MD
Clinical Associate Professor, Department of Anesthesiology, University of Washington School of Medicine; Attending Anesthesiologist, Veterans Affairs Puget Sound Health Care System, Seattle, Washington

Robert A. Pearce, MD, PhD
Ralph M. Waters, M.D., Distinguished Chair of Anesthesiology and Professor of Anesthesiology, University of Wisconsin School of Medicine and Public Health, Madison, Wisconsin

Misha Perouansky, MD
Professor of Anesthesiology, University of Wisconsin School of Medicine and Public Health, Madison, Wisconsin

Isaac N. Pessah, PhD
Professor, Department of Molecular Biosciences, College of Veterinary Medicine, University of California, Davis; Director, UC Davis Children's Center for Environmental Health and Disease Prevention, Davis, California

Jean-François Pittet, MD
Professor in Residence, Departments of Anesthesia and Surgery; Associate Investigator, Cardiovascular Research Institute, University of California, San Francisco, San Francisco, California

Phillip F. Pratt Jr., PhD
Assistant Professor of Anesthesiology and Pharmacology, Medical College of Wisconsin, Milwaukee, Wisconsin

Peter J. Pronovost, MD, PhD, FCCM
Professor, Departments of Anesthesiology and Critical Care Medicine, Surgery, and Health Policy and Management; Medical Director, Center of Innovations in Quality Patient Care; Director, Quality and Safety Research Group, The Johns Hopkins University School of Medicine, Baltimore, Maryland

Marcus Rall, MD
Director, Center for Patient Safety and Simulation (TuPASS), Department of Anaesthesiology and Intensive Care Medicine, University Hospital Tuebingen, University of Tuebingen Medical School, Tuebingen, Germany

Ira J. Rampil, MS, MD
Professor of Anesthesiology and Neurological Surgery, and Director of Clinical Research, State University of New York at Stony Brook, Stony Brook, New York

V. Marco Ranieri, MD
Professor, Department of Anesthesia and Intensive Care, Ospedale San Giovanni Battista, Torino, Italy

Lars Rasmussen, MD, PhD
Consultant, Department of Anaesthesia, Centre for Head and Orthopaedics, Copenhagen University Hospital, Rigshospitalet, Copenhagen, Denmark

J. G. Reves, MD
Professor, Department of Anesthesia and Perioperative Medicine; Professor, Department of Pharmacology; Dean, College of Medicine; and Vice President for Medical Affairs, Medical University of South Carolina, Charleston, South Carolina

Zaccaria Ricci, MD
Attending Anesthesiologist, Department of Pediatric Cardiac Surgery, Ospedale Bambino Gesù, Rome; Fellow, Ospedale San Bortolo, Vicenza, Italy

James M. Riopelle, MD
Professor, Department of Anesthesiology, Louisiana State University Health Sciences Center, New Orleans, Louisiana

Melissa Rockford, MD
Assistant Professor of Anesthesiology, University of Kansas School of Medicine, Kansas City, Kansas

Michael F. Roizen, MD
Chair, The Wellness Institute, and Chief Wellness Officer, Cleveland Clinic, Cleveland, Ohio

Claudio Ronco, MD
Professor of Medicine and Head, Department of Nephrology, Dialysis and Transplantation, San Bortolo Hospital, Vicenza, Italy

Stanley H. Rosenbaum, MA, MD
Professor of Anesthesiology, Internal Medicine and Surgery, Yale University School of Medicine, New Haven, Connecticut

Steven Roth, MD
Associate Professor of Anesthesia and Critical Care, University of Chicago; Chief of Neuroanesthesia, University of Chicago Medical Center, Chicago, Illinois

David M. Rothenberg, MD, FCCM
The Max S. Sadove Professor of Anesthesiology and Associate Dean, Academic Affiliations of Rush Medical College, Rush University Medical Center, Chicago, Illinois

Marc A. Rozner, PhD, MD
Professor of Anesthesiology and Professor of Cardiology, The University of Texas MD Anderson Cancer Center; Adjunct Assistant Professor of Integrative Biology and Pharmacology, The University of Texas Health Science Center at Houston, Houston, Texas

Muhammad F. Sarwar, MD
Assistant Professor of Anesthesiology, SUNY Upstate Medical University, Syracuse, New York

Rebecca A. Schroeder, MD
Associate Professor, Department of Anesthesiology, Duke University Medical Center; Staff Anesthesiologist, Veterans Affairs Medical Center, Durham, North Carolina

Allan Jay Schwartz, MD, MSEd
Professor of Anesthesiology and Critical Care, University of Pennsylvania School of Medicine; Director of Education and Pediatric Anesthesiology Fellowship Director, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

Andrew Schwartz, MFA, BA
A. Schwartz Communications, Albany, California

Johanna C. Schwarzenberger, MD
Assistant Professor of Anesthesiology, Columbia University College of Physicians and Surgeons, New York, New York

Debra A. Schwinn, MD
Professor and Chair, Department of Anesthesiology, Adjunct Professor of Pharmacology and Genome Sciences, University of Washington, Seattle, Washington

Bruce E. Searles, BS, CCP
Associate Professor, Department of Cardiovascular Perfusion, College of Health Professions, SUNY Upstate Medical University, Syracuse, New York

Daniel I. Sessler, MD
Professor and Chair, Department of Outcomes Research, The Cleveland Clinic, Cleveland, Ohio

Christoph N. Seubert, MD, PhD
Associate Professor of Anesthesiology and Chief, Division of Neuroanesthesia, University of Florida College of Medicine; Director, Intraoperative Neurophysiologic Monitoring Laboratory, Shands Hospital, Gainesville, Florida

Steven L. Shafer, MD
Professor of Anesthesiology, Columbia University College of Physicians and Surgeons, New York, New York; Adjunct Professor of Anesthesia, Stanford University, Stanford, California; Adjunct Professor of Biopharmaceutical Science, University of California, San Francisco, San Francisco, California

Andrew Shaw, MB, FRCA, FCCM
Associate Professor, Division of Cardiothoracic Anesthesiology, Department of Anesthesiology and Critical Care Medicine, Duke University Medical Center, Durham, North Carolina

Koh Shingu, MD, PhD
Professor and Chair, Department of Anesthesiology, Kansai Medical University, Hirakata Hospital, Hirakata, Osaka, Japan

Frederick E. Sieber, MD
Associate Professor, Department of Anesthesia and Critical Care Medicine, Johns Hopkins University School of Medicine; Clinical Director and Attending Physician, Department of Anesthesia and Critical Care Medicine, Johns Hopkins Bayview Medical Center, Baltimore, Maryland

Sir Peter Simpson, MD, MBBS, FRCA, FRCP, FRCS(Hon), FCARCSI(Hon)
Immediate Past President, Royal College of Anaesthetists; Past President, European Society of Anaesthesiology; Consultant Anaesthetist (Ret.), Frenchay Hospital, Bristol, United Kingdom

Ashish C. Sinha, MD, PhD
Assistant Professor of Anesthesiology and Critical Care, and Assistant Professor of Otorhinolaryngology and Head and Neck Surgery, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania

Robert N. Sladen, MB, ChB, MRCP(UK), FRCP(C), FCCM
Professor and Vice Chair, Department of Anesthesiology, Columbia University College of Physicians and Surgeons; Director, Cardiothoracic and Surgical Intensive Care Units, Columbia University Medical Center at New York Presbyterian Hospital, New York, New York

Thomas F. Slaughter, MD
Professor, Department of Anesthesiology, Wake Forest University School of Medicine; Head, Section of Cardiothoracic Anesthesiology, Department of Anesthesiology, Wake Forest University Health Sciences, Winston-Salem, North Carolina

Peter D. Slinger, MD, FRCP(C)
Professor, Department of Anaesthesia, University of Toronto; Staff Anesthesiologist, Toronto General Hospital, Toronto, Ontario, Canada

Michael J. Souter, MB, ChB, FRCA
Associate Professor of Anesthesiology and Neurological Surgery, University of Washington School of Medicine; Attending Physician, Anesthesiology and Critical Care, Harborview Medical Center; Medical Co-Director, Neurocritical Care Service, Harborview Medical Center, Seattle, Washington

Mark Stafford-Smith, MD, CM, FRCP(C), FASE
Professor of Anesthesiology, Duke University School of Medicine; Director, Fellowship Education, and Director, Cardiothoracic Anesthesia and Critical Care Fellowship, Duke University Medical Center, Durham, North Carolina

Donald R. Stanski, MD
Emeritus Professor of Anesthesia, Stanford University School of Medicine, Stanford, California; Scientific Advisor to the Director, Center for Drug Evaluation and Research, Food and Drug Administration, Washington, DC

Christoph Stein, MD
Professor and Chair, Department of Anesthesiology and Critical Care Medicine, Freie Universität Berlin, Charité Campus Benjamin Franklin, Berlin, Germany

Paul E. Stensrud, MD
Assistant Professor of Anesthesiology, Mayo Clinic College of Medicine; Consultant in Anesthesiology, Mayo Clinic, Rochester, Minnesota

Gary R. Strichartz, BS, AM (Hon), PhD, FRSM
Professor of Anaesthesia, Pharmacology and Biophysics, Harvard Medical School; Vice-Chairman for Research, Department of Anesthesiology, Perioperative and Pain Medicine, and Director, Pain Research Center, Brigham and Women's Hospital, Boston, Massachusetts

Jan Stygall, MSc
Senior Research Fellow and Health Psychology Unit Research Coordinator, Centre for Behavioural and Social Sciences in Medicine, University College London, London, United Kingdom

Vijayendra Sudheendra, MD
Assistant Professor of Surgery and Anesthesiology, Brown University School of Medicine; Director of Cardiac Anesthesia, Miriam Hospital, Providence, Rhode Island; Medical Director, Southern New England Surgery Center, Attleboro, Massachusetts

Lena S. Sun, MD
Professor of Anesthesiology and Pediatrics, Columbia University College of Physicians and Surgeons; Chief of Pediatric Anesthesia, Columbia University Medical Center, New York, New York

BobbieJean Sweitzer, MD
Associate Professor of Anesthesia and Critical Care, University of Chicago; Director of Anesthesia, Perioperative Medicine Clinic, University of Chicago, Chicago, Illinois

James Szocik, MD
Associate Professor, Department of Anesthesiology, University of Michigan Medical School, Ann Arbor, Michigan

Deepak K. Tempe, MBBS, MD
Professor and Head, Department of Anesthesiology and Intensive Care, G.B. Pant Hospital, University of Delhi, New Delhi, India

Kevin K. Tremper, PhD, MD
Robert B. Sweet Professor of Anesthesiology, University of Michigan Medical School; Chair, Department of Anesthesiology, University of Michigan Medical Center, Ann Arbor, Michigan

Kenneth J. Tuman, MD, FCCM
The Anthony D. Ivankovich Professor of Anesthesiology, Rush Medical College; Chair, Department of Anesthesiology, Rush University Medical Center, Chicago, Illinois

Michael K. Urban, MD, PhD
Associate Professor of Clinical Anesthesia, Weill Medical College of Cornell University; Director, Post-Anesthesia Care Unit, Hospital for Special Surgery, New York, New York

Gail A. Van Norman, MD
Clinical Associate Professor, Department of Anesthesiology, University of Washington; Faculty Associate, Department of Biomedical Ethics, University of Washington, Seattle, Washington

Daniel P. Vezina, MD, MSc, FRCPC
Associate Professor, Department of Anesthesiology, and Associate Professor, Division of Cardiology, Department of Medicine, University of Utah; Director, Echocardiography Laboratory, Department of Anesthesiology, Veterans Administration Hospital, Salt Lake City, Utah

Jørgen Viby-Mogensen, MD, DMSc, FRCA
Professor and Chair, Department of Anesthesia and Intensive Care, Copenhagen University Hospital, Rigshospitalet, Copenhagen, Denmark

David B. Waisel, MD
Associate Professor of Anaesthesia, Harvard Medical School; Senior Associate in Anesthesia, Department of Anesthesiology, Perioperative and Pain Medicine, Children's Hospital Boston, Boston, Massachusetts

David C. Warltier, MD, PhD
Chairman, Department of Anesthesiology, and Professor of Anesthesiology, Pharmacology and Toxicology, Medical College of Wisconsin; Anesthesiologist, Froedtert Memorial Lutheran Hospital; Professor of Biomedical Engineering, Marquette University, Milwaukee, Wisconsin

Denise J. Wedel, MD
Professor, Department of Anesthesiology, Mayo Clinic College of Medicine, Rochester, Minnesota

Charles Weissman, MD
Professor and Chair, Department of Anesthesiology and Critical Care Medicine, Hebrew University Hadassah School of Medicine, Jerusalem, Israel

Paul F. White, PhD, MD, FANZCA
Professor and Holder of the Margaret Milam McDermott Distinguished Chair in Anesthesiology, Department of Anesthesiology and Pain Management, University of Texas Southwestern Medical Center, Dallas, Texas; Visiting Scientist, Department of Anesthesia, Cedars Sinai Medical Center, Los Angeles, California; President, White Mountain Institute, Dallas, Texas

Roger D. White, MD
Assistant Professor, Department of Anesthesiology, Mayo Clinic College of Medicine, Rochester, Minnesota

Jeanine P. Wiener-Kronish, MD
Henry Isaiah Dorr Professor of Research and Teaching in Anaesthetics and Anaesthesia, Harvard Medical School; Anesthetist-in-Chief, Massachusetts General Hospital, Boston, Massachusetts

Christopher L. Wu, MD
Associate Professor, Department of Anesthesia and Critical Care Medicine, The Johns Hopkins University, Baltimore, Maryland

Michiaki Yamakage, MD, PhD
Assistant Professor, Department of Anesthesiology, Sapporo Medical University School of Medicine, Sapporo, Hokkaido, Japan

C. Spencer Yost, MD
Professor, Department of Anesthesia and Perioperative Care, University of California, San Francisco, School of Medicine; Medical Director, Mt. Zion Hospital Intensive Care Unit, San Francisco, California

William L. Young, MD
James P. Livingston Professor and Vice Chair, Department of Anesthesia and Perioperative Care; Professor of Neurological Surgery and Neurology; Director, UCSF Center for Cerebrovascular Research, University of California, San Francisco, School of Medicine, San Francisco, California

Chun-Su Yuan, MD, PhD
Cyrus Tang Professor, Department of Anesthesia and Critical Care, University of Chicago, Pritzker School of Medicine, Chicago, Illinois

Warren M. Zapol, MD
Reginald Jenneg Professor of Anaesthesia, Harvard Medical School; Director, Anesthesia Center for Critical Care Research, Massachusetts General Hospital, Boston, Massachusetts

Jie Zhou, MD, MBA, MS
Instructor in Anaesthesia, Harvard Medical School; Attending Anesthesiologist, Department of Anesthesiology, Perioperative and Pain Medicine, Brigham and Women's Hospital; Consulting Staff, Department of Surgery, Dana-Farber Cancer Institute, Boston, Massachusetts

Maurice S. Zwass, MD
Professor of Anesthesia and Pediatrics, and Associate Director, Pediatric Critical Care Medicine, University of California, San Francisco, School of Medicine, San Francisco, California

Preface to the Seventh Edition

For over 25 years, *Miller's Anesthesia* has been recognized as the most complete and thorough resource on the global scope and practice of contemporary anesthesiology. The seventh edition continues that tradition and represents the most extensive revision we have ever undertaken. These advances include 13 new chapters, more than 30 new authors, and 1500 full-color illustrations. All existing chapters were meticulously revised and updated. The extensive scope of the revision was greatly facilitated by a team of expert and dedicated associate editors: Lee A. Fleisher, MD, Professor and Chair of the Department of Anesthesiology and Critical Care at the University of Pennsylvania; Jeanine P. Wiener-Kronish, MD, Anesthetist-in-Chief, Massachusetts General Hospital and Professor of Anaesthesia at the Harvard Medical School; William L. Young, MD, Professor and Vice Chair of the Department of Anesthesia and Perioperative Care, University of California, San Francisco; and Lars I. Eriksson, MD, PhD, Professor and Academic Chair of Anesthesiology and Intensive Care Medicine at the Karolinska University Hospital in Stockholm.

The 13 new chapters were added in response to an intense analysis of the changes in the scope of anesthesiology. The increasing importance of critical care medicine dictated five separate chapters on nitric oxide, clinical critical care protocols, neurocritical care, renal replacement therapy in the critically ill patient, and prehospital emergency and trauma care, which complements the existing chapter on anesthesia for trauma. The entire state of anesthesia for surgery and other procedures is being examined in more depth in two new chapters on sleep, memory, and consciousness, and perioperative cognitive dysfunction and other long-term implications of anesthetics, the implications being that general anesthesia may have impact long after its administration has been completed. Some rapidly evolving and important subjects in anesthesia are detailed in new chapters on anesthesia for correction of cardiac arrhythmias and anesthesia for bariatric surgery, given that obesity is a major health care issue in many areas of the world, particularly in the United States. The multiple opportunities to interfere with or correct abnormalities in coagulation dictated a separate chapter.

Ultrasound guidance has become a standard of care in the modern practice of regional anesthesia; thus, a dedicated chapter focused on the technique of ultrasound-guided regional anesthesia was clearly warranted. The philosophic question is whether non-ultrasound-guided techniques should continue to be taught, given that many clinicians practice in countries and regions that cannot afford ultrasound technology. Likewise, information technology has become increasingly dominant in medicine as a whole, but especially in anesthesia, necessitating a focused analysis in a dedicated chapter. An ever-growing number of medical centers rely on paperless communication and record keeping, including the anesthetic record. Information technology also allows formation of databases, which can answer important questions related to the institution or individual health care delivery. Chapter 2, entitled Scope of Modern Anesthetic Practice, covers the scope of anesthesia as we know it now with use of modern technology. Lastly, *Miller's Anesthesia* now incorporates the scope and historical development of anesthesia practice in many areas of the world. In Chapter 3, entitled The International Scope and Practice of Anesthesia, the individual contributions from numerous leaders of anesthesia worldwide were compiled into a synopsis of international anesthesia from its origin to the present. Further attesting to the book's global perspective, *Miller's Anesthesia* features contributions from anesthesiologists from all over the world, with 45 contributors to this new edition practicing outside of North America.

Each 2-volume set of the 7th edition of *Miller's Anesthesia* is now accompanied by access to a dedicated *Expert Consult website*, either basic or premium edition. The *basic edition* includes complete, fully searchable online text. The *premium edition* includes all of the above plus additional high-value features such as regular content updates, references linked to Medline abstracts and full-text articles, downloadable image library, drug database, self-assessment questions, and, most importantly, an extensive video library featuring full-length video presentations of anesthesia procedures including airway and ultrasound-guided regional anesthesia techniques.

We wish to acknowledge the long-time participation of Roger A. Johns, MD, and John J. Savarese, MD, who served as consulting editors on the previous edition. We are grateful for the tireless help of Tula Gourdin, who managed all communication with contributors and the publisher, facilitated the flow of manuscripts and page proofs, and checked every detail to make sure the chapters are as accurate and consistent as possible. We also wish to acknowledge our publisher, Elsevier, and the help and dedication of their staff, in particular executive publisher Natasha Andjelkovic, senior developmental editor Heather Krehling, and project manager Fran Gunning.

Ronald D. Miller, MD

Merlin D. Larson

1 History of Anesthetic Practice

Key Points

1. Methods to safely alleviate severe pain are relatively recent discoveries, as viewed within the time span of human history.
2. The public demonstration of ether anesthesia on October 16, 1846, ranks as one of the most significant events in the history of medicine.
3. No single individual can be said to have discovered anesthesia.
4. The specialty of anesthesia rests on discoveries made from several scientific disciplines.
5. Major discoveries were often made by small groups of curious individuals with diverse backgrounds.
6. Techniques in common use at any one time often seem dangerous to subsequent generations of anesthesiologists.
7. Major innovations were sometimes ignored until their rediscovery several decades later.
8. Developments in anesthesia often arose to meet the needs of patients with severe comorbid conditions that required complex surgical procedures. Consequently, advances within the specialties of surgery and anesthesia are closely integrated.

The first anesthetics were given to ameliorate the pain associated with dental extractions and minor surgery. As the complementary fields of surgery and anesthesiology matured together, new skills were required of the anesthesiologist, including expertise in resuscitation, fluid replacement, airway management, oxygen transport, operative stress reduction, and postoperative pain control. Today, personnel from the anesthesiology department are located throughout the hospital, ranging from the ambulatory care center to the intensive care unit. Organizing a coherent historical document is therefore complicated by the diverse roles of anesthesiologists, in the modern hospital, especially in perioperative medicine.

One approach to the history of anesthesiology is to relate in detail the events surrounding the 1846 public demonstration of ether anesthesia by William T. G. Morton (1819-1868).[1,2] This event represents the starting point from which anesthesiology emerged as a specialty. Although the ether demonstration was dramatic and enacted by interesting personalities, it was just the opening act of the pain control story. Since 1846, there has been enormous progress and change in the specialty of medicine that has become known as anesthesiology, and these changes have often occurred in small, incremental steps that are hardly noteworthy on their own. Most operations in the modern operating room could not have been performed before the great progress in anesthetic practice that took place in the years between 1925 and 1960, but historians often overlook these advances because they were introduced without the drama and spectacle of previous developments.

In addition to examining the advancements of the 20th century, the mid-19th century provided the groundwork laid by inquisitive individuals who sought scientific understanding of cardiopulmonary physiology and pain. These fundamental discoveries provide the physiologic foundation for safe anesthetic practice. A brief survey of these early developments is provided in the opening sections of this chapter. Dentists, priests, musicians, pediatricians, engineers, ophthalmologists, neurophysiologists, pharmacologists, urologists, otolaryngologists, surgeons, ministers, dilettantes, philosophers, physiologists, missionaries, chemists, South American Indians, and anesthesiologists all had a role in shaping the practice of contemporary anesthesiology, one of the most fascinating stories in the history of medicine.

I have attempted to describe and reference the origins of ideas related to modern anesthetic practice, but the issue of priority is vague on some topics and may be open to question by other historians of specific subjects.

Cardiopulmonary Physiology

Respiration

Although volatile anesthetics have changed over the past 150 years, there are two gases that will always be part of anesthetic practice. How oxygen and carbon dioxide are consumed and produced and how they interact with the body have been the subject of intense research over the past 400 years. The ability to manipulate the pressure of these gases in tissues has contributed a great deal to the success of intensive care medicine. Because of the importance that carbon dioxide and oxygen have in the practice of anesthesiology, it is worthwhile to consider how our understanding of respiration came about.

Aristotle (384-322 BC) and Galen (120-200 AD) both thought that the air moving in and out of the lungs served merely to cool the heart, which otherwise became overheated in working to sustain life.[3] In 1678, Robert Hook (1635-1703) attached a bellows to the trachea of a dog with an open chest and demonstrated that the animal could be kept alive by rhythmic and sustained contraction of the bellows. Hook proved that movement of the chest wall was not the essential feature of respiration but instead it was exposure of fresh air to blood circulating through the lungs.[4] Richard Lower (1631-1691), who was the first to transfuse blood from one animal to another, demonstrated in 1669 that blood absorbed a definite chemical substance necessary for life that changed venous blood from dark blue to red and that the process was the chief function of the pulmonary circulation.[5]

Joseph Priestley (1733-1804) (Fig. 1-1A), a complex individual who was a dissenting minister in Leeds, England, and later the "resident intellectual" to the Earl of Shelburne, observed that respiration and combustion had many similarities[6] in that a candle flame would go out and an animal would die if left within a closed space. He thought this effect occurred because the air was putrefied with phlogiston. Priestley discovered photosynthesis by showing that placing plants that imbibed the "phlogistic matter" within the contained space could restore this "bad air." By heating mercuric oxide, he generated a gas that would make flames brighter and keep mice alive longer in a closed space. Priestley called it *dephlogisicated* air, and Carl Scheele[7] (1742-1786) in Sweden, who detected it earlier but failed to publish, called it *feuer luft* ("fire air"). Priestley thought that this process absorbed phlogiston and informed the French chemist Antoine-Laurent Lavoisier (1743-1794) (Fig. 1-1B) of his discovery. Lavoisier then outlined the great facts of respiration: absorption of oxygen through the lungs with liberation of carbon dioxide.

Lavoisier thought that the change from oxygen to carbon dioxide was accomplished in the lungs, but Humphry Davy (1778-1829) (Fig. 1-1C), an English teenager who dropped out of school at the age of 16 years, read the works of Lavoisier and designed his own experiments to study the site of metabolism. Davy heated blood and collected the gases that were produced. By showing that these gases were oxygen and carbon dioxide, he surmised that metabolism takes place in tissues.[8] Davy also estimated rates of oxygen consumption and carbon dioxide production and measured the total and residual volumes

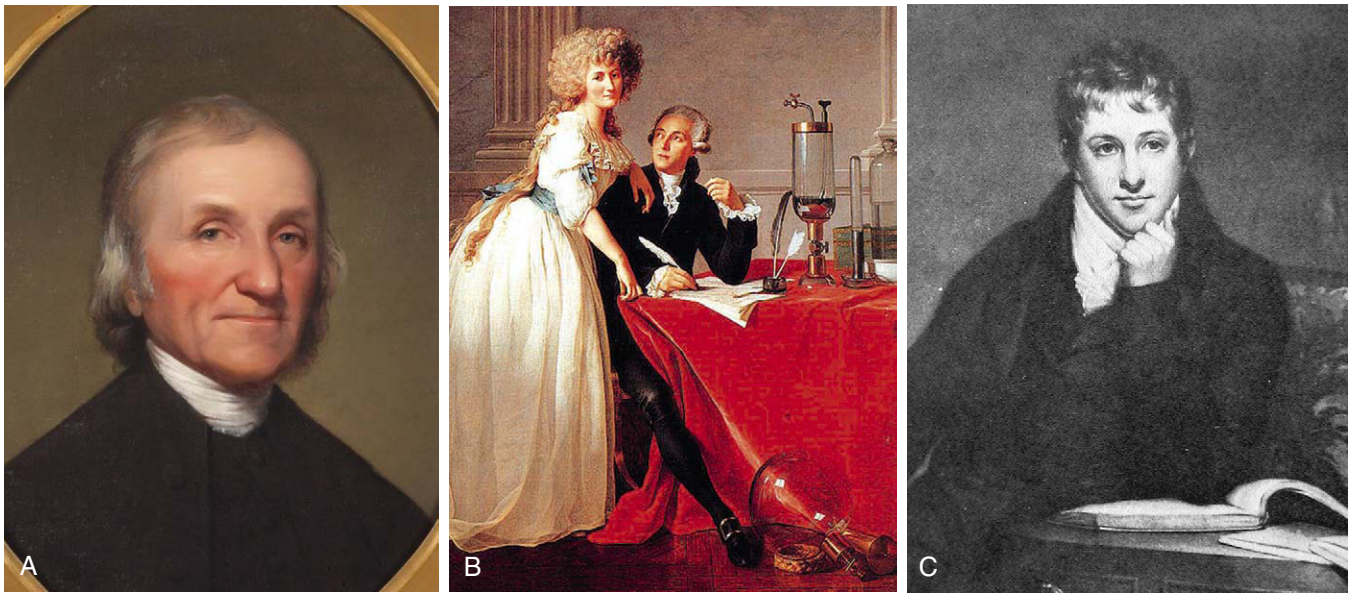

Figure 1-1 A, Joseph Priestley was born in Fieldhead, England, and educated as a minister. His early career was spent as a schoolmaster in Leeds, England. In 1780 he accepted an appointment in Birmingham as minister, where he joined Erasmus Darwin and James Watt in forming the Lunar Society, which met to discuss the new ideas in chemistry and physics emerging at that time. Because of his political views, his chapel and home were vandalized in 1789. Five years later, he joined his sons in Pennsylvania in the United States, where he died in 1804 at the age of 70. **B,** This portrait of Lavoisier and his wife Marie Anne Pierrette Paulz was painted in 1788 by the famous French artist Jacques Louis David. Marie Paulz, who married Lavoisier when she was only 14 years old, was taught to draw by David, and she drew many of the illustrations in Lavoisier's magnum opus *Traite Elementaire de Chimie*. Several experimental devices and gasometers are shown on and below the table. **C,** Humphry Davy was born in Cornwall, England, and became apprenticed to a surgeon, J. B. Borlase of Penzance, at age 17. At 20 years of age he was appointed superintendent of the Beddoe's Pneumatic Institute, where he studied the effects of nitrous oxide inhalation. His later career in chemistry gained him fame and honors. He directed the Royal Institute and was made a baronet in 1818 at the age of 40. *(Courtesy of the Wood Library-Museum of Anesthesiology, Park Ridge, IL.)*

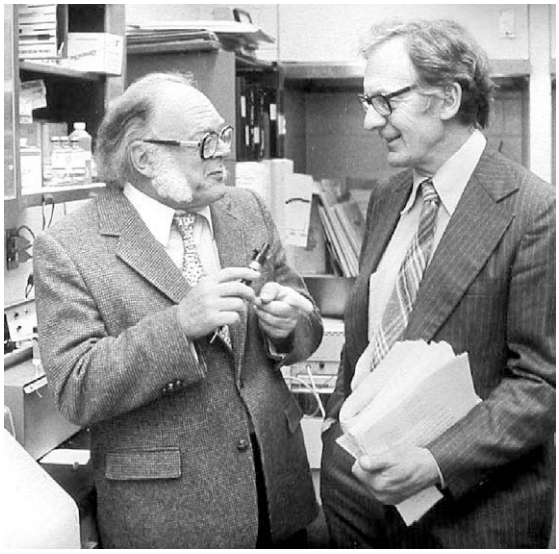

Figure 1-2 This photograph of Leland Clark and John Severinghaus, whose contributions led to modern techniques of blood gas analysis, was taken in Clark's laboratory at the Cincinnati Children's Hospital in 1982. *(From Severinghaus JW, Astrup PB: History of blood gas analysis. Int Anesthesiol Clin 25:1-224, 1987.)*

of the lungs. John S. Haldane (1860-1936) was a pioneer investigator in the study of respiration a century ago. His apparatus for measurement of blood gases was described in 1892.[9] He was the first to promote oxygen therapy for respiratory disease,[10] and in 1905 he discovered that the carbon dioxide tension of blood was the normal stimulus for the respiratory drive.[11] Haldane experimented with self-administration of hypoxic mixtures and coined the ominous phrase that lurks within the inner recesses of the anesthesiologist's mind: "Anoxemia not only stops the machine but wrecks the machinery." He believed until his death, despite experimental evidence, that the lung actively secreted oxygen into the blood from the air. His landmark monograph *Respiration*, published in 1922,[12] summarized his studies on the respiratory system.

At the end of the 19th century it was known that hemoglobin had a vital role in the transport of oxygen to tissues. In 1896, Carl Gustav von Hufner (1840-1908) showed that the presence of hemoglobin in blood greatly enhanced its oxygen-carrying capacity and quantified that 1 g of hemoglobin carried 1.34 mL of oxygen.[13] It was soon observed that delivery of high concentrations of oxygen to patients with advanced pulmonary disease was often inadequate to fully maintain tissue respiration and saturate hemoglobin completely. Gradients for inspired, alveolar, and arterial oxygen partial pressures became apparent after development of the oxygen electrode by Leland C. Clark[14] (1918-) (Fig. 1-2) in 1953. The Clark electrode consisted of a platinum cathode and a silver anode separated from blood by a polyethylene membrane. The platinum was negatively charged to react with any oxygen reaching it through the membrane and was sensitive to the oxygen pressure outside the membrane (i.e., the oxygen tension in blood).

Further understanding of respiratory physiology arose because of the worldwide polio epidemic that occurred roughly between the years of 1930 and 1960. Thousands of afflicted patients were kept alive with mechanical respirators, but the adequacy of ventilation could not be assessed without some measure of carbon dioxide tension (P_{CO_2}) in the blood. Several methods to measure P_{CO_2} indirectly were made by Donald D. Van Slyke[15] (1883-1971) and Paul B. Astrup (1915-2000), but the modern solution rested on development of the carbon dioxide electrode. This problem was solved in 1958, when John W. Severinghaus (1922-) (see Fig. 1-2) improved the accuracy of a prototype carbon dioxide electrode produced by Richard Stow (1916-) that measured the pH of a thin film of electrolyte separated from blood by a Teflon membrane through which carbon dioxide could diffuse and equilibrate. Severinghaus and A. F. Bradley[16] (1932-) constructed the first blood gas apparatus by mounting the carbon dioxide electrode and Clark's oxygen electrode in cuvettes in a bath heated to 37°C. To measure blood P_{O_2} accurately, Severinghaus found it necessary to rapidly stir the blood in contact with Clark's electrode because of its high oxygen consumption rate. A pH electrode was added in 1959. Blood gas analysis made possible rapid assessment of respiratory exchange and acid-base balance. The use of blood gas analysis was rapidly adopted by the anesthesia community and has become one of the most common laboratory tests performed in the modern hospital. The impact of a more in-depth understanding of gas exchange on the practice of anesthesia is summarized by John Nunn in his book *Applied Respiratory Physiology*.[17]

Until the mid-20th century, hemoglobin saturation could be determined only by directly measuring a sample of arterial blood, a technique that required arterial puncture. Oximetry achieves the same measure noninvasively through a finger or ear probe by using optical measures of transmitted light. Glenn Millikan (1906-1947), working in the Johnson Foundation for Medical Physics at the University of Pennsylvania, devised the first ear oximeter in 1942, and it was used to detect hypoxia in pilots, who flew in open cockpits during World War II. Its introduction into anesthesia practice was delayed until the discovery of pulse oximetry by a Japanese engineer, Takuo Aoyagi (1936-).[18] Pulse oximetry added the additional measure of heart rate, and it provided assurance that the signal was actually measuring a biologic parameter. A highly successful commercial product, the Nellcor pulse oximeter was introduced in 1983 and had the unique feature of lowering the pitch of the pulse tone as saturation dropped.

Intravascular Pressures

The first measurement of blood pressure was made by Stephen Hales (1677-1761) (Fig. 1-3A), the curate of Middlesex, England, who occupied himself between sermons with experiments on mechanics of the circulation. He described one of his experiments[19] performed (1733) on an "old mare who was to be killed, as being unfit for service":

> *I fixed a brass pipe to the carotid artery of a mare . . . the blood rose in the tube till it reached to nine feet six inches in height. I then took away the tube from the artery and let out sixty cubic inches of blood, and then replaced the tube to see how high the blood would rise after each evacuation; this was repeated several times until the mare expired. In the three horses, death occurred when the height of the blood in the tube was about two feet.*

Hales also discovered that the resistance of a vascular bed could change by mixing alcohol in the blood, which he observed

Figure 1-3 Two scientists of the Enlightenment era. **A,** Stephen Hales (1677-1761): detail of an oil painting by T. Hudson, 1759, in the National Portrait Gallery, London. Hales was educated at Cambridge University, England, and ordained as a minister in 1703. He spent his career as minister to the parish of Teddington, England. His rudimentary studies on the gas produced by mixing Walton pyrites (i.e., ferric disulfide) and spirit of nitre (i.e., nitric acid) was the spark that prompted Priestley to pursue his studies on nitric oxide, which led to the discovery of nitrous oxide in 1773. Hales was the first to measure blood pressure and cardiac output. He also developed ventilators that brought fresh air into prisons and granaries. **B,** Albrecht von Haller (1708-1777): detail of an engraving by Ambroise Tardieu. Haller was born in Bern, Switzerland. He served as professor of medicine and surgery at the University of Göttingen, Germany, where he began his encyclopedic work, *Physiological Elements of the Human Body*, published in eight volumes between 1757 and 1766. His demonstration that "irritability" was a property of muscle and "sensitivity" was a property of nerves was derived from nearly 600 experiments on live animals. He returned to Bern in 1753, and while there he published a catalog of the scientific literature containing 52,000 references. *(Portraits courtesy of the National Library of Medicine, Bethesda, MD.)*

could account for changes in blood pressure brought about by diverse ingested agents. In 1828, Jean L. Poiseuille[20] (1799-1869) repeated these experiments and devised a hemomanometer that used mercury instead of the long blood-filled tubes used by Hales. Poiseuille also showed that blood pressure varied with respiration.

In 1854, Karl Vierordt[21] (1818-1884) invented a sphygmograph that acted on the principle that indirect estimation of blood pressure could be accomplished by measuring the counterpressure necessary to obliterate the arterial pulsation. Scipione Riva-Rocci's (1863-1937) sphygmomanometer, described in 1896,[22] involved the same principle but used a rubber cuff that occluded a major arterial vessel and then slowly deflated. In 1905, Nikolai Korotkov[23] (1874-1920) described the sounds produced during auscultation over a distal portion of the artery as the cuff was deflated. These Korotkoff sounds resulted in more accurate determination of systolic and diastolic blood pressure. Oscillometric blood pressure measurement relied on a cuff that sensed changes in arterial pulsations and was described by H. von Recklinghausen in 1931.[24] Automatic blood pressure devices based on the oscillometric method were developed in the 1970s and have become the standard noninvasive measure of arterial pressure in most hospitals.

Venous pressure was of less interest to anesthesiologists until convenient methods for placing cannulas into central vascular structures were described more than 50 years ago by Sven Seldinger.[25] Werner Forssman (1904-1979), a urologist, described methods for central venous access and right heart catheterization in humans in 1929[26]; he originally experimented on himself and was awarded the Nobel Prize in Physiology and Medicine for his work on venous pressure in 1956. The introduction of plastic catheters[27] gradually made it possible to measure central pressure in the clinical setting. Although arm and femoral veins were used initially, subclavian and internal jugular vein cannulation eventually replaced the peripheral sites. Pulmonary artery catheterization with a balloon-tipped, flow-directed catheter was described in 1970[28] and has been used extensively since then by anesthesiologists to measure pulmonary artery pressure and cardiac output via the Fick[29] (Adolf E. Fick—1829-1901) principle. The pulmonary artery catheter also allowed clinicians to use the well-known pressure-volume relationships of the heart described by Ernest H. Starling (1866-1927) in 1918 to maximize cardiac output and oxygen delivery to tissues.

Transesophageal echocardiography (TEE) was described in 1976[30] and used in anesthesia practice a few years later. One of the original probes used during anesthesia was fashioned from an esophageal stethoscope combined with an M-mode echocardiographic probe and was used to calculate cardiac output and ejection fraction in a 65-year-old woman undergoing mitral valve repair.[31] An improved electronic phased-array transducer was initially applied at the University of California, San Francisco, for monitoring regional myocardial function in high-risk surgical patients.[32] Biplane TEE and color flow mapping were introduced in the 1980s and resulted in an explosive growth in TEE applications.[33] With experience and training in TEE, the anesthesiologist can quickly evaluate filling pressures of the heart, as well as obtain measures of myocardial contractility and valvular function. TEE has become a routine monitor for certain surgical procedures.

Autonomic Nervous System and Neurohumoral Transmission

The first hint of involuntary control of glandular and vascular function occurred in the 18th century. In a classic paper written in 1751, Robert Whytt (1714-1766) described the reflex nature of many involuntary activities.[34] Thomas Willis[35] (1621-1675) had described the sympathetic chain as early as 1657. He called it the intercostal nerve because it received segmental branches from the spinal cord at each level.

Pourfour du Petit (1664-1741) observed that there was a corresponding miosis and retraction of the nictitating membrane when this "intercostal" nerve was unilaterally cut in the neck of a cat.[36] Jacob B. Winslow (1669-1760) gave the intercostal nerve the name grand sympathique to stress that this nerve brought the various organs of the body into sympathy,[37] a term that was originally coined by the Greek physician Soranus of Ephesus (98-138) in the first century AD (*sym*, "together," and *pathos*, "feeling"). Claude Bernard (1813-1878) observed vasoconstriction and pupillary dilation after stimulation of the same intercostal (now called the sympathetic) nerve and then described the vasomotor nerves arising between the cervical and lumbar enlargements of the spinal cord.[38]

In 1889, John N. Langley (1852-1925) began his work on sympathetic transmission in autonomic ganglia. He blocked synaptic transmission in the ganglia by painting them with nicotine and then mapped the distribution of the presynaptic and postsynaptic autonomic nerves.[39] He observed a similarity between the effects of injection of adrenal gland extracts and stimulation of the sympathetic nerves.[40] The active principle of adrenal medullary extracts was called epinephrine by John J. Abel[41] (1837-1938) in 1897. Abel was one of the first pharmacologists in the United States, and with his discovery of the hormone epinephrine, he uncovered one of the most commonly used lifesaving agents in the anesthesiologist's pharmacopoeia.

Thomas R. Elliott (1877-1961) postulated that sympathetic nerve impulses release a substance similar to epinephrine and considered this substance to be a chemical step in the process of neurotransmission.[42] George Barger (1878-1939) and Henry H. Dale (1875-1968) then studied the pharmacologic activity of a large series of synthetic amines related to epinephrine and called these drugs sympathomimetic.[43] The different effects on end organs produced by adrenal extracts and sympathetic stimulation were analyzed by Walter B. Cannon (1871-1945) and by Ulf Svante von Euler (1905-1983). In a series of papers, these authors demonstrated that the sympathetic nerves released norepinephrine, whereas the adrenal gland released both epinephrine and norepinephrine.

In 1907, Walter E. Dixon[44] (1871-1931) observed that the alkaloid muscarine had the same effect as stimulation of the vagus nerves on various end organs. He proposed that the nerve liberated a muscarine-like chemical that acted as a chemical mediator. In 1914, Henry H. Dale[45] investigated the pharmacologic properties of acetylcholine and was impressed that its effects reproduced the same effects as stimulation of the craniosacral fine myelinated fibers that Walter H. Gaskell[46] (1847-1914) had called the bulbosacral involuntary nerves and had by then been called parasympathetic by Langley.

The final proof of neurotransmission by acetylcholine was provided through the elegant experiments of Otto Loewi (1873-1961). He stimulated the neural innervation of the frog heart and then allowed the perfusion fluid to come in contact with a second isolated heart preparation.[47] The resulting bradycardia provided evidence that some substance was released from the donor nerves that slowed the heart rate of the second organ.[47] Loewi and Navrail presented evidence that this substance was acetylcholine, as Dale had suggested. Loewi and Dale were jointly awarded the Nobel Prize in 1936 for their work on chemical neurotransmission.

Theodore Tuffier (1857-1929) first demonstrated the relevance of the sympathetic nervous system to the practice of anesthesia in 1900. In a series of experiments on dogs, he demonstrated the sympatholysis that occurs after spinal anesthesia.[48] Further studies on the sympathectomy resulting from neuraxial blockade were performed by G. Smith and W. Porter in 1915.[49] Working with cats, they concluded that the decrease in arterial blood pressure was secondary to sympathetic paralysis of the vasomotor fibers in the splanchnic vessels. Gaston L. Labat[50] (1877-1934) encouraged the use of sympathetic stimulants such as ephedrine to counter the hypotensive effects of spinal anesthesia.

Reversal of neuromuscular blockade rests on a fundamental understanding of two types of cholinergic receptors, muscarinic and nicotinic, originally described in 1914 by Dale.[45] Neostigmine, synthesized in 1931,[51] when given alone during reversal of neuromuscular blockade had produced cardiac arrest in several instances before it was learned that previous administration of an antimuscarinic drug would prevent this complication.[52] Atropine, isolated from the plant *Atropa belladonna* by A. Mein[53] in 1831, blocked peripheral and central nervous system muscarinic receptors. Glycopyrrolate was synthesized in 1960 as an antimuscarinic agent that did not pass the blood-brain barrier.[54] Glycopyrrolate is more titratable, has fewer central nervous system side effects, and has gradually replaced atropine as the preferred anticholinergic during reversal of neuromuscular blockade.

Crucial to the control of arterial blood pressure and heart rate in the perioperative period was the realization that there was more than one type of adrenergic receptor. In 1948, Raymond P. Ahlquist (1914-1983) proposed the designations α- and β-adrenergic receptors,[55] and various subtypes of these two main classes have been characterized since then. Esmolol was introduced in 1985 as a short-acting β-adrenergic antagonist that effectively controls the heart rate during anesthesia. Labetalol, a unique agent introduced in 1976, antagonizes α- and β-adrenergic receptors. α_2-Adrenergic agonists such as clonidine and dexmedetomidine have been shown to be useful agents in certain clinical settings. The α_2-adrenergic agonist effects produce sedation and analgesia through a central effect and, because they do not induce respiratory depression, they may have some advantages over opioids as sedatives in awake subjects.[56]

Manipulation of blood pressure can be achieved rapidly by intravenous nitrates such as nitroglycerin and nitroprusside. These drugs act directly on smooth muscle to allow rapid and more precise control of hemodynamics. Nitroglycerin was synthesized in 1846 by the Italian chemist Ascanio Sobrero (1812-1888) by combining nitric acid and glycerol. The first practical use of the drug was made by Alfred Nobel (1833-1896), who mixed the agent with silica to make dynamite, a highly successful explosive used in building tunnels and canals. A portion of the

vast wealth of Nobel was directed by his will to be distributed annually in the form of Nobel Prizes beginning in 1901.[57,58] William Murrell[59] (1853-1912) reported the use of sublingual nitroglycerin in 1879 to treat angina. Intravenous use of the nitrovasodilators during anesthesia was not feasible until the development of continuous arterial monitoring, but for the past 30 years these drugs have been popular for rapid control of hypertensive crises in the operating room.[60] The mechanism of action of nitrates on smooth muscle, through the release of nitric oxide, was demonstrated by Ferid Murad (1936-) in 1986.[61] Nitric oxide, considered a toxic gas by Priestley who discovered it and by Humphry Davy who breathed it, has been shown to be a useful inhaled agent when used in a very low dose of 5 to 10 ppm in cases of life-threatening pulmonary hypertension.[62]

Historical Development of Theories of Pain

An understanding of the mechanism of pain production was not required by the physicians who developed the use of general anesthesia in the second half of the 19th century. Although inhalation of vapors produced a lack of awareness during surgery, anesthesiologists learned that control of perioperative nociception would require a more thorough understanding of pain. Fortunately, by the beginning of the 20th century, there was already a large body of knowledge on pain mechanisms dating from the earliest days of medical inquiry.

In antiquity, pain was thought to be an emotion rather than a sensory modality. Pain control was a function of religious authorities and shamans in primitive cultures, and relief of pain was sought through incantations and prayers. Pain was then often considered to be a punishment for committed sins or a form of religious suffering. The word *pain* is derived from the Greek term *poine* ("penalty"). Aristotle thought that pain was an emotion emanating from the heart, but Galen correctly observed that the brain was required for pain to be manifested in animals. Galen also proposed that sensation was a property of nervous tissue, but his physiologic system was altogether hampered by his idea that an invisible psychic pneuma traveled within hollow nerves.[3]

The 18th and 19th centuries witnessed considerable progress in understanding the mechanisms of pain. Albrecht von Haller[63] (1708-1777) (see Fig. 1-3B) observed that some tissues in the body have a property that he called sensibility: "I call those parts sensible, if the irritation occasions evident signs of pain and disquiet in the animal." Other tissues were insensible, which "if touched occasioned no sign of pain nor convulsion." Some tissues were irritable. "I call that part of the human body irritable, if it becomes shorter upon being touched." von Haller's landmark contribution in 1752[64] concluded that only parts of the body supplied with nerves possess sensibility, whereas irritability is a property of muscular fibers.

The idea of specific neural pathways for painful sensations began with Charles Bell[65] (1774-1842) and François Magendie[66] (1783-1855), who both demonstrated that the dorsal roots transmitted sensory information and that the ventral roots contained the motor nerves. Johannes Müller (1801-1858), in his 1826 paper titled "Of the Peculiar Properties of Individual Nerves," proposed that each sense organ gave rise to its own characteristic sensation and to no other; electrical or mechanical stimulation of the optic nerve, for example, gives rise to only a sensation of light.[67] The evidence that pain was a separate and distinct sense with separate end organs was formulated in 1858 by Moritz S. Schiff (1823-1896).

By the end of the 19th century, the idea was firmly established that acute pain was a distinct sensory modality that was susceptible to interruption through a conduction block initiated with local anesthetics. Pain as a separate sensation that was transmitted through separate neural fiber tracts was supported by clinical observations after neural blockade. Several investigators found, for example, that acute pain could be abolished with cocaine injections, which left some sensory modalities unaffected.[68]

There is evidence that operations undertaken on the battlefield may be associated with less pain than occurs with similar elective operations performed without anesthesia. The amputation of Lord Horatio Nelson's right arm in the battle at Tenerife, Canary Islands, was performed aboard ship after he sustained a musket shot above the elbow that divided the artery and shattered the humerus. Nelson complained only that the knife felt cold and thereafter ordered that all knives on board be heated before entering into conflict because his personal experience had indicated that a warm knife would produce almost no discomfort.[69] Henry Beecher[70] (1904-1976) confirmed during World War II that wounded soldiers had surprisingly little pain.

To further explain some of these central influences on nociception, Ronald Melzack (1929-) and P. D. Wall proposed the gate control theory of pain in 1965.[71] This theory suggested that the nociceptive afferent pain fibers were subjected to the modulating influence of a "gate" at the first synaptic contact in the spinal cord. Whereas large-fiber input tends to close the gate (i.e., inhibit nociceptive transmission), small-fiber input opens it, and descending influences from the cortex and midbrain[72] also profoundly influence the gate. Endogenous opioids, first discovered in 1974 by A. Goldstein[73] and later confirmed by J. Hughes[74] in 1975 and S. H. Snyder and coworkers[75] in 1977, are located at diverse sites in the pain pathway, including the dorsal horn, and they can influence the rostral transmission of pain sensations. Several modalities of pain therapy, such as acupuncture and biofeedback, attempt to activate these endogenous systems to suppress chronic pain syndromes.

The gate theory of pain has had considerable influence on the anesthesiologist's management of pain by focusing attention on the unique pharmacology of the dorsal horn of the spinal cord. By using intrathecal and epidural injections,[76] anesthesiologists have learned to suppress nociceptive transmission at the first synaptic relay in the spinal cord. The technique has implications in acute and chronic pain therapy because neuraxially administered drugs can provide analgesia without some of the systemic side effects of intravenously administered drugs. A typically modern view of perioperative pain is to view it as an impediment to recovery. Aggressive methods are often used to minimize pain and facilitate rapid return to normal functional activity.[77]

Surgical Procedures Before 1846

Greek and Roman surgeons used a variety of surgical instruments that we would recognize today. Drills, saws, syringes, cannulas, probes, and scalpels can all be viewed in the excavations at Her-

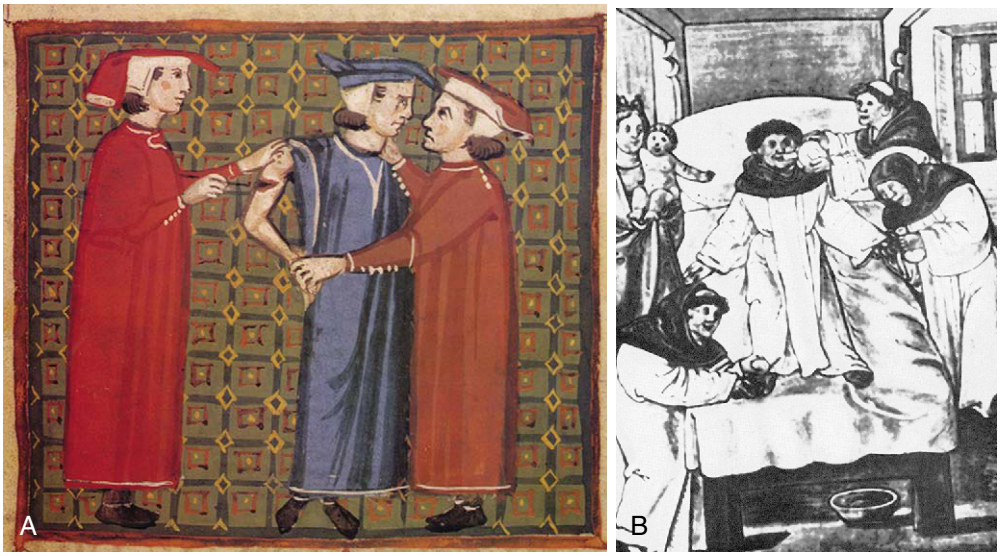

Figure 1-4 A, "Operating on the Upper Arm" is taken from the textbook titled *Chirurgia* by Theodoric of Cervia. It is noteworthy because it shows an intense focus by the patient directly into the gaze of an assistant. Although hypnosis is a 19th century term and its use for pain relief during surgery was not widely promoted until then, induction of trances and altered states of being was known to the ancients. Theodoric apparently realized the value of diverting the patient's attention away from the pain of surgery. **B,** Inhalation of the vapor of alcohol was tried in the Middle Ages as a method for pain relief during surgery. The inhaler shown here is remarkably similar to that used by William T. G. Morton on October 16, 1846, which used ether as the volatile agent (compare with Fig. 1-6).

culaneum, Pompeii, and Rheims. Hippocrates (460-377 BC) wrote a treatise on surgery, but it provided little sympathy for the patient. His advice to the patient was "to accommodate the operator . . . and maintain the figure and position of the part operated on . . . and avoid sinking down, and shrinking from or turning away."[78] The most famous Roman surgeon was Pedanius Dioscorides (40-90 AD), a Greek physician who served in the armies of Nero. His *Materia Medica*, written in 77 AD, was the authoritative work on pharmacology for more than 15 centuries. In this book he described the effects of mandragora and wine to produce "anesthesia" in a patient being cut or cauterized. He also described local anesthesia produced by the "stone of Memphis," which "being cut small, and smeared upon the places to be cut or cauterized, produces anesthesia without danger."[3]

During the Middle Ages, attempts were made to use alcohol fumes as an analgesic during surgery (Fig. 1-4B). Another inhaled technique, the soporific sponge, is mentioned in numerous manuscripts written in the Middle Ages. One example[3] from the 9th century comes from a Benedictine monastery at Monte Cassino, near Salerno, Italy:

> *A hypnotic aid, that is a soporific suitable for those who are treated by surgery, so that asleep, they do not feel the pain of cutting. Rx: opium one half ounce, mandragora the juice from the leaves, eight ounces, the juice of fresh hemlock, hyposcyanus three ounces of the juice together with sufficient water so that it forms a liquor, and then absorb in a fresh dry sponge and dry it carefully. And when thou wouldst employ this sponge, dip it in warm water, place it over the nose and cause the patient to breathe deep until he sleeps. And when thou wouldst wake him up, apply to his nose another sponge well soaked with vinegar and thou willst end the sleep.*

The sponge used by Theodoric of Cervia (1205-1296), a member of the Dominican order who practiced in Bologna, contained the same ingredients as the Salernitan sponge.

The effective agents in this sponge were very likely opium and scopolamine.[3] Theodoric was one of the first surgeons to promote methods to ablate pain during surgery (see Fig. 1-4A). One of the great physicians of the Renaissance, Theophrastus Bombastus von Hohenheim, otherwise known as Paracelsus (1493-1541), was familiar with the soporific action of sulfuric ether, a compound that had been synthesized from sulfuric acid and alcohol by the chemist Valerius Cordus (1515-1544). Cordus called the flammable, volatile liquid "sweet vitriol," and in 1740, Frobenius named it ether (from the Greek word for "ignite" or "blaze"). Paracelsus described the effect of ether on chickens and stated that it "quiets all suffering without harm, and relieves all pain." Although he was appointed "surgeon to the Danish army" when they besieged Stockholm in 1518, he had little interest in surgery, and these ideas were not developed clinically.

The suffering associated with surgery is found by examining accounts written by patients who survived major surgical procedures before that time. One comes from Fanny Burney[79] (1752-1840), a novelist and celebrity of the early part of the 19th century. Here is an abbreviated account of her mastectomy for breast cancer by the surgeon Dominique J. Larrey (1766-1842), the celebrated military surgeon in Napoleon's army, on September 30, 1811:

> *I mounted the bed and a cambric handkerchief was placed upon my face. The bed was then surrounded by 7 men and my nurse. Through the cambric I saw the glitter of the polished steel knife. A silence ensued. . . . Oh what a horrible suspension! . . . When the dreadful steel was plunged into the breast, I needed no*

injunctions not to restrain my cries. I began a scream that lasted unintermittently during the whole time of the incision and I almost marvel that it rings not in my ears still, so excruciating was the agony.

Although Fanny Burney lived for another 29 years after this operation, she observed that anything that would recall the surgery to her mind would reactivate the terror of the horrible experience. Apparently, operations performed without anesthesia produced long-lasting emotional and painful side effects. A modern interpretation of this phenomenon could conclude that these patients lacked any form of "preemptive analgesia"[80] and that they therefore experienced lingering side effects after their surgical wounds had healed.

Even though thousands of patients experienced the terror of an operation, countless others suffered with chronic ailments because the risk associated with surgery was too high or because they feared death or severe pain during the operation. For example, even after the introduction of anesthesia in 1846, textbooks on the treatment of hernia continued to have extensive descriptions of hernia belts and trusses.[81]

Introduction of General Anesthesia

Background

Although surgical technique was in development, the patient presented a problem to the surgeon, chiefly because of active physical resistance and because the cries and screams were distracting and often left the patient emotionally and physically exhausted. These factors, combined with the inevitable sepsis, resulted in high mortality rates. No wonder that by the middle of the 19th century there was greater determination by some surgeons to devise ways of improving operating conditions so that these appalling surgical mortality figures could be decreased, which in some reports reached nearly 50%. Bold approaches and risks were required, and these factors came together in Boston, Massachusetts, on October 16, 1846, when William T. G. Morton demonstrated the use of ether inhalation for surgical anesthesia.

Gas Inhalation

As a result of the growing scientific interest in various types of "airs," popular medical treatments involving gas inhalation evolved. Health resorts were popular attractions and financially successful because of their use by prominent members of society. One important "pneumatic" spa was located at Clifton, near Bristol, England, where Thomas Beddoes[82] (1760-1808) furnished airs for therapeutic use and funded research on the manufacture and use of gases. Nitrous oxide, a gas codiscovered by Priestley and Joseph Black, was by then considered to be a dangerous gas after a pronouncement by the influential American physician and U.S. Senator Samuel Latham Mitchill (1764-1831) that the gas was the "principle of contagion" and if breathed would "spread plague." The young scientist Humphry Davy conducted research on nitrous oxide at the Beddoes institute and, undaunted by these pronouncements, made several important observations. He inhaled nitrous oxide and noticed that it provided relief from the pain caused by an erupting wisdom tooth. In 1800 he wrote: "As nitrous oxide in its extensive operation appears capable of destroying physical pain, it may probably be used with advantage during surgical operations in which no great effusion of blood takes place."[83]

Davy was not a surgeon, and clinicians overlooked his suggestion at the time. He resigned his position at the Beddoes Medical Pneumatic Institute in 1801 and moved to London to lecture at the newly founded Royal Institution of Great Britain. Davy was just 20 years old when he performed his studies on nitrous oxide, and his subsequent, highly successful career took him into other areas of scientific study that led to discovery of the elements potassium, sodium, calcium, barium, magnesium, strontium, and chlorine. He was knighted in 1812, became President of the Royal Society in 1820, and never returned to develop his promising early thoughts on nitrous oxide analgesia. Regrettably, he left no students to continue these studies, although his successor at the Royal Institute, Michael Faraday (1791-1867), briefly experimented with ether inhalation and observed that its "effects were similar to those occasioned by nitrous oxide."[84]

The first research specifically directed toward an effective method of providing pain-free surgery was made by a physician working in the village of Ludlow, Shropshire, in northern England. Henry Hill Hickman (1800-1830) was a practicing surgeon who investigated the use of carbon dioxide to induce insensibility in animals. Because of the widespread interest in inhalation therapy at the beginning of the 19th century, it is not surprising that Hickman used an inhaled gas. Unfortunately for him, he used the wrong gas; if he had selected nitrous oxide, which was known to produce analgesia, his results might have achieved further attention. Although he published his work in 1824 in a private letter to T. A. Knight,[85] Hickman failed to find any support from his colleagues in England or France, and he died at an early age without recognition.

Beginning of Inhaled Anesthesia

The story of anesthesia continues with another amateur and itinerant chemist, Gardner Quincy Colton (1814-1898) (Fig. 1-5A). Colton had attended 2 years of medical school at the Crosby Street College of Physicians and Surgeons in New York. While in school, he perfected the manufacture of nitrous oxide by heating ammonium nitrate, and after 2 years of study, he proclaimed himself to be a "Professor of Chemistry" and went on the road to lecture on chemistry and present "scientific exhibitions."

On the night of December 10, 1844, Professor Colton presented his exhibit featuring inhalation of nitrous oxide at Union Hall in Hartford, Connecticut. It was at the Colton exhibit that the dentist Horace Wells (1815-1848) originated an idea that culminated in the first successful demonstration of inhalation anesthesia 22 months later. Wells had experimented with mesmerism to relieve the pain of dental extractions and was aware of the work of Humphry Davy. He attended the Colton demonstration and observed a young man, Samuel A. Cooley, sustain a significant leg injury without pain after nitrous oxide inhalation. Here was the answer to the problem of painful tooth extractions that had occupied his mind. He arranged for Colton to administer nitrous oxide to him on the following day for extraction of one of Wells' own teeth by fellow dentist John M. Riggs. Only a slight tinge of pain was felt, and Wells proceeded to manufacture nitrous

Figure 1-5 A, Gardner Q. Colton was born in Georgia, Vermont, and studied medicine briefly at the College of Physicians and Surgeons in New York City. His demonstrations of nitrous oxide inhalation were the spark that prompted Horace Wells and William T. G. Morton to use gas inhalation for relief of surgical pain. After a long and adventurous career, he died at age 84 in Rotterdam, Holland. **B,** William T. G. Morton was born in 1819 on a farm near Charlton, Massachusetts. After several business failures, he studied at the Baltimore College of Dental Surgery and, in 1842, entered into a partnership in Boston with another dentist, Horace Wells. This partnership was dissolved within a year on amicable terms. During this association, the two dentists had devised a new method for fitting dentures that required removal of all the diseased teeth, a prohibitively painful procedure for most patients. Morton experimented with laudanum and opium without success, and in proceeding with his investigations, he realized that greater knowledge of medicine was essential for further success. He briefly entered Harvard Medical School while continuing a part-time dental practice. During the summer of 1844, Morton, on the advice of Charles T. Jackson, used sulfuric ether for painless tooth extractions, and study of this agent eventually led to his successful demonstration of ether anesthesia at Massachusetts General Hospital on October 16, 1846. The remainder of Morton's life was spent in efforts to patent and receive monetary recognition for the discovery of ether anesthesia. Broken and despondent, he died of a cerebral hemorrhage in New York City in July 1868. *(Images courtesy of the Wood Library-Museum of Anesthesiology, Park Ridge, IL.)*

oxide according to Colton's instructions and use it for extractions of teeth. He recognized the enormous potential of his discovery and used his connections in Boston to arrange a date at the Harvard Medical School to demonstrate the technique of painless surgery.

Wells' appointment was to administer the gas for a leg amputation. The patient scheduled for this procedure refused to proceed with the anesthesia, and a young male student agreed to breathe nitrous oxide for extraction of a wisdom tooth. During the extraction the subject moved and groaned, only later to proclaim that little pain was actually felt. Nevertheless, Wells was discredited and became despondent, eventually withdrawing from further public promotions of his methods.

William T. G. Morton (see Fig. 1-5B), a young dentist from Boston, was acquainted with Wells, having been a former student and colleague of his, and had attended the failed demonstration at Harvard. Morton had lingering thoughts about a more suitable agent, in part arising from his interest in promoting his business of selling dentures. He had invented a new method for fitting dentures, but the process was prohibitively painful, and few patients would submit to the procedure. An adequate analgesic could accelerate his business.

Morton was initially trained as a dentist but had enrolled briefly at Harvard Medical School. Because of financial difficulties, he abandoned these studies and returned to dentistry. In the course of his education he became acquainted with Charles A. Jackson, a professor of chemistry at Harvard Medical School. On Morton's queries, Jackson advised a trial of sulfuric ether as an alternative to nitrous oxide. Later, Jackson was to claim priority in the discovery of anesthesia based on these consultations, but Morton countered that Jackson's role was negligible. Morton obtained the ether and, after performing experiments on himself and his pet animals, administered the agent successfully on September 30, 1846, to Eben Frost for extraction of an upper bicuspid tooth. Prompted by this success, he promoted use of the agent in his dental practice, thereby gaining the attention of another key figure, Henry J. Bigelow (1818-1890), in the unfolding drama. Bigelow, a prominent young surgeon at Massachusetts General Hospital, privately witnessed Morton's success with ether and arranged the time and date for its public demonstration.

The events of October 16, 1846, a complete triumph for Morton, have been recounted several times by others, but certain points are of special interest. The patient, Edward Gilbert Abbott, whom Morton apparently had never met, was to have a vascular tumor of the neck with large tortuous veins excised in the sitting position by 68-year-old Chief Surgeon John Collins Warren (1778-1856). Fearing a difficult airway or air embolism, a modern anesthesiologist might seek special equipment for this case, perhaps a special laryngoscope and central venous catheters. Morton, however, had only a poorly designed inhaler and no intravenous access. Close examination of the circumstances surrounding administration of this anesthetic indicates how dangerous this bold endeavor by Morton actually was and how likely it was to fail miserably. With the inhaler that he used, it seems unlikely that the vapor could be administered during the surgical procedure. Fortunately for Morton, the kinetic properties of ether result in prolonged emergence, and Mr. Abbott responded only briefly at the end of the procedure (Fig. 1-6).

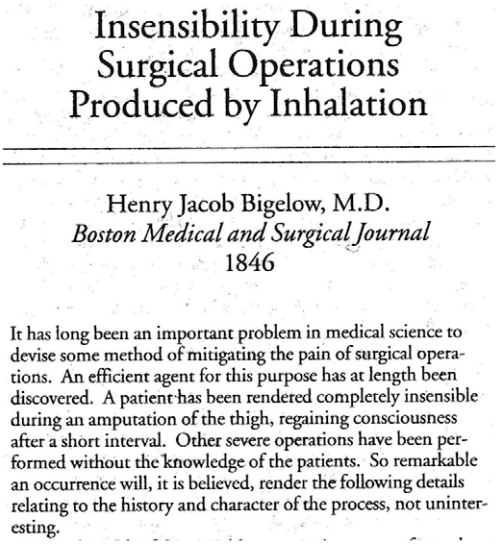
Morton, intending to profit from his discovery, withheld identification of the ether that he used and called it Letheon. He

Figure 1-6 Drawing by H. H. Hall in *Rice's Trials of a Public Benefactor* illustrates the first public demonstration of ether anesthesia at Massachusetts General Hospital on October 16, 1846. From the left are Henry J. Bigelow (1818-1890), the earliest advocate and sponsor of William T. G. Morton at the hospital, who also wrote the classic article describing the first experiences with ether anesthesia in the *Boston Medical and Surgical Journal*; Augustus A. Gould, with whom Morton and his wife were boarding and who suggested the design of the first inhaler (Gould also suggested the name Letheon); Jonathan Mason Warren (1811-1867), son of John Collins Warren, who later devised new surgical procedures for nasal deformity and cleft lip (Hall erroneously places him at this event; others [not shown] who were present are George Heywood, house officer, and Eben Frost, who had a tooth pulled by Morton after ether administration on September 30, 1846); John Collins Warren (1778-1856), 68-year-old Chief of Surgery at Massachusetts General Hospital, who performed the operation that day; William T. G. Morton, to whom credit is given for introducing ether anesthesia to the world; Gilbert Abbott, a 28-year-old house painter and printer with a congenital vascular tumor, visible in the drawing as a tumor below the left mandible; and Samuel Parkman, Morton's anatomy instructor at Harvard Medical School; and George Hayward (1791-1863), 53-year-old senior surgeon at Massachusetts General Hospital, who excised an arm mass under ether anesthesia the following day, October 17, 1846. His operation for vesicovaginal fistula is considered to be an original procedure. Also present was Solomon D. Townsend, one of the prominent surgeons at Harvard Medical School. *(Courtesy of the Wood Library-Museum of Anesthesiology, Park Ridge, IL.)*

masked the aroma and appearance of ether by adding a colored dye and additional scents. For a fee, he intended to provide instruction on its safe use. The surgeons at Massachusetts General Hospital then denied continued use of the agent until its true nature was identified. After Morton disclosed its chemical nature, further operations were performed with success. Bigelow read his manuscript describing the use of ether for operative surgery on November 3, 1846, before the American Academy of Arts and Sciences and published it (Fig. 1-7) in the November 18, 1846, issue of the *Boston Medical and Surgical Journal*.[86] The name anesthesia (Greek *an*, "without," and *esthesia*, "sensation") was suggested by Oliver Wendell Holmes (1809-1894) in a private letter to Morton dated November 21, 1846. Holmes also considered the words antineurotic, aneuric, neuroleptic, neurolepsia, and neurostasis, but he rejected these as being "too anatomical" because the change induced by ether was physiologic.

Aftermath

It is remarkable that without more explicit instructions or actual demonstration by one of the Boston group, ether anesthesia was adopted so rapidly around the world. Only 63 days after the Morton demonstration, ether was administered in England by



Insensibility During Surgical Operations Produced by Inhalation

Henry Jacob Bigelow, M.D.
Boston Medical and Surgical Journal
1846

It has long been an important problem in medical science to devise some method of mitigating the pain of surgical operations. An efficient agent for this purpose has at length been discovered. A patient has been rendered completely insensible during an amputation of the thigh, regaining consciousness after a short interval. Other severe operations have been performed without the knowledge of the patients. So remarkable an occurrence will, it is believed, render the following details relating to the history and character of the process, not uninteresting.

Figure 1-7 Title and opening paragraph of Henry J. Bigelow's description of the first ether anesthetics. *(From Bigelow HJ: Insensibility during surgical operations produced by inhalation. Boston Med Surg J 35:309-317, 379-382, 1846.)*

James Robinson (1813-1862), a prominent London dentist, for extraction of a deep-seated molar in a 13-year-old girl. Robinson had learned of ether anesthesia through a letter shown to him by a neighboring friend, Francis Boott (1792-1863), who had received the letter from Jacob Bigelow (1786-1879), father of Henry Bigelow, in which the effects of ether inhalation were described. Robinson devised a new inhaler and wrote the first textbook on anesthesia, published in London on March 1, 1847.[87] Two days after Robinson's use of ether, Robert Liston (1794-1847) performed the first operation in England—a leg amputation at University College Hospital, London—with ether as the anesthetic delivered by William Squire. Within a few months, ether anesthesia had spread to the European continent. Nikolai Ivanovitch Pirogoff (1810-1881) used ether in St. Petersburg as early as February 1847, and he wrote a treatise on the subject. Of significant importance for the widespread use of ether was the prestige of the Boston surgeons, who firmly supported its legitimacy.

Many who tried to administer the anesthetic did so without proper preparation, and failures were common. Several questions remained unanswered. Bigelow's article was vague about how it should be administered and simply described a number of cases with the use of Morton's inhaler. How the ether was supposed to be administered after loss of consciousness was not addressed. Nasal breathing or failure to purse the lips around the mouthpiece must have placed a limit on the duration of effective vapor administration. It was another lucky circumstance for Morton that ether was chosen as his agent. Subsequent studies with ether have revealed that it stimulates the sympathetic nervous system at deep levels of anesthesia.[88] This unique property of the drug and its high blood solubility result in a remarkably safe agent that requires only marginal skills to avoid overdose.

Priority for Discovery

Claims of priority for the discovery of ether anesthesia arose quickly. Wells, Morton, and Jackson all claimed to have discovered anesthesia. The issue of priority was further complicated by

a report that a surgeon in Jefferson, Georgia, had used ether anesthesia as early as 1842. Crawford Long (1815-1878) published a manuscript in the *Southern Medical and Surgical Journal* in December 1849 describing his use of ether on March 30, 1842, to excise a tumor from the neck of a young man, James M. Venable.[89]

Numerous monuments have been erected to commemorate the man "who discovered anesthesia." At least 15 have been erected for the group of Morton, Wells, and Long. A chair that Charles Jackson sat in while experimenting with ether inhalation is on display in the Pilgrim Memorial Hall in Plymouth, Massachusetts, with the label "Seated in this chair, Dr. Charles T. Jackson discovered etherization February, 1842." In the Public Gardens of Boston, a monument without a name has been erected to those who discovered anesthesia, thus suggesting that the introduction of ether anesthesia was the product of several individuals. Howard R. Raper, in his book *Man Against Pain*, analyzed the controversy about "who discovered anesthesia" and suggested that Crawford Long was the discoverer if only the issue of priority is considered. However, Long continued to use whiskey and other ineffective means after 1842, indicative of his apparent lack of enthusiasm for ether. Wells was the discoverer if the idea of inhalation anesthesia is considered, and Morton was the discoverer if the primary consideration is who introduced inhalation anesthesia to the world. Historians have generally credited the personality who produces the actual change in medical practice, and that individual was William Thomas Green Morton.

Neither honors nor monetary awards were forthcoming during the remaining lives of Wells or Morton. Wells committed suicide in 1848, unaware that the French Academy of Sciences had just named him as the true discoverer of anesthesia. Morton was unsuccessful in his effort to profit from a patent on his discovery or to secure a financial award from the U.S. government and died, broken and despondent, at age 49. Jackson was committed to a hospital for the mentally ill at the age of 68 years, where he died 7 years later. Morton was 27 years old when he demonstrated ether anesthesia. The ages of the other participants at the time of their discoveries were as follows: Wells (1815-1848) was 29; Davy (1778-1829) was 22; Hickman (1800-1830) was 24; Jackson (1804-1880) was 41; Long (1815-1878) was 27; and Colton (1814-1898) was 30 years old.

Development of Inhaled Anesthetics

Chloroform

Within a year after the introduction of ether anesthesia, the search had already begun for other agents that could anesthetize without some of the problems associated with ether. Although ether was a remarkably safe anesthetic, even when administered by untrained hands, there were disadvantages, including flammability, prolonged induction, an unpleasant odor that was persistent, and a high incidence of nausea and vomiting. James Young Simpson (1811-1870), an obstetrician from Edinburgh, Scotland, used ether in 1846 but was determined to find a better anesthetic. As early as January 1847, he began experimenting with a variety of different solvents and volatile liquids.[90]

Marie Jean Flourens (1794-1867) had used chloroform in dogs while studying stages in depression of the central nervous system by chloroform and ether. Simpson and a group of friends learned of the surprising potency of chloroform at a dinner party hosted by Simpson on September 4, 1847. Dinner was followed by the experimental inhalation of volatile drugs, and the use of chloroform was followed by stupor and coma in several participants, including Simpson. Simpson promoted chloroform vigorously, and its use was widely accepted in England. As an obstetrician, he advocated its use during labor and promoted, along with others,[91] the use of analgesics during parturition. Initially, his views conflicted with those of medical authorities, who considered it unsafe during labor, and with those of religious authorities, who opposed it on theologic grounds. Edinburgh had a black history on the issue of pain relief during childbirth. In 1591, a young woman named Euphanie Macalyane was burned alive as punishment for seeking pain relief during labor. Her sentence was on a direct order from the King of Scotland, James VI (1567-1625). Simpson was not a timid man and met the religious controversy with direct quotations from the Bible that appeared to support his views (Genesis 2, 21: "and the Lord God caused a deep sleep to fall upon Adam, and he slept: and he took one of his ribs, and closed up the flesh instead thereof.").

Chloroform was used widely in England, but controversy developed about its safety, particularly in otherwise healthy subjects, those in whom a physician would not anticipate any difficulties. Various commissions and committees were formed, notably the two Hyderabad commissions (1888 and 1890),[92] to investigate the relative safety of chloroform. In the late 19th century, Hyderabad, a city in the middle of the Indian subcontinent, was the capital of the independent state of Hyderabad, ruled by the Nizam Mir Mehboob Ali Khan. The Nizam was persuaded to underwrite an animal investigation into the safety of chloroform anesthesia by Major Edward Lawrie (1846-1915), principal of the Indian Medical School in Hyderabad. Lawrie had a preconceived belief in the safety of chloroform, and the results of his studies understandably concluded that chloroform was entirely safe if given according to his methods. The agent continued in use for several decades, but its slow demise was initiated in 1894, when Leonard G. Guthrie[93] reported several cases of delayed chloroform hepatotoxicity in children. The future use of chloroform anesthesia was doomed after the studies of A. Goodman Levy[94] (1856-1954), who demonstrated that the combination of light chloroform anesthesia and adrenalin produced fatal ventricular fibrillation in experimental animals, thereby explaining the perplexing sudden demise of several healthy subjects who were administered chloroform anesthetics.

Nitrous Oxide

Because of the embarrassing public demonstration by Wells in 1863, revival of nitrous oxide as a surgical anesthetic was delayed until its reintroduction by the same man, Gardner Q. Colton, whose lecture and demonstration Wells had attended in 1844 and from whom he obtained the gas used in his first experiments with inhalation analgesia. Soon after the Wells debacle in 1844, Colton abandoned nitrous oxide demonstrations and joined his brother in California, where he unsuccessfully panned for gold and served briefly as Justice of the Peace for San Francisco. His stay in San Francisco terminated when he was involved in controversial land sales, and he moved to Boston and took a job as a writer for the

Boston Transcript.[95] Colton also resumed his "laughing gas" exhibitions, and in 1863 he joined into a partnership with Joseph H. Smith, a dentist in New Haven, Connecticut, for the "painless extraction of teeth." The business thrived, and between 1864 and 1897, the Colton Dental Association had treated nearly 200,000 patients without a fatality. Colton demonstrated nitrous oxide inhalation in Paris at the First International Congress of Medicine in June 1867, and its wider use in Europe originates from that time. Colton was a unique individual who promoted the continued use of a valuable agent, but he remained ignorant of its true chemical nature. In his writings,[96] he states, for example, the following:

> *The gas is composed of half nitrogen and half oxygen and because oxygen is the life giving principle of the air, a person lives a little faster while under its influence. It acts as an exhilarant, as by supplying an extra supply of oxygen to the lungs, the pulse is increased 15 to 20 beats to the minute.*

Until 1870, nitrous oxide was administered with air, and the livid appearance of many patients raised the question about whether the analgesic properties of the gas were primarily caused by lack of oxygen. The idea of using nitrous oxide with oxygen is usually credited to Edmund Andrews[97] (1824-1904), a Chicago surgeon who was able to provide analgesia without cyanosis, thereby confirming the inherent analgesic properties of nitrous oxide. Andrews noticed that the nitrous oxide provided to dentists in gaseous form was often impure and instead advocated the use of liquid nitrous oxide contained in iron flasks. This pure nitrous oxide, when combined with oxygen, provided satisfactory anesthesia without cyanosis for short procedures. Paul Bert (1833-1886), a French physiologist who contributed significantly to the understanding of blood gas tensions at altered barometric pressures, demonstrated that nitrous oxide and oxygen mixtures produced highly satisfactory surgical anesthesia without hypoxia when delivered at pressures greater than 1 atm. Frederick Hewitt[98] (1857-1916) devised the first anesthesia machine to deliver variable portions of nitrous oxide and oxygen. Johnson demonstrated that the pupillary dilation, lividity, jactitation, and clonic movements of the extremities after the administration of nitrous oxide and air were caused by extreme hypoxia because they could be reproduced exactly by administering nitrogen with only 0.5% oxygen.[99]

These developments led to reintroduction of nitrous oxide into the operating room, where Horace Wells had predicted it would be used with success. Nitrous oxide and oxygen anesthesia was promoted in the United States by Elmer I. McKesson[100] (1881-1935), Paluel J. Flagg (1886-1970), and F. W. Clement (1892-1970). McKesson's method for induction of anesthesia with 100% nitrous oxide did not survive into the latter part of the 20th century. A landmark publication by C. B. Courville described the neuropathologic findings in patients who had sustained hypoxic insults during anesthesia with high concentrations of nitrous oxide.[101] W. D. A. Smith recounts the revival of nitrous oxide after Colton's reintroduction of the agent in an entertaining and informative book on the subject.[102]

Unsatisfactory Inhaled Anesthetics

During the first few decades of the 20th century, practitioners were searching for new and improved anesthetics. An American anesthesia textbook written by James T. Gwathmey (1865-1944) (see Fig. 1-18D) was published in 1914 and briefly discussed more than 600 possible anesthetic agents for the reader to consider. By 1930, all successful anesthetic agents except chloroform and nitrous oxide were explosive. Chloroform by then was thought to be dangerous, and the popularity of nitrous oxide was curtailed by the need for a nearly hypoxic mixture to provide adequate anesthesia. Ethyl chloride was the last agent to be introduced in the 19th century, and like ether, it was flammable. It was a unique agent that was first used as a spray to induce local anesthesia, but if inhaled, it also produced general anesthesia.

In the early 20th century, several unsatisfactory volatile anesthetics were introduced. Ethylene was used clinically in 1923. This agent required high concentrations to achieve anesthesia, had an unpleasant smell, and was explosive. Divinyl ether, developed by Chauncey Leake[103] (1896-1978), had some advantages over ether for induction of anesthesia, but it was also flammable and never widely used. Cyclopropane was introduced in 1934 by Ralph Waters (1884-1979) and was briefly popular, but it was violently explosive. The flammable anesthetics prevented the use of surgical cautery and electronic monitoring. One attempt to produce a nonflammable alternative to ether and cyclopropane was made in 1935, when trichloroethylene was introduced. It was promoted by Christopher L. Hewer[104] (1896-1986) as a nonexplosive agent, but it was eventually withdrawn when it was shown to decompose to the toxic nerve poison dechloroacetylene in the presence of soda lime and to produce phosgene, a severe respiratory irritant, when electrocautery was used. Clearly, new directions were needed.

Fluorinated Anesthetics

In the early 1930s, progress was made in attempts to fluorinate hydrocarbons, and many fluorinated compounds became available commercially, primarily as refrigerants. From a theoretical analysis of hydrocarbon chemistry, it was known that halogenation of the parent hydrocarbon compound would decrease its flammability. One early approach to produce a nonflammable anesthetic was to select a flammable agent and partially fluorinate it. With this in mind, John C. Krantz, Jr., of the University of Maryland, took the flammable anesthetic vinamar, which is ethyl vinyl ether, and produced trifluoroethyl vinyl ether,[105] or fluroxene.

The circumstances surrounding the first anesthesia with fluroxene illustrate the lure of self-experimentation in research related to the advancement of anesthetic practice. Max S. Sadove (1914-1997), an anesthesiologist at the University of Illinois, was a member of the Walter Reed Society, a group of scientists who, following the example of Walter Reed, allowed themselves to be administered the first dose of investigational drugs. Sadove, a close acquaintance of Krantz, insisted that he be given the first fluoride-containing anesthetic, fluroxene, in 1953. Krantz, who had synthesized the drug, was a pharmacologist with no training in anesthesia. Krantz advised Sadove that there was danger that the agent might be administered improperly or might be metabolized to a toxic by-product. Nevertheless, Sadove was insistent, and on April 10, 1953, Krantz administered open-drop fluroxene to Sadove, and recovery was rapid and uneventful.[106]

Fluroxene had marginal success but was eventually withdrawn because of questions about toxicity and the frequent occurrence of postanesthetic nausea and vomiting. Charles Suck-

ling, a chemist at Imperial Chemical Industries, synthesized halothane in 1954 after a theoretical analysis of possible anesthetic halogenated drugs. The pharmacologic properties of halothane were studied by James Raventós[107] (1905-1983), and it was introduced clinically in 1956 by Michael Johnstone.[108] Halothane had definite advantages over ether and cyclopropane because of its more pleasant odor, higher potency, favorable kinetic characteristics, nonflammability, and low toxicity, and it gradually replaced the older agents. Halothane was a highly successful drug that achieved worldwide acceptance, but its unblemished record lasted only a few years before controversy appeared.

In 1958, a case report described a 39-year-old woman who died of fulminant hepatic necrosis 11 days after cholecystectomy with halothane anesthesia.[109] This was followed in 1963 by nine case reports of patients in whom hepatic necrosis developed after halothane anesthesia (also see Chapter 24).[110] The cases were unique in that hepatic failure often followed minor operations in which other causes of hepatic failure were not apparent. Eventually, the term "halothane hepatitis" became a common clinical diagnosis for patients with postoperative liver failure, even when halothane was not used as the anesthetic. A national study formally titled "The National Halothane Study" was established in 1964 and reported that the incidence of liver failure after halothane anesthesia was no more frequent than that reported with other anesthetics.[111] Nevertheless, halothane was extensively metabolized in the body, and in some individuals it seemed that a toxic metabolite might produce liver necrosis. Other halogenated anesthetics were also extensively metabolized, and in the case of methoxyflurane, such metabolism resulted in high levels of fluoride ions. High-output renal failure was an infrequent but potentially morbid side effect of methoxyflurane[112] that was related to increased blood fluoride ion concentrations.

Beginning in 1960, the pharmaceutical industry launched new efforts to synthesize the "ideal anesthetic." Ross C. Terrell at Ohio Medical Products synthesized more than 700 potential anesthetic compounds between 1960 and 1980. During the same period, Edmund I. Eger II (1930-) began a series of studies that significantly enhanced the rational use of inhaled anesthetics. Eger drew on the work of Seymore S. Kety[113] (1915-2000) and Severinghaus,[114] which had previously demonstrated that the end-tidal partial pressure of anesthetic gases at steady state was the same as the brain cerebral partial pressure of those gases. By correlating the end-tidal (alveolar) concentration with the movement response to supramaximal nociceptive stimulation, the concept of minimum alveolar concentration (MAC) was born (also see Chapter 19). By definition, MAC represents the end-tidal concentration of any anesthetic agent at which 50% of patients move in response to a supramaximal stimulus.[115] With this standard measure of potency, new agents could easily be introduced to the anesthesia community. Several further studies by Eger and others on the pharmacokinetics of inhaled anesthetics and factors that alter MAC[116] accelerated an understanding of volatile anesthetic requirements and significantly enhanced the safe use of these drugs.

Two of the anesthetics developed by Ohio Medical Products, enflurane and isoflurane, were introduced about 40 years ago.[117,118] Isofluorane has been highly successful and used extensively since that time. Desflurane was one of the last volatile anesthetics to be synthesized and required a potentially dangerous explosive method of synthesis. Desflurane had a high vapor pressure and the added limitation of requiring more than five times the quantity of vapor to produce anesthesia than needed with isoflurane. Although desflurane was initially overlooked because of these problems, it was studied thoroughly in animals[119] and first used in humans in 1990.[120] Because of its favorable kinetic properties, recovery is more rapid with desflurane than with isoflurane or enflurane.

Sevoflurane was synthesized more than 40 years ago at Travenol Laboratories. Recovery is rapid with this agent, but because the compound is unstable in soda lime, it was not introduced until the late 1980s,[121] first in Japan and then in the United States. The decision to introduce the product was, as with desflurane, spurred by the emphasis on early discharge after anesthesia. Anesthesia has been induced with sevoflurane several million times without apparent complications resulting from the potential by-products arising from contact with carbon dioxide absorbents. Since the introduction of sevoflurane, there have been no additional inhaled anesthetics introduced for clinical use. The inert gas xenon has been under investigation as an anesthetic for several years, but it is expensive and, like nitrous oxide, requires high concentrations to produce anesthesia.

Needles and Syringes

In an attempt to find another parenteral route of drug administration, some physicians raised blisters or excoriated the skin and then deposited drugs on the exposed surface of the wound. Francis Rynd[122] (1801-1861) used a lancet to pierce the skin and devised a syringe to insert medication into the wound by gravity. Alexander Wood[123] (1817-1884) invented a hollow needle that would fit on the end of a piston-style syringe made for him by Daniel Ferguson, an instrument maker from London. Wood used the syringe and needle combination to successfully treat painful neuralgias by local injections of morphine. The syringe and needle combination became a popular item after these reports, and many practitioners used the device to inject morphine subcutaneously for pain relief. The term *hypodermic injection* was coined by Charles Hunter, who argued with Wood that morphine could be injected into the body at any place and achieve the same analgesic effect as that obtained by injection at the site of pain.

The early syringes were inadequate for the work of the developing specialty of regional anesthesia (Fig. 1-8). The rubber or leather plunger cracked or deteriorated after repeated sterilization. During use, the drug contents accumulated proximal to the plunger, or the plunger itself jammed inside the glass barrel. To achieve the fine control required for identification of the epidural space, a more carefully tooled instrument was required. H. Wulfing Luer of Paris introduced the first all-glass syringe in 1896. He sold the patent to partners Maxwell W. Becton and Fairleigh S. Dickinson (Becton, Dickinson and Company) in 1898. The Record syringe was made by Dewitt and Herz of Berlin, Germany, in 1906, and it consisted of an all-metal plunger with a finely ground glass barrel. The fit between the barrel and plunger was precise and sturdy, and Record syringes nearly 100 years old can still be used for identification of the epidural space.

The first hypodermic needles were made of tempered steel, a metal that rusted easily when in contact with water. A small rusted area might not be observed visually, and defective needles sometimes broke below the skin. Meticulous care was taken to

Figure 1-8 Drawing by an unknown artist appearing in *Clysmatica Nova*, a book written by Johan S. Elsholtz (1623-1688) and dated 1667. The artist clearly shows that syringes and rudimentary hollow intravenous tubes were used before the 19th century. Although this book was published in Cologne, Germany, most historians credit the first intravenous injections of pharmaceuticals to Christopher Wren and Timothy Clarck in England. *(Courtesy of the National Library of Medicine, Bethesda, MD.)*

dry each needle after steam sterilization. Specially designed introducers, called rimmers, were used for storage of the needles to prevent rust from developing inside the needle. To avoid the problem with needle breakage, platinum or gold needles were used occasionally. These needles were highly flexible and expensive and never became popular. Stainless steel was produced commercially in 1918 and essentially eliminated the problem with rust. Modern needles are usually disposable stainless steel needles, which has minimized complications resulting from infection and breakage.

The bevel of the needle was a topic of great discussion in the early 20th century. A long bevel produced less trauma to tissues, but it allowed a small portion of the needle to lie in the intrathecal space with the proximal portion of the bevel in the epidural space. To increase the success of spinal anesthesia and minimize side effects, short-beveled needles and pencil-point needles were developed by several regional anesthesia specialists, a process that continues to this day. Fine, 25-gauge spinal needles, designed to produce minimal trauma to the dura, have reduced the incidence of post–dural puncture headache.

Intravenous Fluid Therapy

Awareness of fluid balance had its beginnings in the writings of Claude Bernard, who in his final published work emphasized the importance of extracellular fluid in the support of vital functions.[124] In these writings he stressed that blood and lymph bathe the cells of the body and that these fluids constitute the *milieu interne*, later called the *fluid-matrix* by Walter B. Cannon. These researchers pointed out that an organism's freedom from external disturbances such as hunger, thirst, and cold is brought about by mechanisms that maintain uniformity of body fluids. The concept of the steady state maintained in this internal environment became known as *homeostasis* in the Cannon doctrine. During anesthesia, many of the homeostatic mechanisms are abolished or severely blunted, and the anesthesiologist must assume the role of maintaining a favorable *milieu interne*.

Crystalloids

In the late 19th century, the sodium content of serum was found to be roughly equivalent to an aqueous solution of 0.9% sodium chloride, and this became known as physiologic salt solution. Hartog J. Hamburger (1856-1924) showed a change in the volume of red blood cells at concentrations above and below 0.9% saline.[125] As a result of these experiments, the value of sodium ions in maintenance of osmotic pressure in serum was realized. Ernest H. Starling[126] (1866-1927) extended these observations to explain edema formation on the basis of hydrostatic and colloidal osmotic pressure.

Maintenance of fluid balance was not a priority or even a possibility for those who administered anesthetics during the 19th century. Without intravenous access, there was little that the anesthesia provider could do if the surgeon was recklessly losing blood. The importance of intravenously administered salt to patients with dehydration from cholera was observed in 1831 by William B. O'Shaughnessy[127] (1804-1889). Although there were isolated successful attempts to treat the dehydration of cholera with saline infusions, such treatment did not flourish, and the victory over cholera was finally won only through improved sanitary conditions.

The experimental introduction of saline infusions after surgery was based on work performed by Emil Schwarz[128] (1852-1918), who observed that saline infusions could save the lives of bled rabbits. This work was recognized by Johann J. Bischoff[129] (1841-1892), who reported that a salt infusion saved the life of a woman with severe postpartum hemorrhage. Treatment with salt infusions was generally adopted after surgical hemorrhage, but sepsis and failed attempts to revive the bleeding patient soon became apparent.

Alternative solutions to saline originated with Sydney Ringer[130] (1835-1910), Professor of Medicine at University College, London. Ringer observed that saline prepared from distilled water was not as effective as saline made from pipe water in maintaining contractility of the isolated frog heart. After careful analysis of the pipe water, he learned that it contained calcium and potassium impurities. Adding these cations to the saline made from distilled water proved his hypothesis that these ions played an important role in maintaining normal cardiac function.

In the first decades of the 20th century there were substantial barriers to the successful use of parenteral electrolyte solutions during surgery. Closed sterile administration sets and intravenous cannulas were slow to develop, and alternative methods were therefore used. Most patients received several liters of fluid, usually administered rectally; however, salt was administered, if possible, orally or by subcutaneous injection. With these ineffectual methods, the use of saline in the perioperative period fell into decline. In 1944, a syndrome described as postoperative salt intolerance was caused ostensibly by failure of the kidney to excrete a salt load.[131] These ideas had the support of the influential Francis D. Moore, Chief of Surgery at Peter Bent Brigham Hos-

pital in Boston. When intravenous therapy became more widely available, patients were often administered dextrose and water or dilute sodium-containing solutions. Carl Moyer[132] (1908-1970) presented evidence in 1950 that sodium was avidly retained postoperatively and argued against the use of saline for perioperative fluid maintenance.

The reintroduction of perioperative saline therapy began in 1959, when G. Shires and associates[133] reported the redistribution of extracellular fluid into "third space" compartments during extensive surgical procedures. These reports encouraged preoperative administration of fluid to compensate for the lack of oral intake and intraoperative administration of sodium-containing fluid to replace translocation of extracellular fluid into edematous spaces such as the gut and peritoneum. The increased use of saline reduced the incidence of postoperative renal failure and decreased the requirement for blood transfusions. As a result of these studies, fluid replacement today consists of saline-containing fluids, with the addition of colloid and blood when excessive blood loss occurs. These concepts of fluid management were vigorously promoted by M. T. Jenkins (1917-1994).[134]

Blood Transfusions

The first blood transfusions were not performed as treatment of blood loss. Jean Baptiste Denis (1625-1704) from Montpellier, France, administered lamb's blood[135] to a demented patient with the idea of transferring the attributes of the donating animal to the recipient. Although the first patient survived, a subsequent transfusion resulted in death. Denis was tried for murder, and although he was acquitted, the procedure was condemned and prohibited by the Faculty of Medicine in Paris. Physicians in the 18th and 19th centuries were more prone to remove rather than administer blood.

Successful blood transfusions were performed by James Blundell[136] (1790-1877), who experimented with blood transfusions in animals and rejected the idea of animal-to-human transfusions. Blundell recorded 10 human-to-human transfusions between 1818 and 1828 and recognized that acute blood loss was the primary reason for transfusion. Five of these 10 patients died after the transfusion, possibly as a result of incompatible blood.

In 1900, Karl Landsteiner[137] (1868-1943) described three blood groups: A, B, and O; the fourth blood group (AB) was described by A. V. Decastello[138] 2 years later. George W. Crile (1865-1943) performed the first transfusion of human blood after a preceding compatibility test in 1906. Discovery of the Rh antigens was delayed until 1939.

One hundred years ago, the accepted method of transfusing blood was to surgically anastomose the artery of the donor to the vein of the patient. This method required a long and delicate operation, and there was no way to measure the amount of blood transfused. Blood could not be removed from the body without defibrination, a process that often produced serious reactions and air embolization. In 1914, Albert Hustin[139] (1882-1967) noticed that when sodium citrate was added to blood, it prevented coagulation, and with the addition of dextrose by P. Rous and J. R. Turner in 1916,[140] storage of blood products for up to 21 days became a reality.[141] The familiar drip chamber for estimating infusion rates was devised by R. Laurie in 1909. The effect of these advancements in the use of blood products on the practice of anesthesia is apparent by comparing the American textbook by Gwathmey, dated 1914, in which there is no mention of blood administration, with that of John S. Lundy[142] (1894-1972), dated 1945, which contains an extensive chapter on the subject. Lundy was an early proponent of blood transfusions and opened the first blood bank in the United States at the Mayo Clinic in 1935. The effect of two world wars on the practice of anesthesia in the United States can be appreciated by comparing these two books.

With the increased frequency of contamination of homologous blood by hepatitis virus and human immunodeficiency virus, a new look at an old technique,[143] autologous transfusion, was begun in 1970 (also see Chapter 57). In that year, G. Klebanoff described a disposable autologous transfusion system manufactured by Bentley Laboratories. Klebanoff reported[144] on its use in 53 patients with no deaths if the total volume of blood replaced was less than 3500 mL. Malcolm D. Orr first reported cell-washing techniques in 1975 with the Haemonetics cell-washing system.[145] This system obviated some of the problems when blood was filtered, but not washed after retrieval from the surgical wound. From these early reports it became apparent that washed and concentrated red cells obtained from the surgical site could provide safe alternatives to homologous transfusion. The "cell saver" method of autologous blood transfusion has become an integral part of intraoperative fluid management when large volumes of blood loss are anticipated.

Coagulopathies often develop during large-volume blood transfusions, and their diagnosis and prompt treatment significantly contribute to survival during major surgery. Ronald D. Miller (1939-) and colleagues[146] recognized thrombocytopenia as one of the earliest defects in coagulation after massive blood loss (also see Chapter 55). Advances in specific blood component therapy[147,148] have also contributed to maintenance of normal blood coagulability during large-volume blood loss.

Introduction of Regional Anesthesia

Early Attempts at Local Anesthesia

The first written account of the coca plant being used as a local anesthetic was by the Spanish Jesuit Bernabe Cobo (1582-1657), who chewed the plant to relieve a toothache and wrote about it in 1653.[149] Albert Niemann (1834-1861) of Göttingen, Germany, who isolated the alkaloid from the dried leaves in 1856 (Fig. 1-9B), gave the name *cocaine* to the active drug. Interest in cocaine in Europe and America was directed initially toward the central effects of the drug when taken systemically. Vasili von Anrep[150] (1852-1918) was the first to remark on its local anesthetic properties, and after animal experiments, he suggested its use as a local anesthetic during surgery. This suggestion went unnoticed, and the drug remained a curiosity. A comprehensive pharmacology textbook from 1883 does not mention cocaine or the plant *E. coca*.

Sigmund Freud (1856-1939), a young house officer at the prestigious Allgemeines Krankenhaus in Vienna, had a unique interest in cocaine and tested the drug as a substitute for opioids on a colleague who was addicted to morphine. Although this research met with little success, he had also noticed its ability to

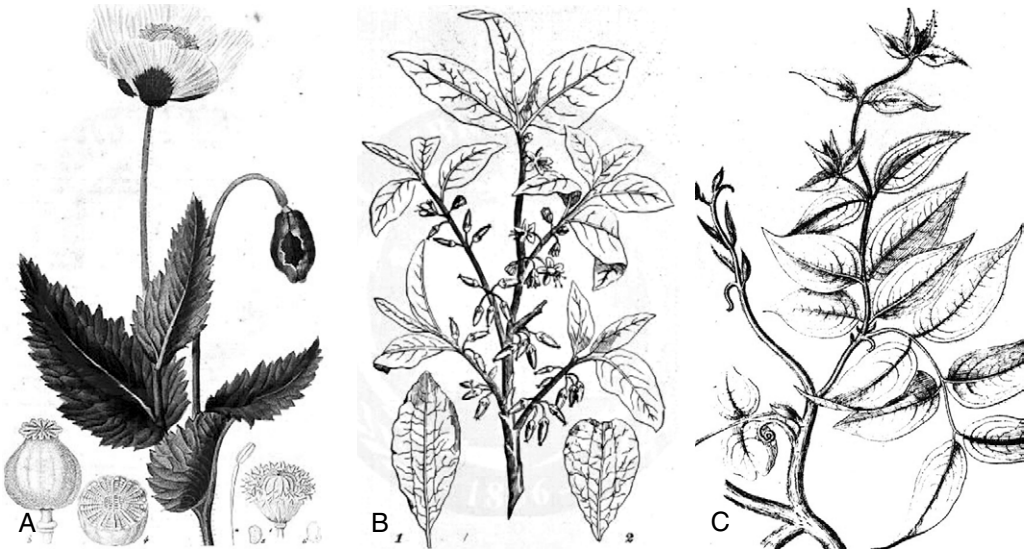


Figure 1-9 Botanical origins of adjuvants used in anesthesiology. **A,** *Papaver somniferum*, from which opium is obtained. The word *opium* is derived from the ancient Greek word for juice because the active alkaloids, which include morphine and codeine, are obtained from juice squeezed from the unripe seed pods. The first undisputed reference to poppy juice is from the writings of Theophrastus (372-287 BC) in the third century BC. **B,** *Erythroxylon coca*, a shrub native to Peru and Bolivia from which cocaine was isolated in 1856. Although the native people of Peru have used the drug for centuries to increase endurance, they may have also used it as a local anesthetic. **C,** *Strychnos toxifera*, a source of curare, as drawn by Robert Schomburgk in 1841. Schomburgk used maps drawn by Waterton to travel into Guiana and obtain several species containing the active drug. Richard Gill's curare was obtained primarily from Ecuador, and the arrow poisons there were made from *Chondodendron tomentosum*. Other botanical drugs that have been used in anesthesia include atropine (*Atropa belladonna*) , scopolamine (*Atropa mandragora*), physostigmine (*Physostigma venenosum*), ether (*Vitus vinifera*), gramine (*Hordeum vulgare*, from which lidocaine was derived), strychnine (*Strychnos toxifera*), ephedrine (*Ephedra sinica*), picrotoxin (*Anamirta cocculus*), theophylline (*Camellia sinensus*), and digitalis (*Digitalis purpurea*). *(Courtesy of the National Library of Medicine, Bethesda, MD.)*

produce numbness of the tongue and provided a small sample to his junior colleague Carl Koller[151] (1858-1944), an intern who was interested in producing local anesthesia for operations on the eye.

Koller had anticipated a career as a scientist in Vienna. He had taken up this question for his research project because the anesthetic methods of the time were highly unsatisfactory for ophthalmic surgery. General anesthetics presented numerous difficulties for the surgeon, and refrigeration anesthesia, although marginally successful for surgery on the extremities, was clearly inappropriate for the eye. Koller observed that after topical application of cocaine he was able to pinch and prick the cornea of dogs without discomfort to the animals. Self-experimentation confirmed complete analgesia of the corneal surface, and he proceeded to use the agent for superficial surgery on the eye.

Koller arranged to demonstrate the use of topical cocaine analgesia at the Ophthalmologic Congress in Heidelberg, Germany, on September 15, 1884. As the time for this presentation approached, he was unable to afford the travel expenses from Vienna, and a colleague from Trieste, Josef Brettauer (1835-1905), presented the three-page manuscript in his absence.[152] The presentation and demonstration were followed by an enthusiastically favorable response. Priority for the discovery was briefly confounded by a report on topical cocaine analgesia at an ophthalmologic meeting in October 1884 by Leopold Koenigstein, who did not mention Koller's previous paper, and by other comments that Sigmund Freud had actually originated the idea of cocaine analgesia. Koenigstein later conceded full credit for the discovery to Koller, and Freud eventually rejected all claims to the idea of topical analgesia with cocaine, although many concede that with his earlier publication on the subject,[153] he was instrumental in reviving interest in a drug that before 1884 was of no interest to pharmacologists.

Koller's career in Vienna seemed secure, but a disagreement arose with another house officer in January 1885. The altercation escalated into a duel with sabers, an activity that was banned in Austria at that time. Koller emerged unscathed from the duel, but the offending party suffered two saber cuts to the face. After this episode, Koller became depressed and ultimately decided to leave Austria. He first immigrated to Holland and then settled in New York City in 1886. There he built a successful private practice while continuing to contribute occasional clinical articles to the ophthalmologic literature. He died in New York City in 1944 after modestly receiving several awards for his seminal role in the development of local and regional anesthesia.[151]

Regional Blocks

It was not obvious that cocaine would produce blockade of sensation if injected directly into peripheral nerves. In 1880, von Anrep had injected cocaine under the skin of his arm and discovered that it produced insensitivity, but this information did not attract attention. At least one Viennese surgeon, Anton Wölfler, first assistant to Theodore Billroth, had attempted hypodermic cocaine injections without producing analgesia and was convinced that it was effective only on the mucous membranes. The idea of injecting cocaine into nerve trunks is credited to William Halsted (1852-1922) and Alfred Hall, who began their injection experiments as early as 8 weeks after the Heidelberg announcement.

Halsted and Hall had studied in Vienna during 1879 and 1880, but it is unlikely that they met Koller during those years because Koller did not finish his medical school training until 1882. During those years Koller was working on a paper about development of the mesoderm and had not developed his interest in cocaine. In 1884, Halsted was occasionally performing operations in the bedroom of his own house in New York City, and it was there that the two surgeons began their work on regional anesthesia. The first report of their success with injection appeared on December 6, 1884, in the *New York Medical Journal* in a letter written by Hall.[154] In this letter, Hall reported that they first injected 4% cocaine (15 mg) into the forearm and concluded that it blocked transmission in the cutaneous nerves because it provided analgesia below but not above the point of injection. They then injected 2 mL (80 mg) into the ulnar nerve at the elbow and produced a block of the entire ulnar distribution distal to the point of injection. Additional blocks were then performed on the brachial plexus and the infraorbital nerves, inferior dental nerves, and the sciatic nerve, all for operative surgery.[155]

With these large doses, it is not surprising that constitutional symptoms developed. Hall described dizziness and nausea. Both Halsted and Hall became addicted to cocaine; Halsted lived with an occult cocaine or morphine addiction the rest of his life. Hall took a position at Columbia University in New York City, but he later moved to Santa Barbara, California, where he died in 1924.

Carl Schleich[156] (1859-1922) introduced infiltration local anesthesia in 1892 as an alternative to direct injection of nerve trunks. His method was to infiltrate cocaine in dilute concentrations (0.01% to 0.2%) directly into subcutaneous tissues. James Leonard Corning[157] (1855-1923), a neurologist from New York, observed that placing a tourniquet on the limb could prolong the analgesic effect of infiltration analgesia, and he reasoned that the tourniquet prevented the blood from removing cocaine from its active site. Heinrich F. Braun[158] (1862-1934) achieved the same prolonged effect of cocaine by adding epinephrine to the solution and producing a "chemical tourniquet." Braun became the pioneer of the new drug procaine, introduced in 1905 as a less toxic drug than cocaine. Braun's textbook,[158] initially published in 1907, was one of the first devoted to regional anesthesia and went through eight editions, with the last one published in 1933.

Although Halsted was the first to block the brachial plexus, he did not use a percutaneous technique. His method in 1884—and that used by George Crile 13 years later—was to surgically expose the roots and then inject each nerve directly. G. Hirschel[159] produced the first percutaneous brachial plexus block in 1911 through an axillary approach (Fig. 1-10A). The axillary brachial plexus block has been modified by several surgeons, including George Pitkin and R. H. de Jong,[160] and remains a popular technique today.

D. Kulenkampff introduced the supraclavicular brachial plexus block[161] a few months after Hirschel described the axillary approach (see Fig. 1-10B). Kulenkampff injected his own plexus with 10 mL of procaine at the midclavicular position, lateral to the subclavian artery, and achieved complete anesthesia of the arm. Early reports indicated a frequent incidence of success with this block, but other practitioners soon reported complications such as pneumothorax and mediastinal emphysema. Several modifications of the supraclavicular block have emerged in an effort to avoid pneumothorax. Infraclavicular approaches to the brachial plexus were described by L. Bazy and V. Pauchet in 1917 and later popularized by P. Raj[162] in 1973 (see also Chapter 52).

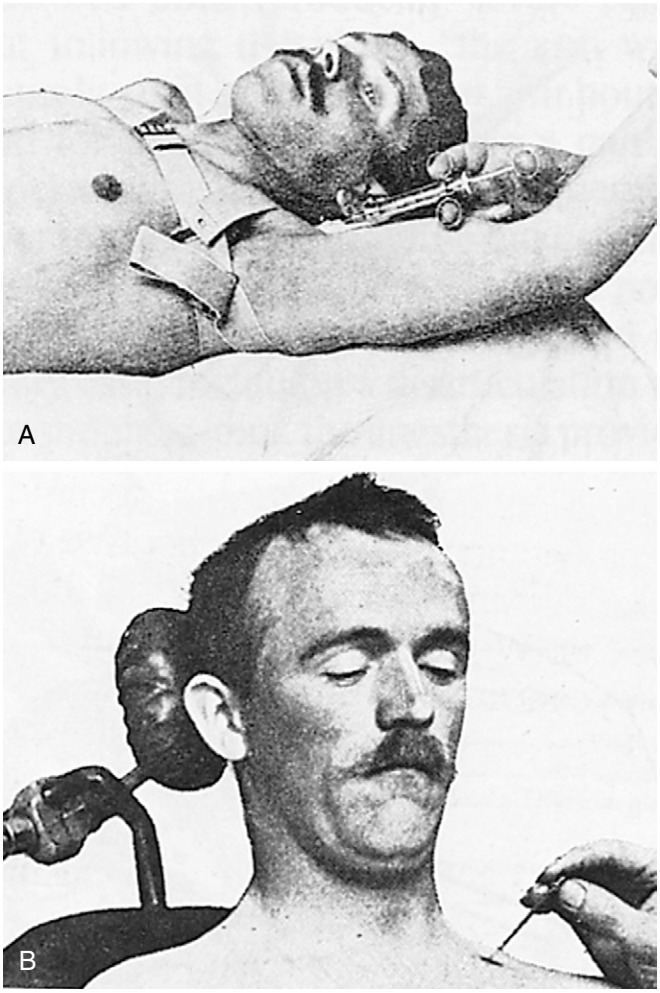

Figure 1-10 **A,** Hirschel performed the first percutaneous axillary block with 20 mL of 2% procaine in 1911. He forced a rubber ball under the pectoral muscles and fixed it with elastic bandages to prevent rapid absorption of anesthetic solution, a maneuver that he later abandoned as unnecessary. **B,** Kulenkampff approached the brachial plexus above the clavicle, just lateral to the subclavian artery. The patients were positioned in the sitting position for the block. An injection of 10 mL of 2% procaine with epinephrine was given only after paresthesia had been achieved. If the first rib was contacted, the injection was directed more medially. (***A,*** *From Hirschel G: Die Anasthesierung de Plexus Brachialis fur die Operationen an der oberen Extremitat, Much Med Wochenschr 58:1555-1556, 1911;* ***B,*** *from Kulenkampff D: Anesthesia of the brachial plexus. Zentrabl Chr 38:1337-1340, 1911.)*

In an attempt to approach the brachial plexus in the neck and thereby avoid pulmonary complications, M. Kappis[163] in 1912 attempted to perform the block through a posterior paravertebral approach. Because of a high incidence of failures with the posterior approach, several investigators, including J. Etienne, V. Pauchet, and G. Pitkin, used various anterior approaches to the brachial plexus in the neck. In 1970, Alon P. Winnie[164] introduced the interscalene brachial plexus block and emphasized that the scalene muscles are more accurate landmarks to the nerves than the subclavian artery or the midclavicular line is. The block has remained popular for operations on the shoulder and upper part of the arm; the nerves are located by paresthesias or direct nerve

stimulation. Continuous infusion into the roots of the brachial plexus has been introduced and can provide long-lasting analgesia after operations on the arm and shoulder.

A novel method of producing regional analgesia for operations on the extremities was described by August Bier (1861-1949) (Fig. 1-11A) in 1908.[164,165] Bier first exsanguinated the arm with an Esmarch wrap and, after placement of two tourniquets, injected a dilute solution of procaine intravenously. Analgesia was found to develop within minutes and persist until release of the tourniquet. The technique, known now as intravenous regional anesthesia, has been modified with new agents and remains a useful anesthetic technique for surgery on the extremities when a tourniquet is used.

The development of regional anesthesia in the United States was accelerated with the arrival of Gaston Labat at the Mayo Clinic in 1924. Labat had learned regional anesthetic methods from the French authority on injection techniques, Victor Pauchet (1869-1936), and expanded on his work while in Rochester, Minnesota. Labat founded the American Society of Regional Anesthesia and was active during its formative years. John Lundy adopted many of the regional techniques introduced by Labat at the Mayo Clinic and continued their use after Labat relocated to Bellevue Hospital in New York City. Labat's 1922 textbook[50] was one of the first English texts on regional anesthesia and has been followed by several authoritative works on the subject. Labat's influence was also evident in New York City, where Emery A. Rovenstine (1895-1960), his successor as Chairman of the Department of Anesthesiology at Bellevue Hospital, established the first chronic pain clinic. The commitment of anesthesiologists to chronic pain therapy arose as a natural sequel to their emerging expertise in neuraxial and peripheral nerve blocks. Chronic pain clinics today are often modeled after the multidisciplinary clinic established by John J. Bonica (1917-1994) at the University of Washington in Seattle.[166]

The continued success of regional anesthetic techniques can be partially credited to ultrasound techniques for localization of the nerves and also to improved local anesthetics with lower toxicity and longer duration of action. Cocaine was highly toxic, addictive, and of short duration. Procaine was synthesized in 1905 by Alfred Einhorn[167] (1856-1917) and was the most commonly used agent until 1932, when tetracaine, a longer-acting agent, became available. Lidocaine, introduced in 1948 by Torsten

Gordh[168] (1907-), had several advantages, including lower toxicity and intermediate duration of action, and it is still widely used. Other local anesthetics include chloroprocaine (introduced in 1952), mepivacaine (1957), and bupivacaine (1963). Concern about therapy-resistant cardiovascular toxicity with bupivacaine[169] led to introduction of the newer agents ropivacaine (1996) and levobupivacaine.[170] Bupivacaine, ropivacaine, and levobupivacaine are popular agents in low concentration for control of postoperative pain and for obstetric anesthesia because of their long duration of action.

Neuraxial Block and Acute Pain Service

The first neuraxial block was performed 8 months after the demonstration in Heidelberg of the local anesthetic properties of cocaine (see Chapter 87). James Leonard Corning (1855-1923) was a neurologist who had learned of the action of cocaine possibly from observation of Halsted's work in New York City. Corning was interested to know whether the blood could carry cocaine to the spinal cord, similar to what had been demonstrated to occur after the injection of strychnine between the spinous processes. On October 12, 1885, Corning injected a total of 120 mg of cocaine between the T11 and T12 spinous processes in a 45-year-old man and obtained loss of sensation of the legs and perineum. He concluded that this proved cocaine's action on the spinal cord and suggested its use in certain cases of spinal spasticity and for operations on the genitourinary system.

The consensus is that Corning produced an epidural injection of the drug[171] because 120 mg (60 mg initially and then 60 mg 8 minutes later) of intrathecal cocaine would be expected to produce a total spinal anesthetic or a block extending into the cervical dermatomes. It is not surprising that Corning's method of neuraxial blockade was not repeated because the technique of consistently injecting into the epidural space had not yet been described. If any investigators had attempted to repeat the Corning experiment with the dose that he used, it might have ended in disaster and thereby have delayed the development of neuraxial blockade by several years.

Spinal Analgesia (also see Chapter 51)

In Kiel, Germany, during the last decade of the 19th century, preparations were being made for the next major advance in anesthetic practice. At the Kiel University Medical School, Friederich von Esmarch (1823-1908) was the senior surgeon and August Bier one of the junior surgeons. Heinrich I. Quincke (1842-1922) was the leading internist in Kiel and had already contributed several useful clinical observations, among them the Quincke pulse and Quincke edema, to the medical literature. In 1891, Quincke observed that the dural sac, described by Domenico Cotugno (1736-1822) in 1787, could be punctured by inserting a needle between the lumbar spinous processes.[172] This procedure, independently reported by Walter Wynter (1860-1945) of Leeds, England, in the same year, at first was a curiosity without any real purpose. Quincke unsuccessfully attempted to treat hydrocephalus by draining fluid from the dural sac. Microscopic examination of the fluid did have some diagnostic value in cases of inflammation of the central nervous system.

On August 15, 1898, August Bier and his assistant August Hildebrandt (1868-1854) used the Quincke method of entering the intrathecal space and injected between 5 and 15 mg of cocaine to produce spinal anesthesia in six cases for operations on the lower part of the body. They also reported the results of spinal anesthesia given to each other in what has become one of the classic clinical papers in medical literature.[173] Bier thought that it would not replace general anesthesia because of the severity of side effects such as nausea, vomiting, dizziness, and headache. He proposed that these undesirable side effects were caused by escape of cerebrospinal fluid from the dural sac. The method whereby Bier arrived at the correct intrathecal dose of cocaine on the first attempt remains a mystery.

After Bier's report, interest in spinal anesthesia spread rapidly. J. B. Seldowitsch[174] successfully provided spinal anesthesia in St. Petersburg on May 11, 1899; Frederick Dudley Tait (1862-1918) and Guido Caglieri[175] (1871-1951) in San Francisco on October 26, 1899; Theodore Tuffier[176] (see Fig. 1-11B) in Paris on November 9, 1899; and Rudolph Matas[177] (1860-1957) (see Fig. 1-11C) in New Orleans on November 10, 1899. By one report, more than 1000 manuscripts relating to spinal anesthesia had been published within 2 years of the original paper by Bier.

Not all researchers agreed on the technique and indications for spinal anesthesia. Tait and Caglieri suggested the use of cervical intrathecal injections for operating on the upper extremities. A. W. Morton[178] reported success with total spinal anesthesia after lumbar puncture for operations on all parts of the body. Thomas Jonnesco[179] reported no adverse effects from 398 spinal anesthetics administered between vertebrae at the thoracic and lumbar levels with a novocaine and strychnine mixture. Jonnesco called the method general spinal anesthesia. Remarkably, in his series there were 14 operations on the skull, 45 on the face, and 25 on the neck. In 1909, Bier[180] claimed that to be successful with spinal anesthesia, the anesthetist should inject the solution only at body temperature and that tropacocaine was preferable to cocaine.

The early reports of cocaine spinal anesthesia mentioned that after injection, patients frequently became restless and excitable, often exhibiting a significant rise in body temperature. One of the first physicians to specialize in anesthesia, S. Ormond Goldan, maintained accurate anesthesia records from several cases of spinal anesthesia with cocaine.[181] His records reveal a typical increase in heart rate, pupil size, and body temperature after cocaine spinal anesthesia. Matas reasoned that these effects were secondary to an action of cocaine on the central nervous system. He learned that mixing 1.5 mg of morphine with cocaine was useful in mitigating these symptoms. In his 1900 report on spinal anesthesia, he regarded a mixture of cocaine and morphine as his standard agent. This report by Matas appears to be among the first attempts to use spinal opioids to enhance neuraxial analgesia.[177] The Japanese anesthesiologist Otojiro Kitagawa[182] (1864-1922) used intrathecal morphine (10 mg) in the same year to treat the chronic painful conditions of two patients.

It is not surprising that serious complications from the spinal technique were soon observed. F. Gumprecht[183] reported 15 cases of sudden death from lumbar puncture in 1900. Several investigators observed respiratory arrest after high spinal injections. After the introduction of routine blood pressure measurements by Cushing in 1903, it was observed that severe hypotension could occur after spinal anesthesia.

The scientific study of spinal anesthesia began within a few years after its introduction. Investigations were undertaken by Arthur E. Barker[184] (1850-1916) to determine factors involved in spread of the local anesthetic within the subarachnoid space. Barker advised meticulous sterile technique and introduced the use of dextrose to produce hyperbaric solutions. His emphasis on gravity as an essential determinant of local anesthetic spread remains an important facet of the spinal technique today.[185] Several researchers reported the dangers of total spinal anesthesia. Gaston Labat[50] and George P. Pitkin contributed clinical observations that improved the safety of spinal anesthesia.

A widely publicized malpractice trial in 1953 had a negative impact on the use of spinal anesthesia.[186] Albert Woolley and Cecil Roe were healthy subjects who received dibucaine spinal anesthetics on the same day in 1947 at the Chesterfield Royal Hospital in England. Permanent painful spastic paraparesis developed in both patients. Although the cause of the paresis was inconclusive, it was thought that the injuries were caused by contamination of the spinal solution by phenol, in which the dibucaine ampules had been immersed for sterilization. The Wooley and Roe case was followed by other reports of paralysis after spinal anesthesia.[187] However, in 1954, a reassuring study of 10,098 spinal anesthetics with only 71 minor neuropathies, most unrelated to the block itself, was published in a widely circulated medical journal.[188] Spinal anesthesia then re-emerged as a safe anesthetic method, provided that attention was directed to meticulous technique.

Consideration has been given to a syndrome characterized by transient paresthesias after lidocaine spinal anesthesia.[189] However, with the introduction of disposable spinal kits and improved techniques, the spinal route of drug administration is now firmly established. Research is continuing on new drugs and methods of delivery. Reports of cauda equina syndrome after the introduction of lidocaine through spinal microcatheters[190] emphasize the importance of careful clinical observations when new methods of spinal delivery are introduced.

Post–dural puncture headache was an annoying problem for the first practitioners and their patients. The exact cause of this reaction was not agreed on for several years. As late as 1924, Labat had suggested removal of cerebrospinal fluid for the treatment of spinal headache. However, an extensive study by Leroy D. Vandam (1914-2004) and Robert Dripps (1911-1974) confirmed Bier's original suggestion that leakage of cerebrospinal fluid through the dural rent was the causative factor.[191]

The use of small-diameter spinal needles has decreased the incidence of spinal headache after spinal anesthesia. However, inadvertent dural puncture with larger needles can sometimes occur during the placement of epidural catheters. An innovative treatment of headache after dural puncture, the epidural blood patch, was suggested by James B. Gormley[192] in 1960 and further described by Anthony J. DiGiovanni and Burdett S. Dunbar[193] in 1970. The blood patch has been reported to be successful in a high percentage of cases and has withstood the test of time as an effective treatment of this condition.

Epidural Analgesia (also see Chapter 51)

Jean Enthuse Sicard (1872-1929) and Fernand Cathelin (1873-1945) independently introduced cocaine through the sacral hiatus in 1901, thereby becoming the first practitioners of caudal (epidural) anesthesia. Sicard was a neurologist and used the technique to treat sciatica and tabes, but Cathelin used the technique for surgical anesthesia. Arthur Läwen[194] (1876-1958), a pupil of Heinrich Braun (1862-1934) and an early proponent of regional anesthesia, successfully used caudal anesthesia with large volumes of procaine for pelvic surgery. It soon became apparent that caudal anesthesia was sufficient for operations on the perineum, but the drug would have to be deposited into the epidural space at higher levels if the surgeon anticipated operating on the abdomen or thorax. Initial attempts to provide epidural anesthesia through needles placed at higher levels were unsuccessful. B. Heile[195] published an extensive study of the epidural space in 1913, but the focus of his final report was on the treatment of neurologic conditions with epidural injections. His unique approach was to enter the epidural space through the intervertebral foramina (a technique that has recently been revived). Tuffier[196] was aware of the need for entry at higher levels but was unable to perfect a reliable technique for lumbar or thoracic epidural injections.

In 1921, Fidel Pagés[197] (1886-1923), a Spanish military surgeon, devised a technique to introduce epidural procaine at all levels of the neuraxis. His method was to use a blunt needle and then feel and hear entry of the needle through the ligamentum flavum. His report of 43 cases of lumbar and thoracic epidural anesthesia represents a landmark article that went unnoticed because of its publication in an obscure medical journal. Pagés died in an automobile accident soon after his report on epidural analgesia, and no students at the time had learned his technique. Pagés had the idea of producing segmental anesthesia through epidural injections, thereby avoiding some of the side effects of complete neuraxial blockade, which occurred after high subarachnoid administration of local anesthetics. He provided the anesthetics himself and then performed the operations, noting that much time was saved with the epidural technique as compared with general anesthesia. Of the 43 cases, it appears that one subject experienced total spinal anesthesia but survived after assisted ventilation.

Achille Mario Dogliotti[198] (1897-1966) (see Fig. 1-11D) described epidural injections of local anesthetics in 1931, apparently without previous knowledge of the work of Pagés. Dogliotti performed extensive studies to determine the spread of solutions within the epidural and paravertebral space after injection. His work launched one of the most valuable techniques in the modern practice of anesthesiology. An important innovation was Dogliotti's method of identification of the epidural space. His 1939 textbook illustrates the use of continuous pressure on the plunger of a saline-filled syringe as the needle is advanced through the ligamentous structures. In contrast to the methods of Corning and Pagés, the Dogliotti technique was reproducible and easily learned. Dogliotti also observed the extent and duration of analgesia after injection into various spinal interspaces.

Initial acceptance of epidural analgesia was slow to develop in North America, although it gained early acceptance in Europe and South America. A. Gutierrez of Argentina became an enthusiastic advocate for the epidural method and collected valuable data on a large series of successful epidural anesthesia. He also developed the "hanging drop" sign, which is still used by some anesthesiologists to identify the epidural space. Dogliotti's anesthesia textbook was translated into English in 1939 and contained an extensive chapter on epidural analgesia. Textbooks by American authors several years later[142,199] contained only a short

description of the technique and considered it a novelty practiced only by those with special expertise. There were some early practitioners of epidural anesthesia in North America. Charles B. Odom of New Orleans published 285 cases of lumbar epidural anesthesia in 1936 and introduced the concept of a test dose to detect intrathecal injection.[200] In Odom's series there was one death attributed to the poor condition of the patient. John R. Harger and coworkers[201] of Cook County Hospital in Chicago reported 1000 cases without a fatality when using single injections of 45 to 50 mL of 2% procaine. Oral Crawford and colleagues[202] reported more than 600 cases of thoracic epidural analgesia for thoracic surgery in 1951, with two deaths.

One major limitation of the neuraxial techniques was the short duration of action of procaine. Bier experimented with the addition of rubber and latex to the spinal anesthetic solution in an attempt to prolong the duration of blockade.[180] These ideas were not expanded on because of complications or lack of effect. To deal with the same problem, William T. Lemmon (1896-1974) used a 17-gauge, malleable, silver needle that was connected through a hole in the operating room table to rubber tubing and a syringe. Injections could then be made at intervals to maintain the spinal block for several hours. Edward B. Tuohy[203] (1908-1959) used a ureteral catheter threaded through a large Huber-tipped spinal needle to provide continuous spinal anesthesia. The Tuohy needle, a simple modification of the Huber needle, was used by him to thread the catheter into the subarachnoid space. Beginning in 1947, Manuel Martinez Curbelo[204] of Havana, Cuba, used the Tuohy needle and a small ureteral catheter to provide continuous lumbar epidural analgesia. He reported 59 successful cases, and in one patient the catheter remained in place for 4 postoperative days with intermittent injections of local anesthetic.

Caudal anesthesia experienced a resurgence in popularity after the report by W. B. Edwards and Robert A. Hingson (1918-1996)[205] in 1942 that analgesia for labor and delivery could be achieved with caudal injections of tetracaine through a malleable needle left in situ within the sacral canal. Their report was widely publicized, and within months the technique was adopted by several hospitals. Although caudal epidural injections had been used for obstetric analgesia for many years, it became apparent that the lumbar approach to the epidural space was more consistent, and it eventually replaced the caudal approach.

Beginning in 1960, coincident with its rising popularity in obstetric anesthesia, the epidural method was taken up by several practitioners in North America. Philip R. Bromage and John J. Bonica performed several studies on epidural dose-response relationships and the hemodynamic changes that followed initiation of the block. Textbooks soon followed that introduced epidural analgesia into the operating room.[206] Although Dogliotti thought that general anesthesia was contraindicated after the initiation of epidural blockade, Massey Dawkins (1905-1975), Philip R. Bromage, and later Michael Cousins[207] discussed the advantages of providing general anesthesia during prolonged surgery while extending epidural analgesia throughout the surgical procedure and into the postoperative period. Although lumbar epidurals were widely used for postoperative pain relief, problems with ambulation and inadequate analgesia led to the current practice of placing epidural catheters between the appropriate interspaces to provide selective antinociception along the surgical incision site.

A report in 1979 by J. Wang and associates[208] demonstrated long-lasting analgesia from the intrathecal administration of morphine in eight patients with cancer pain. This clinical study had firm groundwork from previous basic studies on the spinal effects of opioids in animals. In 1976, Yaksh and Rudy[209] reported that intrathecal morphine produced spinal analgesia in rats. Duggan and North[210] demonstrated evidence of spinal analgesia after iontophoretic application of morphine into the dorsal horn region of the spinal cords of animals. Autoradiographic studies demonstrated a high density of opioid receptors in the substantia gelatinosa of the spinal cord.[211]

The use of spinal opioids spread rapidly after the initial report by Wang and coworkers.[208] Samii and colleagues[212] confirmed that selective opioid spinal analgesia occurs in humans. Cousins and associates[213] noticed that 1 to 2 mg of intrathecal morphine injected into the thoracic intrathecal region relieved the pain of breast or lung cancer for more than 24 hours. Behar and collaborators[214] reported epidural opioid therapy in 1979. The explosive interest in neuraxial opioids that followed these reports was equal to the enthusiasm after the initial report of cocaine spinal anesthesia. The use of epidural catheters to provide long-lasting pain relief after surgery led to the formation of acute pain services.[215] With special attention to drug concentrations and rates of infusion, patients were able to recuperate without pain and ambulate on the first postoperative day, even after extensive thoracic, abdominal, and orthopedic operations. The special advantage of epidural opioids was the synergistic effect that they exhibited with local anesthetics, which allowed a marked decrease in the dose of both drugs to achieve the same level of analgesia.[216]

Intravenous Anesthetics

The development of intravenous anesthetics has been an important component of anesthetic management for more than 70 years (see Chapters 26 and 27). Before the introduction of rapidly acting intravenous agents, induction of general anesthesia necessarily required inhalation of gases or vapors, an unpleasant experience for some patients.

Pierre-Cyprien Oré (1828-1891) performed the first successful attempt at intravenous anesthesia in 1872 by using chloral hydrate to anesthetize a human subject. Although he believed it was superior to chloroform, his contemporaries did not adopt the method. Intravenous paraldehyde was briefly used as an anesthetic during and after World War I. At the same time, the combination of intravenous morphine and scopolamine gained wide popularity, particularly in obstetric anesthesia. The method became known as twilight sleep, but this drug combination was slowly abandoned because of unpredictable side effects when given to some patients. Tribromoethanol (Avertin) was originally promoted as a full anesthetic agent to be administered rectally. Although rectal administration of agents had been promoted by Pirogoff, Gwathmey, and others, the use of rectal tribromoethanol fell into disfavor when rectal ulcerations were reported after use of the agent. Thereafter, tribromoethanol was used briefly as an intravenous agent, but because it had a prolonged duration of action and produced profound respiratory depression and probable hepatotoxicity, other suitable intravenous agents were sought.

Adolf von Baeyer discovered the first barbiturate, barbituric acid, in 1864, but the drug had no sedative properties. It is said

that Baeyer celebrated discovery of the compound on Saint Barbara's Day, and he coined the word barbiturate as a combination of Barbara with urea because barbituric acid results from the combination of malonic acid and urea. The first sedative barbiturate was synthesized in 1903 by Emil Fischer (1852-1919) of Berlin, but short-acting intravenous agents such as hexobarbital were not introduced until nearly 30 years later. Helmut Weese[217] (1897-1954), considered by many to be the originator of successful intravenous anesthetic methods, reported several thousand cases of hexobarbital use in 1932. Sodium thiopental followed hexobarbital in 1934, and the first detailed analysis of its use was described by John Lundy of the Mayo Clinic.[218] The use of thiopental was a further refinement of his earlier concept of balanced anesthesia, whereby anesthesia is achieved with the use of multiple agents. According to Lundy, general anesthesia was safer with the use of multiple agents because the dose of any one particular agent was smaller and fewer side effects were observed.

It was soon learned that thiopental could be dangerous to administer in certain circumstances. When the drug was used for induction of anesthesia in injured personnel after the bombing of Pearl Harbor in 1941, the frequent occurrence of sudden death emphasized the profound depressant effect that this drug has on the cardiovascular system.[219] Later analysis of the use of thiopental at Pearl Harbor, however, did not implicate the drug as the cause of the high mortality rate observed at that time.[220] The only other commonly used short-acting barbiturate is methohexital, an oxybarbiturate that has similar depressant effects on the circulation. Because of its unique proconvulsive effect, methohexital is used as an anesthetic for electroshock therapy.

There have been several attempts to replace the barbiturates with shorter-acting drugs that have less cardiovascular depression. Some of these drugs, such as althesin,[221] propanidid, and eltanolone, were withdrawn from clinical use because of unwanted side effects. Etomidate, an intravenous anesthetic introduced in 1973 that was used to induce anesthesia, produces only minimal hemodynamic depression and has found use in patients with hypovolemia and those with significant cardiovascular disease.[222] Etomidate can cause undesirable myoclonic movements during induction in some patients.

The benzodiazepines midazolam, diazepam, and lorazepam are useful intravenous agents that relieve anxiety without the same degree of sedation produced with the barbiturates. Experimental studies on this class of drugs began in 1933 at the University of Cracow in Poland, with the first clinically useful drug, chlordiazepoxide (Librium), introduced in 1960. Diazepam (1963) and midazolam (1978) followed. A specific antagonist can be used to treat overdosage.[223]

Ketamine was synthesized in 1962 as an alternative to phencyclidine, a drug that resulted in severe psychological effects in the postoperative period. Ketamine was one of 200 phencyclidine derivatives that were studied, and it was introduced as an anesthetic in 1966.[224] It was initially used intravenously or intramuscularly as a complete agent by itself, but reports of postoperative hallucinations led to re-evaluation of its use, and it is now typically used only in combination with other sedative agents. Ketamine is a unique agent in the armamentarium of the anesthesiologist because it does not depress the cardiovascular system, even when used in full anesthetic doses.

Propofol, introduced clinically[221,225] in 1977, is an alkylphenol compound that has some advantages over thiopental. It appears to have antiemetic properties and suppresses laryngeal reflexes to a greater extent than thiopental does, thus allowing easy placement of supraglottic airways. It has achieved widespread use since its introduction, partially because of its rapid recovery profile. Propofol is often administered as a continuous infusion for general anesthesia, with or without the addition of inhaled anesthetics. When combined with analgesic agents such as opioids, propofol can provide all the components of satisfactory general anesthesia. This method, often called total intravenous anesthesia (TIVA), can eliminate the need for any gaseous or volatile agents. Propofol is a profound cardiovascular depressant, and it can produce significant pain on injection.

Although intravenous opioids were once considered unsafe in the private rooms of hospitals, a modality of administration called patient-controlled analgesia (PCA) is now routinely used in most hospitals. The rationale is that because pain is a subjective experience, only patients can assess the need for analgesics and balance that with their experience of side effects. Overdose is obviated by lock-out intervals and by the inability to perform the task of drug administration as somnolence ensues. Methods for intravenous PCA therapy in the postoperative setting were developed by anesthesiologists more than 30 years ago,[226] but they are now used by several specialty groups within the hospital.

Muscle Relaxants

Neuromuscular blocking drugs or muscle relaxants are firmly entrenched as an integral part of everyday anesthetic practice (see Chapter 29). Anesthesia providers practiced for nearly 100 years without these drugs, but it would be difficult to provide the same level of anesthetic service today without their use.

Initial Contact with Arrow Poison

Homer (*Odyssey*, I, 260) and Virgil (*Aeneid*, IX, 772) mention poisoned arrows. The word *toxin* is derived from the Greek root *toxon* ("bow"). Medical fascination with the specific arrow poison now called curare began nearly 500 years ago when the first returning explorers from South America told of a poisoned arrow that was used in warfare and to kill game. In 1505, Pietro Martyr d'Anghiera (1457-1525), an Italian monk who visited South America in the early 16th century, wrote the following:

> *This Indian King layd wait for oure men . . . set on them with about seven hundred men armed after theire maner, although they were naked. For only the King and his noblemen were appareled . . . So fiercely assayling oure men with theire venomous arrowes that they slewe of them fortie and seven . . . for that poyson is of such force, that albeit the wounds were not great, yet they dyed thereof immediately.*

Sir Walter Raleigh[227] (1552-1618) was one of the first to report on the wonders of the drug, which his first lieutenant, Laurence Keymis, called ourari, the first English attempt to reproduce the Macusi Indian pronunciation of the poison. Remarkably, the flesh of the poisoned animal was eaten with impunity. The native inhabitants were greatly impressed with gunpowder but noticed that the noise from guns frightened the game, and they

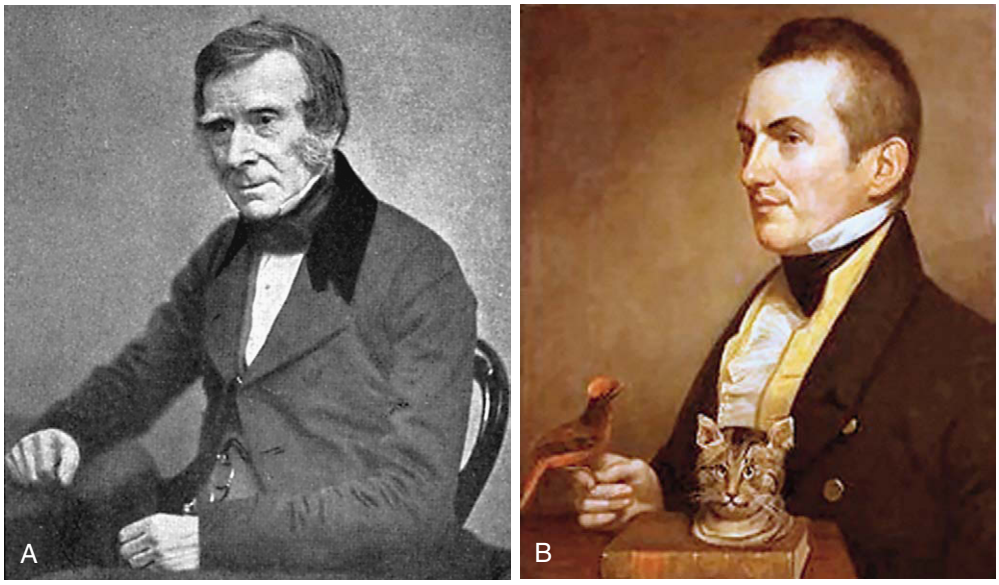

Figure 1-12 Benjamin Brodie (**A**) and Charles Waterton (**B**) collaborated in demonstrating that animals could survive curare poisoning if artificial ventilation was provided. *(Courtesy of the National Library of Medicine, Bethesda, MD.)*

preferred a poison-tipped arrow that was sent quietly from a blowgun. Initial reports indicated that the poison was made from a mixture of rat bones and bark.

Charles-Marie de la Condamine (1701-1774) was the first to bring creditable samples back to Europe. His samples were used by Richard Brocklesby (1722-1797) to demonstrate that the heart of a cat continued to beat for 2 hours after it was apparently dead from curare poisoning. The Florentine Abbot Felix Fontana (1720-1805) injected the drug directly into the exposed sciatic nerve and observed no effect. He concluded that the curare impaired irritability of the muscle.[228]

Mechanism of Action

The collaborative project of Benjamin Brodie (1783-1862) (Fig. 1-12A) and Charles Waterton (1783-1865) (see Fig. 1-12B) initiated our modern understanding of muscle relaxants.[229] Benjamin Brodie was the principal figure of English surgery at that time, and Waterton was the eccentric Squire of Walton Hall, near Wakefield, England. Waterton had traveled extensively, including several expeditions into British Guiana, where he owned property and eventually obtained several samples of the arrow poison.

In 1814, Brodie and Waterton demonstrated that an animal could survive an injection of curare provided that ventilation was continued after injection. For this famous experiment, it seems that Waterton supplied the curare and the animal—a donkey—and Brodie supplied the experimental idea. They injected the donkey with poison in the shoulder, and it was immobilized within 10 minutes.

> *An incision was then made in its windpipe, and through it the lungs were inflated for two hours, with a pair of bellows. The ass held up her head, and looked around, but the inflating being discontinued, she sunk once more in apparent death. The artificial respiration was immediately recommenced and continued without intermission for two hours. This saved the ass from final dissolution: she rose up and walked about; she seemed neither in agitation nor pain.*

Waterton named the donkey Wouralia and nurtured her on his estate, where she died 25 years later. Curiously, in their later correspondence, neither partner mentions the collaboration of the other individual. Waterton's book, titled *Wanderings in South America* and dated 1879, contains an extensive description of the preparation and use of curare, as well as the manner of use of the blowpipe, which he called the "extraordinary tube of death."

The experiment performed by Claude Bernard[230] (1813-1878) demonstrating the action of curare at the junction between the nerve and muscle was deceptively simple (Fig. 1-13). In his studies with curare, Bernard used the drug to open a new area of investigation, the physiology and pharmacology of the junction between the nerve and muscle. Experiments on the specialized apparatus where the action of curare is primarily located, the neuromuscular junction, were begun by one of Bernard's students, Willy Kuhne (1837-1900).

Introduction into Clinical Medicine

Waterton suggested the use of his woraria for the treatment of tetanus and rabies, and the few successful trials of the small samples of curare that were available then were used to treat these conditions.[231] For the next 175 years in Europe and North America, the drug remained a curiosity with no definite purpose. The medical community ignored an early report from 1912 suggesting its use to provide muscular relaxation during closure of the abdomen:

> *Thus far I have used solution of curarine up to 2% by intramuscular injection. With this dose, closure of the abdominal wall was achieved readily. There is not sufficient curare available, so I have not yet been able to ascertain the correct dose for this purpose.*

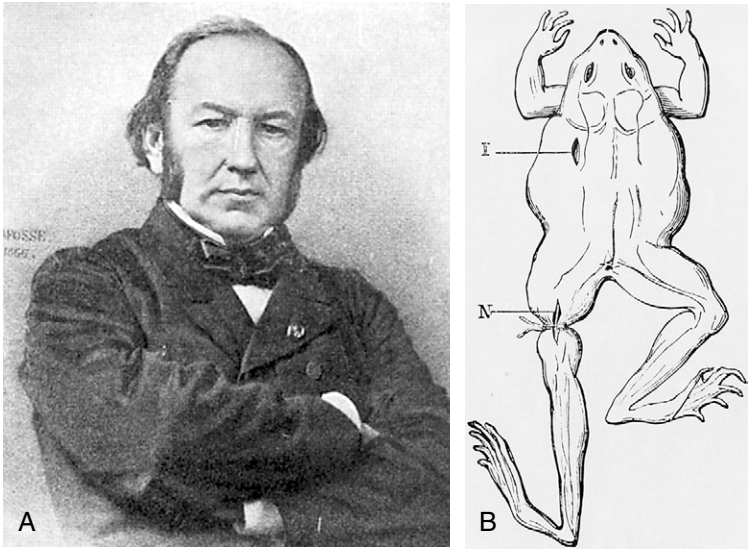

Figure 1-13 A, Claude Bernard (1813-1878) was one of the greatest physiologists of all time and made several contributions to the anesthesia literature. Bernard was born in Saint Julien, France, and educated in Paris. After medical training, he became an assistant to François Magendie, the leading physiologist of that era. He never practiced medicine, but his research contributions pervade every field of modern medicine. In 1855, he succeeded Magendie as Professor of Physiology at the College de France. A special Chair of General Physiology was created for him at the Sorbonne. **B,** Experiment by Claude Bernard illustrating the site of action of curare at the junction of the nerve and muscle. A ligature prevented injected curare (I) from reaching the muscle of the frog's hind limb. After systemic injection of curare, Bernard observed that the limb contracted in response to a neural stimulus (N) applied above the ligature. The opposite limb would contract only to direct electric stimulation of the muscle but not to a neural stimulus. He showed that the nerve and muscle were unaffected but that the connection between the nerve and muscle was blocked.[230] *(Courtesy of the National Library of Medicine, Bethesda, MD.)*

The active principle was eventually found in several plant species, primarily *Chondodendron tomentosum* and *Strychnos toxifera* (see Fig. 1-9C). King isolated the active compound from the *Chondodendron* species that he called D-tubocurarine in 1935.

Curare was initiated into clinical practice by several individuals, beginning with Richard C. Gill[232] (1901-1958), whose contributions, like those of Waterton, arose out of a strong sense of wanderlust, combined with an interest in primitive medicine. As a young man growing up in Washington, D.C., Gill was expected to follow his father and older brother into the practice of medicine. Instead, his degree in 1929 from Cornell University was in English, and his career as a teacher was brief. He took a position with a rubber company in Lima, Peru, but with the stock market crash of 1929, he consolidated his savings and, together with his wife Ruth, purchased 750 acres of land in the Ecuadorian jungle. By 1930, Richard and Ruth Gill were the proud owners of a large hacienda on the Eastern slopes of the Andes,[233] where they raised tropical fruits and vegetables and studied the local Indian customs.

While returning to the United States in 1932 for a brief holiday, Gill fell from his horse and a neurologic syndrome, initially thought to be multiple sclerosis, developed and eventually progressed to a painful spastic disorder. His neurologist Walter Freeman (1895-1972) advised him that the arrow poison from South America might help cure his painful spasms, but it was nearly impossible to obtain the drug. Procuring curare and other herbal remedies thereafter became the focus of Gill's life until his death in 1958 at 57 years of age. Gill obtained funding from Sayre Merrill, a wealthy Massachusetts businessman, for an expedition to retrieve indigenous medicinal plants from the Ecuadorian jungle. The primary aim was to retrieve adequate amounts of the crude curare preparation to begin clinical trials with the drug in cases of spasticity. It is noteworthy that Gill was in a unique position to obtain large quantities of curare because the Indian "medicine men," who jealously guarded the secrets of making the poisonous darts, trusted him.

After 4 years of planning, Gill's neurologic condition had improved, and the expedition was launched. In 1938, Richard and Ruth Gill returned with 11 kg of a crude curare mixture and 75 other indigenous medicinal preparations obtained from the Indian shamans. Sadly for the Gills, there was no interest in their jungle remedies. Initially, even the curare failed to generate any interest. Freeman was acquainted with Abram E. Bennett, a psychiatrist at the University of Nebraska who had expressed interest in the drug. Bennett had the crude concoction standardized by the pharmacologist A. R. McIntyre but failed to find any prolonged benefit for it in cases of spasticity (Fig. 1-14A).

Bennett then turned his attention to the use of curare during Metrazol convulsive therapy, which at that time was thought to be therapeutic for depression and mania but was complicated by a high incidence of bone fractures and joint dislocations. By then, E. R. Squibb and Sons had taken the remainder of Gill's curare and was distributing a small quantity of the drug as Intocostrin, an unpurified form of D-tubocurarine. Bennett[234] reported on the successful use of Intocostrin in cases of Metrazol convulsive therapy in 1940. His method was to administer Intocostrin until a head lift was impossible and then give Metrazol. Surprisingly, he reported no respiratory embarrassment and no complications and thought that patients preferred his new method.

E. R. Squibb and Sons, together with their anesthesiologist consultant Lewis H. Wright (1894-1974), were convinced that the true home for curare was with the anesthesiologist, and in 1940, with some urging, Wright convinced Harold R. Griffith (1894-1985) (see Fig. 1-14B) of Montreal, Canada, to use the drug during general anesthesia when muscular relaxation was required by the surgeon. Previous attempts by Wright to generate interest in the drug had failed until Griffith agreed to use Intocostrin during cyclopropane anesthesia. Griffith and his junior colleague Enid Johnson reported the successful use of curare in 43 patients to provide muscular relaxation during surgical anesthesia in 1942.[235] They concluded that the agent provided relaxation without interfering with respiration. This was followed by a study in Iowa by Stuart Cullen[236] (1909-1979), who enthusiastically supported use of the drug to provide muscular relaxation without the need for deep levels of general anesthesia. T. Cecil Gray[237] (1913-) of Liverpool popularized the drug in England and developed an anesthetic technique consisting of profound muscular paralysis and nitrous oxide–oxygen anesthesia. Phyllis Harroun[238,239] used

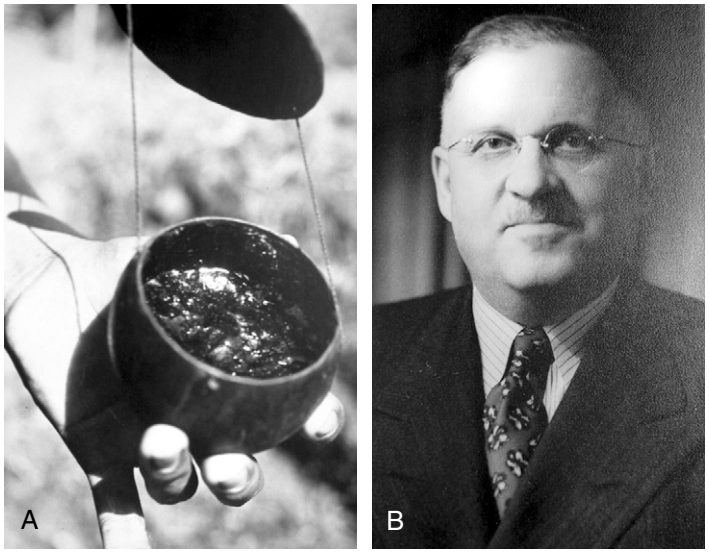

Figure 1-14 A, Richard Gill returned from Ecuador in 1938 with 11 kg of a dark tarlike paste from which Squibb and Sons, Inc., prepared the sterile, injectable solution Intocostrin. **B,** Harold Griffith and Enid Johnson (not shown) used Intocostrin in 43 abdominal surgeries with success in 1942. *(Courtesy of the Guedel Memorial Anesthesia Center, San Francisco, CA.)*

high-dose curare, nitrous oxide, and morphine for thoracic surgery, thereby providing muscular relaxation without the use of flammable agents, a novel technique at the time. In 1947, William Neff used nitrous oxide and oxygen supplemented with meperidine and curare and reported favorable anesthetic conditions. Although Griffith and Cullen had both maintained spontaneous respiration, the technique of Harroun, Gray, and Neff provided profound muscular paralysis with controlled respiration.

In a report from 1954, Henry K. Beecher (1907-1976) and D. P. Todd[240] concluded that the use of curare led to a nearly sixfold increase in postoperative complications and deaths. Similar cautionary articles followed their report but were refuted by others. Churchill-Davidson and Richardson[241] advised in 1952 that a useful technique for monitoring the degree of neuromuscular blockade was to stimulate a peripheral nerve and observe the resulting muscular contraction. Specific devices designed to stimulate the ulnar nerve were promoted in the 1960s.[242,243] Various modifications of the stimulus array to ensure complete return of neuromuscular function before allowing the patient to breathe unassisted have been described since that time.[244]

Since the introduction of curare into anesthesia practice, numerous additional neuromuscular blocking agents have been developed. Gallamine triethiodide was introduced in 1947, but like curare, it had undesirable effects on the autonomic nervous system, which prompted a search for other drugs. Exploration of the structure-activity relationships of plant alkaloids led to development of the methonium compounds. In 1949, the neuromuscular blocking activity of one of this class of drugs, succinylcholine, was recognized,[245] and it was introduced clinically soon thereafter.[246] Daniel Bovet (1907-1992) won the Nobel Prize in 1957, in part related to his discovery of gallamine and succinylcholine. Succinylcholine and other similar agents were shown to depolarize the end plate, thereby preventing additional motor contractions as a result of activity in the motor nerve. Advances in chemistry allowed the synthesis of neuromuscular blocking agents that lacked the autonomic effects of curare. Since the discovery of curare, nearly 50 neuromuscular blocking agents have been introduced, but many of these drugs have been abandoned because of undesirable side effects. Drugs that have maintained favorable safety records are steroid-based synthetic neuromuscular blocking agents such as pancuronium (1966),[247] vecuronium (1980),[248,249] and rocuronium (1991),[250] and they have replaced older drugs such as curare and gallamine in the modern drug armamentarium.

Anesthesia Apparatus

Early Delivery Systems

For the first public demonstration of ether anesthesia, Morton used a specially constructed glass bottle with an attached mouthpiece (see Chapter 25). In England, John Snow developed a new type of ether inhaler and took up the practice of ether anesthesia as a full-time endeavor. His apparatus provided valves to prevent rebreathing, and although he experimented with methods for absorption of carbon dioxide, he did not develop it into a clinically useful technique. John Snow was aware of the difficulties associated with the simple mouthpiece that was used with a noseclip by Wells and Morton. In his book on ether published in 1847, he states the following:

> *For some of the adult patients, after they lost their consciousness, made such strong instinctive efforts to breathe by the nostrils, that the air was forced through the lachrymal ducts, and occasionally they held the breath altogether for a short time, and were getting purple in the face, when the nostrils had to be liberated, for a short time, to allow respiration of the external air, and thus a delay was occasioned.*

Many types of anesthesia machines were developed to provide anesthesia via the insufflation method, whereby a small catheter was placed with its tip near the carina to deliver air and ether or chloroform. These continuous-flow machines did not rely on respiratory movement for oxygenation and were based on the work of Samuel Meltzer (1851-1920) and John Auer (1875-1948), who demonstrated their safe use in animals.[251] It was one

solution to the problem of pneumothorax and respiratory decompensation during thoracic surgery. C. A. Elsberg's (1871-1948) continuous-flow machine was described in 1911 and went through several modifications.[252] The popular Shipway model was used by Francis E. Shipway (1875-1968) to provide anesthesia to King George V of England for rib resection and drainage of empyema, a feat for which Shipway was knighted. In retrospect, it is clear that these continuous-flow machines were not capable of eliminating carbon dioxide in all cases,[253] and anesthesia machines eventually were developed that allowed to-and-fro respiration through one large-bore endotracheal tube.

Compressed Gases and Reducing Valves

Of major importance in design of the modern anesthesia machine was compression of gases in metal cylinders. Oxygen and nitrous oxide were available under compression as early as 1885 through the manufacturers S. S. White of Philadelphia and Messrs. Coxeter of London. This allowed the development of compact machines capable of prolonged delivery of anesthetics without the cumbersome feature of low-pressure reservoirs. Frederick Hewitt's first anesthetic gas machine designed for administering oxygen and nitrous oxide mixtures had two nitrous oxide cylinders and one oxygen cylinder; the mixture was fed into a large breathing bag through a double cylinder yoke.[98] Oxygen concentrations could be adjusted at the stopcock near the mask. His preferred oxygen concentrations were 5% to 8%. With the addition of oxygen, he attempted to "dispense with cyanosis, jerky and irregular breathing, deep stertor and clonic movements of the extremities."

Invention of the reducing valve is accredited to Jay Albion Heidbrink (1857-1957), an anesthesiologist from Minneapolis who observed that the opening from high-pressure cylinders often froze closed as the gases were released. He described a valve that reduced the high tank pressures to working pressures and incorporated this device into his Heidbrink Anesthetizer. In Germany, Heinrich Drager (1847-1917) and his son Bernhard Drager (1870-1928) developed reducing valves to control an even, accurate flow of carbon dioxide gas drawn from beer cylinders, and these valves were later used in the early anesthesia machines. Further refinements to the early machines were added by James T. Gwathmey and H. Edmund G. Boyle (1875-1941), chiefly through the addition of bubble-through heated water baths for estimation of gas flow. The Boyle machine passed various amounts of oxygen through ether with a "water-sight" meter. This flow meter estimated the flow through the vaporizer from how many of the holes were generating bubbles. Heidbrink further improved the flow meter by using an inverted float in a tube of varying taper with calibrations marked on the side. Rotating floats, also called rotameters, have slanted grooves cut into the rim that cause them to rotate, and they are more accurate than ball or nonrotating floats. Rotameters were introduced in 1908 by Karl Kuppers and first used in anesthesia in 1910.

Carbon Dioxide Absorption

Anesthesiologists from the first half of the 20th century were not privileged to visit just one hospital during a day's work. Visits to several institutions might take place in a single day, with the practitioners bringing their own delivery systems and drugs with them as they traveled. Understandably, portability and elimination of waste were a priority because these anesthesiologists paid for the agents themselves. One development that conserved gases and vapors was the use of systems that absorbed expired carbon dioxide and allowed rebreathing of expired gases.

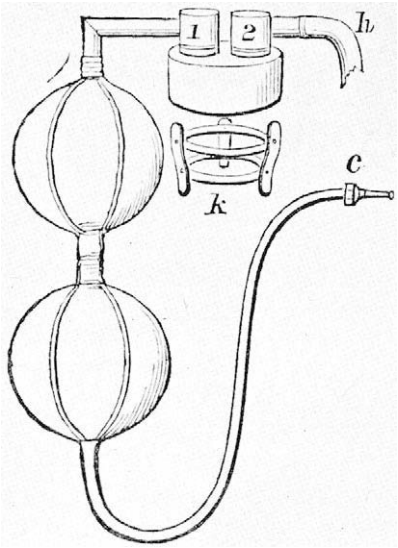

Figure 1-15 Alfred Coleman's economizing device. The anesthetic gases entered the lower bag and passed into the upper bag through a one-way valve. Gases were inhaled and exhaled through the tube (h) and passed over a lime container (1, 2) held in a frame (k) that eliminated carbon dioxide; c, gas inlet. The conserved gas in the upper bag was used during a later anesthetic administration. *(From Coleman A: Mr. Coleman's economizing apparatus for re-inhaling the gas. Br J Dent Sci 12:443, 1869.)*

Several ineffectual attempts were made to introduce carbon dioxide absorption methods in the 19th century. John Snow and Alfred Coleman (1828-1902) were motivated to conserve anesthetic gases that escaped into the atmosphere through nonrebreathing valves. Coleman devised a system of absorbing carbon dioxide by passing the expired gases over slaked quick lime.[254] The recovered gases were then used for subsequent anesthetics (Fig. 1-15). Franz Kuhn (1866-1929) described soda lime absorption of exhaled carbon dioxide in 1905, but the report did not attract attention.

Dennis E. Jackson (1878-1980) demonstrated the use of soda lime absorption to maintain stable levels of anesthesia for several hours in animals with minimal ether consumption.[255] The animals were given additional oxygen to meet metabolic needs, but the anesthetic gases were rebreathed, thereby resulting in economy and improved maintenance of body temperature and airway humidity. In 1923, Ralph Waters (1884-1979) (see Fig. 1-18B), then working as an anesthesia practitioner in Sioux City, Iowa, contacted Jackson and devised a soda lime canister for clinical use.[256] The canister was attached to a breathing hose close to the face, and although it was cumbersome to use, the device was widely distributed. The in-line soda lime canister launched the academic career of Waters, who later became one of the most prominent figures in anesthesiology during the first half of the 20th century. In 1930, Brian C. Sword[257] altered the Waters canister by attaching it to the chassis of a movable cart with two hoses directed to the airway, one for inspired gases and one for exhaled gases.

Controlled Vaporizers

With the introduction of more potent volatile anesthetics such as halothane it became important to control the concentration of inspired vapor carefully. To solve this problem, Lucien Morris[258] invented the copper kettle to vaporize liquid anesthetics. Its advantage rested on the fact that as the agent was vaporized, there was little change in the temperature of the anesthetic liquid. The copper kettle could be used with any agent provided that the practitioner was cognizant of the vapor pressure of the agent and the flow rates of the inspired gases. Without the addition of diluent gases such as nitrous oxide or oxygen, the copper kettle could deliver lethal concentrations of vapor. The vaporizers in common use today use bimetallic strips that bend as the temperature drops and permit more fresh gas to enter the vaporizing chamber. Vaporizers have been designed for all the agents in use today, including halothane, enflurane, isoflurane, desflurane, and sevoflurane. Modern anesthesia machines are also equipped with scavenging systems designed to minimize escape of anesthetic vapors and nitrous oxide into the operating room. Although controversial, some studies have shown that daily exposure to anesthetic vapors in low concentrations can have deleterious side effects.

Ventilators in the Intensive Care Unit

The earliest ventilator, the Fell-O'Dwyer apparatus, was described in 1892.[259] It was used as early as 1896 to provide respiratory support in cases of opium poisoning. Rudolph Matas, a surgeon in New Orleans who contributed significantly to the early development of regional anesthesia in the United States, was one of the first to use the Fell-O'Dwyer ventilator during thoracic surgery.[260] During the polio epidemic, thousands of afflicted patients were kept alive with the Drinker respirator,[261] often referred to as the *iron lung*, a negative-pressure device that surrounded the patient and provided air movement into and out of the lungs. A Swedish ventilator called the Spiropulsator was introduced in 1934 and modified in 1947 by E. Trier Moerch (1908-1995).[262] This ventilator used a piston pump to deliver a fixed volume of gas. Ventilators today are usually an integral part of the anesthesia machine and direct compressed air into a rigid container containing a bellows that inflates the lungs. Bjørn Ibsen[263] (1915-), a Danish anesthesiologist, initiated the concept of intensive care units in the early 1950s to care for polio patients and guided the transition from iron lungs to modern ventilators. Intensive care units have since become an integral part of the modern hospital, with anesthesiologists actively involved in their daily operation.

Stress-Free Anesthesia

Procedures before the discovery of anesthesia were necessarily of short duration. Raper relates that surgical cases lasting longer than 20 minutes would usually result in death of the patient because the stress associated with such intense nociception would exhaust the patient's reserves. Highly stressful procedures such as abdominal surgery were rarely attempted before 1846. Ephraim McDowell[264] (1771-1830), a rural surgeon from Kentucky, performed the first successful intraperitoneal procedure when he excised a 10-kg ovarian cyst from Mrs. Jane Todd Crawford in 1809. McDowell's publication of the case achieved for him a small measure of fame, unusual for a rural practitioner. However, intraperitoneal procedures are among the most highly stressful operations, and McDowell's accomplishment was rarely repeated. The first successful upper abdominal procedure occurred only after the advent of general anesthesia. Theodor Billroth (1829-1894) performed the first gastrectomy with chloroform anesthesia on January 29, 1881.

The idea that reduction of perioperative stress had a beneficial effect on recovery was championed by George W. Crile (1864-1943), chief surgeon at the Cleveland Clinic at the beginning of the 20th century. Crile's operative technique was to infiltrate all tissues with dilute procaine before incision. Patients were lightly anesthetized by mask inhalation of nitrous oxide and oxygen.[265] He describes these concepts of stress-free anesthesia in his book *Anoci-Association*, published in 1914.[266]

An early devotee of Crile's ideas was the prominent neurosurgeon Harvey Cushing[267] (1869-1939), who promoted the use of regional blocks before emergence from ether anesthesia to ensure a smooth postoperative course. Cushing was the first surgeon to use blood pressure measurements on his patients after he learned the Rovi-Rocci method in Italy (Fig. 1-16). Accurate anesthetic records were maintained during Cushing's cases and confirmed his opinion that shock could be prevented by careful attention to avoiding the stresses associated with surgery.

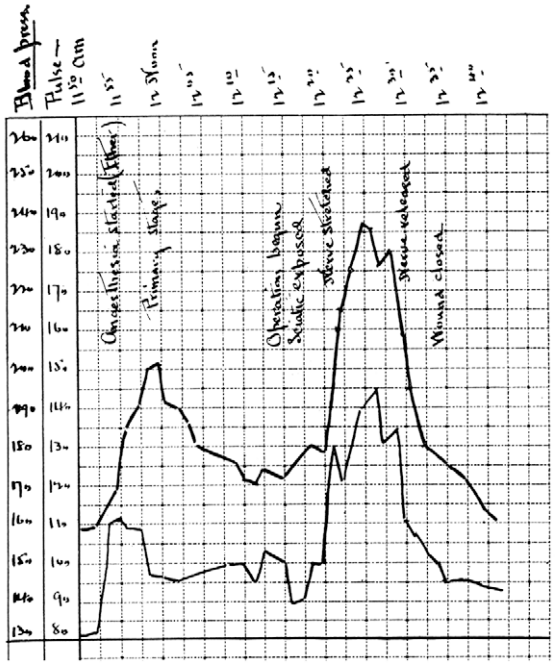

Figure 1-16 One of Harvey Cushing's early anesthesia records shows systolic blood pressure (*top tracing*) and pulse rate (*bottom tracing*). The first rise in blood pressure occurred during the excitement phase of ether induction, and the second rise occurred during the release of adhesions of the sciatic nerve. *Vertical lines* take place 2.5 minutes apart. Systolic blood pressure rose to greater than 230 mm Hg during the operation. Cushing was an early proponent of regional anesthesia, possibly stemming from his observations on blood pressure and heart rate.[267] *(From Cushing H: On routine determination of arterial tension in operating room and clinic. Boston Med Surg J 148:250-256, 1903.)*

Crile's ideas have had a significant impact on how the modern anesthesiologist defines general anesthesia. In 1957, P. Woodbridge[268] defined general anesthesia as consisting of four components: (1) sleep or unconsciousness, (2) blockade of undesirable reflexes, (3) motor blockade, and (4) sensory blockade. These ideas have been discussed and modified by M. Pinsker[269] into three components: (1) paralysis, (2) unconsciousness, and (3) attenuation of the stress response. Lundy's balanced anesthesia is another formulation of the idea that several drugs can be used in combination to produce the state of unconsciousness and analgesia that we define as general anesthesia.

An enduring question during the past century, since Crile's introduction of the concept of stress-free anesthesia, has been how to evaluate the analgesic component of the ideal general anesthetic. Michael Roizen[270] (1947-) observed in 1981 that general anesthetics did not prevent the increase in sympathetic activity in response to a skin incision, even in concentrations that prevented movement. Surgical stimulation often results in intraoperative hypertension and tachycardia, with the corollary that interventions that prevent these hemodynamic reflexes provide "analgesia." Hemodynamic instability was of marginal significance until surgeons began to operate on patients with significant ischemic heart disease. Studies have demonstrated that perioperative β-adrenergic blockade reduces the risk for perioperative myocardial infarction in patients at risk for this complication.[271]

It became apparent that intravenous opioids were highly successful in ablating the hemodynamic markers of stress. Edward Lowenstein and coworkers[272] used large doses of morphine to stabilize the heart rate and blood pressure during cardiac surgery. In 1967, the short-acting opioid fentanyl was introduced to provide intraoperative hemodynamic stability. Theodore H. Stanley and colleagues[273] reported its successful use in large doses for cardiac surgery without the side effect of histamine release that sometimes occurs after administration of morphine. Other short-acting opioids tailored for the anesthesiologist have been added since that time. Alfentanil, sufentanil, and remifentanil have different pharmacokinetic profiles that make them suitable agents for selected procedures. Naloxone, a specific antagonist for this class of drugs, was first used clinically in 1971.[274] Increased understanding of opioid pharmacology has opened up a new role for anesthesiologists, including acute pain management. Rapid detoxification of opioid addiction by using general anesthesia combined with opioid antagonism is a new technique that if combined with judicious follow-up, can be a useful treatment of this condition.[275]

The combination of opioids with tranquilizers such as phenothiazines and butyrophenones provides a form of anesthesia called neuroleptanesthesia, which was introduced by DeCastro and Mundeleer[276] in 1959. Patients administered this form of anesthesia are immobile and tranquil and have stable hemodynamics, even during major surgical procedures. One goal of this technique is to block the autonomic and endocrine response to stress. This unique method of providing anesthesia is another technique for ablating the stress response, but unless other agents such as nitrous oxide or other intravenous agents are administered, there can be a high incidence of awareness. Side effects from dopamine antagonism, such as dysphoria and uncontrolled extrapyramidal motor movements, have limited the widespread use of neuroleptanesthesia.

During the past 30 years, several investigators began a series of studies to measure markers of the stress response during and after surgery. It was learned that during major surgery, patients anesthetized with traditional vapor anesthetics, with or without opioids, displayed increased levels of catabolic hormones postoperatively.[77] Significant elevations in catecholamines and in adrenocorticotropic hormone, cortisol, antidiuretic hormone, and growth hormone were observed. Various methods of preventing postoperative catabolism have been under investigation for several years. The resulting catabolic state is thought by some to delay recovery and, with some operations, can be prevented with the use of neuraxial blockade.[77,277,278] It is apparent from recent reviews on this subject that the formulations of George Crile are still valid 100 years after he promoted them and are likely to be the subject of further studies in the future.

Airway Management and Resuscitation

Masks and Airways

Ventilation during anesthesia was managed without specialized airway devices for more than 50 years after Morton's discovery, and a survey of anesthetic complications during this era attests to the relative safety of inhalation techniques in spontaneously breathing patients (see Chapters 50 and 93). Deaths occurred during this era, and in some reports the anesthetic death rate was alarmingly high, but an obstructed airway was rarely mentioned as the primary cause of death. Friedrich von Esmarch[279] described the jaw thrust (Fig. 1-17) as a lifesaving maneuver in some cases of airway obstruction that resulted from chloroform or asphyxia:

> *Press the lower jaw forwards with both hands by placing the forefingers behind the ascending ramus . . . by this movement the hyoid bone and root of the tongue, and the epiglottis are drawn forwards, and the entrance to the larynx is thus freed from obstruction.*

In 1874 the same maneuver had been previously described, but not popularized by J. Heiberg, a Norwegian surgeon.

Various problems with the Morton inhaler in the United States led to abandonment of inhalers in favor of a simple towel or sponge saturated with ether. In 1850, John Warren,[280] in his

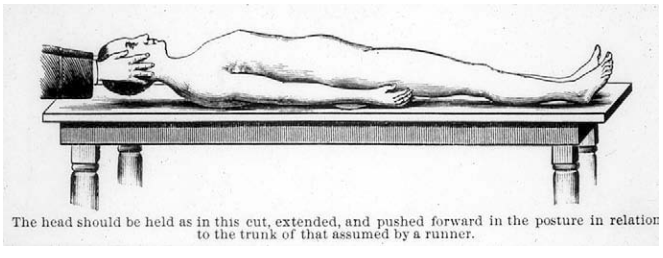

Figure 1-17 Illustration in a treatise by von Esmarch[279] showing the technique of maintaining an open airway in an unconscious patient. *(From von Esmarch F: Handbuch der kriegschirurgischen Technik. Hanover, Carl Rumpler, 1877.)*

address to the American Medical Association, described his preferred technique for administration of ether at the Massachusetts General Hospital: (1) no oral intake for at least 3 hours before surgery, (2) a horizontal position for induction, (3) bleeding the patient before surgery for bloodless operations, (4) pulse and respiration watched carefully by an assistant to the anesthetist, (5) ether applied with a large sponge soaked with ether, and (6) avoidance of cautery.

Several wire frame masks were devised to replace the sponge or folded towel. The popular mask devised by Curl Schimmelbusch (1860-1895) had a trough-shaped rim to prevent liquid chloroform or ether from dropping onto the patient's face. Friederich von Esmarch[279] used a wire mask with a clip that enabled it to be strapped to the patient. The advantages of these masks were low cost, simplicity, and portability. Disadvantages included delivery of vapor throughout the operating room, cooling of the patient, and waste of anesthetic agent.

Development of the modern facemask originated with Francis Sibson[281,282] (1814-1876), who devised a mask made of pliable tinned iron and covered with glove leather. The mask covered the mouth and nose and therefore eliminated the need for noseclips. Snow quickly recognized the superiority of the Sibson mask and incorporated it into his practice.

The first anesthetics were of short duration and rarely required special devices to maintain patency of the airway. With the increasing complexity and duration of surgical procedures, special devices were fashioned to facilitate an open airway. Frederick Hewitt promoted a simple metal tube that projected through the mouth into the hypopharynx. The commonly used Guedel rubber curved airway was described in 1933.[283] At the same time, cuffs were sometimes used on oral airways, a design that has been resurrected in the form of a modern product, the cuffed oral pharyngeal airway (COPA).

Tracheal Tubes

In the 18th century, tubes were passed into the trachea during resuscitation from drowning, but these tubes were passed without direct visualization and were not used for delivery of anesthetic agents. Similarly, the intubations of pediatrician Joseph O'Dwyer (1841-1898) in cases of diphtheria were performed with metal tubes passed blindly.[284] The O'Dwyer metal tube was later attached to a bellows by George Fell (1850-1918) for the treatment of opioid respiratory depression. Placement of tracheal tubes was vigorously opposed by the influential Parisian surgeon Armand Trousseau (1801-1867), who quoted the failures experienced by M. Bouchut in attempting to pass metal tubes for airway obstruction. Bouchut had lost five of seven patients during his procedure, called *le tubage du larynx*, and the other two were rescued only by tracheotomy.[285] Trousseau was the first to perform a tracheotomy in Paris and wrote a treatise promoting its use during airway compromise in 1851.

John Snow had administered chloroform through tracheotomy tubes in animals, and Friedrich Trendelenburg (1844-1924) used the same technique in humans.[286] Sir William Macewen (1848-1924) was the first physician to intubate the trachea orally for the sole purpose of administering anesthesia, and it was done to permit continued administration of chloroform during an operation in the mouth. On July 5, 1878, Macewen[287] performed a blind oral intubation on an awake patient with an ulcerating epithelioma of the tongue. An extensive operation was performed, and the results were excellent. Subsequently, Macewen tracheally intubated three other patients, two for edema of the larynx, and a fourth for another surgical procedure in the mouth. In the fourth case, the pulse was suddenly lost after chloroform was administered, and the patient died on the table.

The use of tracheal intubation was accelerated to meet the needs of surgeons operating on the face and in the thoracic cavity. To operate within the thoracic cavity, some means was required to avoid respiratory compromise, which followed the inevitable pneumothorax when the chest was opened. Ernst Ferdinand Sauerbruch[288] (1875-1951) studied the problem as a young assistant to Johann von Mickulicz-Radecki (1850-1905) in Breslau, Germany, and his solution, the Sauerbruch Box, elevated him into a position of international prominence at a young age. The Sauerbruch Box was a cumbersome solution to the problem of pneumothorax and entailed placing the surgeon and the patient (below the neck) in a negative-pressure chamber while the head of the patient and the anesthetist were outside the box at normal atmospheric pressure. The use of such an awkward construction indicates that surgeons were determined to solve this problem at any cost. The modern solution, endotracheal intubation and controlled ventilation, as it unfolded was relatively simple, but it took several years to become established.

Franz Kuhn (1866-1929) perfected a flexible metal tube and used blind oral or nasal intubation for anesthetic purposes when the surgeon operated in the mouth. Kuhn's first report on tracheal intubation was in 1905 and included an extensive description of a technique using carbon dioxide absorption cartridges. He proposed but did not use inflatable pharyngeal cuffs to prevent air leaks. Insertion of catheters directly into the trachea to insufflate anesthetic agents was begun in the first decades of the 20th century. With this method, gases were introduced under continuous pressure through catheters that allowed exhalation through the space between the catheter and tracheal wall.

The use of to-and-fro respiration through one large-bore endotracheal tube is credited to Ivan W. Magill[289] (1888-1986) (Fig. 1-18A) and Edgar S. Rowbotham[290] (1890-1979) to meet the demands of the maxillofacial surgeon. Their technique of blind nasal intubation was to position patients as if they were "sniffing the morning air." Occasional failures of blind intubation were solved with a special instrument designed by Magill to lift the tube off the posterior wall of the pharynx into the glottic opening. The so-called Magill tubes were formed to fit the airway and were made of red mineralized rubber. The cuffed endotracheal tube was promoted by Arthur Guedel (1883-1956) (Fig. 1-19) and Ralph M. Waters (1883-1979) (see Fig. 1-18B) in 1928,[291] and this refinement allowed the use of intermittent, controlled, positive-pressure ventilation and the potential for one-lung ventilation, introduced by Gale and Waters in 1932.[292] Four years later, Magill introduced the bronchial blocker to confine the secretions of an infected lung to one side. Magill's technique was to pass the blocker before induction of anesthesia with a specially designed bronchoscope.[293] Double-lumen tubes for bronchospirometry were introduced by Carlens in 1949,[294] but the small lumen size made these tubes inconvenient for anesthetized subjects. The commonly used disposable double-lumen tubes in use today are modeled after the Robertshaw tube[295] for the left side and after the Green-Gordon tube[296] for the right side. An opening called the Murphy eye, on the side of the standard endotracheal tube,

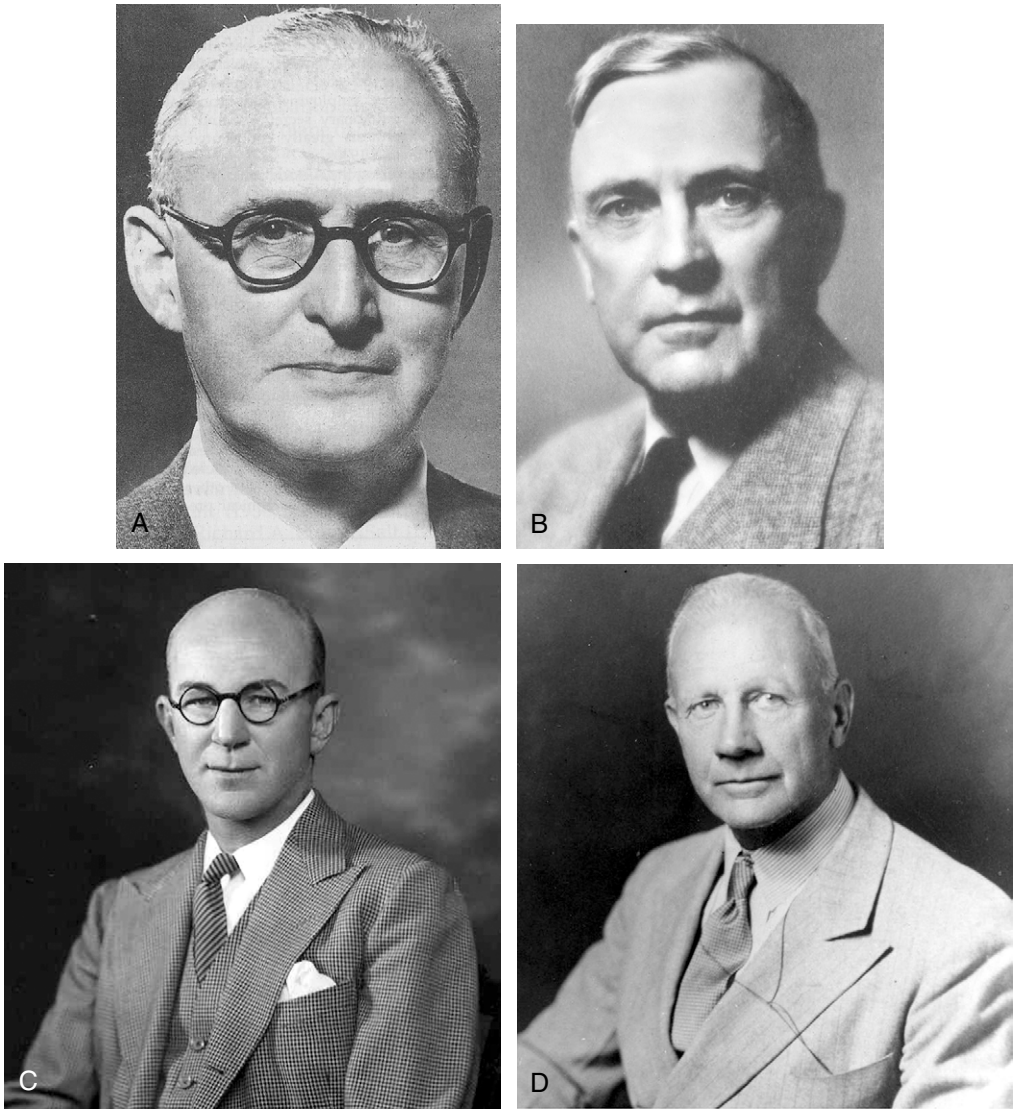

Figure 1-18 Prominent anesthesiologists of the 20th century. **A,** Sir Ivan Whiteside Magill (1888-1986) was born in Larne, Northern Ireland. He obtained a medical degree from Queen's University, Belfast, in 1913. During World War I, he served with the Irish Guards in the Medical Corps. After the war, he and Stanley Rowbotham (1890-1979) pioneered the use of large-bore endotracheal tubes to allow plastic surgeons to operate on the facial injuries of wounded soldiers. He designed many pieces of equipment for the anesthesiologist, some of which are still used today. Before his death at the age of 98 years, he received many awards, including a knighthood awarded personally by the Queen of England in 1960 and the Henry Hill Hickman Award. **B,** Ralph M. Waters was born in North Bloomfield, Ohio, and obtained his medical degree from Western Reserve University in Cleveland. He began his career in general practice in Sioux City, Iowa, and specialized in delivering anesthesia in 1916. Waters established the first academic program of anesthesiology in Madison, Wisconsin, in 1927. His contributions were many and included the carbon dioxide absorption method, endobronchial anesthesia for thoracic surgery, and introduction of cyclopropane. His chief legacy is the many residents he trained who then became leaders within the specialty in the following generation. **C,** Sir Robert R. Macintosh (1897-1989) was born in New Zealand and was a prisoner of war during World War I. He finished medical training in London after the war and began the practice of anesthesia there. In 1937, he was appointed the first Nuffield Professor of Anaesthetics at Oxford University. He was primarily a clinician, and his innovative techniques of airway management were eventually accepted worldwide. He received honorary degrees from universities in several countries and was knighted in 1955. **D,** James T. Gwathmey was born in Roanoke, Virginia, in 1865 and graduated from the Vanderbilt School of Medicine in 1899. In 1903, he limited his practice to the administration of anesthetics, and he is considered one of the first full-time private practice physician-anesthesiologists in the United States. He devised several innovations for the delivery of anesthetic gases and introduced these machines to his European colleagues during World War I. He was an original member of the Long Island Society of Anesthetists, which eventually evolved into the American Society of Anesthesiologists. *(Courtesy of the Wood-Library Museum of Anesthesiology, Park Ridge, IL.)*

Figure 1-19 Photograph of Arthur Guedel while he was serving in the American Expeditionary Forces in France during World War I. During the war, he was responsible for the safe administration of thousands of anesthetics, often delivered without properly trained personnel. As a guide for teaching nurses and orderlies to administer ether, he devised a wall chart describing the various stages and planes of ether anesthesia that eventually resulted in his classic publication on this topic in 1919. He used a drug sequence of ethyl chloride, chloroform, and ether, which prepared the patient for surgery within 2 minutes.[353] *(Courtesy of the Guedel Memorial Anesthesia Center, San Francisco, CA.)*

was suggested in 1941 as an alternative air passage in the event of distal tip occlusion.[297]

Laryngoscopes

Although blind or tactile tracheal intubation of awake patients could be mastered with extensive practice, an improved technique to accomplish tracheal intubation was developed by Alfred Kirstein[298,299] (1863-1922), Chevalier Jackson[300] (1865-1958), and Gustav Killian (1898-1912), all contributors to the introduction of the hand-held laryngoscope. Before the pioneering efforts of these innovators, the only way to visualize the larynx was by indirect laryngoscopy, a technique introduced by the Spanish singing instructor Manuel Garcia (1805-1868). In 1854, Garcia read a paper before the Royal Society titled "Observations on the Human Voice," wherein he described his use of mirrors to view his student's and his own larynx during vocalization.[301] Alfred Kirstein was charting unknown territory in 1895 when he boldly suggested that the larynx could be directly visualized with instruments similar to the commonly used esophagoscope.[298] Although he abandoned the procedure after 1 year, it was revived 3 years later by Gustav Killian,[302] whose portable laryngoscope was remarkably like the current instrument, but with no light attached.

Direct laryngoscopy did not gain in popularity among anesthesiologists until Chevalier Jackson promoted the use of his hand-held laryngoscope for insertion of tracheal insufflation catheters. Even then, the technique was slow to gain acceptance, but the accelerated use of muscle relaxants eventually required the anesthesiologist to be adept at rapid placement of tubes within the trachea. The first hand-held laryngoscopes, as perfected by Jackson, were U shaped and had no curve at the tip. A light at the end of the blade was a unique contribution by Jackson that has been retained, with the modification that some instruments today use a fiberoptic bundle in the blade.

Anesthesiologists soon began to design their own laryngoscopes that were more suitable for insertion of endotracheal tubes. Robert A. Miller[303] designed a new blade that was remarkably similar to Killian's instrument, except for a slight curve at the distal end. Robert R. Macintosh's (1897-1989) (see Fig. 1-18C) improved laryngoscope featured a short, curved blade that elevated instead of retracted the epiglottis.[304] This promoted a new concept in laryngoscopy specifically designed with the anesthesiologist in mind for timely tracheal intubation. Many intubations were then performed without muscle relaxants, and the Macintosh blade was able to expose the glottis without coming into contact with the sensitive posterior surface of the epiglottis. By this time a detachable joint had been placed between the blade and the handle. The batteries were located in the handle, thereby conveniently avoiding the trailing wires attached to the distal bulb.

Alternatives to the Laryngoscope

Unfortunately, not all patients could be successfully intubated with the hand-held laryngoscope. Several new blades were developed in the 1940s and 1950s to solve the problem of a difficult airway, but none were 100% successful, and it soon became apparent that some airways could not be intubated with any hand-held instrument. In such cases, the few remaining members of the hospital staff who had been trained in blind tactile intubations were called in to secure the airway.

The problem of a difficult or impossible intubation is now solved with a variety of tools, including various modifications of the laryngeal mask airway (LMA) and the flexible laryngoscope, both established tools in the modern anesthesia department. The LMA was developed by A. J. Brain of the Royal Berkshire Hospital, Reading, England, with the commercial product first appearing in 1983.[305] This device is well named, for it is indeed a small mask that covers the glottic opening. The LMA eliminates the need for tracheal intubation in many cases and is useful in managing a difficult airway.

The beginnings of flexible laryngoscopy were rooted in the 19th century. John Tyndall (1820-1893) succeeded the more famous Michael Faraday as Superintendent of the Royal Institution in London in 1867 and published his observation in 1854 that light could follow a curved path through a water tube. In 1930, H. Lamm[306] used this property of light when he introduced the flexible gastroscope, with glass fibers used instead of water. S. Ikeda[307] transferred the same technology to a smaller-diameter instrument and thereby introduced flexible bronchofiberoscopy in 1968. The definitive work followed in 1971.[308]

Resuscitation (see Chapter 97)

Resuscitation from drowning was successfully accomplished by a variety of methods as early as 1792, when James Curry used digital intubation of the trachea and forced air into the lungs with a bellows (see Chapters 93 and 97). J. Leroy criticized the use of

positive pressure with bellows as a dangerous procedure in 1827 by showing that it could rupture the alveoli and produce fatal tension pneumothorax. Consequently, several ineffectual techniques developed, such as administration of stimulating vapors, swinging the arms up and down, and pulling the tongue forward in a rhythmic motion, and these futile techniques were slow to dissipate. Largely through the work of O'Dwyer, Tuffier, and Matas, positive-pressure methods were reintroduced in the first few decades of the 20th century. James O. Elam (1918-1995) instinctively demonstrated the efficacy of mouth-to-mouth ventilation in 1946 when ventilators were in short supply during the polio epidemic. Peter Safar (1924-2003) and Elam were influential in converting teaching of the ineffectual arm-lift method to mouth-to-mouth breathing techniques by demonstrating the proficiency of the later technique on volunteer medical students.[309,310]

Rational methods of resuscitation from full cardiac arrest awaited development of the electrocardiogram and its interpretation. Augustus Waller[311] (1856-1922) first produced tracings of the electrical activity of the heart in 1887, but Willem Einthoven[312] (1860-1927) is credited with producing the first modern electrocardiogram by using a string galvanometer in 1903. Tracings compatible with occlusion of the main coronary vessels were demonstrated first in animals and then confirmed in patients by James B. Herrick[313] (1861-1954) of Chicago. John MacWilliam[314] (1857-1937) described ventricular fibrillation in 1887 and provided a case report showing it to be the cause of death in one subject.[315] In 1899, J. L Prevost and F. Battelli[316] showed that small electrical currents passed across the heart could induce ventricular fibrillation and that larger currents could convert fibrillation to a normal rhythm. Claude Beck[317] (1894-1971) performed the first successful use of electric defibrillation in a patient in 1947.

Open cardiac massage was first performed in Norway in 1901[310] and in the following year by Starling,[318] and external massage over the chest was described by W. W. Keen (1837-1932) in 1904.[319] Brief anecdotal reports had been presented on closed chest massage as early as 1883 by Franz Koenig of Göttingen, Germany.[320] William B. Kouwenhoven (1886-1975), Dean of the School of Engineering at Johns Hopkins from 1939 to 1953, began his studies on resuscitation from cardiac arrest in 1929 and 31 years later published the full sequence of external cardiac massage, combined with electric countershock, to restore cardiac rhythm.[321] These methods of resuscitation have been promoted by the American Heart Association and, with some modifications, have become the basis for the widely disseminated educational programs of advanced cardiac life support (ACLS).

Anesthetic Accidents and Complications—Preventive Measures

Anesthetic accidents have occurred since the early days of administration of ether and nitrous oxide. Wells and Morton described patients who required resuscitative measures during anesthesia. Several near deaths were reported after the October 1846 demonstration. Bigelow's first description of ether anesthesia provides a case report of a patient who nearly died after ether administration and was resuscitated by cold effusions, ammonia inhalation, and syringing of the ears.[86] Two other patients "failed to be affected by ether." George Hayward (1791-1863) reported a death occurring after ether inhalation in August 1847. Snow's book on chloroform appeared in 1858 and discusses a number of frightening cases and deaths during administration of anesthesia. The first such tragedy with chloroform struck in 1848, when an anesthetic was given to a 12-year-old girl, Hannah Greener, for a minor surgical procedure. The postmortem examination of this young girl was inconclusive, but the anesthetic was thought to have been administered properly. The controversy surrounding this death has occupied the minds of numerous anesthesiologists for the past 150 years.[322,323]

Most anesthetic deaths were not attributed to the agent or the method of administration but resulted simply from "the patient not taking the anesthetic well." A frequent diagnosis after death during anesthesia was the vague syndrome of "status lymphaticus."[324] Although this phrase was convenient for the anesthesiologist to use, it thwarted a review of causes that might help prevent future disasters. A major change occurred in anesthetic practice with the introduction of morbidity and mortality conferences to examine causes of anesthetic accidents. Originally introduced by Ralph Waters in Madison, Wisconsin, these meetings sought to carefully scrutinize anesthetic complications, thereby shifting the focus of investigation from the patient to the provider and the equipment used to deliver the anesthetic. The postanesthesia care unit, originally designated the recovery room, was promoted for safety reasons by two anesthesiologists from Washington, D.C., in an influential paper in 1951,[325] and these units are now mandated by the accreditation process for all hospitals.

Curtis L. Mendelsohn, an obstetrician from New York City, presented one of the early useful reports of anesthetic complications. In 1945, he reported 66 cases of aspiration of stomach contents during general anesthesia for labor and delivery.[326] He further observed that aspiration of even small volumes of low-pH stomach contents in rabbits would result in fatal pulmonary edema. Since his classic descriptions, the syndrome of acid aspiration is often called the Mendelsohn syndrome.

The cuffed endotracheal tube was one solution to the problem of acid aspiration. Authur Guedel and Ralph Waters were motivated to devise a truly closed system of anesthetic administration with carbon dioxide absorption that would conserve anesthetic gases and body heat. Their 1928 report of the cuffed endotracheal tube[291] achieved these goals with the added benefit of protection of the tracheobronchial tree from aspiration. Others had devised cuffed endotracheal tubes before them,[327] but Guedel and Waters used a novel method to demonstrate and promote the safety features of the cuffed tube. Guedel anesthetized and then intubated his pet dog, appropriately named Airway, with a cuffed endotracheal tube. The dog was submerged in a water tank for several minutes and then removed and awakened unharmed. The demonstration was repeated at several meetings, and this publicity enhanced rapid acceptance of the new endotracheal tube. The cuffed tube is regarded today as an effective measure for preventing acid aspiration.

In 1961, Brian A. Sellick[328] (1918-1996) described rapid-sequence induction for prevention of acid reflux. The method involves the application of firm pressure over the cricoid cartilage to occlude the esophagus during endotracheal intubation. John Hunter[329] had previously described the technique in 1776 for use in resuscitation of individuals "apparently drowned." Rapid-

sequence induction remains a popular technique for induction of patients at risk for acid aspiration.

Although few defects in apparatus could occur while applying ether onto a folded towel, the increasing complexity of the anesthetic delivery system brought with it the unfortunate side effect of equipment failure. One of the earliest equipment defects occurred with the simple Morton inhaler. George Hayward reported that a defective intake port led to restricted breathing, lividity, and convulsions in an elderly woman having a leg amputated in January 1847. Wrong gas, wrong agent, wrong concentration, sticky or jammed valves, contaminated agents, and hypoxic mixtures—all of these and others were reported as routes to disaster.

Open discussions of these complications led to adjustments in equipment design.[330] Pin indexing of gas cylinders and hoses eliminated the possibility of introducing air or nitrous oxide into the oxygen lines of the gas machine. In-line oxygen analyzers were placed on the inspiratory limb of the breathing circuit. Fail-safe devices prevented the use of any machine that was not supplied with oxygen. Uniform connectors were adopted, thereby providing rapid assembly of breathing circuits. The American Society of Anesthesiologists (ASA) initiated formation of the Z-79 Committee of the American Standards Institute. This committee recommended safe construction of endotracheal tubes, needles, and connectors. The American Society for Testing and Materials (ASTM), a not-for-profit organization that writes standards for materials and products (through their committee designated F-29), describes the requirements used in the design of safe anesthetic gas machines. The International Standards Organization is also developing global standards for anesthesia equipment.

Further progress in reducing anesthetic-related complications resulted from the formation of professional societies, specialty journals, and certification boards. One of the earliest journals limited exclusively to anesthesiology was *Current Research in Anesthesia and Analgesia*, founded in 1922 largely through the efforts of Francis Hoffer McMechan (1879-1939).[331] McMechan was an anesthesiologist who had retired at an early age for health reasons and devoted the remainder of his career to promoting organizational and political causes of anesthesiologists. An independent American Board of Anesthesiology was formed in 1940 and, through its examination process, continues to elevate standards of anesthetic care. Specialty societies of professional anesthesiologists have formed in most countries practicing modern anesthetic techniques. The ASA was founded as the American Society of Anesthetists in 1936 and currently has approximately 38,000 members. *Anesthesiology*, the official journal of the ASA, began publication in 1940. National anesthesia societies promote safe anesthetic practice through annual meetings, refresher courses, and direct communication with members. Practice guidelines for general anesthesia, obstetric anesthesia, and ambulatory surgery are sent annually to each member of the ASA. Subspecialty societies in cardiac, ambulatory, transplant, pediatric, neurosurgical, and obstetric anesthesia have been formed and strive to improve the anesthetic management of patients within their respective groups.

The Anesthesia Patient Safety Foundation (APSF) was conceived in October 1985, largely through the organizational efforts of Ellison C. Pierce, Jr. This highly successful organization promotes safe anesthesia practice through research grants and periodic mailings to members. As a result of these efforts, anesthesiologists have been recognized as forerunners in promoting agendas that enhance patient safety.[332,333]

Improved monitors have provided the anesthesiologist with methods to fine-tune anesthetic delivery and detect early signs of danger. Auscultation of the chest, an obligatory skill in the current era, had its beginnings in the early 19th century when Rene T. Laennec[334] (1781-1826) used a cylindrical paper tube to listen to the chest. The term *stethoscope* was a combination of the Greek words *stetho* ("chest") and *scope* ("I see") and was used by anesthesia providers as early as 1896 to monitor cardiac and respiratory sounds. The esophageal stethoscope, introduced in 1954 by C. Smith,[335] has been used extensively to detect breathing circuit disconnects, airway obstruction, and bronchospasm in anesthetized patients.

A. E. Codman (1869-1940) of Boston introduced the first anesthetic records in 1894, and the practice was encouraged by Harvey W. Cushing (1869-1939), who promoted recordings of blood pressure, pulse, and respiratory rate on all of his cases.[336] Practice guidelines for minimal monitoring standards were first issued[337] at the nine teaching hospitals of Harvard Medical School, and 2 years later, the ASA issued similar standards that included measures of oxygenation, ventilation, circulation, and body temperature. Electronic monitoring has contributed to the safe practice of anesthesiology significantly. Continuous electrocardiography displays, often with ST-segment analysis, are attached to most anesthesia machines. End-tidal gas analysis using infrared technology developed in the 1940s is in common use. Thermistors offer a continuous measure of core body temperature, thereby providing an early warning of the rare, but potentially lethal syndrome of malignant hyperthermia.[338] Awareness of complications associated with hypothermia in anesthetized patients and the use of methods to prevent its occurrence have contributed significantly to a safer environment for surgical patients.[339,340]

Some complications that may seem trivial to the provider can be highly significant for the patient. Surveys have shown, for example, that postoperative nausea and vomiting are feared complications in a large percentage of patients contemplating surgery.[341] Progress has been made in eliminating this complication through the use of agents with less emetogenic potential. Increased understanding of the neurochemical substrates that regulate the vomiting reflex has resulted in specific therapies to prevent or lessen the gastrointestinal side effects of general anesthetics and opioids.[342] Dopamine antagonists and serotonin 5-HT_3 antagonists have been particularly cost effective.[343]

The increasing use of muscle relaxants by anesthesia providers has led to the terrifying complication of an awake, paralyzed patient who is fully aware of surgical pain. Although early pharmacologic studies of muscle relaxants suggested a central depressant effect of these drugs, this issue was settled when Scott M. Smith[344] (1912-) allowed himself to receive curare without other agents and reported that no sedation or analgesia was present during complete paralysis. R. S. Blacher[345] noticed that complete paralysis with awareness during surgery could sometimes lead to a postoperative traumatic neurotic syndrome characterized by anxiety, irritability, and repetitive nightmares. Various monitors have been used to avoid this rare, but dreaded complication. Tunstall[346] described the isolated arm technique whereby one arm is excluded from the circulation, thereby allowing an awake, paralyzed patient to follow commands by moving that extremity. The electroencephalogram was described in 1929 by Johannes Hans Berger[347] (1873-1941) and first used during

administration of anesthesia by Albert Falconer, Jr.[348] (1911-1985). Within the past 30 years, new technologies have been developed that process the electroencephalographic raw signals and provide a number that is indicative of anesthetic depth. The bispectral index (BIS) monitor is a recent commercial product that analyzes the electroencephalographic pattern and provides some assurance that the paralyzed patient is also asleep.[349] Some exceptions have occurred with this device, with paradoxically low BIS numbers being associated with awareness, and solutions to the problem of awake and paralyzed patients continue to evolve.

Allergic reactions to drugs can be life threatening. Anaphylaxis (meaning "without protection") is appropriately named, especially for anesthetized patients, because the symptoms of hypotension and bronchospasm can have many causes and specific treatment can often be delayed. The syndrome was described in 1913 by Charles R. Richet[350] (1850-1935), who was studying the toxicology of various fish poisons and observed the rapid onset of death in dogs that more than 15 days earlier had withstood a much larger dose of the toxin. Richet postulated that an immune response had developed in the interim and produced a fatal reaction to the injection. The role of histamine and vasomotor instability was described in 1932,[351] and this understanding led to the role of vasopressors and antihistamines as treatment.

Even though enormous progress has been achieved toward the goal of zero anesthetic-related morbidity and mortality, no such claim can yet be made at any institution. In part, this is because more extensive procedures are being performed on sicker patients than was the case 100 years ago. In 1914, Gwathmey (see Fig. 1-18D) reported a 0.01% anesthetic-related mortality rate with ether anesthesia, a surprisingly low figure in view of the anesthetic methods in use at the time. However, in 1914 they did not perform extensive procedures such as liver and heart transplantation on patients with life expectancies (without surgical intervention) of only a few weeks. Anesthesiologists have recently focused on postoperative as well as intraoperative pain, and this extension carries with it additional risks to anesthesia providers.

The quest for improving the perianesthetic experience is far from over. A physician has only to ask patients about the experience of having a major surgical procedure to conclude that it is far from pleasant, even in the absence of complications. It is futile to attempt to summarize the current hardships that a surgical patient must undergo in the modern hospital or even attempt possible solutions. Change will occur—that is certain—and if we can learn anything from the past 150 years, there are possibilities for improvement and modalities of practice that we cannot even imagine today. Some methods in use today will appear nonsensical to future practitioners. As portions of the preceding historical survey demonstrate, one barrier to progress is failure by those entrenched in their routines and biases to recognize a breakthrough when it occurs. Perhaps the smarter we are, the more we fail to see our failures. In 1775, while Joseph Priestley[352] was hopelessly lost in the phlogiston theory of combustion, we find these words written in his classic manuscript *Experiments and Observations of Different Kinds of Air*: "The more ingenious a man is, the more effectually he is entangled in his errors; his ingenuity only helping him to deceive himself, by evading the force of truth."

Truth in clinical medicine is perhaps even more difficult to recognize than answers to the questions that chemists were contemplating at the end of the 18th century. However, anesthesiology has made remarkable progress in the more than 150 years since the public demonstration of ether anesthesia, and this progress should continue until safe elimination of all unwanted pain from human experience has been attained.

2 Scope of Modern Anesthetic Practice

Key Points

1. With the increase in the elderly population, more of the surgeries performed will be procedures required by elderly patients.
2. Minimally invasive procedures are increasing; anesthesiologists will be performing more anesthetic procedures outside operating rooms. Anesthesia may be the major risk to patients as the surgical procedures become more minimal.
3. The mandates for quality, competency, and uniform process will change the way anesthesia is delivered. More standardization and protocols will be used; this will allow more evaluation and research as to what optimal anesthesia is and what competent anesthesiologists are required to do.
4. The increase in nurses with degrees will change the number of anesthetics delivered by physicians. Team management and relationships between physicians and nurses will become more crucial, and the demand for skills in personnel management will increase.
5. Not enough research is being done by anesthesiologists. Anesthesiologists will need to engage in research to maintain an academic foothold. Opportunities for multidisciplinary research are increasing, and they need to be embraced to increase the number of research-trained anesthesiologists.

Forces That Will Change Anesthetic Practice

Multiple changes are occurring that will affect the role of the anesthesiologist in the United States and perhaps globally. The population of industrialized nations is *aging* so that many more operations are performed on elderly patients; this dictates which operations are being performed. The *cost of medical care* is increasing globally, and perhaps most rapidly in the United States. The increased cost will lead to more scrutiny regarding the need for operations, increased focus on quality and use of care that has documentation by research, changes in Medicare reimbursement, changes in the ability of patients to pay, and a demand for the use of less costly health care providers whenever possible. Technologic advances are leading to less invasive procedures that can be done on patients who heretofore would be denied routine surgical procedures. The mandates for *quality metrics* and *evaluation of processes* will change the way we practice medicine. Changes in *personnel* also will affect the workforce in practices. We can only speculate as to what the practice of anesthesia will be like in the next 10 years, but these forces will likely have a major effect (Fig. 2-1).

Aging of Society

With the aging of the population and improvements in anesthetic and surgical methods, the fraction of the elderly population undergoing surgical procedures is increasing in the United States (see Chapter 71). Use of surgical services in older patients is not unexpectedly higher than in younger patients. In the Centers for Disease Control and Prevention report of inpatient hospitalizations for 2005, there were 45 million procedures performed on inpatients with a similar number of outpatient procedures. From 1995 through 2004, the rate of hip replacements for patients 65 years old and older increased 38%, and the rate of knee replacements increased 70%. There seems to be a direct correlation between age and use of surgical services.[1]

Changes in Location of Care Delivery

Because of the high costs to the insurance industry, the pressure to move less invasive surgical procedures to locations remote from the hospital setting will continue, frequently motivated by changes in reimbursement.[2] Providing anesthesia in ambulatory surgical settings and offices has increased dramatically over the

Figure 2-1 Changing scope and settings of anesthesia and perioperative medicine. **A,** *The Cure of Folly,* by Hieronymus Bosch (c. 1450-1516), depicting the removal of stones in the head, thought to be a cure for madness. **B,** Friedrich Esmarch amputating with the use of anesthesia and with antisepsis. Woodcut from Esmarch's *Handbuch der Kriegschirurgischen Technik* (1877). **C,** Harvey Cushing performing an operation, with the Harvey Cushing Society observing, 1932. **D** and **E,** Placement of deep brain stimulator for the treatment of Parkinson's disease using a real-time magnetic resonance imaging technology (MR fluoroscopy). The procedure takes place in the MR suite of the radiology department. The patient is anesthetized (**D**) and moved into the bore of the magnet (**E**). **F** and **G,** A sterile field is created for intracranial instrumentation (**F**), and placement of electrodes is done using real-time guidance (**G**). last several decades (see Chapter 78). As procedures become less invasive than those currently performed in the operating room, they will be performed in procedure units. It will be important to determine the need for anesthesiologists to provide traditional anesthesia and moderate to deep levels of conscious sedation in these settings. Postoperative care has been shifted from the medical setting to the families, which may present difficulties in elderly patients. Anesthesiologists must be involved in determining which patients are appropriate candidates to have different procedures in these different locations of care, and the level of monitoring needed to perform these procedures safely.[3]

Cost of Medical Care

As the cost of health care in the United States approaches 15% of the gross national product, there has been increased interest in determining the factors that are increasing the costs, attempting to find methods to decrease the cost, and obtaining more valuable health care for the money spent. The primary driver of cost in the United States apparently is technical progress, as health care costs are increasing throughout the world, regardless of the insurance system.[4-6] The increase in elderly patients and patients with chronic disease in the population also is increasing health care costs.[7]

The increase in cost has led to a movement to get more value for the money spent. Pay-for-performance programs have been created (i.e., rewarding medical care that is consistent with published evidence and not paying for care that is inconsistent with evidence).[8-10] The concept and reality of pay-for-performance programs has now moved to other countries, including the United Kingdom.[11]

In the nonsurgical arena, the concept of pay-for-performance has been studied for several years.[12,13] In addition to paying for performance, in the United States, there is increasing emphasis on not paying for "never" events, such as decubitus ulcers or urinary tract infections, unless they are present on admission to the hospital. Because of the role of anesthesiologists in the entire continuum of perioperative care, including postoperative intensive care and pain management, we have an opportunity to influence many of the practices that can be associated with poor outcomes and increased cost, but that traditionally have not been considered under our domain of care.

Appropriate and timely administration of antibiotics has a significant impact on surgical site infection, but before the initiation of the Surgical Care Improvement Project, many anesthesiologists were arguing that control of antibiotics was not within

their domain (see Chapter 5).[14] Anesthesiologists tend to focus on intraoperative cardiac arrests and other short-term outcomes, such as postoperative nausea and vomiting (see Chapters 33 and 86). Anesthesiologists will need to rethink this approach for other "never" conditions, such as urinary tract infections because they help determine the need for Foley catheters. Anesthesiologists and intensivists also can have a significant impact on the rate of ventilator-associated pneumonia. Some of these proposed measures, particularly the use of ventilator-associated pneumonia as a quality measure, have become quite controversial, however.[15] Pain is considered the fifth vital sign, and the management of postoperative pain is another area in which anesthesiologists can have a significant impact with respect to cost and potential interaction with other members of the hospital team.

Process Assessment and Quality Metrics

Anesthesiology was among the first professions to focus on reducing the risk of complications, and anesthesiologists were among the first groups to develop evidence-based guidelines and standards, as shown by the American Society of Anesthesiologists standards and practice parameters (see Chapter 5).[16] It will be important to continue to be involved in multidisciplinary approaches to surgical care. Examples where anesthesiologists were initially less involved include the Society of Thoracic Surgeons database and the National Surgical Quality Improvement Project.[17,18] More recently, anesthesiologists have become involved in both groups, and the Society of Cardiovascular Anesthesiologists have begun discussions with the Society of Thoracic Surgeons. Anesthesiologists have been involved from an early stage in quality initiatives with the Institute of Healthcare Improvement and the Surgical Care Improvement Project.[19]

Other quality measures that will have an impact on anesthesiologists include the new demand for metrics of competency, to be measured on a focused and an ongoing basis. Defining competency will demand that anesthesiologists adhere to more protocols, and that the concept of safe anesthesia be standardized. Rather than stifling medical innovation, standardization should be viewed as a mechanism for evaluating process and outcomes because comparisons cannot be made without standardization. Anesthesiologists will need to engage in creating quality and competency metrics, or these instruments will be created by others. This is an opportunity to formulate meaningful metrics that can be used in training physicians. Metrics also will be sought for nurse anesthetists and other health care professionals.

Changing processes has become a cottage industry in medical care, with courses being offered on how to change behaviors and processes in medical care. These mandates offer the opportunity for more research as to whether changing processes leads to improved patient outcomes. These mandates also allow anesthesiologists to assume a leadership role in team management. For anesthesiologists to accomplish this role, new skills need to be taught, including leadership training, improved communication skills, and improved relationship training.

One advantage that anesthesiologists have is a long tradition and training in system approaches to care. These date back to the original checklists for the anesthesia machine. It is crucial that this skill set be disseminated beyond the intraoperative setting. Many ambulatory surgery centers are directed by anesthesiologists.

Changes in Personnel

There are approximately 250,000 active physicians, one third of whom are older than 55 years old and likely to retire by 2020.[20] Although in the 1960s enrollment in U.S. medical schools doubled, during the years 1980 through 2005, the enrollment has been flat. There has been zero growth in U.S. medical school graduates. In this same interval, the U.S. population grew by more than 70 million, creating a discrepancy between the supply of medical school graduates and the demand for physician-associated care.

There also has been a significant increase in the number of women in medical schools, so that about 50% of medical students are now women.[21] Women tend not to work as many hours as their male counterparts, even when part-time status is taken into consideration.[22] Also, today's younger physicians choose to work fewer hours than their older counterparts, regardless of gender.[20,23]

There has been a steady use of international medical graduates; 60,000 international medical graduates are used as residents and constitute 25% of all residents in training.[24] There also has been an increase in the number of osteopath schools and schools offering advanced degrees in nursing, including training of nurses to become nurse anesthetists.[20] Given the increase in demand for medical care resulting from the increase in the geriatric population, this need will most likely be met by a combination of physicians and nonphysician personnel.

Research

In terms of creative new investigations, most benchmarks suggest that the specialty of anesthesiology fares poorly compared with other disciplines, especially clinical disciplines. Using data gleaned from publicly available National Institutes of Health (NIH) sources, Reves[25] produced a troubling figure showing that anesthesiology ranked second to the last for many medical disciplines. The exact position on any such figure would undoubtedly change from year to year. The fact that U.S. anesthesiology inhabits the lowest quartile is of concern, however, because the external forces on the practice components are generally applicable to all specialties.

NIH is not the only source of funding that may influence the specialty of anesthesiology; it is not even the largest portion of total research funding in the United States (Fig. 2-2).[26] For all sources, there has been a doubling over the last decade in research expenditures for health and biomedical science research, although compared with biologically based disciplines, health services research is considerably less well funded. In anesthesiology journals, the fraction of non-U.S., original peer-reviewed articles has increased dramatically. This increase does not seem to be attributable directly to research support. Adjusted per capita, research support in Europe is only 10% of that in the United States, even though the proportion of scientists in the population is similar.[27]

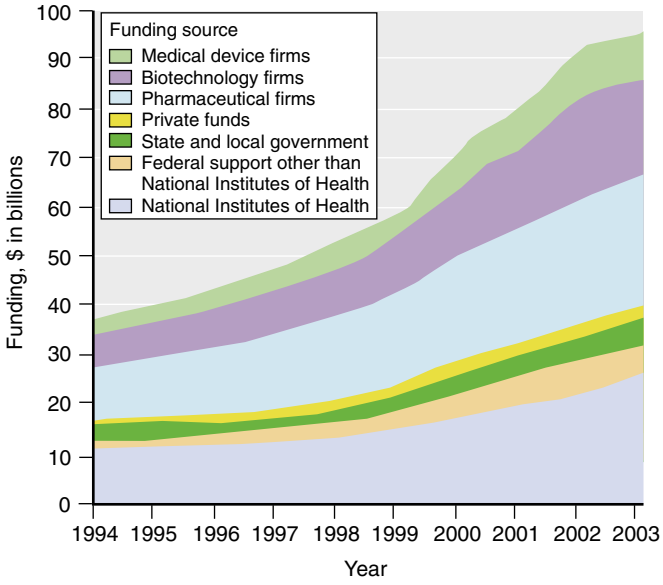

Figure 2-2 Research expenditures in the United States, 1994 to 2003, by funding source (see text).

There is no a priori reason why anesthesiology should differ from any other medical specialty in terms of research output. In our opinion, it should excel. One might argue that practitioners at academic institutions might be better compared in terms of surgical versus medical specialties, but even in that comparison we fare poorly. One line of remedy is to develop clinician-scientist training programs further, such as the NIH T-32 model. This approach is limited, however, by the fact that *selection* of individuals entering the specialty has already occurred.

One of the most exciting and promising developments in this regard has been the initiative by several programs in the United States to construct a special residency track that allows training for scientific independence to occur roughly in parallel with clinical residency training over the course of a 4-year track after internship. Such an approach recognizes that, to change the culture of the specialty, we must build from the ground up. Not all physicians who enter anesthesiology training go on to participate in the research/academic sector. Similar to other highly visible specialties, however, a sufficiently large cadre will be available to replenish those who leave active practice and further build up intellectual capital for future generations.

One of the challenges in training is the inherent and increasingly diverse nature of the disciplines involved in any one-subject area. The term "interdisciplinary research" has become a tautology. Practically all new frontiers lie at the boundaries of established departmental or specialty divisions, which are largely a historical relic of 19th century or early 20th century conceptualizations. A look at any large institution's roster of academic divisions yields a growing number of "centers," "programs," and "institutes," reflecting the ever-increasing interdependency of branches in biomedical knowledge.[28,29] In basic science departments, with conjugate names such as "Physiology and Cellular Biophysics," "Anatomy and Cell Biology," "Biochemistry and Biophysics," and "Cellular and Molecular Pharmacology," it is becoming increasingly difficult to differentiate one faculty research program from another, solely on the basis of the topics and methods of study. Although this differentiation is clearly less complicated for domains that do not involve patient care, the trend is evident. One might cite the example of endovascular surgery as an example in the collision of science, technology, and historical boundaries of medical specialties.[30]

Medical research is at one level original creative work that involves systemic investigation of medical phenomena with the direct or indirect consequence of improving health care. Activity that might be subsumed under "medical research" is scholarly synthesis of available data to generate new insights into phenomena. Scholarship that involves this synthesis is perhaps underappreciated and underemphasized. The most common type of publication in this category is the review article. Although often review articles are written by the individuals performing the original research, this is neither a necessary nor a sufficient precondition for a meaningful review. Especially for clinically oriented reviews, a broad perspective on a particular clinical practice may not only be sufficient, but also desirable.

Ramachandran[31] quotes Medwar: "An imaginative conception of what might be true is the starting point of all great discoveries in science." Ramachandran says that if he would show the reader a talking pig, it is unlikely that he or she would respond: "Ah, but that's just one pig. Show me a few more, and then I might believe you!" In this regard, an unintended consequence of moving toward quantitative indices for impact of biomedical journals has led to the demise of the case report. The case report is just such a Medwarian "imaginative conception of what might be true." It is also an ideal setting in which to perform a synthesis of available knowledge on a particular topic. Well-written and timely case reports can add significantly to the medical literature and provide an "early warning" function before laborious efforts are undertaken to conduct larger scale efforts to characterize a particular complication or phenomenon. Finally, case reports are "entry-level" scholarly activities that students, residents, and junior faculty can use as a stairstep to more complex modes of writing.

An area of potentially increasing contribution of anesthesia and perioperative care is in the realization of clinical trials for efficacy of surgical therapy. It is not unreasonable to assume that reimbursement for delivery of clinical care in the future may be increasingly tied to participation in some form of organized assessment of efficacy, such as a randomized controlled trial (e.g., the case of lung reduction surgery).[32] Such considerations are especially pertinent for procedures that are highly reimbursed, but controversial in terms of efficacy, as in the case of minimally symptomatic cerebrovascular diseases.[30,33] Perverse incentives can drive clinical practice and influence expert opinion. In addition to insights into the delivery of perioperative medical care, anesthesiologists can help provide an "honest broker" function in such settings.

In the clinical and policy research domain, anesthesiologists have an opportunity to study all aspects of surgical care. By joining or leading multidisciplinary teams, they can ask questions relevant to the patient undergoing surgery and not just undergoing anesthesia. Anesthesiologists must take leading roles in helping to define best surgical practice.

Why is it important that anesthesiology maintain the strongest possible profile in research and scholarly contributions to medical knowledge? Besides the intuitive sense that medical specialties must strive for advancing their domains, there is a strategic necessity of significant proactive involvement in scholarly and investigative pursuits. In the modern medical market-

place, physicians are not the only stakeholders in the delivery of health care. Physicians, particularly those in professorial tracks, traditionally conduct the bulk of investigative research, however. The advent of higher-level, doctoral degrees in nursing could significantly change this dynamic. The public that we serve, and the various governmental and institutional bodies that regulate health care delivery, should have a clear vision of our mission and approach.

The Modern Period: Essentials of Modern Anesthesia around the World
- Roles and Responsibilities of Anesthesia Providers
- Facilities and Equipment
- Education, Accreditation, and Availability of Practitioners
- Subspecialization
- Professional and Research Activity

Conclusion

At a recent international anesthesia conference, an American anesthesiologist spoke about the value of using modern electronic monitoring devices in the operating room. Believing that they are essential for improved patient safety, the presenter expressed a hope that hospitals worldwide would adopt and use these devices. During the question and answer session, however, a physician from another country—one whose hospitals have considerably fewer resources than those in the United States—stood to express his frustration with this argument. In his country, he believed, there were other priorities and the sheer cost of monitoring equipment prohibited its widespread adoption. Another physician, also from a country whose hospitals do not have a wealth of resources, disagreed; by understanding what monitoring devices were available, he would pick the most effective monitoring device or devices in accordance with the resources available. A spirited exchange followed. Of course, there is no one right way for hospitals to spend their limited resources. There was, however, enormous value in this exchange among physicians from different countries with different cultures, different resources, and different perspectives. It is through these discussions that the profession can create fully informed baseline standards that foster greater levels of patient safety and improved outcomes worldwide.

Such discussions, which occur with increasing frequency, also inspired this chapter on the global scope and practice of anesthesia. Throughout his career, this book's editor, Ronald D. Miller, has had the privilege and pleasure of speaking and working with leading anesthesiologists from all over the world. His work and discussions with international colleagues spurred a desire to recognize and honor the growth and practice of anesthesia outside North America. He wanted to describe the different ways that anesthesia began from place to place and to follow the regions through time so that we can better understand how the various regions influence each other today.

This chapter is the first step in realizing his hope. Work on this chapter began in earnest when he invited a number of colleagues whom he had met over the years—prominent anesthesiologists in their parts of the world and beyond—to contribute a short summary describing the growth and practice of anesthesia in their country or region. When the contributions arrived, they proved to be a fascinating read: creative, informative, and inspirational. Yet for all their rich content, they also posed an editorial challenge in that the unique cultures, politics, economics, and developments in various regions prompted the contributors to emphasize different ideas, discoveries, or time periods. These differences in emphasis and coverage reflect the freedom that the contributors were given to describe their country or region. In the future we hope to expand on this topic by covering other areas of practice and including world regions not featured in this chapter.

It was in the face of this challenge that Dr. Schwartz was asked to integrate the short individual contributions into a single chapter without compromising their integrity. Dr. Miller and Dr. Schwartz chose to create a chronologic narrative that progresses through three distinct time periods. Each period is broken up by region; each regional narrative draws directly from the work of the international contributors. Our intent was to always acknowledge and document the sources and wherever possible maintain

each contributor's individual voice, and we hope that we have achieved that goal.

Dr. Miller is deeply grateful to all the colleagues who contributed to this chapter, for their insightful writing and the time that they devoted to their tasks, and regrets that because of time and space constraints not more contributions of this kind could be included in this edition. He recognizes that the pages you are about to read are only a first step and by no means a comprehensive look at the development of anesthesia around the world. Future editions will deepen and broaden the international focus.

The first section of this chapter is a sprint through a vast stretch of history, from ancient times through the early 20th century. Over these two thousand or so years, with a few notable exceptions, the practice of anesthesia grew independently by region in response to the need for pain relief during medical procedures.

The second section covers the period from the 1920s through the early 1980s. This was a time when modern communications and international travel expanded dramatically, leading to increased cross-pollination of anesthesia techniques. Physicians and researchers began to regularly travel to foreign countries, receive training and education abroad, and hear others speak at conferences. As international journals grew, knowledge about emerging practices in anesthesia spread further.

The third section covers the time from the early 1980s through the present. This has been an exciting period because today nearly all anesthesiologists, no matter where they practice in the world, can gain access to the information necessary to deliver safe anesthesia at the most basic level. Even though significant differences in resource levels still remain, some of which undermine the practice of safe anesthesia, at least all anesthesiologists worldwide today know how to avoid the common complications of anesthesia that can endanger patients' lives. This section details the state of anesthesia in the regions covered—from education, accreditation, professional exchanges, and actual practice to available facilities and equipment.

The chapter concludes by raising questions about what is next in terms of the way various countries and regions practice anesthesia. How integrated should the practice of anesthesia become? What can we do to raise levels of care worldwide? Again, there are no simple answers, but it is a future that anesthesiologists face together.

The Early History of International Anesthesia

Before the early 20th century, those interested in analgesia during surgery rarely had the advantage of being able to learn from what their colleagues around the world were doing. Rather, in response to patient need, physicians from various regions came to different, but often similar conclusions about how to relieve pain. In many, if not most places, herbs, opium, and alcohol were the mainstays of pain relief medication.

Regions were not completely isolated, however. As the narratives herein describe, the traditional ways of spreading culture and information, such as war and trade, enabled at least some sharing of anesthesia techniques. In particular, the first published account of ether used as an anesthetic in 1846 seems to have been anesthesia's "shot heard 'round the world."

India (Deepak K. Tempe)

The history of anesthesia in India dates back to the era of Susruta, the great surgeon of ancient India. During his time, around 600 BC, operations were performed with the use of opium, wine, and Indian hemp (an herb). Surgical science was called "salya-tantra" (*salya*: broken parts of an arrow and other sharp weapons; *tantra*: maneuver).[1]

Much later, in 980 AD, Pandit Ballala mentioned in *Bhoj Prabandh* that Raja (King) Bhoj underwent a cranial operation under the anesthetic influence of a plant called "sammohini." The same plant was applied as healing balm to surgical wounds. A drug called "sanjivan" was administered to revive the Raja and help him regain consciousness.[2]

Nearly 900 years later, after the first widely publicized demonstration of ether anesthesia in the United States in 1846, India quickly followed suit by administering ether anesthesia on March 22, 1847, in Calcutta under the supervision of a surgeon named Dr. O'Shaughnessy.[3] Later, chloroform was also used but fell into disrepute because of the high morbidity associated with it. Despite this—and the fact that the world began to discard chloroform in preference for ether by 1890—India continued to use chloroform until 1928.

Among the several interesting case reports related to anesthetic practice is the emergency appendectomy performed on Mahatma Gandhi on January 12, 1925, at Sassoon Hospital, Pune. During an electricity failure, the mahatma was administered open-drop chloroform anesthesia, with the surgery being completed by the light of a kerosene lamp and battery-operated torch.[4]

The Middle East (Anis Baraka and Fouad Salim Haddad)

With the decline of the Greco-Roman Empire in the fifth century AD, the Middle East witnessed the rise of an Arab/Islamic civilization that within a hundred years (632-732 AD) expanded over a 3000-mile stretch extending from the western borders of India, through north Africa and Sicily, to Andalusia on the Atlantic coast of Spain. This civilization interacted with the ancient Egyptian, Hellenistic, Byzantine, Syrian, Persian, and Indian cultures. Many Arab/Islamic, Christian, and Jewish scholars translated, refined, and augmented the knowledge contained in these cultures. The new civilization that evolved lasted for around 1000 years, carried the torch of knowledge in the Middle Ages, and through its transmission via Spain and Sicily, contributed to the European Renaissance.

In this epoch, some prominent Arab/Islamic, Christian, and Jewish scholars made important contributions in the fields of medicine, philosophy, astronomy, mathematics, and chemistry. A wealth of knowledge was thus inherited by several succeeding ages. Of special interest, the following scholars made contributions to the field of anesthesia: (1) Al-Rhazi (865-925 AD), born in Ray, Persia, described the pupillary reaction to light and the laryngeal branch of the recurrent laryngeal nerve[5]; (2) Avicenna (980-1037 AD), born near Bukhara, Persia, enumerated agents that

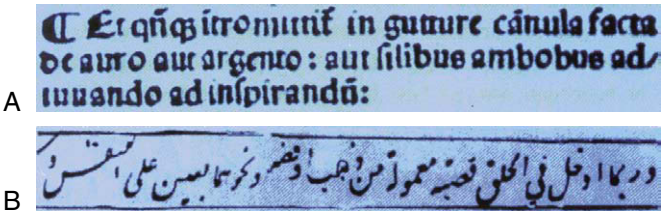

Figure 3-1 **A,** The Latin version of oral intubation: *Et quandoque intromittiture in gutture canula facta de auro aut argento: aut silibus ambobus, adjuvando ad inspirandu*. **B,** The Arabic version of oral intubation: When necessary, a cannula made of gold, silver, or another suitable material is advanced down the throat to support inspiration. *(From Haddad FS: Ibn Sina [Avicenna] advocated orotracheal intubation 1000 years ago: Documentation of Arabic and Latin originals. Middle East J Anesthesiol 17:155-162, 2000.)*

alleviate pain: opium, henbane, and mandrake; in his *Canon of Medicine*, he advocated oral intubation: "When necessary, a cannula of gold, silver, or another suitable material is advanced down the throat to support inspiration" (Fig. 3-1)[6,7]; (3) Ibn Al Nafis (1208-1288 AD), born in Quresh, near Damascus, Syria, criticized in his *Sharh Tashrih Al Qanou* Galen's theory of blood movement, which said that blood from the right ventricle passes into the left ventricle through small invisible pores in the septum (Fig. 3-2A); Ibn Al Nafis asserted that there is no direct pathway between the chambers and the thick septum of the heart is not perforated, and he described the pulmonary circulation as we know it today (see Fig. 3-2B)[8,9]; and (4) Al-Khawarizmi (died 840 AD), born in Balkh, Persia, who was a famed mathematician; the word "algorithm," a mathematical tool, is attributed to him. Algorithm is defined as "a step-by-step problem-solving procedure."[10]

THE USE OF SPONGIA SOMNIFERA. In the Middle Ages, the concept of inhalation to induce sedation before surgery with use of the sleeping sponge, or *spongia somnifera*, is attributed to Arab origins.[11,12] With the Arab conquest of Sicily in the ninth century and the Latin translations of Arabic medical books that followed, Arabic medicine, including the soporific sponge, took hold in southern Italy (Salerno, Monte Cassino). From there it spread to other parts of Europe and was used in the Middle Ages.[12] A probability also exists that it was carried from the Andalus of Spain by Michael Scot, who in the 13th century transmitted scientific culture from Toledo to Bologna via the Court of Frederick II Hohenstaufen in Sicily.[13,14]

After the Middle Ages, major political events in the 19th century affected the development of medicine throughout the countries of the Middle East. First, with Napoleon's invasion of Egypt in 1798, the medical awakening of Middle Eastern countries to western medicine can be said to have started. To win the cooperation of the Egyptian people, Napoleon brought with him men of all specialties.[15] After Napoleon's departure from Egypt and the assumption of power by Mohammad Ali in 1805, efforts to propagate knowledge and education continued. Mohammad Ali brought doctors from Europe and France to take care of the health of his army. Of those, the most remarkable was Dr. Antoine Berthelemy Clot (later Clot Bey) (1793-1868), who was brought to Egypt in 1825. In 1835 Bey established a medical school in Kasr Al Aini Hospital in Cairo, the only Arab medical school in the Middle East at the time.[15]

The developing renovation of Egypt then influenced other regions of the Middle East, either through students flocking to

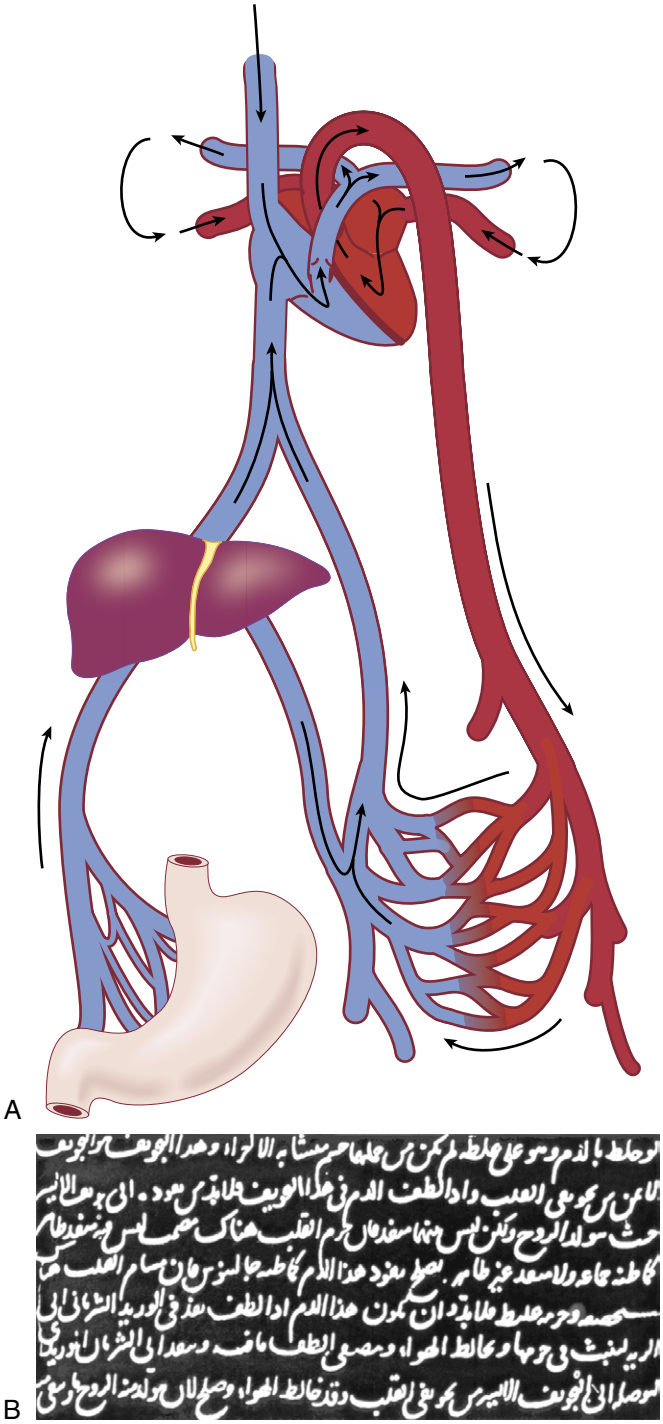

Figure 3-2 **A,** Galen's theory of blood movement. According to Galen, blood reached the periphery through the veins (most of it departing from the liver), as well as through the arteries (departing from the heart). Little blood went to the lungs from the right ventricle of the heart. He thought that most of the blood passed from the right to the left ventricle through pores in the intraventricular septum. **B,** Photographic reproduction of the original manuscript of Ibn al-Nafis denying the presence of intraventricular pores and describing the pulmonary circulation as we know it today.

study medicine in Kasr Al Aini Hospital or through the influence of the Egyptian military campaign (Ibrahim Pasha, son of Mohammad Ali) against the then known Syria (1831-1840). Graduates from the medical school in Cairo practiced in all big cities of the Middle East: Beirut, Damascus, Allepo, Jerusalem, Safad, Nablus, Haifa, and Nazareth. It is assumed that the analgesia practiced in major cities of the Middle East was the same technique used in Cairo. Relief of surgical pain in Cairo then consisted of herbal medications and antispasmodics.[15] No kind of inhaled anesthesia was known.

After the invasion of Syria by Ibrahim Pasha from 1831 to 1840, the Egyptians, with the influence of Western missionaries, built two military hospitals—one in Allepo and one in Damascus—and established free medical clinics.[15,16] The presence of Clot Bey in the campaign was instrumental in sending the first five Lebanese students to study medicine at Kasr Al Aini Hospital.[15]

Finally, after massacres in 1860, western powers (American, French, and British) intervened in Lebanon, and with the inflow of missionaries, more medical schools and hospitals were established. In 1866, the Americans founded the Syrian Protestant College, which in 1920 became the American University of Beirut. In 1883, the French founded their medical school (Faculté Française de Médecine).[15]

Introduction of Modern Anesthesia to the Middle East. In 1846, the first published account of the use of ether anesthesia for a surgical operation appeared, and the innovation spread rapidly,[17,18] including to London in December 1846 and Paris in January 1847. Twenty-seven years later, in 1873, it arrived in Beirut[15] with the help of an American surgeon, Dr. George Post.

In 1863, Dr. Post had arrived in Lebanon to assist in missionary work. In 1867, he and others established the medical school of the then Syrian Protestant College, and in 1873, Dr. Post wrote a book on surgery in the Arabic language, which included a chapter on general anesthesia, the first of its kind in the Middle East. It was in this book that for the first time mention was made of administering chloroform to reduce a dislocated shoulder of a patient, which was performed at the Syrian Protestant College's Johanniter Hospital in Beirut. To describe this action, Dr. Post coined the word "kulfera," an Arabization of the word chloroform. Dr. Post rightly deserves the title of the First Pioneer of Modern Anesthesia in Lebanon and the Middle East.[15]

Graduates of the Syrian Protestant College in Lebanon and other graduates of medical schools in the Middle East probably administered open-drop ether or chloroform along with local and spinal anesthesia through the rest of the 19th century and middle of the 20th century. Physicians, students, nurses, nuns, and technicians were most likely also involved.

Russia (Olga N. Afonin)

The history of Russian medicine has its roots in the history of medieval European medicine. Right through the 18th and 19th centuries, much of the information about anesthetic techniques—applying "snow" 15 minutes before surgical procedures and analgesics for the cardiovascular and respiratory systems and wound healing, as well as the use of bellows for lung ventilation—came from various leaders in European medicine. In addition, like their colleagues in the Middle East and India, Russian physicians of course heard of the use of ether on October 16, 1846; that day is still a professional holiday for anesthesiologists in Russia. A brief 4 months later, Dr. F. I. Inozemtzev of Moscow became the first in Russia to use ether for anesthesia during surgery.

Around the same time, the art of local anesthesia was developing rapidly after the publication of an article by the Russian doctor Vassili von Anrep. He described the effects of cocaine as a topical and subcutaneous local anesthetic in 1879. Isolated by the German chemist Friedrich Gaedcke in 1855 and purified by University of Gottingen student Albert Niemann in 1859, cocaine was first given to a patient in 1884. It was the only local anesthetic until 1904, when procaine was synthesized.

von Anrep's ideas of local anesthesia were very popular. Famous physicians of Europe and Russia (Shleich, Lukashevich, Vishnevskiy, Bier) were developing the knowledge of local anesthesia, which gave rise to new methods of preventing pain: local field anesthesia, local infiltration anesthesia, nerve blocks, plexus anesthesia, intravenous anesthesia, and neuraxial anesthesia.

In general anesthesia, the Russian physician Nikolay Pirogov (1810-1881) was a prominent physician and surgeon, well known in Europe. He was the first to describe the negative effects of general anesthesia and the possibility of severe complications. He postulated the necessity of acquiring detailed knowledge of the physiologic and clinical effects of anesthetics and requiring a separate course on anesthesia during medical education. He also described many of the modern methods of anesthesia, including inhaled endotracheal anesthesia, intravenous anesthetics, rectal use of anesthetics, and spinal anesthesia. This had a huge impact on the analgesia provided to wounded soldiers in terms of increasing surgical success and rates of survival.

In 1904, the Russian physicians S. P. Feodorov and N. P. Kravkov described and demonstrated total intravascular anesthesia with the intravenous anesthetic Gedonal. They were also the first to use combined narcosis through induction with Gedonal and maintenance with inhaled chloroform.

Another area in which Russian physicians made advances was in the field of blood transfusions. In 1901, Karl Landsteiner reported his discovery of the possible existence of blood types. In 1909 he expanded his initial discovery by establishing the A, B, AB, and O blood types. He demonstrated that transfusions between individuals with the same blood group do not result in the destruction of new blood cells and that this catastrophe occurs only when a person is transfused with the blood of a person belonging to a different group. In 1930, Landsteiner received the Nobel Prize for his work. In 1907, Russian physician Yanskiy had described four blood types and created the basics of blood transfusion. His work, however, went unnoticed.

Just a few short years later, World War I began, followed by the October Revolution in 1917, which destroyed the monarchy in Russia. Civil war, general poverty, and empowerment of the Communist Party in the early 1920s led to dramatic changes in Russia's political philosophy, economics, and technical and scientific progress, all of which affected the development of medicine. With Joseph Stalin coming to power in the 1920s, communication with other countries in Europe was terminated, exchange of information stopped, and Russian physicians had to continue treating their patients while developing the art of medicine separate from the knowledge and advances in the rest of the world. On the other hand, advances in Russian medicine were not known to the world and, frequently, had to be reinvented.

The Cross-Pollination Period: Approximately 1920-1980

In the late 1970s, the editor took a sabbatical in Holland, during which time he lectured at a local university hospital. Also there at the time was a young anesthesiologist from Ecuador. Over time, the two physicians became friends as they shared ideas about the practice of anesthesiology and its future. This rich exchange about their profession continues to this day. This was the beginning of the editor's understanding of the interesting and varied approaches in different parts of the world to achieve the status of anesthesiology as it now stands.

Their cross-cultural exchange, however, is no aberration. Over the approximately 60 years from the end of World War I through the early 1980s, anesthesiologists from around the world began to meet in a variety of forums facilitated by the advent of air travel and modern communications.

Physicians received training and education abroad. Lecturers from diverse nations spoke frequently outside their home country and brought in new ideas and techniques. Academic and research journals proliferated, as did international congresses and access to textbooks, thereby laying the groundwork for a common understanding about how to practice anesthesia.

India (Deepak K. Tempe)

Up to about 30 years ago, anesthetic equipment in Indian operating rooms often consisted solely of a simple anesthesia machine, a suction unit, and perhaps an electrocardiographic monitor. Even the oxygen supply was mainly via cylinders, with very few hospitals having a centralized medical gas supply. The first medical pipeline system was installed in Vellore in 1954.

Today it is widely accepted that postoperative care is crucial for the success of surgery, but in previous days, many patients were sent back to the ward directly after surgery and only a few would go to the recovery room. In recognition of the fact that surgical patients often need to be observed in a specialized area, India commissioned its first intensive care unit (ICU) in 1963 in an Army hospital in Delhi. Interestingly, that was the same year that an ICU was first established by an anesthesiologist at the University of California, San Francisco.

During this stretch of the 20th century, Indian anesthesiologists also recognized the need for professional societies. The idea of an Indian Society of Anaesthesiologists (ISA) was conceived in 1946; the group was established in 1947. The first ISA meeting was held in 1949 during a surgeons' conference in Mumbai, and the first independent ISA conference was held in Hyderabad in 1965. Professors Macintosh and Gray were the distinguished guests during the conference. The ISA published its first official journal in July 1953 and joined the World Federation of Societies of Anesthesiologists (WFSA) in 1956. The group has grown from 19 members when it began to nearly 12,000 members in 2007.

The Middle East (Anis Baraka and Fouad Salim Haddad)

At the end of World War I, the Middle East was divided by Western powers into small countries that were placed under British and French mandate. The major pattern in the practice of anesthesia was complete dependence on foreign surgeons, who could administer anesthetics, as well as on local and foreign nurses or nonanesthesiologists and technicians, who administered ether or chloroform. This period also witnessed the foundation of faculties of medicine in some countries of the Middle East (Syria, Sudan, and Iraq).[16]

By the end of World War II, the beginning of oil production contributed to an improving economy, which meant more funds available for anesthesia machines, endotracheal tubes, and thiopental, all of which began to appear in many countries of the Middle East. An influx of newly trained surgeons increased the demand for qualified anesthesiologists, thus prompting anesthesia residencies. In addition, in response to a manpower shortage in many countries of the Middle East, nurse and technician training began as well, although this was gradually phased out as locally and internationally trained and certified anesthesiologists began arriving in many countries of the Middle East.

During the second half of the 20th century, all countries of the Middle East were striving to attain state-of-the-art anesthesia. The World Health Organization (WHO) played a great role in encouraging and sponsoring graduate physicians for training in anesthesia at the World Anesthesiology Training Center in Copenhagen.

Raising the Professional Profile of Anesthesia. As in many other places in the world, the status of anesthesia in the Middle East depends partly on the establishment of fully independent departments of anesthesia that have their own structure, staff, residency training, research, and certification by international academic institutions and that offer fellowships in cardiovascular, obstetric, and pediatric anesthesia, as well as pain management. To that end, certain landmark strides were taken during this period.

In 1966, the *Middle East Journal of Anesthesiology* (ISSN 0544-0440) was founded; it continues to thrive to this day. Its main objectives are to act as a forum for education and exchange of opinions and to promote research and publication of Middle Eastern medicine and anesthesia. The journal is accepted for inclusion in the Index Medicus and MEDLARS system.

In addition, in the 1960s and 1970s, many Middle Eastern countries founded their own national societies of anesthesia, which promoted the practice and image of the specialty. In 1990, The Pan Arab Society of Anesthesia and Intensive Care was founded and became a member of the WFSA. Every 2 years, the Pan Arab Society holds The Pan Arab Congress of Anesthesia and Intensive Care in one of the member countries.

Russia (Olga N. Afonin)

In the midst of the economic difficulties and political upheaval after the Russian civil war, medical services underwent dramatic reorganization and expansion, and some positive developments ensued. Campaigns were carried out against diseases and poor hygiene. Thousands of unpaid men and women underwent short courses in nursing. They went all over the country to educate people and treat deadly diseases, often risking their own lives. This remarkable effort was rewarded in just a few years. The epidemics were stopped, and control of many diseases was established. This

experience emphasized the importance of preventive measures, including vaccinations, and Soviet physicians began working on preventive medicine.

Meanwhile, in Moscow, Dr. Yurevich was first in the world to begin using citrate for blood conservation. His colleague Dr. Shamov was first to use cadaveric blood for transfusion in 1928, thus giving birth to a new field of medicine—transplantation.

The very first Institute of Blood Transfusion, a scientific center for study and development of the science of blood and blood component use and storage, was formed in 1926 in Moscow by Professor A. A. Bogdanov. Physicians of the institute developed and published the first systematic approach to the treatment of shock, including traumatic, hypovolemic, and "burn related." Another dramatically important innovation of Russian physicians was the introduction of methods of diagnosis and treatment of electrolyte and acid-base imbalances with complex salt solutions, blood substitutes, and total parenteral nutrition solutions.

In 1924, the Russians S. S. Bryuchonenko and S. I. Chechulin constructed and used the very first artificial heart machine in the world, the parent of what is now known to us as a cardiopulmonary bypass machine. Surgical procedures were becoming more complex and required more advanced methods of exposure of the abdominal and thoracic organs. The bellows of Dr. Henry Hickman was transformed into many different machines to provide artificial ventilation, including the famous "iron lung" of Harvard, used first in Boston in 1928.

In 1939, N. L. Gurevich and G. S. Yun'ev developed the physiologic basis and methods of indirect heart massage and electrical defibrillation. These methods were used successfully on patients requiring complicated cardiothoracic surgeries in Russia.

As all these developments grew into complex surgical procedures and as the use of neuromuscular blocking drugs spread, it became necessary in Russia to develop a new kind of subspecialty in medicine: anesthesiology. This would require extensive and detailed knowledge of many disciplines, including physiology, biochemistry, surgery, medicine, neurology, pharmacology, traditional anesthesia, and critical care.

The first Department of Anesthesiology in Russia branched out of the Department of Cardiothoracic Surgery (now the Russian Medical Academy of Physicians Postgraduate Education) in 1959 in Moscow (this is also the same year that the current Department of Anesthesia was formed at the University of California, San Francisco). The first postgraduate courses for physicians to become anesthesiologists lasted 4 months. Later, there were additional courses of anesthesiology that included the basics of intensive care and another couple of months of additional training. The broad variety of topics covered and the complexity of the potential patient care issues meant that the new specialists needed more time to properly prepare for their careers. These careers were in demand as newly formed anesthesiology and intensive care departments required more and more anesthesiologists to teach and take care of patients.

It was in 1969 when the Ministry of Health of the Soviet Union released the "Order of improvement of anesthesiologic and reanimatologic (intensive care) services in the country." That was when anesthesiology finally received the financial and administrative support required at that time for any significant changes to take place.

Figure 3-3 The Ombrédanne anesthesia delivery device.

South America (Guillermo Lema)

The main influences on the South American practice of medicine in general, and anesthesia and surgery in particular, come from Europe. For many years and particularly during the first 6 decades of the 20th century, many doctors were trained in different parts of Europe: France, Germany, and Scandinavian countries among others. The European influence was as strong in medicine as it was in other aspects of daily life.

One example of Europe's influence was South Americans' wide use of the Ombredanne (Fig. 3-3). This device, used to deliver anesthesia, was invented in France in 1908 by the surgeon Dr. Louis Ombrédanne (1871-1956). It is believed that South America is the only continent where this particular equipment was clinically acceptable and used widely.

Of course, ether was not the only anesthetic used during this time. Cyclopropane was another, although Chile had a dramatic experience with this gas that eventually caused it to be banned. In 1963 at the Manuel Arriarán Hospital in Santiago, a cyclopropane tank exploded in a pediatric operating room. Two small boys and four physicians—two of them anesthesiologists—died. This remains one of the worst anesthesia-related accidents ever to happen in the world. New standards, including the banning of cyclopropane, were imposed to avoid further accidents.

China (Yuguang Huang)

In the early 20th century, with the introduction of Western medicine into China, modern anesthesia began to be applied in clinics. At that time, anesthesia was implemented mainly by nurses or surgeons. Only a few Western professional anesthesiologists, such as Mr. Yueqing Ma from the Peking Union Medical College, could undertake clinical anesthesia in China.

After the foundation of the People's Republic of China in 1949, some early pioneers—such as Jue Wu and Xingfang Li from Shanghai and Rong Xie, Deyan Shang, and Huiying Tan from Beijing—returned from the United States and Europe to help modern anesthesia take shape in China.

In the 1950s, only simple anesthesia was available in China, such as the ether open-drop method, inhaled tracheal intubation anesthesia, and single procaine spinal anesthesia. Peripheral nerve block and continuous epidural anesthesia were introduced gradually.

From the 1950s to the 1980s, intravenous procaine combined anesthesia and continuous epidural anesthesia were the most common methods in China. When anesthetic drugs and monitoring tools became scarce in the 1960s, Chinese anesthesiologists tried to develop acupuncture anesthesia based on the pain-relieving mechanisms of traditional Chinese acupuncture. In addition, in the 1970s Chinese anesthesiologists investigated the anesthetic effect of Chinese herbal medicine. However, beginning in the late 1970s, because of the success of reform and the government's opening-up policy, many new anesthetic drugs and instruments were introduced into China. At that time, acupuncture anesthesia and herbal anesthesia stepped down from the clinical stage as a result of their unsatisfying anesthetic efficacy and adverse effects.

Raising the Professional Profile of Anesthesia. Chinese anesthesiologists also began raising their profile as early as the 1950s, when they took part in the rescue of critically ill patients via cardiopulmonary resuscitation. For example, in 1959, Professor Yuanchang Wang from Tianjin Medical College shared his experience in the *Chinese Journal of Surgery* by reporting that a woman whose life was in danger during cesarean section was saved by chest compressions. Partly because of the influence of anesthesiologists, since the 1970s ICUs and postanesthesia care units (PACUs) have gradually been established in many domestic hospitals.

China has also participated in numerous international conferences and professional groups (Fig. 3-4). The First National Conference on Anesthesia was held in Nanjing in 1964, during which the development and achievements of Chinese anesthesiology were systematically reviewed. In 1979, the Chinese Society of

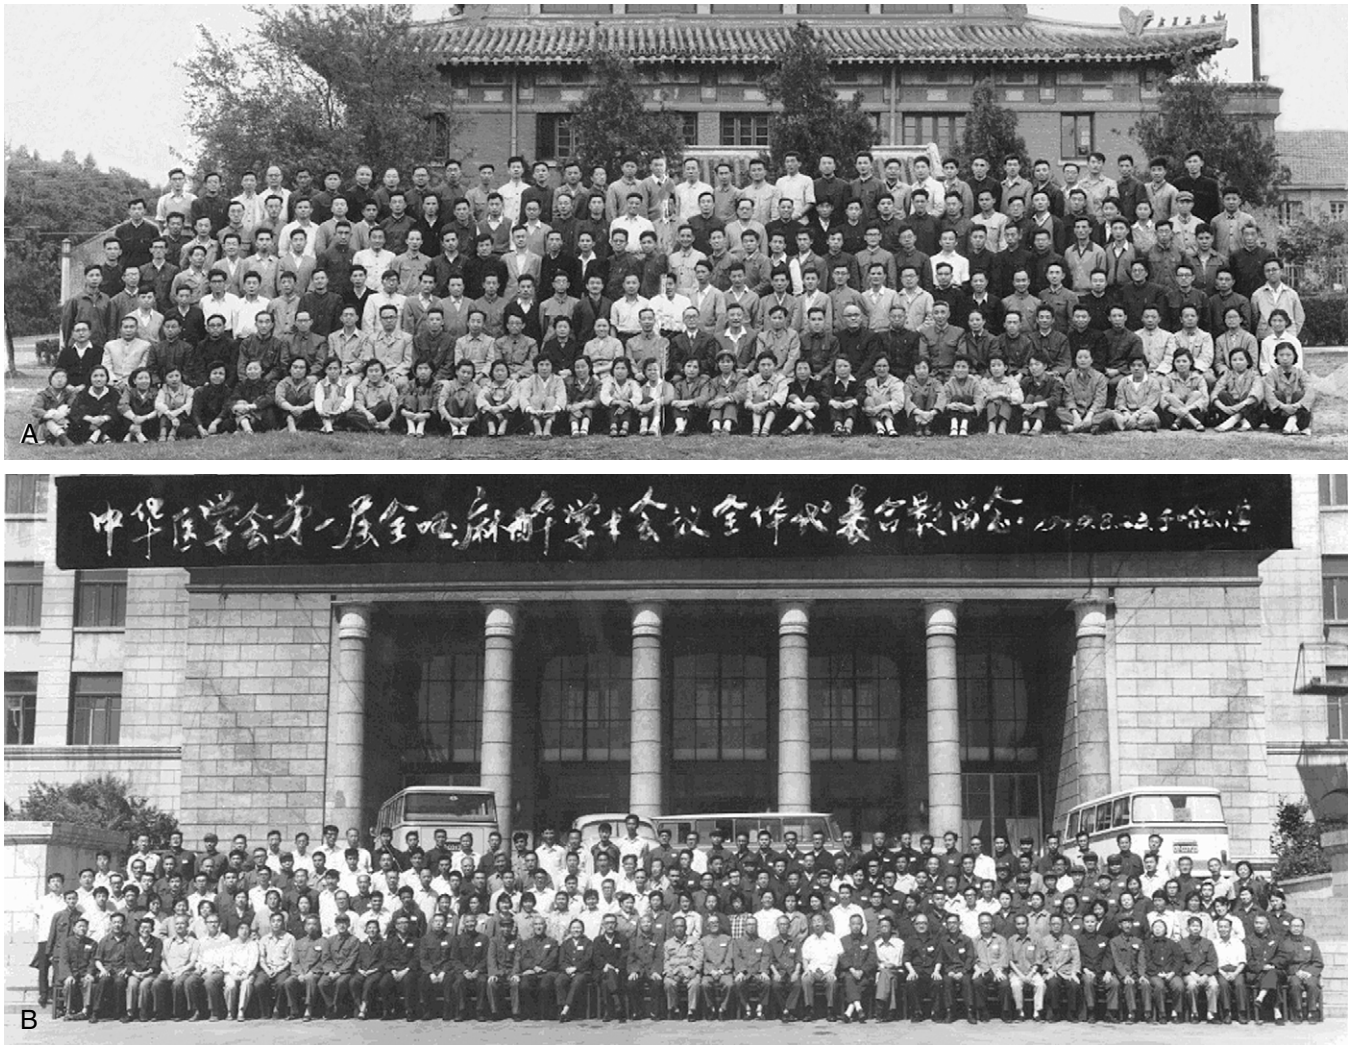

Figure 3-4 A, Participants of the First National Conference on Anesthesia, Nanjing, 1964. **B,** Participants of the Second National Conference on Anesthesia, Harbin, 1979, during which the Chinese Society of Anesthesiology was founded.

Anesthesiology (CSA) was founded during the Second National Conference on Anesthesiology held in Harbin. Professor Deyan Shang was elected as president of the first CSA committee. Since then, national CSA conferences have been held every 3 or 4 years.

During this period there was also a foray into professional publications, most notably Professor Jue Wu, the leader of Chinese anesthesia, who was the lead editor of *Clinical Anesthesiology* in 1954 and *Practical Anesthesiology* in 1976.

Western medicine introduced by the United States also helped promote the development of modern medicine in China. A good example is Peking Union Medical College (PUMC) Hospital, which was founded by the Rockefeller Foundation in 1917. Even today, PUMC Hospital is still regarded as an "ivory tower" of Chinese medicine. Some professors from PUMC Hospital moved to Taiwan in 1949, and some of them changed their specialization from surgery to anesthesiology and became the early practitioners of anesthesiology there. They made important contributions to the foundation and development of modern anesthesiology in Taiwan.

The Modern Period: The Essentials of Modern Anesthesia Around the World

The last 25 years has been an exciting period for anesthesia, largely because the ability to share clinical and research experience has made the practice safer and better than it ever has been.

Today, all anesthesiologists, no matter where they practice in the world, can gain access to the information necessary to deliver safe anesthesia. However, there are still places in the world that do not have access to the equipment or supplies needed to implement that knowledge. This section details the essentials: the roles and responsibilities, the facilities and equipment available, the education and accreditation, the professional societies, and the research conducted by anesthesiologists around the world.

Roles and Responsibilities of Anesthesia Providers

India (Deepak K. Tempe)

In India, anesthesia can be administered only by a qualified anesthesiologist or by a trainee anesthesiologist under the supervision of a qualified anesthesiologist. In some states, such as Delhi, a directive from the government has been issued that states, "Anesthesia must be administered by a qualified anesthesiologist, i.e., an anesthesiologist with a postgraduate qualification and who has been actively working."

The duties and responsibilities of anesthesiologists have been evolving, but they have not yet been clearly defined by the ISA or health care officials (Ministry of Health). Nevertheless, it is now well recognized that an anesthesiologist's work is not limited to the operating room (OR). Typically, anesthesiologists in India are involved in the following types of care: (1) preoperative assessment and preparation of patients; (2) perioperative care of patients; (3) pain relief during the perioperative period; (4) management of critically ill patients; (5) management of acute, chronic, and cancer-related pain; (6) management and teaching of resuscitation skills; (7) provision of outpatient anesthesia services; (8) administrative involvement in setting up and managing health care organizations; (9) disaster management coordinator in the hospital; and (10) teaching and training of the medical and paramedical staff.

In addition to the duties just listed, both natural and man-made disasters have provided an extra challenge for anesthesiologists. By virtue of their ability to administer emergency life support measures, as well as their perioperative management skills, anesthesiologists were at the forefront during the Gujrat earthquake and tsunami disasters and actively participated in setting up operating theaters on site and providing care to victims. Likewise, during the Mumbai and Delhi bomb blasts, anesthesiologists played a leading role in carrying out emergency surgery and perioperative management.

Preoperative Evaluation. Despite preoperative evaluation and preparation of the patient being integral components of safe surgery, there were no dedicated preoperative anesthesia clinics (PACs) in India until recently. That began to change in the early 1980s, and today almost all hospitals have a dedicated PAC in which all patients are screened before surgery (including outpatient day surgery). PACs have become increasingly important because of a growing incidence of cardiovascular and other systemic diseases in patients undergoing surgery. In PACs anesthesiologists review and optimize the treatment of other systemic diseases, as well as detect new diseases and health concerns. In addition to improving patient outcomes, PACs help develop the patient-physician relationship and patient awareness about anesthesia. A few hospitals have started awareness programs wherein a lecture is delivered (with illustrations) on a monthly basis to patients and their relatives to make them familiar with the anesthetic techniques and procedures that they will undergo.

Operating Room. The OR continues to be the mainstay of anesthetic practice, but because ORs are the major consumers of hospital resources, as well as a major source of income for private hospitals, it is imperative that ORs be managed in the most efficient manner. However, there is no consensus on an ideal system to ensure efficiency in this area. The anesthesiologist is actively involved in trying to improve efficiency, especially with triage and scheduling of urgent and emergency cases. Safety is another concern. The professional risks (especially those related to needlestick injuries) of anesthesiologists, as well as other workers in the OR, are well recognized, and preventing such health care hazards has become an important consideration.

Recovery Room and Postoperative Intensive Care Units. Appropriate postoperative care is crucial for the success of surgery. Today in India, depending on the nature of the surgery and the patient's condition, the patient is transferred to either a recovery room or an ICU; some version of an ICU or recovery room exists in almost all major hospitals in India today. The nomenclature of these areas is not uniform, though, so terms that include postoperative ward, recovery room, high-dependence unit, critical care unit, and PACU are often used to describe the same facility. At some hospitals, especially those in which major and complex surgery requiring postoperative ICU management is not performed regularly, there is no demarcation between an

ICU and the recovery room. A single area designated as a recovery room is used for both purposes.

Where there is a distinction, the decision about where a postsurgical patient belongs is governed by the degree of morbidity. If a patient is very sick and requires ventilation and careful hemodynamic monitoring, the patient is transferred to an ICU. If mechanical ventilation and continuous hemodynamic monitoring are not required, the patient is transferred to a recovery room, which is perhaps the equivalent of the PACU. Patients undergoing daycare surgery (if practiced in a given hospital) are also transferred to the recovery room before discharge.

Most recovery rooms are under the charge of an anesthesiologist; in the case of ICUs, sometimes the anesthesiologist is in charge and sometimes not. Practice varies from place to place and is generally governed more by the logistics involved in a particular hospital than by any definite norms.

Ambulatory Care and Other Areas. Although it is recognized and appreciated that ambulatory care is a distinct possibility in a substantial number of patients, it is not practiced as much as it should be. It is difficult to provide exact figures in this matter, but in general, it is the private/corporate hospitals that practice ambulatory care. The number of government hospitals practicing ambulatory care is relatively small, mainly because of logistic reasons. That is likely to change, however, with the increasing availability of short-duration anesthetic drugs and modern surgical facilities (tools for minimally invasive surgery). Saving cost to the patient and the hospital and increasing patient turnover have been the major factors influencing interest in ambulatory care. The safety issues related to ambulatory care are well recognized, but there are no guidelines or recommendations from the ISA or any other regulatory body on this matter.

Anesthesia services are also frequently required in several other areas outside the OR. These areas tend to be less familiar to most anesthesiologists and provide less access to the facilities typically available in an OR. Their proliferation, however, has increased the demands on our profession. Areas where anesthesia is playing an increasingly prominent role include radiology suites (computed tomography, magnetic resonance imaging [MRI], and interventional radiology), the cardiac catheterization laboratory, electrophysiologic laboratories, the endoscopy room, and the electroconvulsive therapy room. In most of these areas patients require sedation, but with some lengthy procedures—such as MRI, electrophysiologic studies, and some interventional procedures—patients tend to get restless and may require general anesthesia. In addition, special considerations such as long breathing circuits or MRI-compatible equipment may be necessary. The anesthesiologist should be familiar with these requirements to maintain safety standards.

Critical Care Medicine. In the beginning, the anesthesiologist's focus on critically ill patients was ventilatory care because anesthesiologists are well versed in cardiorespiratory physiology and ventilatory management. Furthermore, managing a critically ill patient was considered an extension of the job that anesthesiologists performed in the OR. Therefore, the anesthesiologist managed patients receiving controlled ventilation via a ventilator and, ultimately, weaned the patient from mechanical ventilation.

Subsequently, however, it became obvious that respiratory function was only one aspect (albeit a crucial one) of the care of the critically ill. Anesthesiologists therefore became well informed about cardiovascular support, nutrition, infection, and various other diagnostic procedures. However, the interest of anesthesiologists in critical care medicine has been waxing and waning, and other specialists have entered this field. Currently, management of critical care units in India tends to be split: some are managed by physicians not trained in anesthesia, others by anesthesiologists.

There is widespread agreement that a critical care specialist who is devoted full-time to the care of critically ill patients should manage a critical care unit. The consensus includes three key items: (1) a dedicated expert irrespective of the specialty (if not holding a critical care qualification) should be in charge of the critical care unit; (2) each hospital can follow practices according to the availability of trained or experienced personnel with the primary aim of giving the best possible care; and (3) care of critically ill patients is always a team-based process, and the practice of taking the advice of different experts in managing a particular case is encouraged to achieve better outcomes.

Critical care training has long been part of the anesthesia residency program in India, but in 2001 the National Board of Examinations initiated a full-fledged 2-year training program in critical care medicine with 6 seats throughout India; the number has now increased to 25. Anesthesiologists, chest physicians, and general physicians are eligible to seek admission to this program. Clearly, the number of these specialized intensivists is not sufficient to cater to the critical care units that have mushroomed all over the country, so some disparities exist in the personnel involved in the management of critically ill patients.

In summary, critical care medicine has emerged as a new specialty but is still evolving in India. Because the number of persons having a qualification in the critical care area is not sufficient to fill current needs, anesthesiologists and physicians with interest in the specialty continue to practice critical care medicine. Out of a total of around 25 training seats, anesthesiologists account for about half, followed by general physicians (30%) and chest physicians (20%). The fact that all the seats in this program get filled suggests the growing interest in this specialty area.

Pain Management. Interest in managing pain, both acute and chronic, has been growing over the last 2 decades. Nevertheless, the specialty is in its infancy in India, the number of pain clinics is limited, and there is no formal training program. The focus has largely been on the treatment of chronic pain, including cancer pain. Most anesthesiology departments perform nerve blocks, with a few even practicing acupuncture. There are, however, very few departments that have the facilities to conduct procedures such as radiofrequency ablation, implantation of intrathecal pumps, or spinal cord stimulation. The thrust now is toward treating pain as a disease, especially in patients suffering from nervous disorders or in terminal cancer patients where the only possible form of management is alleviation of pain.

There is also growing awareness of the management of acute pain, including the possibility of providing the patient with a totally pain-free surgical experience. After all, the WHO now recognizes pain as the fifth vital sign, and alleviation of pain is regarded as a basic human right. Various forms of medicine and equipment (patient-controlled analgesia pumps; intrathecal, epidural, and intrapleural techniques) can now offer the possibility of a relatively pain-free course of surgical treatment. Indeed, management of acute pain during the entire perioperative period is a leading concern of all anesthesia departments and is also actively practiced in recovery rooms or PACUs. However, much needs to be done regarding pain management in India. The Indian Society

for the Study of Pain was formed in the late 1980s and currently has about 3200 members. The society is working toward improving pain management, but it is facing tough challenges, mainly because of lack of awareness. One looks forward to improving pain relief facilities in the country.

Russia (Olga Afonin)

Until the 1980s, Russia's anesthesia educational system was unified and structured into courses for nurse anesthetists and postgraduate education for physicians that included either a 1-year anesthesiology internship or a 2-year "Orditatura" (analogue of residency). All the programs included intensive care (reanimatology) as an obligatory part of the education. Participants were working in operating rooms and ICUs under the supervision of attending physicians and had a required course of lectures. Self-education was encouraged as well. After completion of training, graduates had to pass an oral qualification examination and were granted a Diploma of a Physician Anesthesiologist-Reanimatologist.

The quality of the education and the amount of experience varied significantly from program to program, and there were no universally accepted standardized examinations. Many conscientious anesthesiologists took additional courses on "qualification improvements" from the Academy of Physicians Postgraduate Education. However, there were also "specialists" whose education was finalized on completion of the courses.

By the end of the 1980s it became clear that the quality of education had to be monitored and the need for standardized examinations was debated to acceptance. Meanwhile, the Iron Curtain had become partially permeable to some of the information about accepted standards of education and care in the other countries. The future promised improvements, but not for long. The "era of stagnation" of the 1980s led to economic imbalance and a gradual decline in political structures. By the end of the 1980s, Communist leaders embarked on major reforms in an effort to revive the country's economics, which led to the collapse of the Soviet Union.

In turn, the continued financial support from the government for the entire medical structure became very thin and eventually disappeared. All the financially unsound programs, such as research, education, and development of new technologies or educational methods, were frozen. The government-funded health care system did not exist any more. Many professionals had to quit their careers for their families to survive. The private sector was in the very beginning of its development, and the great majority of the population could not afford private health care. It was not uncommon for patients to be asked to bring supplies for the medical care that they required, even for surgeries, and it was not uncommon for people to die as a result of the lack of proper medications or proper medical care. This continued until the mid-1990s, when things began to turn around. The damage, however, has not been completely overcome, even now.

As of today, anesthesiology education in Russia still requires revision and improvements. There is a need for structured residency programs that would teach the standards accepted around the world, which are based on decades of experience in the safe practice of anesthesiology. The Academy of Postgraduate Education recently introduced new standardized tests, comparable to internationally accepted graduation examinations, that would permit objective measurement of the knowledge of newly graduated anesthesiologists.

That said, with the exception of very few medical centers, most anesthesiologists have to practice their art of extremely invasive and possibly dangerous science without sufficient monitoring. Pulse oximeters, gas analyzers, and capnographs are still a luxury in many medical centers. Medical science is again government financed, but it is often still subject to the good will of the physicians who carve out time for research from their private lives. Russian anesthesiologists, as well as medics in other specialties, have been raising their concerns to the government. The Ministry of Health recently accepted a new national program for improvement in medical services, but it will take dramatic measures and significant investments in the health of Russian citizens for the country to achieve the goal of a safe and effective health care system in compliance with international standards. Statistics and the experience of multiple countries prove that the huge initial investments are returned as improvements in population health decrease medical and illness-related costs. It would be great to see Russia, the country that contributed so much to the growth and development of medicine and anesthesiology, return to the international scene as a partner in health promotion in all forms of medical science and art.

South America (Guillermo Lema)

For the past 50 years, anesthesiologists have been involved in PACUs and more recently have been responsible for them, including determination of the standards of care for these areas. Pediatric and cardiovascular anesthesia is generally performed by physicians with subspecialty training in these areas. Pain management and critical care reflect important areas where the influence of the anesthesiologist has been important. Anesthesia-trained personnel run most of these units.

Another area of interest is the choice that many physicians, including anesthesiologists, must make between public and private hospitals. For many years, anesthesiologists worked in public hospitals. Private practice came about afterward, in small clinics and in other institutions, with anesthesiologists generally continuing to work in public hospitals in the mornings. Nowadays, anesthesiologists tend to work solely in one hospital, either public or private.

Economic groups own most of the private clinics and run them under strict financial criteria. There are very strict professional duties, and the cost containment issue features heavily. Anesthesiologists, as well as other specialties, have lost control of these institutions, although a few have dedicated their time to administrative duties.

The resources given to public hospitals are increasing, but the benefit of these resources is less than one might expect, probably because of central and nonprofessional administration. Thus, economic restraints and inadequate conditions for anesthesiologists make posts in public practice less attractive than in private institutions.

Southeast Asia (Florian R. Nuevo)

The Association of Southeast Asian Nations (ASEAN) includes Brunei Darussalam, Cambodia, Indonesia, Laos, Malaysia, Myanmar, the Philippines, Singapore, Thailand, and Vietnam. While maintaining their operating room presence, anesthesiologists in this region are beginning to assume duties outside the operating room.

First, having gained the respect of their medical colleagues, anesthesiologists have become an important part of perioperative

care and critical care management teams. Many are also moving toward pain management, which has paved the way to the Association of Southeast Asian Pain Societies, with the main goal of promoting further advancement in the study of pain in the region. Some anesthesiologists also practice anesthesia in conjunction with intensive care medicine. Hospice care and palliative medicine are also areas where anesthesiologists are now part of the team. In addition, ASEAN anesthesiologists have emerged as leaders in their national medical organizations and have become essential stakeholders in almost every aspect of medical and surgical care.

However, as we enter areas outside the delivery and operating suites, we must caution ourselves to slow down. ASEAN anesthesiologists must remain focused in our work, within that small space in operating theaters, where we remain the unsung heroes. Physician anesthesiologists should take full responsibility for safeguarding all patients who entrust their whole being to us while undergoing a diagnostic or therapeutic procedure—asleep, immobilized, unable to protect himself from harm—with the hope that as patients regain consciousness, they will not only be healed but comforted as well.

Europe (Lars I. Eriksson and Peter Simpson)

The main areas of work in European anesthesia departments are delivery of operating room anesthesia, postoperative care, critical care medicine, pain medicine, emergency medicine, and prehospital care. In some countries, such as Italy, Germany, Norway, and the United Kingdom, more than 30% of the daily activity of anesthesiologists is devoted to critical care medicine, and in some countries a large proportion of anesthesiologists are also involved in acute and chronic pain medicine.[18]

Delivery of anesthesia in the operating room is most often performed by anesthesiologists and nurse anesthetists, although the number of operating rooms staffed by nurse anesthetists and supervised by a certified anesthesiologist varies between countries. A recent survey has indicated that Greece, Ireland, Italy, Spain, the United Kingdom, Lithuania, Bosnia-Herzegovina, and Israel do not have programs for nurse anesthetists.[18] In all remaining countries, the number of nurse anesthetists per 100,000 population varies largely, from 0.7 in Albania and 4.9 in Turkey to 106.4 in Luxembourg. In most Western European countries (except Luxembourg and Switzerland), nurse anesthetists have undergone formal examination before graduation.

In Western European countries, surveys estimate that more than 70% of an average clinician's time is spent providing operating room anesthesia, with about 20% being spent in critical care medicine, 5% in pain control, and 5% in prehospital care.[18] A similar distribution of working time is found among non–European Union (EU) member countries from all parts of Europe, including the former Eastern Europe. Although most critical care units are staffed by anesthesiologists who have an interest and training in critical care medicine and who are associated with departments of anesthesia, in some countries an increasing number of departments of critical care medicine are staffed by dedicated specialists in critical care medicine.

Facilities and Equipment

India (Deepak K. Tempe)

In India, the journey from open-drop chloroform and ether anesthesia to the present-day high-tech operating theaters with anesthesia workstations and monitors, ICUs, PACUs, pain clinics, and preanesthetic checkup clinics is nearly complete. In fact, the ORs in India have undergone huge change during the last 2 to 3 decades. The present day OR is totally modular in structure with high-tech anesthesia workstations, monitoring systems, and online networking of the various equipment that is used. Such a change has been largely due to the arrival of private investment and management in the health care business. These corporate hospitals have built state-of-the-art ORs that match the best of the ORs in the rest of the world.

One should remember, however, that like many other things in India, diversity is also a hallmark of the health care system. Although corporate and other private hospitals have state-of-the-art ORs, government hospitals—other than those in cities such as Delhi and Mumbai—may not. In general, government hospitals cater to the general population and are overcrowded with long waiting lists. The situation in rural areas in particular is not up to the mark because these places typically have only primary health centers with basic facilities and the ORs are equipped to deal with just minor surgical procedures. Thus, ORs of several varieties can still be seen in India, and one hopes that this diversity gradually changes to uniformity in times to come.

It has been quite a challenging and turbulent journey from the days when Mahatma Gandhi was operated on with the open-drop chloroform technique to today. However, it is satisfying to see that developments in anesthesia have kept pace with time in India. Consider that recently the present Prime Minister Dr. Manmohan Singh underwent prostatectomy at the All India Institute of Medical Sciences (AIIMS). During that procedure, anesthesiologists used a balanced general anesthesia with drugs such as fentanyl, midazolam, sevoflurane, and atracurium and full-fledged monitoring. In addition, they used a patient-controlled analgesia pump for postoperative analgesia.

The Middle East (Anis Baraka)

The anesthetic machinery, monitoring equipment, and anesthetics used match the international standards that are approved by international societies, such as the American Society of Anesthesiologists. Figure 3-5 shows the operating room and illustrates monitoring of a patient undergoing coronary artery bypass grafting at the American University of Beirut Medical Center, which has updated anesthesia equipment.

South America (Guillermo Lema)

In South America, as in other places in the world, the economic resources invested in medicine and anesthesia depend on the economic situation of the country. The huge disparity in economic growth among countries in the region has produced an enormous difference in public resources allocated to health care, which has created diverse conditions for public health management. Moreover, anesthesia has been a relatively low government priority in many countries because governments often perceive anesthesia as having high cost (because of the technology) and little impact on the improvement of health care.

Nevertheless, countries with anesthesia as a mature specialty (Argentina, Brazil, Colombia, Chile, and Uruguay) have modern equipment, advanced monitoring technology, and access to all types of anesthetics and ancillary drugs, comparable to the United States and Europe. Anesthesia techniques vary, and many different types are being practiced. Anesthesia with volatile anesthetics has been used widely for many years and in all of these

Figure 3-5 The operating room at the American University of Beirut Medical Center, which shows the updated anesthesia equipment and monitoring of a patient undergoing coronary artery bypass grafting.

countries. Total intravenous anesthesia is also common these days, and the use of regional anesthesia has been widespread. Other countries, because of resource constraints, practice a more basic form of anesthesia. Regardless of resources, however, all anesthesiologists in South America need to have a strong focus on cost containment. Indeed, this situation is common globally.

Uganda/Sub-Saharan Africa (D.G. Bogod)

In a 2007 survey of more than a quarter of Uganda's anesthetic practitioners, 23% thought that their facilities met all of the widely accepted minimal standards for the practice of safe, adult anesthesia. Categories surveyed included access to updated information, basic operating room equipment, and the most basic supply of anesthetic drugs. For safe pediatric anesthesia, only 13% thought that their facility met the basic requirements.[19]

For spinal anesthesia techniques, more than half of the anesthesiologists surveyed did not have regular access to the necessary local anesthetics, and others did not have a ready supply of spinal needles. Only 23% could guarantee being able to find a brush to clean their tracheal tube between procedures.[19]

For cesarean sections in women during childbirth, nearly all of the respondents (94%) said that they did not have the facilities to perform this procedure safely. More than three quarters did not have reliable access to magnesium sulfate, and half of them said that they could never get it.[19]

As D. G. Bogod, editor-in-chief of *Anaesthesia*, wrote in the editorial of the issue in which these numbers were published:

> *The figures revealed by this survey show that despite the best efforts of all involved, 27 million Ugandans essentially enter a lottery every time they undergo anaesthesia—a lottery with poor odds of a happy outcome. What the authors cannot tell us is whether this problem is confined to Uganda alone . . . it would be foolish to try to extrapolate from one country to another, but it is unlikely that Uganda data differ wildly from most of sub-Saharan Africa. . . . If the situation in Uganda is bad, it is likely to be far worse in Ethiopia, Somalia, Tanzania and many other neighbouring countries.*[19]

Japan (Michiaki Yamakage)

The following summary of the practice and scope of anesthesia in Japan was excerpted, with permission, from the *Journal of Anesthesia*.[20]

> *In the 1980s, general anesthesia was mainly conducted using halothane or enflurane with nitrous oxide (laughing gas). Fentanyl, an opioid analgesic, was also available, but was rarely used because it was believed to cause delay in awakening. Epidural anesthesia was used more frequently then than it is now. For example, cervical epidural anesthesia was generally used in surgery on upper limbs or for breast cancer. The only intravenous anesthetics available at that time were thiamylal and ketamine, which was administered to asthma patients despite its known secretion-promoting effects. The depolarizing neuromuscular blocking drug (NMBA) succinylcholine was used for induction of anesthesia and the nondepolarizing NMBA pancuronium was the only NMBA available for maintenance of anesthesia. During the 1980s, there was no awareness of the progression of acute renal failure during emergency surgery, and some patients did not awake from anesthesia for a long time after surgery due to the prolonged effect of pancuronium.*
>
> *Since the 1980s, various anesthetic agents have become available in Japan. The availability of a large range of anesthetic agents together with the development of anesthetic monitors has made anesthesia a much safer and more comfortable procedure for patients. However, Japan (maybe due to its unique medical system) lags behind the US and Europe with regard to the use of anesthetic agents other than sevoflurane. The ultrashort-acting opioid analgesic remifentanil has finally been launched in Japan, and the fast-onset nondepolarizing NMBA rocuronium is expected to become available soon. The selective relaxant binding agent sugammadex that is currently being used in phase III clinical trials throughout the world is also expected to be approved for clinical use in the near future.*
>
> *General anesthesia with airway management using a laryngeal mask is increasing in Japan due to the promotion of this device and the widespread use of ProSeal (Laryngeal Mask, Jersey, UK), which has high sealability. The indication for this method of anesthesia depends on the anesthesiologist, although it is generally not used for laparotomy, thoracotomy, or for prolonged general anesthesia. If the device has high sealability and can withstand positive pressure ventilation, anesthetic management is sometimes performed under artificial ventilation with the use of NMBAs. The use of the laryngeal mask is expected to increase further.*
>
> *In the US and Europe, day surgery has become popular due to the high costs of hospitalization. Day surgery in Japan, however, is rare as most patients have national and private medical insurance. However, the duration of hospitalization is expected to become shorter with the introduction of a comprehensive medical system, though it is impossible to predict at present whether this will have an effect on the methods of anesthesia used.*

Methods used for postoperative analgesia differ greatly between countries, and between institutions in Japan. In the US and Europe, patient-controlled analgesia is popular, and intravenous opioids alone are used in about two-thirds of patients. The combination of intravenous opioids with epidural analgesia appears to be used only for patients who have undergone upper abdominal surgery or thoracotomy. In Japan, epidural analgesia with or without intravenous opioids is used for postoperative pain control in almost 50% of patients. When delivery of fentanyl by iontophoresis (Ionsys; Ortho-McNeil, Titusville, NJ, US), which is currently being tested in trials, becomes applicable for clinical use, the methods used for postoperative analgesia might undergo great change.

Finally, . . . the number of surgery cases in specialized hospitals, including university hospitals, is expected to continue to rise in Japan. Due to the increasingly advanced age of patients and an increase in incompatibility complications, the number of cases anesthetically managed by neural block or general anesthesia alone is also growing.

In Japan, with the launch of remifentanil, the anticipated approval of rocuronium, and when sugammadex and the fentanyl iontophoretic transdermal system become available, the methods used for anesthesia will continue to change significantly in the future.

Clinical use in Japan of xenon, an ideal anesthetic, and dexmedetomidine, a respiratory-sparing sedative, is unknown and controversial due to their high cost and prolonged effect/"off label" use, respectively.

Education, Accreditation, and Availability of Practitioners

India (Deepak K. Tempe)

In India, there are mainly two types of postgraduate qualifications that one can obtain in the field of anesthesiology. The first, provided by medical colleges (MD in anesthesiology, a 3-year degree program), is governed by the Medical Council of India (MCI), which oversees the syllabus and other teaching and training standards. The second one is provided by the National Board of Examinations, which awards a degree called Diplomate of National Board (DNB). In addition, the MCI also regulates the "diploma in anaesthesiology (DA)," which is a 2-year training program that is available at medical colleges.

In 1992 it was determined that no new medical college or postgraduate course could be started without the prior approval of the MCI, and the recommendations of the MCI became mandatory for all medical colleges. Thus, it was only after the addition of this section, known as 10a, that teaching and training in the medical field in India were standardized and minimum standards were enforced. The strength of the MCI as a regulatory body was further reinforced in 1998 by a Supreme Court judgment, which ruled that the regulations of the MCI are mandatory and must be applied to all medical colleges in India. As of now, the recognition awarded by the MCI for undergraduate courses must be reviewed every 5 years by an inspection team of the MCI.

However, this is not so for postgraduate courses. Institutions conducting a postgraduate course today can enjoy the benefit of one-time MCI recognition, but the MCI will soon implement a review process every 5 years for postgraduate courses. Thus, teaching and training in anesthesiology in India are standardized through the setting of minimum standards throughout the country in terms of the facilities (space, equipment, manpower, and infrastructure) and the syllabus.

Growth of the Specialty. The interest of Indian medical students in the specialty of anesthesiology has shown a dramatic increase during the last decade. Candidates for a postgraduate course in anesthesiology used to be admitted on the basis of scores obtained on the MBBS examination. This practice has now changed to conducting a common entrance examination, and admission to a given subject area is decided on the basis of the rank obtained by the student. In a few states such as Delhi, this has been the practice for approximately 20 years.

Table 3-1 shows the top and bottom ranks that were admitted to an MD anesthesiology program between 2002 and 2007 in the states of Maharashtra and Delhi. The table indicates that interest among students to learn and practice anesthesia is increasing. Reasons for the growing interest in anesthesia among students could be related to the increasing scope of anesthesia (as discussed earlier) and better job prospects. It may also be related to resistance to pursuing other fields, such as general surgery and general medicine, which require further subspecialty training. In Delhi, anesthesiology is among the top six specialties preferred by medical students, along with radiology, dermatology, pediatrics, orthopedics, and gynecology. This is in sharp contrast to the situation about 10 to 15 years ago, when anesthesiology was among the last five choices.

There are a total of 269 medical colleges in India with 30,000 undergraduate and 9100 postgraduate seats. Of these, there are 612 seats in MD anesthesia and 528 in DA anesthesia. In addition, the Ministry of Health and Family Welfare of India recognizes the DNB as a qualification in the given field and equates it with the postgraduate degrees awarded by other Indian universities; there are approximately 205 DNB seats in anesthesiology.

One challenge is assigning seats, especially because it remains unclear just how many anesthesiologists India needs. According to one estimate, there are approximately 28,000 anesthesiologists in India and the country requires about 7000

Table 3-1 Overall Rankings of Postgraduate Students Enrolled in Anesthesiology Programs in Maharashtra and Delhi (2002-2007)

	Maharashtra		Delhi	
Year	Top Rank	Bottom Rank	Top Rank	Bottom Rank
2002	228	854	65	98
2004	No exam		53	96
2005	405	642	32	96
2006	160	606	33	99
2007	106	504	61	85

Note: The total number of postgraduate seats in all subjects is 140 in Delhi and 450 in Maharashtra. The students often sit for entrance examinations in several states, which probably explains why the last rank exceeds the number of seats in Maharashtra.

more (data provided by the current president of the ISA at the Uttar Pradesh chapter congress in November 2007).

The Middle East (Anis Baraka)
The departments of anesthesia in the different Middle East countries consist of highly academic staff certified either by the Arab Board or foreign academic bodies, such as the American Board of Anesthesiology of the United States and the Faculty of the Royal College of Anaesthetists of the United Kingdom.

South America (Guillermo Lema)
Training of anesthesiologists is a contentious issue in South America. First, there is a large discrepancy between the views of anesthesia societies and the government with regard to the number of anesthesiologists needed. All countries on the continent have anesthesia training programs of different quality. The governments run a few, but universities conduct most of them.

There is no dispute about the length of time needed for training; regardless of who runs the program, 3 years is required to complete the training. Some countries also have specific scientific organizations run by universities and scientific societies to certify the various places where anesthesia is being taught. There are still places without proper certification that teach residents, but they are gradually being restricted from teaching.

Requirements for anesthesiologists are viewed differently by governments and scientific societies. Governments push for increased numbers of practitioners, whereas universities prefer better trained ones. Despite such difficulties, anesthesiologists and their scientific societies have campaigned for greater influence in the processes of accreditation. To the author's knowledge, only two countries have an anesthesia training program conducted by anesthesia societies; however, in those countries conflict with the government is even greater.

Further training of anesthesiologists is performed abroad, usually in Europe, the United States, or some prominent anesthesia departments in South America: Buenos Aires (Argentina), San Paulo (Brazil), and Santiago (Chile).

China (Yuguang Huang)
In Chinese medical universities, there currently exist 8-year, 7-year, and 5-year options for training in anesthesiology. Specialists in anesthesiology come mostly from undergraduate and postgraduate programs. The system of nurse anesthesiologists is not popular in China. More than 80,000 anesthesia professionals are available in mainland China, based on data from Dr. Shuren Li, Emeritus President of the CSA in 2007.

Southeast Asia (Florian R. Nuevo)
In the Philippines, the certification process for anesthesia includes three phases: a written examination, an oral examination, and practical examinations. Every year, a national anesthesia in-service examination is conducted that gives a percentile assessment of the standing of each trainee. However, even though our medical education has an American flavor, there is no reciprocity with the United States. Everybody must still comply with the licensure requirements or examinations prescribed by the United States to be able to pursue fellowships in anesthesia subspecialties. Thailand, Singapore, Malaysia, and Indonesia have their own framework of certification, one that is more European in context and process.

For basic training on the fundamentals of anesthesiology, many Indonesians prefer to go to the Philippines. In addition, the WFSA supports a regional training center for Southeast Asian countries in Bangkok, Thailand. It is called the Bangkok Anesthesia Regional Training Center and has graduated anesthesiologists from Laos, Myanmar, Cambodia, and Mongolia.

The Anesthesiology Center for the Western Pacific in Manila, Philippines, is a joint activity of the WHO Regional Office for the Western Pacific, the University of the Philippines, the China Medical Board, and the WFSA. It is an 11-month course in anesthesia that was initiated in January 1970. The rationale for this center was to help alleviate the shortage of reliable anesthesiologists in the region and to underscore the importance of administering safe anesthesia. The center does not seek to provide a complete training program, but rather its purpose is to emphasize the basic sciences in anesthesiology. It creates a foundation for students to build on so that they can eventually qualify, through further training, as specialist anesthesiologists. Students come to the center from the Pacific Islands, Southeast Asia, southern Asia, Hong Kong, Taiwan, Korea, Japan, Iraq, Russia, and Sudan. The program has served the region for 16 consecutive years, and many of its graduates have become respected anesthesiologists and contributed to the development of anesthesia programs and safe anesthesia care in their respective countries. If further studies or a fellowship in anesthesia specialties is desired, Singapore and Malaysia are two countries that can offer these particular courses.

At present, only the societies of Malaysia, Singapore, and Philippines have a written monograph on the guidelines for minimum requirements in delivering safe anesthesia practice. The government of Malaysia supports the activity of a national medical audit system and includes respectable physicians from all specialties. Apart from Singapore, most ASEAN anesthesia programs have not developed a quality assurance program. In effect, we have no factual regional database to document and monitor anesthesia-related morbidity and mortality.

Organizations, certification requirements, and recognition of anesthesiologists in Southeast Asian countries are summarized in Table 3-2. Workforce, scope, and type of anesthesiology practice are summarized in Table 3-3.

A shortage of physician anesthesiologists has become a persistent problem in densely populated Southeast Asian countries such as Indonesia, Philippines, and Thailand. The Philippines has the largest number of physician anesthesiologists in this region but is beset by maldistribution of qualified anesthesiologists, with more found in urbanized areas and the majority electing to engage in private (not public) hospital practice.

One strategy to address this personnel shortage is to formally conduct training of nurse anesthesiologists. Unlike the situation in the United States, where nursing programs independently train nurse anesthesiologists, both Indonesia and Thailand have developed formal courses for nurse anesthesiologists. These nurse anesthesiologists are supervised by physician anesthesiologists—and there is a clearly defined demarcation of responsibilities between physician anesthesiologists and nurse anesthesiologists. Hence, through an anesthesia care team composed of physicians and nurses working together, they found the answer to the crying need for anesthesia services in Indonesia and Thailand.

In the Philippines, nurse anesthesia practice is considered illegal. It is not allowed under the Nursing Act of the country. Moreover, the Philippine Society of Anesthesiologists maintains

Table 3-2 Organizations, Certification Requirements, and Recognition of Anesthesiologists in Southeast Asian Countries

	Indonesia	Malaysia	Philippines	Singapore	Thailand
Training	4 years' medicine 1.5 years' internship 3.5 years' residency	Patterned after the British Stringent examination and promotion requirements	Patterned after the United States 3 years' residency	Patterned after the British Stringent examination and promotion requirements	3 years' residency
Certification/certifying organization/continuing medical education	Collegium of Indonesian Anesthesiologist		Philippine Board of Anesthesiology	Singapore Society of Anesthesiologists	Royal College of Anesthesiologists in Thailand
Societies	Indonesian Society of Anesthesiologists & Reanimateurs	Malaysian Society of Anaesthesiologists	Philippine Society of Anesthesiologists	Singapore Society of Anesthesiologists	
Roles outside the operating room			Critical care Pain management	Critical care Pain management	
Recognition by peers/accomplishment	Neuroanesthesia fellowship	National Anesthesia Day		Head of critical care	

that anesthesiology is a practice of medicine and will not allow nurses to deliver anesthesia care.

It is rather sad that the practice of medicine in Philippine government hospitals is not able to provide decent remuneration for the majority of its health care providers, including physician anesthesiologists. Migration of physicians to seek better alternatives in greener pastures is a reality. With the high demand for nurses worldwide, it is also not unusual for some physicians to take a 4-year bachelor's degree in nursing and decide to migrate abroad to work professionally as nurses.

Uganda/Sub-Saharan Africa (D.G. Bogod)

In a survey by Hodges and colleagues, there was only 1 medical anesthesiologist among the 91 anesthesia practitioners who participated in the survey, which means that as is so often the case, many trained physicians in Uganda probably traveled to the West to find a better life for their families. In addition, based on the survey, access to up-to-date textbooks seems iffy at best—fewer than half of those surveyed have access to such texts.[18]

Europe (Lars I. Eriksson and Peter Simpson)

As a geographic area, Europe consists of more than 30 countries, a number of which, during the last decade, have undergone the dynamic process of integration into the EU. Although a core of European countries has had a strong impact for many years on development of the EU, several other countries, many of them belonging to the former Eastern Europe, are still candidates or potential candidates for entry into the EU. Europe is therefore a heterogeneous region and group of countries, which is reflected in the large variation in medical systems, research, and education, as well as language and culture. Over the years, continuous expansion of the number of countries associated with the EU has inevitably affected financial, monetary, labor, and educational systems in the other member states. Inevitably, this has also changed health care systems and provided a new impetus for increased migration of qualified health care workers and academic personnel between member states. Partly because of the large variation in social welfare and financial systems between parts of Eastern Europe and the traditional Western European countries, the net

Table 3-3 Workforce, Scope, and Type of Anesthesiology Practice in Southeast Asian Countries

	Indonesia	Malaysia	Philippines	Singapore	Thailand
Workforce					
Physician anesthesiologist	Yes	Yes	Yes	Yes	Yes
Nurse anesthesiologist	Yes	No	No	None	Yes
Scope of Practice

*Includes anesthesia services for inpatient, ambulatory/office-based, and diagnostic procedures.

migration of health care workers has deprived many low-income countries of their own medical staff. In addition, new working time directives in Western European countries have led to increased demand for physicians, and taken together, these two issues have encouraged emigration from Eastern European countries. In general, the many changes brought about by the integration of new countries into the EU continue to have an impact on the practice of medicine in Europe, and in this context the practice of anesthesiology is no exception.

The average number of anesthesiologists within Western European countries has increased over the last decade from 10.8 to 14.5 per 100,000 population.[18,21] In contrast, among non-EU Eastern European countries, the average number of anesthesiologists is currently 6.1 per 100,000 population.[18] Hence, there is large variation in both the supply and demand of anesthesiologists between parts of Europe.

In most European countries, health care is funded by the government, although local exceptions to this rule exist. Whereas more than 50% of anesthesiologists in some Western European countries (Luxembourg, The Netherlands) are involved in private practice, anesthesiologists within Scandinavia and the United Kingdom rarely (less than 5%) work in private practice.

The European Diploma in Anesthesiology and Intensive Care (EDA). The EDA, introduced in 1984, is a two-part examination intended as a comprehensive test of knowledge of anesthesiology, critical care, and pain management. It provides an international European standard that allows harmonization of training and assessment of knowledge across all European countries and is used by some (Switzerland, Austria, Hungary, and Poland) as part of their internal examination structure. Both parts of the examination take place in designated centers across Europe, depending on demand. Part 1 consists of multilingual, multiple-choice questions available in English, French, German, Italian, Spanish, and Russian. It consists of two multiple-choice sections, one on basic physiology, pharmacology, physics, clinical measurement, and statistics and the other on clinical practice associated with anesthesia and its subspecialty areas. It is intended to be taken after approximately 2 years of anesthesia training. Part 2 consists of four oral examinations, each with two examiners moderating each other. Guidelines for the content of these oral examinations are determined by the examination committee, and each examination is divided again into clinical practice, intensive care medicine, and general anesthesia. Candidates may choose the language in which they wish to be examined within the constraints available at the examination center.

Success in Part 2, which is an end-of-training examination, qualifies the candidate to receive the EDA. Because the EDA is an assessment of anesthetic knowledge, it can in no way substitute for the local assessment of skills and professional attitudes or behavior that takes place in each country according to local systems and is a requirement before an individual can be placed on the specialist register of their country. Because entry onto a person's national specialist register is necessary before award of the EDA, it follows that anyone passing the Part 2 examination also has to provide evidence of specialist registration before receiving the EDA itself. Thus, the EDA examination is a test of knowledge, embedded in and dependent on assessment of clinical skills and attitudes, that is provided by the national training program.

In addition to the examination itself, there is also the option for those wishing to assess their level of knowledge to take the Part 1 EDA as an in-training examination at a much reduced fee. This not only allows personal assessment of one's knowledge but also includes detailed feedback so that candidates can assess their own performance—both in comparison to those in their national peer group and in comparison to candidates in other parts of Europe—in areas as detailed as cardiovascular physiology and other fields.

The ESA/EBA Joint Hospital Visiting and Accreditation Program (HVAP). The HVAP has been in place since January 1996 as a joint permanent committee of the European Society of Anaesthesiology (ESA, formerly the European Academy) and the European Board of Anesthesiology (EBA), its main goal being to encourage and enhance training standards across Europe and to ensure that an academic institution meets the prerequisites of training in anesthesia as set out in the EBA training guidelines (1996). Together with the EDA, the HVAP serves to improve the overall quality of the specialty of anesthesia and to harmonize its activities throughout Europe. The visit consists of a detailed presentation of the staffing and organization of the hospital, the department (or the institute), and the structure of training. This forms the basis for discussion and evaluation of all aspects of the teaching and training process with the staff members involved for the purpose of complementing and building on strengths and encouraging development and change to address areas of weakness. A subsequent comprehensive report of the visit, together with recommendations for improvement or accreditation (or both), is presented by the program committee.

Standardizing the Quality of Patient Care in Anesthesiology and Intensive Care. In recent years the opportunity for accredited specialists in anesthesiology and intensive care to work and move between different European countries has increased considerably. EU legislation allows such free movement of specialists, which in many ways is beneficial to everyone. In such circumstances, it is essential to ensure that the quality and safety of care that patients receive is sustained and enhanced. Training and accreditation programs inevitably vary between member states and even within countries that lack a single national organization. The EBA is uniquely placed to ensure that appropriate standards are set to achieve harmonization in the quality and safety of patient care, and two important areas of standardization are already in place: the joint HVAP and the EDA.

At the present time, although the standards of well-established training and accreditation programs are known and thus acknowledged across many European states, others are not, particularly in some of the countries that have recently joined the EU. As a result, those trained in these countries are potentially unfairly disadvantaged. Their specialists wish to move freely as much as others and should be able to do so. Equally, those appointing them to specialist posts need a uniform quality standard to ensure the delivery of high-quality and safe patient care. Individual countries' specialist qualifications do vary, and an international assessment standard to facilitate free movement of specialists is needed. New proposals for EBA membership and fellowship have been developed and agreed on and build on the initiatives and programs already in place. These proposals are in addition to—but do not replace—national qualifications or competence in discourse or dialogue and allow those who desire to clearly demonstrate their ability to deliver anesthetic care of a uniformly high standard to patients. They are marks of individual

excellence in the specialty and can be awarded only after European national accreditation as a medical specialist in anesthesiology is achieved. They will be open to anesthesiologists who are nationals of any country in the world and who are on the specialist anesthesiology register of a European country. They will be strictly awarded to individuals in recognition of their personal achievement and not automatically to all those working in a particular hospital or anesthesiology department. However, they will have no legal standing and do not in themselves confer a right to practice in a country of the EU.

Subspecialization

India (Deepak K. Tempe)
For more than 2 decades, anesthesiologists have recognized the need for dedicated practice in the field of cardiac anesthesia and neuroanesthesia. There are anesthesiologists who are working exclusively in these specialties, but there are no separate departments of cardiac anesthesia and neuroanesthesia. AIIMS is an exception in this respect because it created two such departments in 1986. Postdoctoral courses in these specialties have been started in the country. AIIMS has conducted the courses in both specialties since 2002, whereas the Sri Chitra Tirunal Institute of Medical Sciences, Thiruvananthpuram, has offered a course in cardiac anesthesia since 2003. The number of seats, however, is grossly inadequate, with four seats in cardiac anesthesia and two in neuroanesthesia. The National Board of Examinations started a DNB fellowship program (2 years) in cardiac anesthesia in 2002; it began with four seats, and the number has increased to 18.

South America (Guillermo Lema)
In South America, only Colombia has a specialty law. In all other countries, physicians can perform professional actions without a law to certify the proficiency and quality of care and protect patients. In fact, physicians with a very low level of training have practiced anesthesia for many years; in most of the countries, paramedical personnel have performed anesthesia because of lack of sufficient medical personnel or interest in the specialty. In some countries, surgeons perform both anesthesia and surgery with the help of technical personnel. This practice has been abandoned in most countries, but in a few—Bolivia, Ecuador, Paraguay, Peru, and Venezuela—this situation persists, with government authorization.

Nowadays, the law in most countries specifies that only physicians can provide anesthesia. The problem is a shortage of trained physicians, so some countries are left with inadequately trained ones. Nevertheless, the process of certification of specialties, including anesthesia, is on the way. Most countries have medical organizations and anesthesia societies demanding proper certification methods. In some countries these medical organizations have obtained the support of the government. So even though a law does not exist, there is an intense effort to gain official certification. Medicolegal issues and increased concern from patients have helped. It is interesting that most anesthesiologists are willing to obtain certification; clinics and hospitals are also requiring certification for physicians to work in these institutions.

Professional and Research Activity

India (Deepak K. Tempe)
Since its inception in 1947, the ISA has grown from 19 members in 1947 to nearly 12,000 in 2007. Today, there are also separate Indian associations of cardiothoracic anesthesia and neuroanesthesia. The Indian Association of Cardiovascular and Thoracic Anesthesiologists (IACTA) is 10 years old and holds an annual meeting. IACTA also publishes the journal *Annals of Cardiac Anaesthesia*, which is now in the 10th year of publication and is the first Indian journal in anesthesia to be indexed in the National Library of Medicine and included in the MEDLINE database. In addition, there are societies of critical care medicine (founded in 1992) and for the study of pain.

The Middle East (Anis Baraka)
Most anesthesiologists in the Middle East are in close contact with developments in anesthesia throughout the world through attending congresses and lectures, publications, subscriptions to various international anesthesia journals, and building of worldwide friendships.

Some anesthesiologists in the Middle East, including those who have emigrated abroad, have become leaders in the specialty and have made original contributions in the fields of muscle relaxants,[22-24] semiopen systems, obstetrics,[25] pediatric anesthesia,[26,27] and the pathophysiology of open heart surgery.[28]

South America (Guillermo Lema)
Time, funding, and expertise are the basic requirements for research of sufficient quality to support publications or communications internationally. These requirements are not found widely in South America. Only a few university anesthesia departments have the capability of producing clinical research of high enough quality to be published in esteemed journals such as the Institute for Scientific Information (ISI), most notably in Chile. Some colleagues have argued that research is not important in a continent that has more pressing priorities. I do not agree.

Research is also a tool for learning and it should be encouraged, at least at university-based anesthesia residencies. Unfortunately, research does not generate income, so most of the clinical groups are not willing to dedicate time to this particular activity. Funding is lacking, and although some countries have national research grants to support clinical research, most do not. Support from drug companies is weak and usually depends on the impact that their drugs have in our clinical setting. Because of economic constraints, a large number of generic drugs are used, so major pharmaceutical companies are not willing to support research activities. In short, basic research in anesthesia virtually does not exist in South America.

Anesthesia meetings achieve the goal of educating residents and older generations of anesthesiologists. Anesthesia journals are in existence, and although none of them are ISI, effort is being made to enter the international medical databases.

China (Yuguang Huang)
The CSA was founded in 1979 at the Second National Conference held in Harbin. Professor Deyan Shang was elected president of the first CSA committee. Since then, a national CSA conference has been held every 3 or 4 years. In 1986, the Beijing International Conference on Anesthesia was held successfully. Many famous

experts from abroad, including Professor Ronald Miller (this textbook's editor), were invited to join as keynote speakers.

From that point on, Chinese anesthesiologists began to communicate more with international professionals. At the first Sino-Japanese Clinic Anesthesia Symposium held in 1986, the CSA and Japan Society for Clinical Anesthesia agreed to hold a symposium every 2 years. Professor Ailun Luo, after being selected president of CSA in 1997, advocated China's integration into the world anesthesia community. The National Conference on Anesthesia is held annually on the second weekend of every September.

Regarding professional publications, Professor Rong Xie was chief editor of the *Encyclopedia of Chinese Anesthesia Medicine* in 1986. Professor Jun Zhao was the chief editor of *Modern Anesthesiology* in 1987. These books have contributed to the development of clinical and research anesthesiology in China. Two academic journals, *Chinese Journal of Anesthesiology* and *Journal of Clinical Anesthesiology*, were launched in 1981 and 1982 by the Chinese Medical Association. Besides these two journals, the *International Journal of Anesthesiology and Resuscitation* and the *Chinese Journal of Pain Medicine* have formed a good platform for rapid communication among Chinese anesthesiologists.

From the 1990s until today, research in Chinese anesthesiology has moved as fast as the economy of China. The CSA has built good cooperative relationships with many international associations, such as the American Society of Anesthesiologists, the International Anesthesia Research Society, and the Association of Anaesthetists of Great Britain and Ireland, among others. Many well-known journals including, *Anesthesia & Analgesia*, *Anesthesiology*, and *Anaesthesia*, have been published with Chinese editions, which has extended their influence among Chinese professionals. These localized journals will become the window for communication in anesthesiology between China and the world.

Southeast Asia (Florian R. Nuevo)

To lessen the variability in medical practice and anesthesia care—and with the vision of fostering more understanding and cooperation among ASEAN anesthesiologists—two pioneering anesthesiologists (Professor Quintin J. Gomez of the Philippines and Dr. Saywan Lim of Malaysia) conceived of the Confederation of ASEAN Societies of Anesthesiologists (CASA). This took place in Kuala Lumpur in September 1974 during a meeting after the Fourth Asian Australasian Congress of Anaesthesiologists, a regional congress of the WFSA.

The main objective of CASA is to enhance and promote the specialty of anesthesiology in the region by hosting biennial congresses of anesthesia called the ASEAN Congress of Anaesthesiologists. These congresses serve as a venue for ASEAN anesthesiologists to meet experts from the United States and Europe, as well as other international anesthesia leaders, and to learn current practices in anesthesia from them. They also inspire trainees and younger anesthesiologists in Southeast Asia to present their clinical trials and modest research activity and participate in scientific activities as resource speakers or workshop facilitators.

The first such congress was held in December 1979 in Manila, Philippines, under the leadership of Professor Gomez, who was then the incumbent president of the WFSA (1976-1980). More than 400 delegates came from Indonesia, Malaysia, Philippines, Singapore, Thailand, Japan, Taiwan, Hong Kong, and the United States. Professor John Bonica (United States) was the guest of honor and main invited speaker; Professor Bonica would later become president of the WFSA.

Over time, the objectives of CASA have grown. The group has strived to promote closer ties among member societies, to enhance the image of the specialty in the region, and to upgrade the specialty through exchange of information between local and international experts in anesthesia. Indeed, through CASA there has been an information avalanche that has paved the way to further upgrade and develop the practice of anesthesia and anesthesiologists themselves.

Unfortunately, of late, economic depression and terrorism—as well as health threats such as bird flu and severe acute respiratory syndrome (SARS)—have threatened these academic activities. Nevertheless, the ASEAN confederation has persisted in hosting its biennial congress. The five founding members take turns, with much enthusiasm and camaraderie, in hosting these meetings. Attendance has grown from 400 to almost a thousand anesthesiologists coming from ASEAN and non-ASEAN countries, such as Japan, Korea, China, Saudi Arabia, Mongolia, Canada, and the Middle East. The faculty of speakers includes local ASEAN and international anesthesia experts from the United States, Europe, Canada, Australia, and New Zealand, some of whom were supported by the WFSA, by industry, by respective anesthesia societies, and by the faculty themselves.

Currently, each of the CASA member organizations is conducting clinical research activities in anesthesia, but there is much room for improvement. Most research studies involve clinical drug trials funded by pharmaceutical companies, but there is a paucity of published papers in peer-reviewed anesthesiology. What is lacking is translating the research activities into well-written research papers.

The *ASEAN Journal of Anesthesiology* (AJA) is only 8 years old. Thus far it has served as an avenue to publish all of these research endeavors in the region. We encourage all member societies to submit their research papers for publication. The current seat of editorship of the AJA is located in Singapore. Perhaps to encourage more output, future ASEAN Congress of Anaesthesiologists meetings may provide incentives for participation in free papers and poster discussion sessions.

Europe (Lars I. Eriksson and Peter Simpson)

Before formation of the European Academy of Anaesthesiology in 1978 there was no formal representative structure for the specialty within Europe. The five statutory aims of the academy were to (1) raise the scientific level of the discipline; (2) improve the training of anesthetists, their clinical and theoretical education, and their competence at the completion of the training period by holding examinations; (3) hold scientific meetings, conferences, and seminars; (4) facilitate research in anesthesia and its associated disciplines; and (5) promote exchange among anesthetists and discussion of all matters concerning their profession.

The European Academy of Anaesthesiology had a limited number of members and academicians and, as European anesthesiology grew, was perceived by many to be an exclusive organization. In 1992, the ESA was formed and was open to everyone. Its chief aims were to conduct an annual Euroanesthesia meeting to replace the European Congress, which had formerly run on a 4-year cycle alternating with the World Congress, and to support educational and research activities by awarding grants and fellow-

ships. Whereas the ESA was concerned with the practice of clinical anesthesia and supporting its membership, the European Academy of Anaesthesiology had developed formal initiatives such as the EDA, the *European Journal of Anaesthesiology* (EJA), and a system of hospital visiting and accreditation training in conjunction with the Anesthesiology Board and Section of the UEMS (Union Européenne des Médecins Spécialistes or European Union of Medical Specialists).

The fourth organization that existed at that time was the Confederation of European National Societies of Anesthesiology (CENSA), which was effectively the European section of the WFSA.

For some years, the roles of all the various organizations were increasingly complementary, thus making it necessary for an individual anesthesiologist to be a member of more than one body to participate in and benefit from all the variety of activities. As a result, in 1998 a decision was made to amalgamate the former ESA, the European Academy, and CENSA into one organization. A temporary organization, the European Federation of Anaesthesiologists, was established in 2001, under which amalgamation was successfully achieved, and the new European Society of Anaesthesiology, which thus represents every anesthesiologist in Europe, was launched in January 2005 in its interim form before becoming fully established in January 2006. Moreover, because the formal, declared responsibilities of the parent organizations were essentially different and there was very little overlap between them, a strong and comprehensive organization could be established right from the start. Under this new organizational structure, CENSA became the ESA's National Anaesthesiology Societies Committee, now ESA National. Each country has a number of delegates to ESA National, depending on the number of members of its National Society.

The ESA now provides a comprehensive range of activities to support European anesthesiology, primarily aimed at sustaining and enhancing the safety, efficacy, and quality of care of patients. Through publication of the EJA and the Euroanaesthesia organization and other meetings, it supports the interests of its members and facilitates the exchange and dissemination of information related to anesthesiology, critical care, pain, and emergency medicine. It encourages research and scientific progress both by conducting academic meetings and by awarding grants and fellowships and has a key role in raising and harmonizing the standards of anesthesiology. This is achieved by delivering education, training, continuous medical education, and accreditation of anesthetists through educational programs, the EDA, and in-service training examinations, as well as through the HVAP run jointly with UEMS.

UEMS represents national associations of medical specialists in the EU and its associated countries. UEMS provides general and specialist medical advice to ministers. It is also responsible for the European Accreditation Council for Continuing Medical Education. Each specialty has its own board and section, the members of which are drawn from all the EU member states together with Norway and Switzerland. The EBA has two delegates per country, one professional and one academic. UEMS itself is a nonprofit organization concerned with (1) the study, promotion, and harmonization of the highest level of training of medical specialists, medical practice, and health care within the EU; (2) study and promotion of free movement of specialist doctors within the EU; (3) representation, within this framework of medical specialists in the member states of the EU, to EU authorities and to any other authority with similar responsibility; and (4) protection of the professional interests of European medical specialists. UEMS defines a medical specialist as a physician who has satisfactorily completed a specialist training program in a recognized specialty that conforms to the UEMS charter on specialist training.

Thus, European anesthesiologists are represented in several ways. Those in EU member states, together with Norway and Switzerland, are represented nationally through their country's membership in the UEMS Anesthesiology Board and Section. Additionally, anesthesiologists in all European countries are represented nationally as members of their respective national society through that society's delegates to the ESA, through the ESA council via their national elected council member, and individually as active members of ESA.

THE *EUROPEAN JOURNAL OF ANESTHESIOLOGY*. The EJA is the official journal of the ESA and is distributed to all ESA members. It is published and owned by the ESA. The EJA is also the official journal of a variety of organizations (EACTA, UEMS, FEEA) and is distributed to all members of these societies. It is published monthly and run by an editorial board that is not directly involved in any editing or editorial work and by a 19-member "group of editors" who are responsible for the content of the journal itself. The EJA has two main functions: to publish peer-reviewed original articles and reviews in the field of anesthesia, pain, emergency medicine, and critical care, together with correspondence pertaining to these articles, and to provide educational material with appropriate methods of self-assessment for ESA members. The ESA also publishes a newsletter four times a year, separately from the EJA, that contains items of interest to ESA members together with information and formal announcements.

Conclusion

As demonstrated in this chapter, anesthesiology as a discipline and a profession has grown dramatically around the world. Differences in the rate of growth and scope of practice exist for a variety of reasons, largely because of disparities in resources and socioeconomic and political factors. Nevertheless, regardless of country of residence, patients can feel much safer today with regard to receiving anesthesia than even 20 or 30 years ago. As noted repeatedly throughout this chapter, some of the most powerful advances are the spread of knowledge, professional integrity, curiosity, and the utmost desire to practice anesthesiology at the highest possible level. This means that anesthesiologists not only can learn of the advances of their colleagues elsewhere but can also better understand and respond to the needs of others.

So where do we go from here? Some authorities suggest that we take advantage of the latest advances to further the interconnectedness of our profession, such as conducting more in-depth comparisons of the effectiveness of various techniques from country to country and engaging in more joint research. Others believe that such comparisons would serve no useful purpose given the disparities in resources and different approaches to care. The editor has dreamed of the day that anesthesiologists worldwide would form global think tanks to ask and answer the most important questions to advance our intellectual foundations and benefit society.

As is noted in the opening paragraph, the purpose of this chapter is not to invite comparisons or highlight differences in the practice of anesthesiology around the world, but rather to encourage and invite anesthesiologists globally to keep talking to each other. The editor was thrilled and honored that his invitation to contribute to this chapter has resulted in so many interesting contributions from leaders of anesthesia worldwide. When viewed together, the journey of anesthesiology has been an amazing story worldwide.

C. William Hanson

4 Medical Informatics

Key Points

1. A computer's hardware serves many of the same functions as those of the human nervous system, with a processor acting as the brain and buses acting as conducting pathways, as well as memory and communication devices.
2. The computer's operating system serves as the interface or translator between its hardware and the software programs that run on it, such as the browser, word processor, and e-mail programs.
3. The hospital information system is the network of interfaced subsystems, both hardware and software, that coexist to serve the multiple computing requirements of a hospital or health system, including services such as admissions, discharge, transfer, billing, laboratory, radiology, and others.
4. An electronic health record is a computerized record of patient care.
5. Computerized provider order entry systems are designed to minimize errors, increase patient care efficiency, and provide decision support at the point of entry.
6. Decision support systems can provide providers with best-practice protocols and up-to-date information on diseases or act to automatically intervene in patient care when appropriate.
7. The Health Insurance Portability and Accountability Act is a comprehensive piece of legislation designed in part to enhance the privacy and security of computerized patient information.
8. Providers are increasingly able to care for patients at a distance via the Internet, and telemedicine will continue to grow as the technology improves, reimbursement becomes available, and legislation evolves.

Computer Hardware

Central Processing Unit

The central processing unit (CPU) is the "brain" of a modern computer. It sits on the motherboard, which is the computer's skeleton and nervous system, and communicates with the rest of the computer and the world through a variety of "peripherals." Information travels through the computer on "buses," which are the computer's information highways or "nerves," in the form of "bits." Bits are aggregated into meaningful information in exactly the same way that dots and dashes are used in Morse code. Bits are the building blocks for both the instructions, or programs, and the data, or files, with which the computer works.

Today's CPU is a remarkable piece of engineering, totally comparable in scope and scale to our great bridges and buildings, but so ubiquitous and hidden that most of us are unaware of its miniature magnificence. Chip designers essentially create what can be thought of as a city, complete with transportation, utilities, housing, and a government, every time they create a new CPU. With each new generation of chips, the "cities" grow substantially and yet remain miniaturized to the size of a fingernail.

For the purposes of this text, the CPU can be treated as a black box into which flow two highways: one for data, the other for instructions. Inside that black box, the CPU (Fig. 4-1) uses the instructions to determine what to do with data—for example, how to create this sentence from my interaction with the computer's keyboard. The CPU's internal clock is like a metronome pacing the speed with which the instructions are executed.

Most people think that the clock speed of the CPU, which is measured in megahertz, or millions of instructions per minute, determines the performance speed of the unit. In reality, the performance of a CPU is a function of several factors that should be intuitive to anesthesiologists when an operating room (OR) analogy is used. Let us compare the clock speed to surgical speed, where a fast clock is comparable to a fast surgeon and vice versa. CPUs also have what are called caches, which are holding areas

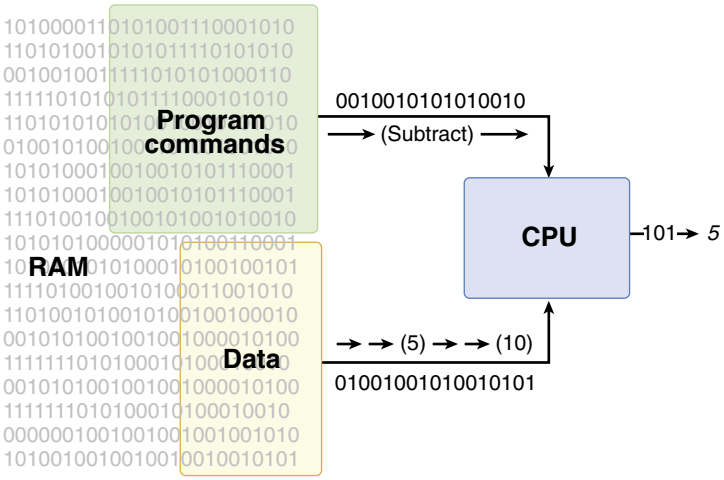

Figure 4-1 Programs and data are stored side by side in memory in the form of single data bits—the program tells the central processing unit (CPU) what to do with the data. RAM, random-access memory.

for data and instructions, quite comparable to preoperative holding areas. Information is moved around in the CPU on buses, which can be likened to the number of ORs. In other words, it is possible to have a CPU that is limited because it has a slow or small cache, in the same way that OR turnover is limited by the lack of preoperative preparation beds or too few ORs for the desired caseload.

The speed of a processor is a function of the width of its internal buses, clock speed, the size and speed of internal caches, and the effectiveness with which it anticipates the future. Although this last concept may seem obscure, an OR analogy would be an algorithm that predicts a procedure's length based on previous operations of the same type by the same surgeon. Without going into detail, modern processors use techniques called *speculation*, *prediction*, and *explicit parallelism* to maximize efficiency of the CPU.

True general-purpose computers are distinct from their predecessor calculating machines in that regardless of whether they are relatively slow and small, as in dedicated devices such as smart phones, or highly streamlined and fast, as in supercomputers, they can perform the same tasks given enough time. This definition was actually formalized by Alan Turing, who is one of the fathers of computing.

Each type of CPU has its own instruction set, which is essentially its language. Families of CPUs, such as Intel's processors, tend to use one common language, albeit with several dialects, depending on the specific chip. Other CPU families use a very different language. A complex–instruction set computer (CISC) has a much more lush vocabulary than a reduced–instruction set computer (RISC), but the latter may have certain efficiencies relative to the former. It is the fact that both types of computer architecture can run exactly the same program (i.e., any windowed operating system) that makes them general-purpose computers.

Memory

Computers have a variety of different kinds of memory ranging from very small, very fast memory in the CPU to much slower, typically much larger memory storage sites that may be fixed (hard disk) or removable (compact disk, flash drive).

Ideally, we would like to have an infinite amount of extremely fast memory immediately available to the CPU, just as we would like to have all of the OR patients for a given day waiting in the holding area ready to roll into the OR as soon as the previous case is completed. Unfortunately, this would be infinitely expensive. The issue of ready data availability is particularly important now, as opposed to a decade ago, because improvements in central processing speed have outpaced gains in memory speed such that the CPU can sit idle for extended periods while it waits for a desired chunk of data from memory.

Computer designers have come up with an approach that ensures a high likelihood that the desired data will be close by. This necessitates the storage of redundant copies of the same data in multiple locations at the same time. For example, the sentence I am currently editing in a document might be stored in very fast memory next to the CPU, whereas a version of the complete document, including an older copy of the same sentence, could be stored in slower, larger-capacity memory (Fig. 4-2). At the conclusion of an editing session, the two versions are reconciled and the newer sentence is inserted into the document.

The very fast memory adjacent to the CPU is referred as cache memory, and it comes in different sizes and speeds. Cache memory is analogous to the preoperative and postoperative holding areas in an OR in that both represent rapidly accessible buffer space. Modern computer architectures have primary and secondary caches that can either be built into the CPU chip or be situated adjacent to it on the motherboard. Cache memory is typically implemented in static random-access memory (SRAM), whereas the larger and slower "main memory" consists of dynamic random-access memory (DRAM) modules. RAM has several characteristics, including the facts that it can be read or written (in contrast with read-only memory), it disappears when the electricity is turned off, and it is much faster than the memory on a disk drive.

To understand the impact of the mismatch in memory access times and CPU speed, consider the following. Today's fastest hard disks have access times measuring about 10 milliseconds (to get a random chunk of information). If a 200-mHz CPU had to wait for 10 milliseconds between each action requiring new data from a hard disk, it would sit idle for 2 *million* clock cycles between each clock cycle used for actual work. Furthermore, it takes 10 times longer for the computer to get data from a compact disk or digital video disk than it does for data from a hard disk.

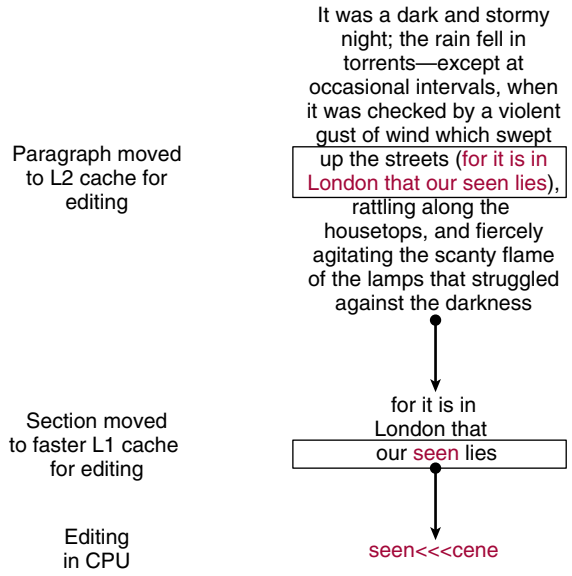

Figure 4-2 Processing of text editing using several "memory" caches in which duplicate copies of the same text may be kept nearby for ready access.

Communications

There are many functionally independent parts of a computer that need to communicate seamlessly and on a timely basis. The keyboard and mouse have to be able to signal their actions, the monitor must be refreshed continuously, and the memory stores have to be read and written correctly. The CPU orchestrates all of this by using various system *buses* as communication and data pathways. Whereas some of the buses are dedicated to specific tasks on newer computers, such as communication with the video processor over a dedicated video bus, others are general-purpose buses.

Buses are analogous to highways traveling between locations in the computer (Fig. 4-3). In most computers, the buses vary in width, with the main bus typically being the widest and other buses narrower and therefore of lower capacity. Data (bits) travel along a bus in parallel, like a rank of soldiers, and at regular intervals determined by the clock speed of the computer. Older computers had main buses 8 bits wide, whereas newer Pentium-class computers use buses as wide as 64 bits.

Input-output buses link "peripherals" such as the mouse, keyboard, removable disk drives, and game controllers to the rest of the computer. These buses have become faster and increasingly standardized. The universal serial bus (USB) is a current widely accepted standard, as is Apple's proprietary Firewire bus. These buses allow "on-the-fly" attachment and removal of peripherals via a standardized plug, and a user can expect that a device plugged into one of these ports will identify itself to the operating system and function without the need for specific configuration. This is a distinct improvement over the previous paradigm, in which a user typically needed to open the housing of the computer to attach a new peripheral and then configure a specific software driver to permit communication between the device and the computer.

In addition to their local computing function, modern personal computers have become our conduits to networks and must therefore act as terminal points on the Internet. As with houses or phones, each computer must have an individual identifier (address, phone number) to receive communications uniquely intended for it. Examples of these kinds of specific addresses are the IP (Internet protocol) address and the MAC (media access control) address. The IP address is temporarily or permanently assigned to a device on the Internet (typically a computer) to uniquely identify it among all of the other devices on the Internet. The MAC address is used to specifically identify the network interface card for the computers that assign IP addresses.

The computer must also have the right kind of hardware to receive and interpret Internet-based communications. Wired and wireless network interface cards are built into all new computers and have largely replaced modems as the hardware typically used

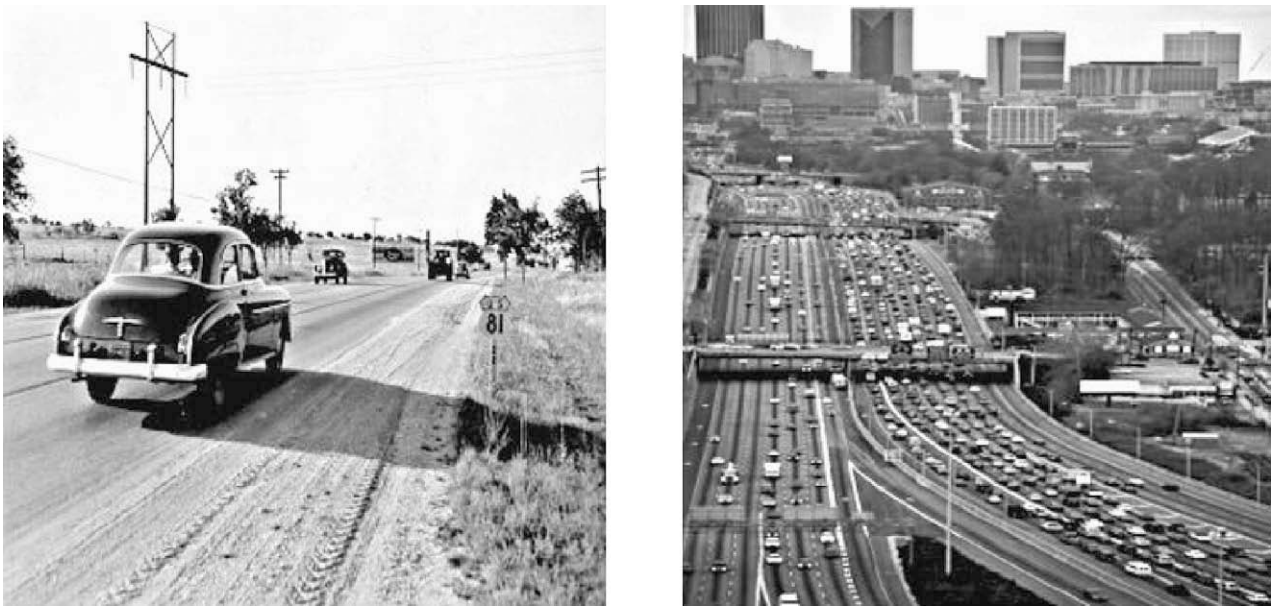

Figure 4-3 Buses are like highways, where the number of available "lanes" relates to bus capacity.

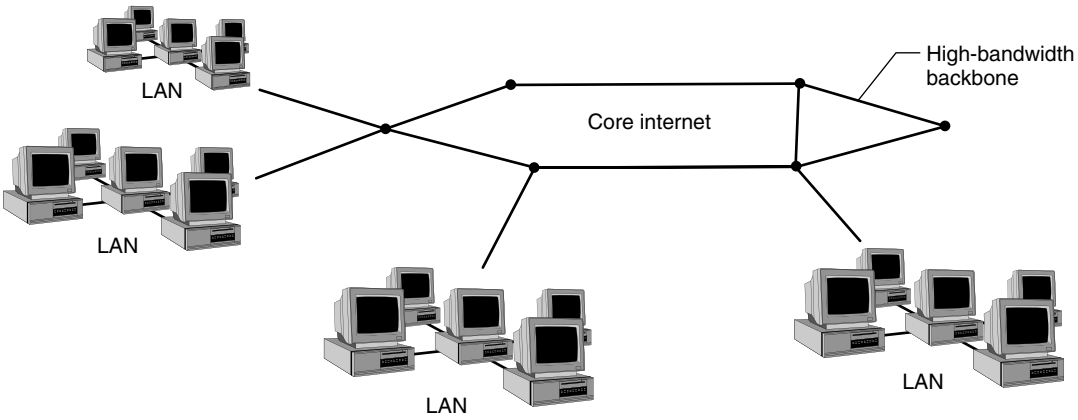

Figure 4-4 Lower-speed networks are attached to high-speed "core" networks that span the globe. LAN, local area network.

for network communications. Whereas a modem communicates over existing phone lines also used for voice communication, network cards communicate over channels specifically intended for computer-to-computer communications and are almost invariably faster than modems.

Although we commonly think of the Internet as being one big network, it is instructive to understand a little bit about the history of computer networking. In the beginning there were office networks and the progenitor Internet. The first office network was designed at the Palo Alto Research Center, which is the Xerox research laboratory where a number of major computer innovations were developed. That office network was called Ethernet and was designed as part of the "office of the future," where word-processing devices and printers were cabled together. Separately, the ARPAnet was the Defense Advanced Research Project Agency's creation and linked mainframe computers at major universities. Over time, the two networks grew toward one another almost organically, and today we have what seems to be a seamless network that links computers all over—and above—the world.

Networking technology has evolved almost as rapidly as computer technology. As with buses in a computer, the networks that serve the world can be likened to highways. Backbone networks (Fig. 4-4) are strung across the world and have tremendous capacity, like interstate highways. Lower-capacity systems feed into the backbones, and traffic is directed by router computers. To facilitate traffic management, before transmission messages are cut up into discrete packets, each of which travels autonomously to its destination, where they are reassembled. Internet packets may travel over hard-wired, optical, or wireless networks en route to their destination.

Computer Software

Operating System and Programming

The operating system (OS) is the government of the computer. As with a municipal government, the OS is responsible for coordinating the actions of disparate components of a computer, including its hardware and various software programs, to ensure that the computer runs smoothly. Specifically, it controls the CPU, memory, interface devices, and all the programs running on the machine at any given time. The OS also needs to provide a consistent set of rules and regulations to which new programs must adhere to participate.

Although most of us think of Apple and Windows synonymously with OSs, there are other OSs that deserve mention. Linux is an open-source, meaning nonproprietary, OS for personal computers that is distributed by several different vendors but continuously maintained by a huge community of passionate programmer devotees who contribute updates and new programs. In addition, every cell phone and smart device has its own OS that performs exactly the same role as for a personal computer OS.

OSs can be categorized into four broad categories (Fig. 4-5). A real-time OS is typically used to run a specific piece of machinery, such as a scientific instrument, and is dedicated solely to that task. A single-user, single-task OS is like that found on a cell phone, where a single user does one job at a time, such as dialing, browsing, or e-mail. Most of today's laptop and desktop computers are equipped with single-user, multitasking OSs, whereby a single user can run several "jobs" *simultaneously*, such as word processing, e-mail, and a browser. Finally, multi-user, multitasking OSs are usually found on mainframe computers and run many jobs for many users concurrently.

All OSs have a similar core set of jobs: CPU management, memory management, storage management, device management, application interfacing, and user interfacing. Without getting into detail beyond the scope of this chapter, the OS breaks a given software job down into manageable chunks and orders them for sequential assignment to the CPU. The OS also coordinates the flow of data among the various internal memory stores, as well as determines where that data will be stored for the long term and keeps track of it from session to session. The OS provides a consistent interface for applications so that the third-party program that you buy at a store will work properly on a given OS. Finally, and of most importance for many of us, the OS manages its interface to you, the user. Typically, today that takes the form of a graphic user interface (GUI).

E-mail

E-mail communication over the Internet antedated the browser-based World Wide Web by decades. In fact, the earliest e-mail

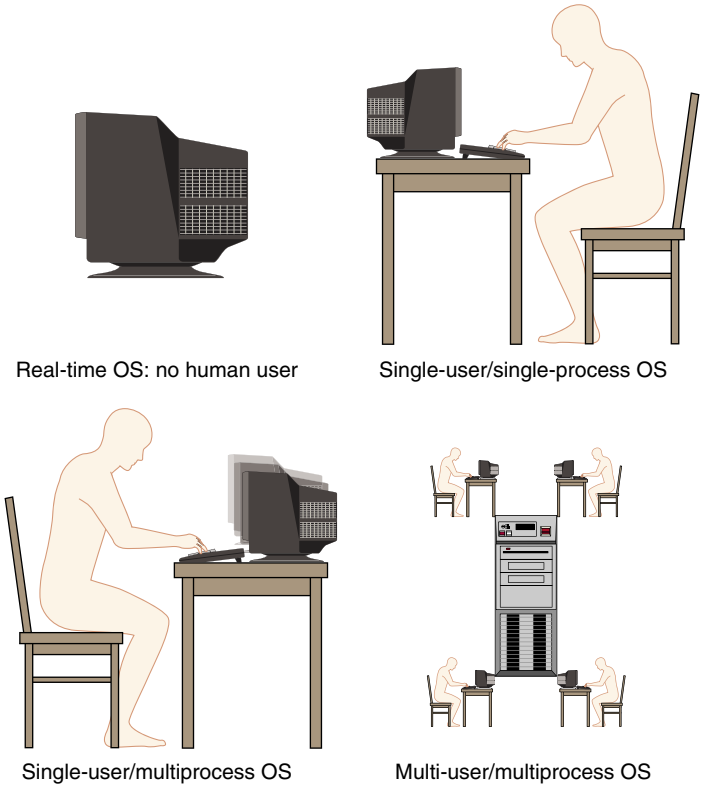

Figure 4-5 Several operating system configurations.

was designed for communication among multiple users in a "time-sharing," multi-user environment on a mainframe computer. E-mail was used for informal and academic communications among the largely university-based user community. Without going into great detail, an e-mail communication protocol was designed so that each message included information about the sender, the addressee, and the body of the message. The protocol is called the Simple Mail Transfer Protocol (SMTP), and the process of message transmission proceeds as follows. The sender composes a message via a software-based messaging program (such as Outlook, Gmail). The sender then applies the recipient's address and dispatches the message. The message travels through a series of mailboxes, much as a regular letter does, and eventually arrives at the addressee's mailbox, where it sits awaiting "pickup."

Although e-mail has had dramatic and largely positive implications for the connectedness of organizations and people, it has also created hitherto unimagined problems, including spam, privacy issues, and the need for new forms of etiquette.

The term *spam* is said to have come from a Monty Python skit. Spam is such a ubiquitous problem that most e-mail crossing the Internet is spam at this point. Spam is essentially bulk e-mail and was never envisioned by the creators of SMTP. Spam is a generic problem with e-mail communications, but the issues of privacy and etiquette are of much greater relevance for medically oriented e-mail.

The American Medical Informatics Association has taken a lead role in defining the issues associated with e-mail in the medical setting. The organization defined patient-provider e-mail as "computer based communication between clinicians and patients within a contractual relationship in which the health care provider has taken on an explicit measure of responsibility for the client's care."[1] A parallel set of issues relates to medically oriented communications between providers.[2-5] Another category of medically oriented communications is that in which a provider offers medical advice in the absence of a "contractual relationship." An egregious example of the latter is the prescription of erectile dysfunction remedies by physicians who review a Web-based form submitted by the "patient" and then prescribe a treatment for a fee.

In theory, e-mail is a perfect way to communicate with patients.[6-9] Because of its asynchronous nature, it allows two parties who may not be available at the same time to communicate efficiently (Fig. 4-6), and it represents the middle road between two other types of asynchronous communication: voice mail and traditional mail. E-mail can also be tailored to brief exchanges, more structured communications, and information broadcasts (such as announcements). As such, a patient could send interval updates (blood pressure, blood sugar) to the physician. Alternatively, the physician could follow up on an office visit by providing educational material about a newly diagnosed condition or planned procedure.

Even though e-mail has many advantages in medicine, there are a variety of risks associated with its use, which has slowed adoption.[10] Some of the problems are generic to any e-mail exchange. Specifically, it is a more informal and often unfiltered form of communication than a letter and often has the immediacy of a conversation but lacks its visual and verbal cues. Emoticons (such as the use of ":)" to indicate that a comment was sent with a "smile") evolved as a remedy for this problem.

E-mail is also permanent in the sense that copies of it remain in mailbox backups even after deletion from local files (Fig. 4-7). Every e-mail should therefore be thought of as discoverable from both a liability and recoverability standpoint. Before dispatch e-mail should be scrutinized for information or content that might be regretted at a later date.

E-mail is also vulnerable to inadvertent or malicious breaches in privacy or disclosure through improper handling of data at any point along the "chain of custody" between the sender and the recipient. Alternatively, a hacker could potentially acquire sensitive medical information from unsecured e-mail or possibly even alter medical advice and test results in an e-mail from physician to patient.

The Healthcare Insurance Portability and Accountability Act (HIPAA) legislation mandates secure electronic communication in correspondence regarding patient care. Three prerequisites for secure communication include authentication (that the

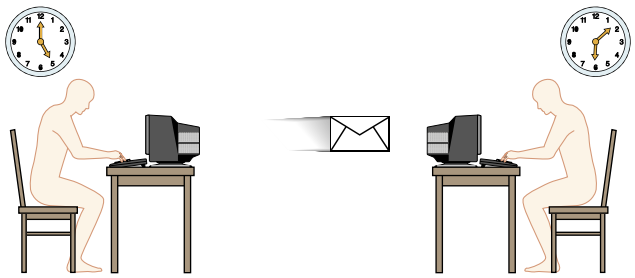

Figure 4-6 E-mail is an effective form of communication between a patient and a physician because it does not require both parties to be present at the same time.

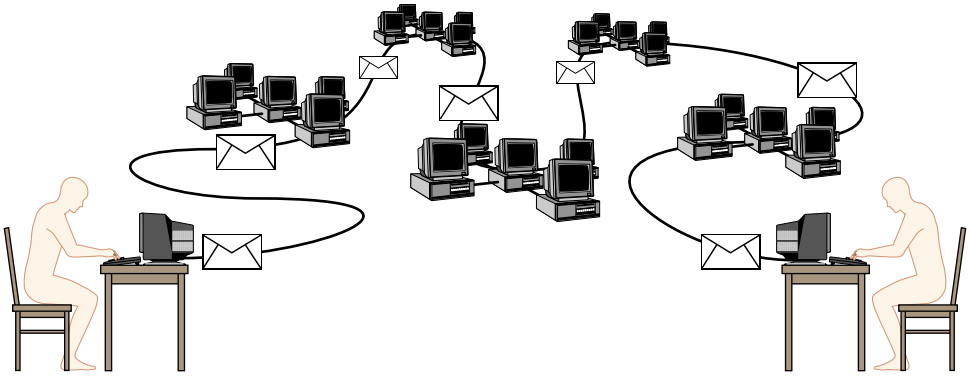

Figure 4-7 E-mail leaves copies of itself as it travels across the Internet.

message sender and recipient are who they say they are), encryption (that the message arrived unread and untampered with), and time/date stamping (that the message was sent at a verifiable time and date), although these techniques are not yet widely deployed in the medical community.

It is beyond the scope of this chapter to go into great detail about the methods used to authenticate, encrypt, and time-stamp e-mail. However, it is possible to ensure that each of these elements by using mathematically linked pairs of numbers (keys), in which an individual's public key is published and freely available through a central registry (like a phone book) whereas a linked private key is kept secret (Fig. 4-8). Public key encryption combined with traditional encryption is used to transmit messages securely across public networks, ensure that messages can be read only by a specific individual, and digitally sign the message.

Although the use of e-mail for medical patient-provider and provider-provider communications is growing, it is not yet universally adopted for several reasons, including physician distrust of the medium, unfamiliarity with software, lack of standards, and lack of clear methods for reimbursement for time spent in e-mail communications. Nevertheless, several professional societies have published consensus recommendations about the management of e-mail in medical practice. Common consensus-based elements are enumerated in (Box 4-1).

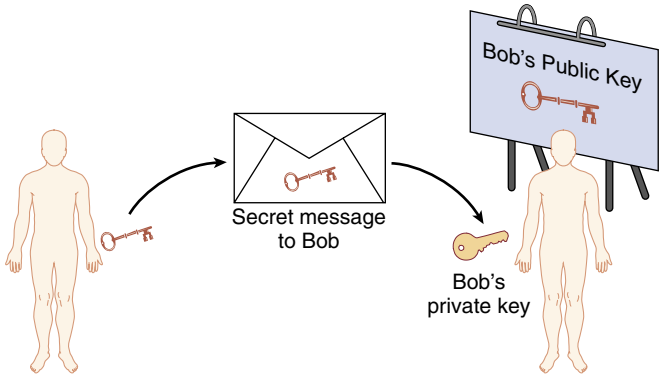

Figure 4-8 Public/private key encryption in which Joe sends a message intended only for Bob by using Bob's public key—the message remains encrypted until Bob decrypts it with his private key.

Box 4-1 Suggested Rules for E-mail Correspondence in a Medical Setting

All patient-provider e-mail should be encrypted.

Correspondents should be authenticated (guarantee you are who you say you are).

Patient confidentiality should be protected.

Unauthorized access to e-mail (electronic or paper) should be prevented.

The patient should provide informed consent regarding the scope and nature of electronic communications.

Electronic communications should (ideally) occur in the context of a preexisting physician-patient relationship.

On-line communications are to be considered a part of the patient's medical record and should be included with the same.

Browser

Many people think of the Internet and the World Wide Web as one and the same. The Internet is the worldwide network, whereas the Web is one of its applications characterized by the browsers with which its users interact. The browser was invented by Tim Berners Lee at the European Organization for Nuclear Research, commonly known as CERN, in 1990. Marc Andreessen wrote the Mosaic browser and subsequently the Netscape browser, which like all subsequent browsers, has a GUI and uses a specific "language" called hypertext markup language (HTML). Microsoft eventually developed its own version of the browser, Internet Explorer, after recognizing the inevitability of the Web.

The browser is a computer program, just like a word-processing or e-mail program, with a GUI. It can be thought of as a radio or television insofar is it serves as an interface to media that do not originate within it. The address of a webpage is analogous to the channel or frequency of a television or radio, and the browser "tunes in" to that address. In actuality, the local browser on your machine communicates with a server somewhere on the Internet (at the address specified in the address line) and uses a communication protocol called HTML as its language. The webpage displayed on your local browser was first constructed on the server and then sent to you.

The original HTML was extremely spare and permitted the construction of very simple webpages. A variety of new "languages" and protocols have subsequently come into existence, such as Java, Javascript, ActiveX, Flash, and others, that allow enhancements to HTML. New browsers support interactivity, security, display of audio and video content, and other functions. Even though the scope of topics that could be covered in discussing browser communications far exceeds that of this chapter, certain issues deserve mention.

"Cookies" is the term used for short lines of text that act like laundry tickets and are used by an Internet server (such as a Google search engine server) to "remember" things about the client computers with which it interacts. Cookies allow the server to keep track, for example, of the items that you have put in your virtual shopping cart as you shop (Fig. 4-9). Although cookies are not inherently risky, there are other risks to the use of a browser.

Like a television, the browser acts like a window on the Internet, and for a long time it was safe to think of that window as being made of one-way glass. Unfortunately, many of the new innovations that allow us to function interactively with websites also have built-in flaws that permit malicious programmers to gain access to your computer. The best way to protect a computer involves timely application of all updates and patches issued by software manufacturers and the use of antivirus software with up-to-date definitions.

Computers and Computing in Medicine

Hospital Information Systems

Modern hospital information systems invariably fall somewhere on the spectrum between a monolithic single comprehensive system design, wherein a single vendor provides all of the components of the system, and a "best-in-breed" model consisting of multiple vendor-specific systems interacting through interfaces or, more typically, an interface "engine."[11-14] The monolithic system has the advantage of smooth interoperability, but some of the component elements may be substantially inferior to those offered by best-in-breed vendors.

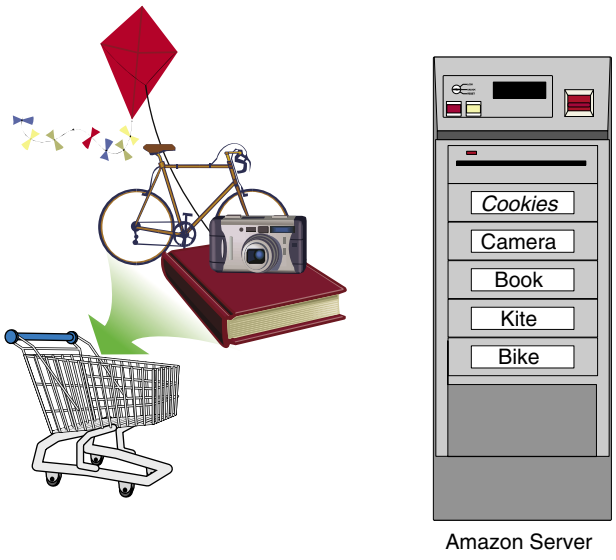

Figure 4-9 Cookies are used by a website, for example, to keep track of the items that a user has put in the "shopping cart."

Component elements of a hospital information system include administrative, clinical, documentation, billing, and business systems.[15-17] Medical information technology is increasingly subject to governmental regulation, security concerns, and standards. Standards are essential for interoperability among systems and to ensure that systems use uniform terminology.[18]

Health Level 7 (HL7) is an accepted set of rules and protocols for communication among medical devices. Clinical Context Management Specification (also known as CCOW) is a method to enable end users to seamlessly view results from disparate "back-end" clinical systems as though they were integrated. Some of the common medical terminologies or vocabularies include the Systematized Nomenclature of Medicine (SNOMED) and the International Classification of Diseases (the ICD family of classifications).[19]

Modern complicated medical information systems often weave a host of disparate systems at geographically dispersed locations into an extended "intranet." A core hospital, for example, may share an intranet with a geographically remote outpatient practice, or several hospitals in the same health system may coexist within the same intranet. Some of the elements may be physically connected (Fig. 4-10) along a network "backbone," whereas others may use virtual private network (VPN) connections that allow the user to appear to be part of the network while at a remote location.[16]

Electronic Health Record

The electronic record (see Chapter 99) has been described variously as a computerized medical record, computerized patient record, electronic medical record, and electronic health record (EHR).[20-23] It is clear that various settings require radically different EHRs and that EHRs will eventually need to interface seamlessly.[24,25]

The current evolution of software-based EHRs is recapitulating the evolution of hospital information systems as it occurred over the 1980s and 1990s. Best-in-breed commercial systems or "home-grown" site-specific systems are evolving, such as automated anesthesia EHRs[26,27] and intensive care unit (ICU) EHRs (Fig. 4-11). At the same time, large vendors have developed generic inpatient and outpatient EHRs. Health systems will inevitably be faced with the same choices about whether to go with monolithic or best-in-breed EHR software that they have with clinical systems.

The Institute of Medicine issued a recent report characterizing key aspects of an EHR, including an integrated, longitudinal view of patient data; concurrent access to the body of knowledge pertaining both to the patient's condition and to the rules and regulations associated with reimbursement in this age of managed care; order and data entry; and decision support tools that provide current knowledge about diseases, treatments, drug interactions, and risk profiles.

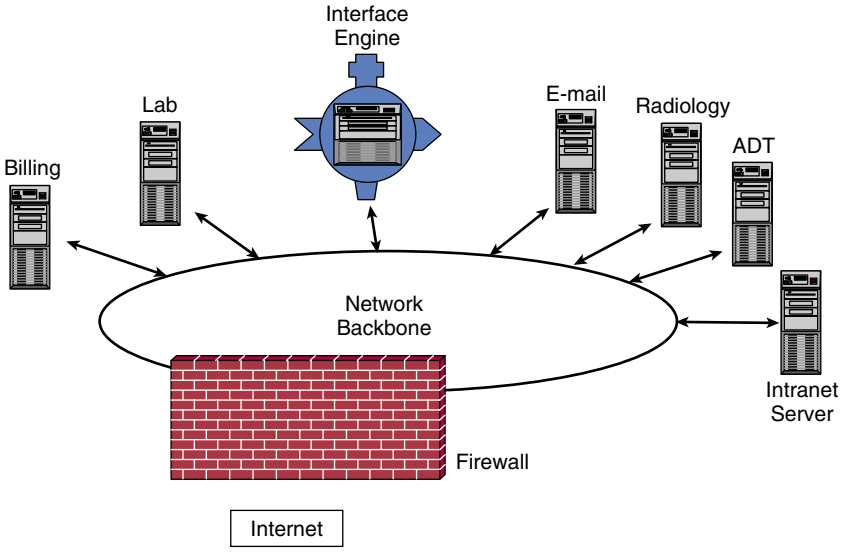

Figure 4-10 Modern health care information systems consist of elements attached to a backbone. ADT, admission, discharge, and transfer.

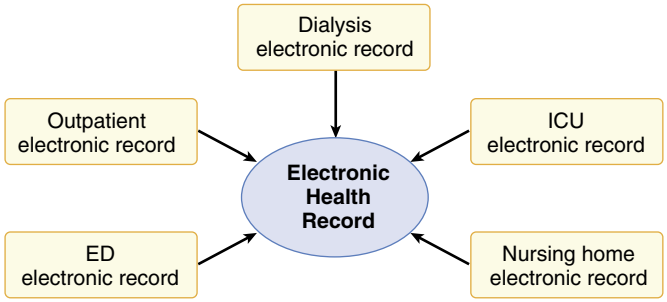

Figure 4-11 Vendors have developed specialty electronic health records. ED, emergency department; ICU, intensive care unit.

Ideally, the electronic record will provide tools for communication among providers. The EHR should also provide immediate access to population-level information for administrative and research applications.

The Veteran's Health Administration of the United States is an example of a very successful EHR implementation; however, in most hospitals, orders, notes, and reports are still maintained on paper. Additionally, very few small-practice environments have undergone any degree of computerization because the barriers to computerization are formidable.

Technical obstacles to computerization of the medical record are relatively obvious, but there are also organizational, financial, and policy obstacles.[28-30] Adoption of an EHR implies a fundamental reorganization of the way that medicine is practiced in a clinical environment.[31,32] For example, many older physicians have had little occasion to use a computer and are likely to be slowed in their performance of formerly routine tasks, which is a major barrier at a time when demands for efficiency are increasing substantially (Fig. 4-12).

Despite the barriers, governmental and private stakeholders are developing incentives, bonuses, and low-cost capital to encourage use of the EHR. Providers may eventually mandate EHR systems as a condition of participation in certain U.S. insurance plans, such as Medicare.

The EHR is designed to automate the medical record, but once that process occurs, a number of follow-on opportunities become available, such as enhanced patient care delivery, improved efficiency of support processes (e.g., laboratory, radiology, housekeeping, transport), and automated administrative functions (e.g., billing and reimbursement). The EHR can also be used as a vehicle for education, provider regulation, research, public health, and policy support (see Fig. 4-12).

The core functions expected of EHRs fall into eight general categories. The first is management of patient health information and data. Second is presentation of results acquired from patient testing. The third function of EHRs is computerized order entry (CPOE). A fourth key benefit of EHRs is decision support, whereby automatically generated reminders and prompts are used to inform the behavior of clinicians. EHRs may be equipped

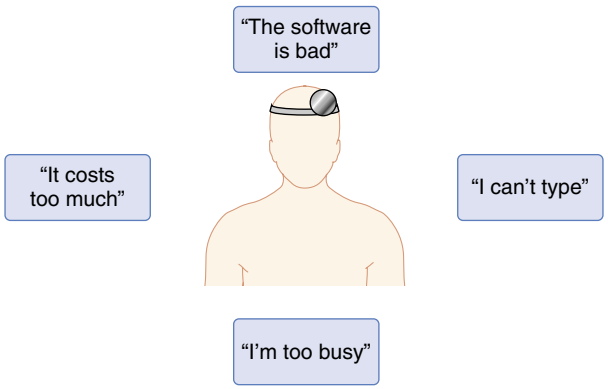

Figure 4-12 Various barriers to adoption of electronic health records.

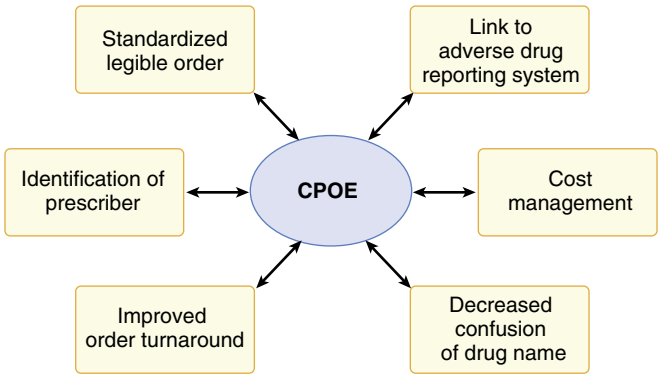

Figure 4-13 Various benefits of a computerized order entry (CPOE).

with communication tools. Patient support tools such as pamphlets describing a disease or discharge directions can be generated automatically. Administrative processes can be integrated into EHRs, including scheduling systems, billing management, and insurance validation. Finally, internal and external reporting requirements can be simplified by using reporting systems built into EHRs.

The concept of a universal medical record deserves specific attention. It has always been desirable for providers in one location to have access to data from a medical record generated at another location, and although there are many models of a universal medical record, such as a record owned and kept by the patient on a piece of hardware such as a flash drive, there are a variety of problems with this approach. A more practical approach is currently being deployed by large vendors such as Microsoft and Google, which now offer patient medical "vaults" that are maintained on line and over which the patient has read-write and access control.

Computerized Order Entry

CPOE systems have begun to gain a foothold in the provision of care at many hospitals, although 50% of American hospitals still lack one. Prescribing errors are the most common source of adverse drug event, and CPOEs, with or without decision support tools, are widely viewed as being integral to reduction in errors and formulary control. CPOEs came into the spotlight after the Institute of Medicine's 1999 report "To Err Is Human: Building a Safer Health System," in which 44,000 to 98,000 deaths per year were attributable to medical errors; however, although CPOE has great potential, poorly designed or deployed systems will either not be adopted or potentially cause errors.

Broadly, the term CPOE is used to refer to computer-based ordering systems designed to automate the ordering process, be it for drugs or for requesting pathologic or radiologic tests. Benefits include the output of standardized, complete, legible orders consistent with the hospital's formulary and automatically sent to the pharmacy (Fig. 4-13). CPOE is also almost invariably associated with a decision support system (DSS), which will be discussed in more detail in the next section.

Successful deployment of CPOE will occur only when the system is deployed as part of a fundamental redesign in the delivery of patient care. The organizational aspects of CPOE deployment have been described by a recent consensus panel from the American Medical Informatics Association in which nine elements of successful systems were highlighted. The first is the development of a clear understanding of all of the institution-specific drivers for implementation of a CPOE system, be they regulatory, regional competition for patients, or internal. A second critical element is sustained internal leadership-level support during implementation of the CPOE system. Third, the CPOE system must be adequately funded in all respects, including training of personnel. A fourth and critical element is prospective understanding of the way in which CPOE will affect workflow at all sites in the organization (Fig. 4-14). A corollary to this element is the fifth, which is ensuring a positive "cost-benefit" ratio for each of the providers who use the system by the creation of time savers such as order sets. The sixth element of successful CPOE systems is the selection of an appropriate deployment strategy, whether it be an all-at-once or a staged approach. The seventh consideration relates to the technical details of CPOE implementation, such as the replacement of legacy systems. Training and support must be comprehensive and is the eighth element. The ninth and final critical aspect is the design of a plan for continuous quality improvement after implementation of the system.

Decision Support Systems/Artificial Intelligence

Decision support tools integrated into the EHR and CPOE can provide immediate access to current medical knowledge, institutional best practices, billing compliance information, and administrative functions and can facilitate cost control. Although there is a wide range of architectures, DSSs fall somewhere on the spectrum between expert systems, in which rules developed by domain experts are used to drive decision support, and autonomous systems that have the ability to "learn" and make observations about large data sets. An example of the latter might be a system that automatically culls through a physician's orders to develop a profile of prescribing patterns.

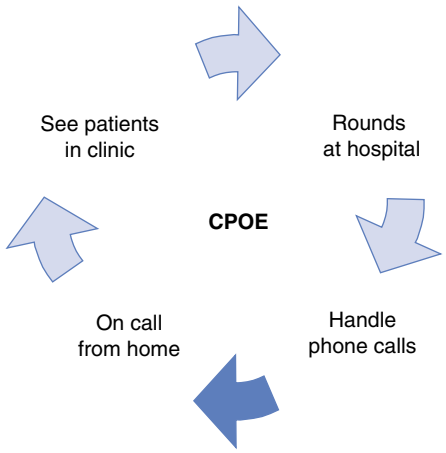

Figure 4-14 Integration of computerized order entry (CPOE) into the workflow of an organization.

A DSS can "act" in one of three ways. It may be a passive system that responds with information when asked. Alternatively, it may be semiactive and provide alerts or alarms only when certain conditions are met. Finally, a system may be active and autonomous and generate an order set or manage a medical process automatically, such as automated weaning of mechanical ventilation according to built-in rules.

Clinicians want certain functions from a DSS, such as access to national consensus guidelines when available, concurrent presentation of relevant patient information when ordering, intelligent alerts, reminders to engage in patient-specific activities (such as immunizations), and the ability to measure their performance versus that of peers in a way that results in continuous improvement in performance.

HIPAA and Data Security

Enacted in 1996, the HIPAA was initially designed to protect workers from losing their health insurance (portability) during job transition and to protect the integrity, confidentiality, and availability of their medical information (accountability). HIPAA covers three critical aspects of automated health care information: privacy, universal coding formats, and security.[33-38]

The target of the privacy element is what is known as protected health information, and the bill ensures a patient's right to control the use of that information as it relates to health care, the business of health care, and research. The HIPAA mandates the creation of universal code sets that cover, for example, the classification of diseases and describes both a national provider and national patient identification number. There are a variety of concerns about the latter that have prevented its adoption to date. The security aspect of the legislation relates to the physical and electronic aspects of ensuring the protection of patient health information (Fig. 4-15).

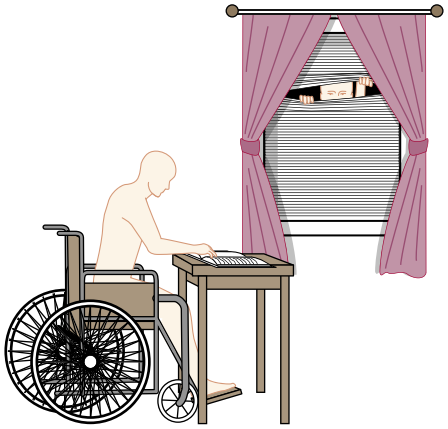

Figure 4-15 Security aspects of the HIPAA legislation relate to the physical aspects protecting unauthorized access to protected health information.

Telemedicine

Telemedicine and telehealth are the application of health care services across space, time, and social and cultural barriers. Telemedicine has been demonstrated in a variety of disciplines, including surgery, emergency medicine, cardiology, dermatology, ophthalmology, neurology, gastroenterology, rehabilitation, and critical care medicine.[26,39-50] However, although telemedicine has already had an enormous impact on the ability of patients to access medical information, there are a variety of barriers to widespread implementation of clinical care at a distance, including licensure, credentialing, malpractice, and reimbursement.

Telemedicine holds great promise as a means of making medical care available to underserved areas, providing access to specialists at remote locations, and allowing patients to receive medical attention in their home when physical contact is not a critical element of an encounter. In addition, new technologies are currently under development, including teleimmersion and telepresence. Teleimmersion permits geographically dispersed people to collaborate in a shared virtual space, whereas telepresence refers to a system in which the human practitioner may have visual and mechanical actuators and sensors permitting them to "see," "feel," and "move" objects in a remote environment (Fig. 4-16).

Telesurgery demonstration projects have been done, for example, with both laparoscopic and robotic instruments to operate at a distance. A number of other demonstration projects are under way in various fields of medicine, and reimbursement agencies are beginning to develop methods of reimbursement for

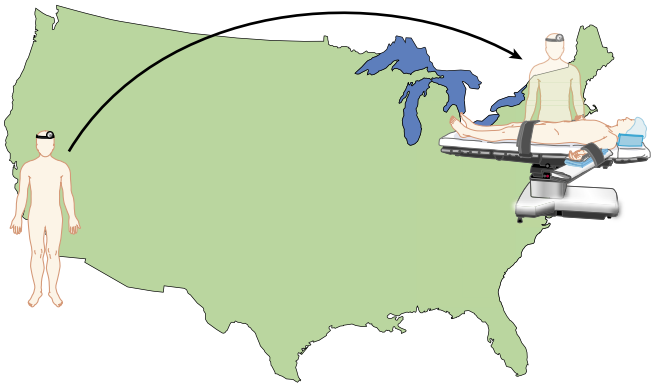

Figure 4-16 Telepresence relates to the ability to be virtually present at a patient's bedside.

telemedicine-based activities. In addition, there are a few commercially available models for delivery of telemedicine, including remote radiographic interpretation, in some cases from appropriately credentialed radiologists interpretation from international locations, and critical care coverage from remote, virtual ICUs.

Telemedicine will eventually change the way that medicine is practiced in many fundamental ways. It is equally certain that the speed of technologic change will outstrip that of regulatory, reimbursement, and legislative change.[51]

5 Quality Improvement

Key Points

1. Quality is a characteristic of the system in which care is delivered, and every system is perfectly designed to achieve the results that it achieves. If we want to improve the quality of care that we provide, we need to reorganize the way that we work.
2. The growing demand for improved quality and safety in health care from patients, providers, insurers, regulators, accreditors, and purchasers calls for anesthesiologists to evaluate the quality of care that they provide.
3. Improving quality of care entails measuring performance. However, health care providers have limited ability to obtain feedback regarding performance in their daily work, in part because of a lack of information systems and lack of agreement on how to measure quality of care.
4. The goal of measurement is to learn and improve. The measurement system must fit into an improvement system; caregivers must have the will to work cooperatively to improve, they must have ideas or hypotheses about changes in the current system of care, and the team must have a model for testing changes and implementing those that result in improvements.
5. Previous efforts to measure performance have focused predominantly on outcome measures, including in-hospital mortality rates. Although important, hospital mortality alone provides an incomplete picture in that it does not provide insight into all domains of quality. A balanced set of structures (how care is organized), processes (what we do), and outcome measures (results we achieve) is needed to obtain a more accurate picture of the quality of care.
6. Future efforts to improve quality of care in the field of anesthesiology should focus on the development of valid, reliable, and practical measures of quality.
7. Developing a quality measure requires several steps: prioritize the clinical area to evaluate; select the type of measure; write definitions and design specifications; develop data collection tools; pilot-test data collection tools and evaluate the validity, reliability, and feasibility of measures; develop scoring and analytic specifications; and collect baseline data.
8. One of the greatest opportunities to improve quality of care and patient outcomes probably will not come from discovering new therapies but from discovering how to better deliver therapies that are known to be effective.
9. Strategies that have been used successfully in the aviation industry to improve performance include interventions to reduce complexity and the creation of redundancies in the system to ensure that critical processes occur. These strategies have not been fully evaluated in the practice of anesthesia.
10. Health care providers can organize their patient safety and quality improvement efforts around three key areas: translating evidence into practice, identifying and mitigating hazards, and improving culture and communication. Although each of these areas requires different tools, they all help health care organizations to evaluate progress in patient safety and quality.

Quality improvement (QI) programs have become a compelling force in virtually all branches of medicine. The Centers for Medicare and Medicaid Services (CMS) and The Joint Commission have put forth regulatory policies to further ensure that patients receive interventions that are evidence based and are broadly accepted as the standard of care. The Agency for Healthcare Research and Quality (AHRQ), the health services research arm of the U.S. Department of Health and Human Services, maintains a website that contains information on clinical practice guidelines and QI initiatives along with data to support their use. These

guidelines and initiatives are increasingly being used to maintain accreditation of facilities, achieve optimal reimbursement, and provide quality patient care.

The goal of this chapter is to present a practical framework for developing and implementing QI programs in anesthesiology and critical care medicine that are both scientifically sound and feasible. To accomplish this goal, we review the science of QI, present measures that help evaluate whether QI programs are valid, and offer examples of successful QI efforts.

What Is Quality?

The word *quality* is used to describe the degree or grade of excellence of a trait or characteristic of a system. It is a key word used ubiquitously by many professions and businesses. "Quality is job one" was once the well-known slogan of the Ford Motor Company. It implied that they got it right. However, the recalls on their cars and trucks revealed that such was not always the case. In health care, our "recall" was the 1999 Institute of Medicine (IOM) report *To Err Is Human*.[1] By estimating the number of preventable deaths per year caused by medical errors, the report showed that the need to improve quality in health care was substantial. It still is.

The medical profession has been working for more than a century to improve health care quality. In the early 1900s, Dr. Ernest Codman, a surgeon at Massachusetts General Hospital, began his lifelong pursuit of tracking patient outcomes to serve as a foundation for improving the care of future patients.[2] He went on to lead the founding of the American College of Surgeons and its Hospital Standardization Program, which has become what is known today as The Joint Commission. Over time, quality assurance programs were developed whereby selected indicators were monitored by retrospective chart review to measure compliance with recommended practices. However, we learned that this did not necessarily ensure quality and that it led to fears of punitive action for the health care worker. The intention of monitoring quality of care was, and still is, to learn and improve, not to judge or punish. With this realization, quality assurance became quality improvement. Today, the focus of health care quality is on continuous QI programs.

QI is better facilitated when an interdisciplinary group of health care providers and administrators regularly reviews performance, designs interventions to improve, and creates a team to implement the interventions.[3] It is common to describe "quality improvement" in terms of "patient safety." At times, it is difficult to separate the two. The 2001 IOM report *Crossing the Quality Chasm* classified safety as a component of the broader concept of quality.[4] However, the boundaries between the two remain poorly defined. Among the domains of quality, patient safety generally includes efforts to translate evidence into practice, identify and mitigate hazards, and improve safety culture and communication.

A growing demand continues for improved quality and safety in health care from patients, providers, insurers, regulators, and accreditors. This demand is warranted; evidence suggests that safety and quality of care in hospitals can be improved.[5-7] Improvement is not limited just to programs developed to prevent mistakes of *commission*—things we do to patients—but also includes programs to prevent mistakes of *omission*, whereby patients do not receive the therapies that they should.[8]

Historical Methods of Quality Assessment

Before QI, there was quality assurance. Review of adverse events or defects—peer review, morbidity and mortality conferences, isolated liability claims, and incident reports—has been used historically for quality assurance programs. However, the information provided by these sources is often haphazard and biased. Typically, these adverse events are rare for any given practitioner and are not linked to denominators, thereby limiting the ability to estimate rates and risk, nor do they necessarily reflect quality of care or progress made by QI programs. Moreover, these efforts generally focus on assigning blame (who made the error) rather than on how to reduce the risk for future patients (learning from the mistake).

In an effort to encompass a larger group of adverse events, the American Society of Anesthesiology (ASA) began a Closed Claims Database in 1985.[9] Closed malpractice claims against anesthesiologists provided an enriched environment for collecting information about rare but often catastrophic events. The database provided an opportunity to examine a large set of rare events that might reveal hazards that were common in hospitals and insights that would be otherwise difficult to discern. To be certain, these events represent a biased sample. Most adverse events do not result in claims, and many claims are not the result of preventable adverse events.[10] The information derived from the ASA Closed Claims Database was the impetus for development of QI safety and educational programs with the goal of reducing risk to patients. As an example, a review of adverse respiratory events in the Closed Claims Database, published by Caplan and colleagues in 1990,[11] was followed by organization of an ASA taskforce that established practice guidelines for the difficult airway,[12,13] founding of a Difficult Airway Society in 1995 (http://www.das.uk.com) with its difficult airway guidelines,[14] and development of multidisciplinary difficult airway programs.[15]

Voluntary incident reporting that identifies hazardous systems has been used successfully to improve patient care and foster QI programs.[16] As the potential of voluntary incident reporting is being realized in health care, reporting has become less punitive and more focused on systems rather than individuals. Voluntary incident reporting, when appropriately applied, helps identify hazards to patients, which can then become the focus of QI efforts that seek to mitigate these hazards.[17] Unlike other methods that evaluate harmed patients, voluntary incident reporting provides the potential to also learn from near misses—incidents that did not lead to harm but could have. Although voluntary reporting systems are growing rapidly, most of the effort has been focused on encouraging the actual reporting of events; even more important is the need to focus on learning from these events and reducing risks to patients.

The Intensive Care Unit Safety Reporting System (ICUSRS) project is an example of such an incident reporting system.[18] In the ICUSRS, researchers and caregivers created a web-based, anonymous reporting system that sought to uncover unsafe conditions that could lead to patient harm. They partnered with the Society for Critical Care Medicine to provide expert analysis and feedback to members on lessons learned regarding how to improve patient safety. The ICUSRS has assembled a large community of intensive care units (ICUs) across the United States and is realiz-

ing the potential for incident reporting to improve patient care.[19,20] This type of reporting system could be widely applied by anesthesiology to develop QI programs and evidence-based practice.

Measures of Quality Improvement

Key to improving quality in patient care is the ability to measure the progress made. Health care currently has few scientifically sound, feasible measures, and significant effort is necessary to further develop such measures. Health care has borrowed tools from other disciplines (e.g., organizational psychology, sociology, and human-factors engineering) that have developed basic quality and safety-related principles. As Brennan and coworkers noted, other disciplines can be considered the basic science of quality.[21]

At the end of World War II, W. Edwards Deming, an American statistician, introduced the concept of QI in industry, thereby heralding the advent of the modern-day science of improvement. Deming's work helped improve productivity in the United States but made an even bigger impact in Japan, where implementation of his QI methods resulted in Japan becoming renowned for producing innovative, high-quality products.[22] Deming's components for improvement were summarized by Langley and associates[23] as (1) appreciation of a system (people, procedures, equipment), (2) understanding of variation (is a change in outcome a result of a change in practice or simply due to luck?), and (3) theory of knowledge and psychology of change (how people react to change, why they resist, and how to overcome the resistance).

Japan's increased productivity, plus the subsequent adoption of these techniques globally, was a clear measure of the validity of Deming's methods. These methods are rooted in science and depend on robust evaluation. Developing similar measures of quality in health care was (and still is) a challenge. Although patient care cannot necessarily be equated with industry, some similarities exist. Avedis Donabedian was one of the masters of designing measures of health care improvement programs. In the 1980s, Donabedian proposed that we measure the quality of health care by observing its structure (the attributes of the settings where care is delivered), process (whether good medical practices are being followed), and outcome (the impact of the care on health status); this is known as the Donabedian Quality-of-Care Framework.[24,25] This framework may be applied to the clinical setting as follows: First, caregivers must have the will to work cooperatively to improve. Second, the group must have ideas or hypotheses about making changes in the current system of care that are based on scientific fact or expert consensus. Third, the team must have a model for testing changes and implementing those that result in improvement.[23] This ability to measure change in terms of improvement is fundamental to any QI program.[26]

Process and Outcome Measures

As stated earlier, QI measures can be an outcome (morbidity, mortality, length of stay, quality of life, or perceptions of care), a process (β-blockers for patients with coronary artery disease), or a structural measure (ICU physician or nurse staffing ratio).[27,28] Each of these measures has advantages and limitations.[29] Process measures are readily accepted by health care providers because they demonstrate the degree to which caregivers can influence a process, with the intention of improving patient outcomes. Providers generally feel more accountable for the process of care than for its outcomes because outcomes may be affected by many other variables.[29] An obstacle to using process as a measure of quality is sustainability; frequent updating is required as the science of medicine advances.

Process measures that evaluate how care is delivered may be easier to measure and implement and can provide important insight into care.[30] Process measures can provide immediate feedback regarding performance, thereby allowing rapid improvements in care. Additional important advantages of evaluating process measures are (1) that they generally have face validity for providers, which means that providers believe that they can use the data to improve care, and (2) because risk adjustment is less important, broad implementation is feasible. Moreover, joint efforts among providers, professional societies, and external government or payer agencies have made them more feasible.[30]

To be valid, process measures should have causal links to important outcomes; a change in the process should produce a desired change in outcome. One of the greatest opportunities to improve patient outcome may well come from discovering how to deliver therapies (processes) that are known to be effective in producing a desired outcome.[31] For example, prior hand washing and application of chlorhexidine to sterilize the skin site before insertion of a central venous catheter (CVC) are two of five processes known to reduce catheter-related bloodstream infections (CRBSIs).[32] Process measures such as these are indicators of whether patients reliably receive evidence-based interventions known to prevent complications.

When measuring processes, it is essential to remember that patient factors, bias in measurement, and interventions already in place as part of standard practice all play a role in outcomes. The linkage of process to outcomes must be previously demonstrated scientifically or must be widely accepted by peers, although the latter risks being accepted but wrong. In general, a balanced set of process and outcome measures helps to inform improvement efforts and provides evidence that such efforts have made a difference in the lives of patients.

The need for risk adjustment and long-term follow-up is complex. If an outcome occurs infrequently, it will take considerable time before providers can obtain meaningful feedback. For example, evidence of improved rates of CRBSI (an outcome measure) may require 3 months of data (because infections develop in few patients), whereas improved adherence to evidence-based practices to reduce infections (process measures) may be observed within a week (because all patients can be evaluated to determine whether they received the intervention). Nevertheless, consumers and employers are increasingly requesting outcome measures. The relative focus on outcome and process measures will depend on finding the balance between collecting data that are scientifically sound yet feasible.

Analysis of Quality Improvement Data

The QI team must decide how the data will be analyzed and how clinical and statistical significance will be determined. A common feature of a well-run QI project is correlation of several measures

over time. The horizontal (*x*) axis can represent time in days, weeks, or months, and the vertical (*y*) axis can represent the performance measure (Fig. 5-1). The analyst annotates the plots with the timing of the interventions or other significant events such as, in this example, implementation of an educational program for the appropriate timing of administering antibiotics preoperatively.

Although analysis of rates or proportions is generally clear, analysis of continuous data, such as time, is less clear. There is often uncertainty regarding the unit of analysis when plotting data over time (commonly called a *control chart*). Should the unit of time be days, weeks, months, or years? The unit of analysis should be selected so that learning is optimized; it is influenced by sample-size requirements and by the frequency with which the investigator plans to provide feedback or launch interventions, or both.[33] In general, feedback regarding process measures can be provided more frequently than feedback for outcome measures can. Scales and units of measure should be chosen to optimize learning of the user.[34] Therefore, the user of the information should be involved in deciding which unit of measure to use.

Time series consisting of data from small samples collected continually over time is the standard for QI work. It is less costly to implement than measurements associated with the large, one-time data collection of controlled trials. Study of the patterns of variation in the measures over time determines the performance of the system and its stability. The patterns in time series data contain important information; other methods that rely on averages or other summary statistics can hide this information (e.g., comparing results across the arms of a randomized, controlled trial).

Uncontrolled observational measurement holds higher risk for unrecognized bias and incorrect conclusions about cause and effect than more rigorous designs do. However, unlike these designs, in which measurement ends when the researchers leave, in a health care setting, time series measurement continues to determine whether the perceived improvement is sustainable. This is contingent on having a system to collect, analyze, and report back data. Incorrect claims of improvement that result from faulty inference become apparent in time.

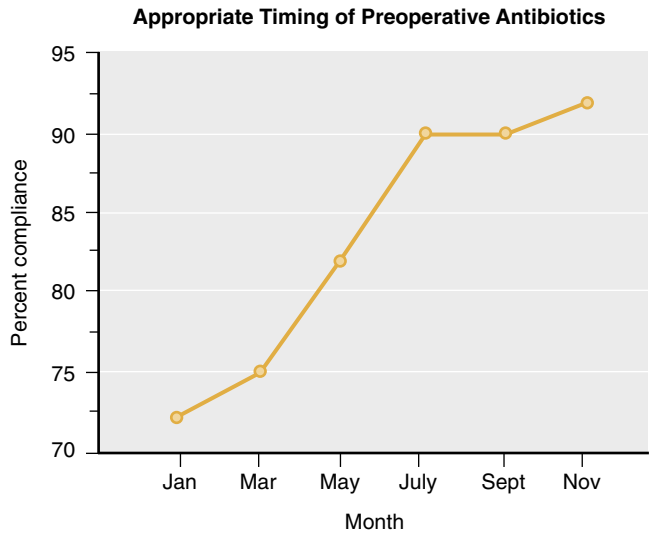

Figure 5-1 Example of a plot of a performance measure over time. The horizontal (*x*) axis represents time in months, and the vertical (*y*) axis represents the performance measure—percent compliance with the timing of administration of preoperative antibiotics.

Periodic measurement can be built into daily work and allows the clinical team to continually evaluate performance. Any decline in performance is evident, and a clinical team can quickly respond. If properly planned and coordinated, such local outcomes tracking, when combined with descriptions of evolved systems of care, can enhance learning at both the local and regional level, as well as the national level. This widespread learning and improvement are consistent with the "call for action" issued in 1997 by Lundberg and Wennberg.[35]

Examples of Quality Improvement Programs and Tools

Voluntary Incident Reporting

Providers who are given a readily available means of reporting incidents can be an excellent source of information for the development of QI programs. However, data from these voluntary reporting systems should not be interpreted as rates or be used to evaluate progress in patient safety. The following is an example of a self-reported medication error and the actions that were taken after a detailed (root cause) analysis of the factors that led to the error.

An ICU patient was administered Zosyn (piperacillin/tazobactam) intravenously despite a documented allergy to penicillin. On cursory review, the physician who wrote the order and the nurse who administered the medication appeared to be at fault because they failed to note the penicillin allergy. An in-depth investigation of this medication error was undertaken, with appropriate scrutiny to identify the system failures that resulted in this error. First, we will review the circumstances that led to the error through the eyes of the caregivers involved.

The patient was exhibiting signs of pneumonia. The physician was interrupted (distracted) while writing the order for Zosyn and failed to review the patient's allergies. The bedside nurse did not realize that Zosyn contained piperacillin and was contraindicated for a patient with an allergy to penicillin. The bedside nurse did know that administering the antibiotic within 1 hour of the diagnosis of pneumonia would dramatically improve the patient's outcome and that the 1-hour rule was a core measure for pneumonia therapy. On further discussion with staff, investigators discovered that the nurse's concern over administering the antibiotic quickly was perpetuated by a broken fax machine and a nonfunctioning pneumatic tube transport system. Orders were normally faxed to the pharmacy, and medications were then dispensed through the pneumatic tube system for a quick turnaround. Because the system for quickly obtaining medications failed, the nurse borrowed the Zosyn from floor stock.

This case is a powerful example of how each step aligned to achieve a catastrophic outcome. By borrowing the antibiotic from floor stock, a crucial safety check of potential medication allergies by the pharmacist was bypassed. The root-cause analysis demonstrated the frontline caregivers' commitment to quality, uncovered several defects that resulted in the event (the drug name Zosyn was unfamiliar and did not indicate that the drug

contained piperacillin, the fax machine was broken, the pneumatic tube transport system was broken, and the pharmacy safety check was bypassed), and provided solutions to fix the problem (ongoing preventive maintenance to ensure the functionality of equipment, electronic provider order entry, and possibly hiring staff for transport backup to ensure that medications come from the pharmacy and not floor stock).

It is important to recognize that QI projects often require resources. In this case example, a QI project was undertaken by senior leaders in the organization to intensively evaluate the pneumatic tube used for transport to identify sources of malfunction and reduce defects, develop protocols for handling transport capsules, and determine whether adding staff for transport backup was needed. A plan for electronic order entry was being developed. Each step required measurement and analysis, with the understanding that changes made in a system may introduce new hazards that must be guarded against.

Collaboratives

A collaborative involves the participation of multidisciplinary care providers within a clinical area, across clinical areas, or across multiple health care organizations to improve care. It incorporates a structured program with a shared goal. The team leading the collaborative will (1) determine the evidence-based interventions to be used and, if none are available, generate interventions based on local and broad expert consensus and (2) establish the data collection approach (define measures, collection methods, and feedback mechanisms).

As with all successful QI projects, baseline compliance and change over time are key data points to collect. Collaboratives are successful when they involve a sharing process of interventions and obstacles. Through group discussions (meetings, conference calls), teams can learn about best practices and innovative methods used by other teams to approach a problem. In addition, collaboratives bring a shared momentum that can increase sustainability.[26,36]

Multicentered and single-hospital projects can fail because of inadequate resources, lack of support by leadership, vague expectations and objectives for team members, poor communication, complex study plans, inadequate management of data collection, and wasted effort to "reinvent the wheel" rather than adopting practices proven to be effective. Successful collaboratives require a local culture (the set of values, attitudes, and beliefs of the group) that is ready for change and participants with a shared view of safety, who understand the science of patient quality and safety (i.e., the technical components of how care is organized and delivered). Pronovost and colleagues reported the reproducible success of a collaborative that has adhered to the following steps, which have been validated in several large collaborative efforts.[37,38]

1. Identify evidence-based interventions associated with improved outcome through review of peer-reviewed publications.
2. Select goal-oriented interventions that have the biggest impact on outcomes and transform them into behavior. In selecting behavior, focus on interventions with the strongest treatment effect (lowest number needed to treat) and the lowest barrier to use.
3. Develop and implement measures that evaluate either the interventions (processes) or the outcomes.
4. Measure baseline performance and establish databases to facilitate accurate data management and timely feedback to teams.
5. Ensure that patients receive evidence-based interventions through four basic steps: engagement, education, execution, and evaluation (Table 5-1).

Table 5-1 Four Steps to Ensure That Patients Receive Evidence-Based Interventions through a Collaborative As Illustrated by the Example of Catheter-Related Bloodstream Infections

Step	Action	Example
Engage	Make the problem real	Share information of the local CRBSI rate vs. the national rate
Educate	Develop an educational plan to reach *all* members of the caregiver team	Present evidence-based practices at Grand Rounds and multidisciplinary team meetings Present plans to improve care and measure outcome
Execute	Develop a safety culture Reduce complexity of the processes Introduce redundancy in processes Hold regular team meetings	Develop a culture of intolerance for CRBSI Make certain that all equipment and supplies for sterile CVC insertion are in one place and easily available Use checklists that identify key steps to reduce CRBSI Focus on 1-2 tasks per week and identify team member responsible for the tasks
Evaluate	Measurement and feedback	Develop a data collection plan and database to track progress Give staff real-time feedback; post the progress in a highly visible location Identify causes of defects

CRBSI, catheter-related bloodstream infection; CVC, central venous catheter.

Comprehensive Unit–Based Safety Program: A Strategy To Learn from Mistakes and Improve Culture

The Comprehensive Unit–Based Safety Program (CUSP) is a six-step program that has been tested and successfully used to improve quality and safety in ICUs (Table 5-2).[39,40] It provides a structured approach to improve safety culture and mitigate hazards (i.e., learn from mistakes).[39,41]

Safety culture is assessed in the first step of CUSP and reassessed after 1 year to evaluate the impact of the program. The Safety Attitudes Questionnaire—valid, reliable, and widely recognized—is the survey tool used to assess safety culture.[42,43] The initial measure provides a baseline assessment of staff perceptions of safety culture in their clinical areas and their perceptions of the organization's commitment to patient safety.

Education is a crucial aspect of CUSP; it provides staff with a new set of lenses through which to identify hazards and recommend system changes to improve care. The objectives of

Table 5-2 Six-Step Comprehensive Unit–Based Safety Program

Step	Description
1. Measure safety culture	Assess safety culture by all staff members in each clinical area through the Safety Attitudes Questionnaire
2. Present educational material	Educate staff on the science of safety though lectures and other educational material
3. Complete forms identifying patient safety issues	Ask the following questions: How will the next patient be harmed? How can this harm be prevented? Establish voluntary incident reporting
4. Assign a senior executive responsible for a specific area	The senior executive meets with all staff members of the clinical area to: Help prioritize safety efforts Remove barriers for system changes Provide resources Demonstrate hospital commitment to patient safety Foster relationship between senior leadership and staff
5. Implement projects	Focus on two to three safety issues Keep goals simple: Reduce complexity in the process Create independent redundancies to ensure that critical steps are being accomplished
6. Repeat measure of safety culture	Remeasure safety culture; determine whether scores improve

these educational efforts are to ensure that staff members (1) understand that safety is a system property, (2) learn concepts for reliable health care design, and (3) understand the basics of change management. After an educational lecture on the science of safety, staff members are requested to identify patient safety hazards in their clinical areas and suggest interventions for improvement. For this phase, staff members review incident reports, liability claims, and sentinel events from their unit. In addition, two questions are asked: "How do you think the next patient will be harmed?" and "How can we prevent it from happening?"

After completion of the survey and educational component, a senior leader of the institution (e.g., hospital president, vice-president, director) is partnered with a unit or clinical area and attends monthly rounds on the unit with the staff to help them prioritize safety efforts, ensure that they have the resources to implement improvements, and hold staff accountable for evaluating whether safety has improved. Staff members are asked to learn from one defect per month and implement one tool per quarter that is designed to improve delivery of care, such as a daily goals sheet (see later) to improve communication and teamwork.[44,45]

Our institution pilot-tested CUSP in its ICUs and subsequently implemented it throughout the hospital. In the pilot test, a patient safety team that consisted of staff from the clinical area was responsible for oversight of the program. To be most effective, this team included the ICU director as the ICU physician safety champion, the nurse manager, another ICU physician and nurse, a risk manager or patient safety officer, and a senior executive from the institution. We found that the program worked best if the physician and nurse who led the program dedicated at least 20% of their time to improving patient safety and QI. The first unit was the beta site; subsequent teams from other clinical areas would learn from their successes and failures. The ultimate goal was to have every area in the hospital organizing and managing safety through CUSP.

CUSP has been associated with significant improvements in safety culture. The proportion of staff members reporting a positive safety climate increased from 35% before CUSP to 60% after CUSP.[39,41] In addition, teams identified and mitigated several specific hazards through CUSP. As a result of asking staff how the next patient will be harmed, the ICU created a dedicated ICU transport team, implemented point-of-care pharmacists, put into practice a daily goals sheet, clearly labeled epidural catheters to prevent inadvertent intravenous connection, and standardized the equipment in transvenous pacing kits.[46] Moreover, the use of CUSP was associated with a reduction in patient length of stay and nurse turnover.

In summary, CUSP provides several benefits for improving safety culture and is a primer for compliance of staff in implementing any safety or QI intervention or project. It provides enough structure to convert the often vague goals of improving safety into a focused strategy yet is malleable enough to allow units to work on issues most important to them. CUSP provides a venue to introduce rigorous research methods, acts as a learning laboratory to identify and mitigate hazards, and has the potential to improve patient outcomes.

Quality Improvement Tools

Efforts in QI and patient safety have produced tools with which to reorganize the way that care is delivered. Some of these tools are described briefly in the following sections.

Daily Goals Sheet

The daily goals sheet has been used since July 2001 during multidisciplinary rounds in the ICU at Johns Hopkins to improve communication.[44] A one-page checklist, this tool is completed every morning to establish the care plan, set goals, and review potential safety risks for each patient (Fig. 5-2). The goals sheet stays with the patient, is updated as needed, and is used as an information sheet for all staff involved in the patient's care. It can be modified for use in other nursing units or during operating room sign-out or emergency department rounds.

On initial survey it was found that care team members were unable to answer two simple questions after rounds at each patient's bedside: "Do you understand the patient's goals for the day? and "Do you understand what work needs to be accomplished on this patient today?" The team's inability to answer these questions became the impetus to develop the daily goals sheet. Before implementation of the daily goals sheet, a survey showed that fewer than 10% of the residents and nurses knew the care

	Room Number _____	Shift: ❒ AM / ❒ PM
Safety	What needs to be done to d/c patient from the ICU?	
	Patient's greatest safety risk? How can we ↓ risk?	
	What events or deviations need to be reported? ICUSRS issues?	
Patient Care	Pain & Sedation Management	Pain goal ____ /10
	Cardiac Review ECGs	HR goal ____ ❒ at goal ❒ ↑ ❒ ↓ beta-blockade
	Volume status Net goal for midnight	Even ❒ Pos ❒ Neg ___ Net ___ (cc) ❒ Patient determined
	Pulmonary: Ventilator, ventilator bundle, HOB ↑, wean	❒ OOB/pulmonary toilet/ambulation
	SIRS/Infection/Sepsis evaluation Temp >38°C or <36°C; HR >90 RR >20 or $Paco_2$ <32 WBC >12000 < 4000 or >10% bands	❒ No current SIRS/sepsis issues ❒ Known/suspected infection ❒ Culture blood ×2/urine/sputum ❒ Antibiotic changes ❒ Discontinue sepsis bundle
	Can catheters/tubes be removed?	Y/N
	GI/Nutrition/Bowel regimen: TPN catheter, ND tube PEG needed?	❒ TPN ❒ NPO/Advance diet
	Is patient receiving DVT/PUD prophylaxis?	Y/N
	Can meds be discontinued, changed to PO, adjusted?	
To Do	Tests/Procedures today	
	Scheduled labs	
	AM labs needed/CXR?	
	Consultations	
Description	Has primary service been updated?	
	Has family been updated? Social issues addressed? Long-term/Palliative care	

Figure 5-2 Example of an intensive care unit (ICU) daily goals sheet. CXR, chest radiograph; d/c, discharge; DVT, deep venous thrombosis; ECG, electrocardiogram; GI, gastrointestinal; HOB, head of bed; HR, heart rate; ICUSRS, ICU self-reporting system; ND, nasoduodenal; NPO, nothing by mouth; OOB, out of bed; PEG, percutaneous endoscopic gastrostomy; PUD, peptic ulcer disease; RR, respiratory rate; SIRS, severe infectious respiratory syndrome; temp, temperature; TPN, total parenteral nutrition; vent, ventilator; WBC, white blood cell count.

plan for the day—a finding that is not surprising because traditional bedside rounds tended to focus on teaching staff about the disease rather than the work that was necessary to treat the patient. Approximately 4 weeks after implementing the daily goals sheet, 95% of the residents and nurses understood the goals for each patient. Moreover, after implementing the daily goals sheet, length of stay in a surgical ICU at Johns Hopkins Hospital decreased from a mean of 2.2 days to just 1.1 days.[44]

Briefings and Debriefings

Similar to the daily goals sheet, briefing and debriefing tools are designed to promote effective interdisciplinary communication and teamwork. Both have been used in the operating room, in sign-out from the ICU nursing staff to the intensivist, and between operating room nursing and anesthesia coordinators.[45,47,48] A briefing is a structured review of the case at hand for all team members before the start of an operative procedure. A debriefing occurs after the procedure; the team reviews what worked well, what failed, and what could be accomplished better in the future (Fig. 5-3).

An example of an operating room briefing includes introduction by name (first and last) and the role of each team member; confirmation of the correct patient, site/side, and procedure ("time-out"); and verbal assurance that all team members agree that they understand the procedure and what is required to ensure its success. A check of all necessary equipment (e.g., electrocautery), medications (e.g., appropriate antibiotic), and blood availability is performed. The question "If something were to go wrong, what would it be?" is asked, and plans to mitigate or respond to the potential hazard are discussed.

Checklists

Checklists have been used in health care and in industry in an effort to ensure that important steps in a process are not forgotten. The Food and Drug Administration recommends that a checklist be used when performing checkout and inspection of an anesthesia machine before use to ensure that the equipment and monitors are functioning properly.[49] As part of a QI project to reduce CRBSI, a checklist was one of several interventions implemented

	Briefing: Before Every Procedure
	Team introductions: First and last names, including roles; write names on board
	Verify: Patient ID band, Informed Consent (read out loud), site marking, OR posting, patient's verbalization of procedure (if patient awake), H&P or clinic note
	Are there any safety, equipment, instrument, implant, or other concerns?
	Have antibiotics been given, if indicated?
	What are the anticipated times of antibiotic redosing?
	Is glucose control or beta-blockade indicated?
	Is the patient positioned to minimize injury?
	Has the prep solution been applied properly, without pooling, and allowed to dry?
	Have the goals and critical steps of the procedure been discussed?
	Is the appropriate amount of blood available?
	Is DVT prophylaxis indicated? If yes, describe.
	Are warmers on the patient?
	Is the time allotted for this procedure an accurate estimate?
	Have the attendings reviewed the latest laboratory and radiology results?
	Debriefing: After Every Procedure
	Could anything have been done to make this case safer or more efficient?
	Has the Surgical Site Infection data collection form been completed?
	Are the patient's name, history number, surgical specimen name, and laterality on the paper work? (must be independently verified by the surgeon)
	Did we have problems with instruments? Were they reported?
	Plan for transition of care to postop unit discussed? ❒ Fluid management? ❒ Blood transfusion paperwork in chart? ❒ Antibiotic dose and interval to be continued postop? ❒ Pain management/PCA plan? ❒ New medications needed immediately postop? ❒ Beta-blockers needed? ❒ Glucose control? ❒ DVT prophylaxis?

Figure 5-3 Example of a checklist for operating room (OR) briefing and debriefing. DVT, deep venous thrombosis; H&P, history and physical examination; ID, identification.

to reduce complexity and introduce a redundant safety check. The checklist, typically completed by a nurse, was attached to the CVC insertion cart to ensure compliance with the best practices for CVC placement. The nurse was empowered to stop the procedure if the checklist was not followed or if sterile technique was compromised. This intervention resulted in a 66% reduction in the overall CRBSI rate, with the median rate reduced from 2.7 per 1000 catheter-days before the intervention to 0 by month 3 and through month 18 of the postintervention period.[50,51] In general, these QI tools seek to standardize communication and technical work.

Sources of Quality Improvement Information

Multiple sources of QI data that span both the clinical and administrative arenas include evidence-based medicine and evidence-based clinical practice guidelines, alerts from accrediting agencies and nonprofit safety organizations, standards and guidelines put forth by medical specialty associations, and administrative (such as those maintained by CMS) and claims databases. U.S. governmental agencies, including AHRQ, CMS, and the National Quality Forum (NQF), promote the development and reporting of health care quality measures.[52]

Peer-reviewed journals have published the results of studies that support evidence-based clinical practice guidelines, as well as individual QI programs, and can be a rich source of ideas to improve clinical decision making and patient care by incorporating the best available evidence with patient values and provider preferences.[53,54] In anesthesiology and critical care medicine, guidelines and protocols have been successful in improving performance in some care processes. Sedation and ventilator weaning protocols in ICUs have been shown to decrease the duration of mechanical ventilation and length of stay in the ICU.[55,56] Moreover, individual QI programs have been used to improve delivery of care and have been shown to have a positive effect on job satisfaction and organizational commitment.[57]

National Programs in Quality Improvement

A growing number of regional and national organizations are developing initiatives that are driving the reporting of specific evidence-based practices and outcomes and determining the local selection of areas for QI (Table 5-3).

The Joint Commission has developed quality measures for several areas (www.jcaho.org). Their ORYX initiative was devel-

Table 5-3 Nonprofit and Government Quality Improvement Organizations Pertinent to Anesthesia

Quality Improvement Organization	Website	Description
Agency for Healthcare Research and Quality (AHRQ)	www.ahrq.gov	Lead federal agency charged with improving the quality, safety, efficiency, and effectiveness of health care
American Health Quality Association (AHQA)	www.ahqa.org	Represents quality improvement organizations and professionals working to improve the quality of health care
Anesthesia Patient Safety Foundation (APSF)	www.apsf.org	Promotes investigations and programs that will provide a better understanding of anesthetic injuries
Centers for Disease Control and Prevention (CDC)	www.cdc.gov	One of the major operating components of the Department of Health and Human Services
Emergency Care Research Institute (ECRI)	www.ecri.org	Uses applied scientific research to discover which medical procedures, devices, drugs, and processes are best
Institute for Healthcare Improvement (IHI)	www.ihi.org	Health care improvement organization based in Cambridge, Massachusetts
Institute for Safe Medication Practices (ISMP)	www.ismp.org	The nation's only 501(c)(3) organization devoted entirely to prevention of medication errors and safe medication use
Medicare Quality Improvement Community (MedQIC)	www.medquic.org	A national knowledge forum for health care and quality improvement professionals
National Quality Forum	www.qualityforum.org	Created to develop and implement a national strategy for health care quality and reporting
National Patient Safety Foundation (NPSF)	www.npsf.org	An independent 501(c)(3) organization, the mission of which is to improve the safety of patients

oped to integrate performance measurement data into the accreditation process and to permit rigorous comparison of the actual results of care across hospitals. In 2004, The Joint Commission partnered with CMS to align measures common to both organizations, called "Hospital Quality Measures." These measures are also endorsed by the NQF.

The NQF is a private, nonprofit membership organization created to develop and implement a national strategy for health care quality measurement and reporting (www.qualityforum.org). One of its functions is to endorse certain quality and safety measures (consensus standards), which are then incorporated into other national quality initiatives. The goal is for NQF-endorsed standards to become the primary standards used to measure the quality of health care in the United States. Anesthesia programs are increasingly focusing on standards that are relevant to them because facilities are being evaluated on their compliance and are required to report their performance regarding these standards to the governing bodies.

The Surgical Care Improvement Project

The Surgical Care Improvement Project (SCIP), a national collaborative of public and private entities that has outlined perioperative QI goals (www.medqic.org) and is in partnership with The Joint Commission and CMS national initiative, was initiated in 2003. This multidisciplinary group uses both process and outcome measures (Box 5-1) to focus on key clinical areas that include preventing surgical-site infections, perioperative myocardial infarctions, venous thromboembolism, and mortality and readmission, as well as increasing the use of fistulas in providing hemodialysis for Medicare beneficiaries with kidney failure.

Private Insurers

Many private insurers now collect data on certain quality elements. The Leapfrog group is one such entity. The Leapfrog Hospital Quality and Safety Survey assesses hospital performance according to four evidence-based safety practices: (1) use of computerized physician order entry, (2) evidence-based hospital referral, (3) ICU physician staffing, and (4) a Leapfrog Safe Practices score, which is based on the level of performance of other NQF-endorsed practices (www.leapfroggroup.org). Leapfrog not only reports the results and rankings of its survey but also uses them as a basis for their selection of hospitals to be covered by the plan for the employees of participating companies.

Pay for Performance

Public and private insurers are demanding increased accountability as a result of rising health care costs and threatened budgets. In response, pay for performance (P4P) has been proposed and implemented as a means of improving quality based on successful examples in business. P4P has been defined as the use of incentives to encourage and reinforce the delivery of evidence-based practices and health care system transformations that promote better outcomes as efficiently as possible. Measures that are incorporated into P4P must be evidence based, consistent with national goals, and based on consensus in the absence of evidence (www.jointcommission.org). Furthermore, it is important that measures be reliable, valid, and feasible and that the programs be voluntary. Although the strategy of P4P is to align quality of care and payment, the impact of P4P on quality of care has thus far been modest.

Box 5-1 Process and Outcome Measures of the Surgical Care Improvement Project

Infection
Prophylactic antibiotics:
- Received within 1 hr before the surgical incision
- Appropriately selected for surgical patients
- Discontinued within 24 hr after the surgical end time (48 hr for cardiac patients)

Cardiac surgery patients with controlled 6 AM postoperative serum glucose

Postoperative wound infection diagnosed during the index hospitalization (***outcome***)

Surgery patients with appropriate hair removal

Colorectal surgery patients with immediate postoperative normothermia

Cardiac
Noncardiac vascular surgery patients with evidence of coronary artery disease who received β-blockers during the perioperative period

Surgery patients who had already received a β-blocker before arrival and then during the perioperative period

Intraoperative or postoperative acute myocardial infarction diagnosed during the index hospitalization and within 30 days of surgery (***outcome***)

Venous Thromboembolism (VTE)
Surgery patients with recommended VTE prophylaxis ordered

Surgery patients who received appropriate VTE prophylaxis within 24 hr before surgery to 24 hr after surgery

Intraoperative or postoperative pulmonary embolism diagnosed during the index hospitalization and within 30 days of surgery (***outcome***)

Intraoperative or postoperative deep venous thrombosis diagnosed during the index hospitalization and within 30 days of surgery (***outcome***)

Respiratory
Number of days ventilated surgery patients had documentation of the head of the bed being elevated from the recovery end date (day 0) through postoperative day 7

Patients in whom postoperative ventilator-associated pneumonia is diagnosed during the index hospitalization (***outcome***)

Number of days ventilated surgery patients had documentation of stress ulcer disease prophylaxis from the recovery end date (day 0) through postoperative day 7

Surgery patients whose medical record contained an order for a ventilator weaning program (***protocol* or *clinical path***)

Global
Mortality within 30 days of surgery

Readmission within 30 days of surgery

Vascular Access
Proportion of permanent hospital end-stage renal disease vascular access procedures that involve autogenous arterial venous fistulas

The Physician Quality Reporting Initiative is a program in which anesthesiologists can earn a 1.5% bonus from CMS by reporting their compliance with appropriate timing of perioperative antibiotics. Initial steps in this program are payment for participation, with the ultimate goal that successful compliance with the clinical measures will be the basis for bonus payments. The ASA has identified five "quality incentives" or P4P measures to date (www.asahq.org, accessed September 9, 2007):

1. Timely administration of antibiotic prophylaxis
2. Maintenance of normothermia
3. Comprehensive planning for chronic pain management
4. Prevention of ventilator-associated pneumonia
5. Prevention of CRBSIs

All but the chronic pain measure are adaptations of national quality measures. The chronic pain measure was drafted by the ASA Committee on Pain Medicine and subsequently endorsed by five additional specialty organizations representing pain physicians. Additional measures are being evaluated, and the methods by which they will be incorporated into national initiatives or P4P (or both) will continue to evolve.[51,58]

The Future: Research, Education, and Ethics

Much remains to be accomplished in QI research and practice. The opportunity to improve patient care is substantial, and the pressure to improve the quality of perioperative care will continue to increase. Improving quality of care requires the ability to measure and improve performance. Research is needed to develop measures of quality that clinicians believe are valid and to learn how to ensure that all patients reliably receive the recommended interventions. Innovation is needed to develop information systems that can be used by multiple disciplines. Anesthesiologists and professional societies may need to partner with experts in quality measurement to develop and implement quality measures. Future efforts should balance the feasibility and validity of quality measures and develop integrated approaches to improving quality, including strategies to develop care bundles, decrease complexity, and create independent redundancies.

Providers need to be educated in the skills necessary to improve quality. Health care will cross the quality chasm only

Table 5-4 Six Core Competencies of the Accreditation Council of Graduate Medical Education and Six Aims for Improvement of the Institute of Medicine

ACGME Core Competencies	IOM Aims for Improvement
1. Patient Care	Safe
2. Medical Knowledge	Timely
3. Interpersonal and Communication Skills	Effective
4. Professionalism	Efficient
5. System-based Practice	Equitable
6. Practice-based Learning and Improvement	Patient centered

when all view quality and safety as what they do primarily rather than as an added activity and when health care organizations provide the infrastructure to monitor and improve performance. Frontline caregivers must understand the science of quality and safety and evaluate safety risks with lenses that see hazardous systems, not incompetent people.

Anesthesiologists need to train providers in the methodology of improvement. Integral to this goal is the education of our anesthesia resident trainees. Continuous QI has been touted in anesthesia residency training programs for well over a decade.[59] In recent years, residents in training were presented with six core competencies to master, as mandated by the Accreditation Council of Graduate Medical Education (ACGME),[60] and the IOM put forth their six Aims for Improvement[4] (Table 5-4). In an effort to link these two sets of goals and apply them to the clinical setting for training purposes, Bingham and associates developed a framework called a "Healthcare Matrix" that can be used as an educational tool and a research tool for improvement.[61]

With the increasing amount of intellectual focus and health care resources being directed toward QI programs, the ethics of QI have come to light. QI projects have generally been exempt from the rigorous review of human subject research. However, a Hastings Center Report on the ethics of using QI methods to improve health quality and safety suggests that some QI projects may involve risk to patients and should undergo a formal review.[62] This report lists QI initiatives that may trigger the need for a review, such as those with a randomized design, novel treatments, involvement of researchers, or delayed feedback of monitoring or those funded by external sources. Reporting of QI activities should be encouraged, and requiring approval by an internal review board in addition to having a standardized format for reporting the results supports the premise that delivery of quality care is a science as well as an art.

Summary

Health care organizations need a systematic approach to three areas of patient safety: (1) translating evidence into practice, (2) identifying and mitigating hazards, and (3) improving culture and communication. The underlying principle for all of the approaches discussed is that to improve the quality of care that they provide, providers must be able to measure their performance. Health care providers have traditionally had limited ability to obtain feedback regarding performance in their daily work, in part because of a lack of information systems and lack of agreement on how to measure quality of care.[63] As a result, many in health care do not have access to performance data and consequently do not know the results that they achieve (or fail to achieve). As consumers, payers, regulators, and accreditors require evidence regarding quality of care, the demand for quality measures will probably grow. To meet these demands, anesthesiologists must be able to evaluate the quality of care that they provide with valid measures and implement evidence-based best practices in the perioperative care of patients.

6 Human Performance and Patient Safety

Key Points

1. Clinical excellence is not achieved by the use of sound medical knowledge alone. Human factors and the interaction of team members, as well as organizational conditions in the system of care, also play major roles. Therefore, the study of human performance and related organizational matters is very important.
2. The health care system in general and clinical institutions in particular must provide appropriate organizational characteristics to allow and foster safe patient care practices (e.g., improve safety culture, integrate effective incident reporting and analysis systems).
3. High-reliability organization theory describes the key features of systems that conduct complex and hazardous work with very low failure rates. Errors do occur in such organizations, but their systems make them more impervious to errors and their sequelae (resilience).
4. In dynamic domains such as anesthesia, continuous decision-making, as described in the cognitive process model, is critical to achieving safe patient care.
5. Several error mechanisms have been demonstrated through human factors research. Understanding these psychological "traps" (for example, "fixation errors") can help anesthetists avoid or mitigate them.
6. The introduction and spread of crisis resource management training, including the application of realistic simulation exercises, is likely to improve patient safety in anesthesia and other acute care domains.
7. Like all human beings, the performance of individual anesthetists can be adversely influenced by "performance-shaping factors," including noise, illness, aging, and especially sleep deprivation and fatigue.
8. A particular technique of human factors research called "task analysis" has been useful in understanding the work of anesthetists.
9. Observation of anesthetists during routine operations or in the handling of adverse events (using realistic patient simulators) has improved our knowledge of critical decision-making and team interactions.
10. Future progress on patient safety in anesthesia will require interdisciplinary research and training, improvements in systems safety and organizational learning, and the involvement of all levels of the health care industry.

Impact of Human Performance on Patient Safety

The most important component of every anesthetic regimen is the human performance of the anesthetist and its relationship to patient safety. More than 70% of accidents are due to "human factors." Because the performance of the anesthetist—embedded in a larger system of care—is such a critical and most determining aspect of patient safety, education and training of health care professionals in this area need improvement. This chapter aims to provide an overview of the importance of human performance and systems safety in anesthesia and to provide start-up knowledge of key safety factors and methods.

Anesthesia is an intrinsically hazardous undertaking, but as hazardous activities go, its track record is indeed a model of patient safety for the rest of health care.[1,2] The Institute of Medicine (IOM) asserts: "Anesthesia is an area in which very impressive improvements in safety have been made."[3,4] However, the theory of organizational safety teaches us that safety is a never-ending process; any patient harmed by an anesthetic is one patient too many (in concert with the "zero vision" statement of the U.S. Anesthesia Patient Safety Foundation [APSF]: "That no patient shall be harmed by anesthesia"). Cooper and Gaba[1] wrote: "Anesthesiologists should remain aware of the hazards they still face, take pride in having been the leaders in patient safety efforts, and stay motivated to continue the pursuit of 'no harm from anesthesia' with the passion it still demands."

Because most of the work on human performance (and also on simulation) has been started and has focused on anesthesiology in the operating room (OR), this chapter deals primarily with aspects of performance and safety in the OR setting. Nevertheless, most of the same principles and issues are relevant to the

postanesthesia care unit (PACU), the intensive care unit (ICU), emergency medicine, and to a lesser degree, pain therapy and other domains of importance to anesthesiologists. For readers with a special interest in the ICU, a selection of references is given as a starting point.[5-17]

Safe conduct of anesthesia depends on the appropriate application by skilled anesthetists of knowledge concerning surgical procedures, the physiology of patients during and after anesthesia, the characteristics of anesthetic and adjuvant drugs, and the means of monitoring the patient and the life support equipment throughout the perioperative period. In this chapter the term *anesthetist* refers to any anesthesia professional taking care of a patient, whether a physician, certified registered nurse anesthetist (CRNA), or anesthesia assistant.

Traditionally, an adequately trained anesthetist automatically was assumed to perform appropriately. Deviations from optimal outcomes were understood to be due to imperfections in the art and science of anesthesia, which led to heavy emphasis on the scientific and technical aspect of anesthesia training and care. More rarely, adverse outcomes were ascribed to negligence or incompetence on the part of the anesthetist. Today, there is a more complete understanding that anesthetists themselves, both as a profession and as individuals, have strengths and vulnerabilities pertaining to their work environment. The performance of human beings is incredibly flexible and powerful in some aspects, but is very limited in others. They are vulnerable to distractions, biases, and errors. This chapter surveys some of the human characteristics that define the performance of anesthetists. These characteristics (also termed human factors) are by no means constant; for example, a person may communicate very effectively in one instance and fail to close the loop in the next challenging communication role.

The domain of the anesthetist is very challenging; it is as difficult or more so than other domains that more readily capture the public's imagination, such as aviation. The past 25 years has seen new research on the nature and limitations of professional judgment and decision-making in this dynamic and complex world. Chapter 7, "Patient Simulation," explores developments in the methods of using simulations and simulation technologies that have contributed to this research and that may open new opportunities to prepare anesthetists to handle the challenges that they face in their work.

The literature related to human performance and patient safety is vast (standard reference works are available[18-26]), and this chapter samples only a portion of it as it most closely relates to the work of anesthetists. Moreover, this chapter does not deal to any great extent with human-machine interactions and the physical design of the work environment. These aspects of human factors, or ergonomics, in anesthesia have considerable importance in their own right. The reader is referred to several publications that review these issues in detail.[27-38]

Nature of the Operational Domain of Anesthesiology

The operational domain of anesthesia is a complex, dynamic world that presents a cognitive profile common to many real-world task domains. Analysis of complex dynamic worlds in the last decade has departed sharply from previous conceptions of decision-making.[39] Classic decision-making approaches, such as decision theory and multi-attribute utility theory, are mathematical techniques that were traditionally used as the dominant framework for understanding human performance. They worked well in simplified laboratory experiments on decision-making and action, yet a number of investigators had significant difficulty in applying them to real-world decision and action settings.[39] Orasanu and colleagues[39] identified eight factors that characterize such naturally occurring complex dynamic worlds. They apply to anesthesia as follows:

1. **Ill-structured problems.** Unlike traditional decision experiments, there is not just a single decision to be made. Rather, a variety of interrelated decisions must be made by the anesthetist and surgeon. The patient's physiologic behavior is not an independent random variable but is causally linked to previous decisions and actions.
2. **Uncertain dynamic environment.** Dynamism stems from the frequency of routine and anomalous changes or events, the rapidity with which they evolve, and the unpredictability of the patient's physiology and response to interventions. An anesthetized patient is in a constant state of change during surgery, with many events outside the anesthetist's control. Although preventive measures can reduce the likelihood of some events, others cannot be avoided because they are inevitable side effects of medically necessary procedures (e.g., surgical blood loss). Unpredictable and dynamic occurrences compete with the preplanned aspects of the case and drive the anesthetist's actions. The true state of the patient cannot usually be measured directly. It must be inferred from ambiguous patterns of clinical observations and data from electronic monitors. These data are imperfect because unlike industrial systems that are designed and built with sensors in key areas to measure the most important variables, patients are typically instrumented to measure the variables that are easiest to monitor, predominantly with the use of noninvasive methods. Most physiologic functions are observed indirectly through weak signals available at the body surface and thus are prone to various types of electrical and mechanical interference. Invasive measurements are also vulnerable to artifacts and uncertainties of interpretation. Even if the anesthetist knew the exact state of the patient, the patient's response to interventions would be unpredictable.
3. **Time stress.** Because the OR is a scarce resource, there is an incessant overall time pressure to use it efficiently. There is an even more intense immediate time stress within each case generated by dynamic situations that evolve rapidly and must be dealt with in timely fashion.
4. **Shifting, ill-defined, or competing goals.** Multiple goals of case management (e.g., hemodynamic stability, good operating conditions for the surgeon, rapid emergence from anesthesia) may compete with each other. The surgeon's goals may sometimes compete with those of the anesthetist. All these goals shift as the patient's situation changes dynamically throughout the procedure.
5. **Action/feedback loops.** The time constants of actions and their effects are very short, on the order of seconds to minutes. There is complete intermixing of decision-making and action; these functions are not performed in separate

cycles. Most decisions and actions are implemented and evaluated incrementally, with the effect of one cycle assessed before deciding on further possible actions.

6. **High stakes.** The stakes are high because even for elective surgery in healthy patients, there is an ever-present and very real risk of injury, brain damage, or even death. A catastrophe is often the end result of many pathways that begin with seemingly innocuous triggering events. Each intervention, even if appropriate, is associated with side effects, some of which are themselves serious. Some risks cannot be avoided. Unlike an event such as a commercial flight, which can be delayed or aborted if a problem occurs, during an event in the OR this is not usually possible, and immediate surgery may be necessary to treat a medical problem that is itself life threatening. Analogous to military aviation, balancing the risks of action (anesthesia and surgery) against those of inaction is often extremely difficult.
7. **Multiple players.** Anesthesia domains involve multiple players from different professional backgrounds. Each individual has a set of goals, abilities, and limitations. In some situations, interpersonal interactions, among anesthesia personnel and between them and other OR team members, will dominate the work environment.
8. **Organizational goals and norms.** The anesthetist works within the stated and unstated norms of the OR suite, the anesthesia department, the institution, and the profession as a whole. Decisions are sometimes made to conform to these norms even though they are not wholly subscribed to by the anesthetist.

Although many of these features apply to other domains of medicine, anesthesiology is unique in that all eight factors are prominent. In particular, what sets anesthesia apart from clinic- or ward-based medicine is the intensity of the dynamism, time pressure, and uncertainty, with danger lurking just below the surface.

Safety Culture of the Operating Room and Intensive Care Environment (See Chapters 99-101)

Analyzing the Anesthetist's Domain: The Operational World Versus the Organizational World

Psychologists and cognitive engineers who study real work environments describe each field as a domain. Each domain has specific characteristics that set it apart from others, including the nature of the tasks to be performed, the relationships among the tasks, the time scale over which they must be executed, and the criteria for their successful performance. This chapter deals mainly with the operational domains in which anesthesia care is delivered, primarily the OR, the PACU, and the ICU. However, as pointed out by Reason,[40-43] as well as by Cook, Woods, and McDonald,[44] what goes on in the operational domain is extensively shaped by the organizational and managerial environment in which it is located, even to the point that operational personnel believe themselves to be the "victims" of problematic decisions further back in the system.

In everyday practice, these distinctions are hidden or blurred. The positive and negative contributions of the organizational and management elements are often so embedded in the normal routine that they are difficult to isolate. Interesting information about the system often comes from considering abnormal situations, accidents, or near misses instead of normal events. For example, investigation of the loss of the space shuttle Columbia revealed a variety of latent errors within the procedures and safety culture at the National Aeronautics and Space Administration (NASA):

> *The accident was probably not an anomalous, random event, but rather likely rooted in NASA's history and the space flight program's culture.*[45]

The report placed as much weight on these factors as on the direct technical causes of the accident. Traditionally, one speaks of errors arising in decisions and actions that lead to a mishap. However, the term "error" is increasingly considered an inappropriate way to categorize behavior (being a judgment of attribution and blame) and should be thought of merely as a way to identify behavior at the locus of a critical situation. In this context it must be understood that "errors are not the cause of an accident." Rather, errors are usually the consequence of a combination of several underlying factors. Beyond that, errors must combine with other circumstances to result in an accident or adverse outcome.[46] This concept is illustrated in Figure 6-1. Some errors are actively produced in the operational domain, whereas others are introduced by the organizational environment. James Reason, a psychologist at the University of Manchester, England, described the latter by using the concept of "latent errors"[46]:

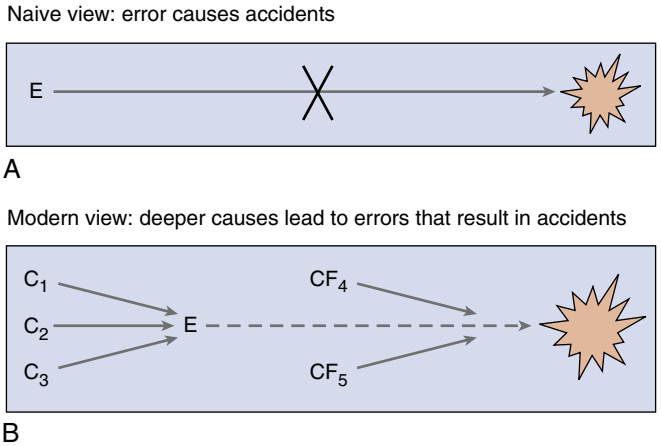

Figure 6-1 Relationship between errors (E) and adverse events. **A,** Errors are not the cause of accidents but in rare cases they lead directly to the adverse event. Multiple root causes (C_1, C_2, C_3) lead to the error (**B**). For the most part, additional contributing factors (CF_4, CF_5) are necessary to allow the error to evolve into an adverse event. Incident reporting systems should try to identify as many of the root causes and contributing factors before an accident happens and try to influence these factors in such a way that no accident will happen. *(Adapted from Rall M, Manser T, Guggenberger H, et al: [Patient safety and errors in medicine: Development, prevention and analyses of incidents.] Anästhesiologie, Intensivmedizin, Notfallmedizin, Schmerztherapie 36:321-330, 2001, with permission.)*

errors whose adverse consequences may lie dormant within the system for a long time, only becoming evident when they combine with other factors to breach the system's defenses. [They are] most likely to be spawned by those whose activities are removed in both time and space from the direct control interface: designers, high-level decision makers, construction workers, managers and maintenance personnel.

Latent errors probably exist in all complex systems, and Reason adopted a medical metaphor to describe them as "resident pathogens." Like microorganisms in the body, the resident pathogens remain under control until sets of local circumstances "combine with these resident pathogens in subtle and often unlikely ways to thwart the system's defenses and bring about its catastrophic breakdown" (Fig. 6-2). This "threat and error model" has also been articulated by the noted aviation-oriented psychologist Robert Helmreich at the University of Texas (Fig. 6-3).[47]

A variety of latent failures can exist in the anesthesia environment. They may include such issues as how surgical cases are booked, how cases are assigned to specific anesthetists, what provisions are made for preoperative evaluation of outpatients, and what relative priority is given to rapid turnover between cases or avoiding cancellation of cases as opposed to avoidance of risk. Latent errors can also result from the design of anesthesia equipment and its user interfaces, which in some cases lead clinicians to err or are unforgiving of errors. Manufacturing defects and routine maintenance failures are also types of latent failure.

Investigation of untoward events must address both latent and active failures and both the organizational and managerial environment and the operational domain. One risk of focusing solely on active failures is that operational personnel may be "victims of the system" in a "Catch-22"–type situation and be pushed to maximize production while admonished to "be safe." Addressing only their actions—and not the latent pressures under which they must work—can make them defensive and uncooperative. Cook, Woods, and McDonald[44] pointed out that if one looks at the chain of events in an accident sequence, one can always find a failure on the part of an operator. If the analysis stops at this point, the operator (i.e., the anesthetist) may be wrongly blamed for a failure, the real roots of which go back to latent failures in the organization. If the underlying latent errors are never identified or never fixed, they remain in the system and

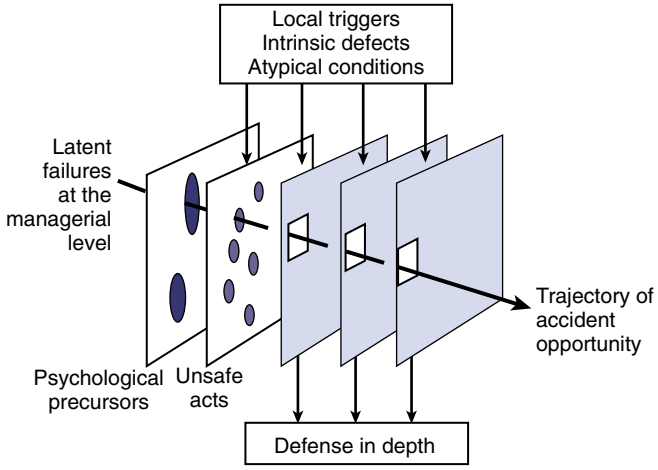

Figure 6-2 James Reason's model of the causation of accidents. Latent failures at the managerial level may combine with psychological precursors and event triggers at the operational level to initiate an accident sequence. Most accident sequences are trapped at one or more layers of the system's defenses. The unforeseen combination of organizational or performance failures with latent errors and triggers may lead to breach of the system's defenses and allow the accident to take place. The diagram should be envisioned as being three-dimensional and dynamic—with "shields" moving around and holes in the defense's opening and closing. *(Redrawn from Reason JT: Human Error. Cambridge, Cambridge University Press, 1990.)*

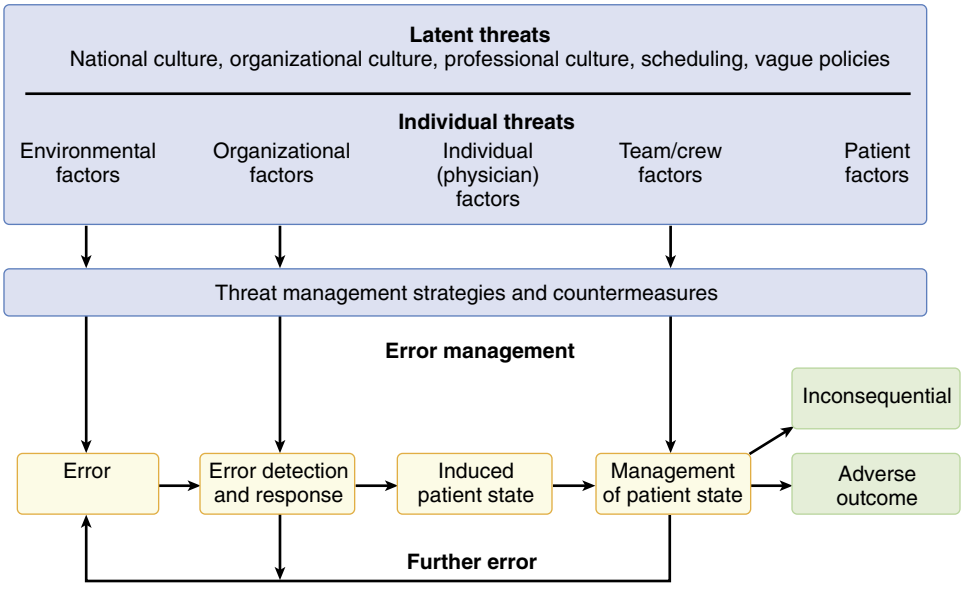

Figure 6-3 University of Texas threat and error model. This model, which illustrates the evolution of errors, is used in the analysis of incidents and accidents (a detailed example is available at http://bmj.bmjjournals.com/misc/bmj.320.7237.781/sld001.htm).

Table 6-1 Asymmetry of Signals of Safety Versus Signals of Production

Production	Safety
Feedback about production is easy to measure reliably and nearly continuously ("revenue,""earnings,"" expenses") and indicates success in a positive fashion	Traditional measures of "safety" are indirect and discontinuous, thus making them noisy and difficult to interpret or even deceptive
Success is indicated "positively" (e.g., increasing earnings), is obviously reinforcing, and has high salience (the bottom line is the "bottom line" for a firm)	Feedback is provided "negatively" (fewer accidents or incidents) and has little reinforcement value in itself. High salience is achieved only after an accident or a scary near miss
The relationship between the application of resources (money, effort, time) and production goals is relatively certain, thus making it easy to use feedback	Even when interpreted correctly, the relationship between application of resources and safety goals is relatively uncertain, thus making it hard to use the feedback

Adapted from Reason JT: Human Error. Cambridge, Cambridge University Press, 1990.

will probably induce another accident chain in the future. This is visualized in Reason's accident trajectory, shown in Figure 6-2.

Asymmetry Between Safety and Production

An additional difficulty in achieving optimal safety is an inherent asymmetry of information and concern about safety versus production (Table 6-1).[46] Investments for production are easy to plan for and measure; feedback about production is easy to obtain and to interpret. Investments for safety are harder to plan for, and the costs are harder to measure. Most importantly, feedback about safety is inherently weak and ambiguous. How can one measure the accidents that could have occurred but did not? Only after a catastrophe takes place do the costs of a safety failure become apparent.

Organizational Safety

Over the last few years there have been many landmark publications and activities concerned with patient safety and the organizational aspects of reducing errors.[3,25,42,48-52] The report of the IOM in 1999, "To Err Is Human,"[3] was a highly publicized awakening in the United States about the problems of patient safety. Summarizing the primary literature, the report stated that "tens of thousands die each year from errors in their care and hundreds of thousands suffer or barely escape from nonfatal injuries that a truly high-quality care system would largely prevent." The most important recommendations of this report, which led to nationwide activities to promote patient safety, are shown in Box 6-1.

The subsequent report of the IOM Committee on Quality of Health Care in America, titled "Crossing the Quality Chasm—A New Health System for the 21st Century,"[48] took a systematic approach to improvement of the entire health care system. It stated that "between the healthcare we have and the care we could have, lies not just a gap, but a chasm" because the health care system today harms too frequently yet routinely fails to deliver its potential benefits. The report concluded: "The current care system cannot do the job. Trying harder will not work. Changing the systems of care will." In the following text we consider the organizational and systems aspects of anesthesia care and patient safety.

There are several schools of thought about organizational safety in highly hazardous activities. Two theories, normal accident theory (NAT) and high-reliability organization theory (HROT), have dominated the discussion of safety in many domains and have been applied individually to health care with increasing frequency over the last 20 years.[43-52,60] NAT was originally promulgated by the sociologist Charles Perrow[57] in the wake of the Three Mile Island nuclear accident and has been applied by him and others to such diverse fields as commercial aviation, maritime transport, and the handling of nuclear weapons. HROT was promulgated initially by a group of researchers at the University of California at Berkeley. It has also been applied to diverse domains, including aircraft carrier flight decks, offshore oil platforms, air traffic control, nuclear power production, and the financial transaction industry (personal communication, Karlene Roberts).

These workers' complementary views of organizational safety are summarized briefly here and in Table 6-2.

Normal Accident Theory (NAT)

NAT focuses primarily on two features of a system: (1) the complexity of interactions among the system's elements and (2) the presence of tight coupling among the system's elements. A system is tightly coupled when a change in one part of the system rapidly alters other parts of the system. For example, some physiologic systems are buffered from changes in others, whereas certain core components, such as oxygen delivery and blood flow, are tightly coupled together and interact strongly. The patient's physiology may become tightly coupled to external systems such as ventilators and infusions of hemodynamically active drugs. When complexity and tight coupling coexist, abnormal sequences of events can sometimes be hidden and have complex or unpredictable consequences. Typically, active errors in the system do not result

Box 6-1 Recommendations of the Institute of Medicine Report "To Err Is Human"

Make patient safety a declared and serious aim.

Provide strong, clear, and visible attention to safety.

Implement nonpunitive systems for reporting and analyzing errors.

Incorporate well-understood safety principles, such as standardizing and simplifying equipment, supplies, and processes.

Establish interdisciplinary programs to improve teamwork and communication by using modalities proven in other industries, including simulation.

Table 6-2 Complementary Views of High-Reliability Organization Theory (HROT) Versus Normal Accidents Theory (NAT)

HROT	NAT
Accidents can be prevented through good organizational design and management	Accidents are inevitable in complex and tightly coupled systems
Safety is the priority organizational objective	Safety is one of a number of competing objectives
Redundancy enhances safety; duplication and overlap can make a reliable system out of unreliable parts	Redundancy often causes accidents because it increases interactive complexity and opaqueness and encourages risk taking by social-shirking and cue-taking behavior
Decentralized decision-making is needed to permit prompt and flexible field-level responses to surprises	Organizational contradiction: decentralization is needed to handle the distributed complexity, but centralization is needed to manage tightly coupled systems
A "culture of reliability" will enhance safety by encouraging uniform and appropriate responses by field-level operators	A military model of intense discipline, socialization, and isolation is incompatible with democratic values
Continuous operations, training, and simulations can create and maintain high-reliability operations	Organizations cannot train for unimagined, highly dangerous, or politically unpalatable operations
Trial-and-error learning from incidents (through effective incident reporting) can be effective and supplemented by anticipation and simulations	Denial of responsibility, faulty reporting, and biased reconstruction of history frequently cripple learning efforts

Modified from Sagan SD: The Limits of Safety. Princeton, NJ, Princeton University Press, 1993.

in an accident because they are trapped at some point by the system's multiple layers of checks and defenses (see Fig. 6-2). Even a minor perturbation can cause normal system behavior to be out of control when there are complex interactions and tight coupling. Perrow called this a "normal accident" because the perturbations are common and arise out of otherwise normal system operations.[57] He suggested that attention should be directed at strengthening the recovery pathways by which small events can be properly handled before they evolve into a serious accident.

Complexity and Tight Coupling: Latent Errors in Anesthesia

Clearly, the anesthesia domain involves complex interactions with tight coupling.[58] The complexity stems to some degree from the variety of devices in use and their interconnections, but these are, in truth, vastly simpler than those found in an oil refinery, a 747 aircraft, or a space shuttle. A more important source of complexity is the "uncertainty complexity" of the patient.[58] The human body is an incredibly complex system containing numerous components, the interactions of which are only vaguely understood. Because many body systems affect each other, the patient is a major site of tight couplings. Furthermore, the anesthetic state tends to ablate the buffers between some of these interconnected systems, thereby strengthening the coupling between them and between the patient and external mechanical supports. Galletly and Mushet[59] studied anesthesia "system errors" and observed tight coupling associated with "the use of neuromuscular blocking drugs, the presence of cardiorespiratory disease, certain types of surgical procedures, and the effect of general anesthetic agents. Looser coupling was observed with the use of high concentrations of oxygen and air mixtures, preoxygenation, and spontaneous breathing techniques."

According to the NAT view, we delude ourselves by believing that we can control our hazardous technologies and forestall disaster; in reality, many of the efforts we make at management and design tend to only increase the opacity and complexity of the system (making more holes in the barriers), thereby increasing the likelihood of accidents. The combination of these factors provides fertile ground for the occurrence of accidents—indeed, according to NAT it makes it inevitable that some of the "normal" everyday faults, slips, and incidents will evolve into tragic accidents. NAT is often considered a "pessimistic" view of the ability of organizations to conduct highly hazardous operations without harmful errors.

The very concept of risk is constructed and negotiated. This was perhaps expressed most clearly by Dianne Vaughan in her powerful analysis of the explosion of the Challenger space shuttle:

> *Risk is not a fixed attribute of some object, but constructed by individuals from past experience and present circumstance and conferred upon the object or situation. Individuals assess risk as they assess everything else—through the filtering lens of individual worldview.*

Vaughan's main thesis is that the Challenger exploded not because "risk-taking" managers "broke the rules" but because the system evolved to make excessive risk a part of "following the rules." This happened because the system had a "culture of production" with ingrained production pressure; it was a regular occurrence that aberrant findings be explained away ("normalization of deviance"), and "structural secrecy" was enforced between departments, between manufacturers and NASA, and between engineers and managers. Sadly, many of these same phenomena occurred yet again and led to the Columbia accident.[45] Unfortunately, each of these system characteristics is also operative in perioperative settings.

High-Reliability Organization Theory

In contrast to these rather pessimistic views of the organizational challenges to safety is the HROT view that although not easy, proper organization of people, technology, and processes can handle complex and hazardous activities at acceptable levels of performance. Even though accidents can never be totally eliminated, high-reliability organizations (HROs) must be judged by the benefits that we derive from their activities and their small absolute risk of failure. This view seems particularly appropriate in anesthesiology because forgoing surgical treatment is not a

Box 6-2 Elements of a Culture of Safety (part of HROT in Box 6-3)

Values
- Safety as the most important goal, overriding production or efficiency
- Preoccupation with possible "failures" rather than past "successes"
- Necessary resources, incentives, and rewards provided for optimal safety, not only for optimal production

Beliefs
- Safety must be actively managed
- Processes and routines of care are as (or more) important to safety as individual dedication, skill, or effort
- Openness about safety and errors is essential; learning from normal and adverse events should be thorough

Norms
- Low-ranking personnel raise safety issues and challenge ambiguity regardless of hierarchy or rank
- Calling for help is encouraged and occurs frequently, even (or especially) by experienced personnel
- Explicit communication is frequent
- The hierarchy is flat—leaders listen to juniors; juniors speak up; and calling for help is routine regardless of rank
- People are rewarded for rationally erring on the side of safety, even when their credible concerns turn out to be wrong

Adapted from Weick KE: Organizational culture as a source of high reliability. Calif Manage Rev 29:112-127, 1987.

viable option for many patients and challenges to safety must often be met head-on. Although the concepts of HROT have varied over the years, the core characteristics of HROs are shown in Boxes 6-2 and 6-3.

A key aspect of HROT is that of a culture of safety (or "safety culture"). Since publication of the reports from the IOM, health care has begun paying attention to certain elements of "culture." However, most of the attention has been devoted to the "culture of blame" in a system whereby problems are addressed largely in terms of who is to blame rather than what can be done to prevent them. Safety culture goes beyond these issues by dealing with how individuals and groups conduct their work. Culture is made up of values (what is important), beliefs (how things should work), and norms (the way things work). These elements are shown in Box 6-2. It is equally important that the culture is highly uniform throughout the organization and be continually reinforced by peers, more so than by enforcement of rules.

High-Reliability Organization Theory in Anesthesiology

Anesthesiology has traditionally been strong at some elements of an HRO, particularly in redundancy and technical safety measures. There is a growing movement in anesthesia to more fully implement HRO philosophies and techniques.[60] In fact, anesthesiologists have not only been promoters of the patient safety movement in general but have also been leaders at applying HROT principles to health care. In 2003, the APSF began initiatives in high-reliability perioperative health care (see Special

Box 6-3 Key Elements of a High-Reliability Organization (HRO) in Medicine

Established Culture of Safety (see Box 6-2)

Optimal Structures and Procedures

Decision-making rests with those with greatest knowledge or experience about specific issues regardless of rank or job type.

The unit integrates crews from different departments (e.g., cardiac surgery, cardiac anesthesia, OR nursing, perfusion, ICU) into a coherent clinical team. Teamwork and resiliency are emphasized.

There are formal procedures to maximize transfer of information to all team members before a case (e.g., briefings or time-out procedures).

Schedules are designed to keep work hours and duty periods at reasonable levels to avoid undue fatigue. Personnel under excessive stress are supported or replaced as needed.

Standardized procedures, techniques, and equipment are adopted whenever possible so that similar tasks or operations are performed similarly regardless of the personnel involved; conversely, when necessary (in an emergency or adverse event), the team is resilient and responds as needed to the situation without slavish dependence on standard routines.

The use of preplanned algorithms, checklists, and cognitive aids is actively encouraged.

Easy access to current information systems is available at all times and all locations.

Training and Practice in Routine Procedures and Simulations

Debriefings are conducted after each case.

Nonpunitive assessment instruments are used on a regular basis to provide current feedback and identify elements requiring special training.

There is initial and recurrent simulation-based single-discipline and multidisciplinary training in crew resource management (see Chapter 7).

Actual clinical crews and teams conduct periodic drills or simulations of critical situations in the real OR, PACU, and ICU.

Resident training uses a guided curriculum; training goals and the level of responsibility assigned to a resident match the current proficiency level of the trainee with the complexity of the procedure.

Organizational Learning

Robust mechanisms are in regular use for organizational learning, both prospectively (considering in advance how to optimize protocols and procedures, such as failure mode and analysis of effects) and retrospectively (from analyzing reports of adverse events, near misses, or problems such as root cause analysis).

Problems are analyzed primarily to determine what can be improved rather than whom to blame. Altered procedures are assessed and adopted as appropriate. Process changes reflect appropriate analysis.

ICU, intensive care unit; OR, operating room; PACU, postanesthesia care unit.

Issue of APSF Newsletter, Summer 2003, at www.apsf.org). Box 6-3 summarizes key elements of an HRO adapted to health care.

Teams and Communication

Unlike teams in aviation, the military, and police and fire services, the OR team is unusual in that the command structure is ambiguous. Physicians (surgeon and anesthesiologist) are nominally superior to nursing and technical staff, but physicians are coequally responsible for the patient during the immediate perioperative period. Surgeons were historically considered the "captain of the ship," with even a legal doctrine giving them responsibility for the actions of all other OR team members. Although this legal doctrine has formally fallen by the wayside, remnants of it still remain in aspects of the organizational structure and culture of OR environments. Nonetheless, when both an anesthesiologist and surgeon are caring for a patient, they are coequally responsible, which can lead to complex issues of command authority, hierarchy, and control.

Each physician, as well as the nurses and technicians, has a primary territory of knowledge, skill, and responsibility, but there is considerable overlap among them.

Strictly speaking, a team is defined as "a distinguishable set of two or more people who interact, dynamically, interdependently, and adaptively toward a common and valued goal/objective/mission, who have each been assigned specific roles or functions to perform, and who have a limited life-span of membership." A team is distinct from a group in that a group is an ad hoc collection of individuals without a specific mission and without specific roles. In the OR, all team members have the common goal of a good outcome for the patient. However, there can be considerable disagreement about how to achieve this goal and which elements of patient care have the highest priority. These differences are probably traceable to the fact that the OR team is itself made up of several "crews" (i.e., surgery, anesthesiology, nursing, perfusionist, radiology), each of which has its own command hierarchy, its own global properties (professional standing, culture, traditions, and history), and its own set of local goals and objectives for management of the patient. The differences among the crews can be so striking that some investigators refer to them as separate tribes (transcript of Conference on Human Error in Anesthesia, Asilomar, CA, 1991).

Each "crew" has one or more members who must work effectively together, and crews combine to form a team. A critical component of the success of this process is the establishment and maintenance of a shared mental model of the situation. To the degree that this can be accomplished, the different individuals will be able to tailor their efforts toward a common goal. Experience working together as a crew or team will improve the likelihood of generating a shared mental model.

Cooke and Salas[61,62] made some interesting statements on teams and team knowledge (Box 6-4). In their view, "team knowledge" is more than the sum of individual team members' knowledge, and they demonstrate the need for new methods to elicit team knowledge (e.g., a collective holistic approach). In team knowledge they distinguish between "team mental model" and "team situation model." To judge team knowledge, information is also needed on the broader aspect of "team cognition," which involves team knowledge itself, team decision-making, team situation awareness, and team perception. Figure 6-4 reflects these components of team cognition and team knowledge.[61]

Box 6-4 Teamwork Principles

Team leadership matters.

Team members must have clear roles and responsibilities.

Shared understanding of the task, teammates, and objectives goes a long way.

Take time to develop a discipline of prebriefing, performance, and postbriefing.

Teamwork effects matter.

Clinical expertise is necessary but insufficient for patient safety; cooperation, communication, and coordination skills matter.

Teams must have clear and valued visions.

Learning from mistakes, self-correction, and adaptability are the hallmarks of high-performance teams.

From Salas E, Rosen MA, King H: Managing teams managing crises: Principles of teamwork to improve patient safety in the emergency room and beyond. Theoret Issues Ergonomics Sci 8:381-394, 2007.

Status and Hierarchy Effects

Status and hierarchy effects are important in team performance. Especially in crisis situations, the lower-status crew member tends to defer to the higher-status individual, even if that individual is performing poorly. In aviation, some airplane crashes have occurred in which overbearing captains were combined with unassertive subordinates (first officer copilot and flight engineers). The team was not able to respond effectively, even when the subordinates knew that something was wrong.

In aviation, as in academic anesthesia, training is an ongoing activity in the domain. Although the captain is in charge of the flight, the captain and the first officer (who is essentially in training to become a captain) traditionally alternate the roles of "pilot flying" and "pilot not flying" on each leg of a flight. Each of these roles is carefully defined and involves separate but interrelated tasks (the pilot flying handles the flight controls, whereas the pilot not flying handles radio communications and other tasks). In anesthesiology, the roles of the trainee and the faculty member during patient care are rarely made explicit. The trainee is often expected to do all tasks with only occasional assistance from the supervisor (part of a training method known as cognitive scaffolding). The exact responsibility for different tasks in a crisis is not predefined. It is interesting that two factors frequently found to be associated with critical incidents in anesthesia have been "teaching in progress" and "inadequate supervision."[63]

A particular issue of hierarchy is known as "cue giving" and "cue taking," in which people give off "cues" (often without even knowing it) that are taken up by others.[64] Those not at the top are very sensitive to cues emitted by their superiors. The cues sent by high-status personnel can inhibit action or even questions from lower-status people. One effect of this phenomenon is that dyads and teams that expect to have redundancy from "multiple sets of eyes" on a patient may not achieve this goal because the views of a single person dominate the thinking of the group.

Figure 6-4 Components of team cognition and team knowledge.

Production Pressure

The social and organizational environment may also act as a source of production pressure on anesthetists. Production pressure encompasses the economic and social pressures placed on workers to consider production, not safety, their primary priority.[57] In anesthesiology, this typically means keeping the OR schedule moving speedily, with few cancellations and minimum time between cases. In principle, safety and efficiency can go hand in hand. Many aspects of high reliability, such as standard operating procedures, preprocedure briefings, and flattening the hierarchy, may smooth operation of the system, as well as make it safer. Frequently, however, the pressure for throughput can erode safety.

For example, when anesthetists succumb to these pressures, they may skip appropriate preoperative evaluation and planning or they may fail to perform adequate pre-use checkout of equipment. Even when preoperative evaluation does take place, overt or covert pressure from surgeons (or others) can cause anesthetists to proceed with elective cases despite the existence of serious or uncontrolled medical problems. Production pressure can cause anesthetists to choose techniques that they otherwise believe to be inadvisable.

Gaba and associates[65] reported on a randomized survey of California anesthesiologists concerning their experience with production pressure. They found that 49% of respondents had witnessed a situation in which patient safety was compromised by pressure on the anesthesiologist. Thirty percent reported strong to intense pressure from surgeons to proceed with a case that they wished to cancel. Notably, 20% agreed with the statement that "If I cancel a case, I might jeopardize working with that surgeon at a later date."

Production pressure also leads to haste by the anesthetist, a psychological precursor to the commission of unsafe acts. In the survey, 20% of respondents answered "sometimes" to the statement that "I have altered my normal practices in order to speed the start of surgery," whereas 5% answered "often" to this statement. Twenty percent of respondents rated pressure by surgeons to hasten anesthetic preparation or induction as strong or intense. Repeated exposure to these conflicts can cause the anesthetist to internalize pressures; 38% of survey respondents felt strong to intense internal pressure to "get along" with surgeons, and 48% reported strong internal pressure to avoid delaying cases. Anesthetists may then feel impelled to go ahead with cases against their better judgment, even in the absence of overt pressure.

Investigating these aspects of the work environment is difficult because such relationships are driven by economic considerations, as well as by the complex organizational and interpersonal networks linking the different medical cultures. Changing the environment will be equally challenging.

Assessing Risk Factors in Anesthesia

An innovative attempt was made by a team of engineers and anesthesiologists to apply a technique called "probabilistic risk analysis" (PRA) to model cascading risks and the effects of different types of organizational interventions.[66,67] PRA has been used extensively in nuclear power and other highly hazardous industries (for example, it was used for analysis of the risks to the space shuttle from thermal tile failure). Complete PRA models are very complex and extensive. In the anesthesiology study, a highly simplified PRA model was used to assess the feasibility of applying this technique to health care. The PRA analysis of organizational changes in anesthesia suggested that patient risk could be reduced best by closer supervision of residents, the use of patient simulators for training and periodic recertification, and regular medical examination of anesthetists for fitness for duty. As yet it has not been possible to develop comprehensive PRA models of anesthesia risk because the number of decision and action elements is very large and knowledge of the probability of success or failure for each of the decisions or actions is very limited. The PRA approach might be a useful heuristic to help clinicians lay out critical decision-making and therapy issues, but it may never make any meaningful contribution as a quantitative safety management technique.

There has been growing interest in applying process-oriented systems analysis to patient care flows and processes. For example, a group in Tübingen, Germany, performed a process-oriented systems analysis at a medical university hospital

to assess the anesthesia work system's ability to regulate variances and disturbances in the work process.[68] These investigators showed that the internal work process can be regulated well but that the high interdependence of the anesthesia work system with other systems requires extensive coordination activities.

Characteristics of Successful Incident Reporting Systems

Incident Reporting Systems for Learning from Problems

An important strategy for improving patient safety (and a core tenet of HROT) is "organizational learning." Such learning can be both prospective (deliberating in advance of process changes how they might affect safety) and retrospective (learning from events that have already transpired). Most high-hazard and high-reliability industries have made special efforts to create systems for retrospective organizational learning, often concentrating on the reporting, investigation, and analysis of both frank accidents or errors and near-miss events with no negative outcome.[25,46,47,69-72] The details of successful incident reporting systems (IRSs) are covered in a number of publications.[5,7,42,52,73-90]

Historically, investigation of errors in the health care system has been hindered by a "culture of blame"[90-92] in which naming, blaming, and shaming are the main features of event reporting and review rather than analysis by experts and focus on the development of systematic countermeasures. A culture of blame in which it is posited that errors, accidents, and near misses are due primarily to a lack of knowledge, a bad attitude, or a lack of commitment to patients leads to a heavy burden on those involved in adverse events. It may also compound internalized negative feelings over having contributed to patient harm.[92,93]

Anesthesiology as a specialty has played a leading role in the attempt to turn this culture of blame into a safety culture—putting safety first[1,2] and trying to understand how errors, incidents, and adverse events evolve.[5,25,42,60,72,73,75,76,94-103]

Errors Per Se Are Not the Cause of Accidents

Only a minor fraction of errors lead to a negative patient outcome. However, the "harmless" error may well point to a systematic weakness (latent problem) in the system, which if investigated further can lead to a systematic change. Unfortunately, the reverse is often true. The lack of a negative outcome is interpreted as "success" of the system, and the underlying vulnerabilities are ignored. In most cases, errors in complex systems are not the sole causes of accidents and rarely lead inevitably to an adverse event (see Fig. 6-1A). In actuality, first hand there are probably underlying reasons (C_1 to C_3 in Fig. 6-1B) that someone commits an error, and then additional contributing factors (CF_4, CF_5) are "needed" to allow an accident to develop. The main idea of modern IRSs is to identify the factors that make errors more likely to occur, as well as additional factors that allow a negative outcome to ensue. By reporting and analyzing factors C_1 to C_3 and CF_4 and CF_5 in Figure 6-1 regardless of the outcome, it might be possible to eliminate or reduce the probability or the harm potential of the accident long before it ever happens.

"If reporting is safe and provides useful information from expert analysis, it can measurably improve safety."[80]

IRSs, if well structured and operated, can make substantial difference in system safety (Fig. 6-5). The present knowledge about weaknesses and strengths of the health care system that is

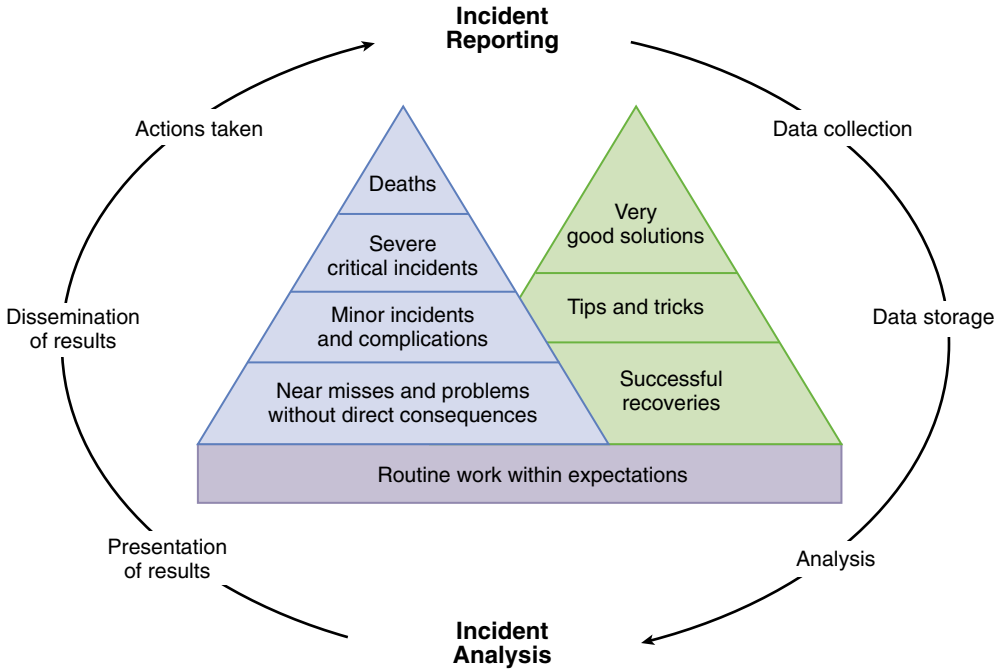

Figure 6-5 Process model of an incident reporting system that is constructed as a complete system. The data need to be collected, saved securely, analyzed independently, and the results need to be visualized in a relevant way, distributed to stakeholders in an applicable way, and result in concrete action by the reporting organization. It should be possible to report all incidents and errors, independent of the outcome. Innovative systems should even include positive reports. (Figure by P. Dieckmann.)

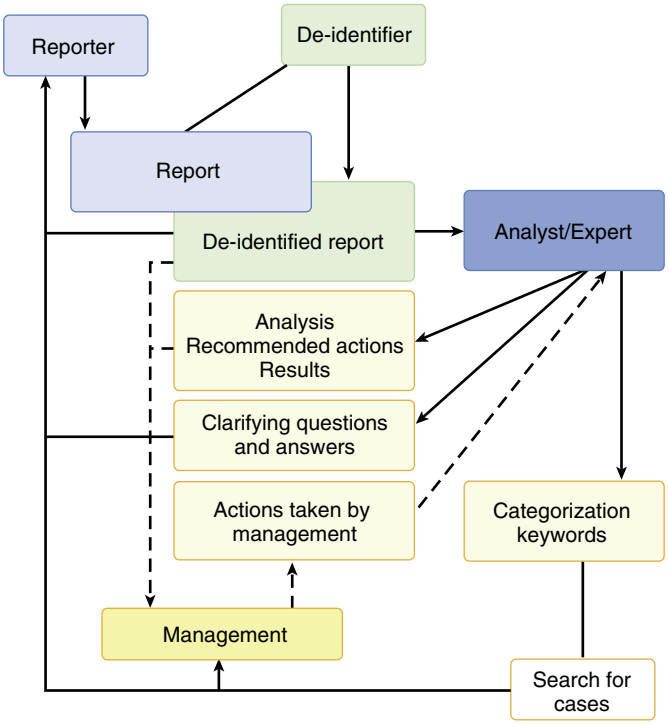

Figure 6-6 Data handling in a modern incident reporting system with de-identification. The incoming reports are first completely de-identified by a trained de-identifier. Only after this step is the report ready to be analyzed. It is important that the reports are analyzed by a multiprofessional team and that recommendations be fed back to the management of the organization from which the report came. The analysis and feedback should be transparent for all stakeholders.

"out there" already can finally be extracted and made available for others. IRSs are often referred to as "learning systems," similar to the National Reporting and Learning System of the National Patient Safety Agency in the National Health Service of the United Kingdom.

Effective IRSs allow insights into the health care system that are otherwise very hard to acquire. In this sense IRSs can open "windows to the system."[94]

Merely having a reporting form or a database of information does not constitute an effective reporting system. They can be effective only when they are constructed, established, and maintained as an entire system (Fig. 6-6; also see Fig. 6-5) and are successfully embedded in the organization or industry. Omission of or faults in any of the requirements in Box 6-5 will limit the success of the system.[88]

What Should Be Reported?

Uncertainty about *what* should be reported is one of the barriers for an IRS.[105] In aviation, it has been necessary to create a reporting system for "incidents" (without negative outcome) that is distinct from systems for reporting or analyzing accidents. Of course, in aviation the occurrence of an accident is usually known immediately, and such events are never "supposed to happen." Yet in health care every human being will get sick and will die; in fact, most people will die in proximity to medical care. Thus, negative outcomes are inherent to the progression of disease, so determining what outcomes are due to "errors" or "accidents" is much harder in health care settings. For this reason many believe that for health care event reporting systems, it should be possible to report all critical incidents, with or without a negative outcome. In fact, the system may also solicit reports of "positive events" in which the outcome was good despite challenging clinical circumstances. In general, the invitation to report should be very broad and cast a "wide net" to find all interesting occurrences.

What Should Report Forms Look Like?

Reporting systems that rely primarily on an array of checkboxes for the reporter to choose from regarding the "causes" of the incident have not proved to be useful. In fact, it is thought in the Aviation Safety Reporting System (ASRS), for example, that "Counting incidents is a waste of time" (quote from Charles

Box 6-5 Important Characteristics of Effective Incident Reporting Systems

Integration of the incident reporting system into the organization and full support by management

No negative sanctions for reporters and people involved

Confidential or anonymous reporting option, with active de-identification (domain expertise required)

Legal protection and state-of-the-art data security

Independence of the organizational hierarchy: reports are sent to a trusted subunit outside the hierarchy of the organization or outside the organization (external trust center, e.g., NASA for the ASRS)

Orientation to a system that enables all stakeholders of patient safety to easily file reports, including physicians, nurses, and technicians

Easy and fast reporting

Training of stakeholders to file valuable reports (e.g., focusing on human factors issues, as well as medical-technical aspects)

Timely feedback about reception of the report, its analysis, and proposed measures to be taken from it

Analysis of each report by experts (a multiprofessional team that has a background not only in the medical domain but also in issues of human performance and analysis methods)

Deep analysis of selected cases using root cause analyses or failure modes and effect analyses with the aim of improving systems safety in the future

Timely implementation of improvements to confirm the "reactivity" of the system and to *make a difference*

Evaluation of improvements and special care to avoid "improvements for the worse" (quick fixes without improving the underlying latent dangers)

Organizational support of reporting and analysis of cases, as well as the implementation of improvements

Supports continuous improvement of the positive proactive safety culture in the department (systems perspective!)

ASRS, Aviation Safety Reporting System; NASA, National Aeronautics and Space Administration.

Data from references 25, 77, 80, 104.

Billings, a founder of the ASRS). In a voluntary reporting system one has no way to estimate the true number of specific problems. Similarly, trend analysis is not feasible because the frequency of events and the frequency of reporting are confounded. A free-text description of the reported incident has been more helpful in identifying what can be learned from the report. This view is also supported by the World Health Organization's Guidelines for Incident Reporting[77]:

> *However, much of what promotes learning in patient safety lacks crisply defined data elements, so most authorities believe it is important for reports to include narrative to convey meaning. Narrative reports provide the opportunity to capture the rich context and storyline that allow the conditions that contributed to the error to be explored and understood.*
>
> *Indeed, some believe that only narrative reports are capable of providing information that provides meaningful insight into the nature of the underlying systems defects that caused the incident (Richard Cook, personal communication).*

Clearly, no reporting system can detect all the problems in a clinical institution, even ones that create a severe vulnerability. For one thing, it is known that between 50% and 96% of critical incidents are not reported[106,107] with current systems, although new thrusts in incident reporting hope to increase the fraction of events that are reported.

Legal Issues of Reporting Systems

Especially in jurisdictions for which medical liability litigation is common, there will be a number of legal issues that affect reporting systems. First, for some kinds of events in some settings there will be legal requirements to report the event to a governmental body. This is true in the United States for certain kind of adverse drug events or for certain failures of medical devices. Moreover, some states have started mandatory reporting programs about so-called never events that are thought should never occur in the absence of a systems failure. In general, voluntary IRSs operate completely in parallel with any other types of reporting systems.

An important question for most reporters is whether the report will be confidential or anonymous and whether the report will confer any immunity to the reporter. Anonymous reporting provides maximum protection for reporters but limits the amount of information that can be acquired about any given event and the cogency of that information. Confidential reporting can allow confidential interaction between analysts and the reporter to acquire all the information and context needed concerning the event, but the linkage between the report and the identity of the reporter exposes a risk even if confidentiality is formally provided. Of note, the ASRS—on which many reporting systems have been modeled—operates as a confidential system but with subsequent de-identification of the reports to make them anonymous. Furthermore, the ASRS was able to offer limited immunity from administrative actions for those who filed a report. This was a major incentive for reporting events. In health care, physicians largely fear malpractice litigation, and it is not possible to offer immunity from litigation to reporters, although offering immunity from administrative action (e.g., an official reprimand) within the hospital itself could be an incentive to report.

Statutory Protection

In the United States there is now both federal and state statutory protection (shield) from discovery of any voluntary event reports that may be available (depending on the locale and many other circumstances). In the United States, Congress passed the Patient Safety and Quality Improvement Act of 2005 (Public Law 109-41). This authorized the Department of Health and Human Services to certify patient safety organizations (PSOs) to collect confidential reports about events and to analyze the information. The act provides strong legal protection (privilege) from any compelled release of the information, as in the process of discovery in a lawsuit. At the time of this writing, rules were in the process of being formulated to govern the certification process for PSOs, so no data have yet been collected that are protected under the act.

Internal reporting systems within hospitals may be protected as quality improvement activities in states that provide privilege from discovery of such reports and deliberations. State laws vary widely on this matter. In addition, the quality improvement protections are often questioned during litigation, and whether the privilege will be applied depends on the ruling of a judge in each individual case.

Reporting systems in other countries have used other strategies. For example, the Center for Patient Safety and Simulation, which runs a national IRS in Germany called PaSOS, has constituted itself as a "press office" (informing the anesthesia public as a journal would); this then brings it under the protection of the "free press act and rights" and makes it almost impossible to use its data in litigation.

De-identification before Information

A common strategy of confidential reporting systems is to quickly convert the data to anonymous status by "de-identification." To do this, it is necessary to edit the reports and delete all information that might be used to identify persons or organizations. Systems vary by what stage of analysis they conduct de-identification and where they set the balance between acquiring needed information versus deleting possibly identifying data. One issue in all reporting systems, especially in health care, is that the key facts of many events might be relatively unique and thereby lead to a high risk of "intrinsic identification" even when all objective identifiers are stripped.

There are now IRSs in many countries with various designs and operational processes (see Appendix 1).[5,7,42,52,73-90] Many systems are installed locally, but more and more national systems, or at least systems with a national common data set, are being installed.[108] Box 6-6 shows some of the features of and lessons learned from the national anesthesia system PaSOS (available at www.pasos-ains.de) in Germany, which is directed by one of this chapter's authors (M.R.).

Human Factors

This part of the chapter deals with human factors in the broadest sense of the meaning. In contrast to the previous part of the chapter, which covered aspects of the health care system and organizational matters, the human factors portion is related to the performance of individuals and teams and to factors influencing their performance and promoting or preventing active or passive errors. Because more than 70% of all errors in medicine can be

Box 6-6 Characteristics of the German National Anesthesia and Intensive Care Incident Reporting System PaSOS (www.pasos-ains.de)

The system is provided by the two German anesthesia societies and run by a professional interdisciplinary group.

Every anesthesia department and ambulatory anesthesia unit in Germany is entitled to take part. The basic functionality, software, server storage, and updates are free of charge (a service by the societies).

The system is Web-based with an anonymous secure login (SSL). No data are stored locally in the hospitals, but users work directly on the central secure server with php technology.

The reports are primarily sent outside one's own institution for de-identification by our independent and interdisciplinary patient safety group (TuPASS), which increases trust of employees in the safety of the system.

All reports undergo a professional four-eye active anonymization and de-identification process by domain experts trained in incident reporting and using checklist protocols to prevent any lapses in de-identification.

After de-identification, most reports can be read in full text by all employees. This is meant to sensitize all by reading all the cases and to stimulate discussion about patient safety in the department and to report your own cases. It also provides very powerful feedback to the reporter, who can read "his" report in the Web.

Every department gets a unique department login that is provided to all employees (physicians, nurses, technicians, etc). This login allows you to separate "your" reports from the national reports. So every department has its own "local" incident reporting system inside the big national system. There are no personal logins because the system is anonymous.

Most reports are readable in the national IRS, open to all anesthesiologists. This should contribute to the national spread of important critical safety information. Of course, on this level, nobody can see where the reports came from. (You can select "your" reports with your department login, but you cannot identify the origin of reports once they are in the national database).

All reports are manually tagged with key words for meaningful search results; they are classified according to the U.K. NHS NPSA contributory factors framework[52,94,95] and also categorized with the CRM key points (see text).[60,109]

A local de-identifier does not exist and can therefore not be interviewed by any legal authorities.

An optional module, "feedback and analysis suggestions," is available on request; it provides expert feedback about every report from the IRS provider team back to the organization's risk management, including systems safety analysis and suggestions for countermeasures.

Several organizational prerequisites need to be fulfilled by departments to take part (organizational embedding before starting to report). For example, all departments have to send their PaSOS representatives to an initial workshop to get briefed about the do's and don'ts of IRS. They also get a set of slides and information material to spread the messages in their local departments (snowball effect).

Departments that do not comply with the minimal requirements, especially prerequisites such as the written "no-blame assurance" to their employees, are not allowed to take part or may even be excluded from the system.

IRS, incident reporting system.
Data from references 60, 104, 108, 110.

attributed to problems with human factors rather than problems with knowledge or practical skills, the impact of human factors cannot be overestimated. On this basis perhaps human factors should take 70% of the whole book! Given that this chapter cannot deal with human factors in a comprehensive way, many topics can be touched on only briefly, and the reader is directed to the available literature. We focus on the most important aspects of human factors that are directly relevant to practicing anesthetists.

Nontechnical Skills in Anesthesia

Over the last 20 years, the health care professions have become more aware of the importance of "nontechnical" skills in the delivery of safe, high-quality medical care. This recognition has brought an increased need for assessment, evaluation, and training of these skills. Patient simulators were perhaps the first opportunity to show and train these skills under realistic stressful conditions.[109,111-113] The introduction of simulators and the associated training concepts accelerated understanding of these human factors by the medical community.[2] Some of the needed "crisis management skills"[20,114] can be trained without the use of simulators, as shown in other domains (aviation, oil platforms, military).[71,115-117] The baseline level of crisis resource management (CRM) performance is somewhat low.[118] Helmreich states that as a first step in establishing error management programs, it is necessary to provide formal training in teamwork, the nature of error, and the limitations of human performance.[47]

There are different ways to group the nontechnical skills that are at the heart of CRM training. One approach is to distinguish between two categories of nontechnical skills: (1) cognitive and mental skills, including decision-making, planning, and situation awareness (Table 6-3), and (2) social and interpersonal skills, including aspects of teamwork, communication, and leadership. Another approach is to split nontechnical skills into five major groups as shown in Figure 6-7.

Crisis Resource Management

What Exactly Is Crisis Resource Management?

Cockpit (later "crew") resource management was introduced in aviation in the mid-1980s and is considered to be successful in

Table 6-3 Nontechnical Skills in Anesthesia: Classification, Markers, and Teaching Points

	Anesthesia Nontechnical Skills (Fletcher et al.[146])		Performance Markers (Gaba et al.[130])	Key Teaching Points in Anesthesia Crisis Resource Management (Gaba et al.[147,148])
Concepts	**Elements**	**Categories**	**Markers**	**Reminders**
Cognitive and mental skills	Planning and preparing	Task management	Orientation to case	Anticipate and plan Know your environment
	Prioritizing		Leadership (also a social and interpersonal skill)	Exercise leadership Set priorities dynamically
	Providing and maintaining standards		Planning	Use cognitive aids
	Identifying and using resources		Workload distribution	Distribute the workload Mobilize all available resources
	Gathering information	Situation awareness	Anticipation	Use all available information
	Recognizing and understanding		Vigilance	Allocate attention
	Anticipating			Anticipate and plan
	Identifying options	Decision-making	Preparation	
	Balancing risks and selecting options		Re-evaluation	Prevent and manage fixation errors
	Re-evaluating			Re-evaluate repeatedly
Social and interpersonal skills	Coordinating activities with team	Team working	Inquiry/assertion	Communicate effectively Teamwork
	Exchanging information		Communication feedback	Communicate effectively
	Using authority and assertiveness		Group climate	Exercise leadership and followership
	Assessing capabilities		Followership	Exercise followership
	Supporting others			
Overall assessment	Not applicable Assessments are made only at the element and category level		Overall nontechnical performance of the primary anesthetist Overall nontechnical performance of the whole team	Teamwork! Concentrate on what is right, not who is right

that industry and other industrial and military settings (although admittedly, there is not what evidence-based medicine would call "level 1 evidence" for this success).[24,25,41,119-122] Crew resource management is now taught systematically to crew members of all major U.S. airlines and at many airlines around the world.[123] A similar program in anesthesiology was first developed by Gaba, Howard, and associates at the Veterans Affairs (VA) Palo Alto Health Care System and Stanford School of Medicine[4,105,109,113,124] originally as anesthesia crisis resource management (ACRM). The ACRM curriculum and its variants have since been adopted by training centers worldwide. A detailed description of the ACRM course is provided.

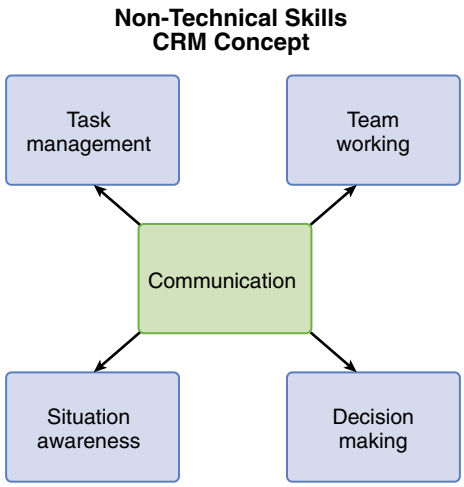

Figure 6-7 Five main groups of nontechnical skills. In this approach, effective communication is like the glue that holds all the other components together.

In overview, CRM means to coordinate, use, and apply all available resources to protect and help the patient as best as possible. Resources include all the personnel involved, along with all their skills, abilities and attitudes—albeit also with their human limitations. Machines, devices, and information sources, including cognitive aids, are also critical resources.

Though termed "crisis management," CRM principles actually also apply before a crisis ensues. CRM includes preventing and intercepting threats and errors and minimizing their negative consequences to the patient.

The key points of CRM as they apply to anesthesia care have been steadily updated and expanded over time (see Box 6-7). Some of the principles might seem obvious or self-evident. However, from our experience in simulation training, it is in fact *not* trivial to actually apply these principles whether during routine work or during crises. More theoretical background on the principles can be found in the textbook on ACRM by Gaba, Fish, and Howard,[125] as well as in related safety literature.[25,41,43,46,47,70,71,72,126-130]

Box 6-7 CRM—Key Points in Healthcare

1. Know the environment.
2. Anticipate and plan.
3. Call for help early.
4. Exercise leadership and followership with assertiveness.
5. Distribute the workload (10-seconds-for-10-minutes principle).
6. Mobilize all available resources.
7. Communicate effectively—speak up.
8. Use all available information.
9. Prevent and manage fixation errors.
10. Crosscheck and double-check (never assume anything).
11. Use cognitive aids.
12. Re-evaluate repeatedly (apply the 10-seconds-for-10-minutes principle).
13. Use good teamwork—coordinate with and support others.
14. Allocate attention wisely.
15. Set priorities dynamically.

Adapted from Rall M, Gaba DM: Human performance and patient safety. *In* Miller RD (ed): Miller's Anesthesia, 6th ed. Philadelphia, Elsevier Churchill Livingstone, 2005.

Like nearly all principles of sound human factors, application of CRM key points to patient care must be supported by top leadership and reinforced in the actual work environment. It is of no worth to study these principles (or even practice them in simulations) only to find that the pressures and culture of the "real OR" make them impossible to implement for real patients. Fully integrating these key points into the structures and processes of clinical practice has proved to be a significant challenge.

Know the environment! (CRM key point 1)

CRM begins before the crisis starts. One of the prerequisites for CRM is to *know the available resources and the details of the specific working environment*. Resources are *personnel*, *equipment* (software, hardware, or cognitive aids), and supplies. It is important to know who can be asked for help, who is available at different times of the day, how to call those helpers quickly, and how long it will take them to arrive. Regarding equipment, it is necessary to not only know *what* is available and *where to find it* but also *how* to operate it. The anesthesiologist is responsible for being well versed in the operation of all relevant equipment and should also use manuals and other cognitive aids to learn to use the gear and as a backup source of information during patient care.

Anticipate and plan (CRM key point 2)

Anticipation is key for goal-oriented behavior. Anesthetists must consider the requirements of a case in advance and plan for the key milestone. They must imagine what could go wrong and plan ahead for each possible difficulty. Savvy anesthetists expect the unexpected, and when it does strike, they then anticipate what could happen next and prepare for the worst. People often talk about "staying ahead of the game" or, conversely, "falling behind" or "being behind the eight ball."

Call for help early (CRM key point 3)

Knowing one's own limitations and calling for help is a sign of a strong character and a competent person. Trying to handle everything alone or toughing out a critical situation is dangerous and unfair for the patient, who should not suffer to protect the anesthetist's pride or ego. In case of an emergency or even a suspected emergency, help should be called early rather than late. Some typical triggers for calling for help that apply to any anesthetist at any level are (1) when there are too many tasks to do, (2) when the situation is already catastrophic (e.g., cardiac arrest, difficulty securing the airway), (3) when serious problems are getting worse or not responding to the usual maneuvers (or both), and (4) when you do not know what is going on. It is important to know in advance who is available and how to call for help and to plan for how best to use the help when it arrives.

Exercise leadership and followership with assertiveness (CRM key point 4)

A team needs a leader. Someone has to take command, distribute tasks, collect information, and make key decisions. Leadership rarely means knowing more than everybody else, doing everything alone, or putting other people down. Leadership is about planning, deciding, and distributing tasks by clear communication. Followership is also an important skill. Followers are key members of the team who listen to what the team leader says and do what is needed. However, it does not mean shutting off their own brains. Followers should be assertive if they think that the team leader is making wrong decisions. It is their responsibility to make sure that the leader is aware of their concerns. Whenever people work together, conflict can ensue; anyone on the team may need to diffuse conflicts to focus the team on care of the patient. Get everyone to concentrate on *what* is right, not on *who* is right.

Distribute the workload "10-seconds-for-10-minutes principle" (CRM key point 5)

One of the main tasks of a team leader is distribution of the workload. Someone is needed to define the necessary tasks and ensure that they are fulfilled properly and that everything fits together. If possible, the team leader should remain free of manual tasks to observe, gather information, and delegate tasks. Team members should also look actively for things that need to be done. It is not a good team if the team leader has to express every idea and nothing is done before it is explicitly ordered.

A corollary is known as the "10-seconds-for-10-minutes principle", which posits that if a team can slow its activities down just a little, it can gain more than enough benefit in rational decision-making and planning to offset the delay. The need to slow down appears to be greatest in critical situations such as the beginning of the diagnosis and treatment planning or when the team "feels stuck" because the usual treatment is not working (Fig. 6-8).

Mobilize all available resources (CRM key point 6)

Everyone and everything that could help deal with the problem at hand should be mobilized, including humans and technology embedded in organizational processes. On the human side, the anesthetist's knowledge and skills (mitigated by knowledge of one's human deficiencies) are the most important resource, com-

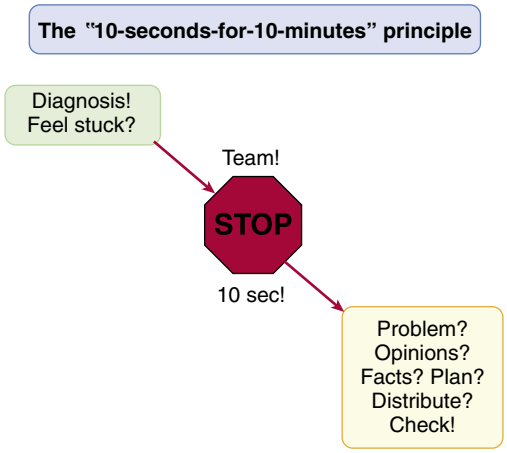

Figure 6-8 The "10-seconds-for-10-minutes principle." When making a *diagnosis* or *feeling stuck*, perform the 10-second team timeout and check to see "what the biggest problem is (the most dangerous aspect right now)" (*Problem*). Clarify this with all available team members (*Opinions*). Gather the information available (*Facts*). *Plan* the treatment, including the desired sequence of actions. *Distribute* the workload by assigning tasks and responsibilities. *Check* with all team members about any further concerns or suggestions.

plemented by the human helpers who can be brought to bear. Equipment and supplies are the means by which knowledge is translated into action. Some equipment will be readily available, but others will need time to be mobilized.

Communicate effectively—speak up (CRM key point 7)

Communication is key in crisis situations. Good team work depends on everybody being on the same page and coordinating their efforts; communication is the glue that holds the disparate members together (see Fig. 6-7). Effective communication is challenging to accomplish. Several aspects make communication difficult sometimes; for example, saying something is meaningful communication only if the messages are received and understood (Fig. 6-9).

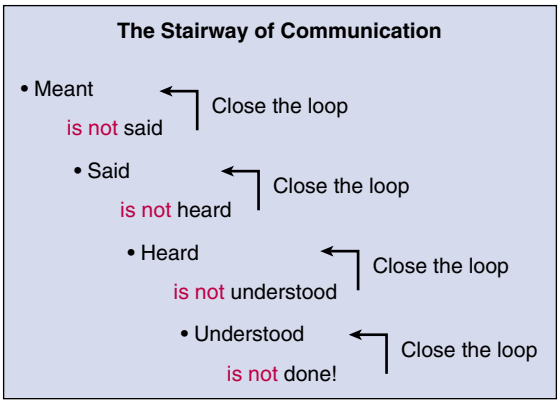

Figure 6-9 Model showing the importance of proper communication. When dealing with complex situations under time pressure, people tend to "mean" a lot but "say" little. It is important to let other team members know what you think (mental model). Not everything that is said is necessarily heard by those who should hear. This is often not the "fault" of the receiving end; acoustic hearing and mental understanding are not the same. It is important for the sender and receiver of a message to close the communication loop. Some tasks need time to be completed and may fail. Let the team know.

Use all available information (CRM key point 8)

Anesthesiology is particularly complex because information must be integrated from many different sources. Every bit of information can assist in understanding a patient's status better and arriving at the correct diagnosis. Information sources include those immediately at hand (the patient, monitors, the anesthesia record), secondary sources such as the patient's chart, and external sources such as cognitive aids (see later) or even the Internet.

Prevent and manage fixation errors (CRM key point 9)

Human actions are based on an instantaneous mental model of the current situation. If the model of the situation is erroneous, the actions will probably be wrong.

The term "fixation error" describes a model that is persistently faulty despite sufficient evidence to correct it. A fixation error is the persistent failure to revise a diagnosis or plan in the face of readily available evidence suggesting that a revision is necessary. This type of error is extremely common in dynamic situations. There are three main types of fixation errors.[131,132]

One type of fixation error is called "**this and only this**"—sometimes also called "cognitive tunnel vision." In this type of error, attention is focused on only one possibility and other (possibly or actually correct) alternatives are not taken into account. Another fixation error is "**everything but this**," the persistent search for irrelevant information and failure to treat a probable cause with serious consequences.

Perhaps the most insidious fixation error is the persistent claim that "**everything is OK**," in which all information is attributed to artifact and possible signs of a catastrophic situation are otherwise dismissed. Another form of "everything is OK" is the failure to transition from "routine mode" to "emergency mode" when the situation demands it.

One principle of managing fixation errors is to get a new view—a second opinion—on the situation from someone unaware of the faulty previous assumptions. Although it is appropriate to brief the new person on the situation, it is best to avoid biasing the person with the conclusions already drawn. Even when working alone the anesthetist can deliberately change perspectives (physically or mentally) and look for information not fitting the picture of the situation, as though entering the room for the first time.

The aforementioned 10-for-10 principle (CRM key point 5) might also be helpful in managing fixation errors. More information on fixation error is provided later in the section "Core Process."

Crosscheck and double-check—(never assume anything) (CRM key point 10)

Crosschecking means to correlate information from different sources. There are often three independent sources of information about the patient's heart rate (electrocardiogram [ECG], pulse oximetry, and blood pressure monitor), for example, and two about the rhythm (ECG and pulse oximetry).

Another aspect of crosschecking involves reviewing the status of actions that have been done or are under way. Human memory about actions performed is vulnerable, especially when interruptions have occurred. Moreover, although we often attempt to check things "at a glance," such fleeting observations are prone to error. Checking numbers and settings on equipment by actually touching them and looking carefully may be worth the effort.

In general it is best to "never *assume* anything"; make sure and double-check important information.

Use cognitive aids (CRM key point 11)

Cognitive aids—such as checklists, handbooks, calculators, and advice hotlines—come in different forms but serve similar functions. They make knowledge "explicit" and "in the world" rather than only being implicit, in someone's brain. Memory and cognitive functioning are vulnerable to error or complete failure, especially in stressful situations. Cognitive aids offload memory and safeguard the recall of critical items. They also help ensure the use of current best practices because during a crisis, people sometimes revert to what they originally learned as the best, not what is the latest recommendation. The use of cognitive aids rather than memory alone is another sign of strength.

Re-evaluate repeatedly (apply the 10-seconds-for-10-minutes principle) (CRM key point 12)

Acute medicine is dynamic. What is correct now might be wrong in the next minute. Some parameters might change slowly over time, and subtle changes can be hard to perceive. Trend monitoring can be helpful to detect slow, but insidious changes.

Furthermore, the dynamic nature of critical events makes it necessary to repeatedly re-evaluate the situation. Box 6-8 shows a set of questions that should be raised repeatedly to check whether one is still treating the most serious problem most effectively.

Implement principles of good teamwork—coordinate with and support others (CRM key point 13)

Teamwork in multidisciplinary teams is at the heart of much patient management in the OR and ICU. Key principles of teamwork in dynamic situations have been delineated, especially in the work of Eduardo Salas and colleagues at University of Central Florida (see Fig. 6-4). Coordination within a team ideally begins before a team gathers. If all members know about the tasks to be done and their roles during these tasks, coordination is easier. Short briefings at the beginning of a task are common in aviation and are worth the time spent. During the acute phase of a crisis situation, it is worth a small amount of time to coordinate the team's activities (see 10-for-10 earlier in CRM key point 5). "Dream teams" support each other continuously, with everybody looking after each other.

Box 6-8 Re-Evaluation Questions—Maintaining Situation Awareness

- Was the initial assessment of the situation or diagnosis correct?
- Did the actions have any effect? (e.g., did the drug reach the patient?)
- Is the problem getting better, or is it getting worse?
- Are there any side effects resulting from previous actions?
- Are there any new problems or other problems that were missed before?
- What further developments can be expected in the (near) future?

Allocate attention wisely (CRM key point 14)

Human attention is very limited and multitasking is very difficult. Attention must be dynamically allocated where it is needed. One can develop rhythms and scan patterns to do this. The "ABC equals airway, breathing, circulation" mnemonic is based on this principle. Other strategies are to alternate between focusing on details and focusing on the big picture and to offload certain responsibilities, tasks, or information streams to other qualified team members, provided that they periodically update the team leader about the situation.

Set priorities dynamically (CRM key point 15)

Dynamic situations demand dynamic measures with decisive, purposeful preliminary decisions and actions that are constantly re-evaluated and modified as new information becomes available or the results of treatment are apparent. What was not a right move at one time may become the right move at another. In addition, having one solution to an obvious problem does not guarantee that it is the best solution to the one problem or that there is only that one problem to deal with. However, one priority is always paramount—ensuring adequate oxygenation and perfusion of critical organs.

How Can CRM Skills Be Learned and Trained

CRM is taught in many different ways. Seminar-based training on human factors and CRM principles has become popular in health care (e.g., programs called "MedTeams," "Medical Team Training," "LifeWings"),[133-140] although the role of such activities versus simulation-based CRM approaches has not yet been fully delineated. Seminars use didactic sessions, group exercises, and sometimes discussion and analysis of "trigger videos." Such training is probably useful for first learning about CRM principles and articulating how they might apply to anesthetists' work environments. Given the experience in the airline industry, it is likely that to completely address CRM skills for both trainees and experienced personnel, a combination of seminars and simulation-based exercises will be needed. We believe that to really practice the execution of CRM skills requires exposure to challenging clinical situations in realistic simulation scenarios, followed by detailed group debriefings (often using video of the simulations) to analyze what transpired. As detailed in Chapter 7, such CRM-oriented simulation training may be available in dedicated simulation centers or as in situ simulation training in actual work environments. Many simulation centers also offer "mobile training," which means that they can bring the simulator and everything else needed (e.g., audio/video equipment) to any facility to train the staff in institutions that do not have a simulator or staff capable of conducting the training.

How Can CRM Skills Contribute to Patient Safety

Although 70% of all errors in anesthesia may be attributable to human factors, interventions to improve this picture have only

partially penetrated the fabric of the industry. CRM-oriented training is one component of a comprehensive approach to addressing human factors issues in anesthesia safety, but it is not yet a standard part of clinical training. There is not yet definitive evidence that CRM training in anesthesia improves patient outcomes, and many believe that it may be functionally impossible to acquire such evidence. Nevertheless, CRM training is an integral and accepted part of training in aviation, nuclear power, and other industries in which human errors can lead to catastrophic events. There is no reason to assume that doctors would be less error prone or would benefit less from human factors–based CRM training than the professionals in other high-hazard industries.

Assessing Nontechnical Skills Is More Subjective Than Assessing Technical Skills

A study by Morgan and Cleave-Hogg concluded that "the simulator environment is somehow unique and allows different behaviors to be assessed."[141] As Glavin and Maran stated, "Any scoring system that attempts to address the assessment of clinical competence clearly has to address both technical and non-technical skills"[142]; consequently, there is still a long road ahead in measuring performance.

Two research groups (VA-Stanford and the University of Basel) have studied adaptations of the anchored subjective rating scales developed by the NASA/University of Texas Aerospace Crew Performance Project. The VA-Stanford group published preliminary data reviewing the inter-rater reliability of subjective ratings of behavior on five-point anchored scales.[130,143] Using a fairly stringent test of inter-rater reliability (the topic is quite complex in the statistical literature), they found only moderate reliability when five trained raters used a five-point scale to score 14 anesthesia teams, each managing two different complex critical events in the simulator (malignant hyperthermia and cardiac arrest). Despite some difficulty in agreement on the operational definitions of each type of behavior, the investigators stated that the largest problem in achieving agreement was the high variability of each behavior over the course of a simulation. For example, an anesthesia crew could show evidence of good communication at one instant, only to be shouting ambiguous orders into thin air at the next instant. Aggregating such behavior into a single rating was extremely difficult, even for bounded time segments of the scenario. These data demonstrate the importance of evaluating performance by more than one rater, who no matter how well trained, may produce scores that differ significantly from another single rater. The investigators suggested combining scores from a minimum of a pair of raters inasmuch as it was shown that the mean of scores from two raters had a very low probability of differing from the mean of five raters by more than a single rating point.

The behavioral markers of their score are shown in Table 6-3 and compared with Fletcher's "anesthesia nontechnical skills (ANTS)" score and the ACRM key teaching points (see Box 6-7).

The ANTS System

Fletcher, from the Industrial Psychology Group of Aberdeen (headed by Rhona Flin) and working with clinicians from the Scottish Clinical Simulation Centre (Glavin and Maran), performed an in-depth review of the role of nontechnical skills in anesthesia. Fletcher stated that nontechnical skills have not been explicitly addressed in the traditional education and training of anesthesiologists, even though they have always been demonstrated and used during clinical work. The group analyzed incident reports and observations of real cases, as well as attitude questionnaires and theoretical models.[144] Like others, they recognized that simulation offers the opportunity to identify, develop, measure, and train nontechnical skills in a safe learning environment, so they also included significant observations during realistic simulations.[145]

Incident reports proved very limited because they did "not provide the finer-grained level of information necessary to understand where the skills broke down."[146] They defined nontechnical skills as "attitudes and behaviours not directly related to the use of medical expertise, drugs or equipment." Although nontechnical skills can be seen under the heading of "human factors," it is preferred that they be addressed as "nontechnical skills," which is more specific.

As in the ACRM instructional paradigm,[109,147,148] Fletcher and colleagues identified two categories of nontechnical skills:

- Cognitive and mental skills, including decision-making, planning, and situation awareness
- Social and interpersonal skills, including aspects of team working, communication, and leadership

Fletcher's ANTS scheme is shown in Table 6-4, along with the behavioral markers of Gaba's team and the ACRM key teaching points. A description of the ANTS categories and elements, including examples of good practice and poor practice, is presented in Table 6-4.

The structure of the new ANTS scheme was derived from a system of behavioral markers that had been developed for aviation in an European project called "NOTECHS," which itself was an evolution of the UT-Markers of the University of Texas (Helmreich). A summarized comparison of the aviation systems and explanations about using nontechnical markers for training and evaluation can be found in the downloadable documentation of the "Group Interaction in High Risk Environments" created by an international group of human factors specialists (available at http://www2.hu-berlin.de/gihre/Download/Publications/GIHRE2.pdf). Several comments about the ANTS approach are appropriate.

ANTS' intent is to score only those skills that can be identified unambiguously through observable behavior. Such restriction may enhance the reliability of the scoring but could exclude relevant personal factors such as self-presentation, stress management, and maintaining perspective. ANTS assumes that "communication" is included or "even pervades" all other categories and does not score communication as a separate skill. This approach is in contrast to that of others who believe that communication is a specific skill that should be rated separately.[115,149] The category "task management" of the ANTS includes the element "providing and maintaining standards," which might be a point of discussion if it can be an observable behavior "not directly related to medical expertise" as stated in the definition. In addition, there might be a problem because there are not so many well-accepted standards in medicine (in strong contrast to, e.g., aviation).

Table 6-4 Example of a Description of the Anesthesia Nontechnical Skills System (ANTS System—V1.0)

Task Management—skills for organizing resources and required activities to achieve goals, be they individual case plans or longer-term scheduling issues. It has four skill elements: planning and preparing, prioritizing, providing and maintaining standards, and identifying and using resources.

Planning and preparing—developing primary and contingency strategies in advance for managing tasks, reviewing these tasks, and updating them if required to ensure that goals will be met; making necessary arrangements to ensure that plans can be achieved.

Behavioral Markers for Good Practice	*Behavioral Markers for Poor Practice*
Communicates plan for case to relevant staff	Does not adapt plan in light of new information
Reviews case plan in light of changes	Does not ask for drugs or equipment until the last minute
Lays out drugs and equipment needed before starting case that are suitable for the patient	Does not have emergency/alternative drugs available
Makes postoperative arrangements for patient	Fails to prepare postoperative management plan

Prioritizing—scheduling tasks, activities, issues, information channels, etc., according to importance (e.g., because of time, seriousness, plans); being able to identify key issues and allocate attention to them accordingly; and avoiding being distracted by less important or irrelevant matters

Behavioral Markers for Good Practice	*Behavioral Markers for Poor Practice*
Discusses priority issues in case	Becomes distracted by teaching trainees
Negotiates sequence of cases on list with surgeon	Fails to allocate attention to critical areas
Conveys order of actions in critical situations	Fails to adapt list to changing clinical conditions

Providing and maintaining standards—supporting safety and quality by adhering to accepted principles of anesthesia; following, when possible, codes of good practice, treatment protocols or guidelines, and mental checklists

Behavioral Markers for Good Practice	*Behavioral Markers for Poor Practice*
Follows published protocols and guidelines	Does not adhere to emergency protocols or guidelines
Cross-checks drug labels	Does not check blood with patient and notes
Checks machine at beginning of each session	Breaches guidelines such as minimum monitoring standards
Maintains accurate anesthetic records	Fails to confirm patient identity and consent details

From Fletcher GCL, Flin R, Glavin RJ, Maran NJ: Framework for Observing and Rating Anaesthetists' Non-Technical Skills—Anaesthetists' Non-Technical Skills (ANTS) System V1.0, 22nd version. Aberdeen, Scotland, University of Aberdeen, 2003.

Flin's group, meanwhile, adapted nontechnical skills scoring systems for several other medical fields, such as for surgeons and ICU care.[25,72,123,128-130,150-152] They have not yet made adaptations that fully describe multidisciplinary crews and teams.

Not all nontechnical skills will be expected to be observed during every scenario or clinical situation. It is important to delineate between "required behaviors" in a given scenario and the generic set of behaviors. If a required behavior is not observed, the rating system advises that one rate that behavior as poor nontechnical skills, whereas the absence of a given nontechnical skill behavior otherwise has no particular meaning and should be rated as "not observed." As in all subjective nontechnical performance systems, training plus calibration of raters is necessary.

Fletcher and coworkers evaluated ANTS by using scripted videotapes taken in a realistic simulator. Fifty consultant anesthetists were given 4 hours of training as raters and then rated eight test scenarios ranging from 4 to 21 minutes each. They rated performance at the level of specific elements and also at the broader level of category (see Table 6-3) by using a four-point scale (they could also enter "not observed"). Three investigator anesthetists also rated the scenarios and agreed on a "reference rating" to be used as the benchmark for the study. In questionnaires the ANTS system was evaluated by raters as relatively complete, possibly with superfluous elements. Raters found that nontechnical skills were usually observable, and most thought that it was not difficult to relate observed behavior to ANTS elements. The inter-rater reliability, accuracy, and internal consistency of the ratings were good to acceptable and are presented in Table 6-5.

Although well performed, there are some caveats about these data. Because scripted videos were used as the basis for

Table 6-5 Results of an Evaluation Study of Anesthesia Nontechnical Skills by Fletcher and Colleagues

Measure	Score	Range	Max/Min	Element/Category
Inter-rater agreement	Element level	0.55-0.67	Highest element	Identifying/using resources
			Lowest element	Recognizing/understanding
	Category level	0.56-0.65	Highest category	Task management
				Team working
			Lowest category	Situation awareness
Accuracy relative to the reference rater's score	% within ±1 point	88%-97%	Highest element	Identifying options
			Lowest element	Assessing capabilities
	Mean absolute deviation	0.49-0.84, depending on elements	Highest element	Authority/assertiveness
			Lowest element	Provide standards

From Fletcher R, Flin P, McGeorge R, et al: Anaesthetists' non-technical skills (ANTS): Evaluation of a behavioural marker system. Br J Anaesth 90:580-588, 2003.

ratings, it is possible that the observability or scorability of the desired sets of behavior was greater than in actual simulation scenarios. The scripted scenarios were rather short (4 to 21 minutes), which perhaps made it relatively easy to remember certain aspects of the performance and reduced the likelihood of raters encountering the problem of aggregating a score from fluctuating behavior over time. The window of "accuracy" as "±1 point" on a 4-point scale seems to be rather wide.

On the whole, the ANTS system appears to be a useful tool to further enhance assessment of nontechnical skills in anesthesia and other medical fields, and its careful derivation from a current system of nontechnical assessment in aviation (NOTECHS) may even allow some interdomain comparisons.

Performance-Shaping Factors

With a few exceptions, the foregoing discussion of the performance of skilled anesthetists has assumed that they are normally fit, rested, and acting in a standard working environment. Experience in human performance in the laboratory and other domains suggests that internal and external performance-shaping factors exert profound effects on the ability of even highly trained personnel. The degree to which performance-shaping factors affect the overall performance of anesthetists and the outcome of patients is highly uncertain. In extreme cases, such as profound fatigue, there is no question that these factors can result in severe degradation of the anesthetist's performance or even complete incapacitation. However, these extreme conditions are quite unusual, and it is unclear whether the levels of performance decrement likely to be induced in typical work situations have any significant effect. Although the practice of anesthesia does require an attentive and skilled individual, it does not require peak human performance. It would be unrealistic to expect peak performance for every anesthetic regimen because on the order of 60,000 anesthetic regimens are administered each day in the United States by a total of approximately 40,000 to 60,000 anesthetists. Although it is unrealistic to expect peak performance for every case, society expects anesthesiologists to come to work prepared—not impaired. As stated in the American Society of Anesthesiologists (ASA) guidelines for the ethical practice of anesthesiology, anesthesiologists have ethical responsibilities to themselves. The guideline goes further by stating that "the practice of quality anesthesia care requires that anesthesiologists maintain their physical and mental health and special sensory capabilities. If in doubt about their health, then anesthesiologists should seek medical evaluation and care. During this period of evaluation or treatment, anesthesiologists should modify or cease their practice."

With these caveats in mind, however, there are several performance-shaping factors that are potentially of sufficient magnitude to be of concern. Ambient noise, music, fatigue and sleep deprivation, aging, illness, drug use, and attitudes are discussed later. Several other issues that are not discussed include the level of illumination and environmental temperature. These factors can be shown to have a performance-shaping effect in the laboratory, but it is uncertain how much they affect performance in the OR. Currently, the responsibility for ensuring fitness for duty rests solely with the individual clinician. In HROs, the institution implements measures to mitigate performance-shaping factors.

Ambient Noise and Music in the Operating Room

The OR is a relatively noisy work environment.[153-156] Mean sound levels are considerably higher than in most offices or control rooms (continuous movement of air through an open surgical suction tip is a common source of continuous noise), and peak sound levels can be quite high. Some sources of noise are uncontrollable, such as surgical drills, monitor alarms, and inadvertently dropped instrument pans; other sources are controllable, such as conversation and music (see later). There is evidence in the general literature that noise can adversely affect human performance.[153] Furthermore, studies by Murthy and colleagues[157,158] demonstrated that volume-accurate replay of recordings of OR noise significantly interfered with the speech discrimination ability of anesthesia residents during laboratory testing. The OR noise also caused a significant reduction in residents' performance on psychometric tests of mental efficiency and short-term memory.[157] The potential interference of noise with communication and situation awareness among personnel in the OR is particularly worrisome to those concerned with optimizing teamwork in this complex work environment.

The use of music in the OR is now widespread. Many health care professionals believe that music enlivens the workday and can build team cohesiveness when all team members enjoy the music. A controversial study by two social psychologists, Allen and Blascovich,[159] suggested that surgeon-selected music improved surgeons' performance on a serial subtraction task and reduced their autonomic reactivity (i.e., "relaxed" them) when compared with control conditions consisting of experimenter-selected music or no music at all. The methodology of this study has been criticized.[160]

In response to Allen and Blascovich, several anesthesiologists challenged the notion that the surgeon's preference for the type or volume of music can or should override the needs of other members of the team.[160,161] This issue generated considerable controversy among surgeons and anesthesiologists. In a reply to some of the letters to the editor commenting on their study, Allen and Blascovich[162] stated: "The letters here suggest that not everyone on the surgical team always appreciates the type of music chosen by the surgeon, and anesthesiologists in particular appear to prefer silence in surgery. When we asked the surgeons in our study about this issue, we were told that the environment of surgery does not lend itself to the democratic process, and music was part of the environment in which they felt most comfortable."

Murthy and colleagues studied the effect of OR noise (80 to 85 dB) and music on knot-tying ability in a laparoscopic skill simulator. They found no difference in time or knot quality in the conditions tested and concluded that surgeons can effectively block out noise and music. Invited commentary that accompanied the article brings up important issues: what impact does noise have on other members of the surgical team, how does noise affect communication between team members, does noise affect judgment, and other unanswered questions.

There is no simple answer to the question of the proper role of music in the OR. Clearly, optimal patient care is the primary goal. Some surgical and anesthesia personnel explicitly forbid any type of music in the OR. A more common approach of many OR teams is to allow any team member to veto the

choice or volume of music if they believe that it interferes with their work.

Reading in the Operating Room

The observation that some anesthetists were observed to read journals or books casually during patient care led to a vigorous debate of the appropriateness of such activity.[163] Although it is indisputable that reading can distract attention from patient care, there are no data at present to determine the degree to which reading does distract attention, especially if the practice is confined to low-workload portions of a case. Furthermore, many anesthetists pointed out that reading as a distraction is not necessarily any different from many other kinds of activities not related to patient care that are routinely accepted, such as idle conversation among personnel. Many comments about the issue were related not to the actual decrement in vigilance induced by reading but rather to the impact of the negative perception of the practice (and of those who do it) by surgeons and by patients (if they were aware of it).

A noted researcher on human performance in anesthesia, Matt Weinger, was asked to comment on the practice of reading in the OR.[164,165] He pointed out that reading can combat boredom, which can be a significant distractor in its own right. He concluded that in the absence of data specifically on the topic, it is unscientific to condemn the practice outright, but that reading—like all other distractions—should not be allowed to impair vigilance and patient care.

In our training course on ACRM, we teach that the anesthetist is responsible for modulating all controllable distractions—for example, allowing music during routine work (if all agree) but eliminating it when the situation becomes complex or urgent. Similarly, although our own institutions do not have a policy against reading in the OR (or against casual conversation for that matter), we do expect the anesthetist to terminate all incidental activities when necessary and to have a very low threshold for abandoning potential distractions.

Sleep Deprivation and Fatigue*

General Principles

Scientists are discovering the importance of adequate sleep to allow normal human performance. A consensus report[166] by leaders in the field of sleep medicine stated the following:

> *[we] evaluated scientific and technical reports on the distribution throughout the 24-h day of medical incidents (such as heart attack and stroke) and performance failures (such as vehicular accidents and human errors in industrial and technical operations that can affect public safety). We found that these events occur most often at times of day coincident with the temporal pattern of brain processes associated with sleep. It thus appears that the occurrence of a wide range of catastrophic phenomena are influenced by sleep-related processes in ways heretofore not fully appreciated.*

This report goes on to give many examples of catastrophes that have occurred at least in part because of the effects of sleep deprivation and fatigue.

Investigations in other complex industries (aviation, nuclear power, maritime, long-haul trucking) have identified fatigue as the probable cause of or a contributing factor in many accidents. Unlike health care, the transportation industries have a body—the National Transportation Safety Board (NTSB)—that actively evaluates accident causation, including performance-shaping factors such as fatigue and sleep deprivation. By formal analysis, fatigue has been implicated in many famous accidents. For example, fatigue was a contributing factor in the Exxon Valdez grounding, the nuclear disasters at Three Mile Island and Chernobyl, and the decision-making process that led to explosion of the space shuttle Challenger. We have no such mechanism for evaluating fatigue causation in medical error, so what is not looked for will not be found.

Based on these findings, however, it is likely that chronic sleep deprivation, circadian rhythm abnormalities, and fatigue can be blamed for some iatrogenic adverse patient outcomes. As previously mentioned, the IOM report published in 1999 revealed that thousands of patients are harmed each year by preventable error. Some of these errors may have fatigue as a causative factor, and this should be an area of active study. However, it is difficult to determine the degree to which this is true because there is no blood test equivalent for level of impairment secondary to fatigue. Although these factors have long been minimized or ignored by health care professionals, an understanding of them is critical to maximize patient safety, as reflected in recently published reviews.[167,168]

Normal Sleep

Carskadon and coworkers[169] referred to sleep as a reversible behavioral state of perceptual disengagement from and unresponsiveness to the environment that is usually accompanied by postural recumbency, quiescence, closed eyes, and other indicators commonly associated with sleeping. Sleep can be thought of as a physiologic drive state similar to hunger or thirst and is necessary for maintenance of alertness, performance, and overall well-being. The intensity of this drive can be inferred by noting how quickly an individual falls asleep. Just as eating and drinking satiate hunger and thirst states, sleeping reverses the desire to sleep.

The amount of sleep required by any individual is genetically determined and is the amount that allows that individual to be awake and alert throughout the day. The average sleep time for young adults is 7 to 8 hours per 24-hour period, with an approximately 15% inter-individual variation. These sleep requirements do not change with age, and humans can do little to train their physiology to function optimally on less sleep than what is required.

Sleep Debt

If adequate sleep is not obtained for whatever reason, daytime sleepiness and impaired performance ensue. Sleep loss is cumulative and results in what is referred to as sleep debt. An individual who has obtained an optimal amount of sleep is better prepared to perform long periods of sustained work than one who is operating from a sleep debt.

*This section was co-written by Steven K. Howard, M.D., staff anesthesiologist, Veterans Administration Palo Alto Health Care System, and associate professor, Stanford University School of Medicine, Stanford, California.

Because of the additive effects of chronic partial sleep loss, even minor sleep restriction on a nightly basis can insidiously accumulate into a substantial sleep debt.[170] It is important that the only way to pay back a sleep debt is with sleep.

Sleep debts are commonplace in our culture. The National Sleep Foundation's annual survey continues to reveal that Americans chronically undersleep by 60 to 90 minutes each day (website: http://www.sleepfoundation.org/site/c.huIXKjM0IxF/b.3933533/). Shift work, long and irregular work hours, and the demands of family and recreation lead to irregular sleep patterns and prevent restful sleep. This is particularly true for physicians, who often work in shifts, have long duty periods, and must frequently care for patients for long periods.

Circadian Rhythms

Rhythms that fluctuate on a 24-hour time scale are known as circadian rhythms. The biologic clock that is responsible for these rhythms is located in the suprachiasmatic nucleus in the human brain. The best-known circadian rhythms are those of body temperature, hormone secretion, metabolism, and the sleep/wake cycle. The circadian system is synchronized to the 24-hour day by external stimuli referred to as "zeitgebers," the most influential of which is the light/dark cycle of day and night.

The circadian system is biphasic in that it produces a state of increased sleep tendency and decreased performance capacity during two periods throughout the 24-hour day—from 2 AM to 6 AM and from 2 PM to 6 PM. These periods are sometimes referred to as circadian lulls. The circadian clock is very resistant to alterations, and it does not adjust rapidly to changes such as those produced by jet lag or shift work. Disruption of the normal circadian rhythm or incomplete circadian adaptation leads to acute and chronic sleep deprivation, decreased alertness, increased subjective fatigue, and decreased physical and mental performance.[171]

Sleepiness and Alertness

Sleepiness and alertness are at opposite ends of a continuum. Daytime sleepiness is the most obvious effect of failing to obtain adequate sleep. Healthy adults are maximally alert by midmorning. This is sequentially followed by a circadian lull in the early afternoon (causing some cultures to incorporate an afternoon "siesta"), increased alertness in the early evening, and finally increased sleepiness that normally results in falling asleep at night.

The most extreme periods of sleepiness become manifest when one is out of sync with the circadian clock (either staying awake and working when our clock is pressuring sleep or attempting to sleep when our clock is pressuring wakefulness). Data from the U.S. Department of Transportation reveal that the greatest number of single-vehicle accidents takes place during the early morning hours when people are at a circadian lull of alertness. These accidents are thought to be due to inadvertent lapses in driver attention brought about by extremes of sleepiness.[172]

Determinants of Sleepiness

The major factors causing sleepiness are decreased quantity of sleep, poor quality of sleep (sleep fragmentation resulting from multiple awakenings or abnormal progression of sleep states and stages), disrupted circadian rhythms, and the use of certain medications. The amount of sleep obtained is directly related to daytime sleepiness. If sleep is restricted in healthy adults, daytime sleepiness can be demonstrated the following day.[170] If one is allowed to extend sleep beyond the usual sleep time, increased alertness can be demonstrated in the laboratory.[4] Sleep quality is affected by many factors. Sleep fragmentation affects the elderly and patients with sleep disorders such as sleep apnea and periodic limb movements. Sleep fragmentation commonly occurs in physicians who are awakened from sleep to care for patients while in the hospital.

Caffeine[173] and other stronger stimulants are known to reduce nocturnal sleep if ingested close to bedtime, hence decreasing sleep quantity and quality. Potent stimulants such as amphetamines do produce increased alertness and performance, but they have significant side effects and are not an option for health care personnel (e.g., the individual must undergo a substantial amount of recovery sleep ["crash"] after their effect is gone). Newer, nonamphetamine alertness-enhancing drugs (e.g., modafinil) are currently under study and being used in shift workers, including health care workers (see "Fatigue Countermeasures").

Mood

Long work hours, fatigue, and sleep deprivation have also been shown to bring about consistent and dramatic changes in mood and emotions.[174,175] Depression, anxiety, irritability, anger, and depersonalization have all been shown to increase during testing of chronically fatigued house staff. These emotions are an obvious source of stress between anesthetists and their coworkers, patients, and families. The relationship of mood, performance, and patient safety has yet to be determined.

Vigilance

Vigilance, the centerpiece of the ASA logo, is defined as "alert watchfulness." Vigilance is critical, although studies of the performance of anesthesiologists make it clear that vigilance is not the only key characteristic of careful anesthesiologists. Vigilance is a necessary, but not sufficient condition to permit the safe passage of a patient through the perioperative period. If vigilance and other aspects of decision-making are impaired by performance-shaping factors such as sleep deprivation and fatigue, there is a greater likelihood of an adverse patient outcome.

Monitoring of slowly changing stimuli is a classic vigilance task that makes up a significant proportion of the anesthetist's work. This type of task is most sensitive to the degrading effects of sleepiness and fatigue. During the performance of lengthy vigilance tasks, the most common types of decrements include increased reaction time, lapses (transient periods of unawareness), and a reduction in the probability of detecting an alarm. This type of performance impairment has been documented after as little as 30 minutes of time on a task, and the decrement is even more pronounced if the individual is physiologically sleepy at the beginning of the task.

Microsleep Events

The most extreme cause of impaired vigilance is the occurrence of actual sleep episodes (microsleeps) encroaching into periods of wakefulness. Microsleep events typically last a few seconds to a few minutes. They are intermittent in onset, and their impending occurrence is difficult for the individual to predict. Most individuals underestimate their level of sleepiness when they can be objectively shown to be extremely sleepy, thus making this problem even more insidious. In other words, one can fall asleep and not be perceptually aware of it. This has significant meaning in the workplace and when driving home after long work periods. Microsleep episodes are the probable cause of many single-vehicle crashes.

Microsleeps are a sign of extreme sleepiness and are harbingers of the onset of longer sleep periods. Typically, they occur during periods of low workload or stimulation and when an individual is maximally sleepy. In addition, an individual's performance between microsleep episodes is impaired. Frequent and longer microsleeps increase the number of errors of omission.

Driving while drowsy may be less forgiving than practicing medicine while drowsy. It is easy to imagine that if a driver has a microsleep for only seconds while traveling at 60 miles per hour, there is a high likelihood of an accident. Although the anesthetist's work environment does not (usually) evolve as fast as that of the driver, the safety implications of falling asleep while providing care are similarly obvious.[176]

Scientists at the NASA Ames Research Center studied the occurrence of microsleep episodes in pilots during transmeridian flights.[177] These flights involve multiple time zone changes with long, irregular work schedules and resultant disruption of circadian rhythms. This situation causes fatigue, sleepiness, and decreased performance, which are believed to have an impact on flight safety. This particular protocol compared two pilot groups flying equivalent flights: a control (non-nap) group and a nap group. Electroencephalographic monitoring of the pilots was performed to determine the extent of microsleep episodes and also to document whether pilots were actually able to nap if given the opportunity. In brief, the study revealed that (1) crew members were able to nap seated in the cockpit if given the opportunity, (2) the non-nap crew had significantly more microsleep episodes during critical phases of flight than the crew that had napped did, and (3) performance on a standardized test of visual reaction time was worse in the non-nap group than in the group that had napped. This study demonstrated that microsleeps do occur even in a work environment in which sleep is strictly forbidden and in which work hours are tightly regulated. Napping appears to be a reasonable countermeasure to decrease the likelihood of microsleeps and improve performance. Other work on napping supports these conclusions.

Do anesthetists suffer microsleep events? The answer almost certainly is yes. Anecdotal evidence, as well as unpublished reports from our own surveys, suggests that these events do occur from time to time. Microsleeps occurred in a study of anesthesiologists performing work in a simulated environment.[178]

Shift Work

From a practical standpoint, shift work will remain a common method to provide 24-hour care in the hospital setting.[179-181] Workers and managers should learn how circadian factors, sleep-related factors, and social factors affect the lives of workers and their families. Hospital organizations should make it a priority to establish that workers are appropriately rested, just as they try to ensure that workers are not impaired by drugs or alcohol on the job. Given current knowledge concerning shift work and the many factors that affect an individual's ability to cope, there is no single "best" schedule for shift work. Some workers tolerate systems that others find excessively onerous. If given a choice, many workers choose suboptimal shift work rotations when doing so gives them increased pay or more time off work.

Methodologies for Assessing Sleepiness

There are various methods for assessing an individual's level of sleepiness, including behavioral indicators, subjective measures, and physiologic measures. Behavioral indicators of sleepiness include yawning, ptosis, decreased social interaction, and microsleep events. Many of these behaviors are difficult to quantify.

Subjective measures include various types of numeric or visual analog scales that attempt to measure how sleepy the individual feels. These methods are used frequently in studies of sleepiness because they are very easy to implement; however, subjective feelings of fatigue and sleepiness are often underestimated by individuals in comparison to their level of physiologic sleepiness. Both behavioral and subjective sleepiness can be masked by a stimulating environment, even though the individual remains physiologically sleepy. When environmental stimuli wane, physiologic sleepiness manifests itself as an overwhelming propensity to fall asleep. A person who is physiologically alert does not experience sleepiness as environmental stimuli decrease. For example, without physiologic sleepiness, an individual may become bored during a lecture but does not fall asleep.

Physiologic (objective) measures of sleepiness have been used extensively in sleep research and sleep medicine. Carskadon, Dement, and colleagues[182,183] developed the Multiple Sleep Latency Test (MSLT), which is now the standard method for quantifying daytime sleepiness. The MSLT tests the propensity of an individual to fall asleep in a sleep-inducing environment during the daytime. A short sleep latency (i.e., falling asleep quickly) is a sign of increased sleepiness, whereas a long sleep latency is a sign of decreased sleepiness. A normal MSLT score is greater than 10 minutes, whereas pathologic daytime sleepiness is defined as 5 minutes or less. Pathologic levels correspond to the daytime sleepiness typically seen in patients with narcolepsy or sleep apnea or in healthy individuals deprived of sleep for 24 hours.

Evaluation of Physiologic Sleepiness in Anesthesia Residents

Using the MSLT, Howard and colleagues[168,184] evaluated the physiologic daytime sleepiness of anesthesia residents under three different conditions: (1) "baseline" (daytime shift, no on-call duty period in the previous 48 hours), (2) "post-call" (immediately after a 24-hour work and in-house on-call period), and (3) "sleep extended." In the sleep-extended condition, residents were told to maximize sleep and were allowed to arrive for work at 10 AM (3 to 4 hours later than normal) for 4 consecutive days before testing. They were not on call during this time. The sleep-extended condition was included to provide a true control state of maximal rest and optimum alertness.

In this study, anesthesia residents had an MSLT score of 6.7 ± 5.3 minutes in the "baseline" condition and 4.9 ± 4.7 minutes in the "post-call" condition, both scores revealing the nearly pathologic levels of daytime sleepiness seen in patients with narcolepsy or sleep apnea. The "baseline" group slept an average of 7.1 ± 1.5 hours per night, whereas the "post-call" group reported an average of 6.3 ± 1.9 hours of sleep during their night on call. Ironically, although the on-call periods occurred during rotations that often have very busy call nights, only a few subjects were, in fact, awake most of the night. In the "sleep-extended" condition, the subjects extended their sleep to an average of more than 9 hours per night, and MSLT scores were in the normal range (12.0 ± 6.4 minutes). These results clearly demonstrate that medical personnel who have not been on call cannot be assumed to be "rested" when compared with "fatigued" post-call residents. These data also indicate that under "normal" working conditions, the resident physicians studied were physiologically sleepy to nearly

pathologic levels. This finding documents a previously unknown level of chronic sleep deprivation in this population. Notably, these data cast substantial doubt on previous studies of the performance of medical personnel that have relied on the assumption that individuals working under "normal" conditions are truly rested.

Evaluation of Subjective Sleepiness

In the previously discussed study, Howard and colleagues also investigated the degree of discrepancy between the residents' subjective sleepiness (how sleepy they felt) and their physiologic sleepiness (how easily they fell asleep). Subjective sleepiness was measured with a validated numeric scale (Stanford Sleepiness Scale); physiologic sleepiness was measured with the MSLT, as described earlier. Subjects' self-reported sleepiness immediately before each sleep opportunity during the MSLT did not, in general, correlate with their MSLT score. As in previous studies, subjective sleepiness correlated better with physiologic sleepiness when subjects were extremely alert or extremely sleepy.

The authors also found that subjects demonstrated little ability to determine whether they had actually fallen asleep during the MSLT sleep opportunities. For example, in 51% of trials in which the electroencephalographic/electro-oculographic measurements showed that the subject had fallen asleep, the subjects thought they had remained awake throughout the test. These results support the contention that medical personnel are physiologically vulnerable to degraded alertness yet are unable to perceive this decrement. Thus, an anesthetist could, in fact, fall asleep during a case, awaken, and be totally unaware of the lapse in vigilance.

Sleep Deprivation and Fatigue in Medical Personnel

Human error represents a significant risk to hospitalized patients,[3] and it has been estimated to play a role in more than 70% of anesthesia mishaps.[185] This is similar to the error rate seen in cognitively similar work environments such as aviation.[186] Clearly, the physiologic capabilities and limitations of the human operator in complex work environments remain central to safe and productive performance. The 24-hour demands of medical care parallel the physiologic challenges present in other operational domains; nevertheless, minimal data are available to quantify the fatigue-related risk to performance and alertness in medical personnel.

Providing quality health care requires physicians to attend to details critical for life, such as monitoring of changing vital signs, administering the correct type and dose of medications, and in general, making crucial decisions to achieve optimal patient care. Physicians, like other workers, are affected by all the physiologic, psychological, and behavioral demands that characterize work environments requiring continuous, around-the-clock operation. However, whereas much of the health care system (e.g., nursing) relies on multiple work shifts to cover the 24-hour day (which is also not a perfect system), physicians more typically work long duty periods and frequently experience sleep loss, circadian disruption, and fatigue. Even minimal levels of sleep loss (for example, obtaining as little as 2 hours less sleep than an individual requires) can lead to lapses in performance, increased physiologic sleepiness during the daytime (including microsleeps), and altered moods.[187] This level of degraded performance and alertness almost certainly contributes to medical error and health care mishaps.[167]

Work Hour Regulations

In July 2003, The Accreditation Council for Graduate Medical Education in the United States instituted common duty hour requirements for all accredited residency training programs. The requirements can be found at www.acgme.org and are as follows:

- Eighty hours per week, averaged over a period of 4 weeks (including all in hospital call)
- One day (continuous 24-hour period) in 7 free of all duties (clinical and educational) averaged over a 4-week period
- In-hospital call occurring no more frequently than every third night averaged over 4 weeks
- In-hospital call not to exceed 24 hours; residents may remain on duty for 6 additional hours to participate in educational activities, transfer care of patients to another team, conduct outpatient clinics, and maintain continuity of care
- No new patients accepted after 24 hours of continuous duty
- Provision of a 10-hour period between all daily duty periods and after in-hospital call
- Moonlighting hours to be included as part of the 80-hour limit
- Exceptions: a residency review committee may grant exceptions for up to a 10% increase in the 80-hour limit to individual programs on a case-by-case basis

Training programs were given little direction on how to accomplish the work hour restrictions, but most anesthesiology training programs have been able to successfully adopt them. Interestingly, there are no work hour restrictions for practitioners or any other care providers beyond residency training. There is no proof that the change has had a positive or negative impact on patient or provider safety, although pundits continue to debate both sides of the issue.[188,189] Recent studies show that the number of hospital-wide adverse drug events remained constant after the limitations[190] and that postoperative outcomes were not affected in the programs studied.[191]

Compliance rates for the common program requirements have been tracked by Landrigan and coworkers.[192] In a survey of interns, they found that more than 80% reported some kind of work hour violation during 1 or more months of the study. Average work duration decreased and sleep time increased when compared with an equivalent time before duty hour limits. Reporting of compliance by individual residents is complicated by many factors, so the true amount of work being performed is not known. Many surgical programs have requested and been given a 10% work hour extension, but it is not known how many of these requests have been turned down.

European and Australian Regulations

Work hours regulations in the European Union and in Australia/New Zealand are much more stringent than they are for trainees

in the United States. In 2009, the maximum hours that junior medical staff in the National Health Service (NHS) in the United Kingdom work will be reduced from 58 to 48 under European law. This is a major challenge for the health service and will require new ways of working to be adopted. The NHS National Workforce Projects has been appointed as the lead organization to help support the NHS in finding and implementing solutions to the changes in the work environment (http://www.healthcareworkforce.nhs.uk/). The results of these restrictions on patient and provider safety are still being evaluated, and these findings may have an impact on any further restrictions that may occur in the U.S. system. Empirical studies documenting the effect of the European Union changes are lacking, although there are several argumentative pieces for and against the directive.[193,194]

Harvard Work Hours, Health, and Safety Group Studies

A series of interesting studies has been published recently by a group from the Brigham and Women's Hospital.[195,196] The investigators conducted a randomized study comparing interns working in an ICU on a traditional schedule (every third night on call with shifts longer than 24 hours in duration) and an intervention schedule that reduced work shift duration (to less than 17 hours) and the number of hours worked per week. Interns made 35.9% more serious medical errors and had twice as many attentional failures (microsleeps) during the traditional schedule. Those on the traditional schedule worked more hours per week (85 versus 65 hours) and slept less (5.8 hours), which led the investigators to conclude that elimination of long work shifts reduced errors and decreased manifest sleepiness.

This group also conducted a monthly prospective nationwide survey of interns' first postgraduate year to evaluate the risk for motor vehicle accidents with extended work shifts.[197] They found an increased likelihood of motor vehicle accidents and near-miss accidents after extended work shifts and an increased monthly risk with increasing number of shifts.

Sleep and Performance

Previous studies addressed the effects of sleep deprivation and fatigue on physician performance and well-being. Major reviews of this literature identified little consensus.[198,199] There are several methodologic flaws in the existing literature:

1. The degree of acute sleep deprivation of subjects was poorly defined, and no assessment of chronic fatigue was made. Typically, studies relied on only the previous night's sleep as a level of "fatigue," and subjects could well have been chronically fatigued during baseline (control) trials, which could mask the degree of impairment resulting from the acute fatigue of being on call. This continues to be the greatest weakness in studies of fatigued health care providers.
2. Measuring actual clinical performance is difficult and was not attempted. Most studies had to rely on simple cognitive tasks that probed only short-term memory, immediate recall, and simple reaction time; the validity of using such simple tests to probe complex performance has been challenged because these simple tests do not assess the higher-level cognitive functions most critical to skilled medical care.
3. Most of the performance tests were of very short duration (3 to 5 minutes). Studies have shown that if sufficiently motivated, even fatigued subjects can perform well on short-duration tasks.
4. Practice effects were not adequately accounted for. If subjects have not learned a particular performance test sufficiently to achieve maximum performance, subsequent trials will almost certainly show improvement in performance because of further learning of the task.

Some studies requiring subjects to perform sustained vigilance tasks of long duration have, in fact, shown an impairment in the performance of fatigued physicians. Tasks of this type, which require sustained attention to detail, are highly relevant to the anesthetist's tasks, and they are the most sensitive to the effects of sleep loss and fatigue.

Do Anesthesiologists Perceive Fatigue As a Problem?

The survey by Gaba and associates[200] revealed that more than 50% of respondents believed that they had made an error in clinical management that they thought was related to fatigue. In another survey of anesthesiologists and CRNAs, the majority (61%) of respondents recalled having made an error in the administration of anesthesia that they attributed to fatigue.[201] Data from these surveys and others[202] reveal that issues of sleepiness and fatigue are perceived by anesthesia practitioners as being important causative factors in reducing anesthesia-related patient safety.

Howard and colleagues[178] conducted a study of rested versus sleep-deprived anesthesiology residents using a realistic patient simulator. Multiple measures of performance were collected during this 4-hour experiment (e.g., psychomotor tests, reaction to secondary task probes, response to clinical events). In the rested condition, subjects had 4 consecutive days of sleep extension (showing up at work at 10:00 AM), whereas in the sleep-deprived condition they had remained awake for 25 hours (during a "pseudo"–on-call period) before performing the simulated anesthetic. Subjects in the rested condition were able to increase their total sleep time more than 2 hours from baseline. Psychomotor tests revealed progressive impairment of alertness, mood, and performance over the course of the pseudo–on-call period, as well as on the experimental day, when compared with the well-rested condition. Secondary task probe response times were slower after being sleep deprived, although this reached statistical significance in just one of three probe types. There was no statistical difference in case management between conditions—in fact, subjects in both conditions made significant errors. The behavioral alertness scores in the sleep-deprived condition were different from those of subjects who had increased their sleep time. Even when well rested, the subjects in this experiment did not perform perfectly; however, they did not show any of the behavior indicative of being sleepy (e.g., head nodding, eyes closing). Sleep-deprived subjects cycled (often rapidly) in and out of sleepy behavior, and the most impaired individuals showed such behavior for more than 25% of the experiment (60 minutes).

Fatigue Countermeasures

Studies such as the ones described previously are establishing the true picture of sleepiness and fatigue in medical personnel. From studies of the performance of fatigued individuals in other domains, we know that professionals become increasingly vulnerable to the degrading effects of sleepiness as the sleep debt accumulates. It may be difficult to determine a causal relationship between anesthetist fatigue and patient outcome. However, it is clear that if anesthetists are not awake, they cannot possibly be aware. Such a lapse in vigilance is unacceptable. Furthermore, anesthetists cannot prevent sleep by willpower alone because it is a fundamental physiologic drive. Demands for clinical services must be balanced against the potential for reduced vigilance and error by seriously fatigued practitioners, anesthetists, and surgeons alike.

Because fatigue is such a widespread and insidious problem, it is important to determine ways to counteract its effects. Strategies that institutions or practitioners can use to minimize the negative effects of sleepiness and fatigue on performance, include

- Education
- Improved sleep habits
- Rest breaks at work
- Strategic napping
- Medications
- Light therapy

Education

The first step in addressing sleepiness and fatigue of medical personnel is to educate practitioners and the administrators of health care institutions about the impact of sleep issues on work performance, mood, job satisfaction, and health (see Chapter 8). Education is a relatively simple and inexpensive countermeasure that can be implemented immediately. Educational programs covering sleep deprivation, circadian disruption and fatigue, and countermeasures have been enthusiastically adopted by an increasing fraction of the aviation community.[203,204] Similar programs should be developed for the health care community. Education alone is sufficient for some individuals and institutions to change their work and sleep habits or their organizational and scheduling procedures. However, it is clear at both the individual and organization level that education will not be sufficient to address this issue fully. Other competing forces (e.g., measures of production versus safety) are very powerful and difficult for practitioners to manage.

Improved Sleep Habits

Good sleep habits include the following: regularity of bedtime and wake-up time; sufficient time for sustained and individually adequate sleep; restriction of alcohol, caffeine, and nicotine before bedtime; and use of exercise, nutrition, and environmental factors so that they enhance rather than disturb sleep. A regular sleep schedule is an important part of optimal sleep hygiene, but it is often not possible for medical personnel, given the requirement to cover clinical needs on a 24-hour basis. Medical personnel should make greater effort to maintain as constant a sleep schedule as possible and to maximize sleep opportunities before and after periods of reduced sleep.

Social drug use can have profound effects on sleep. Physicians frequently use caffeine to stay awake during on-call periods, but often its use could be more strategic. Strategic use (i.e., use when its alerting effects are needed) of caffeine requires knowledge about its onset and duration of action. Besides its alerting effects, caffeine produces an increase in awakenings and decreases the total nocturnal sleep time if ingested close to sleep opportunities. Individuals who ingest large amounts of caffeine and who have nocturnal sleep disturbances should limit or cease their intake of caffeine. Chronic use of caffeine, common in our culture, produces tolerance to the alerting effect of the drug, and hence it should be avoided when using it strategically. Nicotine is a stimulant that produces effects similar to those of caffeine. Alcohol is often used successfully to initiate sleep, but its effect on sleep architecture after sleep onset can be devastating. After ingestion of alcohol, frequent awakenings from sleep occur that can be associated with increased sympathetic nervous system activity, often manifested as headache, sweating, and tachycardia. Clearly, use of these substances should be restricted near bedtime.

Physicians often lack good nutritional habits, especially during long duty periods. Meals may be skipped or ingested quickly whenever there is adequate time. If one is hungry before bedtime, it is best to avoid eating or drinking heavily because this, too, can disturb sleep.

The effects of age can make optimum sleep habits difficult to achieve because sleep requirements do not change once reaching adulthood. The number of awakenings per night rises after the age of 45 years and results in decreased sleep efficiency (time in bed versus total sleep time). The ability to initiate sleep at any time during a 24-hour day is diminished after the age of 25 years, and "sleeping in" to make up for lost sleep is more difficult as individuals grow older. Sleep-related disorders such as breathing disruptions (obstructive sleep apnea) and periodic limb movements also become more common with age.

Ideally, the sleep setting should be a dark, quiet room devoid of sources of interruption such as pets, telephones, pagers, and children. The sleeping surface and environmental temperature should be comfortable. Psychological stressors increase baseline physiologic arousal and can impair the quality and quantity of sleep. For example, reviewing the previous day's events or attempting to plan tomorrow's activities while trying to fall asleep is not conducive to sleep. Effort should be made to separate the work of the day with a period of relaxation before attempting to initiate sleep.

Rest Breaks at Work

Although other industries have openly recognized the reality of decrements in vigilance resulting from fatigue and sleepiness, the health care system has not. Rest breaks and rotation of task duties are mandatory for air traffic controllers and are part of naval ship command procedures in an attempt to prevent potential lapses in vigilance. Short breaks have been shown to increase productivity and job satisfaction, and they probably also help alleviate boredom. In anesthesia training programs, residents are frequently given rest breaks during the daytime, but this is often not the case with private practitioners. Private practice anesthesia typically does not provide the mechanisms for rest breaks or task duty rotation, in part because of fiscal issues. An "extra" anesthetist would be necessary to provide these opportunities on a regular basis.

The optimal timing and length of breaks are unknown, but periodic relief from duty should be taken when possible. Cooper and coworkers[205,206] studied the effects of intraoperative exchange of anesthesia personnel. Although in some cases the process of relieving OR personnel caused a problem, it more frequently was

associated with the discovery of a preexisting problem. The positive effect of relief of personnel probably depends on the quality of the handover briefing conducted by anesthetists. Studies are currently being performed to address standardized handover of intraoperative care of patients.

If anesthetists are unable to obtain a break during long work periods, there are other measures that they can take to remain alert. They can engage other OR personnel in conversation (although this, too, can be distracting), thereby increasing the level of stimulation in the environment. Walking around and standing up are also techniques that decrease subjective (but not physiologic) sleepiness. If anesthetists are having microsleep events, which may be noticed by other personnel rather than by the anesthetists themselves, fatigue is already very severe, and complete sleep is imminent. In such a situation the practitioner must secure additional assistance in surveillance of the patient and, if necessary, obtain relief to allow time for sleep.

Strategic Napping

If adequate sleep during the night cannot be obtained, naps can be used to decrease sleepiness and improve performance. The optimal nap length for most individuals is about 45 minutes; this duration acutely improves alertness, allows improved performance, and minimizes the possibility of sleep inertia on awakening. Naps as short as 10 minutes have beneficial effects on alertness. A nap of 90 to 120 minutes allows a full sleep cycle and can additionally boost alertness and performance over that of shorter nap periods. Data from NASA studies of flight crews demonstrate that on the whole, napping is a useful countermeasure to fatigue and sleep deprivation.[177]

Smith-Coggins and associates studied the effect of naps during the night shift on health care providers working in a busy suburban university emergency department.[204] Workers were randomized to work a night shift without rest (as was the norm in this facility) or to receive a 40-minute nap opportunity at 3 AM. They found that a nap taken at this time improved performance on some (but not all) measures. The most important result of this study may be the fact that the subjects were able to (1) successfully use this strategy in the real workplace and (2) improve alertness and performance.

Investigators in the Veteran's Hospital at Palo Alto, California, have developed a Strategic Nap Program that has been successfully piloted at two sites within the Veterans' Administration system. This program has been implemented in ICU settings but is equally applicable to other high-risk, dynamic domains such as the OR. Components of the program include a formal educational program, program guidelines for the individual practitioner and the facility, and other guidance for implementation.

There are issues that complicate the appropriate use of naps by medical professionals. Physicians have an individual and cultural tendency to ignore or to minimize the effect of fatigue and sleep deprivation. The culture of medicine views work breaks and naps as signs of weakness. The military has addressed similar attitudes with the concept of "power napping." Troops are strongly encouraged to take naps of 10 minutes to 1 hour when the situation permits to increase their strength and performance. This approach appropriately presents the idea of napping in a positive light as a sign of wisdom and strength rather than one of cowardice and frailty.

Sleep Inertia

Sleep inertia corresponds to the period of reduced ability to function optimally immediately on awakening.[190,207] This phenomenon usually occurs when individuals are awakened out of slow-wave sleep and is manifested as grogginess and impaired performance lasting as long as 15 to 30 minutes after awakening. Sleep inertia can also occur after being awakened from normal sleep and is most common during the early morning circadian trough (2 to 6 AM). Depending on the preexisting level of sleepiness, individuals who take naps longer than 40 minutes are at greater risk for sleep inertia on awakening. Sleep inertia can be important to health care professionals who may be awakened out of deep sleep to provide emergency care to patients (e.g., emergency cesarean section or emergency intubation). If urgent work can be anticipated, the sleeping individual should be awakened with sufficient time (at least 15 minutes) to minimize the fogginess and decrement in performance associated with sleep inertia. If sleep inertia is unavoidable, it would be wise for the affected person to ask for help until the grogginess dissipates.

Medications

A few studies have evaluated the use of sedative-hypnotics for promotion of sleep during nonduty hours by nonmedical personnel (e.g., to assist in daytime sleep after a night shift). Many questions remain unanswered regarding the quality of sleep obtained after using hypnotics, the severity of hangover effects, and the potential risk of abuse. Melatonin, which is a hormone secreted by the pineal gland, may have promise as a nonaddictive daytime sleep-inducing agent, but the results of existing studies are controversial.

Stimulants may have a role in the maintenance of alertness during periods of extreme sleepiness. Modafinil is a nonamphetamine alertness-enhancing drug that has been approved for use in narcolepsy and shift work sleep disorder.[208] The side effect profile of this drug is so promising that it has been studied extensively by the military and shift workers as a nonaddicting adjunct for alertness management. Its use in health care is also being studied but cannot be sanctioned at this point.[209] The use of sedatives and potent stimulants to manipulate sleep is not considered an appropriate option for anesthetists. Caffeine is used frequently to increase alertness temporarily, but there are caveats about its use, as discussed earlier. Caffeine should be used strategically to maximize its effect when needed. Strategic use of caffeine includes (1) knowledge of its onset (15 to 30 minutes) and duration of action (3 to 4 hours) and (2) use when alertness is required and the opportunity to sleep is minimal.

Countermeasures should be studied and implemented in health care. There are major financial incentives to maintain the status quo.[167] If anesthesiologists know that they are impaired (from fatigue or for any other reason), the assistance of a colleague should be enlisted so that patient safety is not negatively affected.

Light Therapy

Timed cycles of bright light and darkness have been used in certain circumstances to facilitate adaptation to shift work. Exposure to bright light (>7000 to 12,000 lux) and darkness at the appropriate points in the circadian cycle has been shown to reset the circadian pacemaker by 12 hours over a period of 2 to 3 days.[210] This important finding demonstrates the ability to make significant changes in the circadian system relatively quickly. However, resetting the circadian timekeeper is critically dependent on the timing, intensity, and duration of exposure to light and to "total" darkness. Being off by only an hour can prevent the desired effect. Adhering to such time-critical schedules for this

treatment is probably impractical for anesthetists given the many work-related and social factors that affect their activities. Research on light treatment continues and may eventually result in more practical treatment regimens.

Aging

All individuals understand that their abilities cannot be maintained indefinitely as they age. On average, performance on laboratory tests of discrete sensory-motor and cognitive skills can be shown to decrease with increasing age.[211] However, there are large differences among individuals. Again, except at extreme points of performance failure (e.g., severe impairment of vision or hearing), the contribution of isolated changes in physiologic or cognitive performance is difficult to relate to real work situations.[212] For one thing, the work environment is often rich with redundant cues involving multiple sensory modalities. For another, technologic compensation may be possible, as with the use of hearing aids or glasses. Finally, along with possible physiologic changes of age typically comes greater experience with a variety of situations. For many individuals, the lessons learned from experience more than offset the modest degree of physiologic impairment that they face as they grow older. This compensation has, in fact, been documented for skilled typists, chess players, and bridge players. Middle-aged individuals can use their experience to solve everyday problems better than young individuals can; however, for the elderly (on average), compensation by experience is no longer sufficient to offset cognitive slowing.[212] Age takes a toll on short-term (or "working") memory,[213] and there is evidence that aged workers are more sensitive to the interruptions in attention that are so prevalent in dynamic environments. Nevertheless, few of these deficits have been documented in complex work settings, largely because it is so difficult to measure performance in these domains. The issue of the aging anesthesiologist has raised considerable controversy among anesthesiologists.

What do other industries do about this issue? From 1959 until the end of 2007, U.S. and aviation regulations forced airline pilots to retire at age 60 regardless of their health or competence. When the "Age 60 Rule" was put in force, the rationale was that the "increased speeds and passenger loads of commercial airliners placed greater demands on pilots with respect to their physical fitness and piloting skills." Some may argue that the increasingly challenging nature of anesthesia practice also places greater demands on anesthetists than ever before.

After intense debate and many studies over the last 30 years,[54,214] with partially contradictory studies and little data suggesting that pilots between the ages of 60 and 65 are at greater risk, the Age 60 Rule was modified by law (HR 4343) at the end of 2007. The new rule allows airline pilots to continue flying until age 65, although for captains in international operations, a pilot younger than 60 years must be the copilot.

Federal Aviation Administration (FAA) regulations do require air transport pilots to pass "class I" medical examinations every 6 months. However, the medical examination process appears to be largely aimed at identifying individuals with chronic medical conditions that place them at risk for sudden incapacitation (such as significant coronary heart disease). Pilot incapacitation during high-workload phases of flight has been shown in simulator testing to lead to a significant rate of crashes, even when there is a second pilot at the controls. These physical examinations may weed out pilots with severe cognitive or sensory-motor deficiencies, but they are not designed to assess subtle aspects of changes in performance resulting from age. Of course, there are no requirements whatsoever for medical examination or certification of anesthetists, nor is there any limitation on the practice of anesthesia at any age.

It is likely that age alone does not independently cause a significant decrement in performance, but age correlates with other factors that are likely to affect performance. The concern about aging professionals revolves more around the loss of knowledge and skill as one gets farther from initial training rather than the loss of fundamental mental capacity. Thus, the originally well-trained practitioner who keeps abreast of the changing standard of care and who exercises emergency skills frequently is less likely to be affected by advancing age than is a marginal practitioner whose knowledge and skills were frozen immediately after completion of training and who practices in a low-complexity environment. The FAA regulations deal with this issue for air transport pilots by requiring frequent (every 6 months) evaluation of performance by FAA-certified check pilots. These evaluations are performed during actual flights and in realistic simulators, and they, in essence, check fitness for duty regardless of age. There is currently no similar program in anesthesia to assess the competency of practitioners at any age, except for initial board certification, which is voluntary. Periodic maintenance of certification in anesthesiology is now required by the American Board of Anesthesiology for diplomats attaining certification after the year 2000, but it is not mandatory to be board-certified to practice anesthesia, and the recertification examinations are not as intense, as thorough, or as frequent as those required for air transport pilots. Thus, the issue of age-related effects on anesthetist performance is likely to continue to be raised periodically for the foreseeable future.

Illness and Drug Use

Every anesthetist is vulnerable to transient illnesses, which in some cases probably reduce performance ability (see Chapter 101). All personnel are vulnerable to chronic medical conditions that could directly or indirectly affect their fitness and performance capability. The culture of the caring professions often leads individuals to continue to work with illnesses that would cause other professionals to stay at home or to seek medical advice. The performance-shaping effects of the illness can be exacerbated by the use of either over-the-counter or prescribed medications. The degree to which illness and medications affect anesthetist performance is unknown.

A serious problem for anesthetists is that of drug abuse (see Chapter 101).[55,56,215-218] It is estimated that up to 8% of physicians could be classified as alcoholics. In an anonymous survey of anesthesia personnel from one institution, 75% of respondents reported drinking alcohol on a regular basis. They reported drinking an average of 1.6 drinks per day 2.7 days per week. Just less than 10% of subjects reported having been "hung over" while conducting anesthesia, and 40% reported having given anesthesia within 12 hours of alcohol consumption; 84% stated that alcohol use never adversely affected their clinical performance.

The degree to which small doses of alcohol or hangovers affect the performance of complex, real-world tasks is uncertain. Some studies of general aviation and navy pilots[54,219-221] suggested that hangover effects can degrade performance even when more than 8 hours has elapsed since alcohol consumption and there is no detectable blood alcohol level. Nonetheless, though statistically significant, the changes in performance seen in these studies

may not have been functionally significant. These studies[54,219-221] also suggested an interaction among age, workload, and hangover in causing decrements in performance. However, the "aged" cohort was defined as 31 years or older and was compared with a cohort of pilots in their early 20s. Extrapolating these results to the anesthesia domain is difficult.

Nevertheless, the natural history of serious abuse of alcohol, cocaine, sedatives, or narcotics by anesthetists is such that cognitive performance will at some point be seriously compromised. However, addiction specialists frequently report that job performance is one of the last areas of life to become impaired.[222,223] For this reason, the period of time in which an addicted anesthetist's performance in the OR is significantly impaired is a relatively small fraction of the total time during which drugs are abused. Although this in no way excuses the practice of conducting anesthesia while under the influence of drugs, it may account for the fact that reports of addicted anesthesiologists are, unfortunately, common whereas reports of overt patient risk or harm resulting from an addicted physician's errors are unusual.

Anesthesiology has been at the forefront in dealing with impaired medical personnel. Management of those discovered with a drug impairment is fairly standardized,[216,224] but the question of whether to return these individuals to anesthesia practice is increasingly controversial, even when they return under carefully monitored reentry protocols.[216] The main risk appears to be to the addict's own safety, although questions about patient safety can never be eliminated.

Ultimately, in the current medical system the responsibility rests with anesthetists to ensure that their own performance level is sufficient for the work at hand. Pilots use a mnemonic checklist to review the effects of potential performance-shaping factors and are instructed not to fly if they are impaired for any reason. The difficulty in anesthesiology (and to some degree in aviation) is that the real-world organization and incentives of many practice settings do not provide mechanisms for personnel to excuse themselves if they are temporarily impaired. Ironically, there may now be better means to identify and support a practitioner with a serious addiction than there are for the more common occurrences of profound sleep deprivation or impairment by a transient or chronic illness.

The Study of Human Performance

Study of human performance involves research paradigms that are different from those typically used in the science of anesthesia. There are many obstacles to obtaining hard, statistically valid data on human performance. There are no animal models for expert human performance, no "Sprague-Dawley anesthesiologists" to be studied in detail, nor can studies of professional performance be conducted with the psychologist's typical experimental subject, the university undergraduate student. Recruiting expert anesthetists to be the subjects of study is difficult and raises issues of selection bias concerning those who do volunteer. Especially if conducted during actual patient care, investigations of human performance are strongly influenced by concerns about litigation, credentialing, and confidentiality, thus making it difficult to execute optimal studies.

Furthermore, variability among individual anesthetists is quite striking because different anesthetists respond to the same situation in different ways and each individual may act differently on different days or at different times of the same day. The magnitude of this intra-individual variability is often nearly the same as the inter-individual variability.

"Performance" itself is an intuitively meaningful concept that is difficult to define precisely. There are no universal standards for the clinical decisions and actions of anesthetists. They depend heavily on the context of specific situations. In addition, determining how anesthetists perform their jobs, whether successfully or unsuccessfully, means delving into their mental processes. This cannot be measured easily. On the one hand, experimental designs can be used that involve artificial laboratory tasks for which performance can be objectively measured. These tasks will then be far removed from the real world of administering anesthesia. On the other hand, investigating the actual performance of trained practitioners in the real world yields primarily subjective and indirect data. Understanding the anesthetist's performance must be seen as analogous to solving a jigsaw puzzle. Pieces of the puzzle probably come from a variety of sources, none of which by itself captures the entire picture. These pieces include objective data from artificial laboratory tasks, prospective observation of routine patient care, analysis of retrospective reports of near misses or anesthetic mishaps, and prospective observation of the response to simulated events. To achieve the best possible understanding of the situation, it is necessary to accept many data that seem uncomfortably subjective to the physical or biologic scientist. Because the research methodologies may be unfamiliar to anesthetists, some pioneering studies of anesthetist performance are described in detail in this chapter.

Why Study Human Performance in Anesthesia?

How can improved understanding of the human performance of anesthetists help them provide patient care more safely, in a wider variety of clinical situations, with greater efficiency, and with increased satisfaction to both patients and practitioners? The possibilities include the following:

1. Improved operational protocols and enhanced training of anesthetists. The way in which individuals conduct anesthesia is based, in part, on knowing the limits of their performance envelope. Anesthetic techniques and OR practices should draw on anesthetists' abilities and should mitigate their weaknesses. Anesthetists' abilities are strongly affected by training. Understanding the required performance characteristics and inherent human limitations will lead to improved training, which will most fully develop the strengths and counter the existing vulnerabilities of the anesthetist. This process should make patient care safer, less stressful, and more efficient.
2. A more rational view of professional work and legal responsibility (see Chapter 9). Modern medicine, especially in the United States, is strongly influenced by medicolegal concerns. The litigation system has a major selection bias in that every case that comes before it involves an adverse outcome for a patient. The duty of the practitioner is to render care as a "reasonable and prudent" specialist in the area of anesthesia. What is reasonable and prudent? What

type of performance is to be expected from appropriately trained human beings in a complex and dynamic environment? By understanding human performance, it may be possible to generate a more rational view of what is and is not within the standard of care.
3. A more effective work environment. Anesthetists now perform their tasks by using an array of technologies, most of which have not been designed to support the anesthetist's work optimally. By understanding the anesthetist's tasks and performance requirements, the workspace and tools could be improved to better support the most difficult tasks. This, too, can lead to greater safety and to greater efficiency and work satisfaction.
4. A more efficient organizational system (see Chapter 99). Anesthesia is embedded within a larger system of organized medical care that involves interactions among numerous institutions, organizations, and professional domains. Understanding how the anesthetist's work relates to the larger system may enable the development of more rational and efficient flow of information and organizational control.

Although anesthesiologists have been basing analysis of human performance on individual actions, decisions, and mental models and the influence of organizational factors and safety culture for some time (see survey papers[1,2,225]), their importance to health care in general has only recently been appreciated.[3,48]

Cognitive Process Model of the Anesthetist

The empirical data can best be interpreted in accordance with an explicit model of the cognition involved in an anesthetist's performance. Several investigators[44,58,113,144,226-232] have written about the cognitive elements in anesthesiology.[113,144,226,233-235] The model developed here is explicit, comprehensive, and specific to anesthesia. It is described in detail as a framework for understanding the empirical data and provides a vocabulary for discussing the elements of both successful and unsuccessful performance by anesthetists. This model draws heavily on the work of a number of other investigators[126,235-238] who studied human performance in a variety of complex, dynamic worlds.

Decision-Making Involves Multiple Levels of Mental Activity

The entire model, which is shown in Figure 6-10, depicts the anesthetist as working at five different interacting cognitive levels to implement and control a core process (see Box 6-9) of observation, decision-making, action, and re-evaluation. The core process must then be integrated with the behavior of other team members and with the constraints of the work environment.

The division of mental activities into levels follows the work of Rasmussen and Reason.[237,239,240] Having multiple levels supports parallel processing (performing more than one task at a time) and multitasking (performing only one task at a time but switching very rapidly from one task to another). The anesthesia task analyses[241-245] and the direct observations of anesthetists in Toronto[268] and Tübingen[246-249] have provided clear evidence for the occurrence of parallel processing and multitasking. Table 6-6 gives an overview of the mental activity levels.

Box 6-9 Elements of the Core Mental Process

1. Observation
2. Verification
3. Problem recognition
4. Prediction of future states
5. Decision-making
   a. Application of precompiled responses (recognition-primed decision-making)
   b. Decision-making using heuristics and probability
   c. Decision-making including abstract reasoning
6. Action implementation
7. Re-evaluation (avoiding fixation errors)
8. Start again with 1 (loop continues)

At the sensorimotor level, activities involving sensory perception or motor actions take place with minimal conscious control; they are smooth, practiced, and highly integrated patterns of behavior. At the procedural level, the anesthetist performs regular routines in a familiar work situation. These routines have been derived and internalized from training and from previous work episodes. A level of abstract reasoning is used during preoperative planning, and intraoperatively it is used in unfamiliar situations for which no well-practiced expertise or routine is available from previous encounters.

Dynamic Adaptation of the Anesthetist's Thought Processes

Rasmussen's model[237] was extended by the explicit addition of two additional levels of mental activity that provide for dynamic adaptation of the anesthetist's own thought processes. This ability to "think about thinking" in order to control one's own mental activities strategically is called metacognition by psychologists, and it is thought to be an important component of working in complex, dynamic domains. Supervisory control is concerned with dynamically allocating finite attention between routine and nonroutine actions, among multiple problems or themes, and among the five cognitive levels. Resource management deals with the command and control of available resources, including teamwork and communication.

Core Process

An overview of the core process and its elements is given in Box 6-9. The elements are explained in detail in the following sections.

Observation

Management of rapidly changing situations requires the anesthetist to assess a wide variety of information sources, including visual observation of the patient and the surgical field, visual inspection of a multitude of displays from electronic monitors, visual observation of the activities of nurses and the contents of

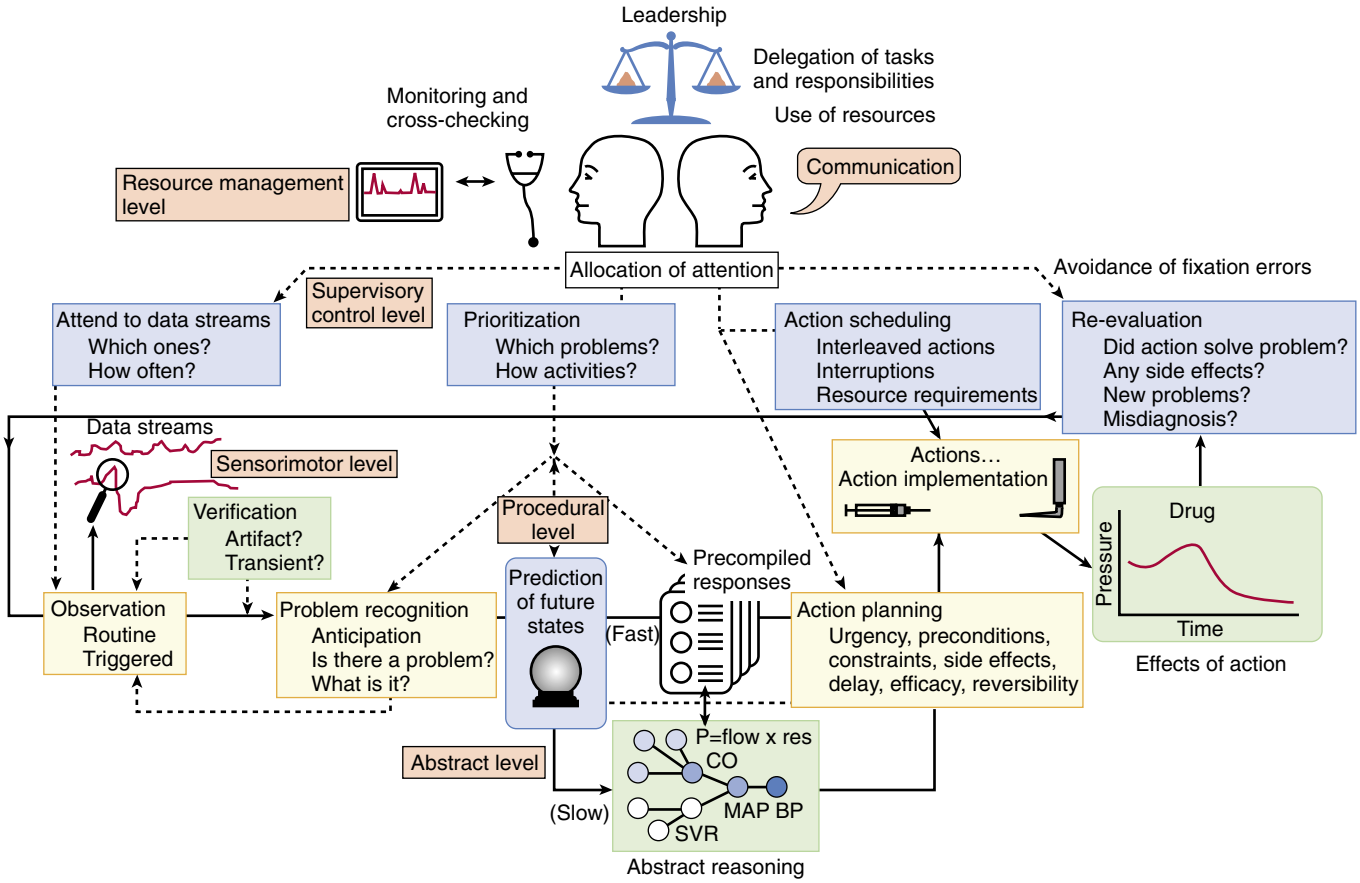

Figure 6-10 Cognitive process model of the anesthetist's real-time problem-solving behavior (see text for a detailed description). Five levels of cognition operate in parallel. The core process involves a main loop (*arrows*) of observation, decision, action, and re-evaluation. The core process is managed by two levels of metacognition that involve supervisory control, allocation of attention, and resource management (above the core process). Each component of the model requires different cognitive skills, and each component is vulnerable to a different set of performance failures or "errors." BP, blood pressure; CO, cardiac output; MAP, mean arterial pressure; SVR, systemic vascular resistance. *(From Gaba DM, Fish KJ, Howard SK: Crisis Management in Anesthesiology. New York, Churchill Livingstone, 1994.)*

Table 6-6 Levels of Mental Activity

Level of Control	Explanation	Comments
Resource management level	Command and control of all resources, including teamwork and communication	Incident analysis shows a huge contribution of lack of resource management and communication skills to the development of incidents and accidents; the importance of these factors is reflected in the ACRM principles and simulation training courses (see Chapter 7)
Supervisory control level	Metacognition: think about thinking	Dynamic adaptation of the thought process, decision-making (e.g., avoiding fixation errors), scheduling, and remembering actions (e.g., prospective memory tasks)
Abstract reasoning level	Use of fundamental medical knowledge, search for high-level analogies, deductive reasoning	Often in parallel with other levels; in emergency situations often too slow and too sensitive to distractions in high-workload situations
Procedural level	Precompiled responses, following algorithms, heuristics, "reflexes"	Recognition-primed decision-making—experts are more often on this level; special errors may occur as a result of not checking for the appropriateness of the "procedure"; less experienced may misuse this level for not-well-considered, unadapted "cookbook medicine"
Sensorimotor level	Use of all senses and manual actions; "feeling, doing, hearing"; sometimes subconscious control of actions	Experts perform smooth action sequences and control their actions by direct feedback from their senses (e.g., action sequences of placing an intravenous line or endotracheal intubation; skill-based errors such as slips and lapses may occur)

ACRM, Anesthesia Crisis Resource Management.

suction canisters and sponges, listening for normal and abnormal sounds from the patient and equipment, interpreting radiographs, and reading the reports of laboratory test results. Because the human mind can attend closely to only one or two items at a time, the anesthetist's supervisory control level must decide what information to attend to and how frequently to observe it.

The multitasking involved in observing multiple data streams was probed by experiments measuring secondary task performance and vigilance. The realistic simulation studies demonstrated the large number of information sources actually used during the response to a critical event. Routine parts of the core process operate primarily at the sensory, motor, and procedural levels and are executed repetitively throughout the course of an anesthetic regimen. Results from the University of California, San Diego (UCSD), and from the Department of Veterans Affairs and Stanford University (UCSD/VA-Stanford group) concerning the vigilance of experienced anesthetists versus novices suggested that novices had not fully developed their core process as a highly automated function and thus were required to devote more mental resources to routine activities.

Verification

In the OR environment, the available information is not always reliable. Most monitoring is noninvasive and indirect and is susceptible to artifacts (false data). Even direct clinical observations such as vision or auscultation can be ambiguous. Brief transients (true data of short duration) can occur that quickly correct themselves. To prevent them from triggering precipitous actions that may have significant side effects, critical observations must be verified before the clinician acts on them. Verification uses a variety of methods, shown in Table 6-7.

It should be noted that if in doubt, it should always be assumed that the patient is at risk and that the parameter in question is real ("rule out the worst case"). The assumption of a technical artifact should be the last step.

Knowing when and how to verify data is a good illustration of strategic knowledge (metacognition). For example, the anesthetist must decide under what conditions it is useful to invest time, attention, and energy in establishing a new information source (e.g., a pulmonary artery catheter) in the middle of a case rather than relying on more indirect information sources that are already in place.

Table 6-7 Methods for Verification of Critical Observations

Method	Explanation, Example
Repeating	The observation or measurement is repeated to rule out a temporary wrong value (e.g., motion artifacts during noninvasive blood pressure measurement)
Checking trend information	The short-term trend is observed for plausibility of the actual value. Trends of physiologic parameters almost always follow curves, not steps
Observing a redundant channel	An existing redundant channel is checked (e.g., invasive arterial pressure and cuff pressure are redundant, or heart rate from an ECG and pulse oximeter)
Correlating	Multiple related (but not redundant) variables are correlated to determine the plausibility of the parameter in question (e.g., if the ECG monitor shows a flat line and "asystole" but the invasive blood pressure curve shows waves)
Activating a new monitoring device	A new monitoring modality is installed (e.g., placing a pulmonary artery catheter). This also adds another parameter for the method of "correlating"
Recalibrating an instrument or testing its function	Checking the quality and reliability of a measurement and testing its function (e.g., if the CO_2 detector shows no values, the anesthetist can exhale through it to see whether the device works). Observation of redundant channels can also help verify a value (see above)
Replacing an instrument	If there is doubt about the function of a device, an entirely new instrument or an alternative backup device may be installed
Asking for help	If the decision on the values remains unclear, help should be sought early to obtain a second opinion from other trained personnel

ECG, electrocardiogram.

Problem Recognition

Anesthetists are taught the importance of scanning their instruments and environment, but they must use these observations to decide whether the patient's course is "on track" or whether a problem is occurring. If a problem is found, a decision must be made regarding its identity and its importance. This process of problem recognition (also known as situation assessment) is a central feature of several theories of cognition in complex, dynamic worlds.[144,250-252]

Problem recognition involves matching sets of environmental cues to patterns that are known to represent specific types of problems. Given the high uncertainty seen in anesthesia, the available information sources cannot always disclose the existence of a problem, and even if they do, they may not specify its identity or origin. Westenskow and colleagues'[253] experiment with the intelligent alarm system mainly probed these parts of problem recognition. In this experiment, subjects were already alerted to the existence of a problem by an alarm, so they could immediately focus their attention specifically on information sources concerning ventilation. In 11 cases, the fault could not be identified, but there was successful compensation for the fault, as described in the next paragraphs.

The supervisory control level mediates the decision when a clear-cut match or "diagnosis" cannot be made. Anesthetists and other dynamic decision-makers use approximation strategies to handle these ambiguous situations; psychologists term such strategies *heuristics*.[254] One heuristic is to categorize what is happening as one of several "generic" problems, each of which encompasses many different underlying conditions. Another is to gamble on a single diagnosis (frequency gambling[239]) by initially choosing the single most frequent candidate event. During preoperative planning, the anesthetist may adjust a mental "index of suspicion" for recognizing certain specific problems anticipated for that particular patient or surgical procedure. The anesthetist must also decide whether a single underlying diagnosis explains all the data or whether these data could be due to multiple causes. This decision is important because excessive attempts to refine the diagnosis

can be very costly in terms of allocation of attention. By contrast, a premature diagnosis can lead to inadequate or erroneous treatment.

The use of heuristics is typical of expert anesthetists and often results in considerable time savings in dealing with problems. However, it is a double-edged sword. Both frequency gambling and inappropriate allocation of attention solely to expected problems can seriously undermine problem solving when these gambles do not pay off if the re-evaluation component of the core process does not correct the situation.

Prediction of Future States

Problems must be assessed in terms of their significance for the future states of the patient.[144,250] Problems that are already critical or that can be predicted to evolve into critical incidents receive the highest priority. Prediction of future states also influences action planning by defining the timeframe available for required actions. Cook and colleagues[255] described "going sour" incidents in which the future state of the patient was not adequately taken into account when early manifestations of problems were apparent. It is also known from research in psychology that the human mind is not very well suited to predict future states, especially if things are changing in a nonlinear fashion. Under such circumstances, which are not uncommon for natural systems such as the human body, the rate of change is almost invariably underestimated and the people are surprised at the outcome.[43] Slow but steady and sustained blood loss in a child during surgery may result in few or subtle changes in hemodynamics for some time until rapid decompensation occurs. If the weak signs of the developing problem were not detected, the ensuing catastrophe may seem to have occurred "suddenly."

Decision-making

Having recognized a problem, how does an expert anesthetist respond? The classic paradigm of decision-making posits a careful comparison of the evidence with various causal hypotheses that can explain them.[39] This is then followed by a careful analysis of all possible actions and solutions to the problem. This approach, though powerful, is relatively slow and does not work well with ambiguous or scanty evidence. In complex, dynamic domains such as anesthesia, many problems require "decisions under uncertainty"[233,256] with quick action to prevent a rapid cascade to a catastrophic adverse outcome. For these problems, deriving a solution through formal deductive reasoning from "first principles" is too slow.

Precompiled Responses and Abstract Reasoning

In complex, dynamic domains, the initial responses of experts to the majority of events stem from precompiled rules or response plans for dealing with a recognized event.[239] This method is referred to as recognition-primed decision-making[236,257] because once the event is identified, the response is well known. In the anesthesia domain, these responses are usually acquired through personal experience alone, although there is a growing realization that critical response protocols need to be codified explicitly and taught systematically. Experienced anesthetists have been observed to rearrange, recompile, and rehearse these responses mentally based on the patient's condition, the surgical procedure, and the problems to be expected.[268] Ideally, precompiled responses to common problems are retrieved appropriately and executed rapidly. When the exact nature of the problem is not apparent, a set of generic responses appropriate to the overall situation may be invoked. For example, if a problem with ventilation is detected, the anesthetist may switch to manual ventilation at a higher F_{IO_2} while considering further diagnostic actions.

However, experiments involving screen-only[258] and realistic[109,143,259,260] simulators have demonstrated that even experienced anesthetists show great variability in their use of response procedures to critical situations. This finding led these investigators to target simulator-based training in the systematic training of responses to critical events.[109,226,261-263]

Even the ideal use of precompiled responses is destined to fail when the problem does not have the suspected cause or when it does not respond to the usual actions. Anesthesia cannot be administered purely by precompiled "cookbook" procedures. Abstract reasoning about the problem through the use of fundamental medical knowledge still takes place in parallel with precompiled responses, even when quick action must be taken. This seems to involve a search for high-level analogies[239] or true deductive reasoning using deep medical and technical knowledge and a thorough analysis of all possible solutions. Anesthetists managing simulated crises have linked their precompiled actions to abstract medical concepts.[258] It is unclear whether this represents merely self-justification as opposed to true abstract reasoning, in part because the particular simulated crises they faced did not require novel abstract solutions. At this time, the degree to which abstract reasoning is necessary for optimal intraoperative crisis management is unknown.[113,226,256]

Taking Action

A hallmark of anesthesia practice is that anesthetists do not just write orders in a patient's chart; they are directly involved in implementing the desired actions.

Although such direct involvement has many benefits in timeliness and flexibility of action, it also poses risks. Implementation of action can usurp a large amount of the anesthetist's attention and can be distracting. This is particularly an issue when other tasks have been interrupted or temporarily suspended. The "prospective memory" to complete these tasks can be erased. (For a more detailed explanation of prospective memory, see later.) In addition, anesthetists engaged in a manual procedure are strongly constrained from performing other manual tasks, as demonstrated in several of the mental workload and vigilance studies described earlier.

Errors in executing a task are termed *slips*, as distinguished from errors in deciding what to do, which are termed *mistakes*.[238] Slips are actions that do not occur as planned, such as turning the wrong switch or making a syringe swap. Thus, when critical incident[185,264] and quality assurance studies described "technical errors" in using equipment, they were referring to slips, whereas "judgment errors" referred to mistakes. One particular type of execution error, termed a *mode error*,[238] is becoming more frequent in all domains with the increased use of microprocessor-based instrumentation and devices.[227] In a mode error, actions appropriate for one mode of a device's operation are incorrect for another mode. An example in anesthesiology is the "bag/ventilator" selector valve in the anesthesia breathing circuit, which selects between two modes of ventilation. Failing to activate the ventilator when in the "ventilator mode" can be catastrophic. Mode errors can also occur with monitoring or drug delivery devices if they assign different functions to the same displays or switches depending on the mode of operation selected.

Particularly dangerous slips of execution can be addressed through the use of engineered safety devices[57] that physically prevent incorrect actions. For example, newer anesthesia machines have interlocks that physically prevent the simultaneous administration of more than one volatile anesthetic drug. Other interlocks physically prevent the selection of a gas mixture containing less than 21% O_2.

Certain very complex issues concerning human-machine interactions and the ways in which technology affects behavior in complex patient care environments are beyond the scope of this chapter. Other publications address these issues.[27,29,31-35,37,38,227,265]

Re-evaluation and Situation Awareness

To cope with the rapid changes and profound diagnostic and therapeutic uncertainties seen during anesthesia, the core process must include repetitive re-evaluation of the situation. Thus, the re-evaluation step returns the anesthetist to the observation phase of the core process, but with specific assessments in mind, as shown in Box 6-7 at CRM key point 12, "Re-evaluate repeatedly").

The process of continually updating assessment of the situation and monitoring the efficacy of chosen actions is termed *situation awareness*.[250-252,266,267] Situation awareness is a very interesting and important topic in analyzing performance and reasons for errors.[144,268,269] There has been a review of situation awareness issues in anesthesiology.[144]

Management and Coordination of the Core Process

Empirical studies have clearly demonstrated that attention sharing is needed among cognitive levels, among tasks, and often among problems. The intensive demands on the anesthetist's attention could easily swamp the available mental resources. Therefore, the anesthetist must strike a balance between acting quickly on every small perturbation (which requires a lot of attention) and adopting a more conservative "wait-and-see" attitude. This balance must be constantly shifted between these extremes as the situation changes. However, during simulated crisis situations, some practitioners showed great reluctance to switch from "business as usual" to "emergency mode" even when serious problems were detected. Erring too far in the direction of "wait and see" is an error that can be particularly catastrophic.

In addition to the attentional demands of the anesthetist's core tasks, the OR environment is full of distractions. Routine events, such as turning the OR table or repositioning the patient, distract attention from the main process of conducting the anesthesia. Noise is prevalent, with peak levels exceeding that of a freeway. Practitioners find false auditory alarms from monitors or other equipment to be extremely distracting.[279-281] Other distractions include teaching in progress,[278] incoming telephone calls, background music, and conversation with OR personnel. Expert anesthetists modulate the distractions by eliminating them when the workload is high and allowing them to occur when the workload is low (to improve morale and team building).

Active Management of Workload

One major aspect of strategic control of attention is the active management of workload. Rather than passively dealing with rising or falling workload, the anesthetist actively manages it. Schneider and Detweiler[163] and Gopher (position paper, Conference on Human Error in Anesthesia, Asilomar, CA, 1991) described the theoretical basis for a variety of strategies of workload management. These strategies have been addressed specifically for anesthesiology by several investigators.[226,228] The anesthetist actively manages workload by the following techniques.

Avoiding High-Workload Situations

Experts may choose techniques and plans that reduce the workload (especially when their individual and team resources are limited), even when those plans are marginally inferior from a technical standpoint. For example, a single anesthetist may choose not to use a high-tech, high-workload monitor such as transesophageal echocardiography (TEE) because of the high workload required to use it properly.

Distributing Workload over Time

The anesthetist can prepare for future tasks when the current load is low (preloading) and can delay or shed low-priority tasks when the workload is high (offloading). Resources that require a significant amount of workload to prepare, such as intravenous infusions, are often made ready before the case starts. Multitasking is also a way to distribute work over time. Every task is made up of several subtasks, each of which has a finite duration. Because close attention may not be required during each of these subtasks, they can be interleaved with a fixed amount of attention (multiplexing). Multiplexed tasks must be scheduled and coordinated in real time at the supervisory control level.

Distributing Workload over Personnel

When workload cannot be distributed over time and when additional resources are available, tasks can be distributed to them. Some resources are internal to the individual anesthetist, whereas others require additional personnel. For example, a single anesthetist can simultaneously ventilate the patient by hand, assess cardiac rhythm, and discuss patient care with the surgeon. A single anesthetist cannot simultaneously insert a pulmonary artery catheter and ventilate the patient's lungs by hand. If these tasks are to be performed at the same time, they must be assigned to different individuals.

Changing the Nature of the Task

The nature of a task is not fixed. Surgery and anesthesia can sometimes be postponed or aborted. Tasks can be executed to different standards of performance; as standards are loosened, the workload required to perform them is reduced. For example, during periods of massive blood loss, the anesthetist focuses primarily on administering blood and fluids and on monitoring blood pressure. In such cases, less critical tasks such as writing on the anesthesia record are offloaded to lessen the workload. The acceptable limits of blood pressure will also be widened.

Action Selection and Scheduling

At any time during an anesthetic regimen there may be multiple things to do, each of which is intrinsically appropriate, yet they cannot all be done at once. Simulator experiments have shown that anesthetists sometimes have difficulty selecting, planning, and scheduling actions optimally. The anesthetist must consider the following factors:

1. Preconditions are necessary for carrying out the actions (e.g., it is impossible to measure a thermodilution cardiac output if there is no pulmonary artery catheter in place).
2. Constraints are placed on the proposed actions (some actions are incompatible with other aspects of the situation; e.g., it is impossible to check the diameter of the pupils when the head is fully draped in the surgical field).
3. Side effects of the proposed actions often play a controlling role in choosing among possible drug therapies.
4. The rapidity and ease of implementation of proposed actions are factors; those that are easily and rapidly performed are preferred over those that require more time, attention, and skill.
5. Certainty of success of the actions is often traded off against rapidity and ease of implementation (under some circumstances, the higher certainty of success of a set of actions justifies the investment of time, attention, and resources needed to implement them).
6. Reversibility of the action and the cost of being wrong are considered, with rapidly reversible actions preferred over those that cannot be reversed, especially when potential side effects are significant.
7. Cost of the action in terms of attention, resources, and money is taken into account.

Experts in other complex, dynamic domains (specifically tank commanders and fire chiefs) have been observed[282] to conduct a mental simulation of the actions that they are contemplating to determine whether there are hidden flaws in their plans. Anesthetists have been observed[228] to rehearse a plan mentally in advance of a case, but the degree to which this is done in real time is not known. Because most actions can be executed incrementally, as in titrating a drug in small aliquots, adverse consequences can often be discovered through repetitive re-evaluation.

Resource Management

The ability of the anesthetist to command and control all the resources at hand to execute the anesthetic regimen as planned and to respond to problems that arise is termed *resource management* (another concept first described in aviation that applies equally well to anesthesiology; see the earlier section on CRM key points). Resource management involves translating the knowledge of what needs to be done into effective team activity by taking into account the limitations of the complex and ill-structured OR, PACU, or ICU domain. Resource management explicitly requires teamwork and crew coordination. It is not enough for the anesthetist to know what to do or even to be able to do each task alone. The anesthetist can accomplish only so much in a given time, and there are some tasks that can be performed only by other skilled personnel (e.g., laboratory tests, taking radiographs). When the task load exceeds the resources available, the anesthetist must mobilize help and distribute the tasks among those present. Many issues concerning optimum resource management and crew coordination are not yet well understood and are the focus of active research by cognitive scientists and experts in many complex and dynamic domains.[24,115-117,283-285] Research in aviation has already demonstrated that a large proportion of aircraft accidents are linked to failures on the part of crews with appropriate technical skills to manage the flight deck effectively.[186] The hallmarks of resource management derived from these studies are discussed in detail in the earlier section on CRM key points.

Dynamic Prioritization of Tasks

Complex multiple personnel simulations of anesthetic crises have been used to address the issue of resource management. Although the data from these simulations are still preliminary, it appears that poor supervisory control and resource management were substantial components of suboptimal management of the simulated crises.[260] In other words, like the pilots, anesthetists had the knowledge and technical skill to manage the patient, but they failed to manage their environment properly to achieve success (hence termed CRM skills or nontechnical skills). (In aviation, such situations have often resulted in what is called "controlled flight into terrain.")

Prospective Memory

Prospective memory describes one's ability to remember in the future to perform an action.[270] It is particularly prone to disruption by concurrent tasks or interruptions. Disruption of intentions or on-going tasks is common in everyday life and has also been described in pilots and air traffic controllers.[271-275] In anesthesia, for example, if the anesthetist suspends ventilation temporarily (say to allow a radiograph to be taken), the intention to restart the ventilator depends on prospective memory and can be easily forgotten. Chisholm and associates performed a study in an emergency department and looked for "interruptions" and "breaks in task." They found that during a 3-hour period, the emergency physician was faced with more than 30 interruptions and more than 20 breaks in task. It is likely that similar results would be found in the ICU.[276]

A variety of methods may preserve prospective memory of intentions. Visual or auditory reminders can be used (physiologic monitor alarms often serve this purpose whether intended or not), although the effectiveness of such methods seems to be less than one would expect. Special actions—such as leaving one's finger on the ventilator switch—can be used to indicate that an important intention is pending.

Fixation Errors

Faulty re-evaluation, inadequate adaptation of the plan, or loss of situation awareness can result in a type of human error termed a *fixation error*.[131,132] Fixation errors have been described by all the investigators conducting experimental studies of responses of anesthetists to abnormal situations.[259,260,277] Avoiding fixation errors in the field of anesthesia is CRM key point 9 and is covered in the section on CRM key points.

Hazardous Attitudes

Attitudes are an important component of ability that can affect performance as strongly as physiologic performance-shaping factors can. Psychologists studying judgment in aviators have identified five types of attitude as being particularly hazardous, and they have developed specific antidote thoughts for each hazardous attitude.[195] These attitudes as related to anesthesia are shown in Table 6-8. Aviation psychologists instruct pilots to

Table 6-8 Examples of Hazardous Attitudes and Their Antidote Thoughts

Hazardous Attitude	Antidote Thoughts
Antiauthority: "Don't tell me what to do. The policies are for someone else."	"Follow the rules. They are usually right.
Impulsivity: "Do something quickly—anything!"	"Not so fast. Think first."
Invulnerability: "It won't happen to me. It's just a routine case."	"It *could* happen to me. Serious problems can develop even in routine cases."
Macho: "I'll show you I can do it. I can intubate the trachea of anyone."	"Taking chances is foolish. Plan for failure."
Resignation: "What's the use? It's out of my hands. It's up to the surgeon."	"I'm not helpless. I can make a difference. There is always something else to try that might help."

physically verbalize the antidote thought whenever they find themselves thinking in a hazardous way.

The *invulnerable* and *macho* attitudes are particularly hazardous for anesthetists. They are compounded by production pressures to handle more cases in less time with fewer cancellations and less opportunity for preoperative evaluation. The feeling that a catastrophe "cannot happen to me" and that perfect performance can always be called on to avert a disaster can lead to cavalier behavior and poor planning. It can alter thresholds for believing that abnormal data represent a problem, thereby leading to the fixation error of "everything's OK." In 1984, Cooper[278] wrote the following about studies of critical incidents in anesthesia:

> *Perhaps the most insidious hazard of anesthesia is its relative safety. The individual anesthetist rarely, on average, will be responsible for a serious iatrogenic complication. It is our impression from the process of collecting incidents, that most seemingly minor errors are not taken seriously and that risk management depends almost solely on the anesthetist's ability to react instinctively and flawlessly every time a problem arises.*

Expert human performance is the anesthetist's most powerful tool to safeguard the patient. However, planning to avoid catastrophe is likely to be more successful than battling to avert it.

The Anesthetist's Tasks

Investigation of a complex work environment typically starts with task analysis (reviews of this technique were published in the journal *Human Factors*[286]). One can perform an abstract analysis of the work goals and constraints and then derive the tasks required to achieve the goals. Alternatively, one can observe what skilled practitioners actually do in their work and classify these actions into task elements. Often the techniques are combined. In this section the anesthetist's tasks are examined in the abstract and then the empirical task analysis approach is reviewed. There are two distinct phases of anesthetic care: (1) preoperative evaluation, planning, and preparation and (2) conduct of the anesthetic regimen and immediate postoperative care.

Preoperative Evaluation and Planning

There are few data on how well anesthetists identify important patient conditions through history taking and physical examination (see Chapter 34). A frequent organizational obstacle to the anesthetist's evaluation task is difficulty obtaining the patient's previous medical records. The performance of anesthetists in selecting appropriate laboratory tests has been found to be relatively poor. Roizen and associates[287] state the following:

> *Even when physicians agree to reduce testing by using specific, agreed upon criteria for selectively ordering tests based on history and physical examination, they still make a surprising number of mistakes when ordering tests. Approximately 30% to 40% of patients who should have certain tests do not get them, and 20% to 40% of patients who should not have tests are subjected to them.*

Roizen has argued for automation of routine patient questioning and selection of laboratory tests and has participated in the development of commercial devices to do so. Whether these devices, in combination with human follow-up for patients with medical problems, will improve the efficiency and accuracy of preoperative evaluation remains to be determined. The performance of anesthetists in interpreting ECGs and chest radiographs also appears to be poor relative to specialists in these fields. The extent to which this factor influences the design of anesthetic plans or patient outcomes is unknown.

Anesthetic Plan

In constructing the plan, the anesthetist uses the preoperative evaluation of the patient to match the technical requirements of the surgical procedure and the physiologic characteristics of the patient to the mental, physical, and technologic resources available. A typical anesthetic plan contains several elements. For example, the plan for general anesthesia includes choices for the means of inducing anesthesia, securing the airway and ensuring proper ventilation, maintaining anesthesia, conducting emergence from anesthesia, and controlling postoperative pain. Skilled planning is as critical as skilled execution in safe patient care. If a significant feature of the situation is missed in formulating the plan, it can leave the patient vulnerable, regardless of how adeptly the plan is implemented.

The technical requirements of most surgical procedures are well known. Most patients do not have medical problems that could significantly alter the anesthetic plan, although Gibby and associates[288] found that 20% of outpatients, most of them with ASA physical status 1 or 2, had conditions identifiable through an anesthetist's history and examination that required changes from a "standard" anesthetic plan. When a procedure is new or challenging, when the patient has significant underlying disease, or when needed resources are not available, creative planning may be needed to identify a set of physiologic goals for the anesthetic regimen. Routine anesthetic plans can be modified or com-

bined to produce a compromise plan that best fits the goals and constraints of the situation.

Although faculty anesthetists routinely critique the anesthetic plans of residents and planning is explicitly probed during the oral examination of the American Board of Anesthesiologists, the process of constructing anesthetic plans has been studied very little. Most of the existing literature on preoperative planning concentrates only on the medical and physiologic aspects of underlying diseases and their anesthetic ramifications.

Pre-use Preparation and Checkout of Equipment

After the plan is established, the anesthetist must prepare the work environment. This involves obtaining the necessary equipment and supplies, assembling infusions, preparing syringes of needed drugs, and conducting pre-use checkouts of life support equipment (see Chapter 38). The performance of anesthetists at these tasks is not optimal. Buffington and coworkers[289] demonstrated that only 3% of anesthetists examining an anesthesia machine could identify all five faults with which it had been rigged; most practitioners found only two of the five. Nearly 30% missed such major faults as complete absence of both unidirectional valve disks in a circle anesthesia breathing system and swap of the nitrous oxide and oxygen cylinders (made possible by a fault in the pin-indexing system).

The Food and Drug Administration (FDA), in cooperation with the ASA, the APSF, and experts from academics and industry, developed a set of recommendations for the checkout of anesthesia apparatus.[290] This checklist was widely disseminated by the ASA and the APSF. However, it was found that use of the checkout procedure was minimal and that the extent of pre-use checkout by practitioners was extremely variable. A newer study[291] was conducted to compare the checkout of anesthesia machines by practitioners with and without use of the FDA checkout procedure. Most of the faults were detected by 50% or fewer participants, regardless of the checkout procedure used. Only for one fault, failure of the oxygen–nitrous oxide ratio protection system, did the FDA checklist offer significant advantages; when using it, the detection rate increased to 65%. Interestingly, 34% of the faults that were not detected were missed by practitioners who had in fact correctly answered three out of three written test questions concerning that fault. This suggests that although some of the performance deficit may be related to lack of knowledge, a substantial proportion are due to the inability to apply abstract knowledge to the practical performance of equipment checkout.

There were many criticisms of the original checklist, particularly its complexity.[292] A streamlined version of the original checklist was published by the FDA in 1994.[293] A study of the new checklist, however, showed no significant benefit from its use and a disturbingly low rate of detection of machine faults (around 50%).[294] In another study, anesthetists using a highly interactive electronic checklist (developed by Blike and Biddle) improved their detection of "easy faults" but still missed a high proportion of difficult faults.[295] A study performed more recently to measure the influence of fatigue on performance in a simulator showed that subjects in both the rested and fatigued conditions left out significant portions of the machine checkout.[178]

Emergency Checklists

One aspect of preparedness is to consider possible emergencies and to mentally rehearse their management. Another approach is the readiness and ability to use critical incident checklists. For example, the Veterans Health Administration has placed a set of emergency checklists on plastic laminated sheets in every OR of 105 hospitals (Fig. 6-11 and Box 6-10 for an example of "anaphylaxis"). Other emergency checklists have been made available electronically.[296,297] Despite these advances, the use of emergency checklists has still not become a regular part of the culture of medical work.

Execution and Adaptation of Plans

Anesthetic plans are dynamic. The anesthetist must monitor the plan as it is executed and must adapt it in response to dynamically changing events. The key features of this task are (1) checking for the achievement of milestones and (2) reactive plan adaptation. These are shown schematically in Figure 6-12. At various points of a procedure there are critical milestones that must be achieved to keep the original plan unaltered. If a milestone is not achieved, the anesthetist must decide whether to delay the next action in the sequence, modify the plan, or suspend or abort the procedure. On some occasions, the milestones are explicitly identified in advance, whereas in others the milestones are implicit.

The anesthetist must also react to a large number of other contingencies, some of which can be predicted in advance based

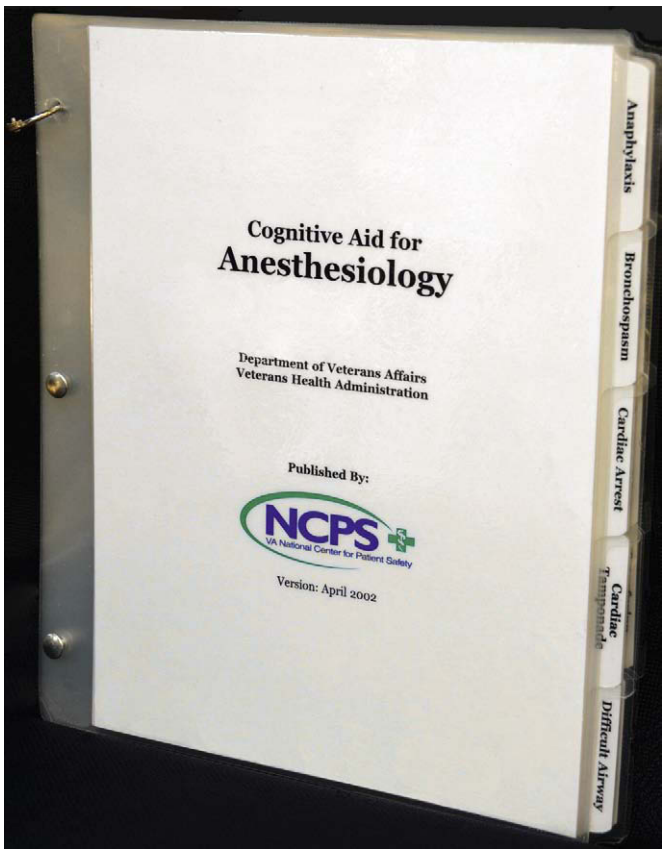

Figure 6-11 Department of Veterans Affairs checklist by NCPS. An example of the cognitive aid is given by Anaphylaxis in Box 6-10.

Box 6-10 VA NCPS Checklist Example (Anaphylaxis)

MANIFESTATIONS

Cardiac

- Hypotension (may be the only sign of anaphylaxis in an anesthetized patient)
- Cardiovascular collapse
- Pulmonary hypertension
- Arrhythmias/tachycardia

Respiratory

- Bronchospasm
- Increased peak inspiratory pressure (high PIP)
- Hypoxemia
- Pulmonary edema
- Stridor, laryngeal edema

Cutaneous

- Rash, flush, hives, angioedema
- In an awake patient, signs and symptoms include
  - Dizziness, decreased level of consciousness, dyspnea and/or chest tightness, pruritus

IMMEDIATE ACTION

- Stop administration of any possible antigen (e.g., antibiotics, muscle relaxants, blood) (transfusion reaction)
- In the absence of any other likely cause, consider *latex allergy*
  - Remove all latex products in contact with the patient
    - Surgical gloves
    - Medications drawn up through a latex stopper
    - Urinary catheter
- Maintain the patient's airway and support oxygenation and ventilation
  - Increase F_{IO_2} to 100%
- Intubate early if the allergic reaction is severe
  - The airway and larynx can become very edematous
- Inform the surgeons
  - Consider terminating the surgical procedure
- Expand circulating fluid volume; ensure adequate intravenous access
  - Immediate fluid needs may be massive (many liters of crystalloid)
- Administer epinephrine intravenously
  - Epinephrine is the drug of choice for the treatment of severe anaphylaxis
    - For hypotension or bronchospasm, 10- to 50-∝g increments; repeat as necessary with escalating doses
    - For cardiovascular collapse, use ACLS doses, 500- to 1000-∝g boluses; repeat as necessary with escalating doses
- Treat bronchospasm if present
  - Administer inhaled bronchodilators
    - Albuterol: initial dose, 4 to 8 metered puffs
    - Depending on the delivery system, a larger dose of any aerosolized medication may be required when administered via the endotracheal tube

ACLS, advanced cardiac life support.

on the patient's history and the type of surgery, whereas others cannot be anticipated. Incoming data streams must be constantly scrutinized (see the "police cars" in Fig. 6-12) to determine whether an expected or unexpected contingency is occurring. If so, the existing plan may have to be modified. As plans are changed, actions may be taken that invalidate other aspects of the previous plan, thereby requiring further adaptation of the plan. In some cases, even the original goals of the anesthetic plan may need to be adapted.

Frequency of Events Requiring Active Intervention by the Anesthetist

The preceding analysis of Figure 6-12 suggests that anesthetists must be prepared to react dynamically to changing events. How frequent is this requirement? In the Multicenter Study of General Anesthesia,[298] 86% of patients had at least one undesirable outcome. Although most events were minor and caused no injury to the patient, more than 5% of patients had one or more severe events requiring "significant therapy, with or without full recovery." This incidence is probably a lower limit for severe events because the entry criteria of the study precluded the enrollment of critically ill patients or emergency surgeries, for which the likelihood of severe problems requiring intervention would be expected to be high.

In another study by Cooper and associates,[299] impact events, defined as "undesirable, unexpected, and which could cause at least moderate morbidity," occurred in 18% of patients either in the OR or in the PACU, and 3% of all cases involved a "serious" event. These figures are also probably lower limits because for technical reasons the study excluded patients going directly from surgery to an ICU.

Moller and coauthors[300] reported 4439 "impact events" in 10,312 patients either in the OR (2441) or in the PACU (1998). Here again, some patients had several events, whereas others had none. The investigators did not compute the frequency of severe events, but overall, these data appear to be consistent with those from earlier studies.

Model of Event Evolution

The findings just discussed, as well as the larger system issues raised by Reason and Perrow, can be summarized in a model of event evolution (Fig. 6-13).[58,113,226]

Similar models incorporating some of the same features have also been described.[59,301] Underlying aspects of the system can gen-

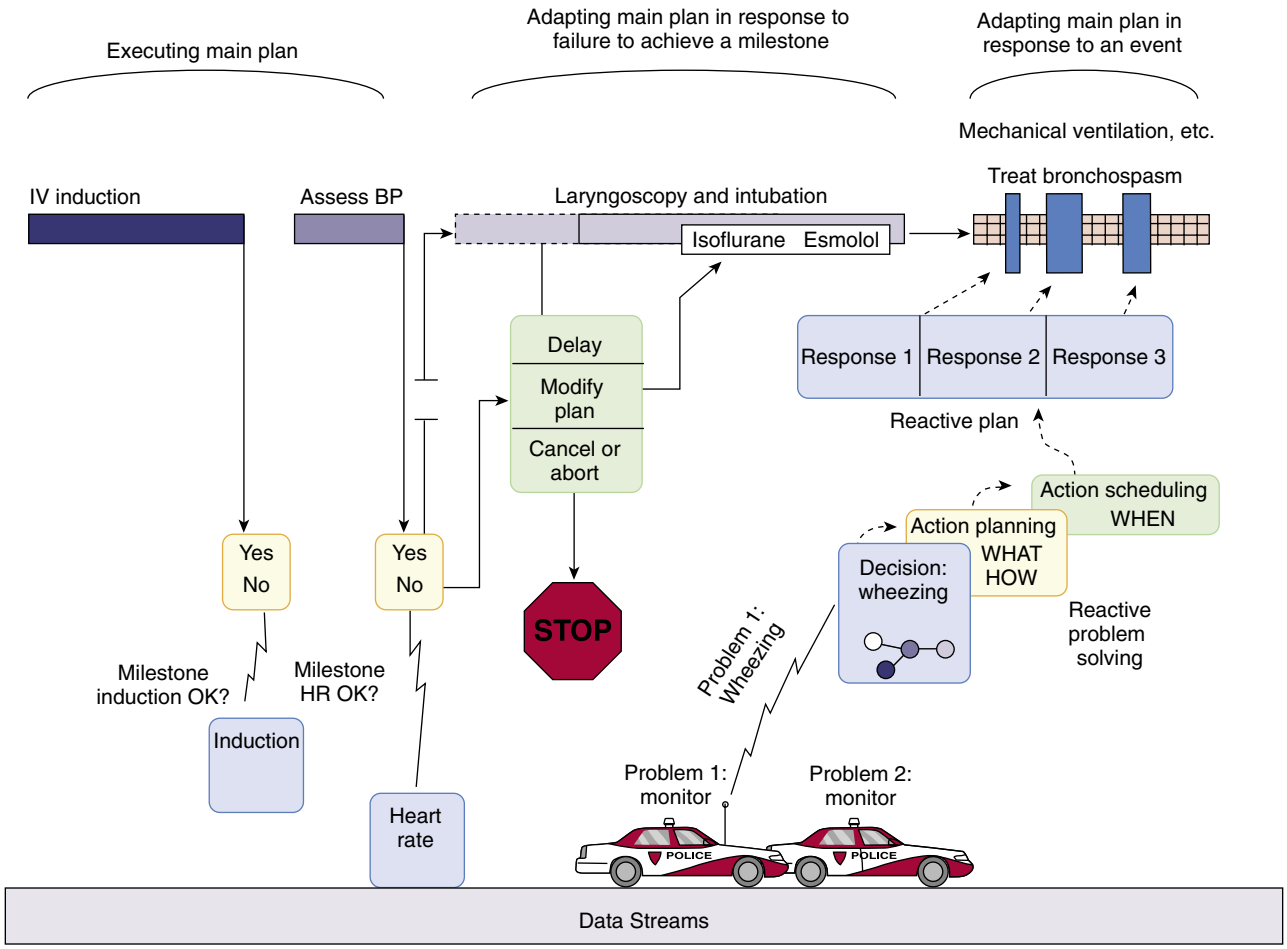

Figure 6-12 Schematic diagram of the dynamic adaptation of preoperative plans. The anesthetist begins with intravenous (IV) induction of anesthesia as planned (*top left*). On achieving the milestone of successful induction of anesthesia, blood pressure (BP) is checked before proceeding with laryngoscopy and intubation (*center*). If BP is not satisfactory, the next step may be delayed and the plan amended to optimize BP. If necessary, the procedure may even be aborted at this stage. Throughout the procedure, the anesthetist is vigilant for the occurrence of new problems ("police cars"). If a problem is detected, a process of reactive problem solving takes place, which may result in new adaptations to the plan (in this case, treatment of bronchospasm). *(From Gaba DM: Human Error in Dynamic Medical Environments. Hillsdale, NJ, Lawrence Erlbaum, 1994, pp 197-224.)*

erate latent failures. Either by random chance or because of interactions between the latent failures, an event may be triggered by one of four components of the operational system in the OR: the anesthetist, the surgeon, the patient, or the equipment. Anesthetists have traditionally been most interested in events that they trigger themselves (such as esophageal intubation), but in fact, most events are initiated by a combination of underlying patient disease and another of the triggering factors. Most problems are not directly harmful to the patient unless they evolve further. Possibilities for evolution of the problem include the following:

1. A single problem worsens and by itself evolves into an adverse outcome.
2. The problem begins to evolve but remains self-limited without any intervention.
3. Multiple small problems combine to trigger a problem that can evolve into an adverse outcome; the original problems by themselves would not have evolved further.
4. A single problem triggers another problem that evolves into an adverse outcome.
5. An evolving problem should be able to be stopped, but the recovery pathway is faulty.
6. Two problems are triggered. Attention focused on one (minor) problem distracts attention from the (serious) evolution of another.

The system has a variety of interruption points at which the occurrence of problems can be prevented (preoperative evaluation of patients and pre-use checkout of equipment). Moreover, although anesthesiology is far more dynamic than many medical domains, it is relatively slow in comparison to many human activities such as sports, driving, and combat flying. Thus, events often evolve slowly enough that the process of accident evolution can be thwarted before an adverse patient outcome actually occurs. The interruption of accident evolution corresponds to the "defense-in-depth" in Reason's "Swiss cheese" model[70] and to recovery from a normal accident in Perrow's paradigm (see Figs. 6-2 and 6-3 and the overview on NAT in Table 6-2).

In the prospective studies of intraoperative events cited earlier, there was a surprisingly high incidence of undesirable situations, whereas the rate of actual patient harm was quite low. The patient's safety was frequently protected only by the skilled intervention of a trained anesthetist. Note that this is a markedly different picture from that in commercial aviation, although the

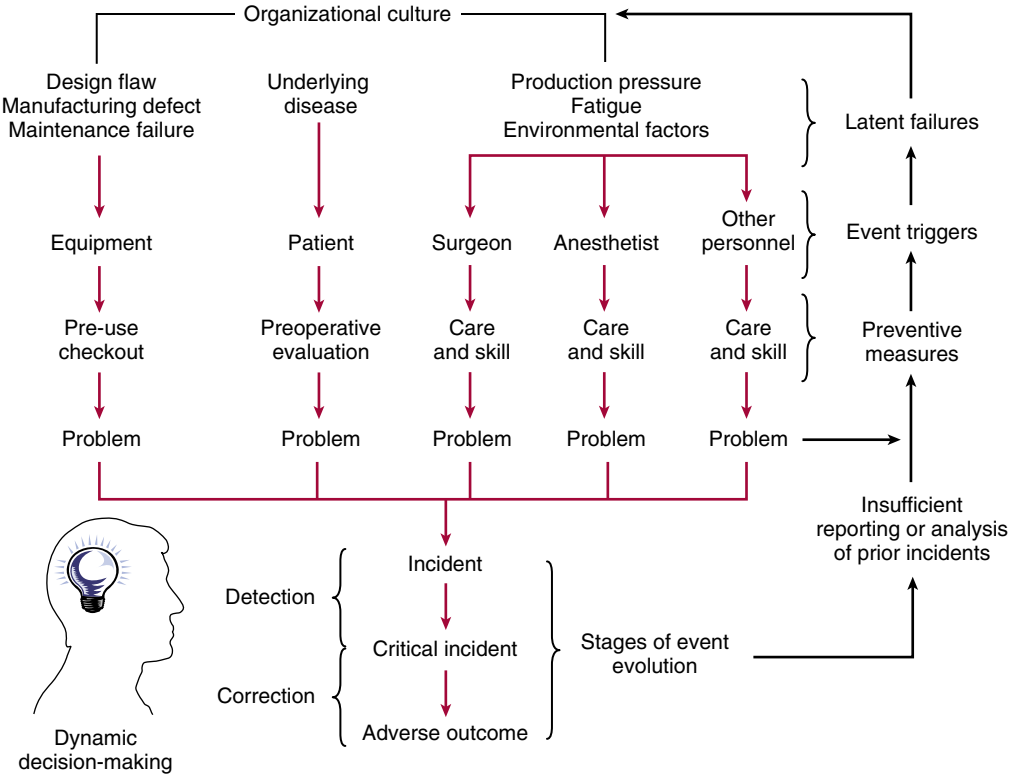

Figure 6-13 Chain of accident evolution in anesthesia. As in Reason's model, underlying latent failures (and the organizational culture) predispose to triggering of an accident sequence by equipment, the patient, the surgeon, the anesthesiologist, and other personnel. This sequence can be prevented by prophylactic measures such as preoperative evaluation and treatment of patient diseases or pre-use checkout of life support equipment. Once a problem occurs, it may remain self-limited or evolve further down the accident chain. Using dynamic decision-making, the anesthetist must detect and correct the problems that do occur at the earliest possible point in the chain of evolution. Interruption of the accident chain is made more difficult when there is tight coupling within the system, when multiple interacting problems are present, or when problems disrupt recovery processes. Efficient use of incident analysis may make it easier in the future to prevent or interrupt problem evolution. *(Redrawn with modification from Gaba DM, Fish KJ, Howard SK: Crisis Management in Anesthesiology. New York, Churchill Livingstone, 1994.)*

accident rate in aviation is very low. About 30,000 airline flights take place each day in the United States, and there are very few serious incidents or accidents, although the exact number is unknown. The total accident rate from all causes (not counting terrorist acts) for major airline flights between 1982 and 2001 was 0.38 per 100,000 departures. Air carrier accidents with one or more fatalities occurred at a rate of 0.045 per 100,000 departures. In 2002 there were no fatalities in U.S. airline or commuter aviation (NTSB website: www.ntsb.gov/aviation/Stats.htm).

The actual number of events in aviation matching the "impact event" criteria given earlier is not known, but it is probably at least 100 times greater than the number of accidents. Even so, this still makes aviation incidents far less frequent than the 3% to 5% rate of "significant" impact events in anesthesia. Based on these data, it is clear that the intraoperative management of abnormal, dynamically changing events remains the critical locus of anesthesia skill.

Empirical Studies of Anesthetists' Tasks

Over the past 20 years there have been a number of studies[31,35-38,40,178,198,235,302-305] of anesthetists' intraoperative activities. In addition, an increasing number of studies have been performed in realistic simulator environments.[2,19,184,306-319]

The earliest studies used time-lapse photography of a handful of anesthetic cases with a frame-by-frame analysis of tasks. One major finding of the first task analysis, by Drui and associates in 1973,[320] was that "the anesthesiologist's attention was often directed away from the patient-surgical field." In subsequent studies,[241-243] it was found that about 40% to 50% of the time the anesthetist's gaze was directed away from the patient or surgical field. McDonald and Dzwonczyk,[242] studying cases from 1981, classified direct patient activity as "one during which the anesthetist had contact with the patient and a view of the surgical field." These investigators explicitly noted "observation of skin color," "palpation of pulse," and "auscultation of heart and breath sounds" as direct patient activities. Observing arterial pressure or the ECG and observing or adjusting the anesthesia machine or intravenous infusions were classified as indirect patient activities. In this study 83% of the anesthetist's time was spent on activities that were not direct patient activities. The same group[243] repeated its study for cases from 1985 and demonstrated a much higher rate of direct patient monitoring than obtained in 1981 (44.8% versus 16.8%). This group attributed the difference to the change from manual ventilation in 1981, which took up much of the anesthetist's visual attention, to the use of mechanical ventilators in 1985, which freed the anesthetist to watch the patient.

It is true that looking at the patient and at the surgical field is a hallmark of an excellent clinician. Opponents of technology

decry the degree to which monitors and therapeutic devices distract the anesthetist's gaze from the patient. However, an important distinction has to be made between the anesthetist's attention, which surely must be directed to the patient's needs, and the anesthetist's gaze, which in fact may best serve the patient by being directed elsewhere. Many of the tasks cited in the study by McDonald and Dzwonczyk[243] were highly related to management of the patient, even though they did not involve direct visualization of or contact with the patient. The critical question, which task analysis by itself cannot answer, is when anesthetists gaze at the surgical field, how often are they gathering information, and how often are they just "watching the scenery"? Put more generally, what is the information content of the various observations being made and what is their relationship to action tasks and to the goals of conducting a safe anesthetic regimen?

Intriguingly, Drui and associates[320] had asked physicians who were helping code their films, "What information, if any, do you gain from the direct performance of this activity?" However, these investigators never described what information was available from each activity, although they seem to have assumed that turning the anesthesiologist's gaze away from the patient and surgical field was bad. Boquet and coworkers[241] not only studied the gaze of anesthetists (using a sophisticated eye-tracking system) but also asked consultant anesthetists to grade the importance of different visual targets and manual tasks. "The patient" was assigned the maximal importance on the scale. However, "the surgical field," which occupied 25% of the anesthetist's time, was apparently not listed by the consultants. Perhaps, in their minds, the surgical field was lumped together with the patient.

Another key finding of the study by Drui and coworkers[320] was that 40% of the anesthetist's time was coded as "idle," meaning that no obvious task was seen on that frame of film. In 1988, McDonald and Dzwonczyk[242] stated that this and other "studies showed that the anaesthetist spends most time performing tasks that are either secondary or unrelated to patient care." However, in their original article, Drui and associates[320] correctly recognized that absence of visually apparent activity did not mean that the anesthetist was truly idle; in fact, they hypothesized that this time was used by anesthetists to make the decisions on which the observable tasks were based.

The most detailed task analyses have taken place in a series of studies[198,235,244,245,304,321] carried out by the UCSD/VA-Stanford group. These analyses have used progressively more task categories (11 to 28 to 32) to analyze the activities of novice and experienced anesthetists in day surgery cases and the activities of senior residents during cardiac surgery. The studies have shown that a small number of tasks, repeated frequently, occupy the majority of case time. In one study, four tasks (observing monitors, recording, conversing with attending staff [for novice residents], and adjusting monitors) accounted for 50.1% of the total case time. Specific activities such as airway management (e.g., bag ventilation, laryngoscopy) occurred in brief, but intense clusters (Fig. 6-14). Given the larger number of task categories, the anesthetist was rarely seen to be idle.

Studies by this group have attempted to determine whether there is a difference between the task patterns of novice versus experienced anesthetists. Confirming a priori expectations, the investigators found that novices perform many of the same tasks as experienced personnel do at specific phases of an anesthetic regimen; however, the novices had a longer dwell time, on average, for each task. These studies also showed that experienced providers had lower heterogeneity of tasks and greater efficiency of tasks per unit time.[322]

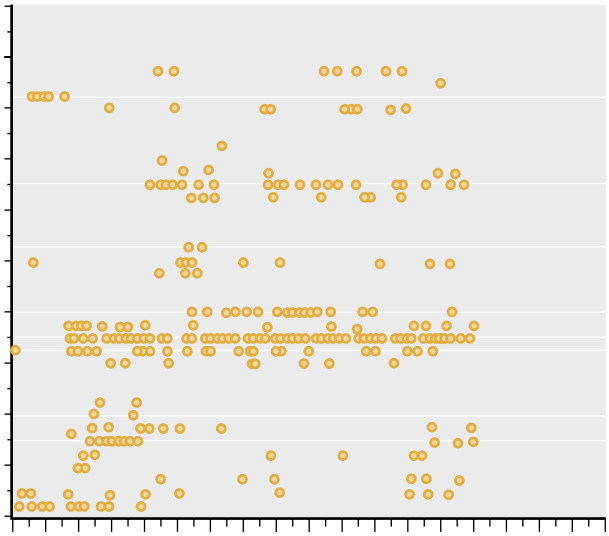

Figure 6-14 Distribution of the anesthetist's tasks during an actual ambulatory surgery procedure. The anesthetist was directly observed by an investigator who recorded a code number for each task as it was performed (there were 28 task codes). Certain tasks, such as bag ventilation, were clustered in specific phases of the case, whereas others, such as observing monitors, were repeated frequently throughout the procedure.

Of note (but also not unexpected), novice residents spent more time speaking to their attending staff (11% of preintubation time) than experienced residents or CRNAs did. Of interest, experienced personnel observed the surgical field more than the novices did. The implications of this finding are not clear. Novices did take longer to complete patient preparation and induction of anesthesia, but it appeared that some of the extra time taken by novices working under supervision was offset by the efficiency of offloading other concurrent tasks to the attending anesthesiologist such that preintubation time was increased by only 6 minutes for novices.[322] This group also reported that as the density of tasks per unit time increased, the dwell time on each task decreased, and vice versa. This finding has important implications for how anesthetists allocate their attention (see "Management and Coordination of the Core Process").

Task Analysis and Action Density

An interdisciplinary research group consisting of the Work and Organisational Psychology Department of the Swiss Federal Institute of Technology in Zurich and the Center for Patient Safety and Simulation of the Department of Anaesthesiology of the University of Tübingen performed several task analysis studies using the Flexible Interface Technique (FIT) system[323] (Fig. 6-15), which facilitates analysis of multiple parallel and overlapping actions.[246] The group produced a set of 41 observation codes—representing a single action (Table 6-9). Because the method allowed true capture of overlapping actions, it was possible to describe a valid task density in the analysis of anesthetists' action sequences.

Figures 6-16 and 6-17 show examples of observations of 24 real OR studies. The observation data contain many short-term fluctuations (dots); the moving average of action density of the previous 5 minutes was charted as well (line). Figure 6-16 shows a complete anesthesia procedure with obvious increases in action

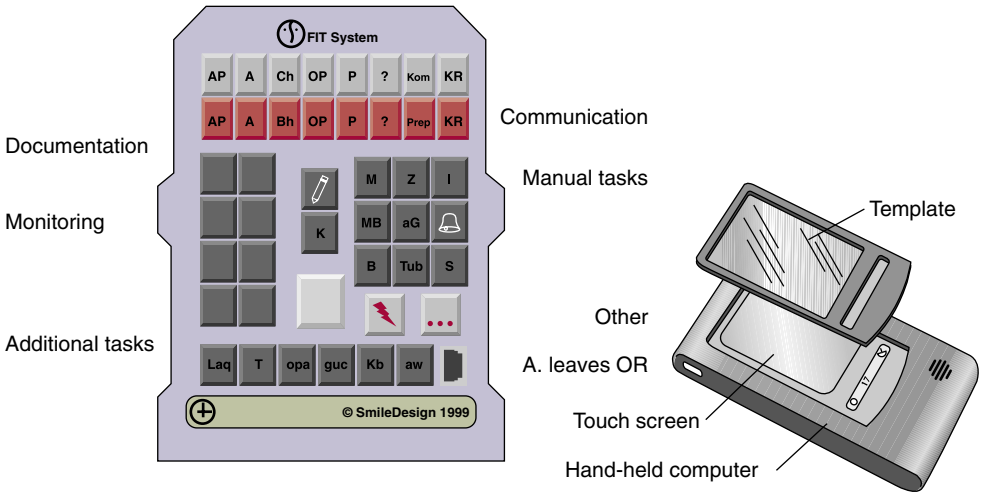

Figure 6-15 Flexible Interface Technique system. The system allows easy reorganization of task analysis items and categories and can properly resolve overlapping actions. OR, operating room.

density during induction and emergence from anesthesia. Figure 6-17 shows two final phases of cardiac cases involving cardiopulmonary bypass. The described task analysis technique was also used successfully by the Tübingen group to study action sequences in a simulator and compare them with findings in the real OR to demonstrate and evaluate the ecologic validity of simulators (see Chapter 7).

Automation

Early task analyses identified repetitive tasks that did not appear to offer substantial information content or therapeutic benefit as candidates for automation. Drui and associates[320] identified filling out anesthesia records, measuring blood pressure, and adjusting intravenous infusions. Kennedy and colleagues[324] identified data display and trend plotting. Many of these tasks have in fact been automated in the past 20 years. Loeb,[325] from University of California, Davis (UCD) showed that anesthesiologists typically observed monitors for about 1 to 2 seconds every 10 to 20 seconds and that it usually took several observing cycles before they detected a subtle cue on the monitor. Gurushanthaiah and coworkers[326] studied the effect of more sophisticated display modalities on detection of signals by anesthesiologists and found that histogram and polygon formats improved response latency in the laboratory setting over formats using raw numbers only. However, the applicability of these laboratory finding to the more complex signal detection that must occur in the midst of patient care is uncertain. Incidentally, the experience in the field of aviation suggests that automation of both monitoring and therapeutic devices produces its own problems in human-machine interactions and may well be a causative or contributing factor in some adverse anesthetic events. Some of the same types of automation-related adverse events seen in aviation are now being observed in anesthesiology.[227]

The impact of automation on task distribution is uncertain. The change to mechanical ventilation did affect the analyses of McDonald and Dzwonczyk,[242] as detailed earlier. A study by Allard and coworkers[327] showed no reduction in time spent recording when automated record-keeping devices were used. However, the UCSD/VA-Stanford collaboration published data demonstrating a 20% reduction in the time spent record keeping when automated record keeping was in use during cardiac anesthesia.[322] There was a slight, but not significant increase in time spent on direct patient care activities when electronic record keeping was in use. There is no clear evidence that electronic record keeping will yield a marked enhancement of the anesthetist's ability to perform other patient care tasks, although automated record keeping may yield other benefits. The UCD and UCSD/VA-Stanford groups demonstrated that electronic automated record keeping does not significantly reduce the vigilance of anesthetists.[328,329]

Table 6-9 Observation Codes Used to Classify Tasks and Actions

Task Group	Actions
Monitoring	Read patient record, observe patient, observe patient monitors, observe anesthesia machine, observe intravenous drip, observe syringe pumps, measurement, scan area
Measures	Placing IV, give drugs, adjust IV, mask ventilation, intubation/extubation, adjust anesthesia machine, use of other equipment, quitting alarms, suctioning
Communication	(1) Active conversation with nurse anesthetist, attending anesthetist, surgeon, OR nurse, patient, others; (2) responsive conversation with nurse anesthetist, attending anesthetist, surgeon, OR nurse, patient, others; and (3) response to pager
Documentation	Patient chart labeling (drugs, drips, laboratory results)
Additional operations	Positioning of patient, patient transfer, tasks of others (circulating nurse, orderly), arrange workplace, conversation with observer ("just looking"), miscellaneous, leaving OR (with possible audiovisual contact with OR)

IV, intravenous line; OR, operating room.

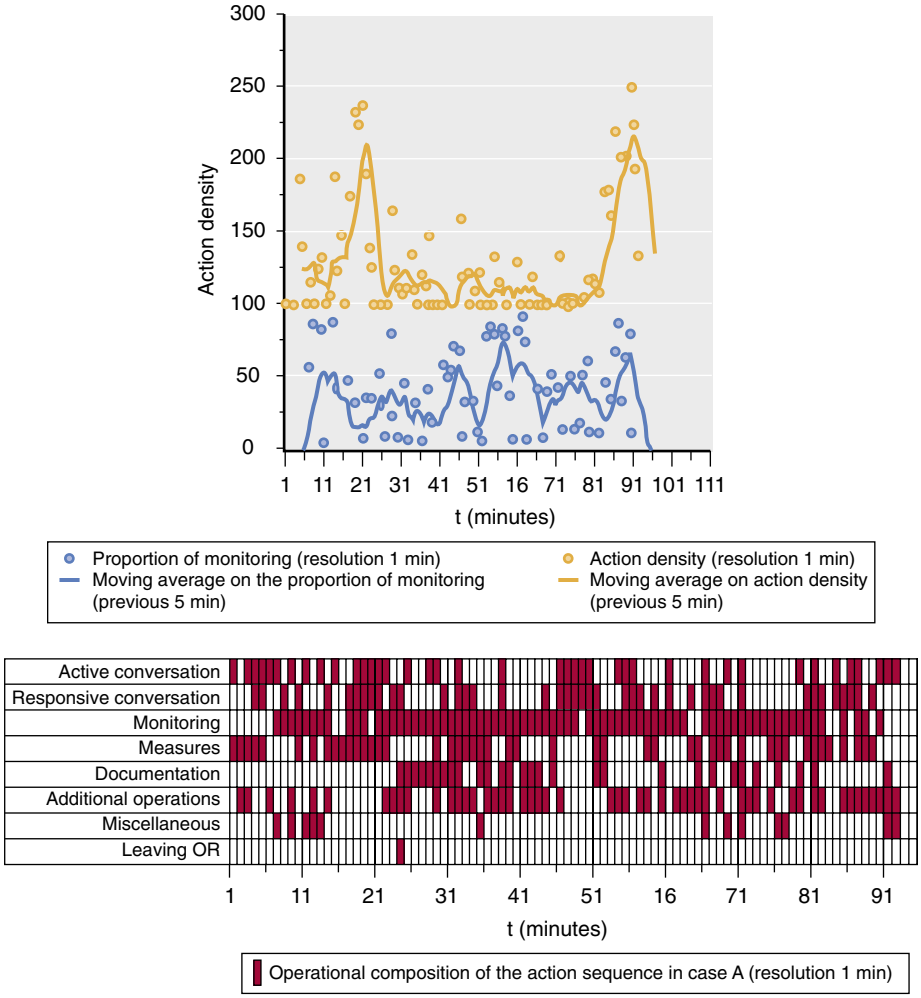

Figure 6-16 Action density diagram illustrating the derived parameter "action density" from induction of anesthesia to emergence in a real anesthetic case. The *top line* in the graph shows the overall action density and the *dots* show the moving average of the density. The *bottom line* shows the contribution of one task group "monitoring" as an example. The table in the lower graph shows the composition of the data for all eight task groups from the same case.

Mental Workload of Administering Anesthesia

The observable tasks do not tell the whole story of what the anesthetist is doing. As Drui and coworkers[320] suggested, mental activity is going on even when the anesthetist appears idle. What, then, is the mental workload of administering anesthesia? Mental workload is another concept that is readily understood but difficult to define precisely. There are various ways to measure workload, none of which are ideal.

Primary Task Performance Measure

The primary task performance measure assesses the subject's performance on standard work tasks as they are made progressively more difficult by increasing the number of tasks, task density, or task complexity. At first the subject is able to keep up with the increasing task load, but at some point the workload exceeds the ability to manage it, and performance on the standard tasks decreases. The disadvantage of the primary task performance measure is that in many complex task domains there is no accepted way to objectively measure the subject's performance on the primary work tasks except by loading to the point of catastrophic performance failure, which is easily detected. In actual high-risk domains, one cannot allow primary task performance to degrade, and one certainly cannot allow it to fail catastrophically. Although experiments of this type are in principle feasible with anesthesia simulators, they have not yet been attempted.

Secondary Task Probing

A more useful technique, secondary task probing, tests the subject with a minimally intrusive secondary task that is added to the primary work tasks. The secondary task is a simple one for which performance can be objectively measured, and the subject is instructed that the primary tasks of patient care take absolute precedence over the secondary task. Therefore, assuming that the secondary task requires some of the same mental resources as the primary task, the performance of the subject on the secondary task is an indirect reflection of the spare capacity available to deal with it; thus, it is an inverse measure of primary task workload (the greater the spare capacity, the lower the primary workload). Secondary tasks such as reaction time (with or without choice), finger tapping, and mental arithmetic have been used for this

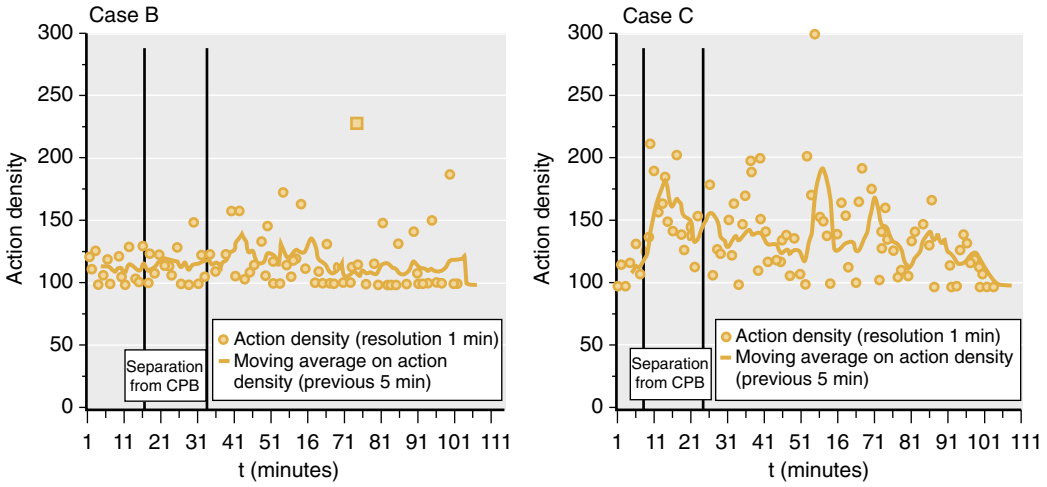

Figure 6-17 Action density during separation from cardiopulmonary bypass (CPB) without and with complications. The graph on the *left* is the density diagram of an uncomplicated case (case B) with a "flat" action density diagram during (between the two *vertical lines*) and after separation from CPB. In contrast, case C, shown in the graph on the *right*, had a complicated weaning from CPB; a very high action density is followed by an elevated density with further peaks after separation.

technique in the psychology laboratory, in high-fidelity simulators, and in some field studies of actual work situations.

Gaba and Lee[330] presented two-digit addition problems on a computer screen placed in the anesthesia workspace at random approximately every 45 seconds. The delay in responding to problems and the number of problems skipped were logged over time and correlated with a concurrent six-category task analysis. The dynamic ebb and flow of mental workload during cases of varying complexity was documented. For example, cardiopulmonary bypass was confirmed as a time of very low workload for the anesthetist, whereas induction of anesthesia was confirmed as a period of high workload. Manual tasks and conversing with the attending physician were correlated with a delayed or absent response to the secondary task.

Subsequent studies by the UCSD/VA-Stanford group[244,245] and the UCD group[325,329,331] used the reaction time to a changing display in or around the clinical monitors as a secondary task to assess mental workload, vigilance, or both. For the UCSD/VA-Stanford group, the display was a red light placed next to the main physiologic monitor. This secondary task was analogous to but totally separate from the standard tasks of clinical work. When the secondary task was embedded in the regular work tasks, it was called an embedded task. The UCD group used a secondary task involving recognition of changes in the alphanumeric display of an unused channel of an actual clinical monitor (a parameter labeled "Vig" on the monitor changed values from "5" to "10"). This task was only partially embedded because although it did involve an actual clinical monitor, it displayed on an otherwise unused channel and was not of clinical significance. The VA-Stanford group has been experimenting with fully embedded secondary tasks during simulator anesthetic cases in which the values of actual clinical variables can be manipulated at will to evaluate the subject's response time to the excursion of data values beyond predefined reporting thresholds.

The mean response time to the red light used by the UCSD/VA-Stanford group was markedly less than 60 seconds for experienced subjects in both the induction and postinduction (maintenance) phases, but it was much higher for novice residents during the induction phase (Fig. 6-18). The probe was not given frequently enough to track the ebb and flow of workload. The response to the UCD task typically (56%) occurred within 60 seconds, but 16% of stimuli overall (27% during the induction period) were not responded to within 5 minutes. The conclusion was that spare capacity may be limited by the workload of the case during certain periods of anesthesia care.

There are several problems with these workload studies. One is interference with the "response channel." If responding to the probe requires manual activity with a mouse or keyboard (as in the studies of Gaba and Lee and the UCD group), it cannot be performed whenever the subject is occupied with a manual task. This is especially true during a sterile procedure. Therefore, it may

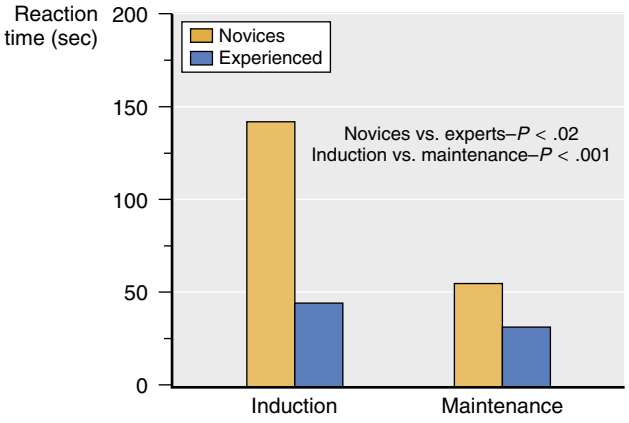

Figure 6-18 A test of the anesthetist's vigilance. Shown is the mean reaction time of novice residents and experienced anesthetists in response to the illumination of a red light placed next to the electrocardiogram monitor display during actual ambulatory surgery procedures. In both groups the reaction was faster in the maintenance phase than during induction of anesthesia. Novices reacted significantly more slowly than experienced anesthetists did. Because the distribution of reaction times was skewed and nongaussian, error bars are not shown and nonparametric statistics were used for hypothesis testing.

be impossible to distinguish between a high primary task load (i.e., no spare capacity to address the secondary task) and a low primary task load that happens to usurp the manual response channel. However, in the Gaba and Lee study,[330] 37% of the problems that were skipped for lack of spare capacity did not occur during a manual task. All of the UCSD/VA-Stanford studies have allowed multiple response channels (manual, voice, and gesture), so there was no response channel interference; however, the potential for interference remains in the UCD studies.

An additional problem with these studies is that even these simple secondary tasks were intrusive when repeated frequently. Thus, there was a tradeoff between temporal resolution of the measurement and its intrusiveness. There is also controversy about whether these probes measure "vigilance" or "workload," although the same techniques probably measure both aspects of performance. When probes occur infrequently, are subtle, have multiple response channels, and are performed with a low level of existing workload, they are more likely to measure vigilance; when they are frequent, readily detectable, require a manual response, and are performed during a high-workload period, they probably are more indicative of spare capacity and workload.

Slagle and colleagues[303] carried out an assessment of an established clinical task analysis methodology regarding intra- and inter-rater reliability. These investigators had one trained observer rating 20 routine anesthesia cases, first rating cases in the OR and then rating the same cases from a videotape, with another observer rating the same videotapes twice. A computerized task analysis program with 38 task categories was used. The results showed good intra-rater reliability and also high concordance between real-time and video analyses. This finding is important because real-time observation is unfeasible in many circumstances. This study had problems in analyzing parallel tasks because the technique of "toggling between the task categories at a rate proportional to the time spent on each task" resulted in big differences in "task duration" and "task occurrences" between the two raters. This problem of recording parallel tasks (two or more) was solved by Manser and colleagues in Tübingen.[246,247,332]

Subjective Measures

A third modality of workload assessment consists of subjective measures in which individuals are asked, either in retrospect or in real time, how much load they were or are under during actual work situations. Subjective measures complement objective measurements because the subjective perceptions of the anesthetist may be an important source of stress and anxiety; conversely, an anesthetist may subjectively underestimate the workload in settings in which objective measurements demonstrate a marked reduction in spare capacity.

Various scales have been proposed to measure dimensions of mental workload that are, in theory, different. However, Gaba and Lee[330] adapted a set of workload scales from those used at NASA and showed that workload ratings on each of the scales were highly correlated. In subsequent studies by the UCSD/VA-Stanford group, a single dimension of overall load was assessed by using an asymmetric numeric scale that minimized biases caused by a tendency to group responses at the middle and extremes of symmetric scales. This group demonstrated that a neutral observer can estimate the subjective workload of the anesthetist in real time with high correlation to the self-rated workload of the subject.[244] Again, as could be expected, subjective workload was highest during induction and emergence from anesthesia, especially for novices.

Physiologic Measures

The final set of techniques for assessing workload consists of physiologic measures. Visual or auditory evoked potentials have been used successfully to assess mental workload, but this technique can be used only in a static laboratory environment. Heart rate is a relatively easily measured variable that may be altered by mental workload. Toung and associates[333] showed that the anesthetist's heart rate increases at the time of intubation and that the amount of increase is inversely related to the amount of overall medical training. Azar and coworkers[334] found that anesthesia faculty members' heart rate and blood pressure increased during induction of anesthesia and that significant ST-segment depression developed in one individual. Bitetti and colleagues[335] confirmed that heart rate changes occurred during anesthesia but did not always correlate with contemporaneous self-recordings of "stress."

Because of the many factors that affect heart rate, the beat-to-beat variability of the heart rate is thought to be a better indicator of mental workload. The frequency components of heart rate variability can be separated by spectral analysis; a component at 0.1 Hz has been linked to mental workload. Although several groups have acquired heart rate data on anesthesiologists, none has reported an analysis of the workload-related frequency components.

Applications of Task Analysis and Workload Methodologies

The results of task analyses and workload measurements have primarily provided objective confirmation of a number of intuitive beliefs about anesthesia practice. The real importance of these studies is that a coherent methodology has been developed that may be useful for studying a variety of interesting questions.[247,336] The question of the impact of electronic automated record-keeping systems was addressed earlier. Another question concerns TEE. This newer monitoring modality has become commonplace during cardiac anesthesia and anesthesia for other patients with cardiovascular disease who undergo complex operations. It is widely recognized that evaluating TEE images and manipulating the TEE probe require substantial visual and mental attention.

The UCSD/VA-Stanford group has published data suggesting that vigilance (as measured by response latency to illumination of a red light) was substantially lower when the anesthesiologist was involved in manipulating, adjusting, or examining the TEE images than when other patient care tasks were being performed (Fig. 6-19).[328] This may be due, in part, to the layout of the workspace. The TEE machine is large and is often placed near the left side of the head of the OR table, whereas the anesthesia machine and attendant monitors, by convention, are typically placed near the right side of the head of the table. Remote displays slaved to the primary monitor are also more likely to be on the patient's right side. This arrangement makes it physically difficult to glance from one modality to another. The degree to which the mental concentration required to use TEE itself detracts from vigilance for other signals remains to be determined explicitly.

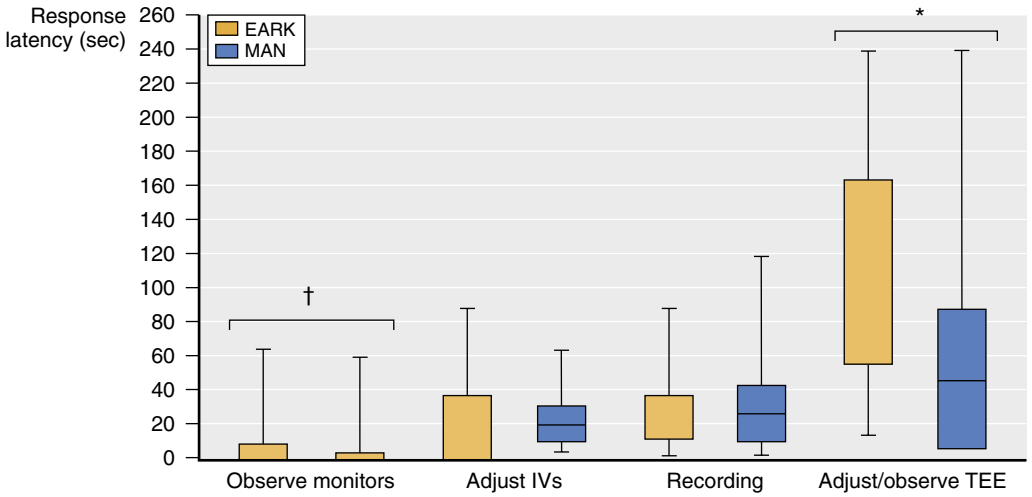

Figure 6-19 Vigilance test data during anesthetic tasks with and without automated record keeping. The range of data is shown for each of four task categories in electronic automated record keeping (EARK) and manual record keeping (MAN). Each box contains 50% of the data for that subgroup (the upper limit of the box is the 75th percentile; the lower limit is the 25th percentile), whereas the maximum and minimum are shown by the upper and lower *horizontal bars*. The response latency during record keeping was not significantly different between EARK and MAN. In both record-keeping groups, subjects had significantly slower responses when observing or adjusting the transesophageal echocardiogram (TEE) than when recording, observing monitors, or adjusting intravenous lines (IVs). Subjects in both groups had faster response latency when observing the monitoring array, which contained a red light, than when performing the other three tasks. *$P < .05$; †$P < .05$. *(From Weinger MB, Herdon OW, Gaba DM: The effect of electronic record keeping and transesophageal echocardiography on task distribution, workload, and vigilance during cardiac anesthesia. Anesthesiology 87:144-145, 1997.)*

It is important to differentiate the various uses of TEE. When it is used to answer specific clinical questions triggered by events or milestones during the procedure, the value of the information may be worth an investment of effort even though there is a reduction in overall vigilance. When it is used as a continuous monitor for myocardial ischemia or when conducting a detailed routine examination, the reduction in vigilance must be considered when evaluating the potential benefits of the technology. Some practitioners describe special ways to handle the attention required for TEE, including tightening alarm thresholds (to provide audio warnings of changed values) and assigning specific patient monitoring functions to another individual while conducting the initial TEE placement and examination.

Many other interesting questions on the performance of anesthetists are still unanswered and can be addressed with the techniques of task analysis and workload and vigilance assessment, including the following:

1. How do task load and task density differ between private practice settings and academic settings?
2. Are there characteristic "patterns" for experts and novices (or should we say for "good" and "bad" anesthesiologists?) in the analysis of tasks and their densities? And if yes,
   a. How do the work patterns of novices change to become those of "experts"? How can the training of novices be focused to support these changes best? Is suboptimal performance of novices detectable through analysis of task distributions and mental workload?
   b. Can work patterns be linked to safe anesthetic practice, or can special patterns be linked to unsafe behavior? Perhaps this could be done by assessing high-workload simulator scenarios. In a proactive safety culture, this would allow us to identify such colleagues and train them individually.
3. How much task load can the average anesthetist handle? How are tasks distributed among personnel (e.g., between resident and faculty, between CRNA and supervisor, and among staff anesthetists) during the high-workload periods of patient care? This question is just beginning to be addressed by applying the task analysis techniques described earlier to videotapes of actual anesthetic cases. With use of these tapes, the task sequences of multiple anesthesia personnel can be elicited separately, as can the communications used to coordinate their activities.

Ability Requirements for Anesthetists

Unlike the situation in military aviation, there are few formal selection criteria for entry into anesthesia practice. Instead, the criteria are decided on by each department's trainee selection committee. Nearly every student who chooses anesthesia as a specialty will be accepted by some training institution. Moreover, few residents are terminated from their anesthesia training—and then usually only because of drug abuse or too persistent or egregious lack of normal or technical skill.

There has been recent work on defining the underlying ability characteristics of a successful anesthetist. Greaves and Grant[21] presented an inventory of 16 characteristics of "good" anesthetic practice—knowledge, skill, perception, confidence, prudence, vigilance, fluency, decisiveness, anticipation, organization, flexibility, responsiveness, good manner, assertiveness, good management, and good communication. This inventory can serve as a basis for discussion of anesthetists' education and training. The authors of the inventory recommended its use for a formalized consultant feedback to trainees, although they pointed out its unproven validity and reliability.

An interdisciplinary group in Germany conducted an evaluation of another list of critical abilities for anesthetists published in German.[337]

Other Studies of "Vigilance" and Decision-Making by Anesthetists

Studies of "Vigilance"

The dominant metaphor for the mental activity of the anesthetist has been that of a vigilance task. "Vigilance" is the motto on the seal of the ASA. What is vigilance and to what degree does it capture the complex nature of the anesthetist's work? "Vigilance, or sustained attention, refers to the ability of observers to maintain their focus of attention and to remain alert to stimuli for prolonged periods of time" (J. Warm, presentation at the Panel on Vigilance, ASA annual meeting, 1992). There is an abundance of literature concerning vigilance. Many laboratory studies have demonstrated decrements in vigilance during prolonged vigilance tasks that are exacerbated or ameliorated by a variety of factors. These studies have generated considerable controversy. Some psychologists believe that the results of laboratory studies of vigilance have little application to complex real-world task domains.[338,339] Certainly, the anesthetist's work involves vigilance as a necessary component because if new stimuli are not perceived, no meaningful work can be accomplished. However, the anesthetist's task is much more complex than just vigilant alertness to stimuli. Therefore, vigilance is a necessary but not sufficient condition for appropriate performance.[58]

Several studies have attempted to quantitate the vigilance of anesthetists to changes in clinically important variables by using low-fidelity simulation. Beatty and associates[340] had anesthetists watch for changes in displays of six vital signs on a video monitor. Denisco and colleagues[341] used videotapes containing abnormal changes in anesthesia flow meter settings and physiologic monitor displays. The raw reaction times were not reported—only the "vigilance scores." Such studies purported to demonstrate a degradation in performance for sleep-deprived and fatigued residents, but there were methodologic flaws. For example, in the study of Denisco and coworkers,[341] the subjects were never told the threshold of change for them to report.

In addition, the work environment of the anesthetist is much more complex than that presented in these low-fidelity simulations. Although it can be argued that complexity will worsen vigilance, such is not necessarily the case. Complexity can combat boredom, which is a distinct possibility in vigilance experiments. In addition, the real work environment often provides redundant data cues on changes, which offers multiple possibilities for their detection.

A study of rested anesthetists[178] using a realistic anesthesia simulator measured detection times (first awareness of a problem) for a variety of intraoperative events embedded within a realistic case situation. Of interest, an event that caused alarms to sound immediately, such as ventricular tachycardia/fibrillation, was detected in 10 seconds or less (thus confirming its veracity, but acting on it took longer in many instances). Another event, occlusion of the intravenous line, was detectable only by visual observation in the direction opposite the anesthesia machine and monitors. This event took several minutes (on average) to detect, but it was corrected quickly after detection. The redundancy of cues in the task domain was confirmed in that six different observational modalities were used by at least 1 of the 19 residents studied to detect endobronchial intubation initially.

Other vigilance studies have focused on detecting the loss of an existing monitoring modality during actual patient care. In one study,[342] the esophageal stethoscope was occluded with a clamp after a staged distraction (conversation or a loud noise). Subjects most commonly detected the occlusion by observing the clamp rather than by noting a loss of sound. Although this study purported to show a difference in vigilance related to the use of automatic blood pressure measurement devices, the artificial distraction could have biased the results; the subjects typically failed to hear the loss of sounds, and there was a significant result for only one group of residents, arbitrarily stratified by length of training. Another study[343] that evaluated reaction time to loss of esophageal stethoscopy more carefully showed that 13% of occlusions were detected after 1 minute. However, this study required a manual response, and the investigators noted that in some instances of delay, the subject was involved in a manual clinical activity such as administering blood or drugs.

Apparent reductions in vigilance could be due either to a reduction in "spare capacity" to attend to the stimuli immediately or to a reduction in the overall alertness of the anesthetist. Enhancements in the display and annunciation of relevant information would be a useful ameliorative strategy in the first case, whereas this strategy would not be useful if the anesthetist's overall alertness were impaired, as by sleep deprivation or illness. The influence and impact of fatigue and possible countermeasures are covered in the earlier section "Performance-Shaping Factors."

Empirical Studies of Complex Decision-Making and Action by Anesthetists

Traditional concepts of decision-making in medicine have concentrated on relatively static, well-structured decisions. For example, should patient A with an elevated blood pressure be treated for hypertension with drug X, or should no treatment be started? Other investigators have looked only at "diagnosis" as an isolated task (specifically, "diagnostic explanation") both in internal medicine[344-346] and in radiology. These approaches to decision-making have not captured the unique aspects of dynamism, time pressure, and uncertainty seen in anesthesiology. Over the past decade, a paradigm has emerged regarding decision-making and action in complex real-world situations.[39,236,250] The cognitive model of dynamic decision-making was described previously. Several teams from inside the anesthesiology profession and from the human performance community have been striving to develop a more comprehensive understanding of the complex performance of anesthetists. Their work has been based on a small number of new experiments (often involving medium- or high-fidelity anesthesia simulators), reinterpretation of previous experiments, direct and indirect observation of the conduct of anesthesia, and extrapolations from other industries to anesthesiology. Each experiment has probed several aspects of decision-making and action, which are described in the following section.

Responding to Simulated Critical Incidents

Using a realistic hands-on anesthesia simulator, Gaba and DeAnda[111,259,347] studied the response of anesthesia trainees and

experienced anesthesia faculty and private practitioners to six preplanned critical incidents of differing type and severity:

1. Breathing hoses too short to turn the table 180 degrees, as requested by the surgeon
2. Endobronchial intubation (EI) resulting from surgical manipulation of the tube
3. Occlusion of intravenous tubing
4. Atrial fibrillation (AF) with a rapid ventricular response and hypotension
5. Disconnection between the endotracheal tube and the breathing circuit
6. Ventricular tachycardia/fibrillation

These investigators measured the detection time (as described in the section on vigilance) and the correction time (the time from the event's onset until any one of a predefined set of corrective actions was first taken). They assessed the information sources by which subjects detected the incidents and then confirmed and diagnosed the problem. They asked subjects to "think aloud" to permit subjective analysis of their decision-making strategies. A summary of the data is shown in Figure 6-20. Major findings from this set of studies included the following:

1. Events differed from each other in their inherent ease of solution. Some events (e.g., airway disconnection) were

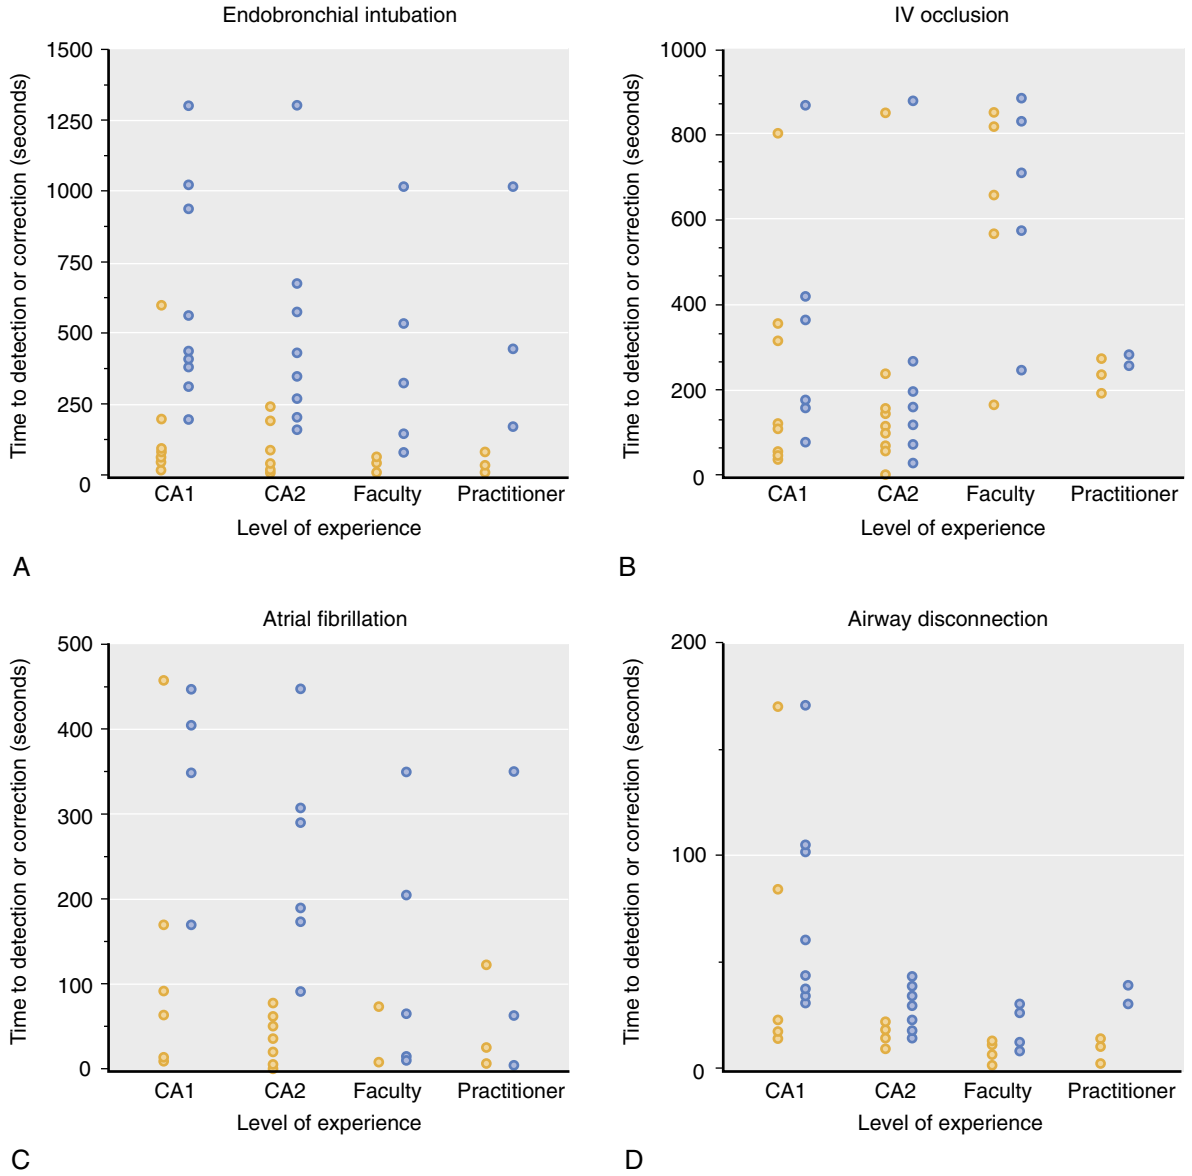

Figure 6-20 Response times of anesthesiologists with different levels of experience to four simulated critical incidents: **A,** endobronchial intubation; **B,** intravenous occlusion (IV); **C,** atrial fibrillation; and **D,** airway disconnection. Detection time is represented by *yellow circles* and correction time by *blue circles* (see text for definitions of these times). Unless there is overlap between response times, each circle represents a single individual. The scale of response times is different for each event. There is substantial variability among incidents and among individuals. Despite a trend to better performance with increased experience, major errors were made by individuals in all groups. *(From DeAnda A, Gaba DM: Role of experience in the response to simulated critical incidents. Anesth Analg 72:308-315, 1991.)*

detected rapidly and corrected. Some problems (e.g., intravenous occlusion) were difficult to detect, but once they were detected, diagnosis and therapy were achieved rapidly. Other problems (EI, AF) were easy to detect by using one of several redundant information sources as the first clue (six for EI, four for AF), but they required additional time (7 to 8 minutes for EI; 1.5 to 4.5 minutes for AF) to confirm the abnormality, establish a diagnosis, and initiate appropriate therapy. Diagnosis and planning and monitoring of therapy used a large number of information sources (11 for EI; 9 for AF).

2. For each incident there was considerable inter-individual variability in detection and correction times, in information sources used, and in the actions taken. In each experience group there were some who required excessive time to solve the problem or who never solved it. In addition, in each experience group at least one individual made major errors that could have had a substantial negative impact on a patient's clinical outcome. For example, one faculty member never used electrical countershock to treat ventricular fibrillation. One private practitioner treated the EI as though it were "bronchospasm" and never assessed the symmetry of ventilation. One resident never found the airway disconnection.
3. The average performance of the anesthetists tended to improve with experience, although this varied by incident. The performance of the experienced groups was not definitively better than that of the second-year residents (who were in their final year of training at that time). Many (but not all) novice residents performed indistinguishably from more experienced subjects.
4. The elements of suboptimal performance were both technical and cognitive. Technical problems included choosing defibrillation energies appropriate for internal paddles when using external paddles, ampule swap, and failure to inflate the endotracheal tube cuff that resulted in a leak. Cognitive problems included failure to allocate attention to the most critical problems and fixation errors.

Schwid and O'Donnell,[258] from the University of Washington, used the Anesthesia Simulator Consultant (ASC) screen-only simulator (Anesoft Corp., Issaquah, WA) (Table 6-10) to perform an experiment similar to those of Gaba and DeAnda with a realistic simulator. This method enabled them to evaluate some elements of anesthetist behavior more carefully, albeit with the limitations imposed by presenting the OR "on the screen." After working on several practice cases without critical incidents, each subject was asked to manage three or four cases involving a total of four serious critical events (esophageal intubation, myocardial ischemia, anaphylaxis, and cardiac arrest). The progression of each event was mediated by the interaction of physiologic and pharmacologic models with the actions taken by the subject. The anesthesiologists studied had varying experience levels. One group was made up of 10 anesthesia residents with at least 1 year of anesthesia training, whereas the other two groups contained 10 anesthesia faculty members and 10 private practitioners, respectively.

Major findings of the study included the following:

1. Significant errors in diagnosis or treatment were made in every experience group. The errors occurred in both diagnosis of problems and in deciding on and implementing appropriate treatment. For example, 60% of subjects did not make the diagnosis of anaphylaxis despite available information on heart rate, blood pressure, wheezing, increased peak inspiratory pressure, and the presence of a rash. In managing myocardial ischemia, there were multiple failures (Table 6-11).
2. Thirty percent of subjects did not compensate for severe abnormalities while considering diagnostic maneuvers.
3. Fixation errors in which initial diagnoses and plans were never revised were frequent, even when they were clearly wrong.

Westenskow and colleagues[253] used a test lung and remotely activated faults in the breathing circuit to test the anesthetist's ability to identify faults related to ventilation and the anesthesia breathing circuit after hearing an alarm. One group of subjects used standard alarms, set to factory defaults, on an anesthesia machine, which included a capnograph. The other group used the same anesthesia machine with the alarms disabled along with a neural network–based intelligent alarm and fault identification system. The mean "human response time," which was the time between sounding of the first alarm and identification of the event, ranged from approximately 15 seconds for airway disconnection to approximately 90 seconds for an endotracheal tube cuff leak. The 10 anesthesiologists tested with the standard alarm setup were unable to identify the fault within 2 minutes on 11 occasions—5 cuff leaks, 3 airway obstructions, and 3 stuck-open expiratory valves. However, in such circumstances they did take appropriate compensatory actions while continuing to search for the cause (e.g., increasing fresh gas flow to compensate for a cuff leak).

The intelligent alarm apparatus used data from three sensors (in-line capnograph, spirometer, and airway pressure). A neural network determined whether any of seven faults was present and, if so, displayed a text message specifying the fault, as well as an animated diagram of the lung, airway, and anesthesia

Table 6-10 Incidence of Totally Correct Diagnosis or Treatment of Simulated Critical Incidents with Use of the Anesthesia Simulator Consultant

Incident	Anesthesia Residents (%)	Anesthesia Attendings (%)	Anesthesiologists in Practice (%)
Diagnosis of esophageal intubation	80	100	100
Treatment of myocardial ischemia	20	40	20
Diagnosis of anaphylaxis	20	60	40
Treatment of cardiac arrest	40	30	20

From Schwid HA, O'Donnell D: Anesthesiologists' management of simulated critical incidents. Anesthesiology 76:495-501, 1992.

Table 6-11 Failure Rate in the Management of Simulated Myocardial Ischemia with the Anesthesia Simulator Consultant

Incident	Anesthesia Residents (%)	Anesthesia Attendings (%)	Anesthesiologists in Practice (%)
Untreated tachycardia	30	50	70
Untreated hypotension	40	60	20
Inappropriate drug	20	10	0
Unable to recall infusion dose	50	20	10
Unable to calculate infusion rate	70	40	40

From Schwid HA, O'Donnell D: Anesthesiologists' management of simulated critical incidents. Anesthesiology 76:495-501, 1992.

breathing circuit with the faulty component highlighted in red. It is interesting that the smart alarm system took slightly longer on average to detect a fault than the conventional alarm system did (25 versus 21 seconds), but the human response time was markedly reduced for three of the seven faults. There were no statistically significant differences between anesthesia residents and faculty members with either alarm system.

The investigators suggested that the more specific alarm messages in their intelligent alarm system could direct the attention of the anesthetist to the occurrence of specific problems and in so doing would decrease workload and reduce the likelihood of fixating on inappropriate information. They stated that such a system's advantages would be even greater in a more realistic clinical environment in which the anesthetist has multiple complex tasks and not just detection and identification of ventilation-related events.

Loeb and Fitch[348] developed and tested an auditory display of six physiologic variables. Encouraged by the popularity of the pulse oximeter's pulse tone,[349-351] they investigated whether the addition of auditory cues would enhance the rate and speed of detection of predefined events. The results showed that the combined display (visual and auditory) lead to faster detection of events, even though the rate for correct identification of the event was slightly higher in the "visual only" display (80% versus 88%). It seems that there is a potential to improve the rate of detection of changes in physiologic variables with more sophisticated display modalities, thereby enhancing the "effective vigilance" of anesthetists.

Complex, Multiple Personnel Simulations of Anesthetic Crises

In the process of evaluating a new type of training for anesthetists involving crisis management, Howard and colleagues[109] collected anecdotal data on the responses of teams of anesthetists, surgeons, and nurses to planned (and unplanned) critical events. These experiments largely confirmed the results of the studies described earlier and extended them to include more complex management issues and team interactions. Howard and colleagues found a substantial incidence of difficulties managing multiple problems simultaneously, applying attention to the most critical needs, acting as team leader, communicating with personnel, and using all available OR resources to best advantage.

Botney and associates[352] analyzed similar videotapes from 18 different simulator training sessions on crisis management. In one event, a volatile anesthetic vaporizer had been left on at 4% and was hidden beneath a printout from the noninvasive blood pressure monitor. Simultaneously, there was a mechanical failure of the capnograph, making it impossible to confirm endotracheal intubation with CO_2 measurements. This event purposefully presented an invitation to become fixated on the endotracheal tube while ignoring other relevant information. Five of 18 subjects never discovered the volatile anesthetic overdose despite catastrophic effects on blood pressure and heart rate and clear evidence that the endotracheal tube was correctly placed. Of those who did detect the vaporizer setting, the average time to detection was nearly 4 minutes, with some subjects taking longer than 12 minutes.

In the second event studied, there was a loss of pipeline O_2 supply while an anesthetist was assuming the care of a critically ill patient who required an F_{IO_2} of 100% to achieve satisfactory blood oxygenation. The O_2 cylinder on the machine was empty (i.e., it had not been checked by the initial anesthetist, who had left the case after becoming ill). The pipeline failure was quickly detected (19 seconds), but the responses to it were extremely variable and showed a variety of problems. Five of 18 anesthetists closed the anesthesia circuit (which preserves the existing oxygen in the circuit), but all 5 subsequently switched to ventilation with a self-inflating bag using room air or to mouth-to-tube ventilation. Five of 18 could not open the reserve oxygen cylinder because they could not locate the tank wrench attached to the machine (it tended to rest between two gas cylinders). Several teams had trouble mounting a new oxygen tank on the anesthesia machine; problems with the gasket disk were frequent. The individuals did not appear to have a well-formulated plan for managing this event, and they did not optimally coordinate their actions with their assistants or with the other OR personnel.

A study by Byrne and Jones[310] looked at differences in the performance of experienced and less experienced anesthetists. Using a self-developed patient simulator system, they measured time to treatment and deficiencies in patient care in 180 simulations. The results showed significant differences only between the first and second year. As seen in other studies,[319] significant errors occurred at all levels of experience, and most of the anesthetists deviated from established guidelines. These studies underscore the importance of recurrent training for experienced anesthetists and the truism that experience is not a substitute for excellence.

The reader is referred to Chapter 7 for discussion of newer studies with the use of patient simulators and performance assessment as such.[17,20,142,148,312,319,353-357]

Indirect Observation of Anesthetists Involved in Difficult Cases

An unusual approach involving indirect observation of actual cases was used by Cook and colleagues[255] at the Ohio State University. Rather than collecting data on the case itself, these investigators transcribed the discussions of interesting cases occurring

at a weekly quality assurance conference. They argued that this approach allowed them to apply a "neutral observer criterion" to the behavior of the anesthetist. The investigators acknowledged the risks of hindsight bias and selection bias with this methodology, but they suggested that their technique provided a unique window on human performance issues.

Fifty-seven cases were analyzed, 21 of which had a full cognitive analysis in the final report. From the presentation and discussion of a case, the investigators classified evolution of the events into one of five categories: acute incident, going-sour incident, inevitable outcome incident, difficult-airway incident, and no-incident incident. For each case, the cognitive analysis was "based on using knowledge about the cognitive demands of the task domain and data about practitioner activities to analyze the practitioner's information-processing strategies and goals, given the resources and constraints of the situation." The investigators postulated a cognitive cycle as a component of data-driven activation of knowledge and knowledge-driven observation and action.

Cook and associates[255] called attention to several issues that surfaced in their cognitive analysis of these cases, including the following:

1. Multiple themes. Many cases involved several lines of concern simultaneously, each of which could have interacted with another (e.g., tight coupling). Each theme had multiple means available to deal with it. Maintaining "situation awareness" was important. The multiple themes sometimes generated competing or conflicting goals. Adaptive planning (as described in the section on abstract task analysis) was sometimes required.
2. Unusual situations. The greatest expertise was seen with infrequent or unusual situations rather than with typical situations.
3. Allocation of attention. Allocation of attention to relevant stimuli or to the most important "theme" was an important issue. The attentional shifts were not always well supported by existing alarm and display technologies.
4. Cognitive workload. Anesthetists attempted to reduce their cognitive workload whenever possible.
5. Team interaction. Cooperative work, team interaction, and communications issues were problems in several cases. These stemmed from both individual and organizational failures to coordinate information and efforts from different organizational components (e.g., ICU and OR, surgeons and anesthesiologists).

Direct Observation of Anesthetists

A team of cognitive scientists and anesthesiologists at the University of Toronto[226] conducted direct observations of anesthesiologists and obtained verbal "think aloud" protocols during actual case management. The group in Tübingen also performed direct observations for their task analysis studies.[247,328] Devitt and coworkers performed a study to assess the validity of performance assessment during simulated scenarios.[19]

Video Analysis of Actual Trauma Resuscitation and Anesthesia

Mackenzie and colleagues[358-362] pioneered in the analysis of actual clinical care of anesthetists captured on videotape, with a focus on trauma resuscitation and anesthesia for trauma patients at the Maryland Shock Trauma Unit. Their sophisticated recording system captures audio, video, and vital signs data and requires only that the clinicians insert a videotape to start the whole system.[363] Analysis of these cases has revealed inadequacies in the availability and arrangement of monitoring equipment, as well as nonexistent or ambiguous communication. Meanwhile, a few groups around the world started to use video for task analysis and assessment of performance for research and training, which is not detailed here.[150,178,270,303,332,364-370]

Problems faced by all investigators are the lack of an accepted standard for objective or subjective evaluation of anesthetist performance and the absence of an agreed-on methodology for analyzing and describing anesthetist performance. Several of the previously mentioned groups are working on methodologies for evaluating technical and behavioral aspects of performance.* Measurement of complex performance is a difficult problem, and it is likely to be some time until there is a well-established metric for assessment of performance.

7 Patient Simulation

Key Points

1. Simulators and the use of simulation have become an integral part of medical education, training, and research. The pace of developments and applications is very fast, and the results are promising.
2. Different types of simulators can be distinguished: computer-based or screen-based microsimulators versus mannequin-based simulators. The latter can be divided into script-based and model-based simulators.
3. The development of mobile and less expensive simulator models allows for substantial expansion of simulator training to areas where this training could not be applied or afforded previously. The biggest obstacles to providing simulation training are not the simulator hardware but are (1) obtaining access to the learner population for the requisite time and (2) providing appropriately trained and skilled instructors to prepare, conduct, and evaluate the simulation sessions.
4. Realistic simulations are a useful method to show mechanisms of error development (human factors) and to provide their countermeasures. The anesthesia crisis resource management (ACRM) course model with its ACRM key points (see Chapter 6 on Crisis Resource Management) is the de facto world standard for human factor–based simulator training. Curricula should use scenarios that are tailored to the stated teaching goals, rather than focusing solely on achieving maximum "realism."
5. Simulator training is being adapted by many other fields outside anesthesia (e.g., emergency medicine, neonatal care, intensive care, medical and nursing school).
6. Simulators have proved to be very valuable in research to study human behavior and failure modes under conditions of critical incidents and in the development of new treatment concepts (telemedicine) and in support of the biomedical industry (e.g., device beta-testing).
7. Simulators can be used as effective research tools for studying methods of performance assessment.
8. Assessment of nontechnical skills (or behavioral markers) has evolved considerably and can be accomplished with a reliability that likely matches that of many other subjective judgments in patient care. Systems for rating nontechnical skills have been introduced and tested in anesthesia; one in particular (Anaesthetists' Non-Technical Skills [ANTS]) has been studied extensively and has been modified for other fields.
9. The most important part of simulator training that goes beyond specific technical skills is the self-reflective (often video-assisted) debriefing session after the scenario. The debriefing is influenced most strongly by the quality of the instructor, not the fidelity of the simulator.
10. Simulators are just the tools for an effective learning experience. The education and training, commitment, and overall ability of the instructors are of utmost importance.

How can clinicians experience the difficulties of patient care without putting patients at undue risk? How can we assess the abilities of clinicians as individuals and teams when each patient is unique? These are questions that have challenged medicine for years. In recent years, these and related questions have begun to be answered in health care by the application of approaches new to medicine, but borrowed from years of successful service in other industries facing similar problems. These approaches focus on *simulation,* a technique well known in the military, aviation, space flight, and nuclear power industries.

Simulation refers to the artificial replication of sufficient elements of a real-world domain to achieve a stated goal. The goals can include understanding the domain better, training personnel to deal with the domain, or testing the capacity of personnel to work in the domain. The fidelity of a simulation refers to how closely it replicates the domain and is determined by the number of elements that are replicated and the discrepancy between each element and the real world. The fidelity required depends on the stated goals. Some goals can be achieved with minimal fidelity, whereas others require very high fidelity.

Simulation has probably been a part of human activity since prehistoric times. Rehearsal for hunting activities and warfare was most likely an occasion for simulating the behavior of prey or enemy warriors. Technologic simulation probably dates back to the dawn of technology itself. Good and Gravenstein[1] pointed to the medieval quintain as a technologic device that crudely simulated the behavior of an opponent during sword fighting. If the swordsman did not duck at the appropriate time after striking a blow, he would be hit by a component of the quintain. In modern times, preparation for warfare has been an equally powerful spur to the development of simulation technologies, especially for aviation, shipping, and the operation of armored vehicles. These technologies have been adopted by their civilian counterparts, but they have attained their most extensive use in commercial aviation.

Simulation in Aviation

Although some aircraft simulators were built between 1910 and 1927, none of them could provide the proper feel of the aircraft because they could not dynamically reproduce its behavior. In 1930, Link filed a patent for a pneumatically driven aircraft simulator. The Link Trainer was a standard for flight training before World War II, but the war accelerated its use and the further development of flight simulators. In the 1950s, electronic controls replaced pneumatic ones through analog, digital, and hybrid computers. The aircraft simulator achieved its modern form in the late 1960s, but it has been continuously refined. Aviation simulators are so realistic now that pilots with experience flying one aircraft are routinely certified to fly totally new or different aircraft, even if they have never flown the actual aircraft without passengers on board. Similar stories of the development of simulators can be told for numerous other industries.

Uses of Simulators

Although simulators originally were used to provide basic instruction on the operation of aircraft controls, the variety of uses of simulators in general has expanded greatly. Table 7-1 lists possible uses of simulators in all types of complex work situations. Simulation is a powerful generic tool for dealing with human performance issues (e.g., training, testing, and research) (see Chapter 6), for investigating human-machine interactions, and for the design and validation of equipment. As described later in this chapter, each of these uses is potentially relevant to anesthesiology. A few books are devoted solely to the topic of simulation and their use in and outside of anesthesia.[2-4]

Twelve Dimensions of Simulation

Current and future applications of simulation can be categorized by 12 dimensions, each of which represents a different attribute of simulation (Fig. 7-1).[5] Some dimensions have a clear gradient and direction, whereas others have only categorical differences. The total number of unique combinations across all the dimensions is very large (on the order of 4^{12} to 5^{12}—4 million to 48 million). Some combinations overlap strongly with others, and some are inappropriate or irrelevant, so the actual number of meaningful combinations is much lower. Nonetheless, although the demonstrated applications of simulation in health care have been quite diverse, the space of possible applications (a large number, although quite a bit smaller than millions) has by no means been fully examined.

Table 7-1 Use of Simulators in Complex Work Environments

Team training, as human factor or CRM training
Training in dynamic plant control
Training in diagnostic skills
Dynamic mockup for design evaluation
Test bed for checking operating instructions
Environment in which task analysis can be conducted (e.g., on diagnostic strategies)
Test bed for new applications (e.g., telemedicine tools such as the "Guardian-Angel-System")
Source of data on human errors relevant to risk and reliability assessment
Vehicle for (compulsory) testing/assessment and recertification of operators

CRM, Crisis resource management.
Adapted from Singleton WT: The Mind at Work. Cambridge, Cambridge University Press, 1989.

Dimension 1: Purpose and Aims of the Simulation Activity

The most obvious application of simulation is to improve the education and training of clinicians, but other purposes also are important. As used in this chapter, *education* emphasizes conceptual knowledge, basic skills, and an introduction to work practices. *Training* emphasizes the actual tasks and work to be performed. Simulation can be used to *assess performance* and competency of individual clinicians and teams, for low-stakes or formative testing and (to a lesser degree as yet) for high-stakes certification testing.[6,7] Simulation *rehearsals* are now being explored as adjuncts to actual clinical practice; for example, surgeons or an entire operative team can rehearse an unusually complex operation in advance using a simulation of the specific patient.[8-10] Simulators can be powerful tools for research and evaluation, concerning *organizational practices* (patient care protocols) and for the *investigation of human factors* (e.g., of performance-shaping factors, such as fatigue,[11] or of the user interface and operation of medical equipment in high hazard clinical settings[12]). Simulation-based empirical tests of the usability of clinical equipment already have been used in designing equipment that is currently for sale; ultimately, such practices may be required by regulatory agencies before approval of new devices.

Simulation can be a "bottom up" tool for changing the culture of health care concerning patient safety. First, it allows hands-on training of junior and senior clinicians about practices that enact the desired "culture of safety."[13] Simulation also can be a rallying point about culture change and patient safety that can

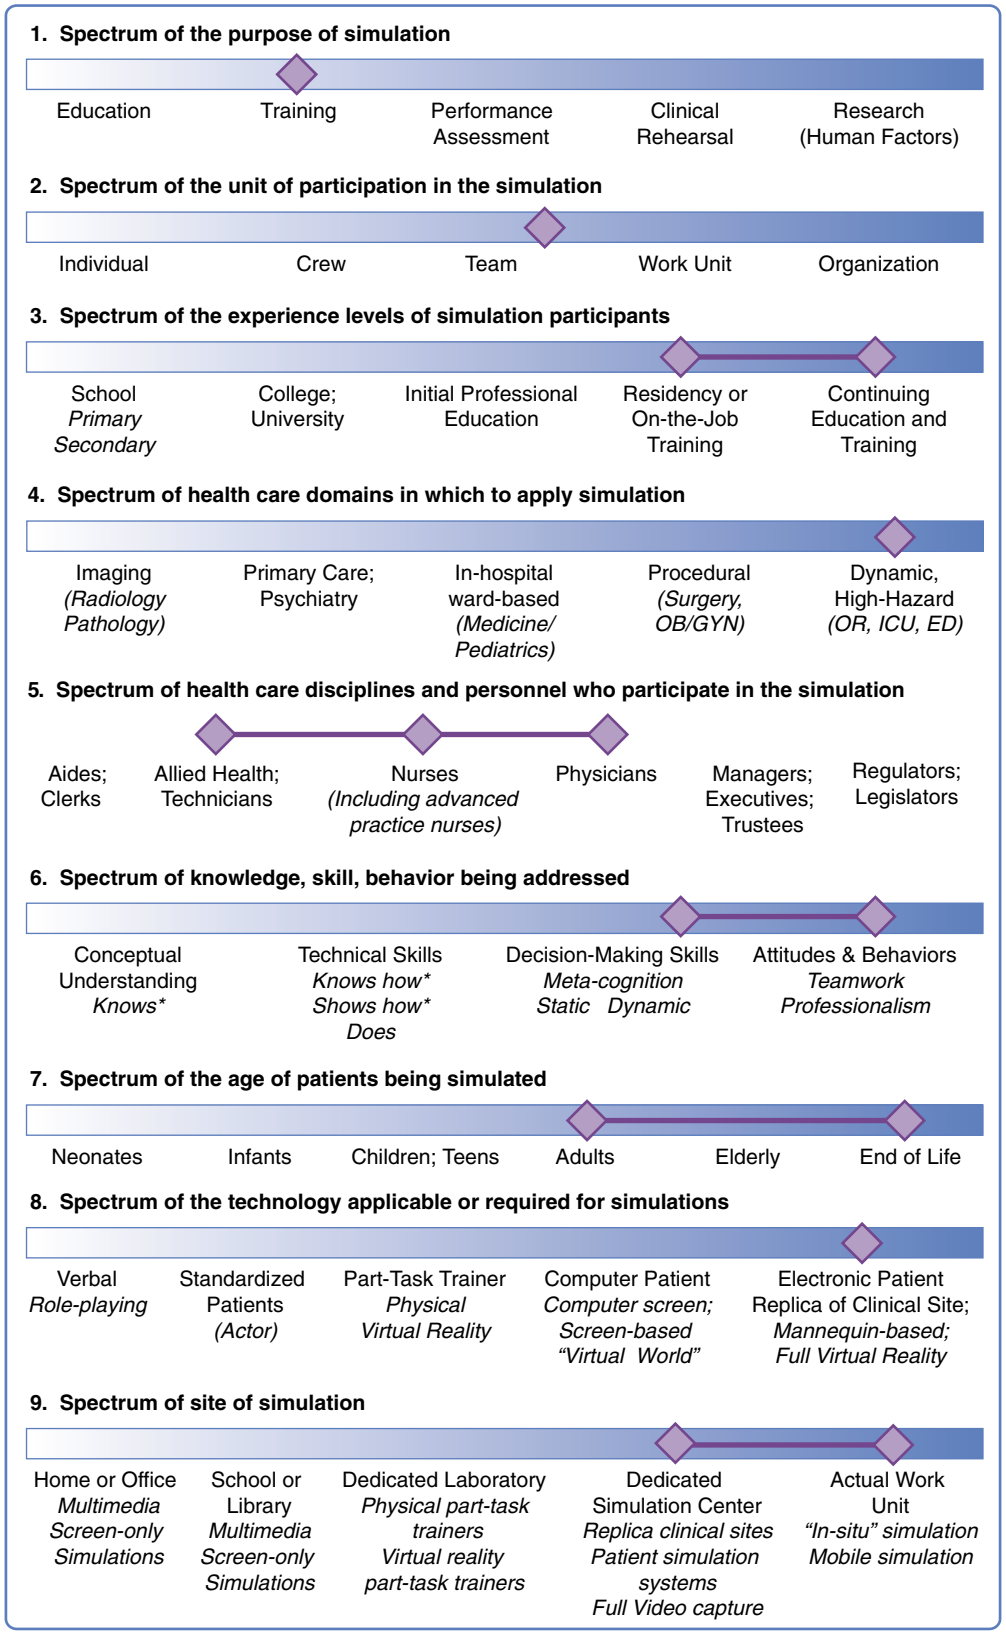

Figure 7-1 The 12 dimensions of simulation applications (10 to 12 shown on next page). Any particular application can be represented as a point or range on each spectrum (shown by *diamonds*). This figure illustrates a specific application—multidisciplinary CRM-oriented decision making and teamwork training for adult intensive care unit personnel. CRM, crises resource management; ED, emergency department; ICU, intensive care unit; OR, operating room. *These terms are used according to Miller's pyramid of learning.

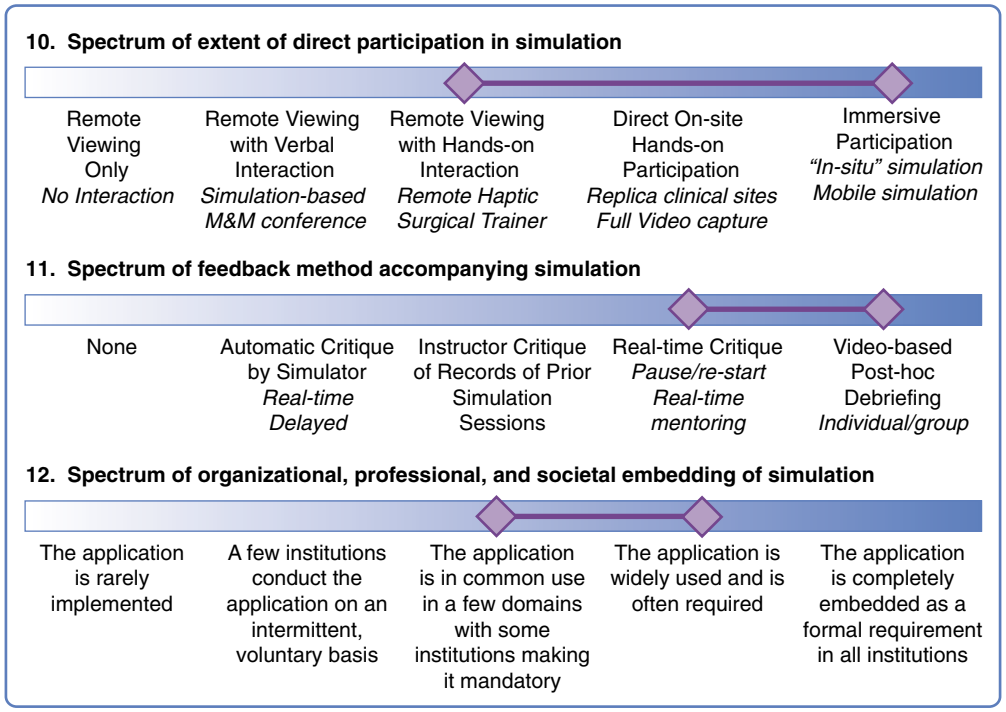

Figure 7-1, cont'd

bring together experienced clinicians from various disciplines and domains (who may be "captured" because the simulations are clinically challenging) along with health care administrators, risk managers, and experts on human factors, organizational behavior, or institutional change.

Dimension 2: Unit of Participation in the Simulation

Many simulation applications are targeted at individuals. These may be especially useful for teaching knowledge and basic skills or for practice on specific psychomotor tasks. As in other high hazard industries, individual skill is a fundamental building block, but a considerable emphasis is applied at higher organizational levels, in various forms of teamwork and interpersonal relations (often summarized under the rubric of *crisis resource management* (CRM) adapted from aviation cockpit resource management) (more on human factors and CRM concepts, see Chapter 6).[14,18] CRM is based on empirical findings that individual performance is not sufficient to achieve optimal safety.[15] Team training may be addressed first to crews (also known as *single discipline teams*), consisting of multiple individuals from a single discipline, and then to teams (or *multidisciplinary teams*).[16] There are advantages and disadvantages to addressing teamwork in the single discipline approach that "trains crews to work in teams" versus the "combined team training" of multiple disciplines together.[21] For maximal benefit, these approaches are used in a complementary fashion.

Teams exist in actual "work units" in an organization (e.g., a specific intensive care unit [ICU]), each of which is its own target for training. There also is growing interest and experience in applying simulation to nonclinical personnel and work units in health care organizations (e.g., to managers or executives)[22] and to organizations as a whole (e.g., entire hospitals or networks).

Dimension 3: Experience Level of Simulation Participants

Simulation can be applied along the entire continuum of education of clinical personnel and the public at large. It can be used with early learners, such as schoolchildren, or lay adults to facilitate bioscience instruction, to interest individuals in biomedical careers, or to explain health care issues and practices. The major role of simulation has been, and will continue to be, to educate, train, and provide rehearsal for individuals actually involved in the delivery of health care. Simulation is relevant from the earliest level of vocational or professional education (students) and during apprenticeship training (interns and residents), and increasingly for experienced personnel undergoing periodic refresher training. Simulation can be applied regularly to practicing clinicians (as individuals, teams, or organizations) regardless of their seniority,[17,18] providing an integrated accumulation of experiences that should have a long-term synergism.

Dimension 4: Health Care Domain in Which the Simulation Is Applied

Simulation techniques can be applied across nearly all health care domains. Although much of the attention on simulation has focused on technical and procedural skills applicable in

surgery,[11,20-22] obstetrics,[23,24] invasive cardiology,[25,26] and other related fields, another bastion of simulation has been recreating whole patients for dynamic domains involving high hazard and invasive intervention, such as anesthesia,[27,28] critical care,[29,30] and emergency medicine.[31-34] Immersive techniques can be used in imaging-intensive domains, such as radiology and pathology, and interactive simulations are relevant in the interventional sides of such arenas.[35] In many domains, simulation techniques have been useful for addressing nontechnical skills and professionalism issues, such as communicating with patients and coworkers, or addressing issues such as ethics or end-of-life care.

Dimension 5: Health Care Disciplines of Personnel Participating in the Simulation

Simulation is applicable to all disciplines of health care, not only to physicians. In anesthesiology, simulation has been applied to anesthesiologists, Certified Registered Nurse Anesthetists, and anesthesia technicians. Simulation is not limited to clinical personnel. It also may be directed at managers, executives, hospital trustees, regulators, and legislators. For these groups, simulation can convey the complexities of clinical work, and it can be used to exercise and probe the organizational practices of clinical institutions at multiple levels.

Dimension 6: Type of Knowledge, Skill, Attitudes, or Behavior Addressed in Simulation

Simulations can be used to help learners acquire new knowledge and to understand conceptual relations and dynamics better. Today physiologic simulations allow students to watch cardiovascular and respiratory functions unfold over time and respond to interventions—in essence making textbooks, diagrams, and graphs "come alive." The next step on the spectrum is acquisition of skills to accompany knowledge. Some skills follow immediately from conceptual knowledge (e.g., cardiac auscultation), whereas others involve intricate and complex psychomotor activities (e.g., catheter placement or basic surgical skills). Isolated skills must be assembled into a new layer of clinical practices. An understanding of the concepts of general surgery cannot be combined only with basic techniques of dissecting and suturing or manipulation of instruments to create a capable laparoscopic surgeon. Basic skills must be integrated into actual clinical techniques, a process for which simulation may have considerable power, especially because it can readily provide experience with even uncommon anatomic or clinical presentations. In the current health care system, for most invasive procedures, *novices at a task typically first perform the task on a real patient,* albeit under some degree of supervision. They climb the learning curve, working on patients with varying levels of guidance. Simulation offers the possibility of having novices practice extensively before they begin to work on real patients as supervised "apprentices."

In this way and others, simulation is applicable to clinicians throughout their careers to support lifelong learning. It can be used to refresh skills for procedures that are not performed often. Knowledge, skills, and practices honed as individuals must be linked into effective teamwork in diverse clinical teams, which must operate safely in work units and larger organizations.[36-38] Perpetual rehearsal of responses to challenging events is needed because the team or organization must be practiced in handling them as a coherent unit.

Dimension 7: Age of the Patient Being Simulated

Simulation is applicable to nearly every type and age of patient literally from "cradle to grave." Simulation may be particularly useful for pediatric patients and clinical activities because neonates and infants have smaller physiologic reserves than most adults.[40,41] Fully interactive neonatal and pediatric patient simulators are now available. Simulation also addresses issues of the elderly and end-of-life issues for every age.

Dimension 8: Technology Applicable or Required for Simulations

To accomplish these goals, various technologies (including no technology) are relevant for simulation. Verbal simulations ("what if" discussions), paper and pencil exercises, and experiences with standardized patient actors[41-43] require no technology, but can effectively evoke or recreate challenging clinical situations. Similarly, very low technology—even pieces of fruit or simple dolls—can be used for training in some manual tasks. Certain aspects of complex tasks and experiences can be recreated successfully with little technology. Some education and training on teamwork can be accomplished with role playing, analysis of videos, or drills with simple mannequins.[44]

Ultimately, learning and practicing complex manual skills (e.g., surgery, cardiac catheterization) or practicing the dynamic management of life-threatening clinical situations that include risky or noxious interventions (e.g., intubation or defibrillation) can only be fully accomplished using either animals—which for reasons of cost and issues of animal rights is becoming very difficult—or a technologic means to recreate the patient and the clinical environment. The different types of simulation technologies relevant to anesthesiology are discussed later in this chapter.

Dimension 9: Site of Simulation Participation

Some types of simulation—those that use videos, computer programs, or the Web—can be conducted in the privacy of the learner's home or office using his or her own equipment. More advanced screen-based simulators might need more powerful computer facilities available in a medical library or learning center. Part-task trainers and virtual reality simulators are usually fielded in a dedicated skills laboratory. Mannequin-based simulation also can be used in a skills laboratory, although the more complex recreations of actual clinical tasks require either a dedicated patient simulation center with fully equipped replicas of clinical spaces or the ability to bring the simulator into an actual work setting (in-situ simulation). There are advantages and disadvantages to doing clinical simulations in situ versus in a dedicated center. Using the actual site allows training of the entire

unit with all its personnel, procedures, and equipment. There would at best be limited availability of actual clinical sites, and the simulation activity may distract from real patient care work. The dedicated simulation center is a more controlled and available environment, allowing more comprehensive recording of sessions, and imposing no distraction on real activities. For large-scale simulations (e.g., disaster drills), the entire organization becomes the site of training.

Video conferencing and advanced networking may allow even advanced types of simulation to be conducted remotely (see dimension 10). The collaborative use of virtual reality surgical simulators in real time already has been shown, even with locations that are separated by thousands of miles (see later for more on Site of Simulator).

Dimension 10: Extent of Direct Participation in Simulation

Most simulations—even screen-based simulators or part-task trainers—were initially envisioned as highly interactive activities with significant direct "on-site" hands-on participation. Not all learning requires direct participation, however. Some learning can occur merely by viewing a simulation involving others, as one can readily imagine being in the shoes of the participants. A further step is to involve the remote viewers either in the simulation itself or in debriefings about what transpired. Several centers have been using videoconferencing to conduct simulation-based exercises, including morbidity and mortality conferences.[45] Because the simulator can be paused, restarted, or otherwise controlled, the remote audience can readily obtain more information from the on-site participants, debate the proper course of action, and discuss with those in the simulator how best to proceed.

Dimension 11: Feedback Method Accompanying Simulation

Similar to real life, one can learn a great deal just from simulation experiences themselves, without any additional feedback. For many simulations, specific feedback is provided to maximize learning. On screen-based simulators or virtual reality systems, the simulator itself can provide feedback about the participant's actions or decisions,[46] particularly for manual tasks where clear metrics of performance are readily delineated.[47,48] More commonly, human instructors provide feedback. This can be as simple as having the instructor review records of previous sessions that the learner has completed alone. For many target populations and applications, an instructor provides real-time guidance and feedback to participants while the simulation is going on. The ability to start, pause, and restart the simulation can be valuable. For the most complex uses of simulation, especially when training experienced personnel, the typical form of feedback is a detailed post-simulation debriefing session, often using audio-video recordings of the scenario. Waiting until after the scenario is finished allows experienced personnel to apply their collective skills without interruption, and then allows them to see and discuss the advantages and disadvantages of their behaviors, decisions, and actions.

Dimension 12: Organizational, Professional, and Societal Embedding of Simulation

Another important dimension is the degree to which the simulation application is embedded into an organization or industry.[19] Being highly embedded may mean that the simulation is a formal requirement of the institution or is mandated by the governmental regulator. Another aspect of embedding would be that—for early learners—the initial (steep) part of the learning curve would be required to occur in a simulation setting before the learners are allowed to work on real patients under supervision. Also, complete embedding of simulation into the workplace would mean that simulation training is a normal part of the work schedule, rather than being an "add-on" activity attended in the "spare time" of clinicians.

Conceptual Issues about Patient Simulation

"The key is the programme, not the hardware," was a truth about simulation learned early in aviation. Using simulators in a goal-oriented way is equally or more about the conceptual aspects of the technique than it is about the technology of the simulation devices. An understanding of the conceptual and theoretical aspects of the use of simulation techniques can be helpful for determining the right applications of the technique and the important matchups that must be made in the design and conduct of simulation exercises to get the best results. When used most effectively, simulation can be—to borrow a line from the band U2—"even better than the real thing."[20] The concepts discussed in this section concern the nature of "realism" and "reality" as they apply to simulation, and the way that these issues relate to the goals of simulation endeavors to generate a complex social undertaking. The ideas and concepts presented here are largely contributed by Peter Dieckmann and his adaptation of broader psychological concepts to simulation in medicine.

Reality and Realism of Simulation

Unless we are dreaming about it or we are an unrepentant solipsist, a simulation exercise is always "real" (it is actually happening), but it may or may not be a "realistic" replication of the reality that is the target of the exercise. Realism addresses the question of how closely a replication of a situation resembles the target. A key distinction is between a *simulator* (a device) and a *simulation* (the exercise in which the device is used). A simulator could be indistinguishable from a real human being (e.g., a standardized patient actor) and yet be used in an implausible and useless fashion. Conversely, certain kinds of realism (see later) can be evoked by simulation exercises that use very simple simulators or even no simulator at all (as in role-playing when the participants in a sense "become the simulator"). Merely creating a realistic simulation does not guarantee that it would have any meaning or utility (e.g., learning).[21,22] A closely related aspect concerns the question of relevance and the social character of simulation.

Three Distinct Dimensions for Simulation Realism

A lot has been written about simulator and simulation realism using a variety of terms and concepts that are subtly different and often overlapping. These include *physical fidelity* (the device replicates physical aspects of the human body), *environmental fidelity* (the simulation room looks like an operating room), *equipment fidelity* (the clinical equipment works like or is the real thing), and *psychological fidelity*[23] (the simulation evokes behaviors similar to the real situation), and a variety of forms of validity, such as *face validity* ("looks and feels" real to participants), *content validity* (the exercise covers content relevant to the target situation), *construct validity* (the simulation can replicate performance or behavior according to predefined constructs about work in real situations), and *predictive validity* (performance during a simulation exercise predicts performance in an analogous real situation).[24,25]

The results of studies trying to investigate roots and effects of simulation "realism" are not conclusive partly because they may each concentrate on a different aspect of this complex whole. It is simply not true that maximum "realism" is either needed or desired for every type of simulation endeavor. For some applications with some target populations, it can be highly advantageous to reduce the realism to heighten the learning experience.[26]

In 2007, we published an article attempting to clarify some issues about realism, reality, relevance, and the purposes of conducting simulations.[21] We applied the model of thinking about reality by the German psychologist Laucken to the realism of simulation.[21] Laucken described three modes of thinking—physical, semantical, and phenomenal, which have been renamed physical, conceptual, and emotional and experiential modes by colleagues in Boston.[27]

Physical Mode

The *physical mode* concerns aspects of the simulation that can be measured in fundamental physical and chemical terms and dimensions (e.g., centimeters, grams, and seconds). The weight of the mannequin, the force generated during chest compressions, and the duration of a scenario all are physical aspects of the simulation reality. Existing simulator mannequins have many "unrealistic" physical elements despite their roughly human shape: they are made of plastic, not flesh and bone; they may have unusual mechanical noises detectable during auscultation of the chest; the "skin" does not change color. Some physical properties are not readily detectable and can be manipulated. Some clinical equipment used in mannequin-based simulation is fully functional and physically identical to the "real thing," although in some cases functional physical limitations may have been introduced for convenience or for safety.[24] Labeled syringes may contain only water instead of opioids, or a real defibrillator may have been modified so that it does not actually deliver a shock (one manufacturer sells a "Hollywood defibrillator"). That certain physical properties and functions have been altered is not usually apparent to participants, at least without special briefings or labels.

Semantical Mode

The *semantical mode* of thinking concerns concepts and their relationships. Within the semantical mode, a simulation of hemorrhage might be described in conceptual terms as "bleeding" of flow rate *X* beginning at time *Y* occurring at site *Z* and associated with a blood pressure of *B* that is a decrease from the prior value of *A*. In this mode of thinking, it is irrelevant how the information is transmitted or represented. The same pieces of *information* could be represented using a vital signs monitor, a verbal description, or the tactile perception of decreasingly palpable pulses. The semantical *recoding* of physical objects is the cornerstone of simulation. It allows the simulation exercise to represent a real situation, and it allows water-filled syringes to be treated as if they contain a drug.

Phenomenal Mode

The *phenomenal mode* deals with the "experience," including emotions and beliefs triggered by the situation. For many purposes, providing high phenomenal realism is the key goal, and the physical realism and semantic realism are merely means to this end.

Relevance versus Reality

A naive view of simulation would suggest that greater realism in all modes would lead to better achievement of the goals of simulation; this view has been criticized repeatedly.[23,28,29] Simulation is a complex social endeavor, conducted with different target populations for different purposes. The relevance of a simulation exercise concerns the match between the characteristics of the exercise and the reasons for which the exercise is conducted. Different elements of realism are emphasized or sacrificed to maximize the relevance of a simulation exercise. When training on invasive procedures, it is typical to forgo phenomenal realism and emphasize physical and semantic realism so that psychomotor skills can be the focus.

Semantic realism may be sacrificed, especially to help early learners. Situations that might become lethal (e.g., trigger a cardiac arrest) very quickly may be slowed down so that inexperienced clinicians can try to think their way out of the problem. If such a situation were allowed to evolve at its normal speed, it would transition to the management of a cardiac arrest before the participants could deal with the original problem. Other realism-sacrificing strategies for early learners include "cognitive scaffolding," providing various forms of assistance or cues to help them as they struggle with decision making and therapy selection. It is important to select which aspects of the simulation are the most relevant to reach the training goal and should be focused on in terms of optimizing their realism in the different modes.

Setting of the Simulation Exercise

Simulation exercises have a purpose and are generally integrated into a larger training context (often a course or a series of exercises), which influences how they are conducted, how they are perceived by participants, and what kind of effects they might have. This context has been called the *simulation setting*. The typical elements of the simulation setting are discussed next and shown graphically in Figure 7-2.

Setting introduction (SI): The introduction delivers general information on how the exercise will be conducted, logistical information, and some of the known pitfalls of the

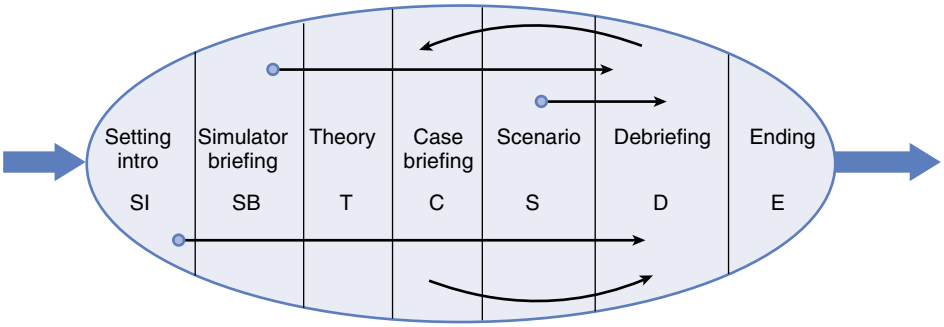

Figure 7-2 The simulator setting. A simulation course consists of different modules or different phases (e.g., setting introduction, simulator familiarization, scenarios, debriefings). This figure shows a typical flow for a course with repeated loops back from debriefing to case briefing for each scenario. The different modules are interrelated, and problems arising in one module can affect other modules (*thin arrows*). For example, it might be difficult to conduct an open, constructive debriefing if the scenario was irrelevant, or the simulator briefing was insufficient, and or the instructor did not succeed in creating an open atmosphere in the beginning of the course. *(Courtesy of Peter Dieckmann.)*

course. Through this introduction and other components of the course, group norms are established explicitly and implicitly.

Simulator briefing (SB) or familiarization: Participants need to be familiar with the simulator and the simulated environment via explanations, demonstrations, and hands-on time. They learn how to use the simulator, what it can and cannot do, what is "normal" (e.g., normal breath sounds), and how they can interact with the environment (e.g., how to call for help, how to request information about the patient that is not directly available in the simulation environment). The familiarization session also is an opportunity for participants to practice the information gathering they must conduct when first entering a new work environment (e.g., for locum tenens practice).

Theory input (T): Most exercises have didactic and theory components on relevant content information. Sometimes this material is made available in advance via readings or online exercises. It may be presented before or after a simulation session. Sometimes there are didactic or group-work modules put in place at different junctures of the course or series.

Breaks (B): For complex courses (e.g., anesthesia crisis resource management [ACRM]), breaks are important for socialization between participants and with instructors. It also is a venue for informal sharing and storytelling.

Case briefing (C): In many simulation scenarios, participants receive a briefing about the upcoming case. Sometimes this is done explicitly before entering the scenario; sometimes it is embedded into a natural "hand-off" of the case from one clinician to another.

Simulation scenario (S): Most simulation exercises involve a scenario that posits a given clinical situation and challenges to be posed for participants to deal with. Commonly, the possible evolutions of the scenario are delineated by instructors in advance, although occasionally an intrinsically challenging situation is started and then allowed to play out naturally depending on how the participants react.

Debriefing (D): Most scenarios are followed by some form of debriefing or feedback. In some courses, there is only minimal feedback, whereas in others there is a dedicated debriefing session (as long or longer than the scenario itself) after each scenario. (See the section on debriefing for more detail.)

Ending (E): Especially for multiple-scenario courses, there may be a separate final session to end the course. This is an opportunity to summarize issues that were covered, to address questions, and to consider how best to apply the principles covered to real patient care.

Components of a course are expected to have a cumulative effect. Similarly, problems in early portions of a course (e.g., inability to create an open learning atmosphere during the introduction) can carry over into later phases. Inadequate familiarization briefings leave participants confused as they try to perform "clinical work" with the patient replaced by a mannequin.

Site of Simulation

Over more than 20 years of experience in simulation, many different variants of simulation have evolved. One particularly rich set of variations is on the site of simulation. The types of "sites" currently in use are described; the advantages and disadvantages of each are summarized in Table 7-2. Many of these variants are not mutually exclusive and can be combined in different hybrids. They are often administratively linked—a simulation group that operates a dedicated center often also conducts in-situ, mobile, and moving patient simulation exercises at various times for different target populations and applications.

Dedicated Simulation Center

One or more simulators are used in a dedicated simulation facility, typically in rooms that can partially or fully replicate, in a relatively generic fashion, various clinical environments (e.g., operating room, ICU, labor and delivery, emergency department). (For more details see the section on Charactistics of Simulation Centers discussed later.)

Table 7-2 Site of Simulation

Site of Simulation	Explanation	Advantages	Disadvantages
Dedicated center	Fixed facility not part of an actual clinical work unit	Equipment permanently installed Facilitates complex audiovisual systems Easy to schedule Personnel not readily "drafted" for clinical work Does not interfere with actual clinical work Multipurpose	Cannot recreate exact work unit, equipment, supplies of diverse target populations May be hard for clinicians to be free to attend training
Temporary in situ	Actual work unit; temporary setup and takedown	Real clinical site Probe or train personnel in their actual work unit, using real equipment and supplies Clinicians can readily attend in proximity to their work	Hard to schedule—may need site for clinical use Interferes with actual clinical work; personnel readily drafted to return to clinical work Great effort of setup and takedown; minimal audiovisual system
Residential in situ	Actual work unit; permanent facility	Same as temporary in situ	Costly to create permanent simulation "bed" in clinical work unit May distract from real clinical work, personnel may be drafted
Patient movement simulations	Transport from site to site is simulated	Transport itself is challenging clinical work Replicates natural flow of patients and handoffs between teams	Requires multiple simulation sites Portable wireless simulators have some technologic limitations
Mobile simulation	Simulation systems and instructor crew travel to client (or neutral) sites	Brings simulation expertise to those who cannot or wish not to invest in it themselves For in-situ use, all advantages thereof	Transport costs can be high (driver, fuel, vehicle) For in-situ use, all disadvantages thereof plus even greater effort for setup and takedown

In-Situ Simulation

In-situ simulation is conducted in an actual clinical workplace; the simulator "replaces" a patient. In-situ simulation is a necessity in the absence of a dedicated center, and can be used in any clinical environment. It is especially useful for unusual workplaces that are difficult to recreate realistically in a simulation center, such as a catheterization laboratory, computed tomography scanner, ambulances, or air rescue aircraft (Figs. 7-3 to 7-9). Most in-situ simulation is performed "mobile" as a temporary setup, but increasingly in-situ simulation is established as "residential simulation," in which a simulator is permanently installed in a clinical workplace (e.g., creating a simulation-specific room in the actual ICU.

Moving Patient Simulation

The advent of completely portable and wireless simulators supports exercises in which the simulated patient can be moved from one clinical site to another. The patient could be brought into the emergency department by ambulance; taken to a computed tomography scanner, interventional radiology, or operating room; and finally transferred to an ICU. Under what circumstances such movements are worth the effort remains to be determined.

Mobile Simulation: "Have Simulator—Will Travel"

Mobile simulation means the simulator and the audiovisual gear are moved (made mobile) outside the originating institution for purposes of the simulation event. In other words, "the simulator comes to the participants." Mobile simulation can be conducted as in-situ simulation in an actual site of a remote client institution, by setting up for simulation in conference rooms or hotel meeting rooms, or by having a simulation facility built into a truck or bus. The built-in mobile facility saves time in setup and takedown, It also is possible to conduct "field exercises" setting up the simulator outside (e.g., in a parking lot or athletic field).

Advantages and Disadvantages of Different Approaches

The advantages and disadvantages of different approaches are summarized in Table 7-2. For sites that lack a dedicated

Figure 7-3 In-situ mobile simulation in a catheterization laboratory. The simulator is placed on the catheterization laboratory tables, surrounded by the x-ray machines, complicating the treatment of the patient by limiting space. The vital sign monitor is connected to the real monitors, providing relevant data to the catheterization laboratory team. The simulator is controlled from the catheterization laboratory control room. Multiple mobile cameras and a scan converter for the vital signs provide a live video transmission to a temporary debriefing area for the nonactive part of the training group and allow for CRM-based debriefings. CRM, crisis resource management. *(Picture by team TuPASS, taken at University Hospital, Tübingen, Germany.)*

Figure 7-5 In-situ mobile simulation team training in an ambulance. The limitations regarding space to work and move around inside an ambulance are very important. This represents a classic need for in-situ training of prehospital teams (in Germany consisting of three paramedics and a prehospital emergency physician). Also, "take-over scenarios" (e.g., the helicopter team is taking over a patient from the ground-based team) are a challenge for CRM expertise (e.g., information transfer and continuous patient treatment). CRM, crisis resource management. *(Picture by team TuPASS, taken at one of the German Air Rescue centers, Germany.)*

Figure 7-4 In-situ mobile simulation in a dentist chair. The simulator was equipped with artificial teeth gum and a chalk tooth preparation to drill, simulating the dentist's procedures (give anesthetic or drilling). Then emergencies developed, and the team response was trained focusing on CRM key points and important medical aspects, including automated external defibrillator use. CRM, crisis resource management. *(Picture by team TuPASS, taken at University Hospital, Tübingen, Germany.)*

Figure 7-6 In-situ mobile simulation team training in a helicopter. The mobile simulation control room with several cameras and microphones is set up outside the helicopter, also providing a multiperspective view inside to monitor the scenario and react to activities performed. *(Picture by team TuPASS at the German Air Rescue/TuPASS training site at Airmed 2008.)*

Figure 7-7 **A,** In-situ mobile simulation training in a simulated apartment for prehospital teams. The apartment (living space) scenarios are very common for prehospital teams, requiring adaptation to the local space availability and other circumstances (e.g., bystanders, dogs). **B,** Emergency department simulation with the prehospital team handing over a patient to the hospital staff—always a phase of high-demand and goal-oriented interactions. From a CRM-training perspective, this scenario is a very good opportunity to highlight problems and unsafe practices (in the sense of high reliability), and to show good team performances using video clips of a scenario. CRM, crisis resource management. (***A,*** *Picture by team TuPASS at a CRM training session with the South Tyrolian White Cross in Bolzano, Italy.* ***B,*** *During an instructor training course at TuPASS, Germany.)*

simulation center, there is no practical alternative to either engage in in-situ simulation or to be a client for mobile simulation. Simulation in the dedicated center facilitates scheduled training and use of complex audiovisual gear. Simulators can be preset, tested, and ready to go. Briefing and debriefing facilities are immediately at hand. In a dedicated center, it is common to use inexpensive discarded, flawed, or outdated clinical equipment and supplies. The major disadvantage to a dedicated center is that regardless of how well equipped it is, it can never replicate the equipment, layout, and clinical processes of actual clinical workplaces. Also, participants know that they are in a simulation center, which may alter their demeanor and reduce the impact of training.

In-situ simulation seems ideal in that it probes and challenges personnel and systems as they actually exist, unmasking real issues of patient care. It is available, in principle, to all sites, even those without a dedicated center, and is conducive to short courses and unannounced mock event drills. In-situ simulation

Figure 7-8 In-situ mobile simulation in an intensive care unit (ICU)/intermediate medical care unit location. The training in actual clinical areas also is especially useful for ICU-like surroundings. CRM-based trainings are very important to highlight the highly complex problems and interactions needed to coordinate high-performing ICU teams. The training also allows for "checking" the local arrangement of equipment and possibilities to react to certain emergencies. There are already a few examples of "residential" in-situ simulation in ICUs (see text). *(Picture by team TuPASS.)*

has disadvantages, however. It is difficult to organize, schedule, and control. The clinical area planned for simulation may not be vacant or may be needed on short notice. The simulations can be distracting to real patient care surrounding them, and the staff engaged in the simulation are prone to being pulled to clinical duty, and there may be constant interruptions of the training sessions. Most clinical supplies must be taken from the stocks of the work unit in order to prevent mix-ups with outdated simulation

Figure 7-9 In-situ mobile CRM-focused simulation team training inside an actual operating room. The figure shows the debriefing room temporarily set up in an induction room. The use of videos for debriefing (here on a 42-inch flat panel placed over the basin) is highly recommended. Training inside a hospital often includes training actual teams and training a large proportion of employees with the same set-up. These mass training sessions seem to offer a much larger impact and longer lasting effects of the lessons learned, including CRM behaviors (see text on subthreshold training). *(Picture by team TuPASS who performed at a full team training of the Anesthesia department at Steinenberg Medical Center, Reutlingen, Germany.)*

supplies, adding expense. There are major limitations to the audiovisual gear that can be deployed in a real clinical site. A permanent in-situ facility could provide the best of both worlds. Such an arrangement offers unique opportunities, such as the ability to "replay" immediately difficult cases in the simulator "next door," the possibility to use low workload times for spur-of-the-moment simulation sessions, and the ability to conduct long-term simulations (team members responsible for a simulated ICU patient over days or weeks). The major drawback to this approach is that to address diverse clinical domains requires such a site in every domain, and this could be extremely costly.

Team Training, Single Discipline, and Crews

Each discipline in health care can be considered a "crew" containing one or more individuals. Several crews may work together closely as a "team." The operating room team consists of an anesthesia crew, a surgery crew, and a nursing crew (and crews of technicians and support personnel).

Further complementarity exists regarding the homogeneity of the target population in simulations. When the simulation is intended to go beyond specific medical and technical skills for individuals (as in crisis resource management–oriented simulations) and to involve nontechnical skills and teamwork, we distinguish between "single-discipline" approaches ("training crews to work in teams") and true "combined-team" (multidisciplinary) training.

The importance of teamwork and team training is widely accepted,[30-35] although it is still not widely implemented. The prerequisites for effective teamwork (e.g., team leadership, mutual performance monitoring, backup behavior, adaptability and team orientation,[35] and the concept of team cognition) are discussed in Chapter 6.

Single Discipline

Training for single-discipline crews (e.g., anesthesiologists) involves curricula in which all participants are from a single discipline, and other crew members' roles are played either by instructors and confederates or by other simulation participants. This approach allows tailoring simulations to challenge skills, knowledge, and situations specific to the discipline, including material that may be of little relevance to other crews and in the context of a wide variety of types of clinical situations (e.g., cardiac, orthopedic, or general surgery; labor and delivery; intensive care). Single-discipline training can emphasize generic skills of dynamic decision making, resource management, leadership, and teamwork applicable to any challenging clinical situation. In the single-discipline approach, scenarios can be designed that present specific types of personalities and behaviors by other crew or team members, rather than relying on the ad-hoc behavior of real personnel from those disciplines. Even without actual personnel from other disciplines, training crews to work in teams also provides a degree of cross-discipline understanding by allowing participants to discuss other team members' views of the same situation.

For dedicated center simulations, single-discipline sessions are simpler logistically because only one discipline needs to be present, rather than scheduling someone from each of the disciplines. In addition, simulations can be applied to some disciplines even in domains where there are not yet credible simulators for the work of each team member. The single-discipline approach may be of particular relevance for trainees who when finished with their training will go on to work in many different settings and with many different kinds of personnel. It also may be of greatest value for individuals who do not work in "fixed" crews or teams and need to acquire generic teamwork skills that can be used with all coworkers.

Combined Team Training

The complementary approach is to conduct *combined team training,* in which all participants of the team, from crews of several different disciplines (e.g., surgeons, nurses, anesthesiologists), undergo training together. Combined team training allows for more natural team interactions and reinforces understanding across disciplines. There are successful examples of such undertakings in many fields, including obstetrics (combining obstetrics, anesthesia, nursing, neonatology/pediatrics) and intensive care (combining physicians from multiple disciplines with nursing, respiratory therapy, and pharmacy).[32,36-46]

Combined team training may be most effective when a specific group of individuals is to work together clinically as a dedicated team. In dedicated simulation centers, combined team training can be hard to schedule, and it may require instructors from several of the disciplines to conduct the debriefings. Combined team simulations may be easiest to organize when they are conducted as unannounced mock events that activate the actual bedside team (e.g., ward or unit team, rapid response team, or code team). In such situations, the real combined team is mobilized as they would be in real life.

Debriefing for Simulation Training

Debriefing refers to a special time and format for talking about an episode of action in the past; it is the counterpoint to a briefing that occurs before an action or task. The term originally came from the military, for after-action reviews of real missions and simulations. In medicine, the debriefing concept was introduced to simulation training by Gaba and colleagues as part of the whole concept of CRM-based simulation training for anesthesia teams.[16,95] This section focuses on debriefings in the context of simulation team training.

Debriefing—Heart and Soul of Simulation Trainings

In aviation and health care simulations, the debriefing after a simulation team training session is a key element—perhaps the most important element—of simulation training.[47] The debriefing offers an unparalleled instance to reflect and discuss openly and understand other team member's intentions, thoughts, and prob-

Table 7-3 Traditional Teaching versus Facilitation in Simulation Training Courses

Traditional Teaching: "Teacher"	Debriefing Facilitation: "Instructor/Facilitator"
Focus on theoretical knowledge	Focus on human factors and CRM aspects
Focus on what	Focus on why and deeper analysis of why it did (not) work
Teacher is the best (expert)	Instructor just moderates, uses knowledge of participants
Teacher tells participants what to do	Instructor helps participants to find what they could have done and what would be the best way
Teacher knows what is important for participants	Instructor helps to self-reflect and gain realistic self-awareness/consciousness Instructor guides toward interesting areas
Talks most	Stimulates discussion among participants
Domain expert	CRM expert
No teaching training	Extensive instructor training
No video	Use of video of own and others' scenarios
Teacher knows what has been learned (or not)	Instructor might not be aware of all aspects that participants take home

CRM, crisis resource management.

lems. Much of the learning occurs in this self-reflective episode. Eventually, these routines will be applied to clinical medicine (e.g., surgical team timeout).

New Way of Teaching

The debriefing as described in aviation and introduced and refined for medicine by Gaba and others[48,49] requires a complete understanding by instructors of their role in promoting learning (see Chapter 8).[50] The philosophy of teaching and learning in a debriefing of a CRM-based simulation course differs from the traditional clinical teaching style (Table 7-3). The instructor's role is to *facilitate* the learning process, *directing the participants* to the most interesting and important areas for consideration, and *stimulating discussion* among participants to *find the underlying issues* and to seek solutions for future events of similar type.

Facilitation is a new way of teaching and often must be learned anew by instructors, even though they have many years of traditional teaching experience. The use of video for debriefing can advance further the self-reflective component of debriefings, but requires additional expertise to integrate it successfully with self-reflection. Generally, faculty intending to be primary debriefers need special training and practice in this teaching method (see section on Instructor Qualification). Several simulation centers conduct instructor training that emphasizes debriefing skills.

Technique of Debriefing

Although debriefing styles and philosophies differ at centers around the world, a common ground is shared by most centers: A debriefing should *stimulate self-reflection,* and analyze *how* something happened, and what the *underlying concepts* for doing so were, rather than merely finding out *what* happened. Usually the debriefing lasts at least as long as the scenario itself.

Detailed discussions about the different techniques appear in the literature.[47,48,50-54] To prepare a good debriefing, the instructor is challenged during the scenario with performing several tasks in the control room, such as listening to trainees, talking to the instructor team, controlling the simulator, and making notes for the debriefing. Figure 7-10 illustrates the different levels of attendance.

Debriefings by nature have different phases, as shown in Table 7-4. The phases are not meant to be followed in this time sequence and order. Often two or more phases are covered regarding one problem of the scenario—especially clinical problems are often covered while discussing the "how" and "when" they happened (analysis). Then another problem is analyzed and discussed according to different phases. Nevertheless, at the end of a good debriefing, all phases should have been covered according to their respective importance. No debriefing style is associated with a proven better learning outcome, and there may never be defini-

Figure 7-10 The multiple levels of work for CRM-based instructors in the control room. The reflections in the one-way mirror of the control room make the multiple levels of activity transparent. The team of instructors has to control the simulation as such, but also make notes for the CRM-based debriefing. The scenario inside and the audio streams (telephone call) need to be monitored. Also, the instructors have to deal with simulation team role players and instructor trainees inside the control room. These complex tasks need some training and good team organization on the side of the simulation center team. CRM, crisis resource management. *(Picture by B. Schaedle, team TuPASS, taken at a PaedSim training at University Hospital, Tubingen, Germany.)*

Table 7-4 Phases of Debriefings: Issues Relevant to CRM-based Simulation Debriefing

Phase of Debriefing	Explanation
Ending the scenario	When possible, the scenario should not be stopped too early. Participants should be allowed to realize the natural end of the scenario. Ideally, it should not be terminated when participants are in the thick of it
Scenario-to-debriefing transition	Most sites use a "hot" debriefing, in which they enter the debriefing room immediately from the simulation room. This allows the instructor to hear and see participants' direct reactions. Another option is to give the participants a few minutes to discuss the scenario itself while the instructor is planning the debriefing
Emotional venting	All participants who were actively involved are given the opportunity to say how they *felt* during the scenario. This vents pent-up feelings, and may be a time to deal with anomalies in the scenario (e.g., simulator malfunction)
Descriptive phase	Participants describe what happened (or portions of the video are replayed). Different points of view (e.g., hot seat versus first responder versus surgeon confederate) are shared
Self-identification of issues	It can be useful, before anyone else including the instructor is allowed to critique the scenario, to allow active participants to say if they themselves detected any errors or actions that they would do differently. It can be painful and rude to critique participants about something they are aware of themselves
Discussion of clinical content	Any major issues of clinical treatment and related CRM points should be covered. A debriefing should not end without discussing and clarifying any significant clinical errors, and ensuring that participants understand the correct management
Analysis	Debriefings should provide considerable "analysis" of *why* things happened vis-à-vis the intentions of all parties, and alternatives and their pros and cons
Opportunities for systems improvement	Based on the analyses, participants can be asked to suggest how the system can be changed to improve the handling of similar situations in the future
Transfer to the "real world"	Participants can discuss how lessons from the scenario or debriefing can be applied in the real clinical world. They should discuss barriers to improvement and ways to overcome them
Providing a "take-home message" from the scenario and debriefing	A summary of the key points of the debriefing can be useful, either by the instructor or the participants themselves
Terminating the debriefing	Debriefings are rich in content and could extend beyond the time available. Marking the end of the debriefing can be a useful transition to preparing for the next scenario or to the end-of-day activities

CRM, crisis resource management.

tive data on the techniques because of the nature of the topic—reflective practice of high-level cognition.

Use of Video for Debriefings

Although the value is not proven, segments of video recordings to support and deepen the debriefing as a learning and self-awareness experience are frequently used. Anesthesia does not allow for much self-reflection and feedback during routine clinical work. Experienced colleagues typically work alone, and there is often little feedback from other anesthesiologists or from other operating room personnel. This situation is now changing, however, with the use of automatic anesthetic records and information technology (see Chapters 2, 4, 5, and 99).

The lack of feedback leaves a large theoretical gap between the way individuals think they perform and how they do act in reality. Video sequences can correct this gap and provide an awareness of how participants have really acted. Also, one's own video recordings can be compared with the recordings of other participants (either their own course co-participants or "trigger videos" meant to stimulate discussion). "Live transmission" of scenarios to participants not actively involved in the scenario also is useful. When this technique is used, the observers can be given special tasks (e.g., look for CRM key points 10 and 11 in Table 7-8). A study in Tübingen evaluated the use of so-called cooperation scripts in the "passive" phase of watching others perform.

The video should be used in the service of the debriefing, rather than the other way around. The authors believe that if the discussion is active and on-target, it is useless to interrupt it just to show video. Video may have a bigger impact for participants' first simulation experiences. Here they are sometimes struck by what can be revealed on seeing themselves and others work. As they gain more experience with simulation, and when debriefers are experienced, they may not need exposure to the video to hone in on key issues to discuss.

Clinical Application of Debriefing Method

The application of the above-described debriefing techniques to the discussion of real world clinical critical incidents seems very promising. Applying the debriefing technique learned in the simulator after a critical incident in short debriefing circles of the involved clinical team has proven quite valuable.[41,50,55-58]

Scenario Design

The design of scenarios for interactive simulation team trainings is demanding and typically differs from preparing training exercises for traditional curricula, such as "mega codes" in advanced life support. Full simulation scenarios are complex enough that

their design is usually an iterative process by which the scenarios are continually improved through experience.

This section can give only an overview of the important aspects of scenario design for realistic simulation team training. The reader is referred to detailed published examples of scenarios in *Simulation in Healthcare*[59] and to more detailed literature about the principles of scenario design.[3,60] The topic also is covered extensively in most of the instructor training curricula that are offered at sites around the world. International and regional simulation meetings often offer workshops on scenario design (IMSH of SSiH, SESAM); the user groups of the major simulator manufacturers also have workshops on the topic. (See section on Simulation Societies discussed later.)

Goal Oriented

Scenarios usually are designed to achieve learning objectives or other goals, such as a formal needs analysis of the relevant target group for training concerning clinical and technical skills or nontechnical CRM skills or both (see Chapter 6). Alternatively, simulation-savvy clinician educators may intuitively know what kinds of scenarios are likely to be valuable for their participant populations, or they may have learned about good examples in their instructor training or in the literature. The cases are not as important as the nature of the underlying challenges that they pose to participants. *Train the causes not the cases.*

Scenarios should be relevant to the trainees. This relevance is more important than realism and depends on many factors, including the trainees' backgrounds and experience, and the method of conducting the scenario and related parts of the simulation course (e.g., familiarization, case briefing, role players).

Constraints and Limitations

It is easy to suggest a scenario on paper but more difficult to translate it into an effective scenario for actual use. There are limitations and constraints to consider, including features and limitations of the simulators available, personnel resources at hand, the props or external systems that would be needed to engage participants, and time available for the proposed scenario. In our experience, most scenarios are first generated with an idea or a "nubbin." The idea is fleshed out by discussion and on paper in an iterative fashion, with limitations addressed either by creative redesign of the proposed situation or by minor technical modifications using the simulator software or simulation environment. The new scenario usually is tested out first by instructors and "simulationists" (the technical staff who operate the simulators and prepare the environment). It can be pilot tested with a volunteer group of participants from the target population. The first one or two sessions typically reveal many problems and flaws in the original scenario layout. After a scenario has been designed and tested, it is advisable to add comments and suggestions for improvement continuously after each training session.

Scenario Templates

Many centers have developed templates for the design of their scenarios. Figure 7-11 is an example of a summary sheet of the template used by TuPASS and taught during their instructor courses. The full version of it is available online (www.tupass.de/scenarioscript.html). Other scenario templates are popular, including the Duke University template (http://simcenter.duhs.duke.edu/SimTemplate1203.doc). The peer-reviewed journal *Simulation in Healthcare* publishes "Simulation Case Reports," which contain detailed scenario descriptions. Some professional societies have created scenario repositories for members; the American Society of Anesthesiologists (ASA) Simulation Committee has a repository for scenarios to be shared between its ASA-endorsed simulation programs.

Instructor Qualification

Teaching with simulation covers a diverse spectrum of applications. In some cases, it is similar to teaching at the bedside, only the patient is a simulator, in which case the skills needed are nearly identical to those used in ordinary clinical supervision and teaching. There are special implications for instructing in courses that involve complex realistic scenarios, with multiple personnel in crews and teams, using video-facilitated debriefings in small groups, and with a focus on human factors and CRM principles and countermeasures. In such courses, the skills needed to be a successful instructor go considerably beyond those typically used by teaching clinicians. Quality of the instructors is *the* key element for any simulation course, captured by the statement "The key is the program, not the hardware."[10] Ensuring instructor competence in using simulation and in debriefing facilitation skills is very important.

Advanced simulation course formats generally reflect very well Kolb's[60a] circle of adult experiential learning: (1) self-experience (participate in the scenario) or vicarious experience (observe scenario live), (2) reflect on experience (debriefing), (3) abstract conceptualization (debriefing, relate to theoretical material), and (4) active experimentation (future scenarios and use of skills in real cases) (Fig. 7-12).

Tasks of Instructors

The tasks of a simulation instructor differ from the tasks of a classic medical educator or a trainer for part-task or skills training. The most prominent differences are the following:

- Need to brief the course participants about an unfamiliar environment
- Creation of relevant, plausible scenarios to reach the intended learning goals
- Theatrical aspects of enacting complex realistic scenarios
- Need for simultaneous control of the simulator, the simulation personnel (instructors, actors, and confederates), and learning objectives during multiperson complex scenarios with built-in problems and challenges and an uncertain flow pathway of action by participants
- Need to provide debriefing and feedback after the scenario, often assisted by replay of video recordings, primarily using a "facilitation style" in small groups; handling group dynamics and individual sensitivities is required

The template also includes a script to explain the different fields and their best use. The template is a regular part of the instructor training courses. It can be obtained from the TuPASS webpage (www.tupass.de/scenarioscript.html). *(Template by P. Dieckmann and M. Rall, TuPASS, Germany.)*

- Concentration largely on CRM nontechnical skills of decision making, team management, interpersonal relationships, communication, and professionalism

Instructor Training

For such complex instructor skills, formal training seems warranted. One of the authors (D.G.) pioneered instructor training for CRM-oriented simulation courses in a consortium of the VA–Stanford Simulation Center with the Boston Center for Medical Simulation and the University of Toronto Sunnybrooke Simulation Center. This consortium spread the ideas and format of CRM simulation instructor training around the world. Another author (M.R.) has been running instructor courses in cooperation with a third author (P.D.) for more than 1,000 international participants. Many institutions offer different instructor courses nationally and internationally (ranging from 2 to 6 days in length depending on the course and its scope); the reader is referred to the simulation societies for information about such courses (SSiH, SESAM). The process and impact of instructor training are being evaluated much as the process of simulation training itself is being assessed. Some early evidence is emerging that such courses have value. Also, shorter introductory courses on instructor skills are offered every year at the international health care simulation meetings (e.g., SSH's IMSH conference or the SESAM annual meeting), and there are many workshops at the meeting that cover topics such as debriefing, instructor training, and CRM training.

Table 7-5 presents an example of learning objectives for an instructor training course. For experiences and effects of the instructor course by P. Dieckmann and one of the authors (M.R.), a poster presented at the IMSH 2006 with a short description of the InFacT course and results from a response-shift bias analysis can be downloaded from our website (www.tupass.de/downloads/InFacT.html). The most difficult task for traditional medical teachers is to learn to stop "instructing" and start "facilitating"—guiding participants toward a deep learning experience.

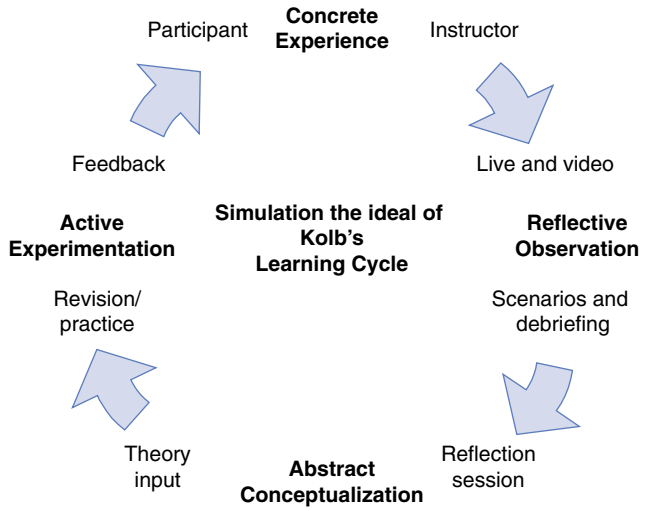

Figure 7-12 Simulation team training with live video transmission as an "ideal" representation of Kolb's learning circle. During the scenario, trainees get a hands-on experience. This is actively reflected in the debriefing. The live video to the nonactive group in the current scenario allows useful reflective observation. During the debriefing, all trainees have a phase of conceptualization, in which the instructor uses generalizations of factors and root causes to show how behavior developed as it did in the scenario (deep learning). During the feedback in the debriefing, but also in the next active scenarios, participants have opportunities to apply and experiment with the newly learned input. *(Figure by P. Dieckmann, modified from Kolb. DA: Experimental learning: Experience as the source of learning and development. Englewood Cliffs, NJ: Prentice Hall, 1984.)*

Certification of Instructors

The original simulation instructors were self-taught in these skills. Should instructors receive documented formal training and certification? CRM-oriented simulation training is probably the most difficult level to achieve. Many institutions have internal systems of levels of training for simulation instructors; they have their own mechanisms for assessing instructor skills and moving instructors up the levels of instructor competency. There is at this time, however, no guideline or agreement regarding criteria for advancement from one level to another.

Certification of instructors is just one piece of a larger puzzle of the certification of simulation centers and programs and the certification of specific simulation-based curricula. The ASA in 2008 started a process to endorse (as opposed to accredit or certify) reputable simulation programs capable of delivering high-quality continuing medical education (CME) to ASA members. The Society for Simulation in Healthcare is planning an accreditation program for simulation centers to be accredited in one or more of the areas of assessment, research, training, and patient safety integration. Various other organizations have started or are considering starting similar programs. Specialty and subspecialty societies within anesthesia (including the ASA Simulation Committee) are considering defining one or more uniform curricula to be offered at accredited or approved programs.

It is likely that the skills and certification needed for an instructor would vary greatly with the particular course or curriculum being taught. Competence in conducting a video-based CRM debriefing would not be needed, and would not help, to teach central line placement using part-task trainers for this procedure, and vice versa. Instructor certification probably would be tied to the specific types of courses each individual is capable of conducting. A tiered instructor certification system also would likely provide for advancement from novice instructor to grand master as experience and special training are acquired.

Table 7-5 Learning Objectives for CRM-oriented Simulation Instructor Courses*

Understand how it feels to be a participant in a simulation scenario, and to be debriefed in a group, seeing oneself on video
Understand the interdependent influence of the different course phases (see Fig. 7-2), and apply this knowledge to a simulation course
Reflect on the changing instructional styles that can be applicable to simulation courses (instruction—facilitation)
Understand basic concepts of human factors, systems theory, and organizational safety
Be able to detect, explain, and discuss CRM key points in the debriefing of scenarios
Use recorded video of scenarios well, selecting the most relevant portions for replay and discussion
Be able to facilitate a debriefing in a nonjudgmental atmosphere with appropriate boundaries
Understand how to manage the individual sensitivities and group dynamics of participants during debriefing
Be able to focus debriefing on the analysis of what happened, why things happened the way they did, and how to apply these lessons to real patient care

*Adapted from the learning objectives of old instructor courses by the authors and P. Dieckmann.

Classification of Patient Simulators

No accepted classification scheme has been devised for the use of patient simulators in anesthesia. Any classification involves some overlapping and gray areas.[19] Cumin and Merry[61] have published a review about available simulators. The following classification and definitions are used in this chapter. In addition to simulators, there are computer-assisted instruction programs and computer-based training devices. Although training devices may replicate certain portions of the clinical domain, they do not attempt to replicate the bulk of the work environment. Some individuals consider the screen-only microsimulator (also known as a screen-based simulator) to be a training device and not a simulator. Computer-assisted instruction programs and training devices are not reviewed in this chapter. This chapter addresses patient simulators in anesthesia that present the overall patient as would be seen by anesthesiologists, intensivists, or others. Devices related purely to emergency medicine (e.g., ResusSim), surgical or procedural simulators that present only the technical work of surgery or invasive manipulations (e.g., bronchoscopy, intravenous access), and partial-task screen-based simulators (e.g., GasMan) are not discussed here.

In this chapter, a *patient simulator* is a system that presents a patient and a clinical work environment of immediate relevance to anesthesiologists (e.g., operating room, postanesthesia care unit, ICU) in one of the following ways:

1. In actual physical reality, defined as a mannequin-based simulator (former and still commonly used synonyms are full-scale simulator, hands-on simulator, realistic simulator, high-fidelity simulator). These simulators can be subdivided in terms of the way that vital signs monitoring is accomplished (interfacing to real clinical monitoring devices or using its own virtual replica of a monitor screen) and in terms of the primary control logic of the simulator (by individual controls and scripts or by using physiologic and pharmacologic modeling).
2. On a computer screen only, defined as a screen-only or screen-based simulator (some prefer the term microsimulator).
3. Using virtual reality, defined as a virtual reality simulator. In such a device, parts or all of the patient and environment are presented to the user by three-dimensional representations with or without "touch" to create a more "immersive" experience. A screen-only simulator could be viewed as a very limited virtual reality simulator.

Components of a Patient Simulator

A patient simulator system contains several components (Fig. 7-13).[19] A set of outputs make up a representation of the patient, the clinical environment, and diagnostic and therapeutic equipment. For screen-only simulators, this representation is generated graphically on the computer screen. For mannequin-based simulators, the representation is generated by using a patient mannequin, plus either actual clinical equipment or virtual replicas of monitor screens, placed (typically) in a recreation of an actual clinical setting. The mannequin and, where appropriate, the clinical equipment are stimulated or actuated by interface hardware. Mannequin-based simulators often use physical stimulation of clinical equipment in addition to electronic stimulation. The mannequin can actually be ventilated with any desired mixture of inspired gases. Carbon dioxide and other gases can be introduced physically by the simulator into the mannequin's lungs to provide the desired elements of gas exchange. A real respiratory gas analyzer can be used to measure the inspired and expired gases. The currently available features of full-scale, mannequin-based patient simulators are presented in Table 7-6.

Any simulator must have control logic by which changes in the simulated patient's condition can be generated, controlled, and sent to the appropriate output of the representation. Originally, the control logic was embedded in the software as a fixed sequence of events, or it consisted largely of continuous input from the instructor working from a script. Some current simulators use upgraded types of manual control logic that allows scripting of combinations of changes in control input. Other current simulators incorporate a more sophisticated technique using mathematical differential equations that model a patient's physiology and pharmacology to provide the bulk of the control logic. These models can be tailored to represent different patients with different pathophysiologic abnormalities.

Not all states or changes in a patient can be modeled by differential equations. Ventricular fibrillation is a totally different state of heart rhythm that does not evolve continuously from normal rhythms. No model can predict exactly when a patient will have a myocardial infarction or when an ischemic heart will begin to fibrillate. A model can only predict factors that increase the likelihood of such events. Most simulators incorporate other modeling techniques in addition to the basic physiologic and pharmacologic mathematical equations, including finite-state

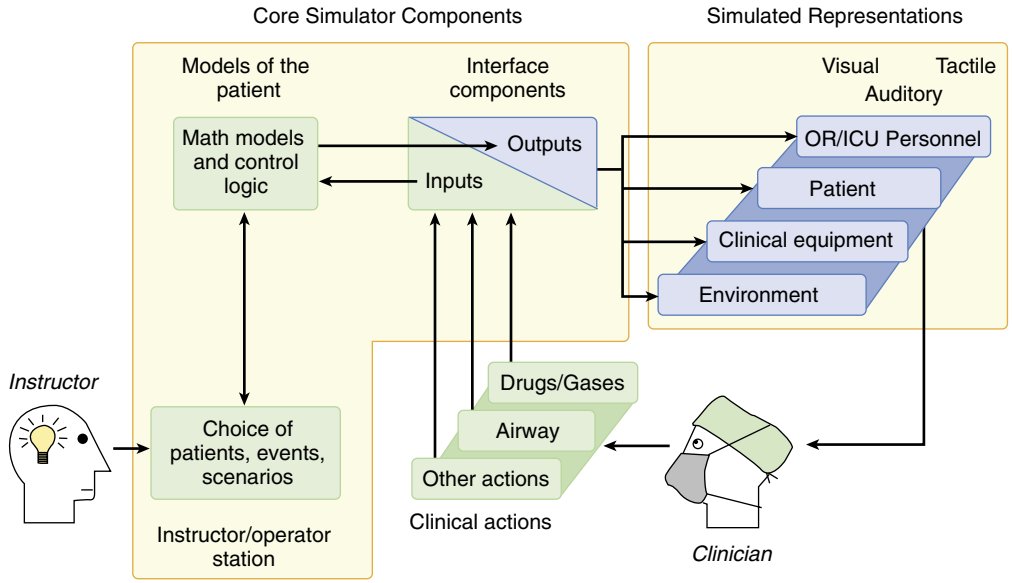

Figure 7-13 Schematic diagram of the generic architecture of patient simulator systems. The simulator generates a representation of the patient and the work environment with appropriate interface hardware, display technologies, or both. The representation is perceived by the anesthesiologist, whose actions are input to the simulator through physical actions or input devices. The behavior of the simulated scenario is manipulated by the instructor or operator through a workstation that allows selection of different patients, abnormal events, and other features of the simulated patient. The control may be manual, script-based, or model-based with manual adaptation to reach optimal learning outcomes. ICU, intensive care unit; OR, operating room. *(Figure by D.M. Gaba, Stanford.)*

Table 7-6 Functionality of Current Mannequin-based Simulator Systems

Clinical Area	Features and Functions	Remarks
Airway	Appropriate pharyngeal and glottic anatomy Placement of facemask, ETT, LMA, LT, Combitube Laryngospasm, tongue and airway swelling, cervical immobility, jaw closure, breakable teeth Cricothyrotomy Transtracheal jet ventilation Bronchial anatomy (to the lobar bronchus level)	Airway often provides acceptable seal for ETT, LMA, Combitube and LT Facemask seal is often difficult as well as placement of ETT
Head	Eyelid movement, pupil dilation, and reaction to light or medications Patient voice and sounds such as coughing and vomiting (through built-in loudspeaker) Palpable carotid pulses Cyanosis by blue light Tearing	Sweating as prototype available The authors prefer "live" voice over prerecorded audio clips, due to higher flexibility in scenarios
Chest	Physiologic and pathophysiologic heart and breath sounds Spontaneous breathing with chest wall movement Bronchospasm Adjustable pulmonary compliance Adjustable airway resistance Pneumothorax Needle thoracotomy and chest tube placement Defibrillation, transthoracic pacing ECG Chest compressions	Breath and heart sounds through loudspeakers; sounds contain artifacts and mechanical noise. Often sound level depends on position of stethoscope relative to loudspeaker
Extremities	Palpable pulses (dependent on arterial pressure) Cuff blood pressure by auscultation, palpation, or oscillometry Modules for fractures and wound modules Intravenous line placement Thumb twitch in response to peripheral nerve stimulation Arm movement Representations of tonic clonic spells	Still very limited movement capabilities at best (as of 2008)
Monitoring (waveforms or numerical readouts)	ECG (including abnormalities in morphology and rhythm) Spo_2 Invasive blood pressure CVP, PAP, PCWP Cardiac output Temperature CO_2 (may be actual CO_2 exhalation) Anesthetic gases (may have actual uptake and distribution of agents) Cardiopulmonary bypass	Simulators interface to actual clinical monitors or provide a simulated virtual vital signs display (or both); may include a virtual heart-lung machine
Automation and sensors	Chest compressions Ventilation rate and volume Defibrillation and pacing (including energy measurement) Gas analyzer (inspired O_2, anesthetics) Drug recognition (drug identification and amount)	Quality of sensors varies greatly from rough ventilation yes/no to almost realistic ventilation loops, etc.

Note: The features listed are each present in some existing simulators, but not all features are present on any single device. Sets of features depend on the device and model.

CVP, central venous pressure; ECG, electrocardiogram; ETT, endotracheal tube; LMA, laryngeal mask airway; LT, larynx tube; PAP, positive airway pressure; PCWP, pulmonary capillary wedge pressure.

Table 7-7 Desirable Features of Future Mannequin-based Simulator Systems

Advanced skin signs such as Change in skin color to cyanotic or pale Diaphoresis Change in skin temperature (e.g., as a result of shock or fever) Rash, hives, or generalized edema
Regurgitation, vomiting, airway bleeding or secretions
Physical coughing (currently only sounds are simulated)
Realistic convulsions
Purposeful movements of extremities
Support for spinal, epidural, or other regional anesthesia procedures
EEG signals (e.g., for BIS, AEP, PSI)
Intracranial pressure
Support for physical central venous and arterial cannulation
Fetal/maternal cardiotocogram

Note: This table shows what features are not currently incorporated (April 2008). Some features may be under development and could be available after publication of this book. In addition, some features are currently available as third-party or homemade add-ons.
AEP, auditory evoked potential; BIS, bispectral index; EEG, electroencephalographic; PSI, patient state index.

models, instructor initiation of abnormal events, and manual modulation of modeled parameters. In finite-state models, different underlying clinical states are defined, each of which has appropriate entry conditions and transition conditions to other states. When an entry or transition condition is met, a new state becomes active, which may directly trigger new observable phenomena (e.g., ventricular fibrillation), or may alter constants in the mathematical models that then evolve in time.[62-64]

The control logic of most simulators is manipulated through an instructor/operator's station that allows the instructor to create specific patients, select and implement abnormal events and faults, and monitor the progress of the simulation session. The system may have a remote-controlled, hand-held instructor/operator's station in addition to the main instructor/operator's station. The instructor/operator's station typically provides logs of physiologic changes and the anesthesiologist's response, and may provide graphics to support the analysis of a simulation run. Some screen-based simulators provide advice and tutorials linked to the management of simulated events. With mannequin-based simulators, especially for applications in which complete work environments are recreated, it is common to obtain detailed records of the simulation and the actions taken from video and audio recording of the personnel working in the replicated clinical environment.

Modern simulators still do not provide many of the desired features listed in Table 7-7. Many different simulator systems are available. No single system is the best choice for all uses, so the decision about the type of simulator required must be based on the objectives and needs of the application. In our experience, the success of a simulator program would not be determined primarily by the type or fidelity of the simulator used, but mostly by the enthusiasm, skill, and creativity of instructors, and the time and effort devoted to preparing and performing credible simulation scenarios.[28]

Virtual Reality Simulators

Virtual reality refers to a set of techniques in which one interacts with a synthetic (*virtual*) environment that exists solely in the computer.[65] In the typical conception of virtual reality, representation of the synthetic environment is fed directly to the eyes (three-dimensional head-mounted displays), the ears, and possibly the hands and limbs (special instrumented "gloves" and sensors). The actions of the user in the environment are translated directly from typical physical activities, not through manipulating a special pointing device. Realization of this ideal is a continuum involving compromises in these input/output modalities. At one end of the continuum, which we call a *complete virtual reality simulation,* the participant is immersed in a virtual world that fully replicates at least three sensory inputs—full three-dimensional vision, hearing, and touch (the last is more technically known as a haptic/kinesthetic system)[65]—and allows complete physical interaction with the world. The "Holodeck" of "Star Trek" would be an example.

At the other extreme of the continuum is a screen-based simulator that generates a limited virtual setting, restricting its output to a screen display, and provides interaction with the virtual world only through a pointing device. Screen-based simulators provide an interface to the human sensory system that is very far from physical reality, whereas a complete virtual reality simulation may be, in its most advanced form, nearly indistinguishable from the real world. A "partial" virtual reality simulator would replicate fewer senses (or less complete replication, such as a three-dimensional visual representation on a two-dimensional screen) or could restrict physical interaction with the world, or both. Finally, one can imagine hybrids of realistic simulators and virtual reality simulators (sometimes called *mixed reality*) in which the virtual reality representation is overlaid onto a real physical environment.

Some surgical and procedural part-task trainers/simulators, such as those used for laparoscopic, endoscopic, or endovascular procedures, might be considered virtual reality because the real procedure is performed only using a two-dimensional television display that can be recreated by the simulator. A comprehensive virtual reality patient simulator would be very complicated, however, because it requires the following:

- Complete computer model of the patient, the environment, and the function of every object in the environment that could be used (e.g., monitoring devices, carts)
- Means of tracking visual, audio, and touch fields of the user to determine what is to be displayed, and to identify what physical actions are being performed
- Appropriate display hardware for every sensory modality and appropriate input hardware for each action pathway (e.g., touch, speech)
- Hardware to compute all the models, to conduct the tracking, and to produce all the output to the display hardware in real time

Immersive virtual reality is a rapidly developing field. It has stimulated intense interest in numerous domains, particularly space flight, the military, and entertainment. Although the potential of this approach is very exciting, virtual reality is still under development. Prototype virtual reality patient simulators in anesthesia or intensive care have been discussed informally, but

as of this writing, there is no published experience with any meaningful immersive virtual reality patient simulation system.

A related type of simulation is the virtual environment or virtual world. According to the Wikipedia, a virtual world is a computer-based simulated environment intended for its users to inhabit and interact via "avatars" (users' graphical [often perspective three-dimensional] representation of their "selves"). Such systems typically allow multiple participants each to control simultaneously over a network their own avatar (including speech) and to interact verbally and by virtual physical actions within a commonly perceived virtual environment. This technology currently portrays the virtual world as perspective three-dimensional images on a computer screen plus sound. Virtual worlds have been commonly used for games (the popular "World of Warcraft" game has 9 million monthly subscribers), whereas other virtual worlds encompass online communities (e.g.,"Second Life," in which the primary activity is socializing, although commerce and education take place).

In a medical virtual world, the patient may be an automated avatar controlled by the computer, or the patient may be an avatar inhabited by a human participant (an unusual case of a standardized patient actor). Virtual worlds are starting to be used in health care, especially concerning acute care settings such as the ICU, the emergency department, or field resuscitation.

Although virtual reality simulators have many theoretical advantages over screen-based and mannequin-based simulators (e.g., more overall realism in some cases, instantaneous reset of the environment), these advantages are currently offset by the immaturity of the field. Despite considerable hype about virtual reality, such systems are now either very limited in capability or very expensive, and in most cases, they are limited and expensive. A true virtual reality *immersion* experience in a patient care setting comparable to that obtainable with a mannequin-based simulator is not yet on the horizon. Nonetheless, it is likely that virtual reality techniques eventually will eclipse other types of simulators. More than 15 years ago, we (D.G.) predicted this would occur by 2020, but the rate of development of immersive virtual reality has been slower than expected.[66,67]

Development of Patient Simulators

The descriptions given in the following sections are very brief, and the introduction of new or upgraded features in all the simulation systems continues steadily. For up-to-date information about any of the current systems, the reader is advised to contact the manufacturers or authors directly.

The history of the development of patient simulators—particularly the mannequin-based simulators that are in wide use—is well covered in several more recent review articles and book chapters.[5,68-70] The history is of some relevance to anesthesiology because of the dominant role played by anesthesiologists in the early developments in mannequin-based simulation. Anesthesiologists continue to play a major role in this field today, far out of proportion to their numbers relative to other medical domains.

In the late 1960s, a mannequin-based simulator—Sim One—was produced by an aerospace company working with anesthesiologists at the University of Southern California. For that era, it was a technologic marvel and was years ahead of its time.[71] The Sim One project drifted into oblivion, however, largely because the medical professions were not ready to understand the applicability of simulation to key issues of training, research, and assessment, especially regarding the importance of human factors.

Several patient simulators were developed and introduced in the mid to late 1980s. Each was an independent development, and none had any direct connection with the Sim One project. Several factors led to these advances. Most prominent was the new availability of powerful (comparable to advanced minicomputers of a decade earlier) personal computers (PCs) at a relatively cheap price. The popularity of various simulators for PCs (e.g., flight simulators, driving simulators) showed that simulation of complex systems was possible with a PC, and a screen-based simulator could give users some degree of "feel" that they had been in the environment. On the applications side, the public and the anesthesia profession had become more aware of the utility of simulation-based training for military and commercial aviation, space flight, automobile driving, shipping, military command and control, and the operation of nuclear power plants. Media coverage of the space program and corrective responses to the Three Mile Island nuclear power plant accident highlighted the role of simulators. Another pivotal factor was growing interest in anesthesiology in studying the anesthesiologist's performance and the human factors and ergonomics of the anesthesia work environment (see Chapter 6).[72-75]

Screen-Based Simulators (Microsimulators)

Beginning in the mid 1980s, several screen-based simulators were developed by anesthesiologists. These included part-task trainers that simulated isolated aspects of anesthesia, such as the uptake and distribution of anesthetic gases in the body given different physiologic and physical chemistry situations (the well-known GasMan simulator has excelled in this role). Other "full" screen-based simulators represented nearly all aspects of the patient and clinical environment. Originally the control logic was based heavily on mathematical models of physiology and pharmacology, some of the screen-based simulators have converted to control largely from scripts and finite-state models. Originally, the patient was represented by drawings or animations, but increasingly in these systems the representation of the patient is by photos or videos. Vital signs appear on virtual monitors that may mimic real clinical devices. Actions are selected typically using a graphical user interface, pointing and clicking on menus and buttons, and using sliders and numerical entry boxes to allow control of most kinds of interventions that clinicians use on a regular basis.

Experience with Patient Simulators in Anesthesia

Several companies now offer mannequin-based patient simulators with a wide range of capabilities (the term *fidelity* is reserved for the apparent veracity of the simulation; the simulator device

has a set of features or capabilities) and with different user interfaces and control logics. The bulk of simulators in use today (coming from several vendors) are considered medium-capability devices. They do approximately 70% as much as a top-of-the-line simulator, but at approximately 15% of the cost of the most expensive simulators. This value proposition has been persuasive to most customers, although for certain applications the high-end simulators still may be required.

The new patient simulators have been in use in anesthesia for more than 20 years, and considerable collective experience with the devices already has been achieved. This section and subsequent sections cover the use of simulators for education, training, evaluation, and research (the last especially in decision making and human factors). The results of simulator studies as regards human performance and patient safety are discussed primarily in Chapter 6.

Simulation for Education and Training of Health Care Personnel

The various available patient simulators offer an unparalleled opportunity for students to experience physiologic and pathophysiologic reactions in a realistic manner. Different objectives are possible for teaching sessions. A study by Morgan and Cleave-Hogg[76] concluded that "the simulator environment is somehow unique and allows different behaviors to be assessed." The objectives of *education* are to provide conceptual understanding and an introduction to skills, whereas the objective of *training* is to implement specific skills and behaviors applicable directly to real-world surroundings. Consistency in objectives is important for evaluating education and training; if we are teaching conceptual understanding, but assessing specific skills, we may obtain misleading results.[77]

A Best Evidence Medical Education (BEME, www.bemecollaboration.org) review by Issenberg and colleagues[25] concluded that high-fidelity medical simulations are educationally effective, but only if the right conditions are met, as follows:

Conditions for the Educational Effectiveness of High-Fidelity Medical Simulations (according to a BEME review by Issenbery[25])

- Educational feedback is provided
- Repetitive practice is used or is allowed
- Simulation is integrated sensibly into the standard curriculum
- The range of task difficulty can be adapted to the level of the learner

Simulation for Education and Training of Medical and Other Health Profession Students

The structured review about simulation effects on simulation-based medical education by Issenberg and colleagues[25] showed that (1) the methodologic quality of educational research is often weak, and (2) in the high-quality studies that were evaluated, there was an effect between hours of simulator practice and learning outcomes equaling a dose-response relationship. Studies by Coates and associates[78] and Gordon and coworkers[79] showed that simulator education for medical students on patient management skills related to dyspnea was superior to problem-based learning.

A variety of curricula exist,[54,77,80-90] including the following:

- Educational sessions and demonstrations concerning basic cardiopulmonary physiology or pharmacology; in some institutions, these sessions replace animal laboratory exercises.[91]
- Introduction to integrated management (i.e., interweaving of diagnosis and treatment) of critically ill patients; this training is offered to immediate preclinical medical students as part of their preparation for clinical medicine courses.
- Anesthesia practicum for clinical students during anesthesia or intensive care clerkships.
- Problem-solving skills training; simulation has been tested as a means of educating and training students in the appropriate response to specific critical events. Morgan and Cleave-Hogg[92] tested simulation versus instructor-facilitated viewing of a videotape for this purpose and found no difference between the two. The generalizability of this finding has been questioned, however.[77]
- Adaptation of curricula originally aimed at experienced trainees or practicing clinicians to students; there is increasing interest in providing early exposure to medical students, and possibly students of nursing or allied health professions, to interdisciplinary team aspects of medical practice. The aim is to inculcate concepts of teamwork and communication at the earliest stages of education and training as a vehicle to implement long-term culture change in the health care system.

A stimulating critical overview of medical education in general was written by Hodges, provocatively titled "Medical education and the maintenance of *incompetence*" (emphasis added).[93] The article points out that any type of education runs a risk of creating or maintaining *incompetence* in certain areas, especially areas that are ignored by the actual educational program. Objective structured clinical examination–style methods in particular are criticized because students may learn to pass the objective structured clinical examination, but still have even gross incompetence in important aspects of real patient care that are not covered by the objective structured clinical examination rating scale. Simulation offers the promise of targeting more thorough integration of different kinds of skills into a better representation of the realities of clinical care. Nonetheless, we recommend that all simulation instructors be especially cognizant of the risks that Hodges articulates.

Anesthesia Crisis Resource Management

In 1989, based on the cognitive process model presented in Chapter 6 and the research results of Cooper and coworkers,[72,94] Howard and associates,[95] and Gaba[73,74] of the VA–Stanford group identified gaps in the training of anesthesiologists regarding

several critical aspects of decision making and crisis management that were not systematically taught during standard residency or postgraduate education. These gaps were (1) inadequate learning of precompiled plans for dealing with perioperative events; (2) inadequate skills of metacognition and allocation of attention; and (3) inadequate skill in resource management behavior, including leadership, communication, workload management, monitoring, and cross-checking of all available information. Historically, it had been assumed that anesthesiologists would acquire these plans and skills "by osmosis," solely by experience and by observing role models who had these qualities. As indicated in a previous section, the aviation field had learned that such skills were not acquired unless specifically taught, and CRM training was created to address these issues for flight crews. The VA–Stanford group modeled their ACRM training[95] after CRM, and this approach has been highly influential. ACRM-like curricula are taught at simulation centers around the world, not only in anesthesia, but also in many other domains of health care, including ICU, emergency medicine, labor and delivery, trauma, and field responders.[16,35,38,41,43,44,54,68,96-113] Figure 7-14 shows a typical ACRM team training scenario.

To target the identified gaps in training, approximately 40% of the emphasis of ACRM is on the medical and technical management of specific high-risk perioperative situations, but at least 60% of the emphasis is on generic principles of crisis management that apply to nearly every complex patient care situation. The key teaching points of ACRM are shown in Table 7-8. These points are emphasized during the ACRM simulation course, and their occurrence or omission is highlighted during the video-assisted debriefing sessions (see more on CRM in Chapter 6).

A working group of the original ACRM centers (VA–Stanford, Boston CMS, Toronto Sunnybrooke) has promulgated a set of criteria to be met by a curriculum to be called "ACRM" or "ACRM-like." Table 7-9 presents an excerpt of the criteria. The full set of criteria is available at http://anesthesia.stanford.edu/VASimulator/ACRM_Criteria.htm.

These criteria delineate that special training is needed for instructors in ACRM-like curricula. Experience suggests that the most difficult aspect of ACRM instructing is debriefing, and new instructors require a significant period of experience, preferably under supervision by more senior instructors, before being ready to be fully independent instructors. Several groups working separately or collectively have developed comprehensive training programs on simulation instruction, including substantial modules on debriefing and scenario design.

Table 7-8 Key Points in Anesthesia Crisis Resource Management

1. Know the environment
2. Anticipate and plan
3. Call for help early
4. Exercise leadership and followership with assertiveness
5. Distribute the workload (10 seconds for 10 minutes)
6. Mobilize all available resources
7. Communicate effectively
8. Use all available information
9. Prevent and manage fixation errors
10. Cross and double check (never assume anything)
11. Use cognitive aids
12. Re-evaluate repeatedly (apply the 10 seconds for 10 minutes concept)
13. Use good teamwork
14. Allocate attention wisely
15. Set priorities dynamically

(Detailed explanation of the CRM Key Points are given in Chapter 6.

Figure 7-14 Anesthesia crisis resource management team training scenario. A full operating room team (enacted surgeons and nurses) is doing a complicated endoscopic surgery case (replayed on screen). The anesthesia team consisting of the trainee ("hot seat") and the nurse has to solve complex problems. Video cameras (ceiling), microphones, and loudspeakers provide the necessary connectivity and debriefing tools. *(Picture by team TuPASS, taken at Center for Patient Safety and Simulation, University Hospital, Tubingen, Germany.)*

ACRM-like curricula use several teaching modalities to achieve these goals, including the following:

- A comprehensive textbook on anesthesia crisis management (*Crisis Management in Anesthesiology*). This book includes didactic material on ACRM principles and a comprehensive catalog of critical incidents in anesthesia that provides guidelines for preventing, recognizing, and managing 83 perioperative situations in a uniform format. The catalog section of the text is intended to provide study material to increase anesthesiologists' stock of precompiled response plans to common and uncommon situations. This textbook has been translated into Japanese and German (by one of this chapter's authors).
- A brief presentation reviewing the principles of CRM and patient safety.
- Analysis of a videotape of an aviation accident.
- Small group exercises analyzing a videotape of an actual patient care mishap or analyzing written or video presentations about difficult cases.
- Several hours of complex multifaceted realistic simulations in which training participants rotate through different roles, including primary anesthesiologist, first responder (called "cold" with no knowledge of the situation), and scrub nurse. Other personnel play the roles of surgeons, nurses, and technicians as in a real operating room. Each situation is followed by a detailed debriefing with video feedback (see earlier discussion of debriefing).

Several publications have detailed the response of participants with varying levels of experience to ACRM training.[95,109] Participants have been extremely positive about their experience in the ACRM course, and most believe that it contributes to their

Table 7-9 Characteristics of Anesthesia Crisis Resource Management–like Simulator Training

Objectives
Learn generic principles of complex problem solving, decision making, resource management, and teamwork behavior
Improve participants' medical/technical, cognitive, and social skills in the recognition and treatment of realistic, complex medical situations
Enhance capacity for reflection, self-discovery, and teamwork and building a personalized tool kit of attitudes, behaviors, and skills
Aim
Prevent, ameliorate, and resolve critical incidents
Setting Characteristics
Realistic simulation environment replicating a relevant work setting (or an actual patient care setting with in-situ simulation)
Personnel to represent individually those found in the typical work environment of the participant, including nurses, surgeons, and technicians
Bulk of the training course consists of realistic simulations followed by detailed debriefings
Primary participant can request and receive help from other participants
Participants may rotate between different roles during different scenarios to gain different perspectives
Simulation scenarios may be supplemented by additional modalities, including activities such as assigned readings, didactic presentations, analysis of videotapes, role playing, or group discussions
Training involves significant time (>4 hours, typically ≥8 hours) and is conducted with a small group of participants
Content Characteristics
Scenarios require participants to engage in appropriate professional interactions
At least 50% of the emphasis of the course is on crisis resource management behavior (nontechnical skills), rather than medical or technical issues (nontechnical skills are discussed in Chapter 6)
Observation only is not equivalent to actual participation in the course
Faculty Characteristics
Training is intense and entails high level of involvement of faculty with the participants and a low participant-to-faculty ratio
Faculty, especially those leading debriefing, have special training or experience in conducting crisis resource management–oriented training
Debriefing Characteristics
Debriefings are performed with the whole group of participants together and use (as appropriate) audio/video recordings of the simulation sessions
Debriefings emphasize constructive critique and analysis in which the participants are given the greatest opportunity possible to speak and to critique and to learn from each other (debriefing facilitation)

safe practice of anesthesia. Table 7-10 shows the results of one of the earliest studies on that topic.

At VA–Stanford, ACRM has been extended to a multilevel course conducted over several years (i.e., ACRM 1, 2, 3). As the course levels progress, the scenarios become more complex and involve subspecialties of anesthesia. In addition, additional teaching modules cover other important aspects of organizational safety, such as "systems thinking" in morbidity and mortality conference settings or peer review settings, follow-up response to severe adverse perioperative events, and disclosure to the patient or family of "bad news" after an adverse event.

ACRM courses and ACRM-like variants are now being offered worldwide and are often mandatory for trainees (and in some cases for experienced personnel). In Denmark, ACRM-like training courses are a legal requirement for nurse anesthetists (3-day course) and first-year (2-day course) and third-year residents (4-day course), in addition to some other simulator training courses (e.g., difficult airway). Further plans are being made to require simulation training for ICU and recovery room nurses and ICU residents.[114-116] Salas and colleagues[33] published an excellent critical overview about prerequisites for effective CRM training.

Simulation for Training of Anesthesia Residents

Simulation is now a widely used technique in the training of anesthesia residents. It is used in various ways—for technical training on particular procedures or patient care protocols (especially for airway management), for supplementing didactic instruction about anesthesia equipment, and for training about issues of decision making and nontechnical skills as outlined earlier concerning ACRM. Nearly every anesthesia residency program in the United States now offers some cogent simulation training experiences, although the scope, frequency, and target content vary.

Other disciplines and other countries may not have adequate simulation training coverage during residency, as evidenced by a study by Hayes and colleagues[117] about the perception of Canadian internal medicine residents to be qualified for their service on the cardiac arrest team: 49% felt inadequately trained, 50% felt that the provided advanced life support course did not prepare enough to lead the arrest team, and almost none got postevent debriefing or feedback.

Table 7-10 Evaluation of Anesthesia Crisis Resource Management (ACRM) Course in Harvard Anesthesia Simulation Training

		Attending Staff (n = 30)		Residents and Fellows (n = 34)	
Rating	**Scale**	**Evaluation of Simulator Environment (%)**	**Value of ACRM Course (%)**	**Evaluation of Simulator Environment (%)**	**Value of ACRM Course (%)**
Less favorable	1	13	3	9	1
	2	10	3	6	2
	3	15	15	11	4
	4	10	25	28	28
More favorable	5	33	54	46	75

Modified from Holzman RS, Cooper JB, Gaba DM, et al: Anesthesia crisis resource management: Real-life simulation training in operating room crises. J Clin Anesth 7:675-687, 1995.

Special Considerations in Pediatric Simulation

A sizable body of international experience with simulation in pediatric settings now exists (see Chapter 82).[43,111,118] A study by Overly and coworkers[119] assessing airway management skills in pediatric residents identified many areas of concern about residents' abilities. The authors concluded that high-fidelity simulation can be used to assess residents' airway management, and that the training program was effective to teach these skills.

Many centers use pediatric simulators predominantly for training of the management of critical incidents and medical emergencies, targeting trainees and specialists in anesthesia and pediatric critical care medicine. Because there is frequent organizational and clinical overlap between personnel engaged in pediatric anesthesia, critical care, and emergency medicine, multispecialty (physician crews from different specialties) and multidisciplinary (crews from different professional disciplines), team training can be particularly helpful to prevent failures of cooperation at treatment interfaces (Figs. 7-15 and 7-16). A review by Eppich and colleagues[35] on team training in pediatric acute care settings underlines the impact and effectiveness of team training addressing pediatric teams. The American Academy of Pediatrics now specifically recommends teamwork and communication training for all health care professionals in pediatric emergency settings, and the American Heart Association has included a team concept video and eight elements of team dynamics in its training programs.[120-122]

Figure 7-16 Neonatal CRM and resuscitation training at a neonatal emergency workplace. All treatment steps need to be performed in the simulation to show the need to coordinate and delegate. The experienced instructor (on the right side of the infant) is taking part as a team member, while another instructor team is in the control room, presiding over simulation control and debriefing videos. CRM, crisis resource management. *(Picture taken at Stanford Simulation Center.)*

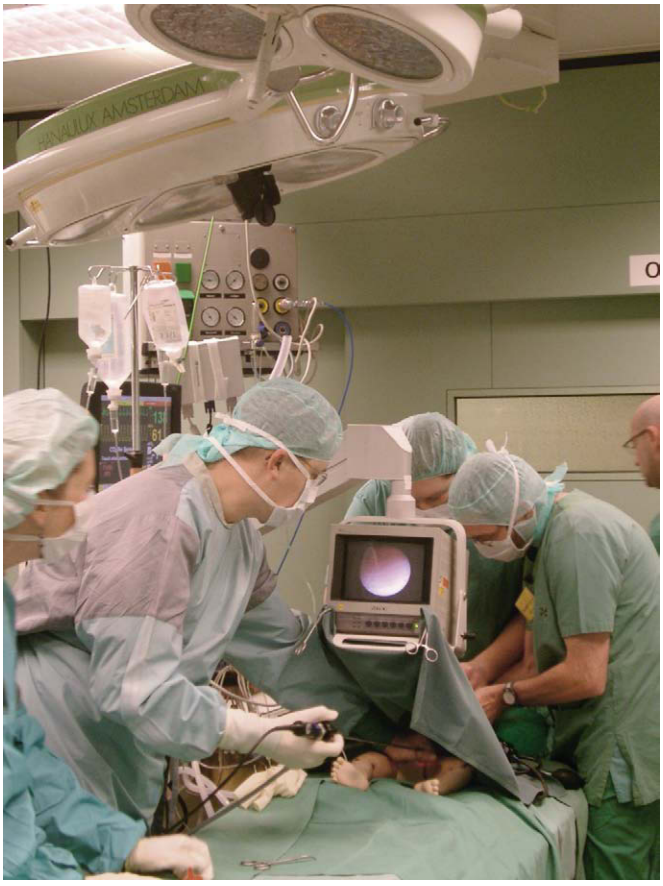

Figure 7-15 Pediatric full team simulation training. The primary trainees (anesthesia) have to solve problems with the infant simulator, while urologic surgical team members perform their procedure. *(Courtesy of C. Eich, University Hospital, Göttingen, Germany.)*

In contrast to adult medicine, the demand in pediatrics for simulation has been largely to address particular points of medical knowledge and technical skill, perhaps because many personnel have little experience with pediatric care, especially for cases involving neonates and infants (Table 7-11).[123] Many simulation courses in pediatric anesthesia or intensive care need extensive involvement by experienced pediatric clinicians. More senior clinical personnel who work regularly in pediatric settings may be comfortable with their pediatric clinical skills, but may be more interested in the generic nontechnical skills that are equally applicable to pediatric and adult care.[120]

There is a positive correlation between the difficulty of pediatric scenarios and the participants' own perception of the learning effect.[123] Scenarios that participants rarely encounter in their clinical practice (e.g., an infant in circulatory shock owing to extensive thermal injury) on the one hand are thought to be threatening, but on the other hand are considered to be particularly beneficial in terms of training effect. A commonplace but interesting aspect inherent in pediatric simulation is the incorporation of role play by family members. Although family members may be present in adult medicine, their presence in pediatrics is nearly ubiquitous.[124] This presence can put further strain and stress on the provider, making it particularly useful to add family role players (either trained actors or instructors or even the participants themselves) to pediatric simulation scenarios.[118]

Continuing Medical Education

Most simulation centers offer CME for experienced practitioners, and nearly all aspects of simulation training for residents (except novice training) can be expanded for this purpose. Several studies

Table 7-11 Unique Aspects of Simulation in Pediatric Anesthesia

Huge discrepancy between high degree of required clinical proficiency and often limited level of expertise
Strong demand for training on medical-technical aspects of management—recommendation to participate in a pediatric advanced life support course before simulation team training course
Need to familiarize with parental presence during pediatric anesthetic care by combination of simulation and role play
The small patient requires an even better organization of the work environment and task responsibilities (in-situ training)
High-impact multidisciplinary team training, including CRM
High level of interest in assessment and certification of trainees and subspecialists for work in pediatric anesthesia

CRM, Crisis resource management.

have shown that experienced anesthesiologists also have deficiencies in the management of critical patient situations and make severe errors comparable to those of anesthesia residents.[64,116,125-129] A study by Jacobsen and associates in Denmark[130] involving 42 specialist anesthesiologists showed major deficiencies in the diagnosis and treatment of anaphylactic shock and in application of the ACRM principles when a score adopted from Gaba and Howard was used.[69,131] Because crisis situations are rare during routine clinical work, these results are not unexpected. In addition, experience in terms of years on the job and hierarchy probably do not correspond to expertise and excellence. It cannot be overemphasized that crisis management training with simulators should be started early in education and training and applied on a recurring basis during practice.

An aspect of CME training in the United States is that it is regulated separately by each of the states, and it is nearly uniformly based only on the number of hours spent in the activity. Reading a short article and answering a handful of questions can generate 1 hour of credit, as can sitting through a lecture. Simulation training is generally much more interactive and much more intensive than other activities. In Australia and Germany, CME requirements are expressed in terms of points to be accrued. Simulation training counts for a large number of points per hour spent, commensurate with its intensity, which might make simulation-based CME financially competitive relative to simpler methods.

The ASA has established a standing Committee on Simulation. The ASA offers an endorsement (analogous to but different from an accreditation) of simulation programs that can show their capability to offer excellent CME curricula to ASA members. The Committee began reviewing applicants for endorsement in 2008.

At the Harvard hospitals, the captive insurer, Harvard Risk Management Foundation, has taken unprecedented steps to link simulation-based CME training to discounts for medical malpractice premium rates for experienced clinicians in anesthesia and in obstetrics (Cooper J: personal communication, 2005). This forward-thinking program is now being adopted by other malpractice carriers. In some jurisdictions, risk managers have chosen to invest directly in simulation activities at their institution, rather than to use the premium discount approach.

Use of Patient Simulation for Training Health Care Personnel outside Anesthesia

Anesthesiology remains a driving force in the use of simulation in health care, but simulation has spread to nearly every discipline and domain. It is proven to be particularly applicable to other areas that share the cognitive profile of anesthesiology—dynamic decision making (played out over seconds, minutes, and hours), with complex teams, wielding highly lethal interventions. ACRM-like training has been performed in settings that include, but are not limited to, intensive care,[113,132] emergency medicine and emergency field responders,[133-138] trauma medicine and surgery, neonatology (neonatal resuscitation and neonatal ICU), labor and delivery (Fig. 7-16),[139,140] cardiac arrest and rapid response teams,[141-143] and radiology. Simulation is such a diverse technique that it is equally applicable—using different modalities of simulation—to nearly all domains. Knudson and colleagues[36] found a significant improvement in overall and teamwork scores in surgical residents when taking care of critically injured simulated trauma patients if they have undergone CRM-like simulation training.

The military and Homeland Security also have been heavy users of simulation in health care, where it has been applied to the initial training of new field medics and to the recurrent training of experienced clinicians and clinical teams.[144] Figure 7-17 shows one room with 10 simulators in a training center for military medics that has more than 100 simulator mannequins altogether.

Simulation is now used more frequently in training for the management of chemical, biologic, or nuclear threats from accidents, weapons of mass destruction, or terrorism. One of our groups in Tübingen, Germany, used their simulator to test the constraints of treating patients in full chemical protection gear (publication of the results is in preparation) to optimize the strategies of the German Ministry of Internal Affairs for dealing with terror attacks or chemical plant disasters (Figs. 7-18 and 7-19) (see Chapter 74). Several investigators have performed multidis-

Figure 7-17 Simulation-based training center for military medics. The room is equipped with 10 SimMan training stations. During training sessions, one instructor team is sitting at each foot of each mannequin. Teaching is provided "on scene" during the sessions.

Figure 7-18 Realistic patient simulation as a test bed for studying the performance of medical rescue teams in full chemical protection gear. Teams wore normal uniforms or full protection suits while performing basic resuscitation actions (e.g., placement of intravenous lines, drawing up drugs, intubation). *(Picture taken at the TuPASS Center for Patient Safety and Simulation, Tübingen, Germany.)*

ciplinary studies with combined simulation modalities (script-based, model-based mannequin simulators, and simulated acted patients) to teach the management of victims of an attack with weapons of mass destruction and terrorism.[59,60] The demand for such training is substantial in nations engaged in active military conflicts or with an ongoing need to prepare for war or terrorist attacks (e.g., the United States and Israel).

Use of Patient Simulation for Research

Research in simulation falls into two categories: (1) research *about* simulation—testing or improving the techniques, technologies, and pedagogy of simulation, and (2) research that uses simulation as a tool to study other things, such as human performance, clinical cognition, or clinical care processes (see Chapter 6). Table 7-12 provides a sampling of these latter types of questions. As a research tool, simulation offers some unique features, and it can be thought of as a complementary window on the clinical world relative to other modalities. One can study clinical work using

Figure 7-19 In rescue situations with full protective gear, communication within the team and with the patient is difficult. *(Picture taken from a video screen at the TuPASS Center for Patient Safety and Simulation, Tübingen, Germany.)*

Table 7-12 Research Issues That Can Be Addressed by Using Simulation

Cognitive Science of Dynamic Decision Making (see Chapter 6)
What is the interaction of precompiled procedural knowledge versus deep medical knowledge and abstract reasoning?
How does supervisory control of observation relate to vigilance, data overload, and visual scanning patterns?
What is the information content of watching the surgical field?
How are optimal action planning and scheduling implemented?
How does re-evaluation fail and result in fixation errors?
Human-Machine Interactions
What is the distraction penalty for false alarms?
Is there an advantage to integrated monitors and displays versus multiple stand-alone devices and displays?
How easy to use are the controls and displays of existing anesthesia equipment in standard case situations and in crisis situations?
Teaching Anesthesia in the Operating Room
How much teaching can be accomplished in the operating room without sacrificing the anesthesia crew's vigilance?
How well can faculty detect and categorize the performance of anesthesia trainees?
What teaching styles are best integrated with case management in the operating room?
Issues of Teamwork
How does an anesthesia crew (attending anesthesiologist plus resident or Certified Registered Nurse Anesthetist) interact during case and crisis management?
How is workload distributed among individuals?
How do crew members communicate with each other, and how do they communicate with other members of the operating room team?
Effects of Performance-Shaping Factors on Anesthesiologist Performance
How do sleep deprivation, fatigue, aging, and the carryover effects of over-the-counter medications, coffee, or alcohol affect the performance of anesthesiologists?
Intelligent Decision Support
Can smart alarm systems or artificial intelligence provide correct and clinically meaningful decision support in the operating room or intensive care unit?
Development of New Devices and Applications: Research Regarding Technique of Simulation
How well do simulators resemble the operating room and provoke the same actions as use in the operating room (ecologic validity of simulators)?
How much does debriefing add to learning from simulation? Are specific techniques of debriefing (e.g., use of video; participant-centered discussion) of significant utility?
How does the setting of simulation scenarios influence aspects of perceived reality, and how does it influence transfer into the real world?
Does simulation training lead to better clinical practice and improved clinical outcomes?

prospective observation of real cases. This has the benefit of being prospective, but by nature, more cases in most domains would be unremarkable, and one would mostly observe the routine and banal. For some purposes, this study would be more than sufficient. Another source of information is in case reports of challenging cases, whether the challenges were expected or unexpected. These also are real cases, and they are out of the ordinary, but the data obtained from such retrospective reports are usually scanty and biased.

Simulation provides an alternative view of clinical work that can be prospective and about challenging cases, albeit simulated cases. The simulation centers around the world probably have the largest experience by far of observing anesthesiologists managing (simulated) malignant hyperthermia. It is hard to imagine how else one might gather systematic data about how clinicians work while managing this uncommon life-threatening situation.

An important milestone for simulation-based research of both types is the publication by the Society for Simulation in Healthcare since 2007 of a peer-reviewed journal titled *Simulation in Healthcare* (one of the authors, D.G., is the founding editor-in-chief of the journal). In addition, for research that is linked tightly to a specific clinical domain, the traditional medical specialty journals have become more welcoming to articles about simulation or that use simulation as an experimental technique.

Cooperation between simulation directors and instructors with psychologists, human factors engineers, or educators has proved to be helpful in research and training. Such collaborations have helped to delineate the theoretical foundations of simulation-based experiential learning, for improving the understanding of debriefing, and for research on work psychology and human performance in health care.[19,21,22,26,27,145,146] Many institutions have integrated psychologists or educators or both into their simulation center staff.[104] Ways to make such collaborations fruitful and rewarding also have been described.

Use of Patient Simulation in Support of Biomedical Industries

Various simulation activities have involved the pharmaceutical or medical equipment industries. Numerous centers (perhaps the University of Florida at Gainesville was the first) offer training to executives and sales representatives of equipment and pharmaceutical manufacturers. The simulator allows these individuals to gain some understanding of the clinician's task demands during patient care and the situations in which their company's drugs or devices could be useful. At the Boston Center for Medical Simulation, this course is dubbed "Anesthesia for Amateurs." Other industrial uses include training personnel in the use of novel pharmaceuticals. Simulators have been featured in a multifaceted approach to launch the opioid remifentanil. Simulators were used to train the manufacturer's representatives and clinicians in safe use of the drug, and it was possible to train anesthesiologists in the application of remifentanil with the simulator before remifentanil was approved by the U.S. Food and Drug Administration (WB Murray: personal communication, 1998.) Besides offering important educational benefits, the industrial activities are an important source of income for simulation centers to help defray the costs of training students and residents.

Simulators have been used to conduct research on human factors issues in the development of new monitoring and therapeutic devices. The simulator also provides a unique test bed and demonstration modality for preprocurement evaluation of the usability of medical devices from different manufacturers. In our own hospitals (Stanford and Tübingen, Germany), simulators enabled us to conduct evaluations of prototype monitoring systems that were not yet approved for clinical use and could not be evaluated in a preprocurement clinical trial.

Other Uses of Simulators

Other unique applications of simulators have surfaced. Some centers use simulators for conducting outreach programs with high school or college students interested in health care. Simulators have been used to help produce educational videotapes on various patient safety issues. It has been suggested that a "legislator day" could be held in a simulator center to familiarize legislators with the demands of dynamic patient care.

Simulators have been used as adjuncts in medicolegal proceedings.[147] Current patient simulators cannot predict the exact physiologic behavior of a specific patient, but they can be used to illustrate typical perioperative situations and the role of different monitors and therapeutic actions, and provide context for the patient management questions of the litigation.

Effectiveness of Simulation Training

Flanagan and associates[148] provide a thorough review on the literature to date on the efficacy of simulation-based training for learning and assessment. The investigators identified more than 3500 articles, of which 458 were included in the review. The conclusion was that "simulation makes a valuable contribution to learning for students, trainees and clinicians. It enables learning of both routine and non-routine procedures and management of patients."[148] They further concluded that simulation is widely used in teaching and learning, is increasingly being used for formative and low-stakes assessments, and is rarely used (but under growing consideration for) high-stakes summative assessment. Flanagan and associates[148] also observed that the range of simulation modalities used for these activities varies widely. Similar to the BEME review by Issenberg[25], they found that many studies lacked a robust design, and that the level of outcome effectiveness as measured with a modified Kirkpatrick scale rarely exceeded 3 out of 6, with most at the level of 2 or below.

The most important question concerning simulator-based training in anesthesia is its cost-effectiveness. This complicated question has two independent components. The first component is the impact and benefit of the training on the performance abilities of participants, and the second is the cost to achieve that impact. In principle, simulation has many advantages as a training tool, as follows[149]:

- There is no risk to a patient.
- Exercises in routine procedures can be repeated intensively, whereas situations and events involving uncommon, but serious problems can be presented at will.
- Participants can learn to use actual complex devices (with a hands-on simulator).
- The same situation can be presented independently to multiple subjects for evaluating individual or group performance.
- Errors can be allowed to occur that in a clinical setting would require immediate intervention by a supervisor.
- The simulation can be frozen to allow discussion of the situation and its management, and it can be restarted or begun anew to show alternative strategies or techniques.
- Recording, replay, and critique of performance are facilitated because patient safety or confidentiality is not an issue.

The fidelity required of the simulator and the choice between screen-only and realistic simulators depend on the intended goals of the training and the relevant target population. A spectrum of computer-based training is possible. Computer-assisted instruction programs and partial-task trainers can be used to teach basic concepts and technical material, such as the uptake and distribution of inhaled anesthetics or the pharmacokinetics of intravenous drugs. These uses are appropriate for students, novices, advanced residents, and experienced practitioners. Screen-only simulators are inexpensive and easy to use. They allow the presentation of and practice with the concepts and procedures involved in managing normal and abnormal case situations. They also are useful for numerous user populations. Realistic simulators can be used to capture the full complexity of the real task domain, including human-machine interactions and the complications of working with multiple personnel. They are most appropriately used for residents and experienced practitioners. Regardless of the device used, the simulator is only a teaching tool that must be coupled with an effective curriculum for its use.[25]

The evaluations conducted so far suggest that simulator-based training is a powerful technique that novice and experienced anesthesiologists believe to be highly beneficial, and that participants and instructors alike believe may improve clinical performance. As the developers of Sim One 7 pointed out, when simulation provides an opportunity to teach material that cannot be taught in another way, as for the systematic instruction of anesthesiologists in handling severe critical events such as cardiac arrest, anaphylaxis, or malignant hyperthermia, there is nothing with which to compare the simulator. Assessing whether the actual outcome of patients can be affected by this or any other training modality would be extremely difficult and expensive. Individuals investigating simulator-based training do not believe that definitive outcome studies of this type are logistically feasible.[150] Determining the impact of a given type of simulator training on the intermediate variables of "performance" and "ability" is feasible, but it would not be easy. The Leiden group provided data supporting the contention that simulation training improves performance in handling a malignant hyperthermia situation. There is a potential, however, for substantial bias when attempting to measure the impact of simulator training by using performance in the simulator as a criterion. The control procedures used by the Leiden group alleviate this bias, but they cannot eliminate it.[151]

Perhaps of even greater importance, no methodology is currently accepted for measuring the clinical performance of anesthesiologists either in the simulator or in actual practice.[152] Ironically, the simulator itself provides a tool for presenting the same calibrated situation to multiple anesthesiologists and may be a crucial tool in developing such performance measures. Many groups around the world are trying to refine performance measurement tools,[107,140,153-172] but no "gold standard" measurement is yet available to assess a simulation's effectiveness (see the later section on evaluation of performance).[152]

How Simulation Can Be More Effective

Health care has not yet scratched the surface of assessing the impact of simulation-based training. Most simulation is currently targeted at students and trainees (i.e., residents), although programs targeting experienced personnel are growing. The assessment of the impact of simulation to date can be seen using the following analogy to drug development and testing. Suppose we wished to test whether a purported antihypertensive drug actually succeeded in reducing blood pressure in patients, and, more importantly, whether it reduced the occurrence of adverse cardiovascular events, such as myocardial infarction and stroke. Imagine then that we proceeded as follows: Administer a relatively small dose of this drug only a few times per year. Acknowledge variable compliance in taking even these few doses of drug. Immerse all subjects in an environment full of stress and other factors predisposing to cardiovascular events. Use only a few patients, and follow them for a very short time.

Using this methodology, would anyone wonder if no significant effect was found even for a drug otherwise known to be effective? Simulation in health care has so far been tested in this way: very small short-term studies of infrequent (often short) simulation sessions, whose lessons are not fully reinforced in real clinical environments full of production pressure and stress. In truth, the question is not "Does one run through a simulation course make a practitioner better?" To follow the lead of other industries of intrinsic hazard, such as commercial aviation or nuclear power production, the real question is: "What is the impact of health care as an industry adopting a comprehensive integrated strategy of intensive simulation-based training and continued performance assessment of clinical personnel, over a long period of time?" This is the approach in aviation, where no matter how senior and how experienced pilots are, they still undergo training and assessment in simulation every year, for the entirety of their careers.

Even so, industries such as aviation do not have anything resembling level 1A evidence for the benefits of simulation, even though such studies could be grafted onto the existing structure of yearly training and testing. It is unlikely that aviation would ever attempt randomized trials. For one thing, as the saying goes, "Pilots are the first ones at the scene of the accident." It seems unlikely that pilots would forgo simulation training and assessment when their own lives are on the line. For another thing, the public has come to expect that there is a regulatory safety floor imposed by the government to ensure the competency of pilots. The regulator is unlikely to forgo its requirement for mandatory training and testing of pilots. If such requirements continue, there may be only two options: conduct them in real airplanes, with the attendant costs (e.g., fuel) and risks, or conduct

them using simulation. With health care heading toward that direction,[37,38,43,46,173-177] we may be able to assess the impact of more effective simulation programs, although we might lose a control group.

Avoiding Subthreshold Training Effects

To date, simulation training has largely been employed in "small doses" given intermittently, not sustained over the long-term, and ignoring many personnel who are crucial in the chain of patient care. When conducted this way, simulation training may not achieve a "critical mass" and may produce a subthreshold effect. It seems likely that a long-term cumulative effect would be achieved only with a long-term comprehensive program of training and performance assessment.

It is possible that it is worth the inherent logistical difficulties and costs to undertake bulk training (>75% of personnel trained in a short time, rather than starting a program of training a few individuals a month and achieving a high penetration rate only in months or years). Where the training is about teamwork and behavioral issues (CRM-focused), this might be especially important so that the lessons taught in the simulator are continuously reinforced by experiences in real patient care. The hope is that creating a critical mass of adherents to CRM principles via simulation would create a self-sustaining reinforcement of safety-oriented behaviors that continues with only occasional refresher sessions of simulation.

An analogy for that effect would be the starting of a fire with wood logs: If you take away the match too early, you do not light the fire, and all you get is a black mark on the wood, but if you keep the match on the wood long enough (similar to activation energy), the fire starts to burn and spread to all logs without any more input—similar to what we would like to see with CRM team behaviors.

Ecologic Validity of Simulators Compared with the Operating Room

The question whether full-scale simulators are an ecologically valid representation of the operating room (i.e., to what extent "the environment experienced by the subjects in a scientific investigation has the properties it is supposed or assumed to have by the experimenter"[178]) has been investigated by an interdisciplinary research group in Tübingen and Zurich.[145] If the actions in the simulator resemble the actions in real operating room environments (*behavioral validity*), it is much more likely that the results of research conducted in a simulator setting or lessons learned in the simulator environment would be transferable to the context of actual patient care. The group developed an improved task analysis method that allows the recording of overlapping activities (41 actions from five categories—monitoring, actions, communication, documentation, and other) to analyze and describe the performance of anesthesia.[179]

This method is described in more detail in Chapter 6. Each of the six anesthesiologists participating in the study was observed during two clinical cases and during three comparable simulator cases (one routine and two involving critical incidents). Analysis of the study showed good comparability of the different action categories (Fig. 7-20). The interpretation of the group is that overall comparability between the operating room and the simulator setting is good, indicating high ecologic validity for simulators in anesthesia. The results of the study also show few, but distinct variations in the task structure of operating room and simulator cases. These variations are mostly due to organizational factors (e.g., fewer "additional tasks" required in the simulator). These studies provide objective confirmation of the favorable sub-

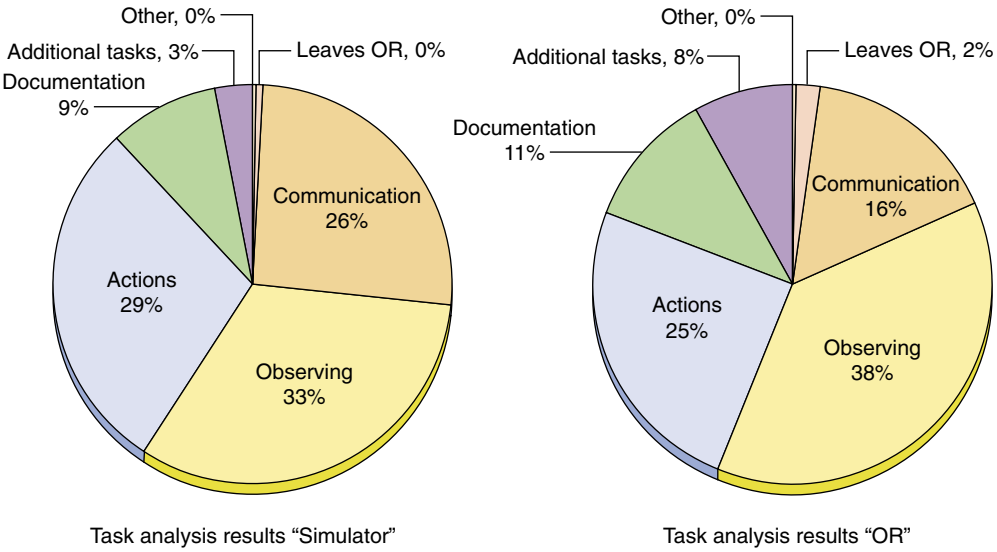

Figure 7-20 Validity of simulator systems versus the operating room (OR). The same anesthesiologists were observed in the OR and the simulator environment with full enactment of the OR personnel, surgical team, and anesthesia nurse. Even though the two settings have some interesting differences, the overall "ecologic validity" of the simulator is good. *(Courtesy of T. Manser, ETH Zurich, and University Hospital, Tübingen, Germany.)*

jective impressions of realistic simulation scenarios by anesthesiologists of varying levels of experience.[126,127,159,161,180-182]

Some differences between simulation and real patient care are inherent to simulation. Subjects realize that they are in a simulator and are likely to be hypervigilant (e.g., many participants neglect documentation in the simulator while waiting for a disaster to happen). In addition, there might be some organizational factors that are usually different in the simulator than in the real operating room (e.g., reflected in fewer "additional tasks" in the simulator compared to the real OR in the study of Manser and Rall). Careful and creative scenario design and introductory briefings may mitigate the hypervigilance and organizational effects.[47,183]

Evaluation of Clinical Performance during Simulation Scenarios

The introduction of patient simulators allowed the study of human performance when responding to critical events (see Chapter 6). Techniques are needed to assess anesthesiologists' performance. Performance can be divided into two components: technical performance, which is the appropriateness and thoroughness of the medical and technical response to the critical event, and behavioral performance, which is the appropriate use of sound crisis management behavior (e.g., leadership, communication, distribution of workload).[184,185] (See Chapter 6 on CRM.) Assessment of medical and technical responses has resulted in "technical scores" suggested by different authors.[151,152,160,161,186-189]

Simulation offers some benefits in assessing performance. Because the nature and cause of the critical incident are known, one can construct in advance a list of essential or appropriate technical activities with relative weights of importance. When assessing technical performance in managing malignant hyperthermia, terminating the trigger agent and administering intravenous dantrolene would be essential items, whereas cooling measures, hyperventilation, and bicarbonate therapy would be among many appropriate (but less critical) technical responses. One also can predict in advance specific technical pitfalls. For malignant hyperthermia, such pitfalls could include diluting dantrolene with the wrong diluent (not sterile water) or an insufficient quantity of diluent. These pitfalls are known to plague clinicians unfamiliar with therapy for malignant hyperthermia.

Can the clinical outcome of the simulator's mathematical physiology predict how a real patient would have fared under that individual's care? This would be possible only where the simulator's control logic used detailed mathematical models of physiology and pharmacology, and not with the script-based control logic. In the latter case, the physiologic state achieved is no different than the checklist of the actions taken that followed the branch points in the script leading to the outcome. The outcome and the actions are essentially the same. Even when mathematical models are used, they are insufficient to predict what would happen to any actual patient after complex sequences of therapy and more subtle patient care judgments. The models have not proven to be robust and have shown a lack of reproducible outcomes even when the same "patient" is given identical perturbations and treatments at exactly the same times.

In extreme cases, the clinical outcome probably does indicate failure or success of performance. A subject who shows totally erroneous decision making (e.g., failure to defibrillate a simulated patient with ventricular fibrillation) unmistakably allows the patient's state to deteriorate quickly. The converse may not be true. Perfect decision making in a resuscitation cannot guarantee that electric countershock would successfully restore a normal cardiac rhythm. We suggest that even with model-driven simulators, the clinical outcome of the simulated patient is at best one datum that can be used to assess the performance of the anesthesiologist on a simulation scenario, but for the foreseeable future, any credible performance measurement technique must involve subjective and semiobjective judgments by clinical experts. In the last few years, there have been many empirical studies attempting to use simulation for different forms of performance assessment in various domains and disciplines.*

Pitfalls of Performance Assessment

Previous trials, experience in other industries, and theoretical analysis suggest that simulation offers substantial opportunities to facilitate performance assessment. Various issues must be resolved, however, to make performance assessment a robust capacity, as follows:

Technical versus nontechnical (CRM) skills. As indicated in previous sections, it is feasible (if difficult) to assess a technical response to specific events and generic nontechnical behaviors (CRM). For which kinds of assessments is it appropriate to measure only technical performance, only nontechnical performance, or some combination of the two?

Number of scenarios. How many different scenarios are needed to achieve robust performance assessment of individuals in all relevant aspects (technical and nontechnical) of patient care? Some emerging results suggest that increasing the number of scenarios is more effective in improving the reliability of ratings than increasing the number of raters is.

Rating individuals versus rating crews or teams. Anesthesiologists work as individuals and in crews and teams with other anesthesiologists and with surgeons, nurses, technicians, and others. Should the performance of individuals working alone be assessed? Should anesthesiologists be able to call for and use help in solving problems? If so, can one still rate the individual when working with a team?

Performance fluctuation. How can performance that fluctuates substantially over time be aggregated into a single rating? This issue was recognized by Gaba and colleagues[185] as a major apparent source of inter-rater disagreement. It is not addressed by the Anaesthetists' Non-Technical Skills (ANTS) system.[162,233] Which techniques would best address this issue, especially as applied to scenarios that represent the actual complexity of clinical practice?

*References 11, 32, 36, 40, 44, 60, 119, 127, 162, 173, 176, 190-215.

Criterion thresholds. What level of performance should be set as criterion thresholds for different purposes? Can benchmarks of performance be established by truly expert clinicians (recognizing that years of experience or hierarchic rank is not a surrogate for expertise or skill)? Similarly, how does the rating system deal with single actions or behaviors that were lethal or harmful in the presence of otherwise good performance? If used for formative assessment, a rating system should indicate the successes of the examinee and the failures. If used for summative or high-stakes assessment, however, it may be critical to ensure that the examinee who risks harming a simulated patient cannot outscore another examinee whose overall performance is less strong, but who at least did not endanger the patient. Not performing chest compressions in a cardiac arrest situation would be such a "knockout" criterion.

Appropriate statistical analysis of validity, inter-rater reliability, and reproducibility of these assessments. Various statistical tests and approaches have been used to evaluate these characteristics. The data on performance show various levels of inter-rater variance and high interindividual (and interteam) variability.[127,151,159-161,180,185,216] As detailed by Gaba and colleagues,[185] some inter-rater reliability statistics are more stringent than others, especially in terms of the nature of the "by chance" benchmark. No firm consensus has been reached regarding which tests are most appropriate to answer key questions about simulation-based performance assessment. Some of the rating systems (including ANTS) have used less stringent tests of inter-rater reliability. Generalizability theory[217,218] offers a set of statistical techniques to sort out the impact of scenario, subject, rater, number of scenarios, and other facets on such assessments. This technique also specifies how comparisons can be made against reference performance levels or as relative comparisons between subjects without a fixed benchmark.

Although simulation should enable performance assessment, a robust set of performance measures of anesthesiologists' skill would be difficult to develop,[219] even if the simulator is used as a tool to present standardized patient scenarios.[220]

Klemola and Norros[221] published a new way of looking at performance that involves anesthesiologists' "habit of actions." These authors distinguish between "reactive habits" (conservative, self-contained, reluctant to construct subjective evaluations) and "interpretative habits" (creative, interactive, continuous integrative reasoning). This article shows that a lot of issues need to be considered when discussing the best method of education and evaluation. Additional issues include defining and assessing professional competence. A more consultant-based method was introduced by Greaves and Grant,[222] who compiled an inventory of characteristics of the anesthesiologist's practice. Epstein and Hundert[223] provide a current review.

Although there are presumed advantages to using simulation as a tool for performance assessment (known scenarios, errors can be allowed to occur and play out, intensive recording and archiving of performance is possible), the anesthesia community should be careful to introduce simulation-based performance evaluation on a slow and measured basis.[224] Performance assessment is expected to be a hot topic for discussion in the simulation and clinical anesthesiology communities in the early 21st century. This controversy should not divert attention from the major application of simulation, which is to improve clinical performance through individual and team training in preventing and managing adverse clinical events.

Can Simulators Be Used for the Evaluation and Testing of Residents or Practitioners?

As discussed previously, patient simulators should be useful tools for evaluating the performance of trainees and others. Scoring or certifying competence by using the simulator is more problematic, however, than using it as a teaching tool.

Anesthesiologists have discussed the possibility of using the simulator as a tool for examinations, either for graduation from a residency or for American Board of Anesthesiologists certification. This use would require independent evaluation of the simulation scenarios and assessment of the predictive power of the subjective judgments made by experts scoring the examinee. An obstacle is the lack of any well-accepted standard for performance evaluation. Another difficulty with using simulation for board certification testing is that the operating room equipment would rarely be the same as that used by the candidate, and the operating room staff's operational protocols could differ from the protocols familiar to the candidate. In the training situation, these difficulties can be overlooked as part of the global suspension of disbelief needed to maximize the benefits of simulator training. In the test situation, these differences potentially could skew the results. This issue could be addressed by allowing candidates preparing to take their examination to undergo sufficient practice sessions to familiarize themselves fully with the standard simulation environment used for the test.

Despite these difficulties, it is likely that if the use of anesthesia simulators does become more widespread, anesthesiologists would become more interested in using them to assist in evaluating performance. The existing system of performance evaluation, which uses a haphazard system of subjective judgment of clinical competency in residency along with written and oral examinations, has itself never been validated. Many believe that the written examination does not correlate well with clinical ability, and the degree to which the oral examination process tests actual clinical skill is unknown. Simulation could offer candidates the opportunity to show their clinical abilities in a controlled clinical domain, while still showing their consulting and language skills through oral examination.

More recently, there have been a few projects on using simulation as a high-stakes test for clinicians.[37,38,96,173,175,197,225,226] Simulation is being used more commonly for "no-jeopardy" formative evaluations of performance in some residencies. This use may then evolve into graded "pass/fail" examinations or demonstrations of skill. Another situation of simulation-based performance assessment would be for the evaluation of residents who have been placed on probation, or for whom dismissal from the residency program is already a distinct possibility. For these residents, the burden of proof is on them to show their skills. The simulator could offer a more controlled environment for them to do so. The same could be true for practitioners who wish to return to clinical work after a hiatus.

Figure 7-21 Multiroom simulation center at the VA–Palo Alto Health Care System and Stanford University. Two control rooms and two audiovisually interconnected lecture rooms provide the opportunity to run three patient simulators at the same time. ER, emergency room; ICU, intensive care unit; OR, operating room.

In Israel, a simulation examination has become part of the Board certification process. In the United States, the American Board of Anesthesiology has been monitoring the progress of simulation for training and performance assessment. As of 2008, however, there is no prospect of simulation-based board examinations in the United States.

Characteristics of Simulation Centers

Although one can install a simulator in a laboratory or conference room, or conduct only in-situ simulation, many institutions have chosen to construct complete simulation centers. Figures 7-21 and 7-22 show floor plans by the authors (D.G. and M.R.) of medium-sized centers (two to four simulation rooms) for mannequin-based simulation. Figure 7-23 shows the equipment of such a center in more detail. Typically, these centers provide a separate control room to allow complex simulations to be presented without an instructor intruding on the simulated case. The center also provides a debriefing room where videotapes of the simulation session can be reviewed. Some centers have elaborate computer-controlled audio-video systems allowing the recording of multiple views with real-time annotation rapid search to annotated portions of the recording. Figure 7-24 shows the simulator control room with advanced audio-video equipment at the TuPASS Center for Patient Safety and Simulation of one of the authors (M.R.) in Tübingen, Germany.

Universities and hospitals or hospital networks are increasingly constructing very large multidisciplinary and multimodal simulation facilities. Often, these facilities combine all the types of simulation and immersive learning in one large unit, including standardized patient actors (usually in clinic settings), mannequin-based simulation, part-task and surgical/procedural trainers, wet and dry work (e.g., plaster casting or procedures on food products), and different forms of virtual reality. Sometimes these also incorporate facilities for dissection of cadavers or the use of anesthetized animals. Having all forms of simulation together also fosters the hybrid techniques, as when a standardized patient actor is combined with a part-task trainer, or when a surgical simulator is combined with a mannequin-based patient simulator. Large multidisciplinary facilities may have anesthesiologists in leadership positions. Figure 7-25 shows an example of such big centers, the floor plan by one of the authors (D.G.) of the new center for immersive learning at Stanford University, currently under construction (2008).

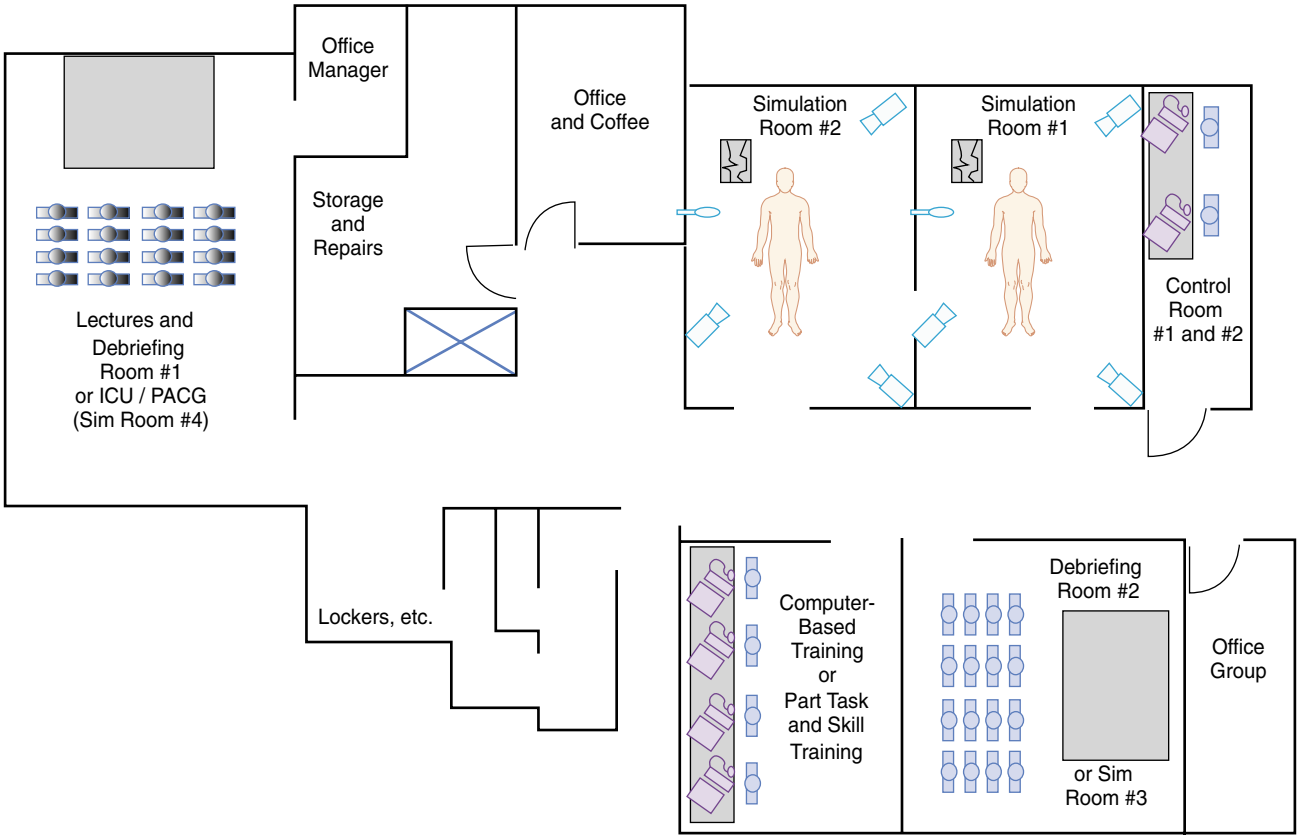

Figure 7-22 An intermediate-sized simulation center with four simulation rooms, a computer-based training room, and several multipurpose rooms, equipped with audio-video patch panels to adjust the room use flexibly to the needs of the different training activities (e.g., the big seminar room also can be used as a big intensive care unit or postanesthesia care unit). *(Picture by E. Stricker from TuPASS Center for Patient Safety and Simulation, Tübingen, Germany.)*

Figure 7-23 Prototypical example of a simulation center (former simulation center at University of Tübingen, Germany). The instructors in the control room look through a one-way mirror into the operating room/intensive care unit (ICU) while they control the "patient" from the simulator workstation and direct the audiovisual recording. Various remote-controllable video cameras, microphones, and loudspeakers in the simulator room provide the best possible view and sound from the "scene." Trainees perform on the simulator mannequin and the vital sign monitors and have to interact with the personnel involved at the same time. Nonactive participants can watch the scenarios live from the adjacent debriefing room, including real-time vital sign transmission, where the video-assisted debriefing session occurs immediately after every scenario. *(From Decker K, Rall M: Simulation in anaesthesia: A step towards improved patient safety. Minim Invasive Ther Allied Technol 9:325-332, 2000.)*

Figure 7-24 Simulator control room. On the left side is the simulator workstation for control of the simulator system itself. In the middle is the audio control desk with integrated control of the simulated patient voice and several wireless headset channels and the remote mixer. On the right are flat screens for selection and control of the multiple views of the video cameras. For anesthesia crisis resource management courses, a multiquad-split view, including the vital sign monitor, is digitally recorded on a hard disk and used for playback. Marks allow jumping to interesting scenes without fast forward or rewind delay. *(Taken at the control room of the TuPASS Center for Patient Safety and Simulation, Tübingen, Germany.)*

The cost structure of a simulation center is a complex issue (see section on Costs). The cost varies greatly depending on the scope of the facility and its programs, the nature of the target populations, and the extent of use by the different possible stakeholder groups. How the costs are allocated to different elements of an institution or consortium is equally complicated and depends highly on local conditions. There is no one formula for success. In some models, the center is wholly responsible for its own costs, but is completely free to generate and retain revenue. At the other extreme is a model whereby the host institution bears all costs of operating a central core facility, but it also collects any and all revenues and may even "tax" components of the institution (e.g., departments) to offset the costs. Perhaps most common are mixed models in which the central authority bears costs of initial construction and outfitting (often funded via philanthropy) and some portion of the ongoing infrastructure (simulation operations personnel, capital refurbishment, utilities), while each user (e.g., department) is responsible for providing instructors and paying for the marginal costs of any specific course or application. To date, few, if any, centers truly generate a profit, but many sites have successfully garnered external funds to offset some of the costs of training their own key target populations.

Costs

What are the costs of simulator-based training? These costs depend on many of the same factors that determine the curriculum, as follows:

Types of training involved, ranging from technology in-service to training in basic anesthesia skills, critical incident management, or CRM

Target populations for the training, whether equipment technicians, medical students, novice residents, experienced residents, nurse anesthetists, teaching faculty, or private practitioners

Organizational and financial characteristics of the institution

The hardware and software costs of the screen-only simulators are quite low (a few hundred dollars), whereas the equivalent cost of a complete hands-on simulator is higher (the prices of commercial simulators range from around $25,000 for intermediate-fidelity simulators to more than $150,000, depending on features; one should contact the manufacturers for detailed information). Cumin and Merry[61] report on available simulators. This cost does not include the necessary clinical equipment (approximately $150,000) and space.[227] Even these large expenditures do not dominate in the cost equation, however, because the capital equipment can be amortized over a relatively long useful life, with appropriate provisions for service and upgrades.

The dominant cost is likely to be the salaries of expert instructors and trainees. An expert must oversee the curriculum, but the type of training and the target population determine the amount of expert instruction required. A single faculty member can review the summaries of exercises performed by residents on a screen-based simulator in a few hours per resident per year. Nonphysician instructors may be suitable for some task training or for drill and practice sessions. A single instructor can use the simulator to show pulmonary or cardiovascular physiology to a whole class of medical students. When training novice residents in basic anesthesia skills, it may be possible to have senior residents or fellows conduct the sessions at a low marginal cost. When training experienced residents and practitioners in complex material, such as the handling of critical events, there is likely to be no substitute for expert instructors. The cost of expert instruction depends on the organizational arrangements of the institution. In a teaching institution where the faculty all have at least some time allocated for teaching or scholarly activities, some of them may choose to fulfill this requirement in simulation-based teaching or scholarship. Where further staffing is needed, payment for clinical release time may be needed.

Another organizational factor that affects the cost has to do with making trainees available for what can be complex, exhausting, and lengthy training sessions. Removing residents from revenue-producing work for training purposes is expensive. If simulator training could allow residents or other anesthesiologists to work more safely and efficiently, the benefit would outweigh the cost. Some residency programs provide protected time for education of residents (e.g., one half day per week). In such cases, residents should be available for educational activities, but faculty time may be even more scarce. Many anesthesia programs have used simulation training as a recruiting tool for residency candidates, although some believe that with the high proportion of programs that already have simulation activities (the scope and quality of which are hard for applicants to judge), the competitive value of simulation has disappeared. Programs that lack such facilities and activities would not be the exception and would likely be seen negatively by applicants.

There is no question that simulation-based training is more costly than exhorting learners to read or putting them in a room with a lecturer. Simulation-based training allows a host of issues to be addressed that cannot be easily tackled in other ways. It is our belief—one that has been borne out by programs "voting with

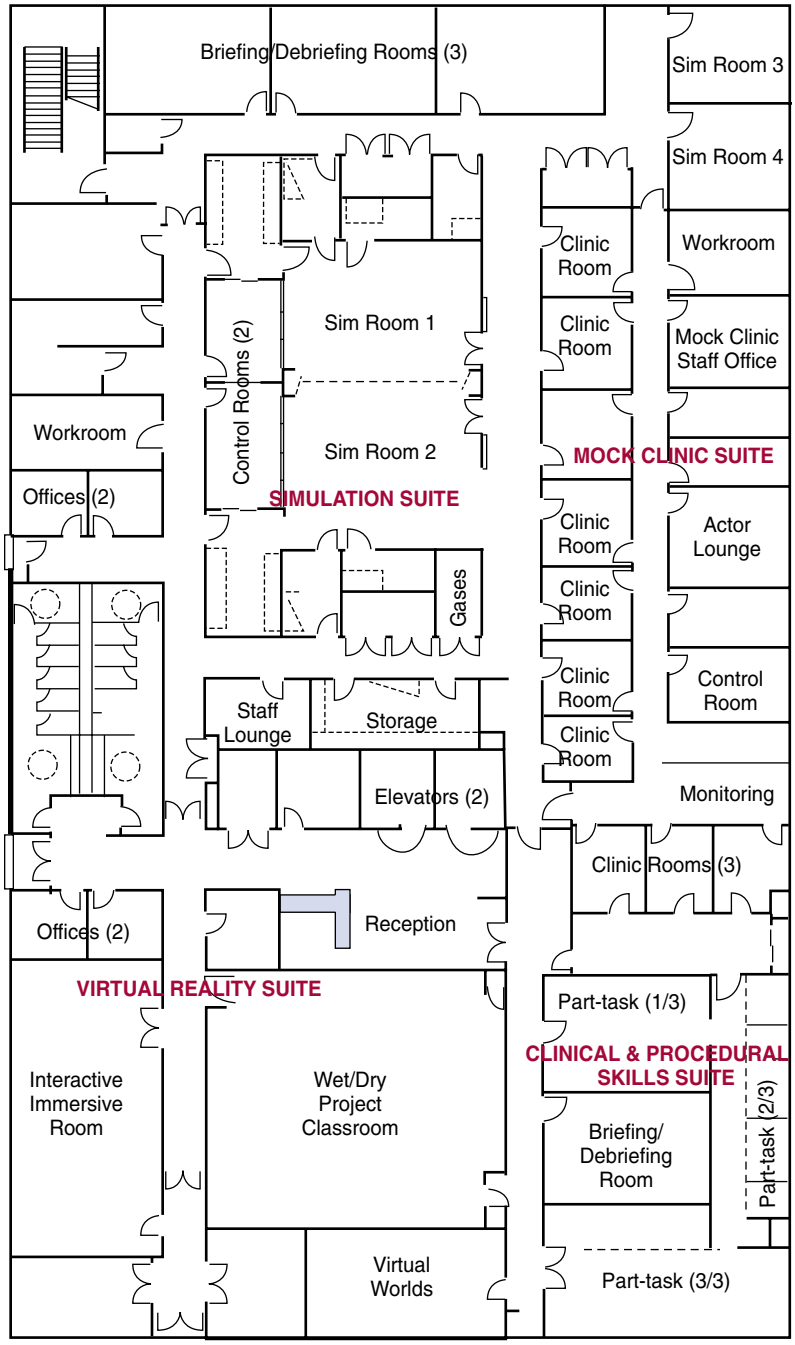

Figure 7-25 Floor plan of a very big interdisciplinary simulation center for multiple domains (anesthesia, surgery, students) with several multipurpose simulation rooms, and skills laboratories. *(Picture by D. M. Gaba, from the Center for Immersive and Simulation-based Learning at Stanford Medical School. Ground floor built as of June 2008.)*

their feet" over the past 15 years—that if simulator-based training is deemed to be desirable, innovative changes in organization would evolve to allow it to occur.

Proliferation of Simulation Centers

Currently, despite the lack of definitive cost-effectiveness data, training with realistic simulators is under way in many sites around the world,[228] with many of them choosing to conduct "high-end" crisis management and critical incident training sessions. Table 7-13 lists useful websites of simulation centers and other resources. These programs have already "voted with their feet" on the issue of cost versus benefit. With so many centers exploring the realities of simulation training, we can expect to see additional data on efficacy and cost within the next few years. A definitive study is in principle possible, but it would require a very large number of subjects evaluated by multiple raters and would be complex and costly.

Still other factors complicate assessment of the effectiveness of simulator-based training. Studying the impact of a single

session of a course that uses a new technology and a new approach to training may underestimate the course's impact when it is used on a regular and repetitive basis. It is widely believed in commercial aviation that CRM training must begin with the initial training of pilots and must be continued throughout their career. Social psychologists Helmreich and Foushee, two of the main architects of CRM training, have written: "Data indicate that even intensive initial CRM training constitutes only an awareness phase and introduction to the concepts, and that continuing reinforcement is essential to produce long-term changes in human factors practice."[229] Similarly, United Airlines states in its CRM manual: "Command/Leadership/Resource management [United's terminology for CRM] cannot be a one-shot approach. It has to be a coordinated long range program. It must therefore be an integral part of the entire training effort: new hire training, transition and upgrade programs, and recurrent training."[230]

Finally, the principles and procedures taught in training must be reinforced within the operational environment. Simulator-based safety training can be totally negated if production pressures or latent failures in the workplace make it impossible to implement its teachings effectively.

It is still too early to make definitive statements about either the benefits or the costs of simulator-based training in anesthesia. To some extent, a "catch 22" is involved. One cannot attempt to determine the true cost-effectiveness until simulation is widespread enough for complex and expensive studies to be undertaken, and until there is more experience on the different organizational aspects of providing the training. Many institutions are likely to shy away from taking the risk until the cost-effectiveness is proven.

Simulation Societies: Society for Simulation in Healthcare and Society in Europe for Simulation Applied to Medicine

One measure of the evolving maturity of simulation in health care is the formation and growth of professional societies focused on this topic. Although anesthesiology was the medical field that initiated work on the fully interactive mannequin-based simulator and that dominated the early developments in the field, simulation is a broad strategy that has now been widely adopted by many different disciplines and domains in health care. For the most part, simulation professional societies have sprung up as explicitly multidisciplinary organizations. Major leadership roles in these societies have been played by anesthesiologists and engineers associated with anesthesiology, however.

The largest simulation organization is the Society for Simulation in Healthcare (SSH; www.ssih.org), which was founded in 2004 as the outgrowth of the group that had operated the International Meeting on Medical Simulation for several years as a satellite to the annual meeting of the Society for Technology in Anesthesia. Under the new auspices of SSH, the meeting was transformed into the International Meeting on Simulation in Healthcare (IMSH), encompassing all health care disciplines and domains, not just medicine. Regular scientific congresses on simulation had been under way since the mid 1990s (the Rochester Conferences on Simulation in Anesthesia). Although they originally had about 100 attendees, Society in Europe for Simulation Applied to Medicine (SESAM) meetings have now around 400 attendees. The IMSH meeting in 2009 is expecting more than 2000 attendees. This puts it in the category of a medium-sized scientific meeting; to put this in the context of anesthesiology, it would rank as the third largest scientific meeting in the United States, falling below only the ASA meeting and the New York Postgraduate Assembly in Anesthesiology (PGA) conference, but ranking ahead of the International Anesthesia Research Society (IARS) annual meeting.

Another sign of the mainstream nature of simulation is that SSH has published a quarterly peer-reviewed journal, *Simulation in Healthcare,* since 2006. It has been integrated in PubMed citations recently (2008). The journal is an official publication of many international professional societies of simulation in health care, including SESAM (www.sesam.ws), the Australian Society for Simulation in Healthcare, and the Association of Standardized Patient Educators. The organizations have become affiliates of the SSH.

Another sign of maturity is the emergence of a trade organization for simulation in health care dedicated to educating and influencing policy makers, primarily concerning federal legislation and health policy. The Advanced Initiatives in Medical Simulation (AIMS) is a 501c6 organization that is allowed to lobby the U.S. government. Supported by universities and industry, AIMS promotes legislation and offers an annual exhibition about simulation in health care on Capitol Hill. What was previously seemingly the province of a few technologically minded anesthesiologists has blossomed into a substantial industry and profession with all the trappings of organizations, meetings, journals, and even lobbyists.

Future of Patient Simulation in Anesthesia

"The future is now—we are it."[231]

Although nearly past 2 decades of consistent development, the field of simulation in health care is still relatively new.[5,16,232] Although there are hundreds to thousands of simulators in use around the world, many targeting anesthesiology and critical care, the fraction of clinicians in these fields who have undergone a meaningful simulation experience is still small.

Simulators have become more sophisticated, and users now can choose from many different models offered by multiple manufacturers. Improvements in simulators depend on the demand for the devices and on the tradeoff between fidelity and cost. Many otherwise desirable improvements may be too costly for the impact that they can be expected to produce. Technologic advances are likely to be targeted at portability and reliability, rather than at supporting increasingly esoteric feature sets. Many users have opted for simpler and cheaper simulators that use direct control, modest scripts, and finite state machines to control the changing state of the simulated patient rather than complex mathematical models. This is partly because the production and use of robust mathematical models has been more difficult than anticipated.

In contrast to aeronautical engineers, physicians do not design and build the system that they wish to model. The fundamental differential equations of fluid mechanics and aerodynamics are firmly established, allowing supercomputers to provide technically meaningful simulations as replacements for many wind tunnel tests. There are still wind tunnel tests, however, and test flights of actual prototype aircraft. Sophisticated instrumentation can be built into test structures to define their behavior accurately. Physicians will never have this type of knowledge about the human body. The advantages and disadvantages of the different types of control logic for different applications is still being sorted out.

There has been growing interest in purely virtual reality simulations, often of a type similar to massive online games or to the popular Second Life system. Participating with others in the same virtual world, linked by the Internet, is appealing for many purposes. Such simulations are only as good as the engines that drive the underlying patients that may be found there, and the quality of the data provided and interventions and choices supported for implementation in these settings. Virtual reality proponents imagine a virtual reality so realistic that it rivals, or is indistinguishable from, the real world. This would approach the Star Trek "Holo-Deck." Although we once predicted that such systems might be in place by 2020, the development of such high-veracity virtual reality has not proceeded as quickly as previously imagined, and it is unclear whether full virtual reality of this nature will be available in the next decade.

Patient simulation has now become a regular part of the initial and recurrent training of most anesthesiologists and many other clinicians in the United States, Australia, and the United Kingdom, and in some European countries. With patient simulation, the human error–based CRM concept was introduced to medicine as ACRM training, revolutionizing the traditional way and content of teaching and learning. The anesthesia community can be proud of its pioneering role in developing patient simulation technology and simulation-based training curricula, and anesthesiologists and others working with them continue to play dominant leadership roles in many settings of simulation, even those devoted to fields outside anesthesia.

8 Teaching Anesthesia

Key Points

1. Education is an all-encompassing process (not merely a specific activity) that results in a change in behavior on the part of the student/learner. The focus of education is the learner, not the teacher. It is the student who is educated by interacting with an environment that provides experiences. Education is change in behavior based on experiences.
2. Adult learners learn anesthesiology. Adult learners are those with strong motivation to participate in a set of experiences to learn a specific discipline. The discipline that they want to learn is one that they are interested in or need to know, or both. Adult learners participate in life-centered situational learning in the area or areas in which relevance is most likely.

   Adult learners enter the learning activity with a wealth of previous experience and view the current education in light of their background. Adult learners can capitalize on this previous learning; however, the previous learning may color how the current learning takes place.

   Adult learners are self-directed and initiate their own activities. Adult learning is goal oriented toward relevant life-centered needs. An adult learner tends to pick and choose some, not necessarily all, of the educational activities available.

   Inherent differences among people tend to increase with aging. Adult education must provide for differences in style, time, place, and pace of learning among adult learners. The time factor for learning is especially crucial for adults. Adults perceive that time passes more rapidly; that is, there is less time available to learn—or to do anything for that matter. With time perceived to be in short supply, adult learners tend to be selective in their learning to use what time they have more efficiently.
3. In 2006, there were 4970 resident anesthesiologists in 131 accredited American core anesthesiology residency programs and 360 subspecialty residents in 213 accredited American subspecialty anesthesiology programs.
4. Silber and colleagues,[29] in their study of almost 6000 patients undergoing prostate or gallbladder surgery in multiple hospitals, demonstrated that patient recovery or "rescue" from an adverse event correlated with the proportion of board-certified anesthesiologists in the hospital.
5. The Accreditation Council for Graduate Medical Education has defined six educational areas for which residents and fellows must demonstrate competency. These areas additionally are major components of Maintenance of Certification in Anesthesiology:
   a. Patient Care—Residents must be able to provide patient care that is compassionate, appropriate, and effective for the treatment of health problems and the promotion of health.
   b. Medical Knowledge—Residents must demonstrate knowledge of established and evolving biomedical, clinical, epidemiologic, and social-behavioral sciences, as well as the application of this knowledge to patient care.
   c. Practice-Based Learning and Improvement—Residents must demonstrate the ability to investigate and evaluate their care of patients, to appraise and assimilate scientific evidence, and to continuously improve patient care based on constant self-evaluation and lifelong learning.
   d. Interpersonal and Communication Skills—Residents must demonstrate interpersonal and communication skills that result in the effective exchange of information and collaboration with patients, their families, and health professionals.
   e. Professionalism—Residents must demonstrate a commitment to carrying out professional responsibilities and adherence to ethical principles.
   f. Systems-Based Practice—Residents must demonstrate an awareness of and responsiveness to the larger context and system of health care, as well as the ability to call effectively on other resources in the system to provide optimal health care.*
6. Full-time anesthesiology faculty positions in U.S. medical schools in 2006-2007 numbered 5836.[30] Anesthesiologists represent 5.6% of the clinical teachers and 4.7% of all American medical school teaching faculty.[30] The 5836 anesthesia faculty members in medical schools bear the

major responsibility for teaching some or all of the 69,028 enrolled undergraduate medical students, the 4970 graduate trainees in anesthesiology residency training programs, the 360 graduate trainees in anesthesiology subspecialty fellowship programs, and many of the approximately 104,879 physician house-staff trainees.[12,32]

7. Effective clinical teachers who are able to succeed at the bedside teaching encounter display specific actions noted by their students and themselves.[35] These actions include
   a. Allocating time for teaching
   b. Creating a teaching/learning environment of trust and concern
   c. Demonstrating clinical credibility
   d. An initial orientation
   e. A final evaluation
   f. Learners being able to present a case
   g. Teachers managing the case presentation
   h. Didactic sessions being used to enhance clinical case material
   i. Teaching taking place at the bedside so that students can learn physician-patient relationships
   j. Teachers and students discussing psychosocial issues
   k. Attention being paid to transferring the teaching responsibility
8. Teaching content requires attention to increasingly complex cognitive functions. As described by Bloom,[39] teaching/learning in the cognitive domain for any topic addresses the following:
   a. Knowledge—recall
   b. Comprehension—understanding
   c. Application—use of abstractions
   d. Analysis—break down; seeing the relationship of parts
   e. Synthesis—put together; creating a new entity
   f. Evaluation—judgment of value
9. A systematic methodology to develop a psychomotor skill lesson includes the following steps[54]:
   a. Analyze and separate the skill into its component parts and determine which aspects of the skill are most difficult to perform.
   b. Provide students with a model of the skill, effectively demonstrated in its entirety, that they are expected to perform.
   c. Make provisions for students to practice until the expected behavior is mastered.
   d. Provide adequate supervision and an evaluation of the final performance.

*Adapted from ACGME Outcome Project. Available at www.acgme.org/outcome.

"Pedantic" is a description teachers wish to avoid. In the interest of doing so, I offer a fifth grader's biography of the great teacher Socrates[1]:

Socrates was a man.
Socrates was a Greek.
Socrates went around telling people what to do.
They poisoned him!

This chapter on anesthesia education is not intended in such a manner that I risk Socrates' fate, but rather it is meant to be provocative, to give cause for thought on an important subject not often reflected on. All anesthesia education can be easily considered in the following question (Greenhow DE: personal communication, 1982):

How shall who teach what to whom for what purpose now and in the future?!

Anesthesia education is presented by using this question as the framework for consideration. This chapter provides a philosophy of teaching anesthesia rather than a detailed account of the many aspects of anesthesia education (e.g., operating room anesthesia versus critical care medicine versus cardiopulmonary resuscitation versus chronic pain management). Also, this chapter is exclusively directed toward the teaching organization, regulations, and philosophy of teaching that exist in the United States. See Chapter 3 for perspectives on how other countries are teaching anesthesia and their philosophic approaches that parallel their needs.

Teaching and Education

Teaching, in a narrow sense, the way most of us think about it, is an activity by an individual aimed at causing another person to know some new fact or to know how to accomplish some new task. The focus appears to rest on the teacher and the activity of teaching. It does not take long to realize, however, that this way of looking at the teaching/learning activity has misplaced emphasis. If not with the teaching activity, where does the emphasis belong? The answer to this question lies in understanding the definition of education.

Education is an all-encompassing process (not merely a specific activity) that results in a change in behavior on the part of the student/learner. The focus of education is the learner, not the teacher. It is the student who is educated by interacting with an environment that provides experiences. *Education is change in behavior based on experiences.* The experience most often includes the student interacting with a teacher, but it is almost never limited to that alone. The entire milieu defines the total experience (Fig. 8-1). When the milieu changes, so may the education;

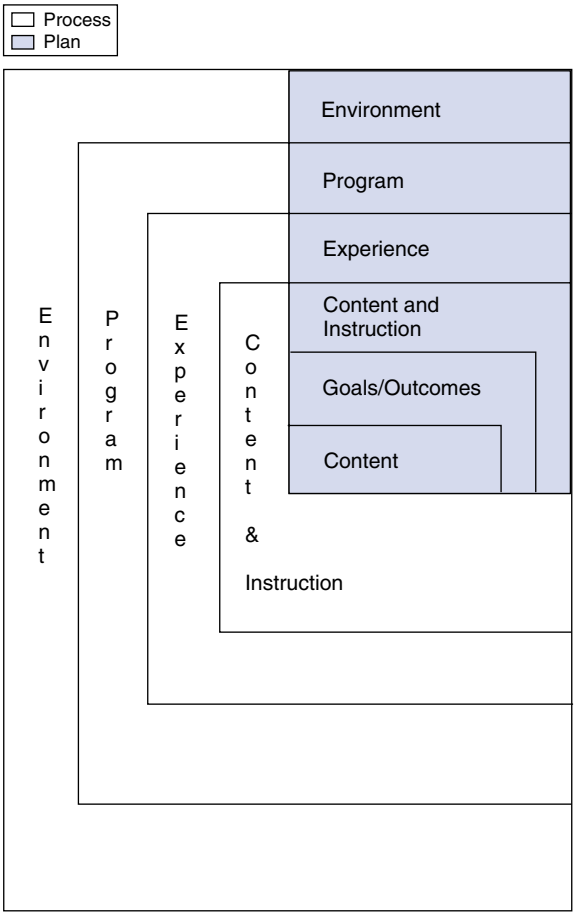

Figure 8-1 Diagrammatic representation of the educational experience. The two major components are the plan for teaching and the process of education that actually occurs. At the core is the content (cognitive, psychomotor, affective, or any combination of the three) to be taught and learned. Growing out of the content are the planned goals of education, the methods and program of instruction, and the environment in which the teaching and learning will occur. In the diagram, each building block of the plan is added to the previous one in an all-encompassing fashion. What is planned as education and what is experienced may or may not be the same. As represented by the diagram, the educational process that actually occurs includes all of the plan and layers on it, both the real environment and the teacher/student interactions that provide the education, that is, the experiences that provide the basis for the ultimate change in student behavior. *(Modified from Atkins E: Curriculum Theorizing as a Scientific Pursuit: A Framework for Analysis [unpublished doctoral dissertation]. University of Pennsylvania, 1982.)*

that is, the change in behavior exhibited by the student may vary dramatically if the milieu is varied.

Picture the educational setting in which an anesthesiology resident is learning how to use epinephrine when weaning a patient from cardiopulmonary bypass. The knowledge and skills that must be learned include application of the pharmacologic principles of catecholamines to the pathophysiology of cardiovascular disease by turning on a mechanical infusion pump to deliver the indicated dose of a medication while technically monitoring for dose response and toxicity. Learning these facts and the skills sufficient to use them is much different when done from a textbook or a preoperative conference with a staff preceptor than when done during the operating room interaction between the surgeon and anesthesiologist, where varied opinions may consider dopamine a more sound physiologic choice or intermittent boluses a better administration technique. The interposition of the concerned surgeon and real-time patient setting between the student and knowledge and skills to be learned changes the learning environment and hence the educational experience for the resident. More is learned than the facts and psychomotor skills. As the attitudes of both the anesthesiologist and the surgeon are displayed during resolution of the question about the "best" drug to use and the "right" way to give it, the resident learns how these two types of practitioners are supposed to relate to one another.

It seems obvious, therefore, that there is more to consider than just teaching. What more is there to the anesthesiologist's responsibility than just teaching those around him or her? The answer is provided by answering the component parts of the question posed at the beginning of this chapter.

Teach to whom?
Why teach?
Who teaches?
What to teach?
How to teach?

Teach to Whom?—The Students

The simplest answer to the question "who learns anesthesiology?" is "those who will provide anesthetic care to patients." Included are the anesthesiologist, nurse anesthetist, and dentist who administers anesthesia for dental procedures.[2] Also to be included are the many varied paramedical personnel who participate in patient care activities related to primary anesthetic care: the anesthesia technician, anesthesia aide, nurse practitioner, postanesthesia recovery room nurse, physician assistant, surgeon assistant, respiratory therapist and aide, intensive care/critical care/emergency room/trauma nurse, perfusionist, emergency medical technician/paramedic, cardiopulmonary technologist, pulmonary function technician, and blood gas laboratory technician.[2] Each of these occupations is intimately related in some way to the body of knowledge that constitutes the practice of anesthesiology.

In a much broader sense, the entire medical community can be considered appropriate learners of anesthesiology. Medical students, for example, are appropriate candidates for learning a core of anesthetic knowledge and skills, specifically those essential for the training of all physicians. Basic central nervous system, cardiovascular, and pulmonary diagnostic monitoring, emergency airway management, and the clinically applied pharmacology of sedative/hypnotic and analgesic medications and local anesthetics are some of these essentials. Medical students, graduate physicians, and paramedical personnel of many types are appropriate learners because all are often faced with the task of educating the lay public about anesthesiology. Who learns anesthesiology, therefore, are those who practice it or perform related duties that require some understanding of the subject.

Another way to address the question of who learns anesthesiology is to answer *adult learners*. What describes an adult learner?[3] How are adult learners unique? Adult learners are those with strong motivation to participate in a set of experiences, such as a curriculum, to learn a specific discipline. The discipline that they want to learn is one that they are interested in, need to know,

or both. The resident actively seeks education in anesthesiology. A sixth grader (a child learner), in contrast, does not seek education in arithmetic. Adult learners participate in life-centered situational learning in the area or areas for which relevance is most likely.

Adult learners enter the learning activity with a wealth of previous experience. They view the current educational experience in light of their background. An internist who enters an anesthesiology residency in preparation for a career in intensive care medicine has a rich resource background in medical practice. Adult learners can capitalize on this previous learning. At the same time, however, the previous learning may color how the current learning takes place. The key for the teacher is to acknowledge the adult learner's expertise and build the new education on it rather than downplay it and, in essence, "reject" the adult learner.

Working together in a mutual peer relationship with the teacher, adult learners are self-directed. Whereas child learners need a set of directions that originate from the teacher, adult learners initiate their own activities. Because adult learning is goal oriented toward relevant life-centered needs, an adult learner tends to pick and choose some, not necessarily all, the educational activities available.

Strong commitment and specific intentional attachments uniquely characterize adulthood. Marriage and child rearing are examples of such commitments and attachments. At the same time that adults make commitments, their lives are evolving and they pass through many critical life stages (e.g., assuming financial responsibility, coping with the illness or death of a parent). These strategic choice points in life have an impact on adult learning. The decision by an anesthesiology resident, for example, to extend education an additional year to learn a subspecialty or to participate in research training may be based on the total financial debt incurred for medical education up to the end of residency and the need to repay that debt, weighed against the acuteness of the family's financial needs.

Inherent differences among people tend to increase with aging. Adult education must provide for differences in style, time, place, and pace of learning among adult learners. The time factor for learning is especially crucial for adults. Adults perceive that time passes more rapidly, that is, there is less time available to learn—or to do anything for that matter. With time perceived to be in short supply, adult learners tend to be selective in their learning so that they use what time they have more efficiently. The anesthesiology resident may devote time to learning in the operating room and weekly departmental case conference but may choose to skip the journal club to spend time with the family.

Recognition of the special traits that adult learners possess allows the anesthesiology educator to provide an educational program embraced by the student rather than one that is rejected. Assessing the needs of the adult learner and using these needs as a springboard from which a curriculum is designed are more likely to result in a good educational outcome than to impose on the learner what the teacher alone thinks is right.

Why Teach?—The Reasons

An obvious reason for teaching anesthesiology is that we as a specialty have defined it as part of our identity (see Chapters 1 and 2)[4]:

> *The American Board of Anesthesiology (ABA) exists in order to . . . maintain the highest standards of practice by fostering educational facilities and training in anesthesiology which the ABA defines as the practice of medicine dealing with but not limited to . . . teaching of cardiac and pulmonary resuscitation, . . . supervision, teaching and evaluation of performance of both medical and paramedical personnel involved in perioperative care, . . . administrative involvement in health care facilities and organizations, and medical schools necessary to implement these responsibilities.*[4]

In addition to our own description, others define anesthesiology in similar terms:

> *[An anesthesiologist] May instruct medical students and other personnel in characteristics and methods of administering various types of anesthetics, signs and symptoms of reactions and complications, and emergency measures to employ.*[2]

Teaching anesthesiology is clearly one component of an anesthesiologist's daily activity. In some instances, it means providing the experience needed for physician trainees to achieve consultant anesthesiologist status. In other settings, it means providing the experience needed for other medical and paramedical professionals to achieve a level of expertise appropriate to their required competencies—as examples, for an internist, the ability to understand anesthesiology sufficiently to relate to anesthesiologists and educate patients about anesthesiology; for a postanesthesia recovery room nurse, the ability to understand anesthesiology sufficiently to care appropriately for patients emerging from anesthesia and to be versed in the critical care aspects of the preanesthesia and postanesthesia periods to provide life support if necessary.

A major purpose of teaching anesthesiology is to provide a common set of learning experiences that when mastered by students, will lead to relatively standardized knowledge and behavior. These standards (minimum standards though they may be) become the criteria by which a student candidate can be evaluated (certified) for entry into a specified mastery level.[4-6]

Becoming a consultant anesthesiologist certified by the ABA depends on being able to demonstrate that one possesses a minimum standard of knowledge of, skills in, and attitudes about anesthesiology.[4] Public trust is gained by this process of specialty certification, which ensures that a certified specialist has met the defined standards of anesthesia practice.[4-6] Although specialty certification in anesthesiology culminates in evaluation mechanisms (achieving clinical competence as attested to by the training program and successfully passing written and oral examinations), the certification process is driven by educational activities focused on teaching the resident how to become a consultant anesthesiologist.[4-6] A key part of this process is establishment of the training curriculum or continuum of education in anesthesiology by the ABA.[4]

A resident trainee in anesthesiology voluntarily enrolls in a graduate medical education program and accepts the ABA's approved curriculum and evaluation (testing) protocol. Coupled with the physician candidate *certification* process is the residency education *accreditation* process.[7] Residency program accreditation is a voluntary process whereby an institution applies for recognition of its anesthesiology graduate medical education as

meeting a minimum set of teaching standards that will support the curriculum. Such recognition is achieved from the Accreditation Council for Graduate Medical Education (ACGME). The ACGME represents the combined "wisdom" of all specialty residency review committees in its publication dealing with institutional requirements of accredited residencies.[7] More focused training guidelines published as program requirements are defined by the Anesthesiology Residency Review Committee (RRC), a group representing the ABA, the American Society of Anesthesiologists (ASA), and the American Medical Association.[8] These guidelines include program requirements for residency education in (1) anesthesiology (the core program) and fellowship education in its accredited subspecialties, (2) adult cardiothoracic anesthesiology, (3) critical care, (4) pain medicine, (5) pediatric anesthesiology, and (6) undersea and hyperbaric medicine.[8,9]

The teaching responsibilities addressed by the candidate certification and the residency and fellowship education program accreditation processes are clearly articulated by the ABA[4]:

Establish and maintain criteria for the designation of a Board certified anesthesiologist.

Inform the Accreditation Council for Graduate Medical Education (ACGME) concerning the training required of individuals seeking certification as such requirements relate to residency training programs in anesthesiology.

Establish and conduct those processes by which the Board may judge whether a physician who voluntarily applies should be issued a certificate indicating that the required standards for certification or recertification as a diplomate of the American Board of Anesthesiology have been met.

A Board certified anesthesiologist is a physician who provides medical management and consultation during the perioperative period, in pain management and in critical care medicine. A diplomate of the Board must possess knowledge, judgment, adaptability, clinical skills, technical facility and personal characteristics sufficient to carry out the entire scope of anesthesiology practice. An ABA diplomate must logically organize and effectively present rational diagnoses and appropriate treatment protocols to peers, patients, their families, and others involved in the medical community. A diplomate of the Board can serve as an expert in matters related to anesthesiology, deliberate with others, and provide advice and defend opinions in all aspects of the specialty of anesthesiology. A Board certified anesthesiologist is able to function as the leader of the anesthesiology care team.

Because of the nature of anesthesiology, the ABA diplomate must be able to manage emergent life-threatening situations in an independent and timely fashion. The ability to independently acquire and process information in a timely manner is central to assure individual responsibility for all aspects of anesthesiology care. Adequate physical and sensory faculties, such as eyesight, hearing, speech and coordinated function of the extremities, are essential to the independent performance of the Board certified anesthesiologist. Freedom from the influence of or dependency on chemical substances that impair cognitive, physical, sensory or motor function also is an essential characteristic of the Board certified anesthesiologist.

Establish and conduct those processes by which the Board may judge whether a physician who voluntarily applies should be issued a certificate indicating that the required standards for subspecialty certification or recertification in an ABA designated subdiscipline of anesthesiology have been met.[4]

The ABA-ACGME model addresses the purpose of education in anesthesiology and clearly outlines the anesthesiologist's responsibilities in teaching colleagues. Other organizational models similar to the ABA-ACGME example serve the same function for teaching physician anesthesiologists outside the United States.

Meeting the teaching responsibilities for nurse anesthesia is standardized in a fashion similar to that of the ABA-ACGME model. For nurses, the Council on Certification of Nurse Anesthetists and the Council on Accreditation of Nurse Anesthesia Educational Programs serve functions similar to those of the ABA-ACGME model. In 2007, 108 nurse anesthesia educational programs of 24 to 36 months' duration (80% are 27/28 months long) graduated nearly 1200 students educated in approximately 1547 clinical training sites staffed by 8248 certified registered nurse anesthetists (CRNAs) and 4689 anesthesiologists serving as faculty (Council on Accreditation of Nurse Anesthesia Educational Programs: personal communication, 2007). After the first 2 years of certification, CRNAs are required to achieve biennial recertification under the auspices of the Council on Recertification of Nurse Anesthetists.

Education of nonphysician health care professionals is coordinated by 26 agencies that accredit/approve training programs in 71 professions.[10,11] These agencies provide guidelines for education in a standardized fashion so that professionals in 71 allied health occupations can gain certification in their respective disciplines.[10,11] More than 50 professional organizations (including the ASA) serve as experts in their fields and work hand in hand with the 26 agencies to accredit/approve the educational programs for health professions.[10,11] The magnitude of this teaching responsibility becomes clear when one realizes that in 2007-2008, 2468 institutions sponsoring 6873 educational programs educated more than 231,000 students.[10,11]

Occupations related to anesthesiology for which standardized educational programs have been defined by the Accreditation Review Commission on Education for the Physician Assistant (www.arc-pa.org), American Society of Health System–Pharmacists (www.ashp.org), Commission on Accreditation for Health Informatics and Information Management Education (www.cahiim.org), Commission on Accreditation of Allied Health Education Programs (www.caahep.org), and Joint Review Committee on Education in Radiologic Technology (www.jrcert.org) (5 of the 26 accrediting agencies referred to earlier) include anesthesiologist assistant, cardiovascular technologist, electroneurodiagnostic technologist, emergency medical technician-paramedic, health information technician, perfusionist, pharmacy technician, physician assistant, radiation therapist, respiratory therapist (entry level and advanced), specialist in blood bank technology, surgical assistant, and surgical technologist.[10,11] In 2006, these occupations were taught in 1572 accredited or approved programs.[10,11] Students enrolled in these training programs during the 2006 academic year numbered 45,285.[10,11]

In contrast to the teaching responsibility for nonphysician health care professionals, in 2006, 4970 physician resident anesthesiologists (5.6% of all residents in the United States) were educated in 131 accredited American core anesthesiology residency programs and 360 physician subspecialty fellows (2.3% of all subspecialty fellows in the United States) in 213 accredited

American subspecialty anesthesiology programs (30 adult cardiothoracic anesthesiology, 49 critical care medicine, 89 pain medicine, and 45 pediatric anesthesiology programs) (Table 8-1A and B).[12,13] A yearly summary of recruitment of graduating medical students into anesthesiology residencies via the National Resident Matching Program (NRMP) process and how these individuals advance through the residency education years is published in the *ASA Newsletter*.[14,15] Adding the tasks of teaching medical and allied health care students, participating in continuing education for anesthesiologists, and teaching other practicing physicians and allied health care professionals increases the educational responsibilities of anesthesiologists in an exponential fashion.

One fundamental reason that we teach anesthesiology is that we recognize the need to provide uniform educational experiences so that students participating in these activities can reach a goal; that is, they will be acknowledged (certified) as competent in their discipline. So important is this process that it has been incorporated into the very definition that we use to describe ourselves. Now more than ever, competence and physician performance are concepts that are key in the minds of the public consuming medical care, the agencies paying for medical care, and the institutions and individuals providing medical education.[16-18] The United States has a system designed to assess medical competence by defining and ensuring the processes of education, licensing, accreditation, and certification.[16-18]

The American Board of Medical Specialties (ABMS) oversees the certification of physician specialists by 24 medical specialty member boards (including the ABA) in more than 130 specialties (residencies) and subspecialties (fellowships) (Table 8-2).

> *The primary function of ABMS is to assist its Member Boards in developing and implementing educational and professional standards to evaluate and certify physician specialists.*[19]

The ABMS states its mission as being

> *. . . the organization that establishes standards for physician specialty certification and Maintenance of Certification (MOC), including performance assessment. ABMS communicates information about these standards to support the public's quest for safe, high-quality healthcare.*[5,19]

The ABMS has eloquently articulated the goal of MOC by stating that

> *. . . ultimately, the measure of physician specialists is not merely that they have been certified, but how well they keep current in their specialty. That's why in 2006, ABMS' 24 Member Boards adopted a program of continuous professional development—ABMS Maintenance of Certification—as a formal means of measuring a physician's continued competency in his or her certified specialty and/or subspecialty. By following MOC, physicians demonstrate their commitment to lifelong learning and ongoing self-assessment to advance specialty practice. They live the standards by which medical care is evaluated and demonstrate leadership in the national movement for healthcare quality and patient safety.*[19]

In 1989, the ABA established a mechanism (continued demonstration of qualifications [CDQ]) for revalidation of an individual's primary board certificate to address the multitude of questions that had been posed about recredentialing and continued "competence" of physicians initially certified as consultants, especially questions related to public trust.[4,20,21] This program allowed anesthesiologists to demonstrate their continuing qualifications through a *voluntary* recredentialing program.[21] The first implementation of CDQ with its two components—documentation of an anesthesiologist's approved practice credentialing and administration of a secure written examination to assess an anesthesiologist's current knowledge of anesthesia practice—took place in 1993. The CDQ certificate allowed anesthesiologists a means to accomplish recredentialing for needs defined by governmental, health care finance reimbursement, hospital, or other regulatory bodies.

The ABA/ABMS has developed more formal recertification processes since implementation of the voluntary CDQ recredentialing mechanism. In 1994-1995, the ABA adopted time-limited certification; all specialty (anesthesiology) certificates issued by the ABA on or after January 1, 2000, were designated valid for only 10 years from the time of completion of the examination for the initial certification and all subsequent recertifications.[4,22] In 1996, the ABA converted the CDQ mechanism to the recertification process containing the same two components described earlier. Anesthesiologists wishing to remain board certified at the end of the time limit on their certification are required to formally recertify and obtain a new board certificate rather than revalidate the primary certificate.[4,22] Current discussion is focusing on shortening the recertification cycle from 10 years to 5 to 7 years from the time of completion of the examination for the initial certification or subsequent recertifications.

The ABA has also had a certification process for its subspecialties (see Table 8-2).[5] A certification process has existed for critical care medicine since 1985. In 1991, the ABA began certification of pain management subspecialists, and in 2006, the ABA began certification of subspecialists in hospice and palliative medicine. In 1998, time-limited certification for subspecialties in anesthesiology was approved. As of January 2000, all newly issued ABA subspecialty certificates in critical care medicine and pain management were designated valid for only 10 years from the time of completion of the examination for the initial certification. Recertification in critical care medicine, pain management, and hospice and palliative medicine is operative in a fashion similar to that described earlier for recertification in anesthesiology. Similar models for continuing medical education and documentation of physician competence are being developed in other countries as well.[23,24]

Maintenance of Certification in Anesthesiology (MOCA) is the

> *. . . program [that] enables ABA diplomates holding non–time limited certificates (issued before 2000) to demonstrate continuing qualifications and those with time-limited certificates to maintain their certification. Each MOCA cycle is a 10-year period of ongoing Lifelong Learning and Self-Assessment; continual assessment of Professional Standing; periodic assessments of Practice Performance; and assessment of Cognitive Expertise. MOCA is an opportunity for physicians to document maintenance of their skills in six general competencies, namely, Medical Knowledge; Patient Care; Practice-Based Learning and Improvement; Professionalism; Interpersonal and Communication Skills;*

Table 8-1 Number of Anesthesiology Specialty and Subspecialty Graduate Medical Education Programs, Residents, Fellows, and U.S. Medical Students and Full-Time Faculty

A. Core Anesthesiology Residencies and Residents in Graduate Medical Education (GME) Programs in the United States Accredited by the Accreditation Council for Graduate Medical Education (ACGME)

Academic Year	Number of Accredited Core Anesthesiology Residency Programs	Total Number of Core Anesthesiology Residents on Duty	Number (%) of Core Anesthesiology Residents on Duty Who Are U.S. Medical Graduates	Number of Residencies/ Residents on Duty in All ACGME-Accredited and Combined Specialty GME Programs
1990	157	4362	3871 (88.7)	4144/69,798
1995	149	5490	4395 (81.1)	4245/85,732
2000	134	3837	1627 (42.4)	4268/85,460
2005	132	4785	3450 (72.1)	4151/86,975
2006	131	4970	3731 (75.1)	4134/89,269

B. Subspecialty Anesthesiology Fellowships and Fellows in ACGME-Accredited GME Programs in the United States

and System-Based Practice. There are four requirements for MOCA:

Professional Standing
Diplomates must hold an unrestricted license to practice medicine . . . no medical license . . . can be revoked, suspended or surrendered. . . .

Lifelong Learning and Self-Assessment (LL-SA) Activities
LL-SA is personalized and self-directed professional development, . . . an assessment of . . . current knowledge and practice of anesthesiology . . . [and] continuing medical education (CME) activities and other learning opportunities that meet . . . professional development needs. . . .

Cognitive Examination
The Cognitive Examination is designed to assess core knowledge of the discipline of anesthesiology. It is very clinically oriented, with an emphasis on customary practice. . . .

Practice Performance Assessment and Improvement (PPAI)
The PPAI process consists of the ABA obtaining attestations and evidence of . . . [an anesthesiologist's] clinical activity and ongoing program of practice assessment and performance improvement. The ABA minimum clinical activity requirement is the practice of anesthesiology or a recognized anesthesiology subspecialty, on average, at least one day per week during one of the previous three years. . . . Evidence of PPAI acceptable to the ABA is a prerequisite for the MOCA Cognitive Examination and is a requirement for maintenance of certification in anesthesiology.[25]

The six general competencies for which anesthesiologists need to document maintenance of their skills for the MOCA program are rooted in the graduate medical education process of residency and fellowship education for anesthesiologists. Being concerned that the full range of learning had not been adequately provided for or ensured by an evaluation process, the ACGME developed its Outcome Project in 1999.[26] The ACGME defined six educational areas for which graduate trainees must demonstrate competency (see Appendix 1).[27] The ACGME Outcome Project places the educational responsibility squarely on the shoulders of the residency programs and their faculty to develop innovative curricula and evaluation methods to ensure that trainees graduate with these competencies.[28]

Anesthesiology education for physicians and other health care professionals is, as described earlier, a specific application of assessing medical competence by process evaluation. An equal, and perhaps even more important, question is how to evaluate the outcome of the education rather than the process by which it is achieved.[16,17] The question of why we teach medicine, specifically anesthesiology, is best answered by saying that we want physicians and other health care professionals to perform the activities of anesthesia patient care at a specific level of achievement. Although we are very good at evaluating knowledge, assessment of patient care outcomes is not easily measured. Outcome assessment, that is, evaluation of the practice aspects of anesthesiology, represents the greatest challenge for the future.[16,17]

One such assessment demonstrates the value of the ABA-ACGME model of educating and certifying physician anesthesiologists. Silber and colleagues,[29] in their study of almost 6000 patients undergoing prostate or gallbladder surgery in multiple hospitals, demonstrated that patient recovery or "rescue" from an adverse event correlated with the proportion of board-certified anesthesiologists in the hospital.

Outcome analysis is also becoming a part of the training process for anesthesiologists.[30] An example of this type of approach has been described in an educational setting that makes use of the quality improvement concepts developed in industry.[30] Such an approach is also appearing in post-training practice settings as a form of continuing medical education, as well as a quality assessment tool.[31] We are seeing more of this type of approach as the pressures of health care economics help restructure our clinical practice.

Who Teaches?—The Teachers

Anesthesiology is taught by physician anesthesiologists, the experts in the field, as well as by other expert individuals in related disciplines, examples of whom include pharmacologists, physiologists, biomedical engineers, pediatricians, and neurosurgeons. Full-time anesthesiology faculty positions in U.S. medical schools in 2006 numbered 5836 (see Table 8-1C).[31] Anesthesiologists represent 5.6% of the clinical teachers and 4.7% of all American medical school teaching faculty (see Table 8-1C).[32] The 5836 anesthesia faculty members in medical schools bore the major responsibility for teaching some or all of the 69,028 enrolled undergraduate medical students, the 4970 graduate trainees in accredited anesthesiology residency training programs, the 360 graduate trainees in accredited anesthesiology subspecialty fellowship programs, and many of the other 104,879 physician house staff trainees (see Table 8-1A to C).[12,32]

Clinical care, teaching, research, and administration are major roles assumed by faculty. For anesthesia faculty, clinical care is a prime activity for obvious reasons. The other functions are attended to as time and resources permit. For this reason, teaching is often relegated to a lower level of priority, not always adequately acknowledged in career advancement decisions. Junior faculty members are frequently expected to take on a large part of the teaching load. This expectation, however, could be viewed as a case of reversal of the proper roles for the junior and senior faculty.[33] Junior faculty members have a heavy teaching load during the phase of their career when they lack experience.[33] Senior faculty members, on the other hand, are responsible for departmental, institutional, and specialty roles that limit their availability for teaching, although these same individuals have vast experience and could teach much.[33] The extreme example of this dichotomy is the expectation that house staff teach the more junior of their ranks and medical students. Perhaps the teaching role for house staff would best be accomplished by making the resident a teaching apprentice who not only receives general medical and anesthesiology specialty education but is also educated about education.

Little specific information exists about the teaching credentials or qualities of anesthesiologists, unlike the situation for other physician groups.[34,35] These descriptions can be used to infer what does or could characterize anesthesiology teachers. Physician teachers in general are not trained as educators.[34] They have not had formal training in educational psychology or methodology.[34] Physicians who teach do not use the educational resources available.[34] When faced with a new or difficult educational assignment, physician teachers rarely read medical education journals, nor do they consult educational experts, as they might consult a cardiologist, for example, when treating a patient with a difficult rhythm disturbance.[34] Physician teachers, for the most part, mimic their own teachers, who also had little or no formal training as educators.[34] It seems curious, for example, that at the same time we would not trust a general surgery resident to perform a complicated neurosurgical dissection and achieve a good outcome for the patient without extensive education, we do entrust an anesthesiology trainee to faculty who have limited educational expertise in the hope of achieving a good learning outcome.

What characterizes a good teacher? Effective clinical teachers who are able to succeed at the bedside teaching encounter display specific actions noted by their students and themselves.[35] Table 8-3 presents a schema that was developed by observing internists teaching internal medicine residents and medical students. The similarity of the attending anesthesiologist teaching at the bedside in the intensive care unit or in the operating room is striking.

A teaching responsibility that anesthesiology faculty might consider is how to blend their "expert" status as anesthesiologists with their "novice" status as teachers. As the experts, teachers of anesthesiology can define educational objectives based on the competencies that they believe newly trained anesthesiologists need. Having set the objectives, the teacher can direct the educational process by selecting the appropriate learning activities and then designing tests that assess the learning. As described, the "authoritarian" teacher, the expert, determines the educational ends that must be met, defines the means to these ends, and requires conformity to these ends by the students.

Table 8-3 Traits of Effective Clinical Teachers

Overall instructional effectiveness depends on	1. Allocating time for teaching 2. Creating a teaching/learning environment of trust and concern 3. Demonstrating clinical credibility
A complete educational experience requires	4. An initial orientation 5. A final evaluation
Teaching rounds are facilitated when	6. Learners are able to present a case 7. Teachers manage the case presentation 8. Didactic sessions are used to enhance clinical case material 9. Teaching takes place at the bedside to allow students to learn physician-patient relationships 10. Teachers and students discuss psychosocial issues
Maintained teaching effectiveness occurs when	11. Attention is paid to transferring the teaching responsibility

Adapted from Mattern WD, Weinholtz D, Friedman CP: The attending physician as teacher. N Engl J Med 308:1129, 1983.

Although anesthesiology faculty provide education with this type of curriculum design, few if any know that they are using Tyler's model, nor do they realize that there might be equally good or better alternatives.[36] Dewey's progressive education offers one such alternative.[37] Dewey's philosophy of education elevates students to a level where they can join in a partnership with the teacher. For students of anesthesiology, the adult learners described previously, this type of student-teacher relationship may make very good sense.

An example of these two philosophies put into action clarifies their differences. Let us consider teaching/learning how to manage a patient who is being mechanically ventilated in the operating room. A Tylerian teacher might lecture to residents on how to use the ventilator. It is hoped that the residents will remember what they heard and be able to put what they have learned into action. In contrast, a teacher using Dewey's approach might create a patient simulation exercise in which residents can "experiment" with differing ventilator setups to infer what might occur clinically. A much more meaningful learning environment might be provided by the simulation—coupled with the anesthesiologist faculty member's reactions to and guidance about how the residents "tinkered" with the ventilator—than might be provided by the lecture format. In addition, a teacher using Dewey's philosophy might be more likely to encourage students with previous experience, such as residents who have used different types of ventilators during their internship, to share their know-how with other, less experienced peers.

This chapter is discussing the component parts of the question "How shall who teach what to whom for what purpose now and in the future?" It should be obvious that individually studying the component parts of the question is an artificial separation for teaching purposes. To fully understand the question, its parts must be linked. The consideration "Who teaches anesthesiology?" is an example of how the blending of the individual parts of the total picture of anesthesia education must occur. It is virtually

impossible to talk about the teacher without bringing the student and the educational needs into the discussion. This key concept, that is, the importance of knowing not only the component parts of education but also how they interrelate, is essential for understanding and implementing anesthesiology education.

The Curriculum—What to Teach?

The table of contents from any standard anesthesiology textbook provides a broad outline of what to teach in anesthesiology. Similar to a medical school course outline, anesthesiology is a mix of the fundamental basic sciences applied to clinical practice as they relate to specific pathophysiologic disease entities. Patients with these problems are encountered in preoperative, intraoperative, and postoperative settings; therefore, the content is taught as it specifically applies to the time progression of their disease process in these different patient environments. This framework of basic and clinical science is used for teaching anesthesiology to all health professionals, with particular emphasis placed on the areas most pertinent to the particular group being taught (e.g., detailed teaching about the mechanics and clinical application of ventilators is provided to student respiratory therapists).

An accepted uniform content outline exists and has been agreed on for teaching physician anesthesiologists.[38] The major outline headings are listed in Appendix 2. Few teachers would be at a loss to define the content of anesthesiology teaching. Anesthesiology education, however, is not limited to content teaching alone.

The three major areas for teaching/learning all subjects are cognitive, psychomotor, and affective. For anesthesiology, it appears that the cognitive teaching/learning area is well defined. It is the responsibility of the anesthesiology teacher, however, to go further than just listing the content topics. Teaching in the content area requires attention to increasingly complex cognitive functions. Described by Bloom,[39] teaching/learning in the cognitive domain for any topic addresses the following:

1. Knowledge—recall
2. Comprehension—understanding
3. Application—use of abstractions
4. Analysis—break down; seeing the relationship of parts
5. Synthesis—put together; creating a new entity
6. Evaluation—judgment of value

Knowing the facts about pulmonary function is obviously much more basic than being able to apply them to the management of a multiple-trauma patient maintained on a ventilator. Teachers of anesthesiology serve students well by considering the more complex aspects of cognitive learning.

A general taxonomy of psychomotor skill teaching/learning for universal application to all educational settings does not exist because of the great variability among disciplines in this type of domain. A broadly accepted, standardized outline of psychomotor skill learning for anesthesiology also does not exist. There are many psychomotor skills that anesthesiologists and other related health care professionals need to learn. Perhaps a major challenge for teachers of anesthesiology is to codify the fundamental and supplemental psychomotor skills that must be taught and learned. This process is beginning to occur with the introduction of practice parameters or practice guidelines developed by medicine in general and anesthesiology in particular.[40-46]

Affective teaching/learning deals with feelings or emotions. The taxonomy of affective learning addresses the following[47]:

1. Receiving
2. Responding
3. Valuing
4. Organizing
5. Value complexing

Although we actively and consciously teach in the cognitive and psychomotor areas, we are much less aware of our affective teaching. Even though we may not be aware of it, we are nonetheless constantly teaching in the affective arena by the role modeling that we perform. Earlier in this chapter, an example of how affective teaching/learning takes place was described. In the real-life setting, the aggressive, passive-aggressive, or passive posture of the anesthesiology teacher interacting with the surgeon provides a lasting lesson in the affective domain for the resident anesthesiology learner.

Thinking about affective learning results in goals for such learning and permits the development of teaching plans to achieve these goals. Only if we decide how we believe we as anesthesiologists and health care professionals in related fields need to behave in relation to others will we be able to teach professionalism and these psychosocial skills to our students.[48]

Another example of the importance of affective learning concerns our approach to the teaching task. When our students sense our own enthusiasm about and commitment to a particular topic, their attitudes about it follow suit. In similar fashion, if we as teachers are negative about some aspect of learning, we can expect our students to mimic these feelings. The charge that teachers of anesthesiology must accept is that they must be conscious of the emotions that they display and prospectively decide on the values that they wish to teach because affective teaching and learning occur all the time.

Defining the areas of learning (i.e., what to teach) makes it possible for the teacher to devise methods to evaluate the success of the teaching endeavor. For anesthesiology education of physicians, the ABA examination and certification protocol evaluates the three areas of learning. The written examination tests cognitive learning, although perhaps at its simpler levels. Psychomotor and affective learning is evaluated in an ongoing manner by the anesthesiology faculty of residency training programs and is attested to by the faculty granting a "certificate of clinical competence" to successful learners.

> *The Board [ABA] requires every residency training program to file . . . an Evaluation of Clinical Competence in January and July on behalf of each resident who has spent any portion of the prior six months in Clinical Anesthesia training in or under the sponsorship of the residency program and its affiliates. . . . Entry into the examination system is contingent upon the applicant having a Certificate of Clinical Competence on file with the Board attesting to satisfactory clinical competence during the final period of Clinical Anesthesia training in or under the sponsorship of each program. . . . The Board, therefore, will deny entry into the examination system until this requirement is fulfilled.*[4]

The oral examination evaluates cognitive learning, one hopes at its more complex levels. In addition, the oral examination may assess affective learning, although such assessment is accomplished in an unsystematic approach. The goal of the ABA oral examination process is to access the candidate's ability to (1) apply knowledge in the development of a treatment plan, (2) exhibit sound medical judgment in making medical/anesthetic decisions, (3) demonstrate adaptability in handling complications and changing medical situations, and (4) communicate logically and in an organized manner the anesthetic issues and plans for anesthesia patient care.[4]

The Methods—How to Teach

When faculty members talk about education, one of their first considerations is how to teach. Although obviously an important aspect of instruction, it is of relatively minor importance when viewed in the entire context of education. Before one can decide whether a lecture is a better method to teach a specific topic than a group discussion or whether slides, a chalkboard, or computer-assisted instructional software should be used to facilitate making a concept clear, it is essential to understand the student, the student's needs, the purpose of the education, and the content to be taught.

Too often, the instructional methodology, which is easy to consider, receives the major emphasis, whereas the difficult questions about education, such as what is its rationale, are glanced over or never even considered. After the fundamental questions about educational philosophy are answered, selection of a particular instructional technique becomes critical. The specific teaching method selected is intended to be the one best suited to the specific educational goal desired.

The use of simulation games is a good example of how the method satisfies the educational goal. In cardiopulmonary resuscitation training, for example, a simulated cardiac arrest is an exercise during which students play the resuscitator roles and use all the real-life equipment in a real-time setting. The involved students, as well as other students and the teacher or teachers who observe the simulation, review and critique the resuscitation to point out correct knowledge, skills, and attitudes displayed and which of these actions could have been performed better. The goal of the exercise is to teach students to coordinate the entire cardiopulmonary resuscitation effort by bringing together the facts and skills in an atmosphere in which reasonable attitudes are exhibited despite the tense nature of the emergency situation, all without jeopardizing any patient. A lecture, a slide show, or even a small group discussion could not achieve this goal.

Simulation is becoming an integral teaching methodology in anesthesia education.[49,50] Borrowed from flight simulation, which is an essential part of the training and certification of commercial and military pilots, anesthesia patient simulators have been developed and used to educate individuals in the discipline of anesthesiology in two major ways: (1) for specific recognition and management of critical events and (2) in the general comprehensive education about all aspects of anesthesia patient care, such as crew resource management. By coupling a mannequin with a computer and anesthesia patient care equipment, a simulation setting is created that so closely mimics real life that it is a virtual reality. Physiology, pharmacology, pathophysiology, and crisis management are a few of the curricular areas that can be most effectively taught by the anesthesia simulator approach, that is, modeling a real patient scenario for students to manage with zero risk to the simulated patient and no real risk to the student (except for the trainee's self-imposed stress to achieve). Use of this technology is limited only by the ability of the educators and students to create and "live" the scenarios.[49-51] Additional advantages of human patient simulators include their use in teaching all types of students (e.g., medical students, student nurse anesthetists, allied health professionals in a wide variety of disciplines, practitioners in continuing education programs) and the ability to conduct educational research and collect "simulated" patient management outcome data.[49-51]

Scientific evaluation of simulation is being conducted, but there are considerable study design difficulties.[52,53] In addition to the difficulty of designing studies to evaluate simulation, the evidenced-based data that are being collected deal with the performance of providers of simulated care and have yet to effectively answer the question about patient benefit related to simulation-educated physicians.[52,53] Undoubtedly, the field of human simulator education and research will continue to grow exponentially in the next few years.

An in-depth study of individual teaching techniques is appropriate after the links between the questions about educational philosophy and rationale and the methods of teaching have been established. At the teacher's disposal for effective use in the proper situation are lectures; small group discussions; the use of questions; clinical problem solving; psychomotor skill learning at the bedside, in the operating room, or in the classroom; and the use of adjunctive educational media such as slides, chalkboard, videotape, audiotape, overhead projector, computer, and teaching models. Each of these techniques can be used more effectively and efficiently when the method is studied and understood.

Effective use of questioning, for example, occurs when the teacher understands the difference between closed and open questions.[54] Closed questions are used when the teacher is interested in having the student remember facts. Because the range of responses to closed questions is limited, students answer with facts and have limited opportunity to delve into more complex cognitive learning (i.e., problem solving). A teacher uses open questions as a teaching device when desirous of directing the teaching/learning activity toward the application of knowledge to new settings or analysis of information for conceptual learning rather than mere regurgitation of facts. There is a considerable difference in the learning that might occur when a question such as "What might explain postanesthetic stupor in a patient operated on for head trauma?" is asked of a student versus asking a question such as "What are the signs and symptoms of increased intracranial pressure?"

Developing a psychomotor skill lesson is another example of how understanding instructional methodology can lead to effective teaching and learning. The old adage about teaching psychomotor skills in medicine is "see one, do one, teach one." The absurd nature of this approach has been highlighted in the following way: "This is akin to a piano instructor playing 'The Minute Waltz' for a beginner and then saying, 'Now, try it yourself.'"[54] Rather than using the repetitive trial-and-error approach to teaching/learning psychomotor skills, systematic methodology can be used.[54]

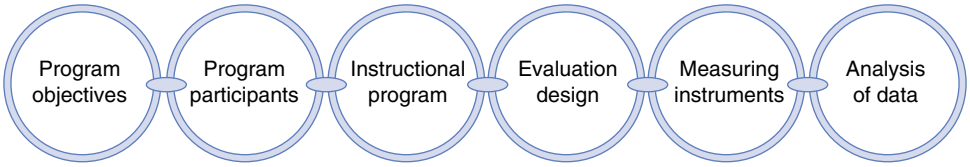

Figure 8-2 Diagrammatic representation of a model to conduct educational outcome analysis. The six components are joined in "chain-link" fashion to signify that the outcome analysis is as strong as its weakest link. Essential to the model, therefore, is sound development and implementation of the educational plan and process. This includes definition of the educational objectives, understanding of both the teaching faculty and student participants, and execution of the instructional activity. Having established the educational experience, its outcome can be assessed by applying an appropriate evaluation design[56] and using the measurement techniques to collect the data for analysis. The final step in the analysis is to apply the results to the program objectives and instructional activities to enhance future desired learner outcomes. *(From Hutchins EB: Unpublished lecture notes: Evaluation Methods in Professional Education. Course ED668, Graduate School of Education. University of Pennsylvania, 1981.)*

1. Analyze and separate the skill into its component parts and determine which aspects of the skill are most difficult to perform.
2. Provide students with a model of the skill, demonstrated effectively in its entirety, that they are expected to perform.
3. Make provisions for students to practice until the expected behavior is mastered.
4. Provide adequate supervision and an evaluation of the final performance.

Anesthesiology instructors need only think of the protocol that they are using to teach, for example, pulmonary artery catheterization by the internal jugular venous route, to assess whether they are expecting their students to perform (learn) with the type of plan just outlined or rather to "learn as they go" on each successive patient as they probe in the neck. The learn-as-you-go method can be quite stressful for both patient and trainee.[55]

A final example of an answer to the question of how to teach comes from review of the effective use of audiovisual aids. Although it is true that "a picture is worth a thousand words," the anesthesiology teacher must be sure that this image is the "text" that the teacher wishes the students to read and absorb. Slides, for example, focus the viewer's attention on an idea or ideas that the lecturer wishes to amplify in some manner. By definition, the entire lecture cannot be put on slides. Only a few important portions of the presentation are conveyed by slides, and these points are emphasized in some specific way by the visual image or images, which add to the verbal presentation. Slides are not the TelePrompTer, although they are often used this way.

Even more basic is the need to understand the proper production formatting of slides so that the message on a 35-mm transparency or a PowerPoint computer image can be seen clearly when projected onto a 12-foot-high screen in a large 800-seat lecture hall. If format is not considered, the slide is not visible and undoubtedly detracts from, rather than enhances, the lecture. Finally, even the best-produced slide is useless if nobody, including the lecturer, knows how to troubleshoot a nonfunctional computer or projector. Surely, the thousands of hours that have been devoted to slide lectures about anesthesiology could have benefitted from teachers taking more responsibility in the preparation of effective visual aids.

Summary

What is the anesthesiologist's responsibility in teaching colleagues and other health care professionals? The answer lies in the answers to the many aspects of the following question:

How shall who teach what to whom for what purpose now and in the future?!

For many, however, this type of review of education is "soft" material that lacks the "hard" research data to prove its validity. Perhaps there is some truth to this. Perhaps by its very nature (i.e., psychosocial) the science of education has its limits. On the other hand, however, enough experimental studies of education may not have been performed. A model to conduct such studies might view the preceding question in terms of educational outcome analysis (Fig. 8-2). Although the educational setting is not a pure, controlled laboratory environment, accepted quasi-experimental design techniques exist for this naturalistic research setting.[56]

What then is the anesthesiologist's responsibility in teaching? It is twofold: to understand all aspects of education and then to scientifically study educational outcome so that future students of anesthesiology will be more effectively taught and better prepared as experts in the field.

Acknowledgment

I wish to thank George E. Miller, M.D., for the insight on Socrates.

Appendix 1

Common Program Requirements: General Competencies (Abridged) Approved by the Accreditation Council for the Graduate Medical Education Board on February 13, 2007

The program must integrate the following Accreditation Council for Graduate Medical Education (ACGME) competencies into the curriculum:

- **Patient Care**
  Residents must be able to provide patient care that is compassionate, appropriate, and effective for the treatment of health problems and the promotion of health.
- **Medical Knowledge**
  Residents must demonstrate knowledge of established and evolving biomedical, clinical, epidemiologic, and social-behavioral sciences, as well as application of this knowledge to patient care.
- **Practice-Based Learning and Improvement**
  Residents must demonstrate the ability to investigate and evaluate their care of patients, to appraise and assimilate scientific evidence, and to continuously improve patient care based on constant self-evaluation and lifelong learning. Residents are expected to develop skills and habits to be able to meet the following goals:
  Identify strengths, deficiencies, and limits in one's knowledge and expertise
  Set learning and improvement goals
  Identify and perform appropriate learning activities
  Systematically analyze practice by using quality improvement methods, and implement changes with the goal of practice improvement
  Incorporate formative evaluation feedback into daily practice
  Locate, appraise, and assimilate evidence from scientific studies related to their patients' health problems
  Use information technology to optimize learning
  Participate in the education of patients, families, students, residents and other health professionals
- **Interpersonal and Communication Skills**
  Residents must demonstrate interpersonal and communication skills that result in effective exchange of information and collaboration with patients, their families, and health professionals. Residents are expected to
  Communicate effectively with patients, families, and the public, as appropriate, across a broad range of socioeconomic and cultural backgrounds
  Communicate effectively with physicians, other health professionals, and health-related agencies
  Work effectively as a member or leader of a health care team or other professional group
  Act in a consultative role to other physicians and health professionals
  Maintain comprehensive, timely, and legible medical records, if applicable
- **Professionalism**
  Residents must demonstrate a commitment to carrying out professional responsibilities and adherence to ethical principles. Residents are expected to demonstrate
  Compassion, integrity, and respect for others
  Responsiveness to patient needs that supersedes self-interest
  Respect for patient privacy and autonomy
  Accountability to patients, society, and the profession
  Sensitivity and responsiveness to a diverse patient population, including but not limited to diversity in gender, age, culture, race, religion, disabilities, and sexual orientation
- **Systems-Based Practice**
  Residents must demonstrate awareness of and responsiveness to the larger context and system of health care, as well as the ability to call effectively on other resources in the system to provide optimal health care. Residents are expected to
  Work effectively in various health care delivery settings and systems relevant to their clinical specialty
  Coordinate patient care within the health care system relevant to their clinical specialty
  Incorporate considerations of cost awareness and risk-benefit analysis in patient- or population-based care as appropriate
  Advocate for quality patient care and optimal patient care systems
  Work in interprofessional teams to enhance patient safety and improve the quality of patient care
  Participate in identifying system errors and implementing potential systems solutions

Appendix 2

Content Outline—Joint Council on In-Training Examinations

I. Basic Sciences
  A. Anatomy
    1. Topographic anatomy as landmarks
    2. Radiologic anatomy
  B. Physics, monitoring, and anesthesia delivery devices
    1. Mechanics
    2. Flow velocity
    3. Properties of liquids, gases, and vapors
    4. Gas laws
    5. Vaporizers
    6. Uptake and distribution of inhalation agents
    7. Physics of the anesthesia machine/breathing system
    8. Monitoring methods
    9. Instrumentation
    10. Ventilators
    11. Alarms and safety features
    12. Defibrillators
    13. Pacemakers
    14. Electrical, fire, and explosion hazards; basic electronics
    15. Drug delivery devices
  C. Mathematics
    1. Simple mathematics
    2. Statistics
    3. Computer
  D. Pharmacology
    1. General concepts
    2. Anesthetics—gases and vapors
    3. Anesthetics—intravenous
    4. Anesthetics—local
    5. Muscle relaxants

II. Clinical Sciences
  A. Anesthesia procedures, methods, and techniques
    1. Evaluation of the patient and preoperative preparation
    2. Regional anesthesia
    3. General anesthesia
    4. Monitored anesthesia care and sedation
    5. Intravenous fluid therapy during anesthesia
    6. Complications (etiology, prevention, treatment)
    7. Special techniques
    8. Postoperative period

III. Organ-Based Basic and Clinical Sciences (Outline for Sections May Include Physiology, Anatomy, Biochemistry, Pharmacology, Clinical Science)
  A. Respiratory system
  B. Cardiovascular system

9 Ethical Aspects of Anesthesia Care

Key Points

1. Anesthesiologists have ethical obligations to promote patients' abilities to make medical decisions, as well as obligations to respect those decisions.
2. Competent patients have the right to refuse medical treatments or tests, even if it appears to be a "bad" decision. Coercing or restraining competent patients is unethical.
3. Children should be involved in medical decision-making to the degree that their abilities allow, and their wishes should usually be respected.
4. Advance directives and decisions by surrogate decision-makers are legally binding.
5. Do-not-attempt-resuscitation orders require reconsideration before anesthesia and surgery and cannot be automatically suspended.
6. Withdrawal or withholding of life-sustaining treatments at the end of life requires specialized training or experience.
7. Anesthesiologists play a pivotal role in caring for both brain-dead and non–heart-beating organ donors and must be familiar with the medical, legal, and ethical issues involved.
8. Human and animal research carries special obligations to protect the subjects from inhumane treatment. Whenever possible, alternatives to human and animal research should be sought.
9. "State-sponsored" activities such as executions (1) are not the practice of medicine, (2) undermine the medical profession, and (3) place the physician on dubious moral grounds.
10. Although physicians have a right to withdraw from some situations in which patient care presents them with personal moral conflicts, this right is limited, and professionally accepted standards and obligations usually prevail (e.g., well-established standards, such as informed consent).

History of Ethics in Medicine and Ethical Theory

Medicine is a respected profession with codes of behavior and definite rules of conduct. In modern times, medical practitioners have tremendous powers, recognized social import, and powerful financial interactions that touch nearly everyone's lives. It is in the context of long-held and highly developed rules and practices that we examine the ethical bases of the practice of medicine and its implications for anesthesiologists.

Ethical Theory

Virtue Ethics, Utilitarianism, and Duty-Driven Ethics

The classic style of medical practice, called "paternalism," is derived from "virtue-based ethics." In this view, the physician is a genuinely virtuous person with inherent qualities of competence, sincerity, confidentiality, and altruism who naturally knows and does what is correct for the patient. The patient, who is not knowledgeable in the art of medicine, should trust the physician to decide what is best. Our society and legal system have changed substantially since paternalism flourished, but some patients and physicians still see this style as a desirable component of medicine.

In utilitarian ethics, actions are judged right or wrong on the balance of their good and bad consequences. A "right" action produces the most good, based on a perspective that gives equal weight to the interests of all affected parties. Although utilitarian theory is compelling (who would not want to do the most good and minimize evil?), it falls short in defining which benefits are most important. Is it the "good" that all reasonable people want or the "good" defined by the individual patient? What if the only way to maximize "good" is to commit an entirely immoral act? Suppose, for example, the only way to win a war is to systematically torture children?

Utilitarian theory may be best when applied to analyzing broad-based policies, in decisions regarding rationing of resources, and when attempting to resolve conflicting ethical obligations.

The premise of Kantian-based ethics (also called "deontological theory") is that there are features of actions other than their consequences that make them right or wrong. Intention is more important than outcome. Furthermore, no person should use another exclusively as a means to an end because each person *is* the end for which we should act. Each person is uniquely valuable and should not be used to further the purposes of other persons without their autonomous consent. Kantian philosophy would, for example, forbid killing one innocent person to save another innocent person.

Deontological and utilitarian theories are both applied to varying degrees in modern medical ethics. Individualism and autonomy are highly valued in Western society, and people tend to turn to Kantian philosophy when ethical questions arise that balance the authority of the physician against the goals and values of individual patients. When broad-based social issues are at stake, such as allocation of scarce medical resources, utilitarian arguments are often used. Some of the toughest ethical questions in medical practice occur when the rights and desires of individual patients are in conflict with social policies. Clashes between deontological and utilitarian principles are common in the intensive care unit (ICU), managed care settings, and the care of poor and elderly patients whose medical management is funded by the government. In each of these settings, the will of the individual patient may be in conflict with the broader principles of minimizing expense, fairly allocating scarce resources, and determining where and how society's health care dollars are best spent.[1]

The American political tradition provides a clear underpinning to individual freedom, hence translation of the Jeffersonian "life, liberty, and the pursuit of happiness" into the contemporary interest in physician beneficence and patient autonomy. It was with the background of this political tradition that contemporary bioethics shifted away from paternalism. At the beginning of the 20th century, the concept of autonomy of patients began to emerge.

Clinical Ethics

Informed Consent

Legal and moral imperatives for informed consent are based on the ethical principle of respect for patient autonomy. "Autonomy" refers to the ability to choose without controlling interference by others and without personal limitations that prevent meaningful choices, such as inadequate information or understanding.[1] Individuals have the right to determine what happens to them to the degree that they are capable of doing so. In the United States, this right is rooted in constitutional guarantees of privacy and noninterference. In 1914, the case of *Schloendorff v Society of New York Hospital* established that it was the right of "every human being of adult years and sound mind to determine what shall happen to his own body."[2] In 1957, the term "informed consent" was first used in the case of *Salgo v Trustees of Leland Stanford Hospital*, which established that it is not sufficient for physicians to simply secure consent; physicians have a duty to inform patients about the risks and alternatives to treatment, in addition to the procedures themselves and their consequences.[3]

Respect for patient autonomy requires physicians to respect decisions made by competent patients and to *promote* autonomy by removing barriers to competent participation in making decisions. Such obstacles range from incomplete or inaccurate information to reversible medical conditions that interfere with a patient's ability to understand the information provided.

Competence or Capacity

Autonomy to make medical decisions cannot exist in the absence of competence. Because "competence" is a legal term, most medical experts prefer the term "capacity" to describe the necessary skills to participate in medical decisions.

Impairment of capacity can be temporary or permanent. Examples include some mental illnesses, dementia, immaturity, anxiety, pain, and effects of medications. The elderly, those suffering from mental impairment, and children are particularly vulnerable to having their participation in medical decisions inappropriately curtailed or even denied because their capacity to participate is frequently underestimated. Hearing loss, dysarthria, and expressive aphasia can create the false impression that capacity is impaired. Many children make medical decisions in ways similar to adults but may be mistakenly excluded from the decision-making process solely because of their age. Language barriers can present significant challenges to communication.

Capacity is both relative and task specific. Patients may be able to understand and make decisions about medical issues while being unable to care for themselves in other ways.

Both prejudice and paternalism permeate physician behavior in the informed consent process. Challenges to patient competence rarely occur unless there is a difference of opinion or values between the patient and physician. Patients are often referred for competency evaluation because they refuse medical advice, although refusal of treatment is not by itself evidence of incompetence.[4] Physicians frequently disagree with patient decisions because they regularly ascribe a lower quality of life to impaired and handicapped patients than the patients themselves do. Doctors are mistaken about patients' preferences regarding life-extending therapies in the majority of cases and underestimate older patients' desire for life-extending therapies in up to 30% of cases.[5] Moreover, surveys indicate that physicians and other health care workers are likely to *act* on personal prejudices regarding handicapped or impaired patients.[6]

Functional capacity for decision-making must be judged separately from the perceived quality of the decision itself. Patients have the right to make "bad" decisions if they are competent and have appropriate information. Otherwise, physicians could merely substitute their own judgment for that of the patient, and autonomy in medical decision-making would be nonexistent.

How do we recognize competence? When assessing a patient for anesthesia care, the anesthesiologist should focus on the following concerns: (1) Can the patient formulate and communicate a decision? (2) Can the patient receive and understand the information relevant to the decision? (3) Can the patient understand potential consequences of the decision, including potential risks and benefits, even if in a very simplified way? (4) Can the patient express a decision and communicate values regarding the medical advice being given?

It is the anesthesiologist's ethical duty to treat reversible conditions that interfere with medical decision-making. Elective surgery may have to be postponed until expert consultation for determination of mental capacity or treatment of reversible

conditions can take place. When surgery is urgent or a patient is impaired by an irreversible condition, anesthesiologists may have to rely on a surrogate decision-maker or proceed with their best determination of the patient's interests in mind.

Disclosure

The informed consent process requires honest disclosure of medical information to the patient. U.S. courts currently rely on two standards of disclosure: the reasonable person standard and the subjective standard. A third, "professional standard," in which the physician is obliged to disclose only what other physicians of the same specialty would disclose, was subject to abuse and manipulation and is essentially no longer recognized. In the "reasonable person" standard, the physician must disclose any information that a theoretical "reasonable person" would want to know. This standard does not require an exhaustive recitation of facts and acknowledges that not all information related to the procedure is integral to making a decision about whether to undergo the procedure. The "subjective standard" recognizes that some patients may have special needs for specific information and that when that need is obvious or has been brought to the attention of the physician, the information must be disclosed. For example, a concert violinist may have a specific need to know about the potential for nerve damage from an axillary block. In general, legal and ethical standards now require that (1) the physician accurately discuss the therapy and its potential alternatives—including no therapy—and (2) disclose the common risks (because they are more likely to happen) and the serious risks (because the consequences are severe).

The doctrine of "therapeutic privilege" is sometimes cited to avoid discussing risks under the reasoning that the stress of discussing risks can harm the patient psychologically or physically. Studies of patient stress during the informed consent process *do not* support this concept.[7] Therapeutic privilege is probably invoked in many cases because the physician is uncomfortable with disclosure or wants to curtail discussion. Although it is ethical to forgo or curtail risk discussions at the patient's request, it is not generally ethical for the physician to unilaterally decide to do so.

The physician-patient relationship is an inherently unequal one because of physicians' knowledge and authority and the patient's dependence on them for care. Physicians have ethical obligations to avoid exploiting their influence for the purpose of accomplishing their own ends. Although it is acceptable to offer a rational basis for a medical choice, it is generally unethical to coerce or manipulate patients into decisions by presenting real or implied threats or by omitting or misrepresenting key information.

Legal implications of Informed Consent

The informed consent process does not prevent legal liability when adverse events occur. Flawed informed consent processes have been cited, however, as evidence of a lack of quality of care by the physician. The American Society of Anesthesiologists (ASA) closed claims database reveals that the absence of informed consent is cited in approximately 1% of claims and that cases with inadequate documentation of informed consent are associated with larger monetary awards.[8] Studies repeatedly show that the risk of filing a malpractice claim is directly related to patients' perception of their relationship with the physician.[9] The informed consent process provides one of the few opportunities that anesthesiologists have to establish that relationship, however brief, and should not be underestimated in its medicolegal importance.

Informed Refusal

Informed consent is meaningless if the patient cannot also refuse medical therapy because the consent process is then merely an exercise in patient acquiescence to the physician's will. Examples of informed refusal in anesthesiology include requests to withdraw or withhold life-supporting care in the ICU; do-not-attempt-resuscitation (DNAR) orders in the operating room; cases in which the patient has objections to certain forms of therapy, such as a Jehovah's Witness who refuses blood transfusions; and cases in which a patient refuses preoperative testing, such as human immunodeficiency virus (HIV) or pregnancy testing.

Informed refusal has similar concerns and requirements as informed consent. When patients refuse medical care or insist on what the physician believes is suboptimal care, disclosure of the risks and benefits becomes even more important because these decisions may veer from options that are already widely accepted and for which the risks are believed to be lowest. It is easier to justify agreeing to the unusual preferences of a well-informed patient than to subject a poorly informed patient to unorthodox care.

Despite full information, patients may sometimes request or demand care that is unreasonable, either because it will adversely affect the performance of surgery or because it would be associated with unreasonably high risk. When a patient demands a technique that is inappropriate or outside the realm of reasonable practice, the anesthesiologist is under no ethical obligation to provide that care. No physician can be compelled by a patient to practice negligently.

Special Issues in Informed Consent and Informed Refusal

Jehovah's Witness Patients

The classic example of a patient who refuses therapy in anesthesia practice is that of Jehovah's Witnesses, many of whom believe that accepting a blood transfusion violates a Biblical injunction (also see Chapters 5 and 6). The Jehovah's Witness doctrine has been subject to change over time, which has resulted in inconsistencies in religious practice with regard to which, if any blood components might be acceptable. Individuals interpret religious doctrines in light of their own spiritual contexts, and not all believers hold to the same tenets with equal fervor. Church doctrines, like medical practices, evolve over time, and practices that are acceptable at one time may not be acceptable years later. Anesthesiologists and surgeons have cited individual and doctrinal inconsistencies as justification for ignoring the wishes of Jehovah's Witness patients—but to do so is no more logical than assuming that every hypertensive patient needs or will respond well to identical treatment or that optimal treatments will not evolve over time.[10] Moreover, it is the right of *any* patient to refuse blood transfusion therapy, regardless of whether this desire is founded in a religious preference. Such refusals have become more common in non–Jehovah's Witness patients because blood transfusion

therapy was connected to cases of acquired immunodeficiency syndrome (AIDS) in the 1980s and patients began questioning the value and necessity of transfusion therapy in light of its risks.

Because beliefs differ regarding which, if any, blood replacement therapies are acceptable, it is important to have a thorough and detailed discussion of possible therapies with a Jehovah's Witness patient before surgery, and the conclusions should be documented in the patient's chart. If anesthesiologists believe that they cannot comply with an adult patient's desire to forgo transfusion, they have the ethical obligation to find an alternative caregiver whenever possible.[11]

The courts strongly support the rights of adult patients to refuse blood products for themselves but have been inconsistent and have interfered in the cases of some pregnant patients. Transfusion of pediatric Jehovah's Witness patients by court order is common at this time but may become ethically and legally less acceptable as therapy other than blood transfusion to maintain oxygen-carrying capacity evolves, as the Jehovah's Witness church further defines its doctrines with regard to children, and as the capacity of children to consent to or refuse therapy is better understood.

The Pediatric Patient and Other Patients with Impaired Competence

The ethical practice of medicine weighs heavily toward adherence to respect for autonomy in patients who are competent to make medical decisions (also see Chapter 82) or who have executed advance directives when they were competent to do so. Medical care of individuals who have never been autonomous relies on principles such as respect for human dignity, beneficence, avoidance of harm, and adherence to the principle of justice.

Children are an example of persons who may or may not yet be autonomous. Laws in each state define the age at which children become *legally* competent to make medical decisions (usually age 18), but many younger children have the mental and emotional capacity to make medical decisions. Forcing such individuals to undergo treatments that they do not want is unethical and could be illegal as well.

Decision-making capacity in children is variable. Most 2-year-olds are clearly not able to make medical decisions, but there is a wide range of capability present in children as young as 7 or 8, and studies suggest that the average 14-year-old makes medical decisions similar to adults. In one study, children from 6 through 9 years of age invited to participate in influenza vaccine research asked pertinent questions about individual risks and benefits and whether their community and other children would benefit.[12]

Most states recognize "emancipated minor" status whereby a court determines that minors can legally make medical decisions for themselves. Legal exceptions to the age of consent are recognized in most states when treatment is believed to be in the minor's best interest and a requirement for parental consent would interfere with the child's ability to receive medical help. The law recognizes that tragically, some conditions for which a minor seeks therapy may even be the result of parental abuse and that seeking parental permission for treatment may actually further endanger the minor. Thus, minors are allowed in many states to consent to treatment for substance abuse, sexually transmitted disease, mental illness, and medical care affecting pregnancy, including abortion. In situations in which a minor has decision-making capacity but is not "emancipated," a judge may declare the child to be a "mature minor" with decision-making rights.

Ideally, individuals of any age should be involved in medical decisions to the degree that their capacity allows. A minor who possesses the capacity to make decisions should not be coerced or restrained under most circumstances.[13] Determining whether a minor has such capacity may require formal consultation and assessment. The term "assent" rather than "consent" is used to refer to agreement with treatment by children who do not fall into legal categories awarding them adult rights. The American Academy of Pediatrics has stated that physicians who care for children "should give serious consideration to each patient's developing capacities for participating in decision-making, including rationality and autonomy."[14]

When children dissent to undergo medical care, persistent refusals may be ethically binding, particularly in the case of participation in research. Medical personnel should respect the wishes of patients who withhold assent and try to gain a better understanding of their situation or deal with their fears. "A patient's reluctance or refusal to assent should also carry considerable weight when the proposed intervention is not essential to his or her welfare and/or can be deferred without substantial risk."[14,15]

Consent for Laboratory Tests: HIV and Pregnancy Testing

HIV and pregnancy testing has serious ethical considerations (also see Chapters 69 and 101), has limited, if any beneficial impact in the setting of surgery, may create serious social and economic consequences for the patient beyond the operating room, and may require the patient's informed consent.

HIV tests are usually ordered for the purpose of singling out patients for whom "extra universal precautions" could be taken to reduce transmission in the operating room. Most surgeons and anesthesiologists believe that compulsory AIDS testing would reduce their risk of exposure, and many believe that it is the physician's prerogative and can be done without the patient's consent.[16]

However, HIV testing does not necessarily yield safer anesthetic management and is more costly than diligent application of universal precautions.[17] In low-prevalence populations, testing is more likely to give false-negative results that wrongly reassure operating room workers that a patient is not infected. This may paradoxically increase the risk for transmission of HIV if relaxation in vigilance is the result.

Positive HIV tests can result in loss of employment or insurance coverage, or both. Seropositive women often experience marital breakup, abandonment, verbal abuse, and physical violence if their status is disclosed.[18] The threat of compulsory AIDS testing almost certainly would prevent some patients from seeking needed surgical care.[19]

Routine preoperative pregnancy testing has ethical ramifications analogous to HIV testing. Despite pervasive beliefs to the contrary, large, well-designed population studies do not demonstrate that anesthetics lead to early fetal loss or an increased frequency of fetal malformations.[20,21] Studies have also shown that even adolescent girls generally report the possibility of pregnancy accurately when asked privately.[22] Legal ramifications of not routinely testing for pregnancy preoperatively have been virtually nonexistent, and less than a third of U.S. practices require it.[23] A positive pregnancy test may have extremely negative consequences if a vulnerable patient is in a social situation in which

pregnancy is not accepted. Abandonment, negative family interactions, and violence to the patient or her fetus (or both) all occur. Adolescent pregnancies are sometimes the result of child abuse or rape, and referral of adolescents who are pregnant to Child Protective Services should be considered.[23] In many states it is illegal to disclose or even insinuate a child's pregnancy status to her parents regardless of her age, thus leaving an anesthesiologist who discovers an adolescent pregnancy with few comfortable or legal options.

Many patients may choose not to undergo elective surgery if they know that they are pregnant. However, coercing a female patient to have a test against her wishes and which she may find insulting explicitly violates patient autonomy. Physician self-interest is not a sufficient justification for disregarding patient autonomy or violating a patient's privacy. It was the joint recommendation of the ASA Task Force on Preoperative Testing and the ASA Committee on Ethics that anesthesiologists offer the *choice* of preoperative pregnancy testing to any female patient who might desire one, explain the potential risks and benefits, and obtain informed consent for the test.[24]

Maternal-Fetal Conflicts

In general, the rights of pregnant women to refuse therapy, even if refusal would be detrimental to their fetuses, are protected under right-to-privacy provisions in the U.S. constitution (also see Chapter 69). These rights are weighed against potential harm to the fetus in a decremental fashion as the fetus approaches and surpasses viable age. When the fetus is of nonviable age, mother's rights prevail. Court decisions have consistently upheld the rights of pregnant women to have abortions, to not be subjected to drug testing, and to forgo transfusions early in pregnancy. Attempts to charge women with child abuse, child endangerment, drug trafficking, murder, and attempted murder for activities deemed dangerous to their fetuses have almost uniformly failed.[25] In general, women do not lose their rights to bodily integrity and informed consent when they become pregnant, and neither fetal "rights" nor state interests supersede a pregnant woman's right as medical decision-maker.

The American Academy of Pediatrics Committee on Ethics has outlined conditions that in their view are necessary to override a mother's refusal of care: (1) the fetus *will* suffer irrevocable harm without the treatment, (2) the treatment is *clearly indicated* and likely to be effective, and (3) the risk to the woman is low.[26] However, the American College of Obstetricians and Gynecologists condemns the use of coercion on pregnant women and advocates counseling the patient carefully about risks, in addition to recommending consultation with an ethics committee.[27]

The Uncooperative Patient—Coercion and Restraint

The use of physical restraint to control medical research subjects was first addressed directly in the Nuremberg Code after the Doctor's Trial in 1947-1949 and is a continuing subject of intense scrutiny (also see Chapter 71).[28] For anesthesiologists, chemical restraints often replace physical ones, but the ethical issues are the same. Anesthesiologists are often asked by medical colleagues to chemically restrain uncooperative patients. Use of restraint is antithetical to promotion of autonomy, and anesthesiologists have both ethical and legal obligations to determine whether such extreme intervention is warranted. Coercing or using physical or chemical means to force competent patients to undergo treatment that they are refusing is both unethical and illegal. Refusal of medical care and angry behavior are not proof of incompetence, intoxication, or inability to make medical decisions.[29]

When faced with an uncooperative adult patient, questions to ask include (1) Is the patient clearly incompetent or merely angry and uncooperative? Is there evidence of neurologic impairment, acute intoxication, or severe mental disability? (2) Is the patient in immediate danger? (3) Does the patient pose a direct threat to staff or other patients? (4) Is there a compelling need to treat life-threatening injuries? In the absence of these considerations, the use of coercion or physical or chemical restraint is neither ethical nor legal. Physicians may be forced in some situations to act within a timeframe that does not permit lengthy evaluation of a patient's competence or a protracted search for a surrogate decision-maker. In such cases, the physician must rely on professional judgment in deciding how to care for uncooperative patients who either cannot speak for themselves or appear incompetent to refuse care at a time when a decision must be made. The standard applied here would be to do what a "reasonable" person would wish. Coercion or restraint (or both) in such situations is not ideal but may be necessary and ethically permissible.

An uncooperative child presents special ethical concerns. When a patient who does not have the capacity to make health care decisions dissents to medical care, the anesthesiologist is ethically required to provide care that is most likely to benefit the patient and prevent harm while preserving the dignity and safety of the patient. Although violation of respect for autonomy is technically not possible in a patient who does not have autonomy, violation of the principles of beneficence, nonmaleficence, and respect for dignity certainly is. Indiscriminate use of physical or chemical restraint is not without physical risk, and the fear and anger provoked by such tactics can lead to future aversion toward medical care and mistrust of health care providers. The American Academy of Pediatrics Committee on Child Abuse and Neglect states that restraint should not be used in pediatric care "unless it is necessary for proper diagnosis and treatment in a sick child, as in the case of a child with a high fever and potential ear infection, or in emergency situations."[30]

Behavioral control in an uncooperative child or incompetent adult should focus on alternatives to physical restraint, such as offering choices on how to go to sleep and use of fantasy or hypnotic suggestion. Although there may be many social, economic, and scheduling pressures to the contrary, delaying or rescheduling surgery on a hysterical patient is better than coercion or force. Delaying elective surgery may reduce stress, allow adequate premedication, and promote safer induction conditions. If medical care is urgent or if delay is unlikely to result in better conditions for the patient, the anesthesiologist should proceed in a manner designed to preserve the patient's dignity and safety.

Advance Directives and Surrogate Decision-Makers

Critical decisions regarding medical care often arise when patients are too ill to formulate or express decisions regarding medical interventions. "Advance directives" were developed after several legal decisions affirmed that patients can refuse even lifesaving medical care and that clear and convincing evidence of the patient's wishes is needed to allow surrogate decision-makers to

request withdrawal of life-sustaining therapies.[31] An advance directive is a document executed by patients before incapacity to provide physicians with guidance in medical decision-making when the patients cannot communicate for themselves. Such directives include living wills, which detail which therapies a patient would accept or refuse in the case of terminal incapacity; DNAR orders; and any other information regarding medical care decisions.

A surrogate decision-maker may be someone whom the patient has appointed to make health care decisions for them (a durable power of attorney [POA]) or an individual with other legally recognized authority by virtue of their relationship with the patient.

A durable POA for health care decisions may be given by patients to a specific person whom they designate to make health care decisions for them if they become incapacitated. The authority vested in a POA supersedes most other decision-makers, including family members, except court-appointed guardians.

When the patient has not designated a durable POA, doctors rely on family members to make decisions for the patient. In many states there is no legally defined hierarchy of decision-makers. Usually, the spouse or legally recognized domestic partner is considered the first-line surrogate. Commonly, the surrogate hierarchy after the spouse is the children, if all are in agreement, and then the parents, if both are in agreement, and then the siblings, if all are in agreement. In cases in which there are no advance directives and either a surrogate decision-maker is not available or family members cannot agree, the courts may appoint a guardian ad litem to represent the patient in medical decision-making.

Surrogates explicitly act in "substituted judgment" to provide what the patient would have wanted and, theoretically, are not being asked merely for their own preferences. However, surrogate decision-makers at best only approximate the patient's decisions because their interpretation is subject to their own biases, values, and psychological agendas. Incompetent patients can be emotionally and financially burdensome, and decision-makers may have conflicts of interest that distort their beliefs and testimony about what the patient would have wanted.

Studies demonstrate that patients and their proxies only infrequently discuss issues and values involving life-sustaining technologies. There are often significant discrepancies between patients and proxies in the assessment of patients' emotional health and satisfaction. Neither physicians nor proxies can always accurately predict a patient's preferences for life-sustaining therapy.[32-34] Nevertheless, with all of its imperfections, proxy decision-making may be the only option if a patient has not left specific directives.

Medical Decisions That Cannot Be Made by a Surrogate Decision-Maker

Some medical treatments have intense cultural connotations, may involve limitation on private freedoms such as reproduction, or may have historically been subject to abuse. Decisions regarding such interventions cannot be made by a surrogate decision-maker, even if one is available, and require court review. Examples in some states are sterilization and electroshock therapy.

The anesthesiologist should review the patient record before taking a patient to the operating room and ascertain (1) whether the patient has advance directives, (2) who the patient's surrogate decision-makers are, (3) if the procedure is legally allowed with consent from a surrogate decision-maker, and (4) in special cases, whether an appropriate court order has been obtained.

Special Issues with Advance Directives—Do-Not-Attempt-Resuscitation Orders in the Operating Room

Up to 60% of anesthesiologists incorrectly believe that DNAR orders are automatically suspended during anesthesia and surgery (also see Chapter 97). The ASA,[11] the American College of Surgeons,[35] the Association of Operating Room Nurses,[36] and the Joint Commission on Accreditation of Healthcare Organizations[37] all have published practice guidelines requiring reconsideration, not abandonment, of DNAR orders in the perioperative period.

The DNAR order is, in essence, documentation of the patient's wishes to avoid the medical interventions associated with resuscitation. Because the causes and outcomes expected with cardiac arrest in the operating room are different from what may happen elsewhere and the prognosis is much more favorable, it is very important to reassess the patient's desires when surgery is anticipated.

The ASA has issued guidelines for the management of a patient with DNAR orders and other directives limiting medical care.[11] Although the patient's primary care physician may have introduced the idea of DNAR orders to the patient or surrogate, it is specifically the anesthesiologist's duty to discuss the risks and benefits of resuscitation in the setting of anesthesia and surgery before undertaking the patient's care. The anesthesiologist should include in the discussion the following steps: (1) determine what the patient's goals are regarding surgery and resuscitation; (2) establish exactly what is meant by "resuscitation," in contrast to routine anesthetic care; (3) educate the patient about the risks and benefits of resuscitation in the operating room setting; and (4) document the agreements reached with the patient about which interventions commonly associated with resuscitation are acceptable to the patient. Such interventions might include, but are not limited to, intubation, administration of vasoactive drugs, administration of DC countershock, and institution of chest compressions. Many patients who express reluctance about resuscitation during surgery are fearful of burdensome outcomes, such as permanent neurologic impairment. Education and discussion may reassure them about the favorable outcomes of resuscitation in the operating room and can establish ground rules for discontinuing interventions postoperatively if they do not lead to a chance of meaningful recovery.

Surgery is dependent on the cooperation of many caregivers with differing expertise, each of whom has independent ethical obligations to the patient. It is therefore imperative that resuscitation agreements be discussed with other members of the operating room team. Such a policy prevents crucial disagreements from occurring during a critical event when treatment decisions must be made quickly. It also allows "conscientious objectors" to withdraw from the health care team.

Advance directives are legally and ethically binding. Despite clear, consistent, and forceful legal decisions, many physicians still resist imperatives to respect patient wishes regarding resuscitative care, life-sustaining therapies, or both. Anesthesiologists have ignored DNAR directives under the false assumptions that the legal authority of advance directives and living wills is not binding in the operating room or that the physician has discretion in deciding when to follow or ignore such directives. In response, courts have awarded significant monetary damages for the cost

of continued health care and punitive damages for the pain, suffering, and mental anguish of the patients' survivors when DNAR instructions are ignored.[38]

Finally, DNAR orders must never be construed as an excuse to not "care" for the patient. A patient's decision to forgo resuscitation does not imply a wish to avoid other beneficial interventions. Placement of a pulmonary artery catheter, for example, may help ensure optimal management of a frail patient who has a DNAR order by enabling the anesthesiologist to avoid situations in which the patient's DNAR status becomes pivotal.

End-of-Life Decision-Making

A 1996 review by the American Medical Association showed that end-of-life issues of foremost importance to patients were control over the timing and location of death; management of symptoms such as pain, dyspnea, anxiety, and depression; financial management of medical care; and maintenance of therapeutic options, including physician-assisted suicide.[39,40]

Withdrawal/Withholding of Medical Therapy—*Curing* versus *Caring*

More than 80% of deaths in the United States occur in health care facilities, and the majority of deaths in ICUs take place after an explicit decision to withdraw or withhold treatment.[40] Patients and doctors alike recognize that aggressive medical therapy may not be desired or even appropriate in the face of advancing disease. Continued therapy may not be warranted or desired when quality of life is extremely poor, even if the patient is not suffering from terminal disease.

Before the mid-20th century, the concept of "beneficence" in the eyes of physicians was strongly tied to preventing death. Ethical distinctions between acts of omission ("letting die") and acts of commission ("killing") were and remain confusing at best. Worse, physicians faced threats of criminal punishment if patient death resulted from withdrawal of medical treatment. In 1976, the case of Karen Ann Quinlan[41] established that patients have a right to forgo invasive treatment, even if lifesaving, and that surrogate decision-makers could ask for withdrawal of lifesaving therapies if they could show that the patient would not have wanted them. The right to forgo lifesaving treatment was later extended in the cases of Claire Convoy and Nancy Cruzan to include *any* treatment if patients refused or there was clear and convincing evidence that the therapy would have been refused if the patients could speak for themselves.[31] These decisions were revisited and reconfirmed in the tragic case of Theresa Schiavo in 2005.[42]

Arguments that withdrawing or withholding life-sustaining therapy does not violate rules against killing patients are based on ethical differences between killing and letting die and between acts of commission (e.g., lethal injection) and acts of omission (e.g., withdrawal or withholding of ventilator therapy).[43] Because such distinctions are confusing to physicians and patients alike, a "principle of proportionality" is often applied when withholding or withdrawing treatment.[44] In this principle, treatment is "indicated" to the extent that it is likely to present more benefits than burdens to the patient based on the patient's perception of such medical, social, and psychological benefits and burdens. Of course, competent patients still always have the right to refuse therapy, even if the treatment is lifesaving and otherwise indicated.

Two common scenarios in which anesthesiologists may be involved in withdrawal or withholding of life-sustaining interventions are in the ICU or operating room before organ donation after cardiac death. In both cases, the issues and principles of withdrawing/withholding treatment are the same.

Withdrawal of life-sustaining interventions heralds the final phase of end-of-life care. Terminal care requires special physician knowledge and experience. It requires expertise in medically supportive therapy, problematic symptom management, knowledge about physiologic changes in dying patients, support and counseling of patients and families, understanding and respect for patient autonomy and religious and cultural practices and beliefs, ability to work within complex health care teams, ability to communicate well, and empathy.[45] Anyone intimately involved in care of a dying patient should also be intimately familiar with the ethical and legal standards.

Withdrawal of life-sustaining care begins with an assessment of the individual patient's physiology, level of dependence on therapy, degree of consciousness, preferences regarding sedation and analgesia, and preferences regarding privacy and level of involvement of family and other loved ones. All of the patient's treatment orders should be reviewed to meet the new treatment goals. Treatments promoting patient comfort should generally be continued, whereas those directed only at physiologic maintenance might all be withdrawn. Family members and others attending the patient at the end of life should be educated about the physical and mental changes that they can expect to see as treatments are scaled back, including the possibility that death will not occur imminently once support is withdrawn.[46]

Several interventions have ethical implications and deserve special consideration—fluid and nutritional management, administration of sedatives and narcotics that have the potential to hasten death, and administration of neuromuscular blocking agents.

Fluid and nutritional support is controversial. Burdens associated with continuation of fluid and nutritional support include prolongation of the dying process and complications and suffering from placement and maintenance of intravenous or enteral access (or both). However, feeding and hydration may have important connotations for family and members of the health care team in that they allow a sense of nurturing and mitigate feelings that they are "abandoning" the patient.[47] Pain, dyspnea, and depression are all common symptoms that cause suffering in a dying patient. Alleviating the pain and dyspnea carries the risk of hastening death. Medical, legal, and religious authorities have all clearly accepted the principle of "double effect," in which an action intended to produce a benefit for the patient produces not only the expected benefit but also the potential for significant harm. It is entirely ethical and legal to administer high doses of pain medication and sedatives for the intended effect of relieving suffering, even if the treatment has the side effect of hastening death. However, to administer any medication with the explicit intention of hastening death is euthanasia and not medical therapy.[47]

Neuromuscular blocking agents have no anesthetic, analgesic, or sedative properties and have no role in palliative care. Such drugs should not be initiated if withdrawal of ventilatory support is anticipated. When withdrawal of ventilator support is anticipated in a patient already receiving such agents, they should be withheld in all but extraordinary cases. Paralyzing the patient to comfort *the family* so that they see no disturbing movements

or respirations as the patient dies is not justifiable. Even worse, it can mask symptoms and signs of distress and prevent relief of suffering during the dying process.[46]

Physician-assisted suicide (PAS) involves the provision of medications or prescriptions to patients by specific request for the purpose of ending their life. PAS requires a patient who is both competent and capable of communicating the request. Euthanasia involves the administration of medication by someone other than the patient for the express purpose of causing death in the belief that this would be best for the patient (but not necessarily at a specific request of the patient). Both practices differ ethically from withdrawing or withholding life-supporting medical treatment. In the former, the primary intent is to cause death, which secondarily ends suffering. In the latter, the primary intention is to discontinue treatments that are causing suffering with an understanding that death may or probably will result.

Currently, euthanasia is legal only in the Netherlands. In the United States, euthanasia remains illegal regardless of circumstance, and PAS is legal in the states of Washington and Oregon at the time of this writing.

Supporters of PAS argue that the right to privacy and respect for autonomy support patients' rights to determine the time, location, and circumstance of their own death. Adequate control of pain, anxiety, dyspnea, and other symptoms at the end of life remains a challenge to the medical profession that has fueled the desire for a means to end life when suffering cannot be controlled. Opponents argue that PAS "medicalizes" death, overly idealizes the physician-patient relationship, and ignores any personal and professional conflicts of interest that might occur. Although many ethicists acknowledge that individual circumstances may make assisted suicide an ethically permissible action, most express concern about potential abuse. Vulnerable members of society, such as the poor, elderly, and handicapped, might be pressed by financial and social factors into a suicide option in preference to palliative care.

An additional argument against PAS or legalized euthanasia is that they might provide simpler and less expensive solutions to the medical, social, and economic problems common to elderly and poor patients than seeking and requiring more difficult, but definitive remedies.

Ethical Issues in Organ Transplantation: Brain Death and Donation after Cardiac Death

Two issues critical to vital organ transplantation that confront anesthesiologists are the concept of brain death and linkage of withdrawal of life-sustaining therapies with organ retrieval and transplantation after cardiac death (donation after cardiac death [DCD]).

Brain Death

Before the 1960s, death was defined as the moment when the heartbeat stopped and respirations ceased. Advances in cardiopulmonary resuscitation and mechanical ventilation then made it possible to postpone death, seemingly indefinitely. In 1968, the Ad Hoc Committee of the Harvard Medical School proposed redefining death as the point at which all cardiorespiratory function had irreversibly ceased *or* all function of the whole brain had irreversibly stopped (brain death).[48] The committee gave two explicit reasons for redefining death. The first was to allow patients to be declared dead and not maintained on machines, thereby limiting expense, reallocating medical resources to other salvageable patients, and allowing the social rituals surrounding death to occur. The second was to allow donation of vital organs before the circulation stopped.

The public has been slow to accept brain death, in part because it requires complete trust in physicians and ignores indicators of death that the public already understands. For nonphysicians, brain-dead donors are superficially indistinguishable in many ways from living persons, and they must therefore rely completely on the physician for both accurate and honest information of a loved one's death.

Diagnosing brain death is relatively straightforward. In the United States it requires demonstration that in the absence of drugs, paralytic agents, hypothermia, and other reversible conditions that mimic loss of brain function, cortical and brainstem function is absent. The diagnosis is usually made either clinically by demonstrating that cortical activity and brainstem reflexes are absent or by radiographic studies demonstrating complete absence of cerebral blood flow.

The definition of brain death is *social* rather than *biologic*. Nevertheless, medical, ethical, theologic, and legal experts generally agree that brain death adequately defines a condition in which a person with ethical and legal rights and moral standing ceases to exist and should no longer be treated as an alive being. Expensive medical interventions can be discontinued without legal ramifications, and vital organs can be donated for transplantation if the patient or surrogate agrees.

Before assuming care of a brain-dead organ donor, the anesthesiologist is obliged to review the chart for documentation of the declaration of brain death, as well as the criteria on which it was based. If there are any questions about the diagnosis, organ donation should be postponed until the anesthesiologist is satisfied that these concerns are addressed.

Donation after Cardiac Death

DCD occurs when a patient desires to have life-sustaining medical therapies withdrawn and also wishes to proceed with donation of vital organs after death. Controlling the time and place of death so that the timing of organ donation can be optimized has obvious medical and ethical advantages. The decision to donate organs is made before death so that discussion and informed consent can take place. Ischemia time can be minimized. The dual decision to withdraw life-sustaining interventions and donate vital organs after death can create ethical conflicts, however. When a dying patient becomes an imminent organ donor, there is a risk that patient interests will be minimized or ignored in favor of the organ recipient.

The Institute of Medicine reviewed DCD in 1997[49] and 2000[50] and found that there were serious ethical questions, such as determining how quickly after asystole organ donation can begin and whether medications can ethically be administered to the donor before death that are solely for the purpose of organ preservation.

Ethical, theologic, and legal principles prohibit us from killing one person to benefit another, but the point at which actual death has occurred in DCD patients is unclear. Although expedient donation is the very purpose of DCD, doctors must never

sacrifice any living patient in the process or even take significant risks of doing so—the mistrust that this would engender in the public could place the entire concept of DCD at risk by reducing potential donors and ultimately harming future potential organ recipients.[51-53] Loss of consciousness occurs quickly after asystole, but brain function can continue for some time and irreversible brain injury may not occur for many minutes. Yet many protocols call for organ retrieval to begin only 2 minutes after the circulation has stopped, and in at least one institution, organ donation is allowed to begin within seconds of cardiac arrest.[54] There is both scientific and philosophic uncertainty about when death is complete—this could even lead to accusations of physicians deliberately killing patients to obtain organs for transplantation. Mistakes have occurred in some cases of brain-dead organ donors for which clear clinical criteria exist; DCD is potentially even more prone to error because no such clinical guidelines are universally accepted.[55]

Donation of vital organs after brain death and DCD is both ethical and legal, but the interests of the dying patient must be absolutely protected until death has occurred. Anesthesiologists can play a vital role in the organ donation process by helping hospitals develop reasonable and ethical policies for the management of brain-dead and DCD donors. Every anesthesiologist should be thoroughly familiar with brain death criteria and should review the process of determining brain death before accepting care of a brain-dead donor. Anesthesiologists involved in organ DCD should have appropriate training or expertise in the relevant ethical, legal, and medical issues involved, including end-of-life care.

Research Ethics

Human Subjects Research

The premise that the physician always puts the best interests of the patient first can be jeopardized when research objectives enter the doctor-patient relationship. Human subjects are asked to put aside their own interests to benefit some future, hypothetical group of patients. In extreme cases, the patient becomes a research "object" who will not benefit personally from the experiment at all. Two examples include experiments in healthy subjects and phase I cancer trials in terminally ill patients in which the goal is to determine the toxicity of treatment—not remission, palliation, or cure.

Human subjects research must balance many conflicting interests, such as the needs and rights of the research subject, the hypothetical interests of future patients, and the physician's financial, professional, and personal goals. Academic or corporate advancement, personal prestige, and financial incentives may be disincentives to researchers who are diligently protecting patient interests or remaining objective in designing protocols and analyzing and reporting their findings. Thus, human subjects research is more closely regulated, supervised, and controlled than any other medical endeavor.

Regulation of research began after World War II, with the Nuremburg Code and the Helsinki Declaration outlining the ethical obligations of physicians engaged in human research. The United States was slow to awaken to the parallels between the concentration camp experiments and the sometimes gruesome treatment to which they subjected their own subjects in similar trials.[56] In the years that followed the Doctor's Trial at Nuremburg, Fox[57] and Beecher[58] found that researchers were aware of the standards set at Nuremberg but regularly did not comply with them. In 1974, the National Research Act established the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research, out of which the modern institutional review board was born.[31]

Ethical conduct of human subjects research follows three principles: (1) respect for autonomy and the obligation to protect subjects with limited autonomy; (2) beneficence, with obligations to minimize risks, maximize benefits, and ensure that the research design is scientifically sound; and (3) justice, the obligation to treat each person with regard to what is morally right and to ensure fair distribution of benefits and burdens.

In addition to comprehensive presentation to research subjects of the risks and benefits of procedures or medications to which they will be subjected, disclosure must include the possibility of commercialization of the results, financial interests of the researchers, and any other actual or perceived conflicts of interest on the part of researchers and their institutions and sponsors. Subjects must be free to refuse or end participation at any time without penalty. "Situational coercion" in which subjects believe that they are not truly free to refuse should be avoided or mitigated. Examples of situational coercion include prisoners whose terms and experiences of incarceration might be affected by their decision to participate or refuse and hospitalized patients who may believe that their care could be compromised if they do not cooperate with researchers.[56]

Monetary or other inducements to participate in research are probably permissible if they do not undermine the freedom of the subject to refuse under reasonable circumstances. Significant monetary awards may have adverse effects on the autonomy of subjects and a negative impact on the scientific quality of the research. If remuneration is high, for example, subjects might conceal factors that would otherwise disqualify them from participating, thereby compromising the research results and exposing themselves to greater risk.

Researchers are obligated to maximize benefit and minimize potential harm, including physical, psychological, social, legal, and financial harm. The research must address a question of sufficient value to justify the level of risk and must follow the approved protocol. Findings must be promptly and accurately reported. The research must be terminated immediately if it is suspected to be harmful to the participants.

Anesthesiology research often involves the treatment or prevention of unpleasant symptoms, such as pain and nausea, for which effective treatments are well established. Such studies should be restricted to comparison of treatments with known efficacy, not placebo-controlled trials, and "escape" analgesics or antiemetics must be provided at the patient's request.[47]

No population group should be unfairly subjected to research without having equal access to its benefits. Finally, in our modern Western research tradition, the interests of the individual subject always prevails over the interests of society.

Children As Research Subjects

Children are particularly vulnerable as research subjects because they may lack the ability to make mature decisions, are subject to the authority of others, may defer to their parents and others in

ways that mask underlying dissent, and may have conditions requiring immediate decisions not consistent with informed consent.[59] Children's rights are frequently undervalued, whereas parental authority may be overvalued. Studies show that even children with decision-making capacity are often excluded from the consent process by both parents and physicians.[60]

If a minor child is "able" to assent, assent must usually be obtained in addition to the consent of any legal surrogate decision-makers. In the United States, federal law requires assent of any minor 7 years and older to participate in medical research. Particularly for research in which no substantive individual benefit is expected, many ethicists believe that a child's dissent *must always be honored*.[60,61]

Ethics of Animal Research

The animal rights movement in the United States has gained significant momentum in the last 25 years, following in the wake of the U.S. civil rights movement and paralleling increasing awareness and concern about the human impact on the environment and other animal species. Federal legislation protecting animal welfare began with the Laboratory Animal Welfare Act of 1966. In 1985, the Health Extension Act and amendments to the Animal Welfare Act required the establishment of Institutional Animal Care and Use Committees to oversee conditions of laboratory animals; review and approve animal research protocols; educate and train investigators in ethical issues and aspects of animal handling such as anesthesia, analgesia, and euthanasia; and act as community liaisons.[62]

Some researchers deny that animal experimentation could be subject to any moral reservations and assert that medical advancements have been and continue to be completely dependent on continued animal research. Many animal welfare activists insist on the moral equivalence of animal and human experimentation and accuse researchers of being blind to or, even worse, of being actually unmoved by the suffering of animal subjects. The simplicity of these polarized views does not do justice to the complexity of the issues.

Advancements in the understanding of animal cognition have led most biologists to now believe that many, if not all animals are capable of feeling pleasure, pain, anticipation, and fear and thus experience both enjoyment and suffering. Many bioethicists accept that the higher animals therefore have sufficient awareness to possess moral standing, although how much moral standing is intensely debated.[63,64] Allowing animal suffering as a result of pain, fear, sickness, or poor standards of care is a moral harm that must be avoided, mitigated, and weighed heavily against the benefits that it produces. Many argue that animals should be protected, not only because they have moral standing but also because people who are cruel to animals are more likely to be cruel to other humans.[65]

Researchers have obligations to provide clean and humane conditions and appropriate veterinary care for animal subjects. Researchers should mind the "3 R's"—replacement, reduction, and refinement—that is, use animal subjects only when necessary, minimize any suffering incurred in the study, and seek nonanimate replacements for animal subjects. Mediocre or repetitive research using animal subjects should not be allowed. It is the responsibility of the medical and scientific community to continue to aggressively seek and promote alternatives to the use of animal subjects.[65]

Physician Participation in Executions

U.S. physician professional organizations have consistently stated that physician participation in executions is unethical, yet many physicians admit that they would agree to be involved. The role of physicians in euthanasia and executions is of particular concern to anesthesiologists, who have been identified as ideal candidates for duties that involve killing because of their particular professional skills. Arguments in favor of physician involvement in executions usually cite the principle of beneficence in allowing a humane death.

Historically, however, beneficence arguments have led to "slippery slope" justifications for physicians to be involved in the killing of persons who have never faced an accuser or had a fair hearing—such killings have included persons with physical or mental handicaps and other "social flaws" for the "benefit" of the individual and society as a whole. Once physicians accept a beneficence argument for participating in executions, it is difficult to draw the ethical line at participation in other dubious state-sponsored activities, such as torture, coercion, and "medical incarceration," because these activities are also usually defended as being beneficial to society.[66]

When physicians agree to participate in an execution, they act as agents of the state while appearing to act on behalf of the "patient." This can lead to eventual erosion of public trust and respect. It also at times undoubtedly leads to physician participation in the killing of innocent persons.[67]

Studies clearly demonstrate that to avoid intolerable self-condemnation, virtually all executioners undergo "moral disengagement" in which they dehumanize the convicts and devalue their lives, thereby deflecting moral responsibility for the execution away from themselves by blaming juries, judges, governors, and "the law," rather than accept the responsibility that they share in ending the prisoner's life.[68] It is difficult to reconcile the medical profession's overt ethical imperatives of valuing human life, respecting individuals, and accepting personal moral responsibility with participation in a process that requires rejection of these very values.

Moral Integrity—Can the Physician Be a Conscientious Objector in Medicine?

Anesthesia care of patients can involve ethical controversy, legitimate disagreement, and moral ambiguity. When a physician's personal values run counter to acceptable ethical standards of care, how should the physician resolve such conflicts? Medical professional societies recognize the right to conscientious objection in

medical practice. The ASA, the British Medical Association, and the Hastings Center have all issued statements recognizing the physician's right to withdraw from situations in which ethical standards of patient care are in serious conflict with their personal values.[69] The ASA specifically recognizes conscientious withdrawal from patient care in the case of patients with DNAR orders or other directives that limit treatment.[11] However, these rights have limitations. Acceptance of moral objections to certain hotly contentious issues such as abortion or physician-assisted suicide may be reasonable, but objections to well-established standards, such as informed consent, are not. Moral objections of physicians are also likely to carry more weight if they involve concepts that physicians believe supports them as ethical doctors—and not just as ethical persons—because these concepts are more likely to be founded in professionally established standards rather than personal beliefs.[69]

Summary

Anesthesiologists face many ethical challenges, including promotion of patient autonomy, resolution of patient-physician conflicts in medical decision-making, ethical obligations in human subjects and animal research, and ethical conflicts during end-of-life care in the ICU and during organ donation. Knowledge about ethical and professional standards in patient care and research is essential in the specialty of anesthesiology, which is more than just the mere provision of technical service on demand. Anesthesiologists may find that at times accepted values in ethical practice conflict with personal values and goals. This is a common challenge to all physicians, but ethical decisions cannot be left to the individual physician's values, and adherence to ethical principles of the medical profession should prevail.

10 Legal Aspects of Anesthesia Care

Key Points

1. The medical malpractice tort system is intended to improve patient care.
2. Medical negligence occurs when a physician's failure to meet the standard of care directly leads to patient injury.
3. A fully informed attorney is the physician's best advocate.
4. Physicians having their medical competence publicly questioned may feel guilt, failure, anger, shame, isolation, depression, fatigue, denial, and physical symptoms.
5. A detailed, legible anesthesia record strengthens the defense against a malpractice suit.
6. More than half the states have laws prohibiting the admission of apology or sympathy as evidence of wrongdoing.
7. The goal of informed consent is to maximize the ability of the patient to make substantially autonomous informed decisions.
8. Evidence of decision-making capacity (the ability to make a particular decision at a specific time) includes the ability to understand medical problems, proposed treatments, alternatives, options to refuse treatment, and the foreseeable consequences of accepting or refusing proposed treatments, as well as the ability to express a preference based on rational, internally consistent reasoning.
9. A reasonable person standard of disclosure requires that the extent of the disclosure be based on what a reasonable person would consider material for choosing whether to undergo the proposed intervention.
10. Anesthesiologists may refuse to provide care when they ethically or morally disagree with the procedure or if they believe that the patient's choice is too inappropriate or likely to result in harm.
11. Competent patients have a virtually unlimited right to refuse life-sustaining medical treatment.
12. Anesthesiologists are responsible for negligent acts made within the scope of defined duties by trainees and certified registered nurse anesthetists.
13. Physicians have been held liable for inadequate pain control.

Statute law, case law, and regulations affect anesthesiologists (Table 10-1).[1-8] Statute law is the body of prescriptive law created by a legislature to achieve a specific purpose. For example, the National Organ Transplant Act is the law that establishes the Organ Procurement and Transplantation Network and authorizes it to maintain a national registry for organ matching. State legislatures subsequently establish state laws governing organ procurement.

When statute laws need interpretation or clash or when there is no definitive statute law, disagreements may be adjudicated by the judicial system. The aggregate of reported cases, known as case law or common law, is used as the basis for future court decisions. The results of these cases are rarely prescriptive and may lead to a collection of confusing, ambiguous, and even contradictory cases that rest on diverse rulings in different jurisdictions. For example, a widow donated the kidney of her deceased husband to a long-time friend. The transplant surgeon, on receiving and examining the kidney, declared it unsuitable because of a renal artery aneurysm. The transplant surgeon then asked for the donor's second kidney. By then, the donor's second kidney had been allocated to another patient. The plaintiff sued, claiming that the organ procurement organization misappropriated the donor's second kidney and alleging in part that under conversion tort, the organ procurement organization interfered with the plaintiff's right of possession of personal property, in this case the kidney. On appeal, the court ruled for the defendant, the organ procurement organization, because the plaintiff had no common law right to the kidney inasmuch as a person cannot have property rights to a dead body.[9]

Regulations often come from administrative authorities such as executive branch agencies or state medical boards. For example, a U.S. Department of Health and Human Services regulation requires hospitals wishing to participate in Medicare to have written polices that an organ procurement organization is notified of potential donors.[10]

Table 10-1 Laws and Regulations That Affect Medical Practice

Law or Regulation	Comment
Health Insurance Portability and Accountability Act (HIPAA)[1]	HIPAA's privacy rules protect individually identifiable health information held or transmitted in any form, whether electronic, paper, or oral. This includes a patient's past, present, or future health or condition, provision of health care, or payment for the provision of health care and either identifies the individual or provides information through which there is a basis to believe that individual may be identifiable. Privacy rules apply to health plans, to health care clearinghouses, and to any health provider who transmits health information. HIPAA is a complex law that includes many other provisions, including making insurance portable from one employer to another.
Emergency in Medical Treatment and Active Labor Act (EMTALA)[2,3]	EMTALA governs when a patient may be refused treatment and when an unstable patient may be transferred from one hospital to another. More commonly stated, the purpose of EMTALA is to prohibit "dumping" of emergency patients onto other hospitals. Hospitals must perform a screening medical examination to determine whether an emergency condition exists, must provide stabilizing treatment if an emergency condition does exist, and may transfer the patient to another hospital only under certain conditions, such as the patient requesting transfer, the patient being stable and transfer will not worsen the patient's condition, and the receiving hospital having treatment abilities unavailable at presenting hospital. The receiving hospital must accept the transfer. Physicians have a central role in this process inasmuch as they must certify that the patient can be safely transferred. EMTALA also requires assigned on-call physicians to respond to emergency situations.
Controlled Substance Act[4]	This act permits the federal government to regulate the manufacture, importation, possession, and distribution of certain drugs to control the traffic of controlled substances. This act permits the federal government to determine whether a drug should be a controlled substance and into what drug schedule it should be placed. This act does not control the medical use of these drugs.
Employment Retirement Income Security Act (ERISA)[5] (A number of amendments to ERISA are relevant to health benefits, including HIPAA)	ERISA established uniform federal standards to protect private employee benefit plans. The U.S. Department of Labor administers and enforces ERISA and federal courts interpret it. The relevance in medicine is that it regulates health benefit plans. Case law interpretation of ERISA affects how, where, and for what indications members may sue health maintenance organizations.[6-8]

Professional Liability

The medical malpractice tort system is intended to "minimize patient injury, maximize patient safety and compensate injured patients." Unfortunately, the malpractice system may not have the desired effects on physician behavior.[11] Physicians are often uninformed about possible standards from malpractice cases.[11] Jury trials of medical malpractice suits do not reliably inform physicians, in part because of inconsistencies in case law and in part because juries tend to correlate liability with severity of harm and not with physician negligence.[12,13] Nonetheless, to improve patient care, anesthesiologists should vigilantly study the medical malpractice tort system.

Medical Malpractice

The most common cause of medical malpractice is medical negligence (Table 10-2). Negligence is breach of a duty that is the proximate cause of a harm.[14] Expanding on that definition, medical negligence occurs when a physician's failure (breach) to meet the standard of care (duty) directly leads (proximate cause) to patient injury (harm). Proximate cause should be tightly coupled and requires proof of "cause-in-fact" and foreseeability. Cause-in-fact, often known as the "but for" test, means that the harm would not have occurred but for the previous negligent act. Foreseeability suggests that injuries must be of the type that would be foreseen by a reasonable practitioner. For example, "but for" the *absence* of an end-tidal carbon dioxide monitor, esophageal intubation would have been recognized because a reasonable practitioner would foresee that this breach of the standard of care may lead to unrecognized esophageal intubation. There must be a harm for which the individual needs to be compensated. Awards

Table 10-2 Causes of Action Most Relevant to Anesthesiologists

Type	Description
Medical negligence	Breech of a duty of a standard of care causing harm
Wrongful death	One that occurs earlier that it would have otherwise. If negligence causes death, survivors may sue for damages
Lack of informed consent	Obligation to provide information material to a reasonable person
Abandonment	Obligation to provide continuity of care once a physician assumes responsibility for the patient
Vicarious liability	Obligation for reasonable oversight of those working for the physician
Loss of chance of recovery or survival	The patient must show that recovery was likely except for the action of the physician
Battery	Touching a person without express or implied consent. There is no need for the plaintiff to prove harm in battery cases
Assault	The attempt to touch another person. There is no need to prove actual harm

From White C, Rosoff AJ, LeBlang TR: Informed consent to medical and surgical treatment. *In* Sanbar AA, Firestone MH, Fiscina S, et al (eds): Legal Medicine, 7th ed. Philadelphia, Mosby Elsevier, 2007, pp 337-343.

may be conferred for noneconomic losses, for the economic costs of repairing the damage, and for loss of income. The amount of time in which a plaintiff can bring an action is governed by state statutes and typically begins on occurrence or discovery of the allegedly negligent act or the harm.

Medical negligence may be adjudged as criminal medical negligence if it deviates greatly from the standard of care, whether unknowingly (criminal negligence) or knowingly (criminal recklessness).[15] Criminal medical negligence is rarely prosecuted, but characteristics of such cases include failure to modify care based on past similar experiences, hiding errors, and practicing in a way that appears to favor financial and personal gains over patient care. For example, an anesthesiologist was prosecuted (but eventually acquitted) for reckless manslaughter when after more than five documented episodes of falling asleep during anesthesia, he fell asleep during a case in which the child died.[16] The anesthesiologist was convicted for criminal medical negligence, although that conviction was eventually overturned because the prosecutors had not brought the criminal medical negligence charge within the legal time limits.[17]

The Process of Being Sued

Some lawsuits may begin "informally" by a request from a potential plaintiff's attorney to review records or to discuss a case. An attorney should be consulted before engaging in these actions to ensure that proper procedure is followed. Lawsuits officially begin with a document called a Summons and Complaint, which is a notification to respond to allegations by the plaintiff.

After initiation of the suit, the process of discovery begins with exchange of documents and a deposition. The purpose of the deposition is for the other side of a legal action to obtain information or clarification otherwise unavailable, particularly about the reasoning underlying actions.[18] At the deposition, oral testimony is taken under oath and transcribed and may be used as evidence at trial. Experts, consultants, clinicians, witnesses to the event, or defendants may be deposed. Some conversations are privileged and may not be discovered by the plaintiff, including discussions with attorneys, risk management personnel, insurance company representatives, personal clinicians (including psychotherapists, clergy, and a spouse). Conversations with close friends are discoverable.

Before the deposition, the physician should inform the attorney about his or her relationship with the plaintiffs and any problems that may have occurred. The physician should educate the attorney about complex medical components of the case and expected weaknesses. A fully informed attorney is the best advocate.

In addition to the defendant, the defendant's attorney, the plaintiff's attorney, and the court reporter, the plaintiff may also be present at the deposition. After the court reporter administers the oath, the plaintiff's attorney will ask standard questions, including education, licensing, and certification. The defendant's attorney will intercede as appropriate. The same questions may be asked several times over. A goal of a plaintiff's attorney is to develop a causal atmosphere to lower the guard of the defendant before asking more relevant questions. A defendant is best served by not speculating about factual matters that may be found in the medical record and answering only the questions asked and asking for clarification if unclear about the meaning of a question.

Malpractice Defense

Physicians having their medical competence publicly questioned may feel guilt, failure, anger, shame, isolation, depression, fatigue, denial, and physical symptoms.[19] It is important to be forthright about these feelings and to manage them, if for no other reason than to be able to participate fully and positively in the legal defense.

Defendants often rebut claims that the standard of care was not met and that the alleged failure to meet the standard of care was a proximate cause of harm. To help support these arguments, expert witnesses, medical texts, journal articles, practice guidelines, and anesthesia records are often used.

Expert witnesses explain the relevant science and offer professional opinions about the standard of care and causation.[20] Although courts commonly accept the expertise of most expert witnesses, courts and juries do use qualifications to modulate the weight that they give the testimony. An expert witness can support the idea that a different explanation or approach, especially one that other physicians would support, may meet a sufficient standard of care. The obligations of expert witnesses include the following: "expert testimony by anesthesiologists should be readily available, objective and unbiased. To limit uninformed and possibly misleading testimony, experts should be qualified for their role and should follow a clear and consistent set of ethical guidelines" (Box 10-1).[21]

Practice guidelines are being used increasingly as evidence of a standard of care.[22] Although authors of practice guidelines routinely state that the guidelines are not intended to set a standard of care, it is highly likely that juries will be strongly influenced by them.[23] Some authors have even proposed that practice guidelines replace expert opinion.[22]

A detailed, legible anesthesia record often strengthens the defense against a malpractice suit. A goal of documentation should be that uninvolved anesthesiologists would be able to recreate the anesthesia care as if they were in the operating room. Uninvolved anesthesiologists should be able to understand interventions, the reasons for interventions, and the outcomes of interventions. Precise documentation and written explanations of thought processes lead to better understanding. For example, when performing regional anesthesia, an anesthesiologist may want to document the length and type of needle used, nerve stimulator type and settings, number of attempts, strength and location of muscle contractions, whether a paresthesia occurred, and how the paresthesia was managed.[24] Alternatively, consider the effect of documentation on the fairly routine event of decreased urine output. Assume that a patient had no urine output over a certain period in a previously functioning bladder catheter. The anesthesiologist treated the decreased urine output with a fluid bolus. The record would ideally indicate a "0" under urine output and indicate a bolus of fluid under fluid administration. Assume, then, that 30 minutes after the fluid bolus there was still no urine output. At this point, it would be reasonable for the anesthesiologist to write a note on the anesthesia record discussing the decreased urine output, the initial interpretation and treatment of the decreased urine output, the results of that

Box 10-1 Guidelines for Expert Witness Qualifications and Testimony

The physician should be board certified in anesthesiology or hold an equivalent specialist qualification. The physician should be familiar with the clinical practice of anesthesiology at the time of the occurrence and should have been actively involved in clinical practice at the time of the event.

The physician's review of the medical facts should be truthful, thorough, and impartial and should not exclude any relevant information to create a view favoring either the plaintiff or the defendant. The ultimate test of accuracy and impartiality is willingness to prepare testimony that could be presented unchanged for use by either the plaintiff or defendant.

The physician's testimony should reflect an evaluation of performance in light of generally accepted standards, as reflected in the relevant literature, neither condemning performance that clearly falls within generally accepted practice standards nor endorsing or condoning performance that clearly falls outside accepted medical practice.

The physician should make a clear distinction between medical malpractice and adverse outcomes not necessarily related to negligent practice.

The physician should make every effort to assess the relationship of the alleged substandard practice to the patient's outcome. Deviation from a practice standard is not always causally related to a poor outcome.

Fees for expert testimony should relate to the time spent and in no circumstances should be contingent on outcome of the claim.

The physician should be willing to submit such testimony for peer review.

Box 10-2 Guidelines for Documentation

Preanesthesia Evaluation

Patient interview

Medical history (medication, allergies, family history of anesthesia problems, pertinent review of systems)

Anesthetic history

Medication history

Appropriate physical examination (including pertinent negatives)

Review of objective diagnostic data (e.g., laboratory, electrocardiogram, radiographs)

Assignment of American Society of Anesthesiologists Physical Status

Formulation of the anesthetic plan and discussion and documentation of the risks and benefits of the plan with the patient

If appropriate, explanations of what may be considered atypical choices of the anesthesiologist or the patient

Intraoperative/Procedural Anesthesia (Time-Based Record of Events)

Immediate review before initiation of anesthetic procedures

Patient re-evaluation

Check of equipment, drugs, and gas supply

Monitoring of the patient

Amounts of drugs and agents used and times of administration

Type and amounts of intravenous fluids used, including blood and blood products, and times of administration

Estimated blood loss and urine output

Specifics about the technique or techniques used

Unusual events during the administration of anesthesia, including explanation of recognition of the event, treatment of the event, and outcome of the event

Status of the patient at the conclusion of anesthesia

Postanesthesia Evaluation

Patient evaluation on admission and discharge from the postanesthesia care unit

Time-based record of vital signs and level of consciousness

Time-based record of drugs administered, their dosages, and routes of administration

Type and amounts of intravenous fluids administered, including blood and blood products

Any unusual events, including postanesthesia or postprocedural complications

Medical interventions

Postanesthesia visits

Data from references 23-25.

treatment, and the current interpretation (including differential diagnoses) and planned treatment of the decreased urine output. The anesthesia record should contain certain information (Box 10-2).[25,26]

Countersuits such as abuse of process, malicious prosecution, and defamation have been consistently rejected by the courts.[27] From a public policy perspective, the courts may be concerned that abuse of countersuits may limit the ability of plaintiffs to seek redress.

Apology and Disclosure

Although often inappropriately conflated, an apology, an expression of regret or sorrow, is distinct from disclosure, which is a revelation about what happened. Apologies and disclosures may occur at the same time.

More than half the states have laws prohibiting an admission of apology or sympathy as evidence of wrongdoing.[19] Some recommendations suggest apologizing for the effect on the patient without admitting fault. Sometimes this may make sense, for example, if a previously acceptable antibiotic caused a rash. However, not to take responsibility may seem stilted, such as when an anesthesiologist errantly administers an antibiotic to a

patient for whom there is clear documentation of an allergy. In the name of good relationships with patients, apologies should not be limited solely to events that may result in a suit. For example, consider a 6-year-old who on initiation of mask induction starts to scream and cry uncontrollably. After a discussion with the father who is present, a decision is made to, in essence, hold her down and apply the mask. A follow-up discussion with the family may include an apology not only for the induction ("I am sorry that was so unpleasant for Becky and you.") but also to acknowledge that this was not the desired reaction ("That is not our goal for induction. We would like it to be smoother." and "Going without sedation turned out to be a mistake."), as well as a recommendation for the future ("In the future, I would recommend giving oral sedation before going to the operating room."). Although this technically seems to admit wrongdoing, it is simply acknowledging what happened and educating the family for the future.

Although it is my belief that it is better to apologize, there are concerns about apologizing. The action for the physician, particularly if the apology is not readily accepted, may be painful. An apology may also embolden an otherwise unsure plaintiff, and it may be construed as admission of error in court.

It is more complicated whether one should admit fault for something that more likely may be medically negligent. Consider, for example, repeated attempts to place an epidural in a patient who is anesthetized and has previously undergone back surgery. The anesthesiologist tries repeatedly without success and without incorporating other methodologies such as fluoroscopy. The patient awakes with a nerve injury consistent with wayward insertion of an epidural needle. Some would suggest that although it is acceptable to express sympathy for the pain and discomfort ("I am sorry for your discomfort."), it would be legally harmful to acknowledge fault and a desire to do it differently ("I am sorry about your injury. In retrospect, although I am not sure what happened, I suspect that it was due to the needle placement. I should have used direct imaging of the back, such as fluoroscopy."). Others would suggest that the second apology with the disclosure is better because it explains what happened, why it happened, and how it may be prevented in the future. Although this combination of disclosure and apology admits culpability, it discloses only information that would eventually be discovered. I would suggest that the potential advantages gained by a genuine apology outweigh the potential harm of admitting culpability.

Full disclosure is gaining favor. From a wholly practical point of view, the patient will eventually learn what was withheld and will wonder, probably with animosity, why such information was not disclosed. Disclosure may have three components.[28] On realization of the problem, the goal is to give as much information as known, but not to speculate about what is not known, particularly about fault. Physicians should clarify the medical implications of the event, any necessary treatment or follow-up, and who will function as a contact for the patient regarding the event. The next step should be to conduct a thorough investigation with an eye toward minimizing problems in the future. Finally, the patient should be informed about what the investigation found, including the cause of the event and how it will be prevented in the future.

It is not unreasonable to consider responding to patient dissatisfaction by waiving part or all of a bill. This is not generally considered an admission of liability, and it may help satisfy a patient.

Legal Aspects of Informed Consent

Until the 1950s, physicians routinely obtained assent, or general agreement of the patient to have a procedure. The 1957 legal case *Salgo v Trustees of Leland Stanford Hospital* codified the modern concept of informed consent. The judge clarified the difference between informed consent and assent by declaring, "A physician violates his duty to his patient and subjects himself to liability if he withholds any facts which are necessary to form [the] basis of an intelligent consent by the patient to a proposed treatment. . . ."[29]

The goal of informed consent is to maximize the ability of the patient to make substantially autonomous informed decisions. The modifier "substantial" is used because it is unreasonable to expect a patient to be fully informed. The more appropriate goal of substantial informed consent acknowledges that consent may be sufficiently autonomous even if not completely informed. Modern informed consent has seven components.

Components of Informed Consent

Decision-Making Capacity

Decision-making capacity is defined as the ability to make a particular decision at a specific time. Evidence of decision-making capacity includes the ability to understand medical problems, proposed treatments, alternatives, options to refuse treatment, and the foreseeable consequences of accepting or refusing any proposed treatments, as well as the ability to express a preference based on rational, internally consistent reasoning. Decision-making capacity is distinct from the legal concept of competency. Courts determine competency and often make a global determination of competency by declaring that a person is either competent or incompetent for all matters. Adults are presumed to be legally competent unless declared otherwise by a court. On the other hand, anesthesiologists are responsible for assessing decision-making capacity and can make this determination only for specific situations.

Anesthesiologists should permit patients to make decisions to the extent of their ability.[30] For most patients, there are no questions about decision-making capacity. However, anesthesiologists need to actively evaluate the decision-making capacity of patients whose decision-making capacity has been temporarily altered, who do not have legal decision-making authority, or who have preexisting limitations in decision-making capacity. Consider a patient who has received pain medication before giving informed consent. The level of impairment varies depending on the medication, the tolerance of the patient to the medication, and the decision to be made. Indeed, some patients, such as parturients, may have improved decision-making capacity when the pain is decreased. To determine whether a patient has decision-making capacity for a specific decision, anesthesiologists need to balance the medication given and its expected effects with the ability of the patient to show evidence of rational reasoning and understanding. When a patient has temporarily lost decision-making capacity, such as when anesthetized, anesthesiologists should not implement nonemergency care until after the patient regains decision-making capacity and gives consent.

However, in emergencies, anesthesiologists should proceed without obtaining informed consent, based on the presumption that patients want life-sustaining treatment unless they have declared otherwise.[31]

Voluntariness

Physicians should perform procedures only on competent patients who participate willingly. Anesthesiologists compromise voluntariness through manipulation and coercion. Manipulation involves the deliberate distortion or omission of information in an attempt to induce the patient to accept a treatment, such as downplaying or omitting information to influence a patient to make a specific decision. Coercion involves the use of a credible threat to ensure complicity.

Anesthesiologists also hinder voluntariness when they physically restrain or sedate patients who have sufficient decision-making capacity. Competent patients have the legal and moral right to refuse treatment, even in life-threatening emergency situations. It is often hard for physicians to accept that a patient wishes to make what the physician perceives to be a foolish decision. *Shine v Vega* illustrates the complexity of these situations.[32] In 1990, Shine, a competent adult, went to the hospital and received oxygen and an unspecified medication for an asthma attack. Vega, the emergency department attending physician, thought that she was very ill and recommended endotracheal intubation. Shine stated her long-standing refusal of endotracheal intubation (confirmed contemporaneously by her sister and father) and continued to receive oxygen by mask. Later, Shine's sister came into her room in the emergency department and noted that Shine was breathing more easily but was arguing with staff. Shortly thereafter, Shine and her sister attempted to leave but were forcibly detained by a physician and security. Shine was placed in four-point restraints and Vega, choosing to disregard Shine's objection, intubated her trachea. On appeal, the Massachusetts Supreme Court stated that a competent patient has a right to refuse potentially life-sustaining treatment, even if her decision is considered unwise.

Another issue of voluntariness occurs when the interests of a woman and her fetus differ. When a woman refuses a recommended diagnostic or therapeutic procedure, such as cesarean delivery for fetal indications, physicians may choose to respect the patient's autonomy and not proceed, encourage the woman to seek health care elsewhere, or seek judicial involvement. Before seeking judicial involvement, physicians should consider the social, physical, and psychological harm of violating individual liberty and the fallibility and limitations of medical knowledge. Physicians may want to seek judicial involvement only when they are highly confident that the recommended treatment will substantially reduce harm to the fetus, that the risks to the woman are relatively small, and that no comparably effective, less-intrusive option exists.[33] Particularly relevant to anesthesiologists is the American College of Obstetricians and Gynecologists position on forced cesarean section. "Even in the presence of a court order authorizing intervention, the use of physical force against a resistant competent woman is not justified. The use of force will substantially increase the risk to the mother, thereby diminishing the ethical justification of such therapy."[33]

Disclosure

The goal of disclosure is to provide information relevant to the decision-maker and the decision to be made. Skilled disclosure builds trust, helps patients make good decisions, and is a fundamental component of the obligation to respect a patient's autonomy.

Established in 1972, the reasonable person standard requires that the extent of the disclosure be based on what a reasonable person would consider material for choosing whether to undergo the proposed intervention.[34,35] Informed consent discussions should routinely include the specific risks and benefits of reasonable anesthetic options and monitoring techniques, as well as the presence and use of a fallback plan.[31] Anesthesiologists may want to inform patients of common, but less severe risks, such as postoperative nausea and vomiting, and uncommon risks of more long-term significance, such as brain injury and death. If appropriate, the patient should be informed of the quality of the data, such as whether the information has questionable certainty. Anesthesiologists should also inform the patient whether an individual or an anesthesia care team will be providing anesthesia services and, if the latter, the names and specific roles of the team members. It may be appropriate to inform patients if the anesthesiologist is inexperienced in a particular situation.[36] To maintain good relationships with patients, they should be told about other practical matters, such as the probable sequence of events on arrival at the surgical unit, who will be with them at the various stages, what to expect for postoperative pain management, and realistic time estimates.

Exceptions to the obligation to disclose material information include patients who choose not to be informed, emergencies in which a valid informed consent cannot be obtained, and situations of therapeutic privilege. Physicians use therapeutic privilege when they choose to withhold information because they believe that disclosure would cause the patient to become "so ill or emotionally distraught on disclosure as to foreclose a rational decision, or complicate or hinder treatment, or perhaps even pose psychological damage to the patient."[34] Therapeutic privilege has a narrow scope and should be used prudently. Simply because information is undesirable or upsetting to the patient does not mean that such information should be withheld. For example, it may be reasonable to invoke therapeutic privilege when discussing the risk of death with a patient who is having an acute infarction of his myocardium; it would not be reasonable to do the same when discussing the risk of death with the parents of an infant.

Recommendation

Anesthesiologists should offer an opinion about which options are preferable and the advantages and disadvantages of each option. By explaining the value judgments and the quality of data supporting their opinions, anesthesiologists allow the patient not only to receive the benefit of their expertise but also to understand the reasons for the recommendations. Patients can then decide for themselves which choices best fit their priorities.

Understanding

Patients need to understand the risks and benefits of the proposed procedures, the recommendations made, and why those recommendations were made. It is difficult to determine whether a patient fully understands the informed consent discussion, and indeed, many patients may not.[37,38] Pain and distress do not seem to compromise the ability to recall risks, particularly among parturients, and do not preclude obtaining a legally sufficient informed consent.[39-41]

Decision

After considering the information and the anesthesiologist's recommendation, the patient chooses an anesthetic technique. Patients vary in their preferences for participation in decision-making, and anesthesiologists should be sensitive to these preferences. The desire to participate in the decision-making process may be a function of the individual, extent of illness, gender, age, and level of education. Anesthesiologists should attempt to tailor the extent of patient and physician decision-making to the patient and the situation.

When a patient refuses an anesthesiologist's recommendation or requests a technique that the anesthesiologist believes is inappropriate, the focus of conversation moves from informed consent to informed refusal. Informed refusal requirements are similar to informed consent requirements in that the patient should be substantially well versed about the risks, benefits, and alternatives before declining. However, although it may be reasonable to permit a patient agreeing with a recommended or acceptable procedure to refuse extensive information (especially if the likelihood of harm is low), it is more difficult to honor a patient's preference to receive limited information when the patient desires a suboptimal approach.[42] The anesthesiologist may wish to provide additional information about the choice to be sure that the patient has all possible information. If in fact the patient chooses without sufficient information, the anesthesiologist has not fulfilled the obligation of informed refusal. Of course, a patient may still refuse to hear information. In either case, when a patient chooses a technique that the anesthesiologist believes is inappropriate, anesthesiologists are not obligated to provide care in nonemergency situations.

Autonomous Authorization

The informed consent process concludes with the patient intentionally authorizing the anesthesiologist to perform a specific procedure. This authorization is the expression of the patient's self-determination and is the basis of informed consent.

Documentation of Informed Consent

In practice, informed consent for anesthesia may be documented on the surgical consent form, by a handwritten note, or by a separate anesthesia consent form. Use of a surgical consent form is suboptimal because surgeons cannot capably discuss the risks associated with anesthesia and therefore it is unclear what is being documented. Both handwritten notes and anesthesia consent forms may be acceptable. Handwritten notes detail specific discussions with patients. Writing a note for each patient, however, may be impractical and time consuming and may miss key aspects of informed consent. Anesthesia consent forms may act as a prompt for anesthesiologists to discuss key aspects of informed consent. Space for handwritten notes on the consent form will permit additional details to be documented. Having the patient sign the handwritten consent or the consent form gives an indication that some form of communication took place. However, because consent forms by themselves do not fulfill the legal requirement of informed consent, an informed consent discussion must still occur.

Theories of Suit in Informed Consent

Negligence related to the informed consent process may occur if the anesthesiologist provides a disclosure that is insufficient to allow a patient to make an informed decision and an injury subsequently occurs, even if the injury was foreseeable and occured in the absence of a treatment error.[31] To determine whether sufficient information was given, the courts look for materiality and causation. Materiality assesses whether the information given met the standard of care. If the disclosure did not meet the standard of care, it may be considered a breach of duty. Causation then assesses whether sharing the omitted information would have caused the patient to choose a different option.[31] Most jurisdictions use the objective standard, which bases causation on whether a hypothetical reasonable person would have used the additional information to make a different decision. Some jurisdictions use the subjective standard, which is contingent on whether the specific patient involved would have made a different decision. A few jurisdictions combine the two standards by heeding the objective standard while considering factors specific to the patient and situation. Courts also consider how the information was given. The informed consent discussion should occur in a setting conducive to decision-making so that the patient has a chance to ask questions and consider answers.

The disclosure process is not intended to be armor against medical malpractice liability if an adverse event takes place. Informing a patient about a risk does not eliminate liability for its occurrence. Liability is based on negligence theory and depends mainly on whether the standard of care was met and whether failure to meet the standard of care was a proximate cause of the injury.

Refusing to Provide Care

Anesthesiologists may refuse to provide care when they ethically or morally disagree with the procedure or situation, such as elective termination of pregnancy.[43] Although physicians have an obligation to altruistically provide care, this requisite does not always oblige physicians to subjugate their morals. Furthermore, society and medicine have a fundamental interest in preserving the moral fabric of individual physicians. Anesthesiologists should provide care that violates their conscience and possibly weakens their moral constitution only in critical, presumably life-or-death, circumstances. More practically, an anesthesiologist who ethically or morally disagrees with a patient's choice will have difficulty providing the care requested. In a nonemergency situation, such an anesthesiologist should withdraw from or refuse patient care. The anesthesiologist may then be obligated to make a reasonable effort to find a competent and willing replacement.

Physicians may also ethically refuse to provide care if they believe that the patient's choice is too inappropriate or likely to result in harm. Determining that a choice of anesthesia is inappropriate is difficult and should not be invoked lightly or out of convenience. The patient's choice and the resultant risks must be sufficiently extreme that they, say, elicit a similar response from at least several other anesthesiologists. In addition, anesthesiologists may refuse to provide care if they do not feel qualified to provide the needed care.

Legal Aspects of End-of-Life Care

Acknowledgement of patients' rights to refuse life-sustaining treatment began in the mid-20th century with the rise of civil liberties, individual rights, and respect for the importance of self-determination (see Chapters 91 and 98). In 1974, the American Medical Association asserted that "the purpose of cardiopulmonary resuscitation is the prevention of sudden unexpected death. Cardiopulmonary resuscitation is not indicated in cases of terminal irreversible illness where death is not unexpected."[44] Policies acknowledging the need to permit patients to limit resuscitation during terminal illness were prominently published several years later.[45]

Progression of the rights of the individual to refuse potentially life-sustaining care may be seen through case law. The 1976 case of Karen Ann Quinlan first established the right to refuse potentially life-sustaining care. In *Quinlan*, the courts upheld the legality of disconnecting the ventilator from a patient thought to be ventilator dependent and in a permanent vegetative state.[46] The court based this decision on the general constitutional right to privacy. In addition, the court determined that a surrogate had the right to decline medical treatment for an incompetent patient if the surrogate concluded that the patient would have preferred limited care. Quinlan's father thus discontinued his daughter's mechanical ventilation. Quinlan lived for nearly a decade sustained by nasogastric feeding.

The right of a competent person to refuse potentially life-sustaining care was established in the 1984 case of *Bartling v Superior Court*.[47] Bartling was a competent adult patient with an incurable disease who for 6 months received medical therapy against his clear wishes. After pneumothorax from a needle biopsy, Bartling became ventilator dependent. He subsequently received a tracheotomy to facilitate weaning attempts. During this ordeal, Bartling made clear his desire not to receive continued therapy and declared at one point, "While I have no wish to die, I find intolerable the living conditions forced upon me . . . ."[47] Although Bartling died before his case could be adjudicated, the appellate court issued an opinion based on the constitutional right of privacy that supported the right of a competent patient to refuse medical treatment.

The 1990 case of *Cruzan v Director, Missouri Department of Health*, concerned a young woman involved in an automobile accident that left her incapable of expressing a preference.[48] Several years before the accident, Cruzan had expressed to a friend in a somewhat serious conversation a desire not to live in a state of diminished capacity. The Supreme Court of Missouri held that Cruzan's informal statements did not meet Missouri's evidentiary standard of "clear and convincing evidence" of a patient's wish to terminate potentially life-sustaining care and thus mandated continuation of treatment. The case was appealed to the U.S. Supreme Court.[49] Unlike *Quinlan* and *Bartling*, the Supreme Court grounded the right of a competent patient to refuse treatment on the liberty interest of the Fourteenth Amendment, which states, "No State shall make or enforce any law which shall abridge the privileges or immunities of citizens of the United States; nor shall any State deprive any person of life, liberty or property . . . ." The decision also upheld the rights of states to determine standards for the level of certainty required, thereby permitting Missouri to use the "clear and convincing evidence" standard.[48,50]

Competent patients have a virtually unlimited right to refuse life-sustaining medical treatment.[51] For an incompetent patient, three hierarchic levels of judgment direct the decision-making process for end-of-life care. A once-competent patient's previously expressed preferences for end-of-life care should be followed as best as possible. When the patient's declared preferences are not known, substituted judgment, or use of a surrogate's intimate knowledge of the patient's attitudes and beliefs to determine what the patient would have chosen, may be used to direct care. Despite being two distinct categories, both levels require the surrogate to know the patient sufficiently to appropriately choose or interpret the patient's preferences. These standards put significant burdens on decision-makers, who may have legitimate doubts about the appropriateness of their decisions. When a surrogate has to make decisions for a patient who has never been competent, such as a young child or a mentally disabled adult, substituted judgment is impossible, and the surrogate must rely on the best interests standard. The best interests standard requires the surrogate to make decisions based on the surrogate's view of what is best for the patient.

Advanced Care Planning

Advanced care planning permits patients to declare preferences for medical treatment if they become incapacitated. Advance directives are designed to minimize the likelihood of undesired overtreatment and undertreatment. Partially as a result of *Cruzan*, the Patient Self-Determination Act (PSDA) was introduced in 1990 to increase the use of advance directives.[52] The PSDA requires health care institutions, such as hospitals, nursing homes, and hospice programs, to notify individuals about their rights regarding advance directives. Two types of advance directives are living wills and health care proxies (also known as durable power of attorney for health care decisions). Living wills allow patients to declare the extent of desirable interventions, but they may not be able to directly address the subtle differences that characterize clinical situations. The difficulty of applying living wills to clinical situations has led some to prefer the greater flexibility provided by the health care proxy, in which the surrogate decision-maker can consider the specific details when making clinical decisions. Health care proxies permit patients to designate surrogate decision-makers (including non–family members) to make decisions for them should they become unable to make such decisions for themselves. If the patient does not assign surrogacy, most jurisdictions have a hierarchy for assigning surrogacy. Surrogacy is not always effective, particularly for patients who do not make their preferences clearly known to the surrogate before losing their decision-making capacity.[53] Given the strengths and weaknesses of each approach, a combination of the two (a designated proxy with some written form of preferences) may be the best option.

Clinically, advanced care planning should be considered an ongoing process, with the advance directive being used in conjunction with family and friends to help guide the decision-making of patients and surrogates.[54,55] Competent patients may obviously modify their previously declared preferences. Demented patients who previously made an informed choice to limit certain therapy may express an interest in receiving that therapy.[56] If

patients have evidence of decision-making capacity, such as being able to provide internally coherent reasoning, their wishes to receive therapy should be honored. However, the process of resolving this situation in a patient without decision-making capacity and with almost no likelihood of regaining decision-making capacity is more complex. In this situation it is better to base judgment on therapy from multiple sources, including significant others, the type of documentation, and the best interests standard.

Refusal of Cardiopulmonary Resuscitation

The right of a patient to reject unwanted therapy in the operating room is now well accepted. Before proceeding to the operating room, preoperative do-not-resuscitate orders should be re-evaluated in light of the surgical procedures, the anesthetic options, and the patient's overall goals. Anesthesiologists are then prepared to clarify and document the desired resuscitation status in the operating room by using either the goal-directed approach or the procedure-directed approach.[57] The process of obtaining and documenting perioperative refusal of resuscitation should comply with hospital policy and jurisdictional law. Written documentation may include the patient's diagnosis and prognosis, the characteristics of perioperative resuscitation, probable outcomes, and the patient's reasoning. If the decision is being made by a surrogate, the record should note the surrogate's relationship to the patient and the basis of the surrogate's decision. It should be signed by the responsible physician.

Refusal of resuscitation in an emergency situation without time to clarify a patient's wishes is inherently different. The traditional bias of providing treatment in the absence of a clear decision not to treat still holds for the anesthesiologist in an emergency situation. The situation can always be clarified later and the patient withdrawn from the ventilator if it is determined that the patient would have preferred not to receive the interventions. In short, the "inconvenience" of a short period of mechanical ventilation is worth the opportunity to correctly ascertain the patient's desires.

The Demand for Life-Sustaining Therapies

Patients or families may demand therapies that clinicians believe are inadvisable because of burden to the patient, cost, or uncertain benefit. When such situations become irreconcilable, the cases may go to court, often not to determine what therapy should be given but to determine who should be the decision-maker for a noncompetent person. For example, an archetypic case involves Helga Wanglie, an 86-year-old patient in a persistent vegetative state who was receiving mechanical ventilation. The medical center believed that further therapy would be futile for Mrs. Wanglie and wanted to withdraw mechanical ventilation. When Mr. Wanglie refused the medical center's request to stop mechanical ventilation, the medical center sought appointment of an independent guardian to supplant Mr. Wanglie as her guardian. The Court declared that Mr. Wanglie was best able to be Mrs. Wanglie's surrogate.[58,59]

In the 1995 case of *Gilgunn*, a jury supported a unilateral refusal of life-sustaining care. Catherine Gilgunn had multiple medical problems, including severe brain damage, and was in a coma.[60] Her daughter Joan, representing the family, requested that everything be done. The Optimum Care Committee of the hospital agreed with the physicians that providing cardiopulmonary resuscitation would be futile in the sense that it was not a genuine therapeutic option. The legal division approved the do-not-resuscitate order because they believed that the physicians were acting in the patient's best interest. Gilgunn was disconnected from ventilator support and died a few days later. The jury supported the actions of the physician and hospital to impose a unilateral do-not-resuscitate order. There was no appeal.

Despite *Gilgunn*, unilateral physician declarations are insufficiently respectful of patient autonomy and may be legally risky. Evidence indicates that negotiation nearly always resolves these problems without the need to resort to unilateral action. However, being able to resolve differences of opinion about applying treatments with a low likelihood of success is important. Policies for resolution based on a procedural approach in which the process for resolving conflict is described are more practical. Good policies are public, reflect the moral values of the community, and include processes for identifying stakeholders, for initiating and conducting the policy, for commencing appellate mechanisms, and for determining relevant information.[61] In a different approach, the Texas Advance Directives Act permits physicians to unilaterally withhold or withdraw treatments that they regard as "futile," provided that they follow guidelines, including obtaining agreement of the hospital ethics committee.[62]

Physician-Assisted Suicide

Physician-assisted suicide is the act of a physician prescribing lethal quantities of medication for self-administration by the patient. In the United states in the cases of *Washington v Glucksberg*[63] and *Vacco v Quill*,[64] the courts held that there was no constitutional right to physician-assisted suicide. It is important to recognize that the courts followed common ethical opinion in drawing a distinction between the positive right to demand an action, such as physician-assisted suicide, and the more powerful negative right to be free of bodily invasion. Although there was no constitutional right to assisted suicide, individual states may choose to legalize or prohibit it.[65] In 1997, Oregon legalized the Oregon Death with Dignity Act, which permitted terminally ill patients to receive prescriptions in lethal quantities for the purpose of self-administration. It does not permit any other forms of physician aid-in-dying, such as another person administering the medication. From 1998 through 2006, 292 patients used 456 prescriptions authorized by this law. The most common diseases in patients choosing to ingest a lethal dose of medication were malignant neoplasms (81% of patients), amyotrophic lateral sclerosis (8% of patients), and chronic lower respiratory tract diseases (4% of patients).[66] In 2006, 40 physicians wrote 65 such prescriptions. Of these 65 patients, 35 used the prescriptions, 19 died of their underlying disease, and 11 lived throughout the year.[66] The financial and educational status of patients did not seem to play a role in the request for physician-assisted suicide.

Other Legal Aspects of Anesthesiology

Care of Jehovah's Witnesses

Jehovah's Witnesses interpret biblical scripture to prohibit taking in blood because it holds the "life force," and anyone who partakes of it shall be "cut off" from eternal life after death (see Chapter 55).[67] Jehovah's Witnesses have different interpretations about the prohibition of blood transfusions, and anesthesiologists must actively clarify what the patient considers acceptable.

Wholly acceptable anesthetic techniques to reduce blood loss include deliberate hypotension, deliberate hypothermia, and hemodilution. Most Jehovah's Witnesses accept synthetic colloid solutions, dextran, erythropoietin, and preoperative iron. Some Jehovah's Witnesses accept autologous banked blood or cell saver blood, and some accept blood removed at the beginning of surgery and returned in a closed loop. Jehovah's Witnesses will colloquially refer to options that are a matter of individual choice as "matters of conscience." Although blood components, autologous blood, and banked blood are generally unacceptable, these specifics must be discussed with the patient. Documenting acceptable interventions crystallizes the patient's desires and provides legal documentation for the anesthesiologist. Anesthesiologists must be certain that they are capable of fulfilling the patient's requests; otherwise, they should not agree to provide anesthesia. Indeed, the anesthesiologist and surgeon should provide nonemergency care to the patient only if all parties can agree on the approach to blood management.

Case law strongly supports the right of an adult patient to refuse blood products. Case law is in flux for pregnant patients, and in such cases the courts are more likely to intervene and mandate transfusion. The ambiguity in legal rulings results from the fact that issues relating to transfusions in Jehovah's Witnesses are based on case law.

Law Regarding Pediatric Patients

For the most part, parents or other surrogate decision-makers of children make health care decisions for minors (in general, children younger than 18 years) (see Chapters 82 and 84). However, the participation of children should increase as they grow older and depends on both the patient's maturity and the consequences involved in the decision. Informed assent acknowledges that although most pediatric patients cannot legally consent to medical care, they should share in decision-making to the extent that their development permits.

Some minors are permitted to consent for themselves.[68] Emancipated minors are patients younger than 18 who have been given the global right to make their own health care decisions. This status varies by state but is generally awarded to patients who are married, parents, in the military, and economically independent and may include patients who are pregnant. The mature minor doctrine holds that minors who have decision-making capacity are legally and ethically capable of giving informed consent in specific situations as determined by a court. Although particulars vary, the mature minor doctrine in general requires patients to be at least 14 years old and tends to permit decisions of lesser risk. The nearer the child is to the age of majority, the more likely the court is to grant the child the ability to consent. The courts will balance the maturity and decision-making capacity of the minor and the risks associated with honoring the minor's wish. As minors near the age of majority, the likelihood increases that the court will support the right of minors to determine therapy. For example, in a case in 2007 that seemed to be on the margin, a judge ruled that a 14-year-old practicing Jehovah's witness would be permitted to refuse transfusion therapy during treatment for a cancer that had a 70% 5-year survival rate. The patient subsequently died.[69]

Even though pediatric patients who are pregnant may be considered emancipated, many states require some form of parental involvement, such as parental consent or notification, before an elective abortion in an adolescent. If a state requires parental involvement, the ability of the minor to circumvent this regulation by seeking relief from a judge, known as judicial bypass, must be available. Requirements and enforcement of statutes vary from state to state. The need for parental involvement in minors having abortions is not always legally straightforward, and it may be best to consult with hospital counsel when determining such issues.[70,71]

Parents and medical personnel may disagree about what is in the best interests of the child. Based on the legal doctrine of *parens patriae*, or the government's obligation to protect the interests of incompetent patients, parents are not permitted to make decisions that are grossly inappropriate overtreatment or undertreatment.[72,73] One way to decide what is in the best interests of the child is to define which choices fall outside the range of acceptable decision-making. The extent to which one intervenes between a patient and the surrogate's decision depends primarily on how harmful the decision is to the patient. Criteria to make this determination include the amount of harm to the child by the intervention or its absence, the likelihood of success, and the overall risk-to-benefit ratio.[74] Charging a parent of not acting in the child's best interests has significant social, fiscal, and familial ramifications. If, however, after exhausting other options the anesthesiologist believes that the parent has chosen unacceptable treatment, the anesthesiologist should report the situation to the proper child welfare authorities for possible legal action.

For anesthesiologists, this is most frequently seen when courts overrule parental wishes and permit transfusion therapy in the children of Jehovah's Witnesses.[75,76] Anesthesiologists caring for a child of a Jehovah's Witness should inform the patient and family that attempts will be made to limit the need for transfusion therapy and abide by their transfusion preferences but that in a life-threatening situation, the anesthesiologist will seek a court order authorizing the administration of life-sustaining blood. In instances in which the likelihood of requiring blood is high or the local judiciary is not that familiar with case law for Jehovah's Witnesses, the anesthesiologist may choose to obtain the court order before the operation. In crisis situations in which no court order exists, anesthesiologists should initiate emergency transfusion therapy before obtaining a court order. As a child becomes older, the courts become less likely to intervene and often grant the emerging adolescent more decision-making latitude. In elective procedures that may be safely delayed, the patient and family may also consider postponing the procedure until the child is of sufficient age and maturity to decide about transfusion therapy.

Supervision and Professional Associations

Attending physicians may be sued because of resident actions. The question of what is considered acceptable resident supervision is affected by local policies and national guidelines, but again, in any individual case, the standard of care is often determined by a jury. Specific guidelines about what trainees are permitted and not permitted to do may provide some protection for the attending physician if the trainee deviates from these guidelines. In addition, residents are being named in lawsuits with increasing frequency. As a general rule, a resident is held to the same standard of care as a practicing attending physician in that specialty.[77]

Under the doctrine of *respondeat superior* and the theory of *vicarious liability*, anesthesiologists are responsible for negligent acts made within the scope of defined duties by certified registered nurse anesthetists.[78] The fundamental issue of vicarious liability is whether the anesthesiologist is controlling the activities of the certified registered nurse anesthetist. Although the question of vicarious liability may depend on who remunerates the certified registered nurse anesthetist, this is likely to be an ineffective defense because anesthesiologists tend to have full authority to medically direct certified registered nurse anesthetists. The scope of defined duties and whether adequate supervision took place may be affected by societal expectations, medical customs, history, practice, manuals, agreements, actions, expert analysis, and written documentation, but it is ultimately determined by a jury in any individual case. For example, in one case, a certified registered nurse anesthetist did not promptly summon the anesthesiologist for help in managing fatal postoperative laryngospasm and bronchospasm.[78] The anesthesiologist was found vicariously liable for negligence, in part because there was a lack of clear understanding between the professional group and certified registered nurse anesthetist about when the anesthesiologist should be called.[79,80]

Many controlling authorities (e.g., state statutes or hospital bylaws) require physicians to participate in certain aspects of anesthesia care when supervising certified registered nurse anesthetists. It is also the responsibility of the professional association to set forth the expectations in a manner that is consistent with law and regulations. Accepting a standard below medically communicated published standards (such as American Society of Anesthesiologists guidelines) risks liability.

Federal regulations for accreditation of hospital and ambulatory surgery facilities require that a certified registered nurse anesthetist be supervised by the physician performing the procedure or an immediately available anesthesiologist.[81,82] State governors may "opt out" of this supervision requirement if they deem doing so to be in the best interests of their citizens. For the opt-out to have practical consequences, however, state laws must also not require supervision. Health care facilities within states that have opted out may still require supervision. To bill for medically directing certified registered nurse anesthetists, anesthesiologists must participate in specific parts of the case.[83]

Anesthesiology professional associations may be held liable if they do not ensure that members are competent and that appropriate policies are followed.[84] Many agreements between professional associations and hospitals require service that complies with governmental and professional standards.[84] Obligations of professional associations may extend to letters of reference. For instance, an anesthesiologist was terminated with cause secondary to abuse of Demerol.[85] When the anesthesiologist went to a locum tenens company, letters of reference from shareholders of the previous professional association did not mention the abuse or that the anesthesiologist was fired with cause. Subsequent negligent care by this anesthesiologist caused severe brain damage to a patient. The court held that the previous professional association was liable for part of the financial award.

Professional associations are responsible for addressing physician impairment. An impaired physician is one who is unable to perform professional or personal responsibilities. Physicians impaired through alcohol and other addictive disorders are considered to have chronic medical illnesses. The Americans with Disabilities Act forbids discrimination against individuals who are in recovery[86] and government agencies from receiving funding if they engage in discrimination. The treatment records of the physician are confidential.

Legal Issues in Pain Management

Inadequate pain management is a health problem, and part of the problem may be due to the tension inherent in unclear regulations, regulatory scrutiny, and criminal investigation and prosecution by state medical boards and drug enforcement agencies (see Chapters 58 and 87).[87,88] For example, the Drug Enforcement Administration's ability to electronically monitor prescriptions for controlled substances gives them access to physicians' prescription histories. Physicians are concerned that knowledge of prescribing practices, divorced from patient-specific context, will lead to misunderstandings and unwarranted investigations. Physicians' concern about being investigated may affect the doses, quantities, number of refills, or even the type of drug used in the care of chronic pain patients.[88] The Drug Enforcement Administration suggests that there should be no effect and has emphasized that only 0.06% of all physicians had investigations initiated, 0.05% of all physicians had actions taken against them, and 0.01% of all physicians were arrested.[89] However, the 0.06% may be fallaciously low because that percentage is out of all practicing physicians. A more relevant percentage would be based on a population of only physicians who prescribe narcotics for pain control and thus are at risk for investigation. A large percentage of the physicians investigated did have actions taken against them.

The *Gonzales v Oregon* decision should comfort physicians because it limits the effects of the Drug Enforcement Administration on physicians.[90] *Gonzales v Oregon* prohibited the U.S. Attorney General from prohibiting physicians in Oregon from prescribing schedule 2 drugs for terminally ill patients to commit suicide.[90] The point of the case is that Congress can set national drug-prescribing rules through the Controlled Substances Act but cannot affect the ability of states to set medical practice standards.[4] The case turns on the Controlled Substances Act. Although there were a number of reasons, the primary reason was that the Controlled Substances Act does not regulate the practice of medicine and, in fact, that the practice of medicine is to be regulated by the state.

Physicians have been held liable for inadequate pain control.[91,92] For example, an 85-year-old man was admitted to a medical center for 5 days in 1998 before his subsequent death several days later.[91] He received inadequate pain control during

Table 10-3 Data Banks

his admission. Although a medical malpractice suit was dismissed and the state medical board did not pursue any action against the physician, the family won a civil suit against the physician under the California's Elder Abuse and Adult Civil Protection Act.

Data Banks

Federal databases are designed to improve health care by tracking performance and flagging suspect health care practitioners and entities (Table 10-3).[93-95] By way of context, from 1991 to 2004, the National Practitioner Data Bank recorded 276,274 medical malpractice payments, 8297 of which were related to anesthesia. Over this time, the number of cases with payments has decreased, whereas the median payment has increased.[96]

11 Sleep, Memory, and Consciousness

Key Points

1. Sleep is an active process generated in the brain.
2. Structures in the brainstem, diencephalon, and basal forebrain control the sleep-wake cycle and are directly modulated by general anesthetics.
3. Sleep and anesthesia are similar states with distinct traits, with each satisfying neurobiologic features of the other.
4. Distinct memory functions are subserved by distinct neural structures.
5. Limbic system structures such as the hippocampus and amygdala are critical for memory and play a role in anesthetic-induced amnesia.
6. Although brainstem, diencephalon, and basal forebrain structures generate wakefulness, the contents of consciousness are thought to be generated by the cortex.
7. Multiple neural correlates of consciousness are thought to be the targets of general anesthetics.
8. Consciousness and subsequent explicit recall of intraoperative events—known as "awareness during general anesthesia"—occur in 1 to 2 cases per 1000.
9. Monitoring anesthetic depth has evolved to electroencephalographic methods, although limitations still exist.

Within 10 years of Morton's public demonstration of general anesthesia, ether, nitrous oxide, and chloroform were all in widespread use. The existence of three agents with diverse chemical structures led Claude Bernard in 1875 to speculate that the state of general anesthesia must arise through a common mechanism of action. Although decades of research have demonstrated multiple, nonoverlapping molecular targets for individual anesthetics (see Chapters 20 and 26) and appear to refute Bernard's hypothesis, a unitary network theory of anesthetic action remains possible from a systems perspective.

Traditionally, the state of general anesthesia is divided into various behavioral end points, including amnesia, hypnosis (defined as a lack of perceptive awareness to non-noxious stimuli), analgesia, immobility, and blunting of autonomic reflexes. These end points are produced by specific interactions of general anesthetics on discrete neuronal loci. Although volatile anesthetics come closest to being complete and thus capable of producing each of the components of the anesthetized state, the majority of anesthetic drugs fail to satisfy all criteria.

Nonetheless, diverse anesthetics acting at distinct receptor targets might produce common neurophysiologic adaptations in relevant circuits culminating in the behavioral end points that are recognizable as general anesthesia. This chapter considers two distinct anesthetic end points, hypnosis and amnesia. Using sleep as a paradigm to understand the system's neuroscience of control of the arousal state, the first section explores behavioral state transitions, as well as the effects of anesthetics on these circuits. The second section describes the neurophysiology and neurobiology of memory formation and concludes with a discussion of their modulation by anesthetics. Finally, in the last section we address the emerging science of consciousness and discuss how anesthetics reversibly alter its expression.

Neuronal Systems That Regulate Arousal States

Exquisite regulation of the arousal state confers a survival advantage. Predators who fall asleep during the chase may starve, whereas prey caught napping at inopportune times suffer an equally dire fate. Thus, the need to regulate the arousal state seems obvious for all. However, the requirement for sleep in the first place remains mysterious. Prolonged loss of sleep leads to impaired thermoregulation, metabolism, and immune function and, ultimately, to death.[1] Given the tremendous cost of sleep in terms of opportunity—time that might otherwise be spent seeking food or shelter or procreating—one might presume that it offers some as yet unclear selective advantage in an evolutionary sense.[2]

Recent hypotheses about the beneficial effects of sleep include restoration of the neuronal homeostasis essential for

synaptic function, consolidation of memories, and initiation and expression of neuronal plasticity (reviewed elsewhere[3-5]).

Whatever its true role, evolution has exerted a selective pressure on organisms to sleep (Table 11-1). Molecular, neuronal, and behavioral conservation of sleep implies that it also carried a survival advantage in ancestral mammals. Hence, it should not be surprising that the neuronal underpinnings for control of arousal lie in subcortical structures deep within the brainstem, thalamus, and hypothalamus in regions where they are conserved across the animal kingdom.

Table 11-1 Sleep Phylogeny—Hours Spent in Each Arousal State

Species	Waking	NREM	REM
Human	16	6	2
Guinea baboon	14.5	8.5	1
Sheep	18.1	5.3	0.6
Horse	20.5	2.5	0.5
Giraffe	19.5	4	0.5
Bottlenose dolphin	14	9.8	<0.2
Platypus	10	6	8
Thick-tailed opossum	6	11.4	6.6
Ferret	9.5	8.5	6
Cat	11	10	3
European hedgehog	13.9	6.6	3.5
Big brown bat	4.3	15.8	3.9
Armadillo	7	14	3
Rat	11	10.5	2.5

NREM, non–rapid eye movement; REM, rapid eye movement.

Passive versus Active Theories of Sleep

The discovery on which the neurobiology of control of the arousal state is built belonged to Frederic Bremer (1892-1982). In 1935, Bremer demonstrated that transection of the caudal medulla, although producing paralysis requiring mechanical ventilation, also produced an animal that remained alert, with normal sleep-wake cycles. Conversely, transection through the mesencephalon, immediately caudal to the nucleus of the third cranial nerve, yielded an animal that breathed spontaneously but was unresponsive and displayed a continuous sleep pattern in its electroencephalogram (EEG) (Fig. 11-1). Bremer's discovery formed the foundation for the passive theory of sleep. However, passive notions of sleep predate Bremer. The roots for this idea exist in the surviving sixth century BC writings of the Greek philosopher Alcemaeon and were known to Aristotle, who expounded on them in his treatise *De Somno et Vigilia* ("On Sleep and Waking"). Bremer's experimental evidence lent credence to the ancient Greek idea that sleep is caused by isolation of the brain from the rest of the body. Bremer hypothesized that sleep results anytime that the brain is deprived of its tonic sensory input. Under this passive view, sleep was nothing more than a default state produced by cessation of the active state—waking. A student of Bremer's, Giuseppe Moruzzi (1910-1986), fortified his mentor's hypothesis in collaboration with the physiologist Horace Magoun (1907-1991). Using electrical stimulation of the brainstem reticular formation (which falls in between Bremer's mesencephalic and caudal medullary lesion sites), Moruzzi and Magoun stimulated wakefulness while suppressing sleep and in so doing made the first description of the ascending reticular activating system.[6] Together, they also narrowed the window for inducing a persist-

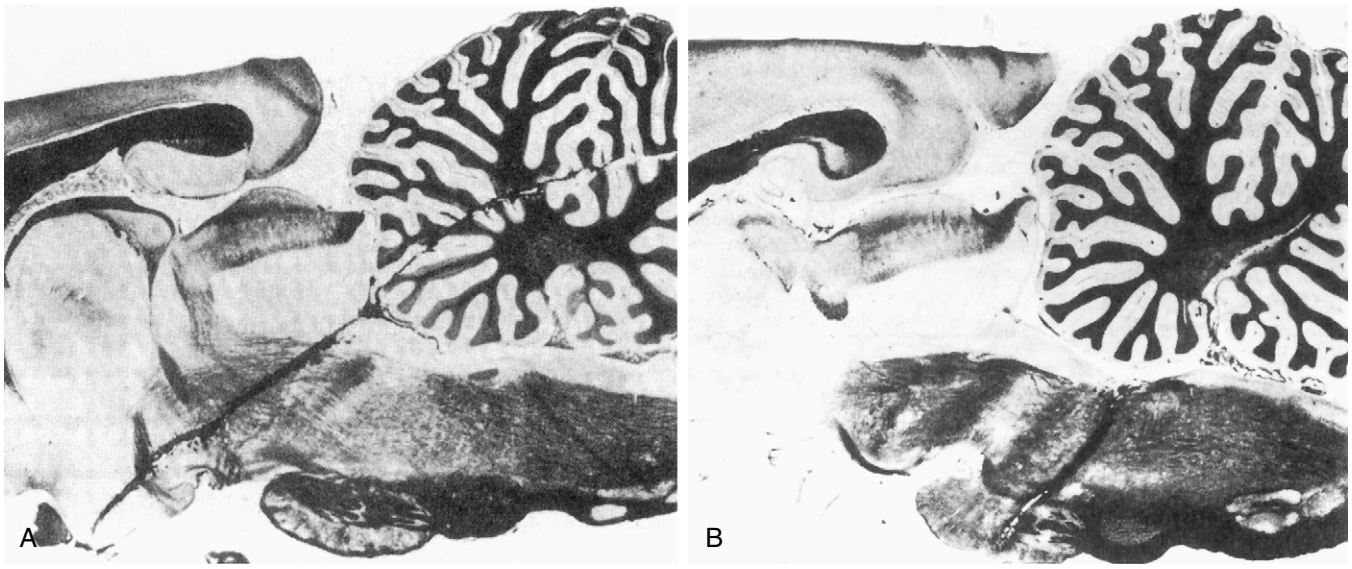

Figure 11-1 Brainstem transections may radically alter the state of arousal. **A,** Bremer's cerveau isole cat in which transection at the collicular level prevents brainstem and hypothalamic arousal-promoting signals from reaching the forebrain, thereby producing a state of deep coma. **B,** This contrasts with the enephale isole cat, in which transection through the caudal medulla disrupts spontaneous ventilation but leaves control of the arousal state intact. *(Modified from Steriade M, Constantinescu E, Apostol V: Correlations between alterations of the cortical transaminase activity and EEG patterns of sleep and wakefulness induced by brain-stem transections. Brain Res 13:177-180, 1969.)*

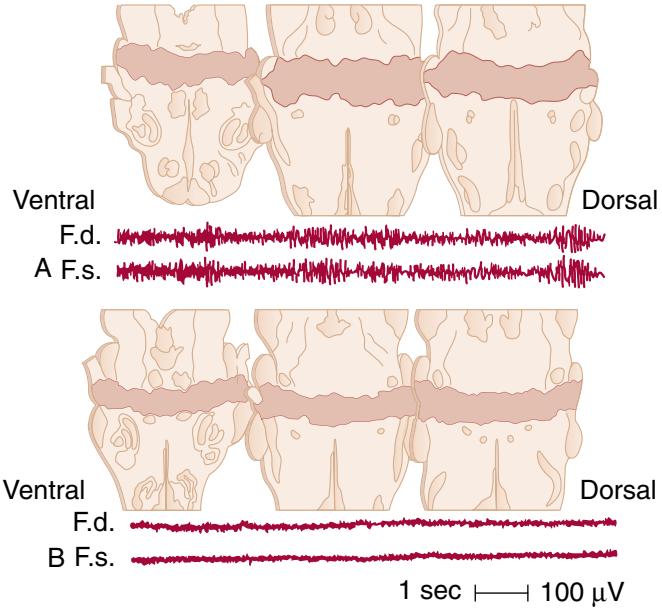

Figure 11-2 Schematic horizontal sections through the cat's brainstem depicting the production of a comatose state resembling continuous sleep in the cat that is immensely similar, if not identical to, the results of barbiturate-induced hypnosis. **A,** Midpontine pretrigeminal lesions that ablate the laterodorsal tegmental (LDT) and pedunculopontine tegmental (PPT) cholinergic neuronal projections to the thalamus and basal forebrain and produce continuous slow-frequency, large-amplitude patterns characteristic of sleep on the electroencephalogram (EEG) in both the right (F.d.) and left (F.s.) frontal EEG leads. **B,** Transections several millimeters more caudad through the rostral pons spare brainstem cholinergic neurons and their projections and lead to preservation of arousal as typified by the fast-frequency low-amplitude patterns on the EEG that characterize normal wakefulness. *(Modified from Batini C, Moruzzi G, Palestini M, et al: Persistent patterns of wakefulness in the pretrigeminal midpontine preparation. Science 128:30-32, 1958.)*

ent state of sleep by demonstrating that lesions through the midpontine pretrigeminal area of the cat did not affect the cyclic nature of control of the arousal state but confirmed that a lesion only a few millimeters more cephalad through the rostral pons at the level of the inferior colliculus produced the identical comatose syndrome as Bremer's (Fig. 11-2).

Nathaniel Kleitman (1895-1999) was another early proponent of the passive theory of sleep genesis. Among his important discoveries was recognition of the paradoxical stage of sleep, termed rapid eye movement (REM) sleep. This state differed dramatically from slow-wave or non-REM (NREM) sleep, as discussed later. For all his careful observations of sleep stages, however, Kleitman pointed out that it was the genesis of wakefulness that required explanation. Before leaving Bremer and the concept of passive sleep, we should return to his studies of the *cerveau isole* cat, in which a mesencephalic lesion deprives the forebrain of all sensory input (save olfactory and visual stimuli, which are carried by cranial nerves I and II). Bremer's insights have direct relevance for anesthetic action. In fact, Bremer's original description of the cerveau isole cat likened the resulting state as being immensely similar, if not identical to barbiturate anesthesia, as well as to natural sleep,[7] a concept to which we shall return in this chapter.

An alternative theory accounting for sleep requires its active genesis. According to the active sleep hypothesis, sleep is generated when specific neuronal systems increase their firing rates and thus inhibit the output of other neuronal structures required for wakefulness. Evidence for an active genesis of sleep has accumulated. During World War I, an outbreak of viral encephalitis reached pandemic proportions. Although many survivors experienced symptoms of profound and prolonged sleepiness (hypersomnolence), a smaller subset of survivors exhibited profound and prolonged insomnia. Based on postmortem neuropathologic observations and correlations with the premortem clinical condition, Baron Constantine von Economo (1876-1931) astutely noticed that the insomniacs had sustained damage within the anterior hypothalamus around the preoptic area, as well as damage to the basal forebrain. Those exhibiting hypersomnolence had sustained posterior hypothalamic damage. von Economo correctly predicted the existence of a sleep-promoting region of brain within the anterior hypothalamus near the optic chiasm, in addition to a wake-promoting region in the posterior hypothalamus.[8] His predictions made more than three quarters of a century ago have withstood the scrutiny of time. Experimental evidence for a hypnogenic center in the preoptic area of the hypothalamus was confirmed in rats and cats inasmuch as insomnia also resulted after lesions to the preoptic area,[9,10] as well as after bilateral microinjection of muscimol, a γ-aminobutyric acid (GABA) agonist, into the preoptic area.[11] Finally, the discovery of a population of inhibitory GABAergic neurons whose activity displays state-dependent firing patterns,[12] with the highest discharge rates occurring during sleep[13] and whose efferent projections inhibit wake-promoting centers (reviewed by Saper and colleagues[14]), fulfills all the criteria for the active generation of sleep.

Although controversy between active and passive mechanisms of the genesis of sleep still remains, these modes need not be mutually exclusive. As we discuss later, the hypnogenic neural substrates that promote sleep antagonize the wake-promoting regions in brain. In the absence of neuropathology, synchronized communication between these sleep- and wake-active neural populations ensures smooth and appropriately timed transitions between arousal states.[15]

Physiologic Patterns of Wakefulness and Sleep

The states of sleep and wakefulness may be characterized physiologically by recording the EEG and electromyogram (EMG). Wakefulness is identified by a fast-frequency, low-amplitude rhythm on the EEG that is "desynchronized," together with the presence of maximal motor activity on the EMG (Fig. 11-3). Broadly speaking, sleep may be subdivided into two distinct patterns, REM sleep and NREM sleep, which is also known as slow-wave sleep. During NREM sleep, the EEG displays large-amplitude, slow frequencies in the δ range of 0.5 to 4 Hz that dominate the power spectrum. Motor tone is lower during NREM sleep than during wakefulness (Fig. 11-3). NREM sleep patterns contrast dramatically with wakefulness, in which the EEG is desynchronized and exhibits low-amplitude, fast frequencies. During REM sleep, the EEG is also desynchronized and is virtually indistinguishable from wakefulness. However, as opposed to wakefulness, EMG activity during REM sleep is minimal to

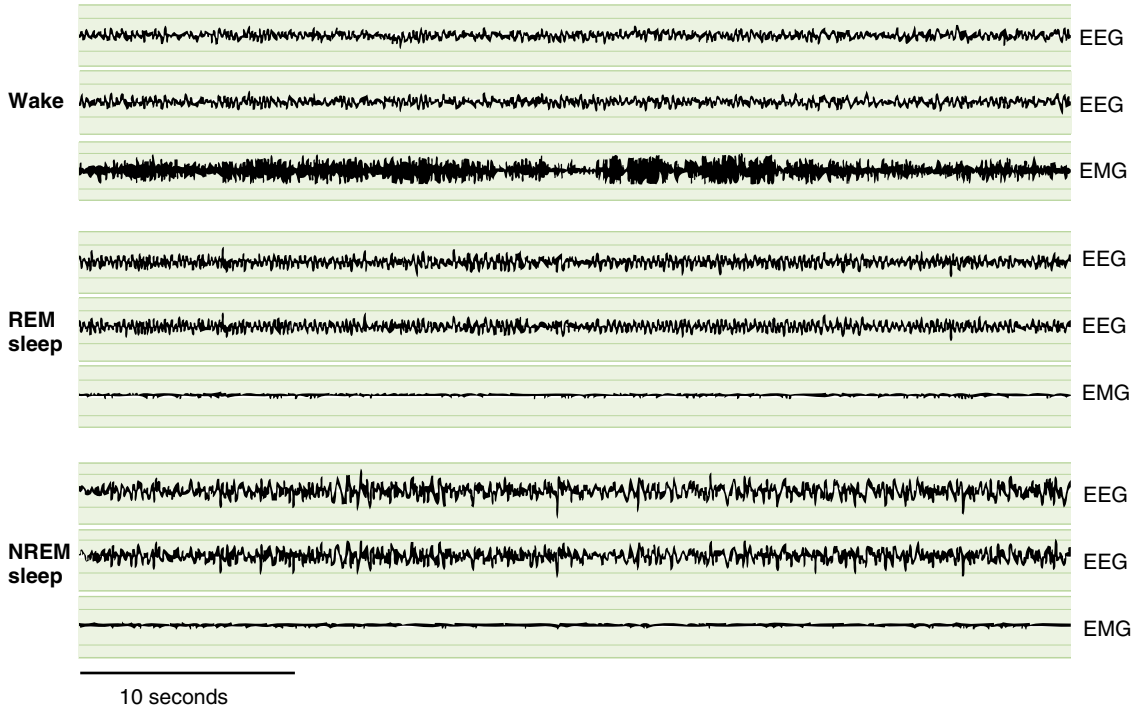

Figure 11-3 Cortical manifestation of wakefulness, rapid eye movement (REM) sleep, and non-REM (NREM) sleep with corresponding muscle tone. Wakefulness is defined by a desynchronized, low-amplitude, fast-frequency electroencephalogram (EEG) with prominent muscle activity. REM sleep shows similar signs of cortical activation with a desynchronized, low-amplitude, fast-frequency EEG in which θ rhythms of 4 to 8 Hz dominate the power spectrum. However, unlike wakefulness, motor activity is minimal in this state. NREM sleep has an EEG appearance that is markedly different from the other two states. During NREM sleep, the EEG displays slow-frequency, large-amplitude oscillations. Motor tone during NREM is dramatically reduced. *(Courtesy of Yihan Chen, University of Pennsylvania, unpublished results.)*

absent. The presence of θ activity (4 to 8 Hz) is also an abundant feature of REM sleep, as is eye movement, which may be recorded with an electro-oculogram (EOG) (for review see Harris[16]).

Wakefulness

Protecting the neural systems responsible for generating wakefulness is so fundamental to survival that evolution has distributed its expression across multiple and partially redundant systems, each contributing in a unique, but nonessential, way to promotion and maintenance of wakefulness. Specific centers in the brain alter their electrical output in proportion to the organism's arousal state. Among these regions, noradrenergic neurons of the locus ceruleus (LC), histaminergic neurons of the tuberomammillary nucleus (TMN), serotonergic neurons of the dorsal and median raphe nuclei (RN), and the newly recognized population of dopaminergic neurons in the ventral periaqueductal gray (vPAG) matter[17] are all monoaminergic centers that display arousal state–dependent firing patterns (Fig. 11-4) (for review see Jones[18]). Their highest discharge rates occur during wakefulness, decrease during NREM sleep, and become virtually quiescent during REM sleep. This pattern contrasts with that of brainstem and basal forebrain cholinergic neurons, which are most active during both wakefulness and REM sleep but decrease their output during NREM sleep, as discussed later. Neurons containing the wake-promoting and wake-sustaining neuropeptide orexin (also known as hypocretin) share similarities with other monoaminergic systems. Although confined to the posterior, lateral, and dorsomedial hypothalamus, orexinergic neurons also innervate the entire neuroaxis of the central nervous system (CNS) from forebrain through the spinal cord. These neurons exhibit maximal activity during wakefulness, reduce their firing during NREM sleep, and become quiescent during REM.[19,20] The orexinergic population positively reinforces wakefulness by stimulating activity in the monoaminergic centers just mentioned. In all mammals studied to date, including humans, impaired orexin signaling causes narcolepsy, a primary disorder affecting the organization of sleep and wakefulness. Although narcoleptics show behavioral state instability and transition to and from sleep at inopportune times, the total amount of sleep and wakefulness remains unchanged. Consistent with this notion, isolated lesion studies in animal models along with pharmacologic and gene knockout experiments have demonstrated that no single monoaminergic, cholinergic, glutamatergic, or orexinergic wake-active center is absolutely required for wakefulness.[21]

Nonetheless, Bremer, Moruzzi, and Magoun demonstrated that complete disruption of the brainstem reticular core, including the laterodorsal tegmentum (LDT) and pedunculopontine tegmentum (PPT), precludes wakefulness. The cholinergic LDT and PPT, the noradrenergic LC, the dopaminergic vPAG, and the serotonergic RN are stimulated by afferent sensory input. Together, these systems ascend through two pathways to stimulate cortical activity and expression of wakefulness (Fig. 11-5). Dorsal fibers synapse in the thalamus, where their input is relayed indirectly to the cortex via glutamatergic thalamocortical afferents. Ventral fibers synapse in the posterior hypothalamus and basal forebrain while communicating with the histaminergic TMN and cholinergic basal forebrain centers on their way to the cortex. Finally, noradrenergic LC and serotonergic RN neurons send afferent input directly to the cortex. Although brainstem and hypothalamic activity modulates wakefulness, the cerebral cortex itself

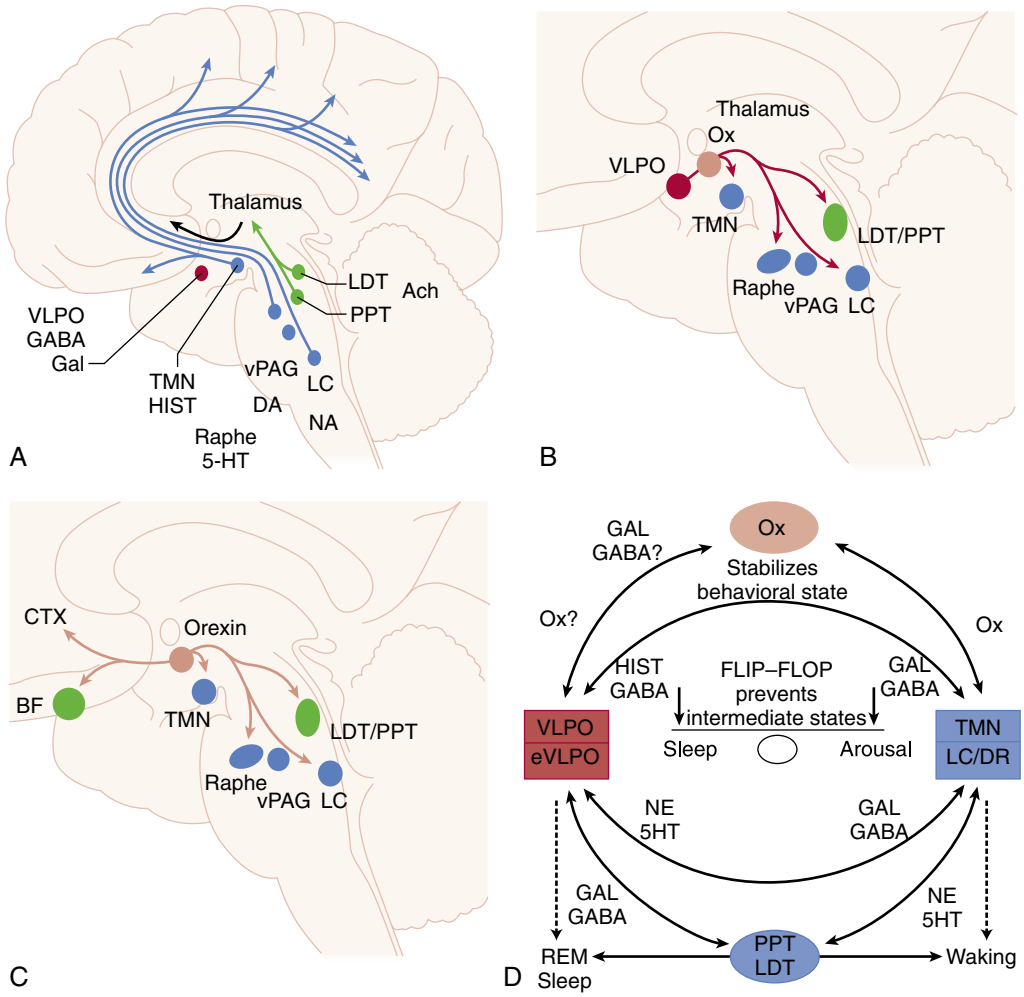

Figure 11-4 Brainstem and hypothalamic regulation of the arousal state. **A,** The ascending arousal system originates in the brainstem and posterior hypothalamus but sends projections throughout the entire central nervous system. Cholinergic neurons of the laterodorsal tegmentum (LDT) and pedunculopontine tegmentum (PPT) project to many forebrain targets, including the thalamus, and are shown in *blue*. Monoaminergic centers (shown in *green*) diffusely project throughout the forebrain and modulate hypothalamic nuclei directly. These wake-active regions include histaminergic neurons of the tuberomammillary nucleus (TMN), serotonergic neurons of the dorsal and median raphe nuclei (Raphe), dopaminergic (DA) neurons of the ventral periaqueductal gray (vPAG) matter, and noradrenergic (NA) neurons of the locus ceruleus (LC). Shown in *red* are the sleep-promoting neurons of the ventrolateral preoptic (VLPO) nucleus, which contain the inhibitory neurotransmitters γ-aminobutyric acid and galanin. **B,** Inhibitory projections from the VLPO antagonize activity in the ascending arousal centers. **C,** Orexinergic (ORX) neurons are confined to the posterior and lateral hypothalamus, yet also communicate with all known arousal centers to promote and reinforce stability of the awake state. **D,** A flip-flop model of control of the arousal state that leads to a bistable circuit in which the individual is predisposed to wakefulness or sleep but should not fluctuate between states of arousal. *(Modified from Saper CB, Chou TC, Scammell TE. The sleep switch: Hypothalamic control of sleep and wakefulness. Trends Neurosci 24:726-731, 2001.)*

contributes to self-awakening through its efferent projections to the thalamus and reticular formation.[22]

NREM Sleep

With a notable exception of the ventrolateral preoptic (VLPO) nucleus, overall electrical activity in most regions of brain is decreased during NREM sleep. This observation correlates with passive notions of sleep in which tonic wake-promoting input dissipates. During NREM sleep, monoaminergic, orexinergic, and cholinergic groups are inhibited by efferent signals emanating from the preoptic anterior hypothalamus, specifically, a cluster of neurons localized to the VLPO nucleus that use the inhibitory neurotransmitters GABA and galanin (see Fig. 11-4). VLPO neurons are sleep active and display increased firing rates and c-Fos immediate early gene expression during sleep.[13,23] Sleep-active VLPO neurons have an antagonistic relationship with wake-active centers such that VLPO activation inhibits firing in wake-active centers. Conversely, rapid firing of wake-active regions inhibits the VLPO nucleus. This network design leads to a bistable behavioral state of arousal favoring either sleep or wakefulness but not rapid transitions between the two. Not surprisingly, destruction of the VLPO nucleus with an excitatory amino acid lesion that destroys cell bodies while leaving fibers of passage intact causes insomnia.[24]

Although preoptic anterior hypothalamic VLPO neurons actively generate NREM sleep, neurons in the thalamus also alter their electrical activity patterns in critical ways during NREM sleep. Thalamic reticular and thalamocortical neurons begin to fire in bursts. This process generates sleep spindles evident on the EEG. Burst firing of thalamocortical neurons transiently causes deafferentation of the cortex by reversibly disconnecting it from sensory stimuli normally conveyed to the cortex from the

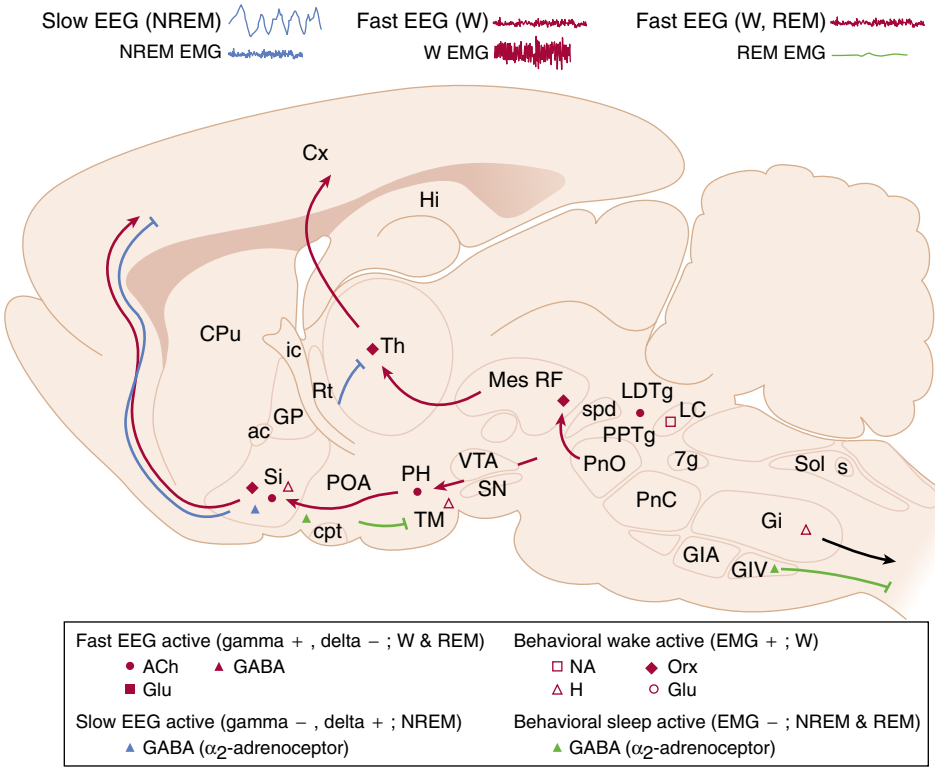

Figure 11-5 Schematic section through a rat brain depicting conserved sleep- and wake-promoting pathways and their corresponding neurotransmitter signaling systems. Neurons that are active during wakefulness (W) include those with ascending projections to the cortex that stimulate a fast-frequency desynchronized EEG (gamma+), along with descending projections to the spinal cord that stimulate the postural muscle tone required for waking behavior. Wake-active neurons display maximal activity during wakefulness, dramatically slow their firing during non–rapid eye movement (NREM) sleep, and become virtually quiescent during rapid eye movement (REM) sleep. Groups shown with *open pink symbols* include noradrenergic neurons (NA), histaminergic neurons (H), orexinergic neurons (Orx), and glutamatergic (Glu) neurons. Additional wake-active neurons shown by *filled pink symbols* are also active during REM sleep. These largely ascending systems include cholinergic (ACh), glutamatergic (Glu), and some γ-aminobutyric acid (GABA)-containing neurons. Sleep-active neurons (*blue* and *green symbols*) include cells whose cortical ascending projections dampen fast cortical activity and those with descending projections to the spinal cord and brainstem, which diminish behavioral arousal and muscle tone. The sleep-active neurons discharge in association with slow EEG activity (gamma–/delta+) during NREM sleep (*blue triangle*) and include some GABAergic neurons in the basal forebrain and preoptic area (POA) that bear α_2-adrenoceptors and are inhibited by NA. Thalamic GABA-containing neurons of the nucleus reticularis discharge in bursts with sleep spindles and slow waves to inhibit and pace thalamocortical relay neurons. In the basal forebrain and preoptic area, α_2-adrenoreceptor–expressing GABAergic neurons with descending projections increase their firing rates as muscle tone decreases (EMG–) during NREM and REM sleep (*green symbols*). Finally, additional GABAergic (and/or possibly glycinergic) neurons of the medulla descend directly into the spinal cord, where they might inhibit motor neurons during sleep. ac, anterior commissure; CPu, caudate putamen; Cx cortex; EEG, electroencephalogram; EMG, electromyogram; 7g, genu of the 7th nerve; Gi, gigantocellular RF; GiA, gigantocellular, alpha part of the RF; GiV, gigantocellular, ventral part of the RF; GP, globus pallidus; Hi, hippocampus; ic, internal capsule; LDTg, laterodorsal tegmental nucleus; Mes RF, mesencephalic RF; opt, optic tract; PH, posterior hypothalamus; PnC, pontine, caudal part of the RF; PnO, pontine oral part of the RF; POA, preoptic area; PPTg, pedunculopontine tegmental nucleus; RF, reticular formation; Rt, reticularis nucleus of the thalamus; s, solitary tract; scp, superior cerebellar peduncle; SI, substantia innominata; SN, substantia nigra; Sol, solitary tract nucleus; Th, thalamus; TM, tuberomammillary nucleus; VTA, ventral tegmental area. *(Modified from Jones BE: From waking to sleeping: Neuronal and chemical substrates. thalamus.[25] Deafferentation of the cortex by intrinsic thalamic activity is reminiscent of Bremer's lesion studies in which permanent deafferentation of the cortex formed the experimental basis of the passive nature of sleep. Together, VLPO and thalamic activity patterns provide mechanistic neuronal network explanations for the active and passive theories of sleep.

REM Sleep

Control of REM sleep is also regulated in the brain. Although several neuroanatomic centers participate in regulation and coordination of REM onset and offset, the main effector responsible for the generation of REM sleep resides in the pontine reticular formation. Transection studies by Michel Jouvet (1925-) in the cat further localized brainstem REM control within the pons to the nucleus pontis oralis (PnO), which appears to be necessary for REM expression. Direct injection of cholinergic agonists into the PnO (which is slightly rostral and just ventral to the LC) produces a state that mimics natural REM sleep.[26] The endogenous cholinergic tone in the brainstem arises from the LDT and PPT, two nuclei located at the junction between the pons and midbrain. Excitotoxic lesions that ablate the LDT and PPT dramatically impair REM sleep.[27] A subset of LDT and PPT neurons fire selectively during REM sleep, whereas other cholinergic LDT and PPT neurons fire during both REM sleep and wakefulness. Notably, the uniquely REM-active subset increases its firing rates prior to the EEG and behavioral features of REM expression,[28,29] thus suggesting that LDT and PPT cholinergic neuronal activity may initiate REM sleep (REM-on neurons). Neurons of the extended VLPO (eVLPO) nucleus also exhibit preferential activation during REM sleep. Because the eVLPO nucleus communicates directly with brainstem cholinergic LDT neurons along with monoaminergic neurons of the LC and RN and because lesions

of the eVLPO nucleus reduce the amount of REM sleep, the eVLPO nucleus appears to play a special role in generation of REM sleep.[30]

The behavioral constellation of REM sleep is dissociable into various components, each with its own specific mechanisms and neuroanatomic controllers. The cardinal signs of REM sleep include rapid eye movement, atonia of all motor groups except for the diaphragm, and activation of a low-voltage, fast-frequency EEG rhythm. Subcortical recordings demonstrate ponto-geniculo-occipital (PGO) waves. This characteristic spiky EEG pattern of REM sleep originates in the pons, is transmitted to the thalamic lateral geniculate, and terminates in the occipital cortex. The REM- and wake-active population of LDT and PPT neurons with rostral projections is important for production of the desynchronized fast-frequency, low-amplitude EEG found in both wakefulness and REM sleep.[26] REM atonia is initiated by a group of pontine reticular neurons that synapse in the bulbar reticular formation before terminating their signal on spinal cord motor neurons. The subset of pontine reticular formation neurons initiating atonia is a non-noradrenergic population of neurons adjacent to the LC, termed either the perilocus ceruleus alpha or subceruleus (SubC) in cats or the sublateral dorsal (SLD) nucleus in rodents.[31,32]

Exit from REM sleep transitions into either NREM sleep or wakefulness and is triggered by "REM-off" groups. The observation that noradrenergic LC neurons decrease their firing rate during NREM sleep and become virtually quiescent during REM sleep, together with pharmacologic and lesion studies, had suggested that inhibition of the LC was a requirement for entry into REM sleep and that LC neurons might serve as REM-off cells. However, genetic studies in noradrenergic-deficient mice have conclusively demonstrated the continued existence of normal, or nearly normal, REM sleep despite the absence of norepinephrine.[33,34] Thus, the adrenergic neurons of the LC cannot be an exclusive REM-off population. Neurons of the ventrolateral periaqueductal gray (vlPAG) matter also serve to terminate REM episodes, as proved by pharmacologic studies during which muscimol inhibition of this region increases REM sleep and also by elegant immunohistochemical mapping combined with vlPAG lesions.[35-37] vlPAG neurons form a mutually antagonistic inhibitory loop with those of the SLD nucleus to efficiently generate or inhibit REM sleep.[35]

Somnogen-Induced Transitions Between Arousal States

Even though cortical EEG and EMG patterns and activity in the sleep- or wake-active centers in the brainstem, hypothalamus, and thalamus are well known during states of sleep or wakefulness, the mechanisms responsible for entry into or exit from a given state remain mysterious. The humoral theory of sleep regulation was independently proposed nearly 100 years ago by French and Japanese neuroscientists. Intrathecal infusion of cerebrospinal fluid (CSF) harvested from sleep-deprived dogs into rested normal dogs caused the recipient dogs to promptly fall asleep.[38,39] This result suggested the existence of an endogenous somnogen, a "hormone" circulating in the CSF whose accumulation could cause the onset of sleep. Over the past century, the list of potential somnogens has grown to include substances as diverse as proteins—δ sleep–inducing peptide (DSIP)[40]; lipids—*cis*-9,10-octadecenoamide[41]; hormones—melatonin; cytokines—interleukin-1; eicosanoids—prostaglandin D_2 (PGD_2); and a nucleoside—adenosine.[42] We shall review data for the latter two putative somnogens, which have been studied most extensively.

Infusion of femtomolar concentrations of PGD_2 into the third ventricle induces both NREM and REM sleep in rats that is indistinguishable from natural sleep.[43] PGD_2 levels fluctuate in the CSF, with circadian frequency paralleling sleep-wake cycles. Sleep deprivation proportionally elevates CSF PGD_2 levels, thus also supporting a role for PGD_2 as an endogenous somnogen. PGD_2 is synthesized by the enzyme prostaglandin D synthetase, which is localized in the arachnoid membrane and choroids plexus (Fig. 11-6), and is secreted directly into CSF, where it is the second most abundant protein. Microdialysis studies confirm a specific sleep-promoting activity of picomolar quantities of PGD_2. However, this somnogenic activity is present only when PGD_2 is infused in the vicinity of the preoptic area of the hypothalamus. The most pronounced activity of PGD_2 is observed when it is

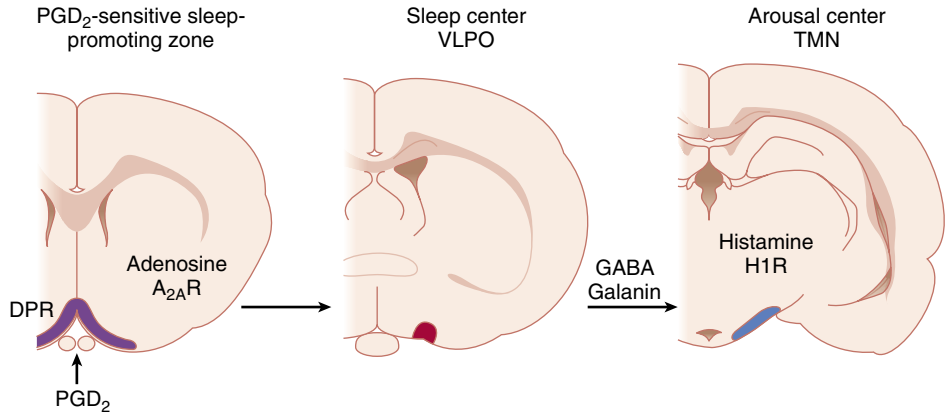

Figure 11-6 Molecular mechanisms of sleep promotion by the endogenous somnogen prostaglandin D_2 (PGD_2). The prostaglandin D_2 receptor (DPR) lines the ventral surface of the basal forebrain and preoptic area (*purple area*). The DPR is thought to transmit the somnogenic PGD_2 signal from cerebrospinal fluid to the ventrolateral preoptic nucleus (VLPO, shown in *red*), with adenosine being used as a signaling molecule. This signal transduction event activates VLPO neurons via the adenosine A_{2A} receptor, which leads to inhibition of wake-active histaminergic groups such as the tuberomammillary nucleus (TMN, shown in *blue*). *(Modified from Hayaishi O, Urade Y: Prostaglandin D_2 in sleep-wake regulation: Recent progress and perspectives. Neuroscientist 8:12, 2002.)*

infused beneath the VLPO nucleus. Infusion of a PGD_2 antagonist into the third ventricle reversibly and dose-dependently inhibits both REM and NREM sleep (for review see Hayaishi and Urade[43]). On binding to the D-type prostanoid receptor (DPR), which is localized to the arachnoid membrane lining the ventral surface of the brain, the somnogenic signal of PGD_2 appears to be transduced indirectly by activation of the VLPO nucleus.[44] The mechanism for VLPO activation after subarachnoid infusion of PGD_2 appears to require adenosine because coadministration of an adenosine receptor A_{2a} antagonist blocks the somnogenic activity of PGD_2. Conversely, administration of an adenosine A_{2a} agonist mimics the somnogenic activity of PGD_2.[45] As adenosine levels accumulate, they activate A_{2a} receptor–expressing neurons to directly or indirectly activate the VLPO nucleus.[46] Hence, it appears that adenosine may function as the neurotransmitter that couples the humoral to the neural mechanisms driving sleep-wake regulation. With this model the homeostatic drive to sleep accumulates proportionally to increases in the endogenous somnogens PGD_2 and adenosine. The existence of such somnogenic substances that accumulate with time argues for active rather than passive generation of sleep.

Anesthesia and Sleep

Anesthesia is a state that shares phenotypic similarities with sleep, and hence the metaphor of "going to sleep" is commonly used to describe induction of general anesthesia in the clinical setting.[47] Not only are anesthesia and sleep similar states, but they also share common neurobiologic traits[48]; indeed, the hypnotic component of anesthesia may result from specific actions of anesthetics on the neural systems that regulate natural sleep. Support for this hypothesis comes from a variety of studies. During sleep and general anesthesia, there is reduced responsiveness to external stimuli. Functional brain imaging during anesthetic-induced unconsciousness has been shown to inhibit thalamic and midbrain reticular formation nuclei.[49] Anesthetic blockade of thalamic information transfer, which disrupts somatosensory input from reaching higher cortical centers, has also been confirmed with more direct microelectrode recordings.[50,51] In both instances, these anesthetic effects on the thalamus resemble the naturally occurring thalamocortical inhibition characteristic of NREM sleep.[25]

Sleep Deprivation

Sleep deprivation potentiates the hypnotic action of anesthetics, including propofol and isoflurane.[52] Moreover, the sleep debt that would otherwise ensue after sleep deprivation dissipates during propofol anesthesia; however, it remains unknown whether other features of sleep deprivation (for example, on immune function) might also be ameliorated by hypnotic doses of propofol.[53] The bispectral index monitor, designed to track the depth of anesthetic-induced hypnosis, also appears to be useful in recording the onset and depth of sleep.[54]

Endogenous Somnogens and Anesthetics

Infusion of adenosine in low doses potentiates the hypnotic actions of intravenous and volatile anesthetics, thereby reducing the amount of anesthetic required to achieve a given depth of anesthesia. This effect is reproduced by 2-chloroadenosine, a potent adenosine analog, and by dipyridamole, an adenosine uptake blocker and adenosine deaminase inhibitor. Conversely, administration of theophylline, an adenosinergic antagonist, produces partial resistance to anesthesia.[55] Mechanistically, these data fit well with an effect of adenosine on activation of the hypothalamic sleep center, the VLPO nucleus (see later discussion). Meanwhile, exposure to anesthetics such as isoflurane affects the levels of endogenous somnogens, with isoflurane altering the balance between prostaglandin E_2, a wake-promoting prostaglandin, and PGD_2, a sleep-inducing prostaglandin, in the hypothalamus.[56]

Effects of Anesthetics on Sleep Circuits

Knowledge of the endogenous arousal systems is an essential prerequisite for any discussion of the mechanisms of action of psychostimulants, sedative-hypnotics, and general anesthetics. Predicted actions of anesthetics based on their known effects at individual cells expressing single recombinant neurotransmitter receptors, including GABAergic, glutamatergic, cholinergic, adrenergic, histaminergic, serotonergic, and orexinergic receptors or voltage-gated calcium, sodium, or potassium channels, allow the generation of testable hypotheses. However, anesthetics distribute throughout the entire brain (Fig. 11-7),[57] and because the majority of sleep- and wake-active nuclei send bidirectional signals that may be either mutually inhibitory, excitatory, or one

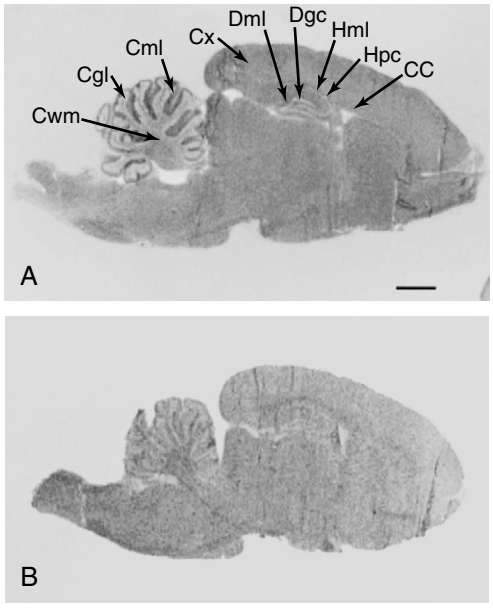

Figure 11-7 Distribution of specific halothane binding throughout the rat brain. **A,** This autoradiogram demonstrates nearly homogeneous binding of the volatile anesthetic halothane at 100 μM by direct photoaffinity labeling with ^{14}C-halothane. Some exceptions to nearly uniform uptake are shown in the cerebellar white matter (Cwm), cerebellar granular layer (Cgl), and subregions of the hippocampus. **B,** Specific binding is competitively inhibited by 2.3 mM nonradioactive halothane. CC, corpus callosum; Cml, cerebellar molecular layer; Cx, cortex; Dgc, dentate granule cell layer; Dml, dentate molecular layer; Hml, hippocampal molecular layer; Hpc, hippocampal pyramidal cell layer. *(Modified from Eckenhoff MF, Eckenhoff RG: Quantitative autoradiography of halothane binding in rat brain. J Pharmacol Exp Ther 285:371, 1998.)*

inhibitory in one direction with an excitatory return, the actual effects of anesthetics on net circuit output must be empirically tested because existing models do not account for all the complexity in the circuits.[58]

Thalamic Sites

The passive theories of sleep set forth by Bremer are similar to many passive concepts of general anesthesia. A central tenet of NREM sleep and anesthesia is that the cortex is deprived of sensory input. Whether by exogenous lesions, as in Bremer's cerveau isole cat, or by endogenous closing of thalamic gates, anesthetics appear to act on NREM sleep circuits, thereby leading to shared mechanisms of action. Within the thalamus, there is a simple architecture of cell types consisting of reticular neurons and thalamocortical neurons that communicate with the cortex while also integrating peripheral input (Fig. 11-8). Activation of the reticular neurons during NREM sleep and anesthesia causes hyperpolarization of thalamocortical relay neurons, which in turn blocks propagation of the action potential through thalamocortical relay neurons. As a result, thalamocortical neurons are prevented from relaying peripheral input to higher cortical centers. This is the mechanism by which the thalamic gates close to transiently, yet reversibly, sever the cortex from the periphery.[25,59,60] Midline thalamic nuclei are thought to play a critical role in generating conscious awareness and appropriately receiving afferent input from most reticular activating arousal-promoting centers.[21] Imaging studies confirm a regionally selective reduction in midline thalamic blood flow, metabolism, and by extension, activity.[49,61] Support for a thalamocortical consciousness switch has recently been strengthened by the finding that microinjection of nicotine into the centromedian nucleus of the thalamus reverses sevoflurane-induced hypnosis (discussed later). These conclusions are mitigated by the fact that administration of nicotine into the centromedian nucleus results in seizures. However, support for the central thalamus as an arousal center that is capable of reversing unconsciousness also comes from literature on the persistent vegetative state. High-frequency stimulation of the central thalamus in the rat has been associated with widespread cortical activation and enhanced cognitive function.[62] Furthermore, deep brain stimulation of the central thalamus has been shown to reverse some of the behavioral deficits in a patient suffering traumatic brain injury.[63]

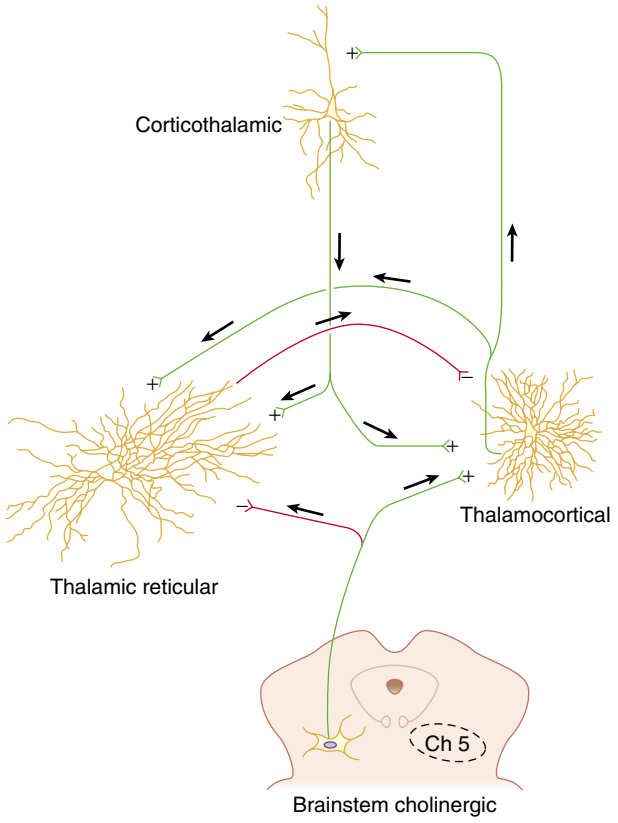

Figure 11-8 The transition from wakefulness to non–rapid eye movement (NREM) sleep is associated with characteristic changes on the electroencephalogram that correlate with underlying changes in the electrical firing patterns of corticothalamic systems. During NREM sleep, thalamocortical neurons are hyperpolarized by thalamic reticular neurons (upper *green* axon). This action prevents incoming peripheral signals from being relayed to corticothalamic neurons in the cortex and transiently, but effectively results in deafferentation of the cortex. Cholinergic input in the brainstem is able to simultaneously hyperpolarize thalamic reticular neurons while depolarizing thalamocortical neurons, thereby returning membrane potential in thalamocortical neurons to baseline and restoring the action potential propagation that transfers peripheral sensory input to corticothalamic neurons. Recent studies suggest that similar changes in the firing properties of corticothalamic loops may also underlie anesthetic-induced hypnosis. Excitatory connections are depicted in *red*, with *plus symbols* at the synapse. Inhibitory connections are displayed in *green*, with *minus signs* at the synapse. *(Modified from Steriade M: The corticothalamic system in sleep. Front Biosci 8:d878, 2003.)*

Because nicotinic acetylcholine receptors are heavily expressed in the thalamus and because many anesthetics inhibit signaling via nicotinic acetylcholine receptors, suppression of the cholinergic arousal system may be one mechanism through which many anesthetics produce unconsciousness.[64] Processed EEG measures of anesthetic depth also reveal an important role for the cholinergic arousal system inasmuch as intracerebroventricular infusions of neostigmine or the muscarinic agonist oxotremorine arouse isoflurane-anesthetized rats.[65]

Hypothalamic Sites

Thalamic nuclei receive input from the ascending brainstem reticular activating system via a dorsal pathway and also receive hypothalamic input from wake-active centers such as histaminergic and orexinergic neurons (see Fig. 11-5). As discussed earlier, the thalamic gates close during NREM sleep and exposure to several anesthetics, and this closure is facilitated by decreased input of monoaminergic, cholinergic, and orexinergic signals during anesthesia. GABAergic anesthetics such as propofol and barbiturates exert their hypnotic effects by inactivating histaminergic neurons of the TMN[66] (see Fig. 11-4). This action may be explained at the molecular level by potentiation of inhibitory GABAergic projection from the sleep center, the VLPO nucleus. Disinhibition of the VLPO nucleus, in turn, shuts down other wake-active groups and further reinforces VLPO activity. This feed-forward mechanism stabilizes the hypnotic state.[14] Blockade of the wake-promoting histaminergic signal is also the mechanism by which the antihistaminergic drug diphenhydramine precipitates sleep. Recovery or emergence from anesthetic hypnosis is facilitated by wake-promoting orexinergic neurons, which are inhibited by volatile anesthetics such as isoflurane and sevoflurane.[67]

Brainstem Sites

One finding that has emerged from studying the hypnotic properties of different anesthetic agents is that there is neither a unitary

molecular target nor an invariant neuronal site of action common to all anesthetics. This point is illustrated by dexmedetomidine, an α_2-adrenergic agonist. The behavioral hypnosis of dexmedetomidine results from the drug's ability to inactivate noradrenergic neurons of the LC (Fig. 11-4). This event disinhibits the VLPO nucleus, which subsequently inactivates other arousal centers via the VLPO's GABAergic and galaninergic inhibitory signaling, as discussed earlier.[68] As with propofol and barbiturates acting on the TMN, the common consequence of VLPO disinhibition is stabilization of the hypnotic state. Pharmacologic and lesion experiments that alter both monoaminergic reticular activating function and anesthetic sensitivity can now be reinterpreted in the framework of integrated arousal network activity. Depletion of CNS catecholamines, including norepinephrine, serotonin, dopamine, and histamine, produces hypersensitivity to anesthetics.[69] Conversely, pretreatment with a monamine oxidase inhibitor or acute exposure to amphetamine, both of which increase catecholamine levels in the brain, produces partial resistance to anesthetics.[70] Focusing once again on noradrenergic neurons of the LC, chemical depletion of norepinephrine with 6-hydroxydopamine[71] and electrolytic destruction of LC neurons[72] both produce hypersensitivity to anesthetics, probably by removing an inhibitory signal to the VLPO nucleus.

These pharmacologic treatments affect other monoaminergic systems in addition to the noradrenergic neurons. Moreover, the action of amphetamines or monoamine oxidase inhibitors on serotonergic or dopaminergic systems might also account for a portion of the anesthetic effects. In support of this concept, destruction of serotonergic RN neurons with the toxin 5,6-dihydroxytryptamine or direct electrolytic lesions of serotonergic RN neurons also cause hypersensitivity to anesthetics.[71,72] Once again, as with lesions of the LC, these actions may be interpreted in the light of partial VLPO disinhibition (see Fig. 11-4).

The discovery that pentobarbital and muscimol, a $GABA_A$ agonist, cause behavioral and EEG signs of hypnosis when microinjected into a discrete upper brainstem site, termed the mesopontine tegmentum (MPTA) in rats, has revealed yet another important anesthetic locus.[73] Neuroanatomic tracing studies have shown that MPTA neurons project to thalamic, hypothalamic, and brainstem sites traditionally recognized as part of the ascending reticular activating system. Like other known wake-active systems, MPTA neurons are spontaneously active during wakefulness and are thought to decrease their firing rates during NREM sleep and under anesthesia.[74] MPTA neurons also project to the septohippocampal system, thus providing a link to yet another anesthetic locus (see later).

Limbic System

Strong emotions such as fear, rage, and joy are accompanied by a heightened state of arousal. Hence, it should not be surprising that the limbic system, which responds to emotional content, connects to arousal circuits. Specifically, within the limbic system the medial septum and hippocampus also participate in modulating awareness. This knowledge of neuroanatomy helps explain how inhibition of the medial septum or hippocampus by local injection of muscimol decreases the doses of propofol and pentobarbital needed for hypnosis.[75] The role of limbic system structures such as the hippocampus and amygdala in memory function and anesthetic-mediated amnesia is discussed later.

Summary

Although once considered a passive process in which the cortex loses afferent input, sleep is now recognized as an actively generated state whose genesis depends on the integrated contribution of multiple neuronal input. Increased understanding of the relevant neuronal circuits controlling sleep and wakefulness has opened a series of investigations into anesthetic-induced hypnosis. These studies suggest that anesthetic-induced unconsciousness may arise in part from selective actions of our drugs on these critical nuclei. One basic principle that appears to tie all the neuroanatomic studies together is that inactivation of structures mediating normal arousal appears to enhance the effects of general anesthetic–induced hypnosis. Conversely, activation of these regions appears to produce partial resistance to anesthetic-induced hypnosis.

Memory

In this portion of the chapter we provide a discussion of the major themes in our understanding of memory as it has developed over the past 100 years. Three major themes are clear.[76] First, there are multiple memory systems that are subserved by specific brain regions and neural circuits. Second, there are multiple stages of memory that are mediated by distinct molecular mechanisms. Third, alterations in the strength of connections between neurons—termed *synaptic plasticity*—is a critical component of the way in which memories are stored in neural circuits. After investigating these three major themes of memory research, we describe the molecular mechanisms by which memories are stored and define potential mechanisms by which anesthetics might induce amnesia. Because the hippocampus and amygdala have been the focus of many studies of memory storage and because modulation of their function may underlie anesthetic-induced amnesia, our discussion will focus on these memory systems.

Over the centuries, memory has fascinated poets, philosophers, and scientists. Memory represents an experience-dependent change in behavior, and it is critical to our sense of self, as well as the development of human society and culture. Thus, it is not surprising that memory remained for centuries the domain of philosophers, many of whom speculated on what memory was and how it might be maintained over a lifetime. In *Theatetus*, Plato proposed that thoughts might be stamped into memory the way a signet ring makes an impression in wax. When he discussed a theory of cognition in *Timaeus*, Plato was among the first to suggest that the brain contains the higher, rational soul that controls our actions, but his idea was that this rational soul interacted with a lower, appetitive soul in the gut to form images on the surface of the liver.[77] Experimental work by scientists on memory had its origins in the 19th century when neurologists and psychiatrists such as Jackson, Ribot, and Alzheimer began to identify patients with memory deficits and psychologists such as Hebbinghaus, Müller, and Pilzecker began to define different types and stages of memory.[78] Importantly, the early clinical work on brain-lesioned patients placed memory into the hands of neuroscientists, who defined the importance of the brain in memory, in contrast to earlier proposals by philosophers, in which it was

suggested that memory was subserved by other organ systems. As this experimental and clinical work was being carried out on memory, anatomists such as Santiago Ramón y Cajal (1852-1934) were identifying the critical cellular components of the nervous system by using histologic stains to identify distinct classes of neurons and glia within the brain. Cajal's "Neuron Doctorine" led him to postulate that it would be these connections between neurons (later called synapses) that might mediate memory storage.[79] With the work of Ivan Pavlov (1849-1936) on the conditioned reflex, the field of memory began to be a central component of the growing field of psychology.[80]

Distinct Memory Systems Subserve Distinct Types of Memory

The field of memory research was revolutionized in the middle part of the 20th century by study of the patient H.M. by Wilder Graves Penfield (1891-1976), Brenda Milner (1918-), and others. Work in the first half of the 20th century that followed on the work of Pavlov had failed to define specific memory systems, as was suggested by the work of Jackson, Ribot, and Alzheimer and popularized by the phrenologist Joseph Gall. Karl Lashley, working at Harvard, suggested that memories might not be localized to specific brain regions inasmuch as his lesion studies in rodents failed to identify such specific circuits. Rather, Lashley proposed his laws of mass action and "equipotentiality," both based on the ideas that the entire cerebral cortex contributes to memory and that other brain regions can compensate for damage to a certain region of the brain.[81] The study of H.M. thus came in striking contrast to these conclusions of Lashley. At 27 years of age, H.M. underwent surgery to remove portions of his temporal lobe in an effort to treat intractable epilepsy that had developed after a childhood accident. As became clear some 40 years later when H.M.'s brain was studied by magnetic resonance imaging techniques, his neurosurgeon Wilder Penfield had removed the bulk of his hippocampus bilaterally and portions of his amygdala[82] (Fig. 11-9). Thus, it is no surprise that H.M. had severe anterograde memory deficits in the ability to acquire new memories.

Neuropsychological evaluation by Brenda Milner and others revealed two surprising aspects of the amnesia that followed H.M.'s surgery.[76,83] First, he also exhibited retrograde amnesia—that is, certain memories of events before his surgery were lost. As this retrograde amnesia was probed in more detail,

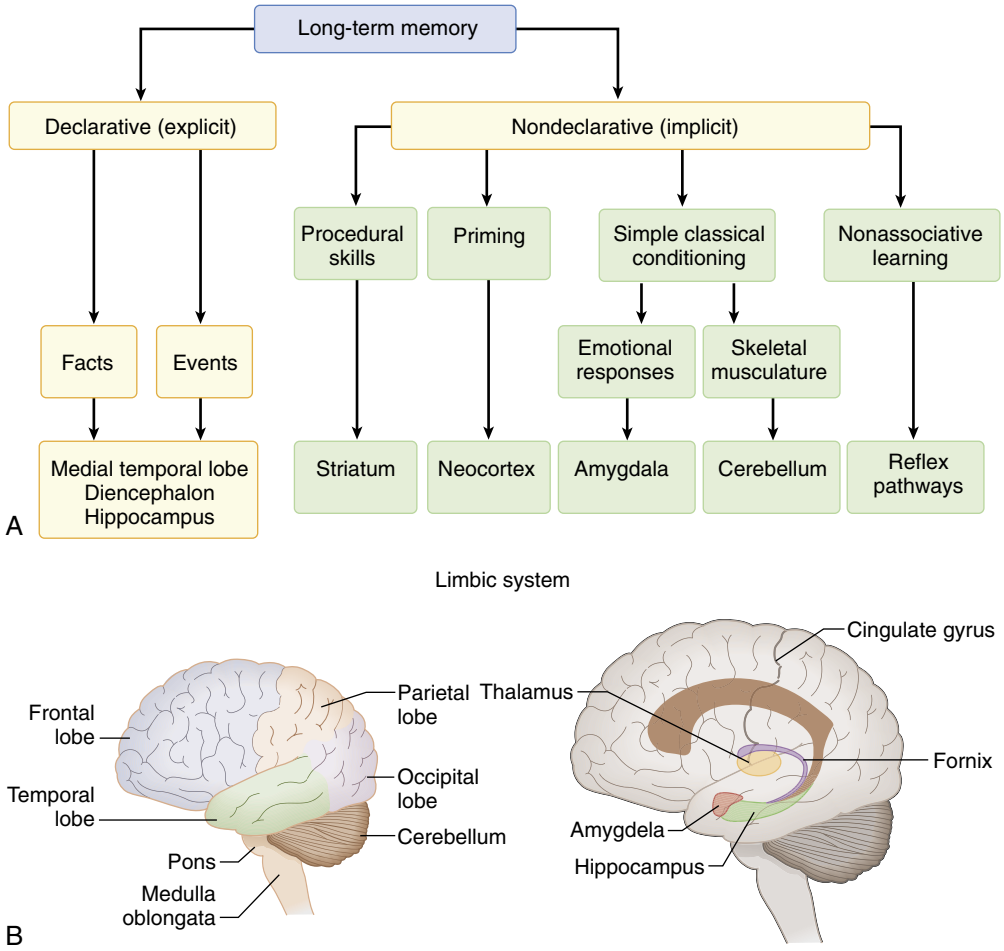

Figure 11-9 There are distinct types of memory (**A**) that are mediated by distinct brain systems (**B**).

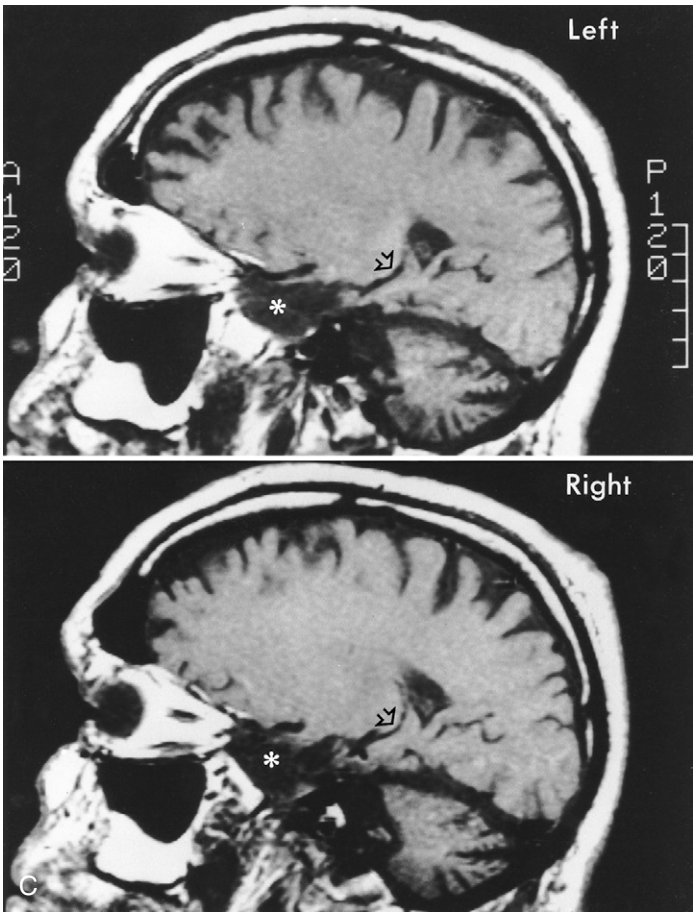

Figure 11-9, cont'd Patient H.M. exhibited selective deficits in declarative memory for facts and events after surgical resection of portions of his medial temporal lobe, including the hippocampus (**C;** the resected portion is marked with an *asterisk*, the remaining portion of the hippocampus is marked with an *arrow*). (**A,** *Modified from Squire LR, Zola SM: Structure and function of declarative and nondeclarative memory systems. Proc Natl Acad Sci U S A 93:13515, 1996;* **C,** *from Corkin S, Amaral DG, Gonzalez RG, et al: H. M.'s medial temporal lobe lesion: Findings from magnetic resonance imaging. J Neurosci 17:3964, 1997.)*

it was found that H.M.'s memory of temporally distinct events was intact, and a "gradient" of retrograde amnesia was revealed that decreased with time. This observation of time-limited retrograde amnesia is in keeping with the "law of regression" proposed by Jackson and Ribot that recent memories are the first to be affected by amnesia.[84,85] This observation also suggests that retrieval and storage of very long-term memories (so-called remote memory) are mediated by neural circuits that were not altered by H.M.'s surgery. We now know that these very long-term memories require the cortex—particularly the anterior cingulate cortex, for storage and retrieval.[86] Second and perhaps most important, H.M. exhibited normal learning and memory for certain tasks, a finding that was first shown for a mirror drawing task. This second aspect of H.M.'s amnesia gave rise to the idea of multiple memory systems, each of which mediate particular types of memory. There appears to be at least two reasons why Lashley did not observe the existence of discrete memory systems. H.M.'s lesions were not precisely focused on specific neural circuits, and his behavioral tasks, which were complex maze tasks, were not configured to probe selectively specific memory systems.

The conclusions from the study of H.M. have been confirmed and extended over the past 50 years, and similar memory deficits have been observed in patients with damage limited to specific subregions of the hippocampus.[83,87,88] A variety of memory systems have been defined by both lesion experiments and functional magnetic resonance imaging studies (Fig. 11-9).

Types of Memory

Memory is divided into two large classes termed *declarative* or *nondeclarative* memories, depending on whether the memory can be consciously recalled or not.[89] Nondeclarative memory includes procedural memory, of which bike riding and mirror drawing represent clear examples. Declarative memory, which is consciously recalled, consists of semantic and episodic memory. The hippocampal formation, lesioned in patient H.M., is a major component of the episodic memory system (see Fig. 11-9). Indeed, H.M. had specific deficits in his ability to store and recall episodic memories—the memory of facts and events that provide most of our conscious recollection of life's experiences. Although much work has focused on the role of the hippocampus in the recollection of episodic memories, recent work has extended the study of the hippocampus to investigate whether patients with hippocampal damage are able to imagine new experiences.[90] Patients with hippocampal damage are impaired at imaging new experience, in

part because their imagined experiences lack spatial coherence and consist of fragmented images in the absence of configural representation of an environmental setting. Beyond its role in our conscious recollection of our past, the hippocampus also makes a critical contribution to our ability to imagine new experiences.

The existence of multiple memory systems provides a critical analytic tool for the analysis of memory deficits observed in patients. A particularly striking example of such a "double dissociation" between types of memory comes from the work of Damasio and colleagues.[91] They examined a patient with bilateral damage to the amygdala and a patient with bilateral hippocampal damage in classic conditioning tasks. The patient with amygdala damage was unable to acquire conditioning of autonomic responses but did acquire declarative knowledge about the conditioning trials. In contrast, the patient with hippocampal damage learned the conditioned autonomic responses but not the facts. One clinical implication of the existence of multiple memory systems is that appropriate neuropsychological testing combined with structural and functional magnetic resonance imaging can be used to identify the basis of memory deficits in patients.

Memory Consolidation and Different Stages of Memory

In 1900, Georg Elias Müller (1850-1934) and his student Alfons Pilzecker (1865-1949), working at the University of Göttingen, Germany, published a seminal 300-page paper describing 40 experiments on the nature of memory.[92] In this work, Müller and Pilzecker presented clear evidence that memory does not immediately develop after learning but instead takes time to be consolidated and stored. Their primary evidence came from two classes of observations termed perseveration and retroactive inhibition. Using lists of nonsense syllables presented as paired associates, Müller and Pilzecker found a strong tendency for syllable pairs to be maintained in a subject's mind for some minutes after learning. Such "perseveration" was interpreted to reflect the persistence of a memory trace that was necessary to encode the memory. In a set of experiments designed to test this idea, they presented subjects with a second list of words at some time interval after the first list. If this second list followed the first list by 30 seconds, "retroactive interference" was observed—subjects showed less retention of the first word list. If learning of the second list was delayed by 6 minutes, such interference was not seen. Müller and Pilzecker concluded: "After all this, there is no alternative but to assume that after reading a list of syllables, certain physiological processes, which serve to strengthen the associations induced during reading of that list, continue with decreasing intensity for a period of time" (quoted by Lechner and colleagues[92]).

With these pioneering experiments, Müller and Pilzecker laid the groundwork for what today is termed memory consolidation—the idea that memories initially persist in a fragile state and are stabilized over time as they are consolidated into long-term memory.[93] Although it was immediately realized that the work on perseveration and retroactive interference provided an explanation for the temporally graded retrograde amnesia observed in patients by Ribot and Jackson, it took some time for this idea to have an impact on animal studies. It was not until 1949 that two papers reported retroactive interference in rodents with the use of electroconvulsive shock to induce retrograde amnesia.[94,95] In theoretical work at the same time, Hebb and Gerard[95,96] proposed that memory consisted of two "traces" of reverberating neural activity that first gives rise to short-term memory and then to long-term memory (Fig. 11-10). An interesting question that is still actively being explored is whether these short-term and long-term memory traces occur in series or in parallel. Although much work assumes that they are serial, some intriguing experiments suggest that they may form independently in parallel. Despite the fact that much work on memory consolidation has focused on impairing memory after training, memory can also be enhanced during the period of consolidation, as revealed by the work of McGaugh.[93] Thus, the existence of periods of memory consolidation provides an evolutionarily important mechanism to modulate our responses to learned experiences.

The concepts of memory consolidation were critically important for the development of biologically based approaches to memory storage. In particular, postulates that structural

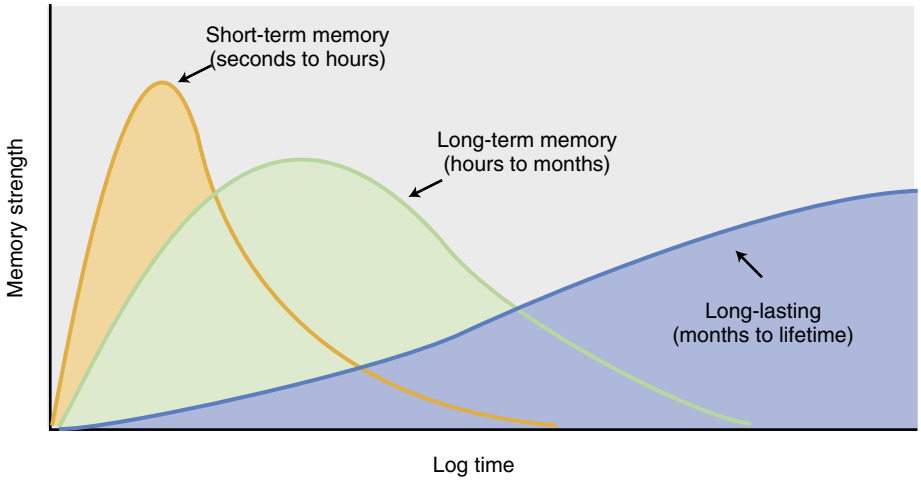

Figure 11-10 Memory consists of distinct phases, including short-term memory, long-term memory, and long-lasting memory. Distinct molecular mechanisms underlie each of these phases. Although these memory phases are shown schematically as though they exist in series, evidence suggests that they may also partially exist in parallel, thus implying that they are mediated by distinct molecular mechanisms acting independently. *(From McGaugh JL: Memory—a century of consolidation. Science 287:248, 2000.)*

changes might underlie memory traces led to development of the idea that proteins might mediate memory storage and then that RNA synthesis was required.[97] With the development of molecular biology, the finding that translation and transcription were critical for memory storage put study of the molecular mechanisms of memory firmly in the realm of the central dogma of molecular biology and led to the use of molecular techniques by many researchers to probe how information is stored in neural circuits. Furthermore, it became clear that it was molecular cascades of signaling molecules, transcription factors, and waves of RNA and protein synthesis that explained the perseveration and retroactive interference observed by experimental psychologists.

Cellular and Molecular Mechanisms of Memory Storage

At the cellular level, the most striking finding about the potential biologic basis of memory came in 1973 when Bliss and Lomo discovered that repeated high-frequency stimulation of input to the hippocampus in vivo resulted in a long-term potentiation (LTP) of synaptic transmission. LTP provides a cellular model of memory.[98,99] Evidence has suggested that processes similar to LTP may mediate memory because induction of LTP impairs ("occludes") subsequent memory formation.[100] LTP is induced after learning.[101] Furthermore, genetic and biochemical manipulations that impair LTP also lead to memory impairment. The development of in vitro slice preparations to study hippocampal LTP and manipulate hippocampal slices pharmacologically and electrophysiologically has been critical for identification of the molecular mechanisms underlying synaptic plasticity and memory.

Like behavioral memory, hippocampal LTP is an experience-dependent process, and extensive evidence suggests that these processes are mediated by similar molecular mechanisms.[98,99] Repeated synaptic stimulation in hippocampal slices, as well as behavioral training, activates the *N*-methyl-D-aspartate (NMDA)-type glutamate receptor, a molecular coincidence detector activated by glutamate and postsynaptic depolarization. When activated, the NMDA receptor becomes permeant to calcium. The resultant influx of calcium into the postsynaptic neuron activates a number of second messenger signaling pathways, including calmodulin kinases (CaMKs), adenylyl cyclase, and mitogen-activated protein kinases (MAPKs)[102] (Fig. 11-11). Synaptic plasticity and behavioral memory are also modulated by neurotransmitters that activate G protein–coupled receptors, such as dopamine and norepinephrine, which in turn also modulate intracellular signaling pathways.

This local synaptic activation mediates plasticity for the first hour or so after induction of LTP. Long-term plasticity, called L-LTP, lasts for many hours and involves the induction of new gene transcription and the synthesis of new proteins.[103] Thus, long-lasting forms of LTP, like long-term memory, are selectively sensitive to inhibition of protein and RNA synthesis. Study of the molecular mechanisms of translational and transcriptional regulation has led to two surprises in recent years. First, the synthesis of new proteins can occur, in part, within the dendrite locally at the synapse, thereby providing a potentially long-lasting synaptic tag to mark synapses that are potentiated.[104] Second, regulation of transcription involves epigenetic mechanisms of chromatin modification, DNA methylation, and chromatin remodeling—mechanisms that were thought to function primarily in a developmental context.[105] It is interesting to suggest that memory may, in part, be stored as epigenetic modifications that alter the expression of select genes.

One important question is how activation of these various signal transduction pathways, changes in gene expression, and epigenetic marks give rise to long-lasting increases in synaptic transmission and memory. The α-amino-3-hydroxy-5-methyl-4-isoxazopropionic acid (AMPA)-type glutamate receptor provides one potential target of these molecular mechanisms. Kinases activated by influx of calcium, such as CaMKII, phosphorylate the GluR1 subunit of the AMPA receptor, which increases its open time and the amount of receptor available on the cell surface at the synapse.[106] Increased levels and activity of the AMPA receptor would increase the depolarization resulting from release of glutamate at the synapse, thereby increasing synaptic strength. Long-lasting forms of LTP activate gene expression and increase transcription of the gene encoding GluR1.[107] Thus, although there are clearly a variety of molecular targets by which synaptic strength can be stably enhanced, the AMPA receptor provides an attractive effector mechanism.

Anesthetic-Induced Amnesia

At larger doses, administration of virtually any anesthetic drug produces loss of consciousness, which in turn results in episodic amnesia. Because monitors capable of assessing memory formation, storage, and retrieval are lacking, one common clinical strategy relies on delivery of hypnotic doses of anesthetics to ensure amnesia. However, anesthetic drugs have the capacity to produce amnesia at subhypnotic doses. The engrams (physical alterations in neural tissue thought to be the substrate for memory) most readily impaired by anesthetic drugs involve episodic memories. Although multiple mechanisms might account for anesthetic-induced amnesia, at subhypnotic doses, benzodiazepines such as midazolam and intravenous anesthetics such as propofol primarily affect either long-term memory storage or its retrieval. At plasma concentrations of 40 ng/mL of midazolam or 0.9 μg/mL of propofol, humans are able to encode and retain memories over a period of 15 to 30 minutes. However, these memories are lost before consolidation.[108]

Even though the circuit-level, neuronal, and molecular mechanisms of anesthetic-induced amnesia remain incompletely understood, animal studies suggest that amnestic doses of anesthetics have the capacity to interfere with memory formation at multiple points. For the volatile anesthetics, memory formation is impaired at drug concentrations between a 25% and 50% the minimum alveolar concentration (MAC) in humans[109] and rodents,[110] with individual agents differing slightly in their amnestic potency relative to their MAC (immobilizing dose).[111]

LTP is a form of synaptic plasticity thought to contribute to memory and it represents a cellular model of memory as discussed earlier. In addition to impairing memory at the behavioral level, anesthetics such as isoflurane may also impair or completely abolish LTP in hippocampal slice preparations.[112] Other anesthetics such as barbiturates, benzodiazepines, and propofol likewise alter the expression of LTP and long-term depression in hippocampal slice preparations, thereby providing cellular correlates of their amnestic properties.[113-115] In these instances, anesthetics are

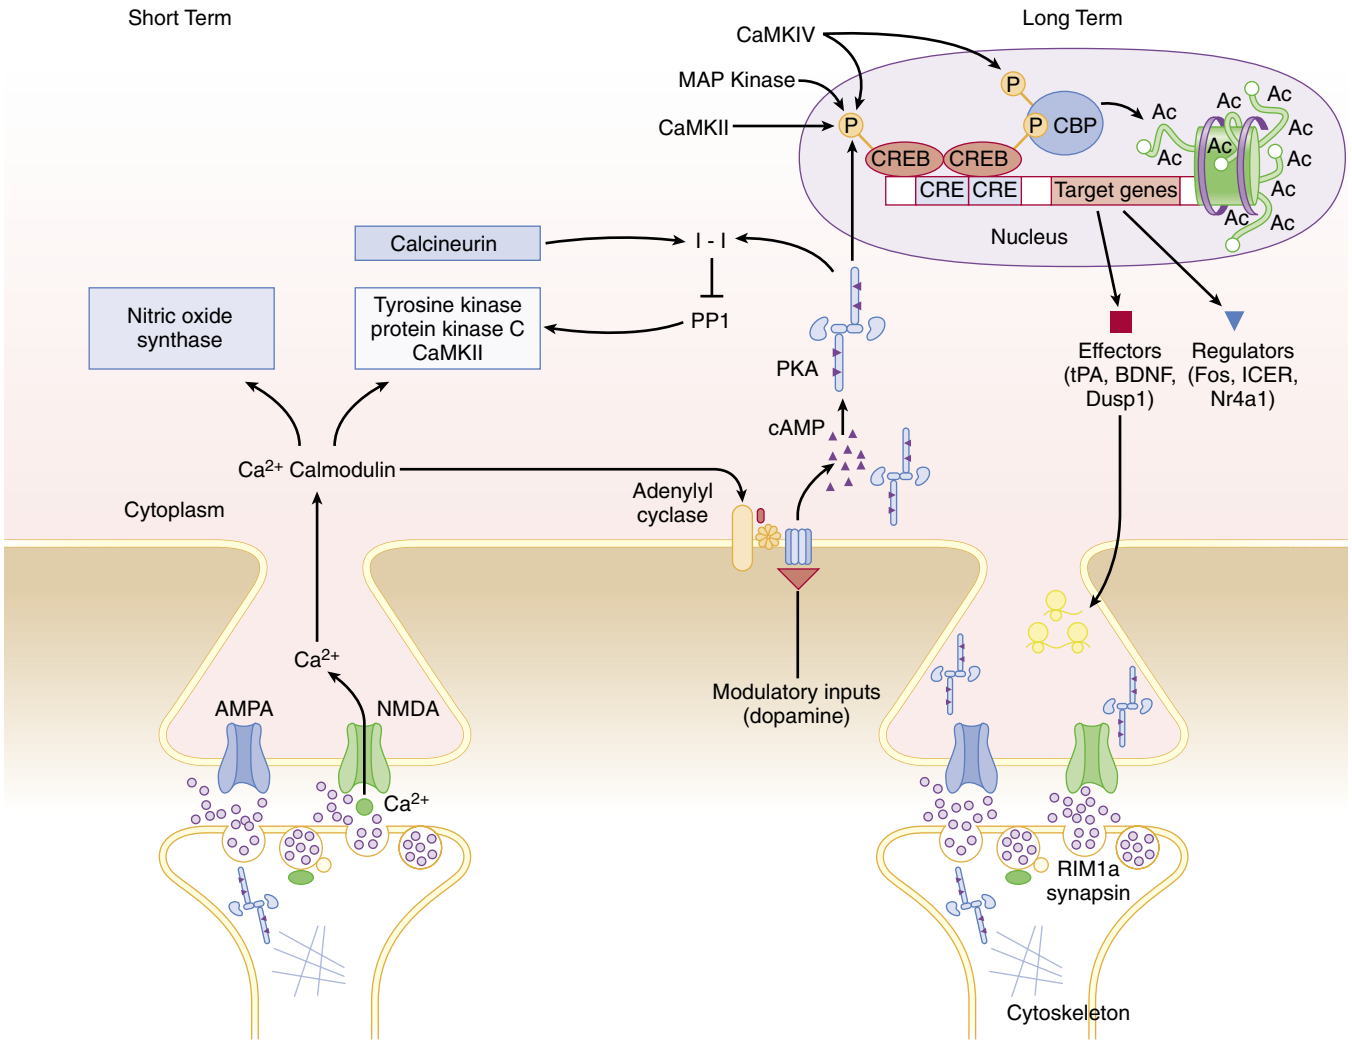

Figure 11-11 Long-term potentiation and long-term memory are mediated by similar molecular mechanisms involving calcium influx through the *N*-methyl-D-aspartate receptor and activation of intracellular signaling pathways that lead to activation of gene expression and synthesis of new proteins. *(Modified from Abel T, Nguyen PV, Barad M, et al: Genetic demonstration of a role for PKA in the late phase of LTP and in hippocampus-based long-term memory. Cell 88:615-626, 1997.)*

thought to impair LTP via GABAergic mechanisms.[112] α_5 Subunit–containing $GABA_A$ receptors are highly sensitive to amnestic concentrations of isoflurane.[116] However, other receptor signaling systems are certainly involved in mediating anesthetic-induced amnesia.[117-119]

Hippocampal θ rhythms (or θ oscillations) are the largest-amplitude synchronous EEG signals that can be recorded from mammalian brain. θ Oscillations have a characteristic frequency in the 5- to 12-Hz range in the behaving rat and dominate the EEG spectrum during NREM sleep (as discussed earlier), as well as during waking behavior essential for survival, such as exploration. Hippocampal θ oscillations are thought to facilitate mnemonic processes in vitro and in vivo. At the circuit level, anesthetics have recently been shown to alter hippocampal θ oscillations, a finding that may underlie anesthetic-induced amnesia.[120]

At the molecular level, propofol inhibits NMDA receptor–mediated activation of one subclass of the MAPK superfamily, extracellular signal–regulated protein kinase 1/2 (ERK1/2), in hippocampal neurons. This results in concurrent inhibition of transcriptional activity inasmuch as interference with MAPKs can uncouple synaptic events from nuclear responses. This finding might provide a molecular mechanism through which an anesthetic impairs transcription-dependent encoding of memory.[117,119] However, whether this mechanism represents a common action of anesthetic-induced amnesia awaits further elucidation.

The hippocampus is not the only limbic system structure thought to be involved in anesthetic-induced amnesia. It has now been established in animal models that the basolateral nucleus of the amygdala is critical for the amnestic effects of general anesthetics. Propofol, benzodiazepines, and sevoflurane lose their amnestic power if the basal nucleus of the amygdala is lesioned.[121,122] These data suggest that the amnestic doses of general anesthetics modulate output of the amygdala in such a way that memory formation is diminished. The role of the amygdala in anesthetic-mediated amnesia may be related to the hippocampus because the two structures are strongly interconnected. Furthermore, the inability of an anesthetic agent to suppress

memory has clinical implications for patients who are experiencing intraoperative awareness, a topic to which we turn in the next section.

Consciousness

Historical Background

It has been known since antiquity that inhalation of certain gases may alter consciousness. As Strabo (64 BC-AD 25) wrote of the Delphic oracles: "They say that the seat of the oracle is a cavern hollowed deep down in the earth, with a rather narrow mouth, from which rises a vapor that produces divine possession. A tripod is set above this cleft, mounting which, the Pythia inhales the vapor and prophesies." Only recently did evidence emerge that the general anesthetic ethylene may have been the vapor in the Temple of Apollo that induced these mystical states.[123]

In the modern era, renowned psychologist William James' experiments with nitrous oxide influenced one of his greatest works, *The Varieties of Religious Experience*, and yielded an 1898 article titled "Consciousness under Nitrous Oxide."[124] By the end of the 19th century, James and others regarded consciousness as a fundamental scientific question. In the 20th century, however, the dominating psychological paradigms of behaviorism and psychoanalysis disregarded or actively discouraged consciousness as a subject of serious inquiry. This antipathy toward the scientific study of consciousness persisted until the 1980s. Although Harvard anesthesiologist Henry Beecher promoted general anesthetics as a tool to study consciousness in the mid-20th century,[125] it was not until the 21st century that a true renaissance of interest in consciousness and anesthesia emerged. The current focus on consciousness within the field of anesthesiology is related primarily to anesthetic mechanisms or intraoperative awareness.

Neural Correlates of Consciousness

Whereas philosophers at the time of the Delphic oracles were concerned with the nature of being (ontology), the focus of 18th century thinkers such as Immanuel Kant was the nature and mechanism of knowing (epistemology). In his *Critique of Pure Reason*, Kant argued that our minds affect the ideas that we have about nature. Human experience of reality has two nonintersecting parts: (1) the part accessed by our senses (the phenomenal realm) and (2) the part outside cognition (the noumenal realm). The mind must possess, according to Kant, innate categories to be able to take the information in the phenomenal realm and make inferences about what lies in the noumenal one. Stated another way, he posited that the mind was modular, with discrete faculties that subserved specific cognitive functions. He recognized, however, that for these specific functions to be translated into a unified perceptual experience, there must be a process of integration that is essential.

Consistent with the philosophy of Kant, neuroscientist Giulio Tononi has proposed a 21st-century "information integration" theory of consciousness, as well as a theoretical model that expresses the capacity of neural systems to synthesize information.[126,127] Tononi suggests that consciousness reflects a higher capacity to integrate information processed in functionally specialized modules, which is why, for example, thalamocortical circuits seem to be more relevant to conscious processes than cerebellar circuits do.

In more concrete terms, the neural correlates of particular sensory modalities (e.g., the visual) must ultimately be combined with other sensory modalities (e.g., the tactile) to generate a unified perception. This is also true of the various submodalities of sensory perception (such as color, form, and motion in visual processing). For example, we do not perceive the sun as sequentially spherical, yellow, and warm, but instead experience all these distinct traits at one time. Thus, there is a unity to our conscious experience. Because, however, the brain processes these traits in a number of discrete neuronal subpopulations (e.g., visual and somatosensory cortices), there must be a higher-order process that synthesizes the information. This process is often referred to as "cognitive binding."[128,129]

Cognitive binding is thought to be necessary, though perhaps not sufficient, for consciousness itself. Several mechanisms for integration of neural information have been proposed, including convergence, assembly, and synchrony.[130,131] Binding by convergence is a hierarchic processing strategy characterized by transmission of information from primary to higher-order brain regions for integration.[132-134] Binding by assembly refers to information synthesized in a Hebbian cell assembly, that is, a group of interrelated neurons whose connections grow stronger with repeated firing together.[135] Finally, binding by synchrony introduces a temporal dimension to synthesis and is thought to be associated with neural events at the frequency of 40 Hz.[136-138]

Many of the neural regions or processes that are considered correlates of consciousness are linked to integration of information. Neural correlates may be identified through a number of methods, including clinicopathologic correlation, functional neuroimaging, and neurophysiologic recording. A number of candidates for the neural substrate of consciousness emerged in the 1980s and 1990s, including

- Extended reticular-thalamic activation system[139]
- Intralaminar nucleus in the thalamus[140]
- Reentrant loops in thalamocortical systems[141]
- 40-Hz rhythmic activity in thalamocortical systems[137]
- Neurons in the superior temporal sulcus[142]
- Neural activity in visual area V5/MT[143]
- Neurons in the extrastriate visual cortex projecting to prefrontal areas[144]
- Anterior cingulate system[145]
- Recurrent processing from higher to lower cortical areas[146]

Rees and colleagues discussed the evidence for many of these neural correlates of human consciousness.[147] As we discuss in the following sections, these correlates may serve as the anatomic or neurophysiologic substrates on which general anesthetics act to suppress consciousness.

Effects of Anesthetics on Neural Correlates

General anesthetics may generate unconsciousness by suppressing the activity of the neural correlates at various levels of neural organization, as well as by disrupting processes of information

integration. It has become clear that many of the proposed neural correlates of consciousness are modulated by general anesthetics.

Subcortical and Thalamocortical Effects

Functional neuroimaging by positron-emission tomography (PET) during isoflurane or halothane anesthesia demonstrated reduced cerebral glucose metabolism in subcortical structures associated with arousal, including the thalamus and midbrain reticular formation.[49] PET has also revealed suppression of thalamic activity in association with propofol-induced unconsciousness.[61] Other subcortical structures affected include the arousal-promoting TMN in the hypothalamus, which has been associated with anesthetic-induced hypnosis.[66]

Recent data acquired by electrophysiologic techniques in humans have brought into question the role of subcortical structures such as the thalamus. Because PET has poor temporal resolution,[148] Velly and associates compared cortical EEG tracings with recordings from subcortical deep brain electrodes in the human subthalamic nucleus. The authors were able to deduce that their field recordings were actually detecting thalamic rather than subthalamic activity. Loss of consciousness with propofol or sevoflurane was correlated with the cortical EEG, whereas minimal changes in the subcortical recording were identified. As discussed earlier, Alkire and colleagues demonstrated that nicotinic cholinergic agonism in the central medial thalamic nucleus could reverse sevoflurane-induced unconsciousness.[64] Although it would appear that these data contradict the findings of Velly and coworkers, administration of the nicotinic antagonist mecamylamine in the central medial nucleus did not induce anesthesia or even reduce anesthetic requirements. Alkire and associates concluded that the central medial nucleus may be an "on" switch for arousal but not an "off" switch for anesthesia.

The thalamocortical system is thought to be critical for consciousness. The resonance of thalamocortical circuits has been proposed as the "dynamic core" of consciousness[141] and is consistent with cognitive binding by 40-Hz oscillations.[137] Alkire and associates described a "unified theory of narcosis" based on the finding that thalamocortical circuits were disrupted under general anesthesia.[49] It has been demonstrated that isoflurane and halothane disrupt functional connectivity between the thalamus and cortex.[149] In this context, functional connectivity refers to the correlation of neurophysiologic activity in two spatially distinct brain regions.[150] Propofol has also been shown to induce a hyperpolarization block of thalamocortical neurons.[151]

Cortical and Corticocortical Effects

General anesthetics have been demonstrated to affect a number of cortical brain regions. Variable electromagnetic tomographic analysis has demonstrated that multiple general anesthetics induce reversible inhibition of the medial orbital and dorsolateral prefrontal and frontal cortex, anterior cingulate cortex, and paracentral gyrus.[152] The finding of frontal and cingulate cortex inhibition was consistent with previous PET findings of propofol-induced anesthesia.[61] As noted earlier, both the prefrontal and anterior cingulate cortices have been proposed as neural correlates of conscious processing.

It has been demonstrated that general anesthetics of distinct pharmacologic properties affect EEG coherence in a similar way during unconsciousness, an effect that is reversed on the return of consciousness.[152] In 176 cases of human surgical anesthesia using a variety of both inhaled and intravenous anesthetics, there were invariant changes in the electrical uncoupling of brain regions. Multivariate analysis of quantitative EEG recordings showed that γ oscillations (35 to 50 Hz) of the rostral and caudal regions of the brain became uncoupled from one another. These changes were associated with the onset of anesthesia, intensified with increasing depth of anesthesia, and reversed with the termination of anesthesia.

Rostrocaudal dissociation is of particular relevance given the proposed scans of 40-Hz oscillations that sweep from the frontal to the occipital cortex and back again.[137] In addition to this functional rostrocaudal disconnection, the hemispheres themselves became functionally disconnected. The effects of anesthesia on rostrocaudal processing have been studied in animal models as well. It has been demonstrated that processing of visual stimuli during anesthesia can be transmitted from the occipital to the frontal cortex, whereas recurrent processing from the frontal back to the occipital cortex is interrupted.[153] This finding is consistent with the proposed neural correlate of recurrent processing of neural information,[146] that is, transmission of signals from higher-order areas back to primary processing areas.

Other studies in humans have shown functional uncoupling of neural regions in association with general anesthesia. Peltier and colleagues demonstrated loss of functional connectivity in the cerebral cortex during sevoflurane anesthesia.[154] This provides further evidence that anesthetics uncouple the activity of cortical regions that might otherwise influence one another in the waking state.

Information Dissociation and Unconscious States

Based on the effect of anesthetic-mediated interruption of neural information synthesis, a "cognitive unbinding" paradigm of general anesthesia was postulated.[155,156] This framework explicitly stated that anesthetics may function by interrupting various cognitive binding processes from the cellular to the global brain level. This was based, in part, on findings by John and associates[152] that demonstrated functional uncoupling of the hemispheric and rostrocaudal axes of the brain (interruption of synchronous binding). The cognitive unbinding paradigm was also based on interruption of synthetic processes in cortical area MT under isoflurane (interruption of convergent binding).[157]

John and Prichep's "anesthetic cascade" supported the concept of cognitive unbinding while at the same time postulated a specific stepwise process by which anesthetics suppress consciousness.[158] The proposed "cascade" is as follows:

- Depression of the brainstem reduces the influence of the ascending reticular activating system on the thalamus and cortex.
- Depression of mesolimbic-dorsolateral prefrontal cortex interactions leads to blockade of memory storage.
- Further depression of the ascending reticular activating system leads to hyperpolarization of GABAergic neurons in the nucleus reticularis of the thalamus, which results in
- Blockade of thalamocortical reverberations and the associated γ oscillations underlying perception,

Functional uncoupling of parietal-frontal cortical activity, thereby interrupting cognition, and finally
Reduced awareness of and increase in frontal δ- and θ-band activity.

Recent data on the temporal relationship of subcortical anesthetic effects bring into question the first step of the cascade.[148] Furthermore, it is unclear how agents such as ketamine or nitrous oxide, which can lead to EEG activation rather than depression,[159,160] fit within the proposed anesthetic cascade. Nonetheless, the anesthetic cascade is one of the most specific and data-driven theories of anesthetic-induced unconsciousness.

Walling and Hicks supported both cognitive unbinding and the anesthetic cascade based on EEG phase-space analysis of emergence from sevoflurane anesthesia in humans.[161] Return of consciousness was characterized by a higher-dimensional phase space, reflecting a complexity of brain dynamics that could sustain consciousness. The fractal "strange attractors" that were identified on emergence were posited to be the coherence of γ-band frequencies associated with consciousness, in what the authors referred to as "cognitive rebinding."

These frameworks of anesthetic-induced unconsciousness as information dissociation are supported by recent studies of other unconscious states. Studies of brain-injured patients in vegetative states have revealed fragmented cerebral activity[162] and loss of effective cortical connectivity.[163] It has therefore been suggested that vegetative states are "disconnection" syndromes.[164] The neural regions affected in vegetative states include the frontal cortex, cingulate cortex, association cortices, and thalamus,[164] which are also targets for general anesthetics. Like anesthesia, recovery from vegetative states is associated with return of thalamocortical connectivity.[165]

As discussed earlier, sleep is a state with a number of traits similar to general anesthesia.[166] Using transcranial magnetic stimulation and EEG recordings of subjects either asleep or awake, Massimini and coworkers[167] demonstrated that NREM sleep is also characterized by loss of effective cortical connectivity. The loss of cortical connectivity associated with sleep suggests a common feature with anesthetic-induced unconsciousness and vegetative states.

Consciousness in the Operating Room

Although consciousness is emerging as an important scientific problem that is intimately linked to the mechanism of general anesthesia, it can also pose a clinical problem intraoperatively. Awareness during general anesthesia—which denotes both awareness and subsequent explicit recall of intraoperative events—is a complication receiving increased attention by both patients and clinicians. Dreaming is another subjective state that can occur during anesthesia, with an incidence of 22% in patients undergoing elective cases.[168] Although some cases represented "near-miss" experiences of awareness, others were thought to occur during recovery from anesthesia.

Despite recent attention by the medical community and the lay press, the incidence of intraoperative awareness—and hence the magnitude of the problem—remains uncertain. A multicenter study in the United States by Sebel and colleagues[169] estimated an incidence of awareness with explicit recall of approximately 0.13%, a rate consistent with large European studies demonstrating awareness in 1 to 2 per 1000 cases.[170] In contrast, a recent study of awareness in a regional medical system reported a much lower incidence of 1 episode of awareness per 14,560 cases, or 0.0069%.[171] The timing and content of postoperative interviews probably play a role in this discrepancy.

A proportion of patients experiencing awareness may subsequently exhibit serious psychological sequelae, including post-traumatic stress disorder.[172] Earlier studies reported a greater than 50% incidence of post-traumatic stress disorder, whereas more recent studies suggest a much lower rate of occurrence.[173] Because of the profound distress that it can induce in patients, a reliable and practical method of detecting intraoperative consciousness would be an important clinical advance.

Assessing Consciousness Intraoperatively

As early as 1937, Gibbs and coauthors reported that EEG measurements were sensitive to the effects of general anesthetics.[174] However, the use of unprocessed EEG data to assess anesthetic depth in the operating room is impractical for a number of reasons: (1) there is no unique electrical "signature" of an unprocessed EEG that is invariant, (2) the use of standard multiple-channel diagnostic EEG devices is cumbersome in the intraoperative setting, and (3) the use of such diagnostic devices—capable of localizing the source of abnormal signal patterns—generally requires a dedicated interpreter. Because of these limitations, EEG monitors with a minimal number of channels that use processing algorithms have been developed in an attempt to monitor anesthetic depth and detect intraoperative awareness (see Chapter 39).

Fourier transformation of raw EEG data enables the derivation of median power and spectral edge frequencies, and a number of devices available for intraoperative use are based on Fourier-transformed EEG data.[175] The bispectral index analyzes burst suppression, β-band power, and bispectral coherence.[176] The Narcotrend Monitor (MonitorTechnik, Bad Bramstedt, Germany) analyzes stages and substages of anesthesia and was based on a similar developmental process as the BIS (with a distinct algorithm).[177] The Patient State Index (PSI; Physiometrix, Inc., N. Billerica, MA) is derived from quantitative EEG techniques and is based on signal relationships between the frontal and occipital brain regions.[178] Entropy monitors (e.g., S/5, Instrumentarium Corp. [Datex-Ohmeda], Helsinki, Finland) are based on the concept of information entropy posited by Shannon[179] and analyze randomness in frequency and phase relationships with the use of both EEG and frontal EMG.[180] Entropy monitors measure state entropy (response over the range of 0.8 to 32 Hz, reflecting the EEG-dominant spectrum) and response entropy (response over the range of 0.8 to 47 Hz, reflecting both EEG and EMG spectra). Whereas the aforementioned monitors record spontaneous EEG, the stimulus-response technique of auditory evoked potentials has also been used to assess anesthetic depth and can be analyzed in conjunction with other EEG signaling parameters.[181,182] Because the BIS has been extensively studied and is the most frequently used monitor to assess depth of anesthesia, it will be the focus of the remaining sections.

Development and Validation of the BIS Monitor

The BIS monitor was developed empirically by analyzing a high-fidelity database of EEG recordings from approximately 2000 patients who received a variety of commonly used general

anesthetics, sedative-hypnotics, and opioids (see Chapter 39).[176] Segments of the EEG were compared with clinical findings of hypnosis; candidate spectral and bispectral features of these segments were computed and tested for their ability to distinguish the clinically described hypnotic states. The best of these features were then combined by multivariate statistical modeling to form a composite index (dimensionless number between 0 and 100, where 0 is isoelectric and 100 is awake), which underwent further prospective testing in a larger database.

In the mid-1990s, a number of studies demonstrated that changes in BIS values were associated with movement in response to noxious stimuli, as well as hemodynamic responses to interventions such as laryngoscopy. A multicentered study using movement as the measured outcome found that BIS values had better response with hypnotic drugs such as isoflurane and propofol than with opiates.[183] Whereas some studies focused on the relationship of BIS to movement in an attempt to validate the BIS in terms of MAC, other studies investigated the relationship of BIS to hypnosis, or MAC-awake. Flaishon and associates[184] used propofol or thiopental to induce anesthesia while continuously monitoring the BIS. BIS values above 60 were highly correlated with the ability of subjects to respond to verbal command. Another multicentered investigation focused on validation of the BIS monitor by comparing BIS values with anesthetic drug concentrations and level of sedation.[185] Other studies confirmed the value of the BIS in measuring hypnotic response to both inhaled and intravenous general anesthetics.[186,187] The BIS has also been validated for assessing the depth of anesthesia in children.[188,189]

One study in a high-risk population showed a significantly decreased incidence of confirmed awareness.[190] When combining both "possible" and "confirmed" awareness events, however, there was no difference between the BIS and control groups. Furthermore, the high number needed to treat (138) and the associated cost ($2200 U.S. dollars) in the high-risk group bring into question use of the BIS to prevent awareness in the general population.

Comparison of the BIS with Other EEG-Based Monitors

Because of validation of the BIS in a number of clinical studies, other emerging technologies have been compared with the BIS for validation. Chen and coworkers[191] demonstrated that the PSI correlated well with the BIS during anesthesia induction, maintenance, and emergence. The PSI and BIS were found to be comparable in a small study of intravenous and inhaled anesthetics, with the PSI reported to have less electrocautery artifact.[192]

The Narcotrend monitor has been shown to correlate well with predicted propofol concentrations in addition to the BIS.[177] The Narcotrend index correlated with the BIS during propofol and remifentanil anesthesia in a small number of patients (n = 26).[193] The BIS and Narcotrend indices were also shown to be comparable in monitoring the depth of isoflurane anesthesia.[177]

State entropy and response entropy show close correlation with the BIS in assessing sevoflurane anesthesia,[194] as well as propofol-remifentanil anesthesia.[195] In a small study evaluating loss of response to verbal command and loss of consciousness during propofol anesthesia, it was suggested that state entropy may be more useful than the BIS.[196] One study also demonstrated comparable performance of the BIS and entropy modules during both intravenous and inhaled anesthesia, with less electrocautery interference by the entropy monitor.[197]

Limitations of the BIS

There are numerous limitations associated with BIS monitoring.[198] One such limitation is that BIS values remain unchanged or even elevated during nitrous oxide anesthesia.[160,199] The intravenous anesthetic ketamine may also elevate BIS levels,[159,200] perhaps reflecting its ability to increase the beta power of the EEG spectrum.[201] It is of interest that both ketamine and nitrous oxide are thought to act primarily through NMDA glutamate receptors.[202] The anesthetic effect of xenon, which also acts on this receptor system, is similarly not reflected with BIS technology.[203] It is of further interest that although spectral entropy values are increased by ketamine in a similar manner to the BIS,[204] the addition of nitrous oxide has been shown to decrease state and response entropy values.[205] Conversely, BIS values are sensitive to nonanesthetic agents routinely administered in the operating room and have been shown to decrease in patients receiving neuromuscular blockers, while fully conscious[206] and while anesthetized.[207] BIS values derived from multiple sensors on the same patient have also been shown to be discordant, suggesting intrapatient variability and poor reproducibility of the index.[208] These and other limitations indicate the need for more sophisticated monitors of anesthetic depth that are linked to the neurophysiologic mechanisms of consciousness.

Conclusion

The oscillating states of sleep and wakefulness are fundamental features of our existence; as such, they have been pondered philosophically since antiquity and explored scientifically in modern times. The field of anesthesiology has much to gain from these investigations and, just as importantly, much to offer in return. Our further understanding of the neuroscientific mechanisms of general anesthesia may provide fundamental insight into the nature of consciousness, unconsciousness, and the memories that bind them together to form a stable sense of self.

12 The Autonomic Nervous System

Key Points

1. The autonomic nervous system works in concert with renin, cortisone, and other hormones to respond to internal and external stresses.
2. The hallmark of the sympathetic nervous system is amplification; the hallmark of the parasympathetic nervous system is targeted response.
3. Inhaled and intravenous anesthetics can alter hemodynamics by influencing autonomic function.
4. β-Adrenergic blockade has emerged as important prophylaxis for ischemia and as therapy for hypertension, myocardial infarction, and congestive heart failure.
5. The sympathetic nervous system demonstrates acute and chronic adaptation to stress presynaptically and postsynaptically (e.g., biosynthesis, receptor regulation).
6. Presynaptic α-receptors play an important role in regulating sympathetic release.
7. Many therapies for the treatment of hypertension are based on direct or indirect effects of sympathetic function.
8. The vagus nerve is the superhighway of parasympathetic function; it accommodates 75% of parasympathetic traffic.
9. Aging and many disease states (e.g., diabetes, spinal cord injury) are accompanied by important changes in autonomic function.

The autonomic nervous system (ANS) controls the body's involuntary (i.e., outside of consciousness) activities. It is, at once, the most primitive and among the most essential of the body's systems—primitive in that its characteristics are largely preserved across all mammalian species and essential in that it oversees the body's responses to immediate life-threatening challenges and the body's vital maintenance needs (including cardiovascular, gastrointestinal, and thermal homeostasis). The ANS is divided into two subsystems, the sympathetic nervous system and the parasympathetic nervous system. A third subsystem, the enteric nervous system, has been added to the original characterization of the ANS. Activation of the sympathetic nervous system elicits what is traditionally called the fight-or-flight response, including redistribution of blood flow from the viscera to skeletal muscle, increased cardiac function, sweating, and pupillary dilation. The parasympathetic system governs activities of the body more closely associated with maintenance of function, such as digestive and genitourinary function. A major goal of administration of anesthetics is maintaining optimum homeostasis in patients despite powerful challenges to a sometimes tenuous physiologic balance. Intelligent administration of anesthetic care to patients requires knowledge of ANS pharmacology to achieve desirable interactions of anesthetics with the involuntary control system and to avoid responses or interactions that produce deleterious effects. Disease states may impair ANS function to a significant extent and thereby alter the expected responses to surgery and anesthesia. In addition, possible harmful effects of the human stress response have long been appreciated, and considerable effort has been expended in examining the possibility that modification or ablation of the stress response may actually improve perioperative outcome.

History and Definitions

Initially, nerves were thought to be connected in a giant syncytium. Claude Bernard, a student of Magendie, postulated the theory of transmission via synapses through the release of chemical mediators. Later, Sherrington initiated a systematic study of reflexes and described some characteristics of reflex function. A chemist, J.J. Abel, first synthesized epinephrine in 1899, and his student Langley demonstrated that it caused effects similar to those produced by stimulating postganglionic sympathetic neurons. Furthermore, Langley found that when the nerve was cut and epinephrine was injected, a more profound effect was produced, thus demonstrating denervation supersensitivity. From these observations, the concept of chemical transmission in the ANS developed. Sir Henry Dale isolated choline and studied an ester, acetylcholine, in animals. He demonstrated

that it causes a marked decrease in blood pressure and vasodilation.

Nerves are traditionally classified by the chemical transmitters that they contain. Nerves containing acetylcholine are called *cholinergic*, whereas those containing norepinephrine are called *adrenergic*. In addition to classifying nerves, the term cholinergic refers to other structures or functions that relate in some way to acetylcholine. For instance, cholinergic receptors (i.e., cholinoceptors) are proteins in cell membranes that react with acetylcholine and cause the cell to respond in a characteristic way (e.g., muscles contract, glands secrete). Cholinergic agonists are drugs that act like acetylcholine on cholinoceptors to cause the cell to react in its characteristic way. They are sometimes referred to as cholinomimetic drugs. Cholinergic antagonists are drugs that react with cholinoceptors to block access by acetylcholine and thereby prevent its action. These drugs may also be referred to as cholinolytic, cholinergic-blocking, or anticholinergic drugs.

Because muscarine, a chemical isolated from a mushroom, causes effects similar to those produced by activation of the parasympathetic nervous system, it was thought to be the endogenous parasympathetic transmitter. Thus, drugs that mimic the effects of muscarine on parasympathetically innervated structures, including the heart, smooth muscles, and glands, have been called *muscarinic* drugs.

In the early 1900s, nicotine was found to act on ganglionic and skeletal muscle synapses and on nerve membranes and sensory endings. Accordingly, drugs that act on these parts of the cholinergic system are called *nicotinic* drugs. Nicotinic drugs that are more specific in their action have been discovered and are referred to by the name of the system that they affect, such as ganglionic drugs or neuromuscular drugs. Agonists and antagonists exist in each category, with little crossover of effect between drugs acting at the ganglia and those acting at the neuromuscular junction.

For the purposes of this chapter, cholinergic nerves include the following (Fig. 12-1):

1. All the motor nerves that innervate skeletal muscle
2. All postganglionic parasympathetic neurons
3. All preganglionic parasympathetic and sympathetic neurons
4. Some postganglionic sympathetic neurons, such as those that innervate the sweat glands and certain blood vessels
5. Preganglionic sympathetic neurons that arise from the greater splanchnic nerve and innervate the adrenal medulla
6. Central cholinergic neurons

Drugs mimicking the action of norepinephrine are referred to as *sympathomimetic*, whereas drugs inhibiting the effects of norepinephrine are called *sympatholytic*. Adrenergic nerves release norepinephrine at the neuroeffector junction, whereas epinephrine and norepinephrine are released by the adrenal medulla.

Adrenergic receptors have been identified and subdivided into α- and β-receptors and further subdivided into α_1, α_2, β_1, β_2, and other types. α_2-Adrenergic receptors are primarily located on the presynaptic membrane and modulate release of norepinephrine, whereas postsynaptic α_1-adrenergic receptors mediate smooth muscle vasoconstriction (Fig. 12-2). β_1-Adrenergic receptors are found primarily on cardiac tissue, and β_2-adrenergic receptors mediate smooth muscle relaxation in some organs. Adrenergic neurons can be defined as follows (see Fig. 12-1):

1. Postganglionic sympathetic neurons
2. Some interneurons
3. Certain central neurons

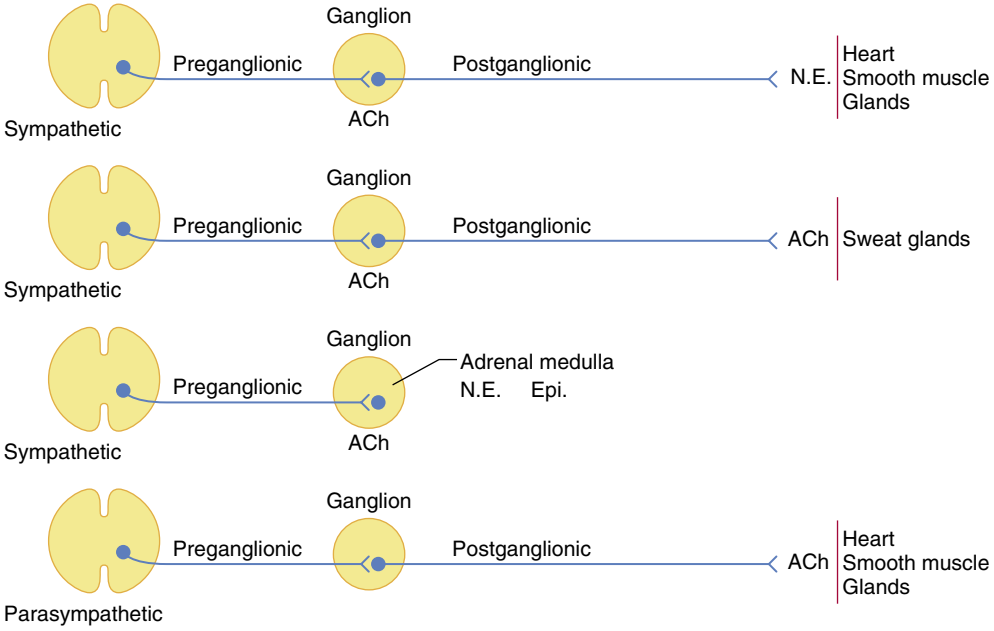

Figure 12-1 Autonomic nervous system neurotransmission. ACh, acetylcholine; Epi, epinephrine; NE, norepinephrine.

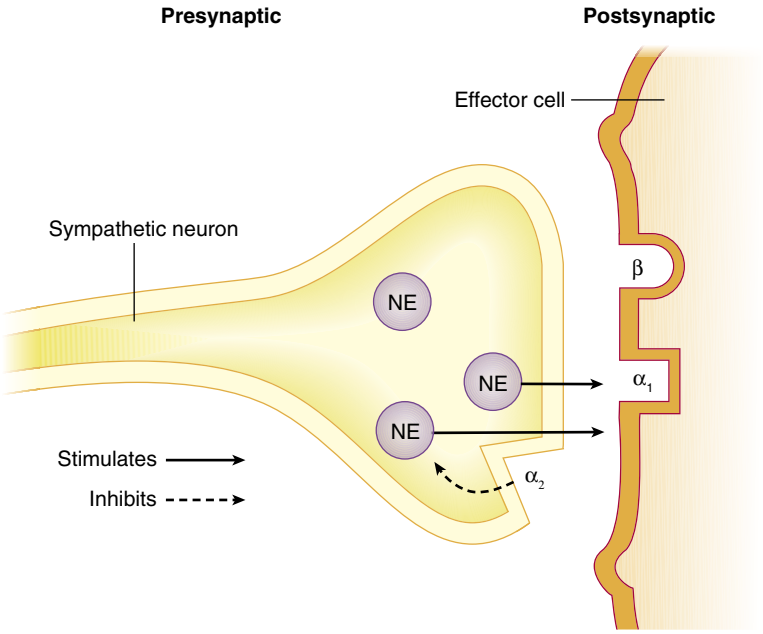

Figure 12-2 Preganglionic and postganglionic α-receptors of the sympathetic nervous system. The α_1-receptor is located postsynaptically on the membrane of the effector cell, whereas the α_2-receptor is located presynaptically on the cell membrane of the sympathetic nerve innervating the effector cell. NE, norepinephrine.

Functional Anatomy

Each branch of the ANS exhibits a different anatomic motif that is recapitulated on a cellular and molecular level. The underlying theme of the sympathetic nervous system is an amplification response, whereas that of the parasympathetic nervous system is a discrete and narrowly targeted response. The enteric nervous system is arranged nontopographically, as would be appropriate for the viscera, and relies on the mechanism of chemical coding to differentiate between nerves serving different functions.

Sympathetic Nervous System

The sympathetic nervous system originates from the spinal cord in the thoracolumbar region, from the first thoracic through the second or third lumbar segment. The preganglionic sympathetic neurons have cell bodies within the horns of the spinal gray matter (i.e., the intermediolateral columns). Nerve fibers from these cell bodies extend to three types of ganglia grouped as paired sympathetic chains, various unpaired distal plexuses, or terminal or collateral ganglia near the target organ.

The 22 paired ganglia lie along either side of the vertebral column. Nerve trunks connect these ganglia to each other, and gray rami communicantes connect the ganglia to the spinal nerves. The preganglionic fibers leave the cord in the anterior nerve roots, join the spinal nerve trunks, and enter the ganglion at their respective level through the white (myelinated) ramus. Leaving the ganglion, postsynaptic fibers reenter the spinal nerve through the gray (unmyelinated) ramus and then innervate the pilomotor and sudomotor (sweat gland) effectors and blood vessels of the skeletal muscle and skin (Fig. 12-3). Sympathetic postganglionic fibers innervate the trunk and limbs via the spinal nerves.

The sympathetic distribution to the head and neck, which enables and mediates vasomotor, pupillodilator, secretory, and pilomotor function, comes from the three ganglia of the cervical sympathetic chain. Preganglionic fibers of these cervical structures originate in the upper thoracic segments. In 80% of people, the stellate ganglion is formed by fusion of the inferior cervical ganglion with the first thoracic ganglion on each side.

The unpaired prevertebral ganglia reside in the abdomen and pelvis anterior to the vertebral column and are the celiac, superior mesenteric, aorticorenal, and inferior mesenteric ganglia. Postganglionic fibers arising from synaptic links of the upper thoracic sympathetic fibers in the vertebral ganglia form the terminal cardiac, esophageal, and pulmonary plexuses. The postganglionic fibers from the celiac, superior and inferior mesenteric plexuses innervate the viscera of the abdomen and pelvis (Fig. 12-4).

Ganglia of the third type, the terminal or collateral ganglia, are small, few in number, and near their target organs (e.g., the adrenal medulla). The adrenal medulla and other chromaffin tissue are homologous to the sympathetic ganglia, and all are derived embryonically from neural crest cells. Unlike sympathetic postganglionic fibers, however, the adrenal medulla releases epinephrine and norepinephrine.

Sympathetic preganglionic fibers are relatively short because sympathetic ganglia are generally close to the central nervous system (CNS), but they are distant from the effector organs; therefore, postganglionic fibers run a long course before innervating effector organs. The distribution is also diffuse and capable of amplification. Preganglionic sympathetic fibers may pass through multiple ganglia before synapsing, and their terminal fibers may contact large numbers of postganglionic neurons. The terminal fibers of preganglionic axons may synapse with more than 20 ganglia, and one cell may be supplied by several preganglionic fibers. Thus, preganglionic sympathetic fibers not only synapse at the ganglion of the level of their origin in the spinal cord but can also course up and down the paired ganglia. Sympathetic response, therefore, is not confined to the segment from which the stimulus originates, thereby allowing an amplified, diffuse discharge.

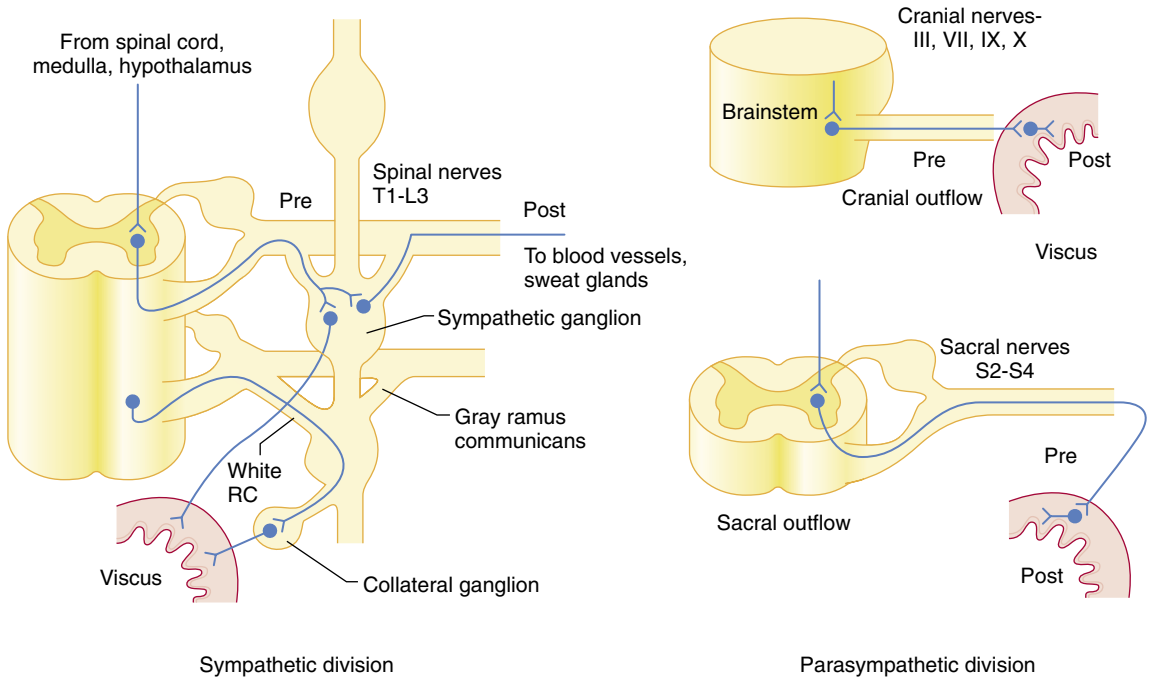

Figure 12-3 Autonomic nervous system. Pre, preganglionic neuron; Post, postganglionic neuron; RC, ramus communicans. *(From Ganong W: The autonomic nervous system.* In *Ganong W [ed]: Review of Medical Physiology, 15th ed. Norwalk, CT, Appleton & Lange, 1991, p 210.)*

Parasympathetic Nervous System

The parasympathetic nervous system arises from cranial nerves III, VII, IX, and X, as well as from sacral segments. Unlike the sympathetic nervous system, ganglia of the parasympathetic nervous system are in close proximity to or within the innervated organ. This location of ganglia makes the parasympathetic nervous system more targeted and less robust than the sympathetic nervous system.

Preganglionic fibers of the parasympathetic nervous system originate in three areas of the CNS: the midbrain, the medulla oblongata, and the sacral part of the spinal cord. Fibers arising in the Edinger-Westphal nucleus of the oculomotor nerve course in the midbrain to synapse in the ciliary ganglion. This pathway innervates the smooth muscle of the iris and the ciliary muscle. In the medulla oblongata lie parasympathetic components of the facial (lacrimatory nucleus), glossopharyngeal, and vagus (dorsal nucleus) nerves. The facial nerve gives off parasympathetic fibers to the chorda tympani, which subsequently synapses in ganglia of the submaxillary or sublingual glands, and to the greater superficial petrosal nerve, which synapses in the sphenopalatine ganglion. The glossopharyngeal nerve synapses in the otic ganglion. These postganglionic fibers innervate the mucous, salivary, and lacrimal glands; they also carry vasodilator fibers.

The vagus is the most important of the parasympathetic nerves and transmits fully three fourths of the traffic of the parasympathetic nervous system. It supplies the heart, tracheobronchial tree, liver, spleen, kidney, and entire gastrointestinal tract except for the distal part of the colon. The preganglionic fibers of the vagus are long, whereas the postganglionic fibers are short. Most vagal fibers do not synapse until they arrive at small ganglia on and about the thoracic and abdominal viscera. Although the parasympathetic nerves may synapse with a 1:1 ratio of nerve to effector cells, the vagal innervation of the Auerbach plexus may connect one nerve fiber to 8000 cells.

The second through fourth sacral segments contribute the nervi erigentes, or the pelvic splanchnic nerves. They synapse in terminal ganglia associated with the rectum and genitourinary organs.

Enteric Nervous System

Given the importance of clinical phenomena such as nausea, vomiting, and alterations in bowel and bladder function associated with anesthesia, it is surprising how little is understood about the third branch of the ANS. The enteric nervous system is the network of neurons and their supporting cells found within the walls of the gastrointestinal tract, including neurons within the pancreas and gallbladder. The enteric nervous system contains as many nerve cells as the spinal cord does. It is derived from neuroblasts of the neural crest that migrate to the gastrointestinal tract along the vagus nerve.

One major difference between the enteric nervous system and the sympathetic and parasympathetic branches of the ANS is its extraordinary degree of local autonomy. Digestion and peristalsis occur after spinal cord transection or during spinal anesthesia, although sphincter function may be impaired.

Although functionally discrete, the gut is influenced by sympathetic and parasympathetic activity. The sympathetic preganglionic fibers from T8 through L3 inhibit gut action via the celiac, superior, and inferior mesenteric ganglia; a spinal or epidural anesthetic covering the midthoracic levels removes this inhibition and yields a contracted, small intestine that may afford superior surgical conditions in combination with the profound

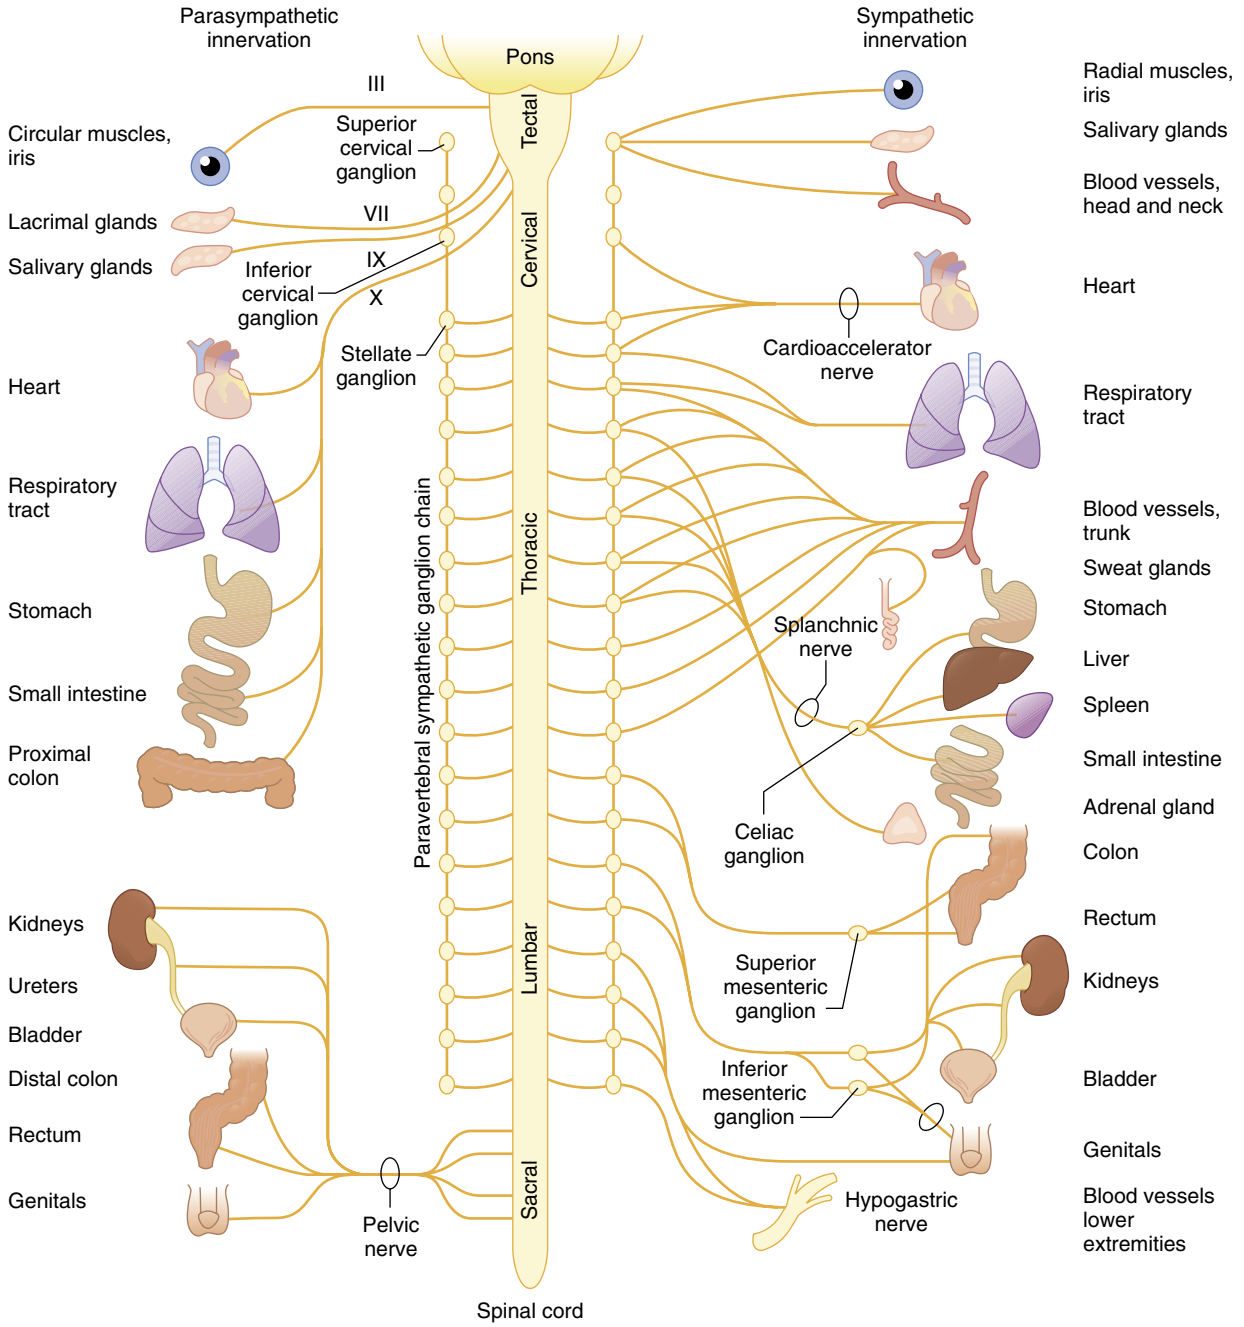

Figure 12-4 Schematic representation of the autonomic nervous system depicting the functional innervation of peripheral effector organs and the anatomic origin of peripheral autonomic nerves from the spinal cord. Although both paravertebral sympathetic ganglia chains are presented, the sympathetic innervation to the peripheral effector organs is shown only on the *right* part of the figure, whereas the parasympathetic innervation of peripheral effector organs is depicted on the *left*. The roman numerals on nerves originating in the tectal region of the brainstem refer to the cranial nerves that provide parasympathetic outflow to effector organs of the head, neck, and trunk. *(From Ruffolo R: Physiology and biochemistry of the peripheral autonomic nervous system.* In *Wingard L, Brody T, Larner J, et al [eds]: Human Pharmacology: Molecular to Clinical. St. Louis, Mosby–Year Book, 1991, p 77.)*

muscle relaxation of a spinal anesthetic. The sphincters are relaxed, and peristalsis is normally active.

Norepinephrine within the gut is the transmitter of postganglionic sympathetic neurons to the gut. For example, if the contents of the upper intestine become overly acidic or hypertonic, an adrenergically mediated enterogastric reflex reduces the rate of gastric emptying. The adrenergic neurons, which run to the myenteric ganglia of the gastrointestinal tract from the thoracic and lumbar spinal segments, are usually inactive in resting individuals. Reflex pathways within and external to the alimentary tract cause discharge of these neurons. When the viscera are handled during abdominal surgery, reflex firing of the adrenergic nerves inhibits motor activity of the intestine for an extended period. This adrenergic inhibition is thought to be the basis of the

common condition known as postoperative ileus. Loss of parasympathetic nervous control usually decreases bowel tone and peristalsis, but over time, the increased activity of the enteric plexus compensates for the loss. Spinal cord lesions may remove sacral parasympathetic input, but cranial parasympathetics may still be carried by branches of the vagus nerve down to the end-organ ganglia; colonic dilation and fecal impaction (which may precipitate hypertension in patients with autonomic dysreflexia) occur more often than small intestinal dysfunction.

Enteric neurons can be sensory and monitor tension in the wall of the intestine or its chemical contents, associative and act like interneurons, or motor and contract intestinal muscles, dilate vessels, or transport water and electrolytes. Motor neurons in the enteric nervous system may be excitatory or inhibitory.

Certain plexuses play important roles in the enteric nervous system. The myenteric plexus, also called the Auerbach plexus, is a network of nerve strands and small ganglia lying in the plane between the external longitudinal and circular muscle coats of the intestine. The submucous plexus (Meissner plexus) consists of nerve cell bodies, glial cells, and glial and neuronal processes, but it does not contain connective tissue or blood vessels. Within the ganglia, many neuronal processes contain vesicles that store neurotransmitters.

Unlike the sympathetic and parasympathetic nervous systems, in which geographic location can confer selective action, this is anatomically impossible in the gut, and an alternative pattern of chemical coding for function assumes an important organizational role. The combination of amines and peptides and their relative concentrations within the enteric neuron determine its function.

Acetylcholine, the principal excitatory trigger of the nonsphincteric portion of the enteric nervous system, causes muscle contraction. Cholinergic neurons have several roles in the enteric nervous system, including excitation of external muscle, activation of motor neurons augmenting secretion of water and electrolytes, and stimulation of gastric cells. Neural control of gastrointestinal motility is mediated through two types of motor neurons: excitatory and inhibitory. These neurons act in concert on the circular smooth muscle layer in sphincteric and nonsphincteric regions throughout the digestive tract and supply muscles of the biliary tree and the muscularis mucosae. Although excitatory motor neurons supply the external longitudinal muscle, the role of inhibitory motor neurons is not well established in this muscular layer. Enteric motor neurons to the circular muscle of the small and large intestine are activated by local reflex pathways contained within the wall of the intestine. Distention evokes polarized reflexes, including contraction proximally and relaxation distally, which in synchrony constitute peristalsis. Nicotinic antagonists abolish enteric reflexes, thus suggesting that the sensory neurons or interneurons in the pathway are cholinergic. In cases of cholinergic overload, such as insecticide poisoning or "over-reversal" of muscle relaxants, the gut (in which cholinesterase is inhibited) has a tendency to become hyperreactive.

There are many neuroactive compounds other than norepinephrine and acetylcholine that participate in the autonomic control of intestinal function. The predominant of these nonadrenergic noncholinergic (NANC) neurotransmitters appears to be nitric oxide (NO), a primary intrinsic inhibitor, but other NANC neurotransmitters such as substance P, a variety of opiate peptides, vasoactive intestinal polypeptide (VIP), and a growing population of peptide hormones are also present (Table 12-1) (see Chapter 31).

Table 12-1 Neuropeptides and Their Actions in the Gastrointestinal Tract

Peptide	Action(s)
Bombesin	Multiple stimulatory effects (including gastrin release)
Calcitonin gene–related peptide	Gastric acid secretion, muscle constriction
CCK8	Unknown
Dynorphin	Opiate effects
Endothelin-1	Vasoconstriction
Galanin	Muscle constriction
Leu-enkephalin	Opiate effects
Met-enkephalin	Opiate effects
Neuromedin U	Muscle constriction, vasoconstriction
Neuropeptide Y	Vasoconstriction
Pituitary adenylate cylase	Adenylate cyclase–activating peptide
Peptide histidine methionine	Muscle relaxation, secretion
Somatostatin	Multiple inhibitory effects (including gastrin inhibition)
Substance P	Vasodilation, muscle constriction
Vasoactive intestinal polypeptide	Vasodilation, muscle relaxation, secretion

Modified from Bishop A, Polak J: The gut and the autonomic nervous system. *In* Mathias C, Bannister R (eds): Autonomic Failure: A Textbook of Clinical Disorders of the Autonomic Nervous System, 4th ed. Oxford, Oxford University Press, 1999, p 120.

Function

Organization and Integration

The sympathetic system, in response to internal or external challenges, acts to increase the heart rate, arterial pressure, and cardiac output; dilate the bronchial tree; and shunt blood away from the intestines and other viscera to voluntary muscles. Parasympathetic nervous input acts primarily to conserve energy and maintain organ function and to support vegetative processes.

Most organs of the body exhibit dual innervation, with input from the sympathetic and parasympathetic systems frequently mediating opposing effects (Table 12-2).[1] Stimulation of one system may have an excitatory effect on the end organ, whereas stimulation of the other system may have an inhibitory effect. For example, sympathetic stimulation acts on the heart to increase the rate and vigor of contraction and enhance conduction through the atrioventricular (AV) node, whereas parasympathetic stimulation acts to decrease the heart rate, atrial

Table 12-2 Responses Elicited in Effector Organs by Stimulation of Sympathetic and Parasympathetic Nerves

Effector Organ	Adrenergic Response	Receptor Involved	Cholinergic Response	Dominant Response (A or C)
Heart				
Rate of contraction	Increase	β_1	Decrease	C
Force of contraction	Increase	β_1	Decrease	C
Blood vessels				
Arteries (most)	Vasoconstriction	α_1		A
Skeletal muscle	Vasodilation	β_2		A
Veins	Vasoconstriction	α_2		A
Bronchial tree	Bronchodilation	β_2	Bronchoconstriction	C
Splenic capsule	Contraction	α_1		A
Uterus	Contraction	α_1	Variable	A
Vas deferens	Contraction	α_1		A
Prostatic capsule	Contraction	α_1		A
Gastrointestinal tract	Relaxation	α_2	Contraction	C
Eye				
Radial muscle, iris	Contraction (mydriasis)	α_1		A
Circular muscle, iris			Contraction (miosis)	C
Ciliary muscle	Relaxation	β	Contraction (accommodation)	C
Kidney	Renin secretion	β_1		A
Urinary bladder				
Detrusor	Relaxation	β	Contraction	C
Trigone and sphincter	Contraction	α_1	Relaxation	A, C
Ureter	Contraction	α_1	Relaxation	A
Insulin release from pancreas	Decrease	α_2		A
Fat cells	Lipolysis	β_1		A
Liver glycogenolysis	Increase	α_1		A
Hair follicles, smooth muscle	Contraction (piloerection)	α_1		A
Nasal secretion			Increase	C
Salivary glands	Increase secretion	α_1	Increase secretion	C
Sweat glands	Increase secretion	α_1	Increase secretion	C

A, adrenergic; C, cholinergic.

contractility, and conduction through the AV node. One of the two systems normally dominates the organ's function and thus provides its "resting tone" (Table 12-3). In a few organs, the sympathetic system alone provides innervation; most blood vessels, the spleen, and piloerector muscles are examples.

To predict the effects of drugs, the interaction of the sympathetic and parasympathetic system in different organs must be understood. Blockade of sympathetic function unmasks preexisting parasympathetic activity, and the converse relationship is also true. For example, administration of atropine blocks the resting muscarinic tone of the parasympathetically dominated heart, and the unopposed sympathetic tone then causes tachycardia. Clinically, cardiac autonomic denervation occurs with cardiac transplantation; it may occur with neuraxial anesthesia, diabetes, and MI; and it can be assessed by changes in the time interval between successive heartbeats (i.e., beat-to-beat or heart rate variability) as a measure of sympathovagal balance.[2]

Adrenergic Function

Overview of the Effects of Sympathetic Mediators

Adrenergic neurons influence and adjust body functions, their effects on circulation and respiration being among the most important (Table 12-4).

The endogenous catecholamines norepinephrine and epinephrine possess α- and β-receptor agonist activity. Norepinephrine has minimal β_2-receptor activity, whereas epine-

Table 12-3 Usual Sympathetic or Parasympathetic Dominance at Specific Effector Sites

Site	Predominant Tone
Ciliary muscle	Parasympathetic
Iris	Parasympathetic
Sinoatrial node	Parasympathetic
Arterioles	Sympathetic
Veins	Sympathetic
Gastrointestinal tract	Parasympathetic
Uterus	Parasympathetic
Urinary bladder	Parasympathetic
Salivary glands	Parasympathetic
Sweat glands	Sympathetic (cholinergic)

phrine stimulates β_1- and β_2-receptors (Table 12-5). α-Receptor–mediated activity is responsible for most of the sympathetically induced smooth muscle contraction throughout the body, including the ciliary muscle of the eye and vascular, bronchial, and ureteral smooth muscle. The gastrointestinal and genitourinary sphincter mechanisms are stimulated by α-adrenergic receptors. α-Receptor agonism also mediates sympathetic nervous system control of pancreatic insulin secretion, with stimulation of α_2-receptors leading to decreased release of insulin from pancreatic beta cells. In the peripheral vasculature, α_1- and α_2-receptors modulate vascular tone in response to humorally borne neurotransmitters and exogenously administered drugs.

β-Receptor agonism is primarily responsible for sympathetic stimulation of the heart, relaxation of vascular and bronchial smooth muscle, stimulation of renin secretion by the kidney,

Table 12-4 Effects of Activation of the Sympathetic Nervous System

Site of Action	Stimulation	Inhibition
Heart	Rate, conduction, contractility	
Blood vessels	Vasoconstriction (skin, gut, liver, heart, kidney)	Vasodilation (skeletal muscle, heart, brain)
Respiration	Respiratory center Bronchodilation	
Gastrointestinal tract	Sphincters	Smooth muscle
Genitourinary tract	Sphincters	Ureteral and uterine muscle
Metabolic and endocrine effects	Glycogenolysis (muscle, liver) Gluconeogenesis Insulin release (β_1) Renin release ADH release	Insulin release (α stimulation or β_1 antagonism) Lipolysis

ADH, antidiuretic hormone or arginine vasopressin.

Table 12-5 Adrenergic Receptor Differentiation

Receptor	Stimulation	Inhibition
Alpha		
Heart		
Blood vessels	Vasoconstriction (skin, gut, kidney, liver, heart)	
Gastrointestinal tract	Sphincters

(1), Mediated by β_1-receptors; (2), mediated by β_2-receptors; (?), controversial.

and several metabolic consequences, including lipolysis and glycogenolysis. The β_1-receptor mechanism is thought to primarily be involved in cardiac effects[3] and release of fatty acids and renin, whereas β_2-receptors are primarily responsible for smooth muscle relaxation and hyperglycemia. In specialized circumstances, however, β_2-receptors may also mediate cardiac activity. Although acute changes in arterial pressure and heart rate can be caused by norepinephrine or epinephrine, chronic hypertension does not appear to be related to circulating levels of these hormones. Eighty-five percent of resting arterial pressure is determined by the level of renin activity (Fig. 12-5). An additional important effect of epinephrine is to increase gap junctions in bone, which causes an increase in circulating blood elements.[4]

Psychological and physical stimuli may evoke different sympathetic compensatory responses. Public speaking activates the adrenal gland with a disproportionate rise in serum epinephrine, whereas physical exercise elicits primarily a marked rise in serum norepinephrine.[5] Thus, the stress response should not be thought of as a uniform response; it can vary in mechanism, intensity, and manifestations.

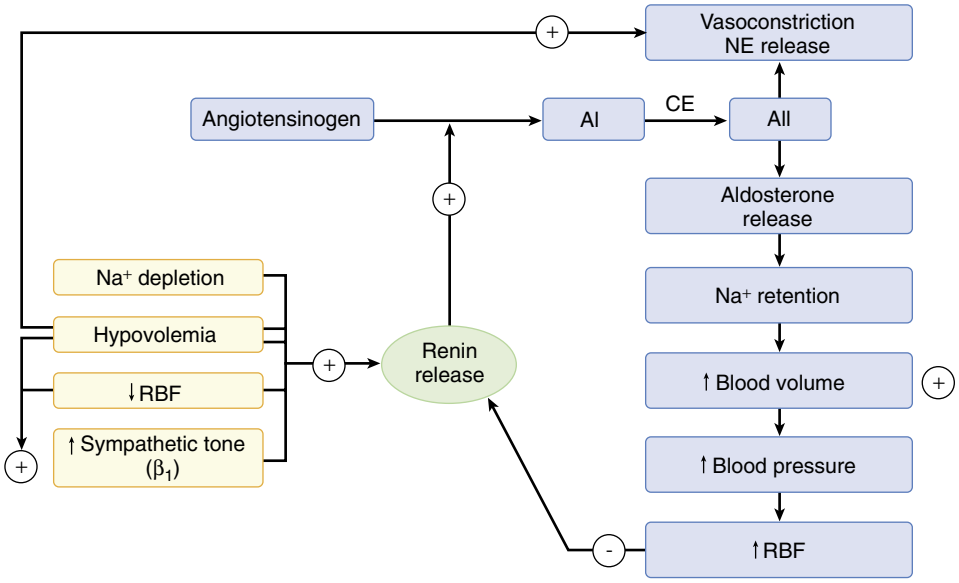

Figure 12-5 Interactions of the renin-angiotensin-aldosterone and sympathetic nervous systems in maintaining blood pressure and volume. AI, angiotensin I; AII, angiotensin II; CE, converting enzyme; NE, norepinephrine; RBF, renal blood flow; +, stimulating effects; –, inhibiting effects.

Blood Glucose

Sympathetic nervous stimulation of β-receptors increases glycogenolysis in liver and muscle and liberates free fatty acids from adipose tissue, thereby ultimately increasing blood glucose levels. In neonates, epinephrine plays an additional role in the exothermic breakdown of brown fat to maintain body temperature (i.e., nonshivering thermogenesis).

Also present in the pancreas are α_2 and β_2 receptors. α_2-Receptor activation suppresses insulin secretion by pancreatic islet cells; blockade of these receptors may increase release of insulin and thus could be associated with significant lowering of blood glucose levels. β_2-Receptor stimulation increases glucagon and insulin secretion and decreases peripheral sensitivity to insulin.[6]

Potassium Shift

Plasma epinephrine also takes part in regulation of the serum potassium concentration. β-Adrenergic activity can initiate transient hyperkalemia as potassium shifts out of hepatic cells with the glucose efflux produced by β_2-adrenergic stimulation. This effect is followed by a more prolonged hypokalemia as β_2-adrenergic stimulation drives potassium into red blood cells and muscle cells. Stimulation of the β_2-receptors of red blood cells by exogenously administered or endogenously released epinephrine activates adenylate cyclase and sodium-potassium adenosine triphosphatase (ATPase) and drives potassium into cells. This leads to a reduction in serum potassium concentration and may contribute to the cardiac arrhythmias accompanying MI and other stresses. β_2-Adrenergic blockade has the theoretical advantage of inhibiting this potassium shift. However, selective and nonselective β-blockers have been shown to be equivalent in protecting the postinfarction heart against arrhythmias.[7-11]

Cholinergic Function

Overview of the Effects of Acetylcholine

In contrast to the diffuse discharge of the sympathetic nervous system that constitutes the fight-or-flight response, the parasympathetic system is anatomically and functionally more localized in its effects. Parasympathetic activation conserves energy and maintains organ function. A massive parasympathetic response would prostrate the organism, leaving it helplessly salivating, weeping, wheezing, vomiting, urinating, defecating, and seizing. Although the sympathetic system is needed for the emergency response to stressful situations, it is not necessary for survival; the parasympathetic system is, however, essential for maintenance of life.

Release of acetylcholine is the hallmark of parasympathetic activation. The actions of acetylcholine are almost diametrically opposed to those of norepinephrine and epinephrine. In general, the muscarinic effects of acetylcholine are qualitatively the same as the effects of vagal stimulation.

Acetylcholine decreases the heart rate, the velocity of conduction in the sinoatrial and AV nodes, and atrial contractility (although this decrease is not as marked as the increase in contractility produced by sympathetic stimulation). In the sinoatrial node, acetylcholine causes membrane hyperpolarization, which delays attainment of the threshold potential and the ability to generate another action potential, thereby slowing the heart rate. In the AV node, acetylcholine decreases conduction velocity and increases the effective refractory period. This decrease in AV nodal conduction accounts for the complete heart block seen when large amounts of cholinergic agonists are given. In the ventricle, acetylcholine decreases automaticity in the Purkinje system, thereby increasing the fibrillation threshold. Cardiac presynaptic and postsynaptic muscarinic receptors are involved in these effects. Acetylcholine inhibits adrenergic stimulation of the heart presynaptically by inhibiting the release of norepinephrine from sympathetic nerve endings and postsynaptically by opposing the effects of catecholamines on the myocardium.

Parasympathetic activation has many effects outside the cardiovascular system. Cholinergic stimulation causes smooth muscle constriction, including that of the bronchial walls. In the gastrointestinal and genitourinary tracts, smooth muscle in the walls constricts, but the sphincter muscles relax, which results in incontinence. Topically administered acetylcholine constricts the smooth muscle of the iris and causes miosis.

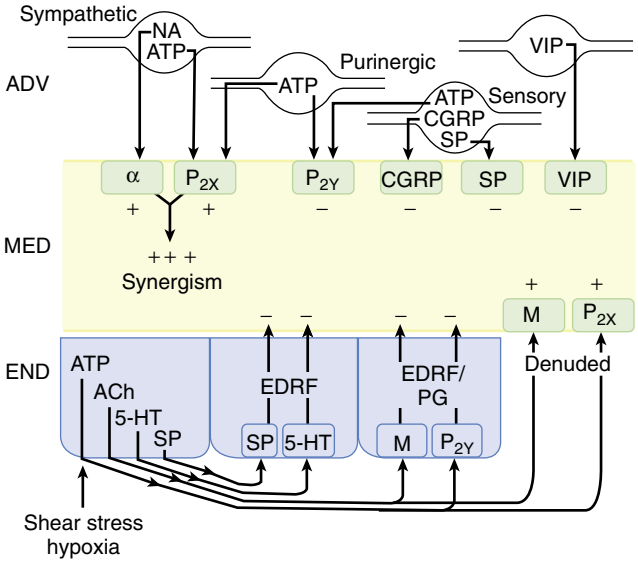

Figure 12-6 Schematic representation of potential modes of regulation of vascular tone by endothelial cell–related mechanisms. Norepinephrine (NA), adenosine triphosphate (ATP), calcitonin gene–related peptide (CGRP), substance P (SP), and vasoactive intestinal polypeptide (VIP) can be released from nerves in the adventitia (ADV) to act on their respective receptors in the media (MED) and cause vasoconstriction or vasodilation. ATP, acetylcholine (ACh), 5-hydroxytryptamine (5-HT), and SP released from endothelial cells (END) by shear stress or hypoxia act on their receptors on endothelial cells to cause release of endothelium-derived relaxing factors (EDRF) or prostaglandins (PG), which act on smooth muscle to cause relaxation. In areas denuded of endothelial cells, opposite effects may be produced by receptors on smooth muscle. α, noradrenaline receptor; M, muscarinic receptor; P_{2X}, P2X purinoceptor; P_{2Y}, P2Y purinoceptor. *(From Lincoln J, Burnstock G: Neural-endothelial interactions in control of local blood flow.* In *Warren J [ed]: The Endothelium: An Introduction to Current Research. New York, Wiley-Liss, 1990, p 21.)*

The signs and symptoms of cholinergic overload reflect all these effects, as well as nausea and vomiting, intestinal cramps, belching, urination, and urgent defecation. All glands innervated by the parasympathetic nervous system are stimulated to produce secretions, including the lacrimal, tracheobronchial, salivary, digestive, and exocrine glands.

Local Control of Vascular Tone

In addition to the pharmacologic effects of acetylcholine that are mediated by the parasympathetic nervous system, blood-borne acetylcholine has a significant effect on blood vessels in that it dilates virtually all vessels in vivo. Endothelial cells respond to acetylcholine stimulation by producing one or more endothelium-derived relaxing factors (EDRFs).[12] It now appears that endothelial cells have receptors for numerous agonists, including serotonin, adenosine, histamine, and catecholamines (Fig. 12-6). The radical NO was the first identified EDRF (see Chapter 31 for details). When the endothelium is damaged, as in atherosclerosis, production of EDRF diminishes and constriction increases. This change explains why patients with damaged or diseased vessels react differently.

An understanding of the biology of NO is fundamental to an appreciation of many vital body functions (see Chaper 31).[13] Endothelial cells play a role in control of the circulation in addition to the production of NO. Endothelial cells metabolize many vasoactive amines, convert angiotensin I to angiotensin II, and secrete prostacyclin and the vasoconstrictive peptide endothelin-1 (ET-1). NO, ET-1, and prostacyclin are local hormones released by endothelial cells to influence their immediate microenvironment. Prostacyclin and NO relax vascular smooth muscle, whereas in the lumen, they act separately or in concert to prevent platelets from clumping onto the endothelium. There is clear synergism between the antiaggregating effect of prostacyclin and subthreshold concentrations of NO. Substances that activate prostacyclin generally stimulate release of NO. Shear stress increases NO as an adaptive mechanism to dilate the circulation actively. NO works by the guanylate cyclase mechanism; prostacyclin works by activation of adenylate cyclase. Thus, although they work in concert, they activate different second messengers.

Whereas prostacyclin and NO are short-lived vasodilators, injection of the vasoconstrictor ET-1 causes a powerful and long-lasting pressor effect. ET-1, which is composed of 21 amino acids bound by two disulfide bonds, is generated enzymatically from the 39–amino acid ET-1 precursor known as big ET-1. The vasoconstrictor action of ET-1 results from activation of endothelin receptors on smooth muscle.[14]

NO, prostacyclin, and ET-1 appear to be operative in local control of the circulation. The prostacyclin system may be a redundant mechanism that reinforces the NO system in the presence of endothelial damage. Acting together, these two dilators are also a strong defense mechanism against intravascular thrombosis. ET-1 can be produced locally in response to trauma, such as wounds to the vessel wall, and it perhaps decreases blood loss. The long-term functions of these local hormones are of considerable interest in the pathophysiology of many disease states, including septic shock, pulmonary hypertension, and renal failure.[15,16] For more information on NO biology, see Chapter 31.

Pharmacology

Adrenergic Pharmacology

Synthesis of Norepinephrine

Norepinephrine is synthesized from tyrosine, which is actively transported into the varicosity of the postganglionic sympathetic nerve ending (Fig. 12-7). Tyrosine is synthesized from phenylalanine. In hypertensive rats, tyrosine may increase central adrenergic transmission, thereby decreasing peripheral sympathetic outflow.[17] In hypotensive (hemorrhaged) rats, tyrosine may increase peripheral synthesis and release of catecholamines. Precursors are taken up in greater amounts in shock and may have beneficial effects on the effort of the sympathetic nervous system to maintain perfusion pressure.

A series of steps results in conversion of tyrosine to norepinephrine and epinephrine (in the adrenal medulla). The first of these steps involves the rate-limiting cytoplasmic enzyme tyrosine hydroxylase (TH). High levels of norepinephrine inhibit TH, and low levels stimulate the enzyme. During stimulation of the sympathetic nervous system, an increased supply of tyrosine also increases the synthesis of norepinephrine. TH activity is modified by phosphorylation. TH depends on a pteridine cofactor and the presence of molecular oxygen. When the quantity of molecular oxygen is reduced, synthesis of norepinephrine may be decreased

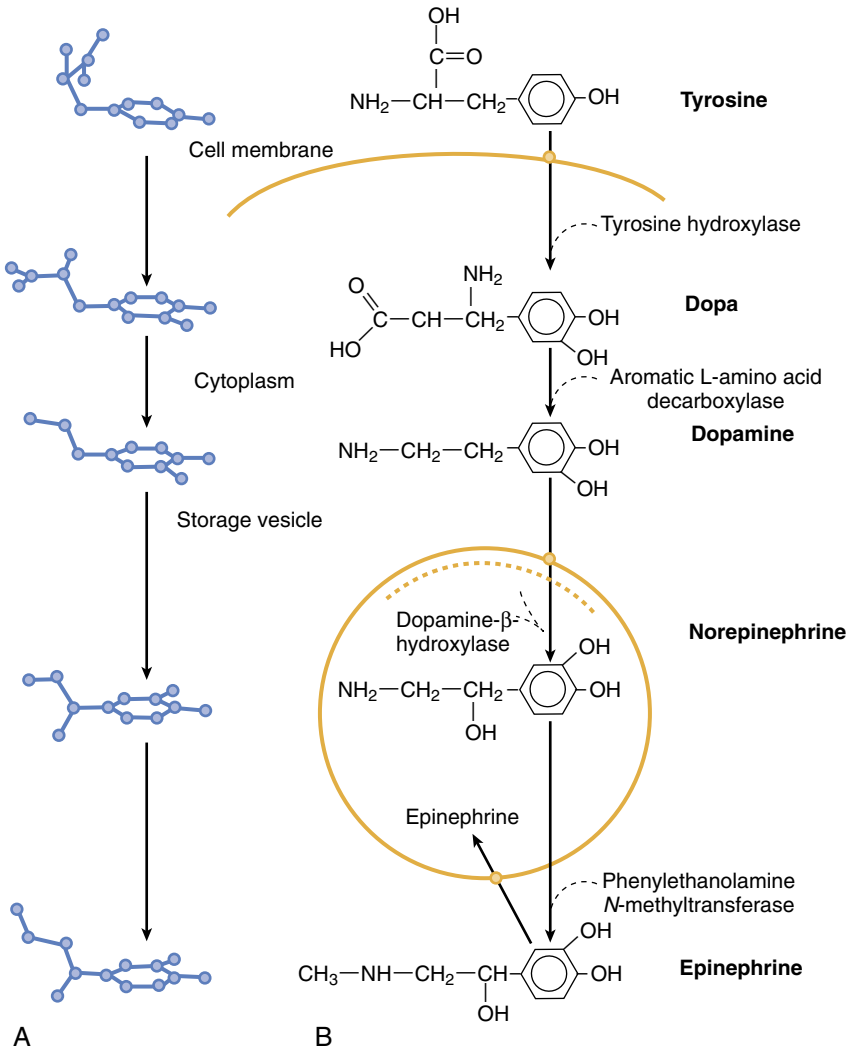

Figure 12-7 Biosynthesis of norepinephrine and epinephrine in sympathetic nerve terminal (and the adrenal medulla). **A,** Perspective view of molecules. **B,** Enzymatic processes. *(From Tollenaeré JP: Atlas of the Three-Dimensional Structure of Drugs. Amsterdam, Elsevier North-Holland, 1979; as modified by Vanhoutte PM: Adrenergic neuroeffector interaction in the blood vessel wall. Fed Proc 37:181, 1978.)*

significantly, which could account for changes in wakefulness. Whereas acute control of TH occurs by altering enzyme activity, chronic stress can elevate TH levels by stimulating the synthesis of new enzyme. Under the influence of TH, tyrosine is converted to dihydroxyphenylalanine (DOPA), which is decarboxylated to dopamine by aromatic amino acid decarboxylase (DOPA decarboxylase), a relatively promiscuous enzyme in its substrate specificity.

Dopamine can and does act as a neurotransmitter in some cells, but most of the dopamine produced is β-hydroxylated within the vesicles to norepinephrine by the enzyme dopamine β-hydroxylase (DβH). In the adrenal medulla and to a limited extent in discrete regions of the brain, another enzyme, phenylethanolamine *N*-methyltransferase (PNMT), methylates about 85% of the norepinephrine to epinephrine. Glucocorticoids from the adrenal cortex pass through the adrenal medulla and can activate the system, and stress-induced steroid release can increase the production of epinephrine. This local circulation amplifies the effects of glucocorticoid release.[18]

Storage of Norepinephrine

Norepinephrine is stored within large, dense-core vesicles. Electron microscopy suggests that the dense cores in these vesicles are filled not only with norepinephrine but also with binding proteins. In addition, the vesicles contain calcium, a variety of peptides, and adenosine 5′-triphosphate (ATP). Depending on the nature and frequency of physiologic stimuli, the ATP can be released selectively for an immediate postsynaptic effect through purinoreceptors. However, norepinephrine is the predominant neurotransmitter at sympathetic nerve endings.

Synaptic vesicles are heterogeneous and exist within functionally defined compartments. An actively recycling population of synaptic vesicles has been defined, together with a reserve population of vesicles that are mobilized only upon extensive stimulation. Functionally, norepinephrine is stored in compartments, 10% of which is readily releasable. In general, 1% of the stored norepinephrine is released with each depolarization, thus implying a significant functional reserve.

Release of Norepinephrine

There are several different processes by which the contents of the vesicle enter the synaptic cleft. The dominant physiologic mechanism of release is exocytosis, during which the vesicle responds to the entry of calcium by initiating vesicular docking, fusion, release of vesicular contents, and ultimately, endocytosis (the process by which the vesicular membrane and proteins are recap-

New York, Raven Press, 1979, p 107.)*

tured) (Fig. 12-8). The entire contents of the vesicle are liberated by stimulation of the nerve. The biology of vesicular release is not a random event, but a highly differentiated process. The fact that exocytosis is so highly conserved from species to species indicates its biologic importance. Angiotensin II, prostacyclin, and histamine potentiate release, whereas acetylcholine and prostaglandin E inhibit release.

Further details on neurotransmitter release are discussed in Chapter 23.

Although chromaffin cells in the adrenal medulla synthesize epinephrine and norepinephrine, the two compounds are stored in and secreted from distinct chromaffin cell subtypes. Pharmacologic differences between cells containing norepinephrine and epinephrine have been described, and data suggest that there may be preferential release from one or another form of chromaffin cell contingent on the nature of the stimulus. Nicotinic agonists or depolarizing agents cause the preferential release of norepinephrine, whereas histamine elicits predominantly epinephrine release.[19-21] Protein kinase C plays an important role in regulating secretion of catecholamine from norepinephrine-containing chromaffin cells.[22]

Inactivation

Most of the norepinephrine released is rapidly removed from the synaptic cleft by an amine mechanism (i.e., uptake-1 mechanism) or by non-neuronal tissue (i.e., uptake-2 mechanism). The uptake-1 mechanism represents the first and most important step in the inactivation of released norepinephrine. Most of the norepinephrine released is transported into storage vesicles for reuse. This uptake of neurotransmitter into synaptic vesicles is driven by an electrochemical proton gradient across the synaptic vesicle membrane. The vacuolar proton pump is a large hetero-oligomeric complex that contains eight to nine different subunits. After reuptake, the small amounts of norepinephrine not taken up into the vesicle are deaminated by cytoplasmic monoamine oxidase (MAO). There are several organ-specific forms of this enzyme.

Since its isolation and cloning in 1991, considerable information on the human norepinephrine transporter has accumulated.[23,24] The pharmacologic characteristics of this binding protein identify it as the cocaine binding site, although tricyclic antidepressants (i.e., desipramine and nortriptyline) are also potent antagonists.

Uptake of norepinephrine into the nerve varicosity and its return to the storage vesicle, albeit efficient, are not specific for the neurotransmitter. Some compounds structurally similar to norepinephrine may enter the nerve by the same mechanism and result in depletion of the neurotransmitter. These false transmitters can be of great clinical importance. Moreover, some drugs that block reuptake into the vesicle or into the synaptic ending itself may enhance the response to catecholamines; that is, more norepinephrine is available to receptors. Such drugs include cocaine and tricyclic antidepressants (Table 12-6).

Activity of the uptake-1 system varies greatly among different tissues. Because of anatomic barriers, peripheral blood vessels exhibit almost no reuptake of norepinephrine; consequently, rapid rates of norepinephrine synthesis are needed in peripheral blood vessels to modulate vascular tone. The highest rate of reuptake is found in the heart. Drugs or disease states that alter biosynthesis or storage (e.g., methyldopa decreases storage) have a more profound effect on blood pressure; those

Table 12-6 Comparison of Direct- and Indirect-acting Sympathomimetics

Pretreatment	Response of Effector Organ to: Direct Sympathomimetics (e.g., Epinephrine): Acts at the Receptor	Response of Effector Organ to: Indirect Sympathomimetics (e.g., Tyramine): Causes Release of NE after Its Uptake by Uptake 1

that affect reuptake would be expected to affect cardiac rate and rhythm.

Typically, the lungs remove 25% of the norepinephrine that passes through the pulmonary circulation, whereas epinephrine and dopamine pass through unchanged. Pulmonary uptake of norepinephrine appears to be a sodium-dependent, facilitated transport process in the endothelial cells of precapillary and postcapillary vessels and pulmonary veins. There is no significant uptake by nerve endings. Primary or secondary pulmonary hypertension diminishes uptake of norepinephrine, presumably because of concomitant thickening of the pulmonary vasculature. Although the functional significance of the endothelial uptake mechanism of the pulmonary vascular wall is unknown, uptake of other powerful vasoactive compounds suggests that the pulmonary endothelium functions to protect the left heart.

Defects in the ANS are common in patients with congestive heart failure (CHF). The heart is depleted of catecholamines, and reuptake of norepinephrine is decreased.[25] Sustained sympathoexcitation results in increased neuronal release of norepinephrine.[26] Cardiac norepinephrine spillover rates differ widely, even among patients with end-stage heart failure awaiting cardiac transplantation, but some studies suggest that elevated plasma catecholamine levels portend a poorer prognosis than can be anticipated with traditional cardiovascular indices.[27,28] Because augmentation of catecholamine release is markedly impaired in patients with CHF, compensation for further decreases in systemic vascular resistance requires activation of the renin-angiotensin system. Together, these events result in increased adrenergic drive, desensitization of β-receptors, and depletion of norepinephrine stores, which contribute to insufficient inotropic function.[29,30]

Metabolism

During storage and reuptake, a small amount of norepinephrine escapes uptake into the nerve ending and enters the circulation, where it is metabolized by MAO, catechol *O*-methyltransferase (COMT), or both in the blood, liver, and kidney (Fig. 12-9).

Epinephrine, which is released by the adrenal medulla, is inactivated by the same enzymes. The final metabolic product of inactivation is vanillylmandelic acid (VMA). Because of its rapid clearance, the half-life of norepinephrine (and most biogenic amines) in plasma is short, less than 1 minute. This short half-life necessitates administration of these drugs by infusion. Another consequence of their short half-life is that a more ideal measure of catecholamine production may be metabolic products rather than the catecholamines themselves. For example, screening for a norepinephrine-producing pheochromocytoma is frequently done by measuring the level of urine metanephrine and VMA. Only a small percentage of norepinephrine appears in the urine for assay.

Inhibition of MAO has a large impact on the sympathetic function of a patient. MAO inhibitors (MAOIs) are generally well tolerated, but the stability of the patient belies the fact that amine handling is fundamentally changed. Clinically important, life-threatening drug interactions are discussed later in the section "Drugs and the Autonomic Nervous System."

Other compounds can be metabolized by catabolic enzymes to produce false transmitters. Though not used therapeutically, tyramine is the prototypical drug studied. Tyramine is present in many foods, particularly aged cheese and wine, and it can be synthesized from tyrosine. Tyramine enters the sympathetic nerve terminal through the uptake-1 mechanism and displaces norepinephrine from the vesicles into the cytoplasm. The released norepinephrine leaks out of the cytoplasm and is responsible for the hypertensive effect of tyramine. However, a secondary effect can occur. In the vesicle, tyramine is converted by DβH to octopamine, which is eventually released as a false transmitter in place of norepinephrine, but without the hypertensive effect because it has only 10% of the potency of norepinephrine.

Adrenergic Receptors

Initially, α-adrenergic receptors were distinguished from β-adrenergic receptors by their greater response to epinephrine and norepinephrine than to isoproterenol. The development of α- and β-antagonists further supported the existence of separate α-receptors. Traditionally, adrenergic receptors have been classified as α or β and more recently as α_1, α_2, β_1, or β_2 based on responses to specific drugs. With technologic advances in molecular biology, classification evolved to three major subtypes and nine subsubtypes (Fig. 12-10).[31] Table 12-7 describes the distribution, response, typical agonists, and antagonists of the α_1-, α_2-, β_1-, and β_2-receptors.

α-Adrenergic Receptors

Functional and binding assays and molecular biologic methods have unequivocally confirmed the classification of α-adrenoceptors into subtypes.[32] Within α_1-adrenergic receptors, $\alpha_{1a/d}$-, α_{1b}-, and α_{1c}-receptors have been characterized. Several α_2-isoreceptors (α_{2a}, α_{2b}, and α_{2c}) have also been described. α_2-Receptors are usually expressed presynaptically or even in nonneuronal tissue. α_2-Receptors are found in the peripheral nervous system, in the CNS, and in a variety of organs, including platelets, liver, pancreas, kidney, and eyes, where specific physiologic functions have been identified.[33] Later, the predominant α_2-receptor of the human spinal cord was identified as the α_{2a}-subtype.[31,34] It appears that mammalian genomes contain two sets of at least three unique genes encoding the α-adrenoceptors. Genes encoding α_2-receptors have been localized to chromosomes 2, 4, and

10. There is more than theoretical relevance in the subclassification of receptors[35] in that mutations that decrease α_{2c} presynaptic function and enhance β_1-receptor linkage cause adrenergic hyperactivity and predispose to CHF.[36]

Amino acid sequence comparisons indicate that α-receptors are members of the seven–transmembrane segment gene superfamily, which uses G protein for signal transduction. A core of 175 amino acids constitutes the seven transmembrane regions and is highly conserved among different family members. The plethora of receptor subtypes remains incompletely explained, although the observation that different signal transduction mechanisms are used suggests finer control and physiologic significance. It may be important that there is considerable variability in α-adrenergic receptor subtypes among species.[37]

Receptors can be presynaptic as well as postsynaptic. Presynaptic receptors may act as heteroreceptors or autoreceptors. An *autoreceptor* is a presynaptic receptor that reacts with the neurotransmitter released from its own nerve terminal to provide feedback regulation. A *heteroreceptor* is a presynaptic receptor that responds to substances other than the neurotransmitter released from that specific nerve terminal. This regulatory scheme is present throughout the nervous system but is particularly important in the sympathetic nervous system.[38]

Although several presynaptic receptors have been identified, the α_2-receptor may have the greatest clinical import. Presynaptic α_2-receptors regulate the release of norepinephrine and ATP through a negative-feedback mechanism.[39] Activation of presynaptic α_2-receptors by norepinephrine inhibits subsequent release of norepinephrine in response to nerve stimulation. A similar inhibitory response is produced by attachment of acetylcholine to presynaptic cholinergic receptors. In the human brain, ligand studies reveal a high density of α_2-receptors, particularly in the cerebral cortex and medulla.[40] This latter distribution may account for the bradycardiac and hypotensive responses to α_2-agonist drugs.

β-Adrenergic Receptors

Like the α-receptor, the β-receptor is one of the superfamily of proteins that have seven helices woven through the cellular membrane. These transmembrane domains are labeled M_1 through M_7; antagonists have specific binding sites, whereas agonists are more diffusely attached to hydrophobic membrane-spanning domains (Fig. 12-11). The extracellular portion of the receptor ends in an amino group. A carboxyl group occupies the intracellular terminal, where phosphorylation occurs. At the cytoplasmic domains, there is interaction with G proteins and kinases, including β-adrenergic receptor kinase. The β-receptor has mechanistic and structural similarities with muscarinic but not nicotinic receptors, primarily in the transmembrane sections.

β-Receptors have been further divided into β_1-, β_2-, and β_3-subtypes, all of which increase cyclic adenosine monophosphate (cAMP) through adenylate cyclase and the mediation of G proteins.[41] Although β_1-receptors were traditionally thought to be isolated to cardiac tissue and β_2-receptors were believed to be restricted to vascular and bronchial smooth muscle, we now know that the β_2-receptor population in human cardiac tissue is substantial and accounts for 15% of β-receptors in the ventricles and 30% to 40% in the atria.[42] β_2-Receptors may help compensate for disease by maintaining response to catecholamine stimulation when β_1-receptors are downregulated during chronic catecholamine stimulation and in CHF.[43] The β_2-population is almost unaffected in end-stage congestive cardiomyopathy.[44] In addition to positive inotropic effects, β_2-receptors in the human atria participate in regulation of the heart rate. Generation of cAMP in the human heart appears to be mediated primarily by β_2-receptors, although this may be an artifact related to the lability of β_1-receptors.[44] Localization of β_3-receptors to fat cells suggests a new therapy for obesity. Polymorphism of this β-receptor subtype is associated with obesity and the potential for the development of diabetes.[45-47] Point mutations in genes encoding β_2-receptors are correlated with decreased downregulation of β-receptors and nocturnal asthma.[48,49]

Dopamine Receptors

Dopamine exists as an intermediate in the biosynthesis of norepinephrine, and in addition, exogenous dopamine exerts α- or β-adrenergic effects (depending on the dose administered). Furthermore, Goldberg and Rajfer[50] demonstrated physiologically distinct dopamine type 1 (DA_1) and dopamine type 2 (DA_2) receptors, and these remain the most important of the five dopamine receptors cloned (Fig. 12-12). DA_1 receptors are postsynaptic and act on renal, mesenteric, splenic, and coronary vascular smooth muscle to mediate vasodilation through stimulation of adenylate cyclase and increased production of cAMP. The vasodilatory effect tends to be strongest in the renal arteries. It is for this action, particularly the redistribution of blood flow to the kidneys, that dopamine is most frequently used. Additional renal DA_1 receptors located in the tubules modulate natriuresis through the sodium-potassium ATPase pump and the sodium-hydrogen exchanger.[50-53] DA_2 receptors are presynaptic; they may inhibit release of norepinephrine and perhaps acetylcholine. There are also central DA_2 receptors that may mediate nausea and vomiting,

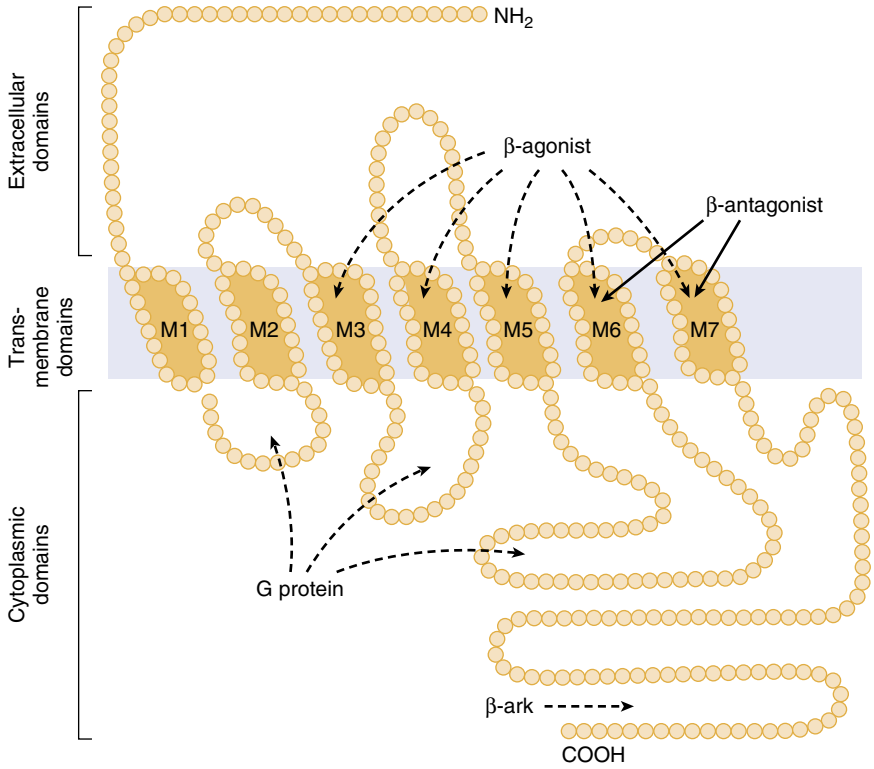

Figure 12-11 Molecular structure of the β-adrenergic receptor. Notice the three domains. The transmembrane domains act as a ligand-binding pocket. Cytoplasmic domains can interact with G proteins and kinases such as β-adrenergic receptor kinase (β-ARK). The latter can phosphorylate and desensitize the receptor. *(From Opie L: Receptors and signal transduction.* In *Opie LH [ed]: The Heart: Physiology and Metabolism. New York, Raven Press, 1991.)*

which may explain why the antiemetic activity of droperidol is thought to be related to its DA_2 activity.

GTP-Binding Regulatory Proteins (G Proteins)

After adrenergic receptor stimulation, the extracellular signal is transformed into an intracellular signal by a process known as signal transduction in which α_1- and β-receptors are coupled to G proteins. When activated, G proteins can modulate the synthesis or availability of intracellular second messengers (Fig. 12-13). The activated second messenger diffuses through the cytoplasm and stimulates an enzymatic cascade. The sequence of first messenger → receptor → G protein → effector → second messenger → enzymatic cascade is found in a wide variety of cells; the specific entities that fulfill the separate roles vary from cell to cell.[54] G proteins located on the inner surface of the cell membrane can also directly modify the activity of transmembrane ion channels.

G proteins are heterotrimeric compounds composed of three subunits labeled α, β, and γ. The β- and γ-subunits form a stable complex and the α-subunit associates with them in a reversible fashion. The β- and γ-subunits show little variation in their structure. In contrast, 20 different α-subunits have been

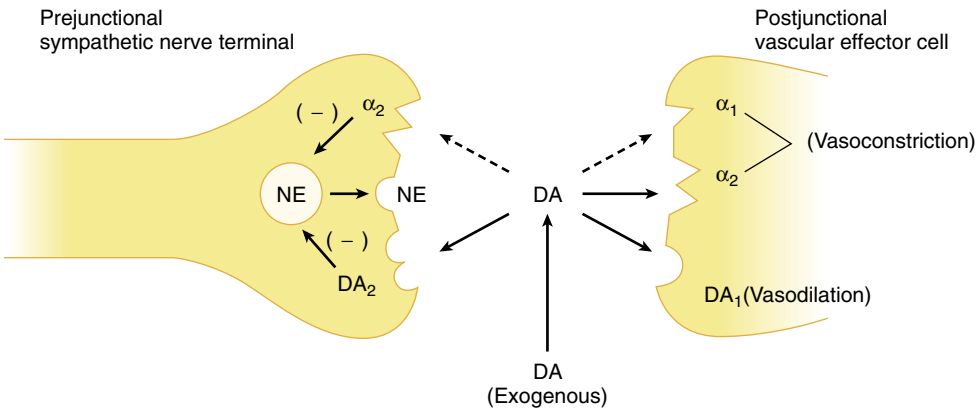

Figure 12-12 Location of dopamine type 1 (DA_1) receptors and α_1- and α_2-adrenoceptors on postganglionic vascular effector cells and DA_2 receptors and α_2-adrenoceptors on the prejunctional sympathetic nerve terminal. When dopamine is administered, activation of DA_1 receptors causes vasodilation, whereas activation of DA_2 receptors causes inhibition (–) of release of norepinephrine (NE) from storage granules. A larger dose of dopamine activates α_1- and α_2-adrenoceptors on the postjunctional effector cells to cause vasoconstriction and α_2-adrenoceptors on the prejunctional sympathetic terminal to inhibit release of NE. NE released from the prejunctional sympathetic terminal also acts on α_1- and α_2-adrenoceptors. *(From Goldberg LI, Rajfer SI: Dopamine receptors: Applications in clinical cardiology. Circulation 72:245, 1985.)*

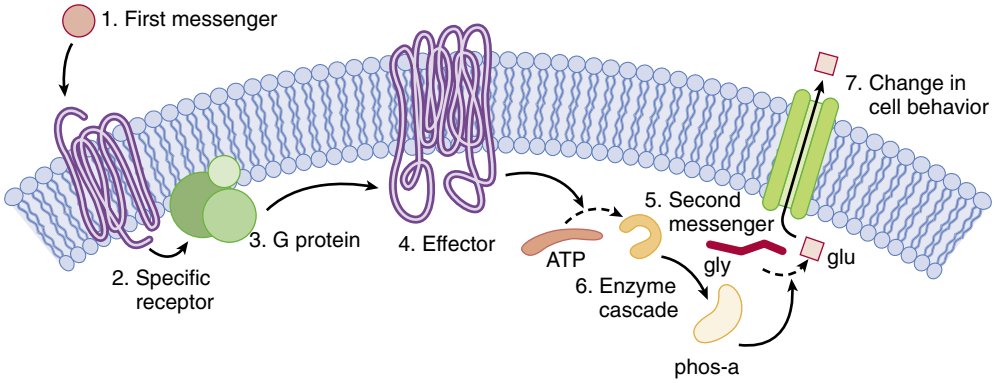

Figure 12-13 Epinephrine-stimulated glycogenolysis in a liver cell demonstrates the role of G proteins in cellular function. The first messenger (epinephrine) binds to its specific receptor and stimulates the G protein (in this case, G_s) to activate the effector adenylyl cyclase. This enzyme converts adenosine triphosphate (ATP) to cyclic adenosine monophosphate, the second messenger, which then triggers a cascade of enzymatic reactions that stimulates the enzyme phosphorylase (phos-a) to convert glycogen into glucose, which the cell extrudes. *(From Linder ME, Gilman AG: G Proteins. Sci Am 267:56, 1992.)*

identified. The structure of the attached α-subunit defines the function of the G protein. Four classes of α-subunits have been defined: α_s, α_i, α_q, and α_{12}. The corresponding G protein complexes formed when these α-subunits bind to the βγ-structure are called G_s, G_i, G_q, and G_o.[55]

Each class of adrenergic receptor couples to a different major subfamily of G proteins, which are linked to different effectors. The major subtypes of α_1-, α_2-, and β-receptors are linked to G_q, G_i, and G_s, respectively, which are linked to activation of phospholipase C (α_1), inhibition of adenylyl cyclase (α_2), or stimulation of adenylyl cyclase (β) (see Fig. 12-10). In its resting state, the G protein is bound to guanosine diphosphate (GDP) and is not in contact with the receptor. When the receptor is activated by the first messenger, it stimulates the G protein to release GDP and bind guanosine triphosphate (GTP) to its α-subunit, thereby activating itself. The bound GTP signals the G protein to split into two parts consisting of the α-GTP structure and the βγ-subunit. The released α-subunit binds to the effector, activates it, and then converts its attached GTP to GDP, thereby returning itself to the resting state. The α-subunit joins with the βγ-unit, and the reconstructed G protein again waits at the inner membrane.

β-Receptor stimulation by G proteins enhances the activity of adenylate cyclase and the formation of cAMP. The briefest encounter of plasma membrane β-adrenergic receptors with epinephrine or norepinephrine results in profound increases (up to 400-fold higher than the basal level within minutes) in intracellular levels of cAMP. Increased cAMP synthesis activates protein kinases, which phosphorylate target proteins to elicit various cellular responses that complete the path between receptor and effect. Stimulation of α_2-receptors results in G_i inhibition of adenylate cyclase. The relative abundance of G proteins results in amplification of receptor agonism at the signal transduction step. The number of G protein molecules greatly exceeds the number of β-adrenergic receptors and adenylate cyclase molecules. It is the receptor concentration and ultimately adenylate cyclase activity that limit the response to catecholamines, which perhaps explains the efficacy of phosphodiesterase inhibitors.[56,57]

Myocardial cells respond to receptor stimulation differently, depending on the identity of the first messenger. Two opposing effects, inhibition and stimulation of contractility, are both produced by the sequence of receptor → G protein → effector → enzymatic cascade. However, the identity of the chemicals in the sequence differs.[58] Norepinephrine causes myocardial cells to contract with more vigor when the α-subunit of the stimulatory protein (G_s) activates adenylate cyclase. The α-subunits of this protein cause potassium channels to open and permit efflux of potassium ion. The force of contraction is diminished when acetylcholine acts as a first messenger and stimulates its receptor to activate the inhibitory protein G_i or G_o. Clinically important, second-to-second changes in heart rate can be explained by the simultaneous activation of G_s and G_o. The current caused by G_o is larger than that caused by G_s, which explains the clinical impression that vagal inhibition of heart rate predominates in the presence of sympathetic stimulation, such as may occur in unpremedicated patients.[58]

Upregulation and Downregulation

β-Adrenergic receptors are not fixed; they change significantly in dynamic response to the amount of norepinephrine present in the synaptic cleft or in plasma. For β-adrenergic receptors, this response is fast; within 30 minutes of denervation or adrenergic blockade, the number of receptors increases. Such upregulation may explain why sudden discontinuation of β-adrenergic receptor blocking drugs causes rebound tachycardia and increases the incidence of MI and ischemia. Many chronic phenomena, such as varicose veins[59] or aging, can decrease adrenergic receptor number or responsiveness systemically.

Clinically and at the cellular level, responses to many hormones and neurotransmitters wane rapidly despite continuous exposure to adrenergic agonists.[60] This phenomenon, called desensitization, has been particularly well studied for the stimulation of cAMP levels by plasma membrane β-adrenergic receptors. Mechanisms postulated for desensitization include uncoupling (e.g., phosphorylation), sequestration, and downregulation. The molecular mechanisms underlying rapid β-adrenergic receptor desensitization do not appear to require internalization of the receptors, but rather an alteration in the functioning of β-receptors themselves that uncouples the receptors from the stimulatory G_s protein. Agonist-induced desensitization involves phosphorylation of G protein–coupled receptors by two classes of serine-threonine kinases. One of these classes initiates receptor-specific or homologous desensitization. The other works through second messenger–dependent kinases and mediates a general cellular hyporesponsiveness called heterologous desensi-

tization. Ultimately, an inhibitory arrestin protein binds to the phosphorylated receptor and causes desensitization by blocking signal transduction. Because enzymatic phosphorylation occurs only in the activated state, transient β-blockade has been used in states of receptor desensitization such as CHF or cardiopulmonary bypass to achieve a "a receptor holiday."[61] Regeneration of a functional β-adrenergic receptor is contingent on sequestration of the receptor, with dephosphorylation and presumed recycling. There has been some evidence that the arrestins contribute to desensitization by uncoupling signal transduction and by contributing to the process of receptor internalization.[62,63] Receptor populations can change rapidly with such sequestration, which does not require protein synthesis.

Downregulation may be distinguished from these rapid mechanisms in that it occurs after hours of exposure to an agonist (as in chronic stress or CHF) and receptors are destroyed. New receptors must be synthesized before return to a baseline state is possible.

Chronic CHF is one of the most important and best-studied pathophysiologic situations in which tolerance or downregulation occurs. It was initially observed that the density of cardiac β-receptors decreases markedly in patients with terminal heart failure in response to the elevated plasma catecholamine levels. This finding explained why administration of exogenous β-agonists was relatively ineffectual in this syndrome. With the demonstration that β_1- and β_2-receptors coexist in human ventricles,[64] Bristow and coworkers, using radioligand techniques, documented that β_1-receptor density decreases without change in the density of β_2-receptors in human ventricles affected by CHF. Consequently, β_2-agonism accounted for 60% of the total inotropic response stimulated by isoproterenol in the failing heart as compared with 40% in a nonfailing heart.[65]

The activity of the thyroid gland influences receptor density, with hyperthyroidism increasing density and hypothyroidism decreasing density. Clinically, β-receptor blockade is important in the acute treatment of hyperthyroidism. There is some evidence that corticosteroids decrease receptor density. Consequently, the reaction of the body to well-characterized sympathetic agonists may be considerably different, depending on the pathologic and environmental circumstances. However, the structural similarity of thyroid hormone and tyrosine suggests that false transmitters may play a role (see Chapter 75).[66]

Cholinergic Pharmacology

Acetylcholine Synthesis

Many of our assumptions about cholinergic pharmacology are drawn from our understanding of cholinergic receptors at the neuromuscular junction. The chemistry of cholinergic synthesis and metabolism is covered in detail in Chapter 14.

Cholinergic Receptors

Traditionally, cholinergic receptors have been organized into two major subdivisions, nicotinic and muscarinic. Muscarinic receptors are present mostly in peripheral visceral organs; nicotinic receptors are found on parasympathetic and sympathetic ganglia (neuronal subtypes) and on the neuromuscular junctions of skeletal muscle (neuronal and muscle subtypes).

Although these two structurally and functionally distinct classes of receptors have significantly different responses to acetylcholine, the chemical itself exhibits no specificity. However, specific antagonists can exploit the difference between muscarinic and nicotinic receptors. As a result, structure-activity relationships have emerged. All cholinergic agonists appear to need a quaternary ammonium group, as well as an atom capable of forming a hydrogen bond through an unshared pair of electrons. The distance between the two sites may determine whether the agonism is nicotinic or muscarinic. With muscarinic agonists, the distance appears to be about 4.4 Å, whereas for nicotinic agonists, the distance is 5.9 Å.

The neuronal and muscle subtypes of nicotinic receptors on ganglia and motor end plates, respectively, differ. Nondepolarizing neuromuscular blocking agents block neuronal nicotinic acetylcholine receptors present in ganglia and at the neuromuscular junction (see Chapter 29),[67] whereas hexamethonium blocks the ganglionic receptors.

Some evidence indicates that ganglionic nicotinic receptors are far more sensitive to anesthetics than receptors in the neuromuscular junction are, but the clinical significance is unclear.[68]

The nicotinic receptors on ganglia and motor end plates are discussed in detail in Chapter 14. In brief, they are pentameric membrane proteins that form nonselective cation channels. There are two α-units (each 40 kd) and one each of the β-, ε-, and δ-units. These five subunits surround each ion channel through which sodium or calcium enters the cell or potassium exits. Each ion has its own separate channel. For the channel to open, acetylcholine must occupy a receptor site on each of the two α-subunits.

In contrast to the ion-gated nicotinic receptors, muscarinic receptors belong to the superfamily of G protein–coupled receptors. Muscarinic receptors therefore have greater homology to α- and β-adrenergic receptors than to nicotinic receptors. Like the other members of the family of receptors with seven helices (i.e., α_2, β_1, β_2, serotonin, rhodopsin, and opsin), muscarinic receptors use G proteins for signal transduction. Five muscarinic receptors (i.e., M_1 through M_5) exist, with the primary structural variability residing in a huge cytoplasmic loop between the fifth and sixth membrane-spanning domains. Although molecular studies have described five forms, four of which are defined pharmacologically (i.e., M_1, M_2, M_3, and M_4), selective muscarinic drugs are not available. The M_2 cholinergic postjunctional receptor predominates in visceral organs. M_2 and M_3 receptors have been identified in the airway smooth muscle of many species. In vitro studies reveal that the M_3 receptor mediates the contractile and secretory response. However, the excess of M_2 receptors could explain the relative ineffectiveness of β-adrenergic agonists in reversing cholinergic bronchoconstriction.[69]

The muscarinic receptors have diverse signal transduction mechanisms. The odd-numbered receptors (i.e., M_1, M_3, and M_5) work predominantly through hydrolysis of polyphosphoinositide, whereas the even-numbered receptors work primarily to regulate adenylate cyclase.[70]

When the M_3 muscarinic receptor is activated, G_q activates phospholipase C, which catalyzes the hydrolysis of phosphatidylinositol bisphosphate into diacylglycerol and inositol triphosphate. Receptors in the muscarinic series are coupled to second messenger systems, such as cyclic nucleotides or phosphoinositides. These are coupled to ion channels. In other cases, influx of a cation is the trigger for cellular response. In some cases, however, the influx of calcium ions acts as a messenger that reacts

with and opens other ion channels. In addition to affecting ion channels, the messenger calcium can stimulate various intracellular proteins to alter cell activity. In cardiac atria, activation of muscarinic receptors leads to the efflux of potassium and hyperpolarization of the cell membrane. This hyperpolarization slows conduction and slows or stops atrial pacemakers. In glands, an influx of calcium or sodium, or both, activates intracellular events and causes the cells to secrete. Similarly, influx of these ions into smooth muscle cells causes them to contract.

Muscarinic receptors are found on central and peripheral neurons; a single neuron may have muscarinic receptors with excitatory as well as inhibitory effects. Prejunctional autoreceptors are not as well studied in the parasympathetic nervous system as in the sympathetic nervous system. Presynaptic muscarinic receptors may inhibit the release of acetylcholine from postganglionic parasympathetic neurons; prejunctional nicotinic receptors may increase its release.

Because of the complex coupling, the response of the muscarinic system is sluggish; no response is seen for seconds to minutes after the application of acetylcholine. Similarly, the effect long outlives the presence of the agonist. Even though the transmitter is destroyed rapidly, the train of events that it initiates causes the cellular response to continue for many minutes. Muscarinic receptors are desensitized through agonist-dependent phosphorylation in a mechanism similar to that described earlier for β-adrenergic receptors.

Nonadrenergic, Noncholinergic Neurotransmission in the Autonomic Nervous System

NANC components such as monoamines, purines, amino acids, and polypeptides are part of the ANS. Other transmitter candidates demonstrated in perivascular nerves by histochemical and immunohistochemical techniques include ATP, adenosine, VIP, substance P, 5-hydroxytryptamine (5-HT), neuropeptide Y (NPY), and calcitonin gene–related peptide (CGRP). Immunocytochemical studies show that more than one transmitter or putative transmitter may be colocalized in the same nerve. The most common combinations of transmitters in perivascular nerves are norepinephrine, ATP, and NPY in sympathetic nerves (Fig. 12-14); acetylcholine and VIP in parasympathetic nerves (Fig. 12-15); and substance P, CGRP, and ATP in sensory-motor nerves. Many of these putative transmitters act through cotransmission, which is the synthesis, storage, and release of more than one transmitter by a nerve. Initially, the multiplicity of transmitters released in various combinations appeared random and bewildering, but a pattern is emerging that clarifies the situation. Autonomic nerves exhibit chemical coding—individual neurons serving a specific physiologic function contain distinct combinations of transmitter substances.[71]

The concepts of cotransmission and neuromodulation have become accepted mechanisms in autonomic nervous control. To establish that transmitters coexisting in the same nerves act as cotransmitters, it is necessary to demonstrate that on release, each substance acts postjunctionally on its own specific receptor to produce a response.

For many perivascular sympathetic nerves, there is evidence that norepinephrine and ATP act as cotransmitters and are released from the same nerves but act on α_1-adrenoceptors and P_2-purinoceptors, respectively, to produce vasoconstriction (see Fig. 12-14).[72,73] ATP, once thought to act only as an electrical buffer for the charged norepinephrine, is believed to mediate contraction through P_2 receptors by voltage-dependent calcium channels.[74] The fast component of contraction appears to be mediated by these purinoceptors, whereas norepinephrine sustains contraction of muscle by acting on the α_1-adrenoreceptor through receptor-operated calcium channels. ATP is stored in vesicles along nerve varicosities. It is released into the synaptic cleft via exocytosis and then binds to postsynaptic purinergic receptors. ATP is then broken down to adenosine by membrane-bound ATPases and 5′-nucleotidases. Adenosine is subsequently taken up into the presynaptic neuron, where ATP is resynthesized and incorporated into vesicles for later release.[75]

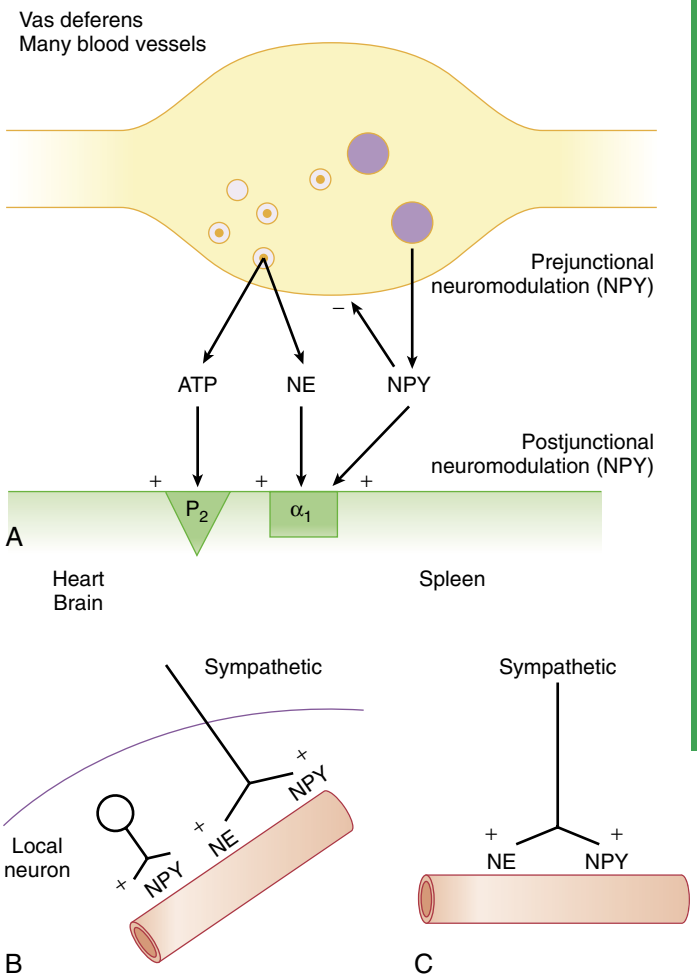

Figure 12-14 Schematic representation of different interactions that occur between neuropeptide Y (NPY) and adenosine triphosphate (ATP) and the norepinephrine (NE) released from single sympathetic nerve varicosities. **A,** Diagram showing what occurs in the vas deferens and many blood vessels, where NE and ATP, probably released from small granular vesicles, act synergistically to contract (+) the smooth muscle through α_1-adrenoceptors and P_2 purinoceptors, respectively. **B** and **C,** Sympathetic neurotransmission in the heart and brain (**B**) and the spleen (**C**). *(From Lincoln J, Burnstock G: Neural-endothelial interactions in control of local blood flow. In Warren J [ed]: The Endothelium: An Introduction to Current Research. New York, Wiley-Liss, 1990, p 21.)*

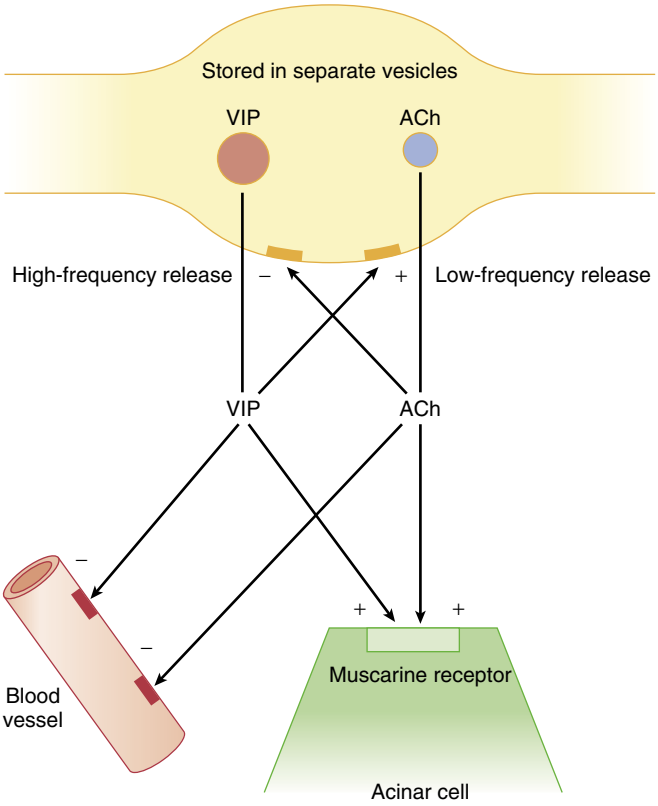

Figure 12-15 The classic transmitter acetylcholine (ACh) coexists with vasoactive intestinal polypeptide (VIP) in parasympathetic nerves supplying the cat salivary gland. ACh and VIP are stored in separate vesicles; they can be released differentially at different stimulation frequencies to act on acinar cells and glandular blood vessels. Cooperation is achieved by the selected release of ACh at low impulse frequencies and VIP at high frequencies. Prejunctional and postjunctional modulation is indicated. *(From Burnstock G: Local mechanisms of blood flow control by perivascular nerves and endothelium. J Hypertens Suppl 8:S95, 1990.)*

Purinergic receptors are categorized as P_1 or P_2 receptors. P_1 receptors bind adenosine, whereas P_2 receptors bind ATP. Four subtypes of P_1 receptors have been identified (A_1, A_{2A}, A_{2B}, and A_3). All the P_1 receptors are coupled to membrane-bound G proteins. There are two subclasses of P_2 receptors (P2X and P2Y). P2X receptors bind ATP and open ligand-gated ion channels. In contrast, P2Y receptors are coupled to G proteins and their associated secondary messenger systems. Seven P2X subtypes ($P2X_{1\text{-}7}$) and eight P2Y subtypes ($P2Y_{1,2,4,6,11,12,13,14}$) have been identified. Some P2Y receptors are preferentially activated by adenosine diphosphate rather than ATP, and some can be activated by pyrimidine nucleosides (uridine triphosphate), as well as purinergic agonists.

ATP released at nerve endings in the setting of hypertension leads to marked decreases in arterial pressure. ATP bound to $MgCl_2$ is a potent pulmonary vasodilator used to treat patients with pulmonary hypertension secondary to congenital heart disease. In addition, it is used to treat postischemic renal injury. Purinergic cotransmission is also seen in the gastrointestinal tract, where ATP (and NO) receptor stimulation inhibits peristalsis.

Neuromodulators modify the process of neurotransmission. They may be circulating neurohormones, local agents, or neurotransmitter substances released from the same nerves or from others nearby. Neuromodulation can occur prejunctionally by decreasing or increasing the amount of transmitter released during transmission or postjunctionally by altering the extent or time course of the neurotransmitter's effect. In all known examples in which prejunctional and postjunctional neuromodulation occurs, these substances act in concert to attenuate or augment effective transmission. The rationale for such effects may reflect the variable geometry of the autonomic neuroeffector junction.[76,77] Unlike the neuromuscular junction, the autonomic neuroeffector junction exists in a dynamic state and manifests only modest postjunctional specialization. Biogenic amines often must traverse wide distances. Given the short half-lives of these chemicals, neuromodulation provides a biologic mechanism for augmentation and prolongation of their action.[78]

NPY is also colocalized with norepinephrine and ATP. However, in some vessels, NPY has little or no direct action; instead, it acts as a neuromodulator prejunctionally to inhibit the release of norepinephrine from the nerve or postjunctionally to enhance the action of norepinephrine (see Fig. 12-14A).[79,80] In other vessels, notably those of the spleen, skeletal muscle, and cerebral and coronary vasculature, NPY has direct vasoconstrictor actions. In the heart and brain, local intrinsic (nonsympathetic) neurons use NPY as the principal transmitter (see Fig. 12-14B). In the spleen, NPY appears to act as a genuine cotransmitter with norepinephrine in perivascular sympathetic nerves (see Fig. 12-14C).[81] The frequency of stimulation determines which vesicles are mobilized to release their transmitters.

A classic transmitter such as acetylcholine coexists with VIP in the parasympathetic nerves of many organs, but in this instance, the two transmitters are stored in separate vesicles. They can be released differentially at different stimulation frequencies, depending on where they are located.[82,83] For example, in the salivary gland, they can act independently on acinar cells and glandular blood vessels (see Fig. 12-15).[73] Cooperation is achieved by the selective release of acetylcholine at low frequencies and VIP at high frequencies of stimulation. Elements of prejunctional and postjunctional modulation have also been described. It is becoming increasingly apparent that in many biologic states, including pregnancy,[84] hypertension, and aging, the relationships among cotransmitters may be an important determinant of a compensatory response to allow finer control of important physiologic function. Additionally, the large number of different receptors may provide targets for potential pharmacologic interventions.

Ganglionic Pharmacology

Ganglia serve far more complex functions than simply being a link between the nerve process of one cell and the cell body of its next connection. Integrative and processing functions contribute to the subtlety of response and organization of the ANS. The electrophysiology of ganglionic stimulation is complex, with at least four different types of responses to electrical stimulation (Table 12-8).[85]

The central event at the ganglion is the excitatory postsynaptic potential (EPSP) when acetylcholine interacts with a neuronal-type nicotinic receptor to depolarize the postsynaptic membrane. Depolarization results primarily from the influx of sodium ions through the nicotinic receptor channel, and it is sensitive to nondepolarizing nicotinic blocking drugs such as hexamethonium. The other changes in electrical potential are

Table 12-8 Fast and Slow Responses of Postganglionic Neurons in Sympathetic Ganglia

Potential	Duration	Mediator	Receptor
Fast EPSP	30 msec	Acetylcholine	Nicotinic cholinergic
Slow IPSP	2 sec	Dopamine	D_2
Slow EPSP	30 sec	Acetylcholine	M_1-cholinergic
Late slow EPSP	4 min	GnRH	GnRH

D_2, dopamine receptor inhibiting adenylate cyclase through inhibitory G protein; EPSP, excitatory postsynaptic potential; GnRH, gonadotropin-releasing hormone; IPSP, inhibitory postsynaptic potential.

related to secondary or subsidiary pathways that augment or suppress; these pathways are insensitive to classic nicotinic antagonists.

Secondary pathways are indicated by the following changes in potential elicited by electrical stimulation of the ganglia: (1) slow EPSP, (2) late slow EPSP, and (3) inhibitory postsynaptic potential (IPSP).

Autonomic ganglia may be stimulated by two groups of drugs, nicotinic and muscarinic agonists. Nicotinic agonists cause a rapid onset of excitatory effects, mimic the initial EPSP, and are blocked by classic nondepolarizing ganglionic blocking drugs. Muscarinic agonists delay onset of the excitatory effects and are blocked by atropine.

Blockade of ganglionic transmission results primarily from action at the nicotinic receptor to stop or inhibit transmission. Two groups of drugs block ganglionic transmission. The first group is classically represented by nicotine and initially stimulates the receptor but then blocks it. This action is similar to the action of persistent depolarization. The second group does not cause initial stimulation or a change in ganglionic potentials. This group includes the drugs hexamethonium, trimethaphan, and mecamylamine. Trimethaphan acts by competing with acetylcholine at cholinergic receptor sites on the ganglia; hexamethonium blocks the channel when it is open. Either mechanism blocks the initial EPSP and ganglionic transmission.

Muscarinic antagonists or α-agonists are incapable of completely blocking transmission, but they may inhibit normal modulation of the nerve impulse. β-Adrenergic stimulation facilitates nicotinic and muscarinic transmission, whereas α-adrenergic stimulation inhibits it. 5-HT is mostly facilitative, but it can be inhibitory in certain areas. Dopamine may also be inhibitory through stimulation of the IPSP. The adrenal medulla is a specialized ganglionic synapse and is therefore under influences similar to those arising on the autonomic ganglia.

Drugs and the Autonomic Nervous System

The structure and function of the sympathetic and parasympathetic systems are discussed in the preceding sections. Pharmacologic manipulation of autonomic function is the basis of therapy for many acute and chronic illnesses. The complex physiology allows many points for intervention, including enhancement or inhibition of synthesis, storage, or receptor-mediated activity. In the following sections, specific autonomic drugs of interest to anesthesiologists and the mechanisms by which they work are discussed.

Drugs Affecting Adrenergic Transmission

Endogenous Catecholamines

The endogenous sympathetic transmitters norepinephrine, epinephrine, and dopamine are catecholamines, an important subclass of the sympathomimetic drugs (Fig. 12-16). The parent compound of this sympathomimetic group is β-phenylethylamine, the structure of which includes a benzene ring and an ethylamine side chain. Substitution of hydroxyl groups at the 3 and 4 positions of the benzene ring converts benzene to catechol, and these compounds are known as catecholamines. Although synthetic, isoproterenol and dobutamine are likewise catecholamines. Noncatecholamine drugs may also act as sympathomimetics and have a similar structure.

The catecholamines are primarily metabolized by COMT. The loss of either hydroxyl group enhances oral effectiveness and duration of action because the drug is no longer metabolized by COMT. Noncatecholamines are primarily metabolized by MAO. The noncatecholamines that have a substituted α-carbon have a

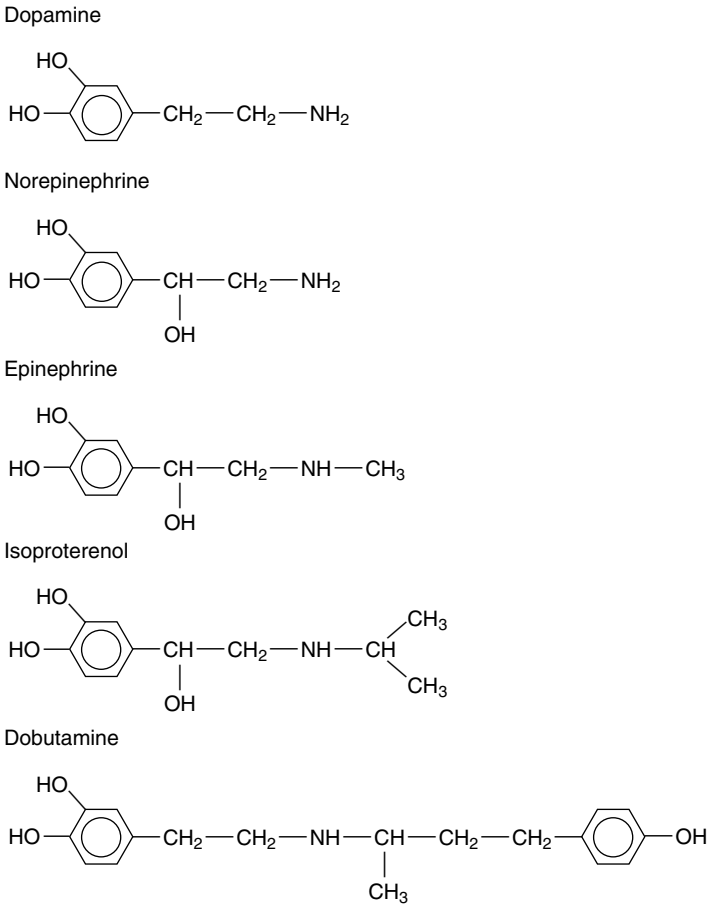

Figure 12-16 Catecholamine structures. A benzene ring with two adjacent hydroxyl groups forms the catechol nucleus.

longer duration of action because they are not metabolized by COMT or MAO.

Epinephrine

Epinephrine is used intravenously in life-threatening circumstances, including the treatment of cardiac arrest, circulatory collapse, and anaphylaxis, but it is also commonly used locally to limit the spread of local anesthetics or to reduce blood loss. The systemic effects of epinephrine are variable and are related to blood levels. The choice of dosing and the route of administration are determined by the indication for use and its urgency.

Epinephrine activates all adrenergic receptors: α_1, α_2, β_1, β_2, and β_3. Potential therapeutic effects of epinephrine include positive inotropy, chronotropy, and enhanced conduction in the heart (β_1); smooth muscle relaxation in the vasculature and bronchial tree (β_2); and vasoconstriction (α_1). With vasoconstriction, aortic diastolic pressure is increased, thereby promoting coronary flow during cardiac arrest, which may be the single most important determinant of survival.[86] Endocrine and metabolic effects of epinephrine include increased levels of glucose, lactate, and free fatty acids.

Epinephrine may be given intravenously as a bolus or by infusion. The usual bolus doses for pressure support begin at 2 to 8 µg given intravenously; 0.02 mg/kg or approximately 1.0 mg is given for cardiovascular collapse, asystole, ventricular fibrillation, electromechanical dissociation, or anaphylactic shock[87] (see also Chapter 97). The larger dose range is recommended in these critical situations to maintain myocardial and cerebral perfusion through peripheral vasoconstriction. High-dose epinephrine (0.1 to 0.2 mg/kg) has been studied in resuscitation from cardiac arrest, but it does not appear to improve rates of survival in adults. In pediatric patients, outcome after asystole and pulseless cardiac arrest is abysmal, and the current recommendation is an initial dose of 0.01 mg/kg repeated every 3 to 5 minutes throughout resuscitative attempts.[41,88] In unusual circumstances, higher doses may be given and doses as large as 0.2 mg/kg may be effective.[89] Patients vary tremendously in their response to epinephrine, and given rates of infusion cannot guarantee the expected serum levels in all patients; the "pressors" should therefore be carefully titrated, and measures to monitor renal, cerebral, and myocardial perfusion are more critical than adherence to a rigid dosing scheme (Table 12-9). A rate of 1 to 2 µg/min, though rarely used, should predominantly activate β_2-receptors, with resulting vascular and bronchial smooth muscle relaxation. A rate of 2 to 10 µg/min (25 to 120 ng/kg/min) increases heart rate, contractility, and conduction through the AV node and decreases the refractory period. Doses in excess of 10 µg/min (100 ng/kg/min) cause marked α-adrenergic stimulation with resultant generalized vasoconstriction. Epinephrine is a potent renal vasoconstrictor that acts directly by α-receptor stimulation and indirectly by stimulation of renin release. Although low-dose epinephrine increases the heart rate by direct β_1-adrenergic stimulation, reflex bradycardia is seen with higher doses because of the marked elevation in blood pressure resulting from peripheral vasoconstriction.

Racemic epinephrine (i.e., mixture of the levorotary and dextrorotary isomers) constricts edematous mucosa and is used for the treatment of severe croup[90] and postextubation and traumatic airway edema. A 2.25% solution (MicroNefrin or Vaponefrin) is diluted with water or saline in a 1:8 ratio and nebulized. Treatments may be given as frequently as every 2 hours, with effects lasting 30 to 60 minutes; the patient should remain under observation for at least 2 hours because initial improvement may be followed by rebound swelling up to 2 hours after administration. Although it is common clinical practice to use the racemic form of epinephrine for these clinical applications, data show that L-epinephrine is 15 to 30 times more potent than the mixture[91] and is equally effective and less expensive for treating these clinical complications.[92]

Bronchospasm may also be treated by subcutaneous administration of epinephrine in doses of 300 µg every 20 minutes with a maximum of three doses. In addition to its direct bronchodilatory effects, epinephrine may decrease antigen-induced release of endogenous bronchospastic substances from mast cells and is particularly useful in anaphylactic reactions.[93] Relative contraindications include advanced age, significant tachycardia, hypertension, and coronary occlusive disease. Absorption of subcutaneous epinephrine is extremely slow because of intense local vasoconstriction, and the effect of a very large subcutaneous dose of 0.5 to 1.5 mg is roughly equivalent to an intravenous infusion of 10 to 30 µg/min. Intravenous injection of epinephrine in a dose appropriate for subcutaneous administration can result in life-threatening ventricular arrhythmias, hypertension, and cerebral hemorrhage. Sus-Phrine, a sustained-release form of epinephrine, may be used in children by subcutaneous injection but should never be given intravenously.

Epinephrine is often applied locally to mucosal surfaces to decrease bleeding in the operative site. It is mixed with local anesthetics for infiltration into tissues or intrathecal injection. The α-mediated vasoconstriction decreases bleeding in the area and slows vascular uptake of local anesthetic, thereby prolonging the duration of effect and decreasing the peak serum level of the

Table 12-9 Dose-Dependent Actions of Inotropes and Chronotropes

Drug* (Proprietary Name)	Receptors	Usual Infusion Rate
Epinephrine (Adrenalin)	β_2 $\beta_1 + \beta_2$ α_1	1-2 µg/min 2-10 µg/min ≥10 µg/min† (bolus: 2-10 µg; 0.5-1.0 mg‡)
Norepinephrine (Levophed)	α_1, β_1, $\gg\beta_2$	4-12 µg/min†
Dopamine (Intropin)	Dopaminergic β α	0-3 µg/kg/min 3-10 µg/kg/min >10 µg/kg/min†
Dobutamine (Dobutrex)	$\beta_1 \gg \beta_2$, α	2.5-10 µg/kg/min†
Isoproterenol (Isuprel)	$\beta_1 > \beta_2$	0.5-10 µg/min
Amrinone (Inocor)	Increase cyclic adenosine monophosphate through inhibition of phosphodiesterase	0.75 mg/kg load over a period of 2-3 min 5- to 10-µg/kg/min infusion

*All agents have elimination half-lives of a few minutes except amrinone ($t_{1/2}$, 3.6 hours; 5.8 hours in congestive heart failure).
†Much higher doses have been used in clinical practice.

local anesthetic. Although clinicians express concern about the possible systemic effects of such injections, the increases in plasma levels from vascular uptake are relatively modest and substantially less than levels seen during psychological stress.[94] This conclusion assumes the absence of overt intravenous injection.

Drug interactions with epinephrine are often predictable. Cocaine and other uptake inhibitors enhance the effect and duration of exogenous epinephrine. Preexisting α_1-blockade can cause the paradoxical phenomenon of epinephrine reversal (a hypotensive and tachycardic response) as the β_2-vasodilating effects are unmasked. Patients receiving nonselective β-blockers may demonstrate unopposed α-responses. Cardioselective (β_1) blockade does not have this effect.[95]

Halothane sensitizes the heart to catecholamines, and the potential for troublesome arrhythmias under light inhalational anesthesia has long been appreciated by clinicians. Epinephrine decreases the refractory period, which renders the heart more susceptible to arrhythmias. In adults, the epinephrine dose required to produce three premature ventricular contractions in 50% of patients (ED_{50}) at 1.25 minimum alveolar concentration (MAC) was 2.1 μg/kg for halothane, 6.7 μg/kg for isoflurane, and 10.9 μg/kg for enflurane.[96] Children appear to tolerate higher doses than adults do. It has been suggested that children undergoing halothane anesthesia can receive a maximum of 10 to 15 μg/kg of epinephrine subcutaneously every 10 minutes.[89] Hypocapnia potentiates this drug interaction.

Norepinephrine

Norepinephrine differs structurally from epinephrine only in its lack of a methyl group. Like epinephrine, norepinephrine acts at α- and β-receptors, but it is typically used for its potent α-agonism. It is frequently the pressor of last resort in supporting systemic vascular resistance. Because of its short half-life of 2.5 minutes, continuous infusion is preferred. Whereas less than 2 μg/min (30 ng/kg/min) may uncover the effects of β_1-adrenergic stimulation, the usual infusion rates of greater than 3 μg/min (50 ng/kg/min) elicit peripheral vasoconstriction from α-adrenergic stimulation.

Peripheral vasoconstriction increases blood pressure and may cause reflex bradycardia. Venous return is increased by the powerful venoconstriction. Cardiac output is frequently unchanged or decreased; oxygen consumption is markedly increased. Because pulmonary vascular resistance may be increased, norepinephrine should be used with caution in patients with pulmonary hypertension.[97]

Like epinephrine, norepinephrine is a potent constrictor of the renal and mesenteric vascular beds and can cause renal failure, mesenteric infarction, and peripheral hypoperfusion. The decrease in hepatic flow is of clinical relevance because plasma levels of hepatically metabolized drugs (e.g., lidocaine) are markedly increased. To ameliorate the renal effects, a low-dose dopamine infusion may be added to norepinephrine (see Chapters 92 and 96).[98] Extravasation of norepinephrine can cause tissue necrosis and may be treated by local infiltration of phentolamine. Prolonged infusion has caused gangrene of the digits. The potential for profound vasoconstriction makes careful patient selection and close monitoring mandatory.

Dopamine

Dopamine acts at α-adrenergic, β-adrenergic, and dopaminergic receptors; it also acts to release norepinephrine and therefore has mixed direct and indirect effects. Although dopamine is a precursor of norepinephrine, its most important ANS effect in the periphery may be to cause peripheral vasodilation. Improvement of blood flow through the renal and mesenteric beds in shocklike states is expected through its action at dopamine receptors on the postjunctional membrane. It is rapidly metabolized by MAO and COMT and has a half-life of about 1 minute. Like other endogenous catecholamines, it is given as a continuous intravenous infusion without a loading dose. At low doses (0.5 to 2.0 μg/kg/min), DA_1 receptors are stimulated, and renal and mesenteric vascular beds dilate.[99] In addition to an improvement in renal blood flow, the glomerular filtration rate and sodium excretion increase. With an infusion rate of 2 to 10 μg/kg/min, β_1-receptors are stimulated, and cardiac contractility and output are increased. Rates higher than 5 μg/kg/min stimulate the release of endogenous norepinephrine, which contributes to cardiac stimulation. In larger doses (10 to 20 μg/kg/min), α- and β_1-receptors are stimulated, the α-adrenergic vasoconstrictive effect predominates, and the benefit to renal perfusion may be lost.[100]

In the past, dopamine was frequently used for the treatment of shock (especially in vasodilated states such as sepsis). It was widely believed that infusions of dopamine, by increasing renal blood flow, could protect the kidney and aid in diuresis.[101] However, more recent studies have suggested that dopamine does not have a beneficial effect on renal function in shock states, and its routine use in these patients has therefore been called into question (see Chapters 92 and 96).[102,103]

Dopexamine hydrochloride (Dopacard), an inotropic vasodilator, is a synthetic parenteral dopamine analog (not available in the United States) that may be of use in CHF. Dopexamine is approximately 60 times more potent at β_2-adrenergic receptors than dopamine is, a third as potent at DA_1 receptors, and a seventh as potent at DA_2 receptors.[104,105] Unlike dopamine, it shows no α-adrenergic effects and negligible β_1-adrenergic effects and is consequently devoid of vasoconstrictive activity.[104,106] Dopexamine has a reported half-life of 3 to 7 minutes in healthy patients and approximately 11 minutes in patients with low cardiac output.[107] β_2-Agonism produces systemic vasodilation and indirect inotropic activity (through inhibition of neuronal uptake of norepinephrine).[104-106,108,109] Stimulation of dopaminergic receptors produces selective vasodilation of renal and splanchnic vessels and increases the glomerular filtration rate, diuresis, and natriuresis.[105,110-113]

The use of dopexamine is preferable when vascular resistance is high. Within the dose range of 1 to 6 μg/kg/min, the combined inotropic, vasodilative, diuretic, and natriuretic effects have shown benefit in the management of CHF,[114-117] but an indeterminate outcome in the treatment of septic shock.[116,118-122] Use of this agent has been limited by dose-dependent tachycardia, mainly at doses higher than 4 μg/kg/min.[123,124] The effects of dopexamine on intestinal mucosal and hepatic perfusion remain controversial.[125-130] In general, systemic vasodilation appears more pronounced with dopexamine, and positive inotropic effects appear more marked with dopamine[131] and dobutamine.[132]

Fenoldopam is a selective DA_1 agonist and potent vasodilator (i.e., six to nine times as potent as dopamine) that enhances natriuresis, diuresis, and renal blood flow.[133-137] Because of its poor bioavailability and varied results in clinical trials, fenoldopam is no longer being investigated as a candidate for the treatment of chronic hypertension or CHF. Instead, intravenous fenoldopam, given by infusion at rates of 0.1 to 0.8 μg/kg/min with incremen-

tal titration at 0.1 μg/kg/min, has been approved to treat severe hypertension. It is an alternative to sodium nitroprusside, with potentially fewer side effects (i.e., no thiocyanate toxicity, rebound effect, or coronary steal) and improved renal function. Its peak effects occur within 15 minutes.[138,139]

Noncatecholamine Sympathomimetic Amines

The β-agonist isoproterenol and the α-agonists phenylephrine and methoxamine act predominantly at only one type of receptor, but most noncatecholamine sympathomimetic amines act at α- and β-receptors because they have two mechanisms of action: directly at a receptor and indirectly by releasing endogenous norepinephrine.

Mephentermine (Wyamine), ephedrine, and metaraminol (Aramine) are mixed-acting drugs. Ephedrine increases blood pressure and has a positive inotropic effect. Because it does not have detrimental effects on uterine blood flow, ephedrine is widely used as a pressor in hypotensive parturient patients (see Chapter 69). As a result of its β_1-adrenergic–stimulating effects, ephedrine is helpful in treating moderate hypotension, particularly if accompanied by bradycardia. It also has some direct β_2-adrenergic–stimulating effects and has been used orally as a bronchodilator. The usual dose is 2.5 to 25 mg given intravenously or 25 to 50 mg administered intramuscularly. Mephentermine is similar to ephedrine in its effects, whereas metaraminol has relatively stronger direct α_1-adrenergic–stimulating effects and may be associated with reflex bradycardia.

Tachyphylaxis to the indirect effect may develop through depletion of norepinephrine stores. Although all sympathomimetic amines are capable of producing tolerance or tachyphylaxis, the mechanism has been studied best with metaraminol. Metaraminol is taken up into the sympathetic nerve ending, where it displaces norepinephrine and produces its sympathomimetic effect. However, after some time, the drug acts as a false transmitter, and subsequent sympathetic nerve stimulation results in much less effect. Consequently, the drug probably should not be used widely when other, more effective drugs are available. Its indirect action is attenuated in the presence of long-term reserpine or cocaine use, but these drugs may still be efficacious at higher doses. Although indirect-acting drugs are widely used as a first-line therapy for intraoperative hypotension, epidemiologic studies of adverse reactions under anesthesia suggest that dependence on these agents in life-threatening events may contribute to morbidity.[140]

α-Receptor Agonists

Phenylephrine and methoxamine are selective α_1-agonists. These drugs are commonly used when peripheral vasoconstriction is needed and cardiac output is adequate, as in the hypotension that may accompany spinal anesthesia, as well as in patients with coronary artery disease or aortic stenosis to increase coronary perfusion pressure without chronotropic side effects. Phenylephrine (Neo-Synephrine) has a rapid onset and relatively short duration of action (5 to 10 minutes) when given intravenously. It may be given in bolus doses of 40 to 100 μg or by infusion at a starting rate of 10 to 20 μg/min. Larger doses of up to 1 mg are used to slow supraventricular tachycardia through reflex action. Phenylephrine is also used as a mydriatic and nasal decongestant. In anesthetic practice, it is applied topically, alone or mixed with local anesthetic gel, to prepare the nostril for nasotracheal intubation. It is also added to local anesthetic to prolong subarachnoid blockade. In contrast, methoxamine (Vasoxyl) is a much longer-acting drug (30 to 60 minutes).[141] In larger doses, methoxamine possesses some membrane-stabilizing and β-blocking properties.

α_2-Agonists are assuming greater importance as anesthetic adjuvants and analgesics. Their primary effect is sympatholytic. They reduce peripheral norepinephrine release by stimulation of prejunctional inhibitory α_2-adrenoreceptors. They inhibit central neural transmission in the dorsal horn by presynaptic and postsynaptic mechanisms and also have direct sympatholytic effects on spinal preganglionic sympathetic neurons. Traditionally, they have been used as antihypertensive drugs, but applications based on their sedative, anxiolytic, and analgesic properties are being developed.

Clonidine, the prototypical drug of this class, is a selective partial agonist for α_2-adrenoreceptors, with a ratio of approximately 200:1 (α_2 to α_1). Its antihypertensive effects are caused by central and peripheral attenuation of sympathetic outflow and central activation of nonadrenergic imidazoline-preferring receptors.[142-144] The decrease in central sympathetic outflow reduces activity in peripheral sympathetic neurons without affecting baroreceptor reflexes.[145] Arterial blood pressure is thereby decreased without the accompanying orthostatic hypotension produced by many antihypertensive drugs.[146] Because clonidine is lipid soluble, it penetrates the blood-brain barrier to reach the hypothalamus and medulla, and unlike methyldopa, it does not require transformation into another substance.[147] Clonidine withdrawal may precipitate hypertensive crises, so it should be continued throughout the perioperative period (perhaps by patch) or at the least be replaced by close monitoring of blood pressure and ready ability to treat hypertension. The administration of nonselective β-blockers during clonidine withdrawal can worsen hypertension by leaving α_1-receptor–mediated vasoconstriction unopposed. Labetalol has been used to treat this withdrawal syndrome.

Although experience with α_2-agonists as sole anesthetics is limited,[148] these drugs reduce anesthetic requirement and provide a more stable cardiovascular course, presumably because of their sympatholytic effect and the need for lower doses of cardioactive anesthetics.[149,150] Data suggest that oral, intravenous, epidural, and intrathecal administration of clonidine potentiates the anesthetic action of other anesthetics, volatile or injectable, and reduces general and regional anesthetic requirements with correspondingly fewer side effects.[149,151-158] Additionally, a meta-analysis looking at the perioperative use of clonidine and the other α_2-agonists dexmedetomidine and mivazerol indicated a marked decrease in myocardial infarction and perioperative mortality in patients undergoing vascular surgery (see Chapter 62).[159]

Dexmedetomidine has a 1600:1 preference for α_2-receptors relative to α_1-receptors[160]; it was introduced into clinical practice as an adjunct to regional, local, and general anesthetics.[161] Dexmedetomidine has a half-life of 2.3 hours, although its distribution half-life is less than 5 minutes,[162] thus making its clinical effect quite short.

In healthy volunteers, dexmedetomidine increases sedation, analgesia, and amnesia and decreases heart rate, cardiac output, and circulating catecholamines in a dose-dependent fashion.[160] The purported MAC-reducing sedative and analgesic

effects demonstrated in preclinical and volunteer studies have largely been borne out in clinical practice. Although dexmedetomidine infusions attenuate the hemodynamic lability of induction, maintenance, and emergence, the dose of other anesthetics must be carefully reduced[163,164] because requirements for other anesthetics may decrease. Another use for this drug is to provide sedation for mechanically ventilated patients during weaning from the ventilator (see Chapter 92).[165]

In addition to their use in the operative setting, α_2-agonists provide effective analgesia for acute and chronic pain, particularly as adjuncts to local anesthetics and opioids. The addition of clonidine increases the duration of analgesia and reduces dose requirements for local and narcotic pain medications.[155,166-180] Epidural clonidine is indicated for the treatment of intractable pain, which is the basis for approval of parenteral clonidine in the United States as an orphan drug.[181] Patients with intractable pain that is unresponsive to maximum doses of oral or epidural opioids benefit from oral, patch, intramuscular, or neuraxial administration of clonidine,[182-185] as do patients with reflex sympathetic dystrophy[186] and neuropathic pain.[187] The intrinsic analgesic effects of α_2-agonists have been demonstrated with large doses of clonidine alone administered intrathecally (as much as 450 µg) or epidurally (1 to 2 µg/kg/hr) to control intraoperative and postoperative pain. Clonidine decreases postoperative oxygen consumption and the adrenergic stress response.[188,189] Although dose-dependent adverse effects such as hypotension and sedation and idiosyncratic adverse effects such as bradycardia do occur, clonidine does not induce profound respiratory depression and only mildly potentiates opiate-induced respiratory depression.[190,191] The relatively minor impact of α_2-induced sedation on respiratory function combined with the short duration of action of dexmedetomidine has led to several reports of the use of dexmedetomidine for awake fiberoptic intubation.[192,193] The authors emphasize the ability to maintain spontaneous ventilation in the context of adequate sedation for the procedure as the reason for selecting the short-acting α_2-agonist for sedation in patients with difficult or at-risk airways. Dexmedetomidine infusions have been used for the perioperative management of obese patients with obstructive sleep apnea to minimize their narcotic needs while providing adequate analgesia.[194]

Aside from its role as an anesthetic adjuvant and antihypertensive agent, clonidine has been used to treat panic disorder[195]; symptoms of opiate, benzodiazepine, and ethanol withdrawal[196]; cigarette craving after smoking cessation[197]; emesis in cancer chemotherapeutic regimens; and diabetic diarrhea. Clonidine may increase blood glucose concentrations by inhibiting release of insulin.[198] Unlike spinal opioids, clonidine does not cause urinary retention and may hasten the time to first micturition after spinal anesthesia.[199,200] Because it has come into wide clinical use only in recent years, the breadth of experience with dexmedetomidine is much less than with clonidine. Nevertheless, infusions of the short-acting intravenous α_2-agonist have been used for sedation during weaning from extubation in the intensive care unit,[201] during neurosurgical cases (to facilitate intraoperative wake-ups and to improve signal quality during neuromonitoring),[202] (see Chapters 46 and 63), and as part of a postoperative pain management regimen.[203] An important characteristic of dexmedetomidine that makes it an attractive choice in these settings is the "rousable" sedation that it creates. Specifically, patients will awaken from apparently deep states of sedation to verbal commands or light tactile stimulation.

β-Receptor Agonists

Nonselective β-Receptor Agonists

Dobutamine. Although at clinical doses it can act at β_2- and α_1-receptors, dobutamine, a synthetic analog of dopamine, has predominantly β_1-adrenergic effects. When compared with isoproterenol, it is reported to affect inotropy more than chronotropy, but it increases conduction velocity through nodal tissue to the same extent. It exerts less of a β_2-type effect than isoproterenol does and less of an α_1-type effect than norepinephrine does. Unlike dopamine, it does not directly release endogenous norepinephrine, nor does it act at dopaminergic receptors.

Dobutamine is particularly useful in CHF and MI complicated by a low-output state, although in cases of severe hypotension, it may not be effective because it lacks a significant α_1-pressor effect. It is relatively safe to use in patients with myocardial ischemia without increasing the size of the infarct or causing arrhythmias. Doses lower than 20 µg/kg/min do not produce tachycardia, but in especially severe CHF, significant tachycardia is the primary adverse effect. Because dobutamine directly stimulates β_1-receptors, it does not rely on norepinephrine stores and may still be effective in catecholamine-depleted states such as chronic CHF. However, in severe chronic CHF, the downregulation of β-adrenergic receptors may hamper its effectiveness.

The β_2-vasodilating effects of dobutamine are almost exactly offset by its α_1-constricting effects, which can be revealed experimentally by administering a nonselective β-blocking drug. Its modest ability to dilate the peripheral vasculature is probably more closely connected with its ability to relieve the high-adrenergic state of decompensated CHF than with specific β_2-mediated vasodilation.[204] Clinical situations that call for distinct afterload reduction may be better served by an agent such as nitroprusside.

Prolonged treatment with dobutamine causes downregulation of β-receptors; tolerance to its hemodynamic effects is significant after 3 days and may be temporarily offset by increasing the rate of infusion.[205] Intermittent infusions of dobutamine have been used in the long-term treatment of heart failure and have improved exercise tolerance[206] but not survival.[207]

Isoproterenol. Isoproterenol (Isuprel) provides relatively pure nonselective β-adrenergic stimulation with no significant effect at α-receptors. Its β_1-adrenergic stimulation is significantly stronger than its β_2 stimulation, but it still causes more β_2-adrenergic activity than dobutamine does. Since the development of other inotropes, its popularity has declined because of its adverse effects of tachycardia and arrhythmias. Isoproterenol was historically used for bradycardia or heart block resistant to atropine, but it is no longer included in the American Heart Association advanced cardiac life support protocol (see Chapter 97). Its primary use at this time is as a chronotropic agent in patients after heart transplantation. These patients are unable to generate an endogenous sympathetic response to challenges because the sympathetic fibers are divided when the native heart is removed. The availability of superior pharmacologic options for most clinical indications has led to removal of isoproterenol from many hospital formularies. Infusion rates start at 0.5 to 5 µg/min for adults. Because it is not taken up into adrenergic nerve endings,

its duration of action is slightly longer than that of the natural catecholamines.

Selective β_2-Receptor Agonists

In the past, isoproterenol was used in the treatment of bronchospasm for its β_2-adrenergic–stimulating properties, but unpleasant and dangerous β_1-mediated adverse effects have limited its use. The development of β_2-selective agents has made β-stimulants a cornerstone of the treatment of bronchospasm. However, this β_2-selectivity is only relative, and it may be lost at higher doses; in addition, β_2-receptors in the sinoatrial node may cause tachycardia when stimulated. The structures of these drugs have been modified to slow their metabolism, thereby prolonging their therapeutic benefit and enabling oral administration. In particular, the addition of bulky structures on the catecholamine amino group increases β_2-selectivity, decreases affinity for α-receptors, and protects against metabolism by COMT. These agents are aerosolized and given by inhaler for rapid onset and to minimize systemic drug levels and adverse effects.

An increase in the annual number of deaths from asthma has been well documented, and it has been suggested that this increase may be related to β_2-agonist use.[208-210] Susceptibility to arrhythmia by direct cardiac stimulation or by β_2-induced hypokalemia is a suggested mechanism of these agents. It has also been hypothesized that long-term use of these drugs may increase airway hyperreactivity. Nonetheless, their safe use in many thousands of patients is well documented.

Commonly used drugs include metaproterenol (Alupent, Metaprel), terbutaline (Brethine, Bricanyl), and albuterol (Proventil, Ventolin). Metaproterenol is probably less β_2-selective than albuterol or terbutaline. Terbutaline is the only β_2-selective agent that can be given subcutaneously and may therefore have particular use in status asthmaticus. The normal subcutaneous dose is 0.25 mg, which may be repeated after 15 to 30 minutes.

β_2-Agonists are also used to treat premature labor (see Chapter 69). Ritodrine (Yutopar) has been marketed for this purpose. β_1-Adrenergic adverse effects are common, particularly when the drugs are administered intravenously. The other β_2-selective drugs have also been used as tocolytics, and all have been associated with significant β_1-adrenergic adverse effects and the occasional development of pulmonary edema. As a consequence, their use for the purpose of tocolysis has been questioned.[211]

α-Receptor Antagonists

α_1-Antagonists have long been used clinically as antihypertensives, but they have become less popular over the years. α_1-Blockade vasodilates by blocking the arterial and venous constriction caused by endogenous catecholamines. The effects are potentiated when standing or in the presence of hypovolemia. Reflex tachycardia and fluid retention can ensue.

Phenoxybenzamine (Dibenzyline) is the prototypical α_1-antagonist, although it irreversibly binds to α_1- and α_2-receptors. New receptors must be synthesized before complete offset of its effects occurs. Its half-life after oral administration is unknown, but after an intravenous dose its half-life is about 24 hours. Phenoxybenzamine decreases peripheral resistance and increases cardiac output, and blood flow to the skin and viscera is increased. As expected, its primary adverse effect is orthostatic hypotension; nasal stuffiness may also occur. In addition to receptor blockade, phenoxybenzamine inhibits neuronal and extraneuronal uptake of catecholamines. Phenoxybenzamine is used for the treatment of pheochromocytoma; with extended use, it establishes a "chemical sympathectomy" preoperatively that aids in blood pressure control, permits correction of the contracted plasma volume, and protects against catecholamine-induced cardiac damage. Thus, phenoxybenzamine treatment allows a smoother perioperative course for patients undergoing removal of a pheochromocytoma. When exogenous sympathomimetics are administered after α_1-receptor blockade, their vasoconstrictive effects are inhibited. The effect of phenylephrine is completely blocked, whereas that of norepinephrine is limited to its β_1-adrenergic effect of cardiac stimulation. Epinephrine reversal caused by unopposed β_2-agonism when exogenous epinephrine is given is manifested as severe hypotension and tachycardia. Despite its irreversible binding to the receptor, the recommended treatment of phenoxybenzamine overdosage is norepinephrine infusion because some receptors remain free of the drug.[212]

Phentolamine (Regitine) is a shorter-acting drug that blocks α_1- and α_2-receptors. Historically used to treat pulmonary hypertension, it has largely been supplanted by nitroglycerin and nitroprusside. It is also used to treat the hypertension associated with clonidine withdrawal or with tyramine ingestion during MAOI therapy, but few data have been collected on its efficacy and safety for these indications. Phentolamine has also been infiltrated into affected tissues after extravasation of agents such as norepinephrine in an attempt to relax vasoconstriction; for this purpose, 5 to 10 mg is diluted in 10 mL of saline. Adverse effects of phentolamine include hypotension and gastrointestinal distress; reflex tachycardia and arrhythmias may result from action at α_2-receptors. Coronary artery disease and peptic ulcer disease are relative contraindications to its use. As in phenoxybenzamine overdosage, severe hypotension may require treatment with norepinephrine rather than epinephrine.

Prazosin (Minipress) is a potent selective α_1-adrenergic blocker often used as a prototypical antagonist in pharmacologic experiments. It antagonizes the vasoconstrictor effects of norepinephrine and epinephrine, thereby causing a decline in peripheral vascular resistance and venous return to the heart. Although the heart rate does not normally increase, orthostatic hypotension is a major problem. Unlike other antihypertensive drugs, prazosin improves lipid profiles by lowering low-density lipid levels while raising the level of high-density lipids. It is primarily used to treat hypertension. It has also been used in patients with CHF, but unlike the angiotensin-converting enzyme inhibitors (ACEIs), prazosin does not prolong life. It is metabolized by the liver. Supplied as 1-, 2-, and 5-mg tablets, its starting dose is usually 0.5 to 1 mg given at bedtime because of the orthostatic hypotension. Eventually, it can be taken twice daily.

α_2-Antagonists such as yohimbine increase sympathetic outflow by enhancing release of norepinephrine. These drugs have proved to be of little clinical utility in anesthesia, although they are used in urology.

β-Receptor Antagonists

Pharmacology

β-Adrenergic receptor antagonists (i.e., β-blockers) are among the most commonly prescribed drugs and are frequently taken by patients about to undergo surgery. Current indications for the use of β-blockade include ischemic heart disease, postinfarction management, arrhythmias, hypertrophic cardiomyopathy, hypertension, heart failure, and prophylaxis for migraine headache.

Concern that patients treated with β-blockers would be hemodynamically unstable under anesthesia has proved to be largely unjustified. These drugs are an important part of the armamentarium of the anesthesiologist in the ongoing attempt to limit stress responses perioperatively and to protect the cardiovascular system. A comprehensive analysis by the Agency for Healthcare Research and Quality found that the use of β-blockers perioperatively reduces morbidity and mortality in noncardiac surgery for patients at risk.[213] Several well-known clinical trials[214-218] and the widespread use and safety of these drugs in heart failure[219] have made β-blockade an evolving standard (see Chapter 34).

A wide spectrum of β-adrenergic blockers are available to the clinician. The most important properties to consider when choosing a β-blocker for long-term use are cardioselectivity, intrinsic sympathomimetic activity (ISA), and lipid solubility. In anesthetic practice, cardioselectivity, duration of action, and a formulation suitable for intravenous use are crucial factors (Table 12-10). β-Antagonists resemble isoproterenol in structure and bind competitively to the β-receptor, thereby blocking access by more potent β-agonists (Fig. 12-17). Competitive inhibition at the β-receptor can be overcome by increasing the available concentration of β-agonist. The potency of a β-blocker is often determined by its ability to inhibit induction of tachycardia by isoproterenol. Propranolol is assigned a potency of 1, and the other drugs are evaluated in relation to it.

Nonselective β-adrenergic blockers act at the β_1- and β_2-receptors and include propranolol, nadolol, pindolol, sotalol, oxprenolol, penbutolol, and timolol. Cardioselective β-blockers have stronger affinity for β_1-adrenergic receptors than for β_2-adrenergic receptors, and the predominant effects are therefore cardiac. With β_1-selective blockade, AV conduction velocity, heart rate, and cardiac contractility are decreased, as is release of renin by the juxtaglomerular apparatus and lipolysis at adipocytes. At larger doses, the relative selectivity for β_1-adrenergic receptors is lost and β_2-receptors are also blocked, with the potential for bronchoconstriction, peripheral vasoconstriction, and decreased glycogenolysis.

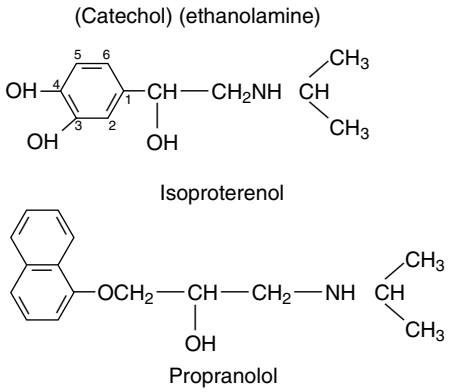

Figure 12-17 Structure of isoproterenol and propranolol. *(From Tollenaeré JP: Atlas of the Three-Dimensional Structure of Drugs. Amsterdam, Elsevier North-Holland, 1979.)*

Cardioselective drugs include atenolol, betaxolol, bevantolol, esmolol, and metoprolol. These drugs may be preferable for patients with obstructive pulmonary disease, peripheral vascular disease, Raynaud's phenomenon, and diabetes mellitus. Although previously a matter of controversy, a meta-analysis concluded that cardioselective β-blockers can be given safely to patients with chronic obstructive pulmonary disease.[220] Nevertheless, because the selectivity is only relative and may be lost at conventional clinical doses, extreme care should be taken when administering a β-blocker in the presence of pulmonary disease. Some β-antagonists also have vasodilatory effects, thus making them particularly useful in the treatment of hypertension and

Table 12-10 Pharmacokinetics and Pharmacology of Selected β-Adrenoceptor Blockers

CHF.[221,222] Labetalol vasodilates by blocking α_1-receptors and by direct β_2-receptor agonism.

β-Blockers exerting a partial agonist effect at the receptor while blocking access by more potent agonists possess ISA. Drugs with ISA include acebutolol, carteolol, celiprolol, dilevalol, oxprenolol, penbutolol, and pindolol. These drugs primarily decrease arterial blood pressure and, to a lesser extent, heart rate and left ventricular function. When sympathetic activity is high, such as during exercise, these drugs behave more like conventional β-blockers. The partial β_2-agonism of pindolol induces bronchodilation. ISA may therefore be useful if β-blockade is required in a patient with bradycardia, peripheral vascular disease, or very mild hyperreactive airway disease. Drugs with ISA may not be as effective in controlling symptoms in severe angina or in reducing mortality after MI.[223] ISA may protect against β-blocker withdrawal syndrome.[224]

Propranolol and acebutolol possess membrane-stabilizing activity (MSA), also referred to as the quinidine-like or local anesthetic effect. This effect reduces the rate of rise in cardiac action potential. The MSA of propranolol may explain the decrease in the oxygen affinity of hemoglobin when it is administered. However, MSA is seen only at concentrations 10 times those required for blockade of β-receptors and is probably of little clinical consequence. Overdose with drugs that exhibit MSA is associated with a higher incidence of fatality.[225]

Indications for Use

Perioperative β-Blockade. In the late 1990s, two important studies established the value of perioperative β-blockade in patients at risk for coronary ischemia who were undergoing noncardiac operations (see Chapters 34 and 35). Patients are labeled as "at risk" if they fit into one of two categories: they are undergoing high-risk vascular surgery and have no evidence of inducible coronary ischemia, or they are undergoing a nonvascular procedure but have traditional risk factors for coronary artery disease (elderly, high cholesterol, hypertension, cigarette smoking, family history of coronary disease, or diabetes).[226] The Multicenter Study of Perioperative Ischemia Research Group[215] enrolled 200 patients about to undergo surgery who had risk factors for coronary artery disease and randomized them to receive placebo or atenolol before and after surgery. Their results demonstrated that although there was no improvement in in-hospital outcomes (cardiac death or MI) in the atenolol-treated group, the treated group did have a lower incidence of cardiac events at the 6- to 8-month follow-up and a marked decrease in all-cause mortality that persisted at 2-year follow-up (survival rate at 2 years: 68% in the placebo group and 83% in the atenolol-treated group). The second study[216] enrolled patients with known ischemic disease demonstrated on preoperative stress echocardiography. The treatment group in this study was given bisoprolol and the dose was titrated to achieve a heart rate below the patients' ischemic threshold. The results of this study, whose participants were at much higher risk for ischemic events than those of the previous study, demonstrated a 10-fold decrease in perioperative cardiac death and MI (3.4% versus 34%). These powerful demonstrations that β-blockade could decrease perioperative cardiac risk and improve survival out to 2 years led to tremendous political and administrative pressure to increase the use of β-blockers perioperatively.[227] Unfortunately, more recent research has brought the value of routine perioperative β-blockade into question. The POBBLE study[228] results showed no reduction in 30-day cardiovascular morbidity in patients undergoing vascular surgery (one of the "at-risk" groups from previous studies). Similarly, the DIPOM study[229] showed no benefit of β-blockade in diabetics (another "at-risk" group) undergoing major noncardiac operations. Finally, a large retrospective study looking at in-hospital mortality in more than 780,000 patients demonstrated a neutral or even negative effect of perioperative β-blockade in patients without clear-cut coronary artery disease. β-Blockade was associated with a reduced mortality rate in only the 3% of patients who had three or more risk factors (based on the revised Cardiac Risk Index) for coronary ischemia.[230] Thus, until larger studies are completed, the only strong indication for initiating β-blockade preoperatively is for patients undergoing vascular surgery who are at high cardiac risk as a result of the finding of ischemia on preoperative testing.[227]

When perioperative β-blocker therapy is initiated, it should be titrated to a non–ischemia-inducing heart rate (usually 60 to 70 beats per minute) and not given as a standard fixed dose to all patients. β-blockers should be continued in patients who are already taking them as treatment of their angina, symptomatic arrhythmia, or hypertension.

The safety of continuing β-blockade perioperatively is well established, and initial concerns regarding interaction with general anesthesia have not been confirmed. Attempts to discontinue β-blockers increase the risk for rebound tachycardia (with or without atrial fibrillation) and myocardial ischemia in patients with coronary disease. These drugs should be given up to the time of surgery, and intravenous forms in appropriate dosages should be used whenever gastrointestinal absorption may be in question. If β-blockers have been omitted from the preoperative regimen, esmolol or labetalol may be used acutely to blunt tachycardia and hypertension. Cardioselective and nonselective β-blockers appear to be effective in blocking the chronotropic effects of endotracheal intubation and surgical stress.[231]

Myocardial Ischemia. Propranolol was initially introduced for the treatment of myocardial ischemia more than 3 decades ago, and β-blocking drugs remain an important part of drug therapy for myocardial ischemia (see Chapter 35). This class of drugs reduces oxygen demand by decreasing the heart rate and cardiac contractility. Cardioselective and nonselective β-blockers are effective. Atenolol, metoprolol, nadolol, and propranolol have been approved in the United States for the treatment of angina; metoprolol and atenolol are the only β-blockers approved for intravenous use in patients with acute MI. Although initially there was concern that β_2-receptor blockade could worsen ischemia through unopposed α-mediated vasoconstriction, this phenomenon is rarely seen, even in patients with variant angina. β-Antagonists are used to treat acute MI and on a long-term basis to reduce reinfarction and mortality in patients after infarction.[232-235] Early administration of intravenous β-blocking agents to patients receiving thrombolytic therapy appears to lower the incidence of ischemia and reinfarction[236] and may reduce the incidence of serious ventricular arrhythmias.[237] Long-term use of β-blockers (i.e., timolol, propranolol, metoprolol, and atenolol) has been shown to decrease mortality after MI. In usual clinical practice, the dose is increased until the heart rate is 60 to 80 beats/min at rest and there is no tachycardia with exercise.

Congestive Heart Failure. Over the past 5 to 10 years, β-blockers have become first-line agents for the treatment of CHF of ischemic and nonischemic origin. Clinicians had been disinclined to use β-blockers for heart failure patients because of the

drugs' negative inotropic effects. These effects have not turned out to be a significant concern in clinical practice. Early studies demonstrated a significant decrease in all-cause mortality for heart failure patients treated with metoprolol or bisoprolol. Several large studies[238,239] were stopped because the decrease in mortality in treated patients with moderate to severe heart failure was so pronounced. The benefits of β-blockers in patients with heart failure have been attributed to normalization and remodeling of the ventricle, which begin after 1 month of β-blockade[240]; to reduced norepinephrine-related cardiomyocyte apoptosis in the presence of β_1-blockade[241]; to decreased sudden cardiac death because of the β-blockers' antiarrhythmic activity; and most recently, to altered expression of genes in the myocardium that regulate contractility and pathologic hypertrophy.[242] To avoid worsening a patient's heart failure symptoms and to minimize negative inotropic effects, β-blockers are started at very low doses and are titrated to the target dose.[243] The only β-blockers approved for the treatment of CHF by the U.S. Food and Drug Administration are carvedilol and metoprolol, although their efficacy in patients with severe (i.e., New York Heart Association class IV) heart failure is still being studied. If decompensation occurs with the β-blocker, phosphodiesterase inhibitors are the inotropes of choice because their effects are not antagonized by β-blockade.[244]

Hypertension. The mechanisms by which β-antagonists treat hypertension are incompletely understood. Arterial blood pressure is specifically decreased in hypertensive patients because long-term treatment of normotensive individuals does not decrease blood pressure. Reduced cardiac output and renin release have been suggested as mechanisms. In hypertensive patients, β-antagonists without ISA may cause a 15% to 20% reduction in cardiac output and a 60% reduction in renin release. However, pindolol, which has ISA and minimal effect on renin, is also successful in treating hypertension.[245] Maximum renin suppression precedes significant changes in arterial blood pressure.[246] Initially, β-blockade increases peripheral vascular resistance and then over time lowers it.[247] The decrease in cardiac output and eventual lowering of peripheral resistance may account for much of the antihypertensive efficacy of these drugs. However, this too is an incomplete explanation because labetalol is an effective antihypertensive despite its lack of effect on cardiac output. A primary CNS effect is not likely to be a major mechanism because the antihypertensive efficacy of lipophilic and hydrophilic compounds is similar. Generally, β-blockade is ineffective as monotherapy in hypertensive African American patients older than 60 years.

Cardiac Arrhythmias. β-Blockers are widely used in the treatment of tachyarrhythmias as class II agents (see Chapters 35, 60, and 61). Two possible mechanisms of action are blockade of catecholamine effects and MSA, although the latter is most likely not clinically significant because antiarrhythmic effects are present in agents without MSA.[248] β-Antagonists slow the rate of depolarization of the sinus node and any ectopic pacemakers, slow conduction through atrial tissue and the AV node, and increase the refractory period of the AV node. These drugs can convert atrial arrhythmias to sinus rhythm,[249] but β-blockade is primarily used to slow the ventricular response. Reentrant tachyarrhythmias and those associated with Wolff-Parkinson-White syndrome, mitral valve prolapse, and a prolonged QT interval may also respond to these drugs. Care should be exercised if AV block is present, as in digitalis toxicity, although these drugs are useful in the treatment of digitalis-associated tachyarrhythmias. Sotalol, a β-blocker with added class III activity, is effective against ventricular tachyarrhythmias; however, in a trial comparing racemic sotalol with D-sotalol in post-MI patients, mortality increased with D-sotalol.[250] The trial was terminated when patients at lowest risk for arrhythmic events after MI had an increased mortality rate with this drug.[251]

Tachycardia. β-Antagonists are frequently used as adjuvants to moderate the reflex tachycardia associated with vasodilators (see Chapter 61). In addition to potentiating a reduction in blood pressure, β-blockade also reduces the velocity of left ventricular ejection (dp/dt) and attenuates the shearing force associated with the increased velocity of ventricular contraction when afterload is reduced with nitroprusside without concomitant β-blockade.[252] Labetalol has been particularly useful in this situation.[253]

Thyrotoxicosis. Cardiac complications are a primary cause of morbidity in thyrotoxicosis (see Chapter 75). β-Blockade can suppress the tachycardia and rhythm disturbances, although very large doses may be required. β-Antagonists also may be combined with digitalis for their synergistic effect on AV node conduction. Propranolol inhibits conversion of thyroxine to the active form triiodothyronine in the periphery.[254]

Miscellaneous Conditions. Timolol (Timoptic) and betaxolol (Betoptic) are β-blocking drugs used topically in the eye to treat glaucoma. They reduce the production of aqueous humor. Even topical use of these agents has been associated with significant systemic effects of β-blockade. β-Blockers are used in patients with idiopathic hypertrophic subaortic stenosis to reduce the dynamic obstruction to left ventricular outflow. The drugs are also effective in the prophylaxis but not the treatment of migraine headaches and in controlling acute panic symptoms and essential tremor.

Adverse Effects

The adverse effects of most concern are those involving cardiopulmonary function. Severe noncardiopulmonary reactions such as cutaneous reactions or anaphylaxis are rare. Life-threatening bradycardia, even asystole, may occur, and decreased contractility may precipitate CHF in vulnerable individuals. In patients with bronchospastic lung disease, β_2-blockade may be fatal. CNS effects, although an appropriate consideration with long-term therapy, are not a concern with the usual anesthetic use of these agents. Diabetes mellitus is a relative contraindication to the long-term use of β-antagonists because hypoglycemia in the face of sympathetic blockade is not accompanied by warning signs such as tachycardia and tremor and because compensatory glycogenolysis is blunted. However, most non–insulin-dependent diabetic patients can tolerate these drugs, although β-blockade may cause insulin resistance in rare cases. In addition to the potential worsening of peripheral perfusion by β_2-blockade in patients with peripheral vascular disease, Raynaud's phenomenon may be triggered in susceptible patients. Sudden withdrawal of β-blockers may cause myocardial ischemia and possibly infarction, but this is less of a problem with β-blockers that have ISA, such as pindolol.[255] Even though β-antagonists may reduce renal blood flow and the glomerular filtration rate, these agents can be used in renal failure. For such patients, the doses of lipid-insoluble drugs should be reduced. To avoid worsening of hypertension, use in pheochromocytoma should be avoided unless α-receptors have

previously been blocked. Nonselective agents may elicit hypertensive responses in cases of high sympathetic stimulation.[256]

Undesirable drug interactions are possible with β-blockers. The rate and contractility effects of verapamil are additive to those of β-blockers,[257,258] and care should be taken when combining these agents, especially the intravenous forms in acute situations such as supraventricular tachycardia. The combination of digoxin and β-blockers can have powerful effects on heart rate and conduction and should be used with special care. Pharmacokinetic interactions are predictable from the degree of lipid solubility of the drug. Cimetidine and hydralazine may reduce hepatic perfusion, thereby increasing plasma levels and half-lives of the lipid-soluble β-antagonists. Barbiturates, phenytoin, rifampin, and smoking may induce hepatic enzymes and enhance metabolism. Propranolol may reduce hepatic clearance of lidocaine and increase the risk for toxicity.

Overdose of β-blocking drugs may be treated with atropine, but isoproterenol, dobutamine, or glucagon infusions (or some combination) may be required along with cardiac pacing to ensure an adequate rate of contraction.

Specific Drugs

The drugs propranolol, metoprolol, labetalol, and esmolol are particularly useful in anesthetic practice because they are widely available in intravenous formulations and have well-characterized effects. If the drug that the patient has taken on a long-term basis is propranolol, metoprolol, or labetalol, it may be continued in intravenous form. In deciding which intravenous β-blocker to substitute in a patient taking a β-blocker on a long-term basis, the need for cardioselectivity is a primary consideration. Cardioselectivity is provided by metoprolol or esmolol. If the long-term agent has ISA, oxprenolol and acebutolol have intravenous forms, but they are not readily available. In many situations, esmolol may be substituted and titrated to effect, with the expectation that its effects will fade relatively rapidly if it is not well tolerated.

Propranolol. Propranolol (Inderal, Ipran), the prototypical β-blocker, is a nonselective β-blocking drug with MSA but no ISA. It readily penetrates the CNS. Because of its high lipid solubility, it is extensively metabolized in the liver, but metabolism varies greatly from patient to patient. Its effective dose is extremely variable: 10 mg to as much as 320 mg may be given orally each day. Clearance of the drug can be affected by liver disease or altered hepatic blood flow. Renal impairment does not require adjustment of dosing. Despite its half-life of 4 hours, its antihypertensive effect persists long enough to permit dosing once or twice daily. Propranolol is available in an intravenous form and was initially given as either a bolus or an infusion. Infusions of propranolol have largely been supplanted by esmolol. For bolus administration, doses of 0.1 mg/kg may be given, although most practitioners initiate therapy with much smaller doses, typically 0.25 to 0.5 mg, and titrate to effect. Propranolol shifts the oxyhemoglobin dissociation curve to the right, which perhaps accounts for its efficacy in vasospastic disorders.[259]

Metoprolol. Metoprolol (Lopressor) is approved for the treatment of angina pectoris and acute MI. It is cardioselective and lacks ISA and MSA. Because it is metabolized in the liver by the monooxygenase system, doses need not be adjusted in the presence of liver failure. The usual oral dose is 100 to 200 mg/day given once or twice daily for hypertension and twice daily for angina pectoris. It may be administered intravenously in doses of 2.5 to 5 mg every 2 to 5 minutes up to 15 mg, with titration to heart rate and blood pressure.

Labetalol. Labetalol (Trandate, Normodyne) is representative of a class of drugs that act as competitive antagonists at the α_1- and β-adrenergic receptors. Labetalol consists of four isomers that block the α_1-, β_1-, and β_2-receptors, inhibit neuronal uptake of norepinephrine (uptake 1), act as a partial agonist at β_2-receptors, and possibly have some direct dilating ability. The potency of the mixture for β-blockade is 5- to 10-fold that for α-blockade. The usual oral dose of labetalol is 200 to 400 mg twice daily, although much larger doses have been used. It is metabolized by the liver, and clearance is affected by hepatic perfusion. The dose need not be adjusted for renal dysfunction. Labetalol may be given intravenously every 5 minutes in 5- to 10-mg doses or up to a 2 mg/min infusion. It significantly blunts cardiovascular responses to tracheal intubation.[260] It can be effective in the treatment of aortic dissection,[252] hypertensive emergencies,[261,262] and postoperative cardiac surgical patients,[263] particularly because vasodilation is not accompanied by tachycardia. It may be used in pregnancy to treat hypertension on a long-term basis and in more urgent situations.[264] Uterine blood flow is not affected, even with a significant reduction in blood pressure (see Chapter 69).[265]

Carvedilol. Carvedilol, a mixed α- and β-antagonist, has been introduced as therapy for mild or moderate hypertension,[266-274] for the management of stable or unstable angina, and after acute MI.[275-279] Clinical trials of carvedilol for the treatment of controlled CHF (New York Heart Association class II to IV) suggest a significant reduction in mortality,[237,238,280,281] especially for patients with diabetes.[282]

Esmolol. Because of its hydrolysis by esterases, esmolol (Brevibloc) has a uniquely short half-life of 9 to 10 minutes, which makes it particularly useful in anesthetic practice. It is administered when β-blockade of short duration is desired or in critically ill patients for whom the adverse effects of bradycardia, heart failure, or hypotension may necessitate rapid withdrawal of the drug. The peak effects of a loading dose are seen within 5 to 10 minutes and diminish rapidly (within 20 to 30 minutes). It is cardioselective and may be given as a bolus of 0.5 mg/kg to blunt cardiovascular responses to tracheal intubation. If used as an infusion for the treatment of supraventricular tachycardia, 500 μg/kg is given over a 1-minute period, followed by an infusion of 50 μg/kg/min for 4 minutes. If the rate is not controlled, a repeat loading dose followed by a 4-minute infusion of 100 μg/kg/min is given, and this sequence is repeated with the infusion increased in 50-μg/kg/min increments up to 200 or 300 μg/kg/min if needed. The effect may persist for 20 to 30 minutes after discontinuation of the infusion. When compared with verapamil, esmolol is more likely to convert atrial fibrillation to sinus rhythm.[248] Esmolol is safe and effective for the treatment of intraoperative and postoperative hypertension and tachycardia.[283-285] If continuous use is required, it may reasonably be replaced by a longer-lasting cardioselective drug such as intravenous metoprolol. It has been used safely even in patients with compromised left ventricular function.[286,287]

Drugs that Inhibit Synthesis, Storage, or Release of Norepinephrine

Some early antihypertensive drugs acted by replacing norepinephrine in the nerve ending with a much less potent false transmitter. Methyldopa (Aldomet) is such a drug and was the most

popular nondiuretic antihypertensive used before the development of β-blockers.[213] Like DOPA, methyldopa enters the biosynthetic pathway for norepinephrine (see Fig. 12-7). It is then decarboxylated to α-methylnorepinephrine. Initially, this chemical was thought to act as a false transmitter, but it was found to be almost as potent as norepinephrine. In the CNS, methyldopa may be further metabolized to α-methylepinephrine, and it acts at α_2-receptors to decrease sympathetic outflow, which reduces blood pressure. Because of its sedating qualities, fluid retention, postural hypotension, and occasional reports of hepatic necrosis, methyldopa is now used much less often.

Methylparatyrosine (metyrosine, Demser) is a potent inhibitor of TH, which catalyzes the formation of DOPA from tyrosine (see Fig. 12-7). Because this is the rate-limiting step in the biosynthesis of norepinephrine, the drug significantly decreases levels of endogenous catecholamines and is useful in treating inoperable or malignant pheochromocytomas.

Reserpine affects the uptake of norepinephrine, not at the neuronal membrane but at the vesicular membrane, thereby inhibiting transport and storage of norepinephrine and dopamine. However, this drug is rarely used in modern medicine.

Guanethidine (Ismelin) acts initially by blocking the release of norepinephrine, and then it is taken up into adrenergic nerve endings by the uptake-1 mechanism and depletes norepinephrine stores. It is used to treat hypertension, usually after many other drugs have been tried. Its inability to cross the blood-brain barrier accounts for its lack of sedative effects. Guanadrel (Hylorel) is similar to guanethidine, but it has a faster onset and shorter duration of action.

Bretylium, a class III antiarrhythmic used parenterally to treat life-threatening ventricular tachyarrhythmias, is now largely of historical interest. Like guanethidine, it is taken up into adrenergic nerve terminals, but its mechanism of action is otherwise quite different. Bretylium initially causes release of norepinephrine and subsequently blocks that release by decreasing sympathetic nerve excitability. Unlike guanethidine, bretylium does not deplete norepinephrine stores. The initial catecholamine release may cause marked hypertension and worsen some arrhythmias, such as those associated with digitalis toxicity and myocardial ischemia.[234] As a consequence, bretylium, which had been part of the advanced cardiac life support protocols for treating ventricular arrhythmias, has been dropped from the algorithms.

MAO and COMT are enzymes important in degradation of the catecholamines. MAOIs bind irreversibly to the enzyme and increase the amine concentration within the presynaptic terminal. Chronic MAOI use is associated with antihypertensive, antidepressant, and antinarcoleptic effects. MAOIs are thought to exert their antihypertensive effect through a false transmitter mechanism. Tyramine is usually oxidatively deaminated in the gut by MAO. With administration of an MAOI, tyramine levels rise. When tyramine is taken up into the sympathetic nerve terminal by the uptake-1 mechanism, it enters the varicosities and is transformed by DβH into octopamine. On its subsequent release in place of norepinephrine, octopamine is only weakly reactive at sympathetic receptors, thereby resulting in lowering of blood pressure. The MAOIs are no longer used as antihypertensives because many other drugs with better risk-benefit profiles have been developed.

MAOIs are primarily used in psychiatric practice. The use of MAOIs as antidepressants is based on the theory that depression is caused by decreased amine in the synapses of the CNS. Inhibition of MAO makes more amine available for release. MAOIs available for the treatment of depression include isocarboxazid (Marplan), phenelzine sulfate (Nardil), and tranylcypromine sulfate (Parnate).

Based on substrate specificity, there are at least two forms of MAO. MAO-A acts on 5-HT, epinephrine, norepinephrine, tyramine, and dopamine, whereas MAO-B is specific for tyramine and dopamine. A specific MAO-B inhibitor, selegiline hydrochloride (deprenyl), has been developed for the treatment of Parkinson's disease in the hope that by blocking central dopamine breakdown, more dopamine will be preserved in the affected areas.[288]

Drug and food reactions have been of great concern in patients taking MAOIs. Tyramine-containing foods such as red wine and aged cheese must be avoided by patients taking these drugs. Consumption delivers a huge amount of tyramine to the adrenergic nerve terminal, with a subsequent massive release of norepinephrine. This release is manifested clinically as a hypertensive crisis with the potential for MI, cerebral hemorrhage, and death. Any intake of biogenic amine precursors can be expected to increase catecholamine levels greatly, as seen with the concurrent administration of levodopa with MAOIs. The effects of sympathomimetic amines, particularly the indirectly acting drugs, are enhanced. Narcotics, most notably meperidine, have been associated with hyperpyrexic coma and death in patients treated with MAOIs. The depressant effects of agents such as sedatives, alcohol, and general anesthetics are enhanced in these patients. Interactions between MAOI and tricyclic antidepressants can be disastrous. Anesthetic interactions with deprenyl have not been reported, but experience with this drug is limited. Great concern has been expressed that patients receiving long-term therapy with an MAOI risk life-threatening drug interactions during anesthesia. Emergency surgery in patients given an MAOI can be punctuated by marked hemodynamic instability. Severe reactions to narcotics and indirect-acting sympathomimetics, as well as altered metabolism of endogenous and exogenous catecholamines, make these patients potentially difficult to manage. Because of the possibly dangerous interactions of many drugs with MAOIs, controversy exists about the best way to anesthetize these patients.[289,290] It has been suggested that the level of concern expressed over the years may be excessive. Although prudence and custom dictate discontinuation of MAOIs at least 2 weeks in advance of elective procedures, there appear to be rational anesthetic choices based on pharmacology and risk-benefit considerations for patients when surgery cannot be delayed or no effective alternative psychiatric medications are available.

Drugs Affecting the Renin-Angiotensin System

The renin-angiotensin system maintains blood pressure and fluid balance. The major end product of the system, angiotensin II, is a potent vasoconstrictor that also stimulates release of aldosterone from the adrenal cortex. Aldosterone causes salt and water retention by the kidney. The mechanism by which angiotensin II

is produced is as follows. The juxtaglomerular cells of the renal cortex secrete the proteolytic enzyme renin, which cleaves angiotensinogen, a protein synthesized in the liver, and produces the decapeptide angiotensin I. Angiotensin I is converted almost immediately to angiotensin II by angiotensin-converting enzyme (ACE). This converting enzyme is located predominantly in the endothelial tissue of the lung. In addition to its direct vasoconstrictive activity, angiotensin II enhances the prejunctional release of norepinephrine from adrenergic nerve ending and increases efferent sympathetic nerve activity. Angiotensin II also affects sodium and water homeostasis by directly decreasing tubular reabsorption of sodium, increasing antidiuretic and adrenocorticotropic hormone secretion, and stimulating the secretion of aldosterone. ACE is also a kinase that degrades the vasodilator bradykinin. ACE inhibition blocks angiotensin II formation and delays the breakdown of bradykinin, along with effects on associated prostaglandins.[291]

Although only a small percentage of hypertensive patients have high circulating plasma renin levels, 70% of patients will respond to the antihypertensive effects of ACEIs. In patients who have elevated plasma renin levels (e.g., patients with CHF or salt depletion states), ACEI therapy must be initiated at lower doses because these patients are extremely sensitive to the effects of ACEIs and significant hypotension can follow the administration of a standard starting dose of these drugs.[213]

ACEIs have proved to be useful in the treatment of hypertension and CHF and have decreased mortality after MI.[292] Captopril (Capoten) was the first active oral agent available, followed by enalapril (Vasotec) and lisinopril (Prinivil, Zestril). ACEIs affect the renin-angiotensin-aldosterone system by inhibiting ACE activity.[293,294] Enalapril is the only ACEI available as an intravenous preparation at this time. Lisinopril offers once-daily dosing.

All the ACEIs are approved for the treatment of hypertension. Captopril, enalapril, ramipril, and trandolapril all decrease morbidity and mortality in patients with CHF. Captopril is associated with more frequent adverse effects than the other agents are, may have a few more drug interactions, and has a dosing regimen of two or three times daily, in contrast to the other ACEIs, which have a dosing regimen of once or twice daily.

Some adverse effects observed with ACEIs are common to the entire class, such as cough, angioedema, acute renal failure, and hyperkalemia. Angioedema, especially after the first dose, affects the face, extremities, lips, mucous membranes, tongue, glottis, or larynx.[295,296] Some occurrences may be fatal.[291,297] Rash and taste disturbances are more frequent with captopril than with the other ACEIs. Because impairment of renal function with an ACEI is usually reversible after withdrawal of the drug, renal function must be monitored, and because hyperkalemia may result from inhibition of aldosterone secretion, serum potassium levels should be monitored. ACEIs can cause fetal morbidity and mortality in humans. These agents should not be used at all during the second or third trimester of pregnancy.[293] The adverse effect profile of the ACEIs has led to the development of angiotensin II receptor blockers (ARBs). Losartan was the first of this new class of antihypertensive agents, which now includes six other ARBs. Initial trials have not demonstrated ARBs to be superior to ACEIs; however, the addition of these agents during chronic ACEI therapy reduced all-cause mortality and hospitalization in patients with heart failure.[298]

Cholinergic Drugs

Overview of Mechanisms of Action

Cholinergic drugs act by mimicking, amplifying, or inhibiting the effects of acetylcholine. Cholinergic drugs do not behave exactly like acetylcholine; their drug action is more specific, with fewer sites affected than with acetylcholine, and their duration of action is generally longer than that of acetylcholine.

Unlike adrenergic pharmacology, in which the clinician can select from a wide choice of drugs, there is a relative paucity of drugs that influence parasympathetic function. In general, drugs that affect the parasympathetic system act in one of four ways:

1. As an agonist by stimulating cholinergic receptors
2. As an antagonist by blocking or inhibiting the actions mediated by the cholinergic receptor
3. Blocking or stimulating receptors on autonomic ganglia
4. Inhibiting the metabolism of acetylcholine, thereby increasing and prolonging its effect

There are no effective clinically used drugs that act through mechanisms affecting the synthesis of acetylcholine (by inhibiting choline acetyltransferase) or by causing indirect release of acetylcholine. Hemicholinium, which interferes with choline uptake and could deplete acetylcholine stores, is not used clinically. Adenosine may inhibit the release of acetylcholine by decreasing the affinity of binding sites for calcium ions; aminoglycoside antibiotics compete with calcium for membrane calcium channels, as does magnesium. Exocytotic release of acetylcholine is inhibited by botulinum toxin. This toxin is sometimes given by local injection to treat strabismus and blepharospasm and has also been used for trigger point injections in pain clinics and to treat age lines. The popularity of off-label uses of this toxin increases the chance of botulism poisoning. In a full-blown botulism-poisoning syndrome, fatalities may result from muscle weakness and respiratory failure.

Cholinergic Agonists

Cholinergic agonists have limited therapeutic use because of their detrimental effects. As a result of its diffuse, nonselective actions and rapid hydrolysis by acetylcholinesterase and butyrylcholinesterase, acetylcholine has had almost no therapeutic use other than as an intraocular medication for transient constriction of the pupil during ophthalmic surgery.

Cholinergic agonists in clinical use have been derived from acetylcholine, but they resist hydrolysis by cholinesterase, which permits a useful duration of action. The different systemic effects of the cholinergic agonists are more quantitative than qualitative, but some limited organ selectivity is useful therapeutically, as seen with the synthetic choline esters bethanechol and carbachol. Methacholine and bethanechol are primarily muscarinic agonists; carbachol has significant nicotinic and muscarinic effects. Adding a methyl group to the β-position of the choline in acetylcholine produces methacholine, which is almost purely muscarinic and nearly totally resistant to hydrolysis by either of the cholinesterases. An intravenous infusion of methacholine causes hypotension and bradycardia; a small subcutaneous dose causes transient hypotension with a reflex increase in heart rate. The sole current

use of methacholine (Provocholine) is as a provocative agent in diagnosing hyperreactive airways, thereby making positive use of the deleterious bronchoconstrictive effect of muscarinic agonists. It is administered only by inhalation; serious adverse effects include gastrointestinal symptoms, chest pain, hypotension, loss of consciousness, and complete heart block when the drug is given orally or parenterally. An excessive bronchoconstrictive response should be treated by an inhaled β-agonist; coexisting β-blockade is considered a contraindication to the use of methacholine.

The carbamate derivative of methacholine, bethanecol (Urecholine), is occasionally used postoperatively to reinstitute peristaltic activity in the gut or to force the extrusion of urine from an atonic bladder. Bethanecol shows preferential activity at intestinal and urinary receptors relative to cardiac sites, so stimulation of the gastrointestinal tract and bladder is achieved with minimal cardiovascular effects. Bethanecol is usually given orally, but if there is inadequate gastrointestinal function to permit absorption of an oral dose, it can be given subcutaneously as well.

Carbachol is used topically or intraocularly to constrict the pupil for the long-term treatment of wide-angle glaucoma. When used topically, it is often better tolerated than the ophthalmic anticholinesterase agents, and it may be effective in patients resistant to pilocarpine and physostigmine. The rapid pupillary constriction is caused by the combination of ganglionic blockade and muscarinic effects. Another natural alkaloid, pilocarpine, was used to treat glaucoma until the advent of more modern drugs.

Muscarinic Antagonists

Muscarinic antagonists are the active ingredients in some common plants used since antiquity for medicinal and poisonous effects. Despite their age, muscarinic antagonists still represent important drugs in anesthesia and critical care.

Muscarinic antagonists compete with neurally released acetylcholine for access to muscarinic cholinoceptors and block its effects. They also antagonize the actions of muscarinic agonists at noninnervated, muscarinic cholinoceptors. Presynaptic muscarinic receptors on the adrenergic nerve terminal may inhibit release of norepinephrine, and muscarinic antagonists may enhance sympathetic activity. With the exception of quaternary ammonium compounds that do not readily cross the blood-brain barrier and have few CNS actions, there is no significant specificity of action among these drugs; they block all muscarinic effects with equal efficacy, although some quantitative differences in effect may be seen (Table 12-11). Research has revealed several subtypes of muscarinic receptors, and agonists and antagonists have been synthesized that bind preferentially to one or another of these subtypes. Pirenzepine preferentially blocks the M_1 receptor, tripitramine shows highest affinity for the M_2 receptor, and darifenacin binds preferentially to the M_3 receptor. The distinctive pharmacology of the various antimuscarinic agents has played a major role in the development of new treatments of overactive bladder disorders. Oxybutynin, tolterodine, darifenacin, solifenacin, and trospium have all been developed to optimize the relief of bladder symptoms while minimizing effects on muscarinic receptors outside the bladder.

Table 12-11 Muscarinic Anticholinergic Drugs

Drug	Duration	Central Nervous System*	Antisialagogue	Heart Rate
Atropine	Short	Stimulation	+	++
Glycopyrrolate	Long	0	++	+
Scopolamine	Short	Sedation	++	0/+

*The effects of atropine are limited with the usual clinical doses, but they can be significant in the elderly.
0, no effect; +, mild effect; ++, moderate effect.

Historically, muscarinic antagonists were used for peptic ulcer disease, various forms of spastic bowel syndrome, upper respiratory illness, and asthma. However, with the availability of specific histamine (H_2)-blocking drugs such as cimetidine for peptic ulcer disease, these uses have markedly decreased. Atropine, once used to treat bronchospasm, was displaced with the introduction of β_2-agonist drugs that did not dry secretions or diminish ciliary motility. Topical use of atropine analogs in ophthalmologic practice to dilate the pupil is still common.

The addition of a muscarinic anticholinergic drug to anesthetic premedication for decreasing secretions and preventing harmful vagal reflexes was mandatory in the era of ether anesthesia, but it is less important with modern inhaled agents. Routine preoperative use of these drugs as antisialagogues continues in some pediatric and otorhinolaryngologic cases or when fiberoptic intubation is planned.

Atropine has a tertiary structure that easily crosses the blood-brain barrier (Fig. 12-18). CNS effects have been seen with the relatively large doses (1 to 2 mg) given to block the adverse muscarinic effects of the anticholinesterase drugs that reverse neuromuscular blockade (see Chapter 29). In contrast, one of the synthetic antimuscarinic drugs, glycopyrrolate (Robinul), does not cross the blood-brain barrier because of its quaternary structure and has gained popularity for this use. Glycopyrrolate has a longer duration of action than atropine does.

Scopolamine, which resembles the others of this class in peripheral actions, has pronounced CNS effects. It is the active ingredient in most over-the-counter preparations sold as soporifics, and it is effective in preventing motion sickness. The patch preparation of scopolamine can be used prophylactically for motion sickness and for postoperative nausea and vomiting, but like the oral and parenteral forms, it may be associated with adverse eye, bladder, skin, and psychological effects.[299,300]

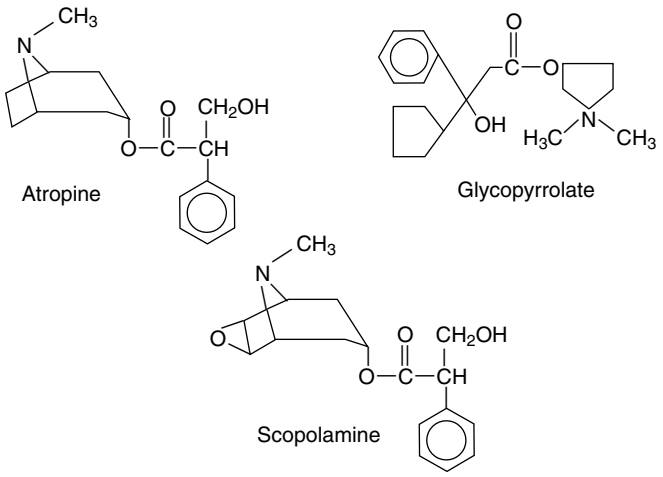

Figure 12-18 Structural formulas of clinically useful antimuscarinic drugs.

The development of ipratropium (Atrovent) reestablished antimuscarinic drugs for the treatment of asthma and bronchospastic disorders.[301] Although ipratropium is structurally similar to atropine and has essentially the same effects when administered parenterally, an important difference is that ipratropium is a quaternary ammonium compound. It is very poorly absorbed when inhaled and has few extrapulmonary effects, even in extremely large doses by this route. Ninety percent of the inhaled drug is swallowed, but only 1% of the total dose is absorbed systemically.

When administered to normal volunteers, ipratropium provides almost complete protection against bronchospasm induced by a variety of provocative agents. However, in asthmatic patients, results vary. The bronchospastic effects of some agents, such as methacholine or sulfur dioxide, are completely blocked, whereas there is little effect on leukotriene-induced bronchoconstriction. The onset of bronchodilation is slow, and the maximum effect is less than that seen with β-agonists. Unlike atropine, ipratropium has no negative effect on ciliary clearance. In general, the therapeutic effect of antimuscarinics, including ipratropium, is greater in patients with chronic obstructive pulmonary disease than in asthmatic patients.[298] Ipratropium is supplied as a metered-dose inhaler that dispenses 18 μg per puff. Two puffs are taken orally four times each day. Maximum bronchodilation occurs in 30 to 90 minutes and may last 4 hours.

The toxic effects of muscarinic antagonists come from the blockade of muscarinic cholinoceptors in the periphery and the CNS. The peripheral effects (e.g., dry mouth) may be irritating but are not life threatening in healthy adults. However, children depend more than adults on sweating for thermoregulation and can become dangerously hyperthermic when given these agents. Moreover, older individuals may not be able to tolerate the cardiac, ocular, or urinary effects of muscarinic blockade.

CNS effects are the usual cause of death or injury. Increasing doses of atropine or scopolamine cause greater distortions of mentation that progress from thought disorders to hallucinations, delusions, delirium, and severe psychoses. These effects are reversible, but the mental dysfunction can persist for weeks. Left alone, an intoxicated individual will die of starvation, dehydration, or trauma. People who have received more than 500 mg of atropine, which is more than 1000 times the usual dose, and have been disabled for weeks have recovered fully.

Small doses of atropine (0.05 mg) can evoke bradycardia, a finding that has led some clinicians to increase the dose in children. It was thought that a CNS effect of atropine could be responsible, but the time course and the fact that bradycardia occurred in vagotomized animals cast doubt on this explanation. Whether this paradoxical bradycardia is a central or peripheral effect, or both, and the role of muscarinic subtypes are still subjects of debate.[302]

Atropine and scopolamine toxicity has been treated for decades with the naturally occurring alkaloid physostigmine (Antilirium), which is an anticholinesterase that penetrates the blood-brain barrier. Use of this drug in doses of 1 to 2 mg given intravenously to treat the postoperative CNS effects of intravenous atropine or scopolamine has been successful. Physostigmine may also reverse the CNS effects of other compounds with anticholinergic activity, including the tricyclic antidepressants, several major tranquilizers, and antihistamine drugs. Physostigmine may also antagonize the sedative effects of the benzodiazepines, but a specific benzodiazepine antagonist, flumazenil (Romazicon), has supplanted physostigmine for this use.[303] Physostigmine must be administered with care because of its potentially lethal nicotinic effects, which are not prevented by the muscarinic antagonists, and because its half-life rarely matches that of the intoxicant.

Cholinesterase Inhibitors

Anticholinesterase drugs are a common means of producing sustained, systemic cholinergic agonism. These drugs are used to reverse neuromuscular blockade and to treat myasthenia gravis and certain tachyarrhythmias.

Three chemical classes of compounds are used as cholinesterase inhibitors: carbamates, organophosphates, and quaternary ammonium alcohols. Physostigmine, neostigmine, and pyridostigmine are carbamates, whereas edrophonium is a quaternary ammonium alcohol. The cholinesterase enzyme is inhibited as long as the esteratic site is bound to an acetate, carbamate, or phosphate. Carbamate and phosphate bonds are much more resistant to attack by hydroxyl groups than acetate bonds are. The acetylated form lasts for only microseconds, whereas the carbamylated form lasts for 15 to 20 minutes. Organophosphates include diisopropyl fluorophosphate, parathion, malathion, soman, sarin, VX, and a variety of other compounds used as insecticides. Although the toxicity of the organophosphate insecticides is primarily related to their anticholinesterase activity, the mechanism of this effect is different from the clinically used anticholinesterase drugs (see Chapter 74). The organophosphates produce irreversible enzyme inhibition and have CNS effects. Consequently, treatment of organophosphate insecticide poisoning relies on chemical compounds capable of displacing the insecticides from the enzyme to reactivate the cholinesterase activity. The best documented of these chemicals is pralidoxime (2-PAM). Physostigmine and most of the organophosphates are not quaternary ammonium compounds and have major effects on cholinergic functions in the CNS (see Chapter 74).

Because these compounds can increase the effect and duration of neurally released acetylcholine, they are useful in situations in which such release is deficient, such as myasthenia gravis. Anticholinesterase drugs are occasionally used to stimulate intestinal function and are applied topically in the eye as a miotic. An irreversible organophosphate anticholinesterase that is used clinically is echothiophate iodide (Phospholine), which is available as topical drops for the treatment of glaucoma. Its major advantage over other topical agents is its prolonged duration of action. Because this chemical also inactivates plasma cholinesterase, it may prolong the action of succinylcholine. Although prudence dictates discontinuation of echothiophate for 1 week before surgery, there are numerous case reports of successful anesthesia performed without discontinuation of echothiophate under emergency conditions.

Ganglionic Drugs

Ganglionic Agonists

Ganglionic agonists are essential for analyzing the mechanism of ganglionic function, but they have no therapeutic use. Nicotine is the classic ganglionic agonist, and its effects have been well described.

Parasympathetic drugs stimulate ganglia, but this action is usually masked by their other parasympathomimetic effects. Experimentally, relatively large doses of acetylcholine adminis-

tered intravenously after blockade of muscarinic receptors by atropine cause ganglionic stimulation and release of epinephrine by the adrenal medulla.

Ganglionic Antagonists

Ganglionic antagonists were the first effective therapy for the management of hypertension and were used extensively during the 1950s and 1960s. However, because of interference with transmission through sympathetic and parasympathetic ganglia, their antihypertensive action was accompanied by numerous undesirable effects. Hexamethonium, the prototypical drug of this class, has minimal neuromuscular and muscarinic activity. The systemic effects of ganglionic blockade are determined by the resting tone of a specific body system before the initiation of ganglionic blockade (see Table 12-3). With the disappearance of trimethaphan from clinical use, these drugs are largely of historical interest.

Autonomic Dysfunction

Assessment of Autonomic Function

The increased operative risk of patients with autonomic dysfunction that may occur with aging and diabetes[304] makes the diagnosis of autonomic neuropathy extremely important. A panel of five tests of cardiovascular function has been developed to evaluate autonomic function in diabetic patients (see Chapter 35).[305] The tests include heart rate responses to the Valsalva maneuver, standing up, and deep breathing and blood pressure responses to standing up and sustained handgrip. The tests involving changes in heart rate measure injury to the parasympathetic system, which precedes changes in the measures of blood pressure that reflect sympathetic injury. Early autonomic dysfunction is defined as a single abnormal or two borderline-abnormal results on the tests involving changes in heart rate. Definite involvement is dignosed when the results are abnormal on two of the tests of changes in heart rate. Severe dysfunction is defined as abnormalities in blood pressure assessments. Application of these standards requires that the investigator understand the proper techniques for performing the five tests and the expected results in patients without autonomic neuropathy (Table 12-12). If patients demonstrate an increase in heart rate of more than 20 beats/min with a vigorous handgrip, it can be assumed that they are incompletely β-blocked. The simplicity and effectiveness of this clinical assessment have led to its use in the evaluation of patients with nondiabetic causes of autonomic dysfunction as well.

Table 12-12 Noninvasive Tests for Assessing the Autonomic Nervous System

Clinical Examination	Technique	Normal Value
Parasympathetic		
HR response to a Valsalva maneuver	The seated subject blows into a mouthpiece (while maintaining a pressure of 40 mm Hg) for 15 seconds. The Valsalva ratio is the ratio of the longest R-R interval (which comes shortly after release) to the shortest R-R interval (which occurs during the maneuver)	Ratio of >1.21
HR response to standing	HR is measured as the subject moves from a resting supine position to standing. A normal tachycardic response is maximal around the 15th beat after rising. A relative bradycardia follows that is most marked around the 30th beat after standing. The response to standing is expressed as a 30:15 ratio and is the ratio of the longest R-R interval around the 30th beat to the shortest R-R interval around the 15th beat	Ratio of >1.04
HR response to deep breathing	The subject takes six deep breaths in 1 minute. The maximum and minimum heart rates during each cycle are measured, and the mean of the differences (maximum HR – minimum HR) during three successive breathing cycles is taken as the maximum-minimum HR	Mean difference >15 beats/min
Sympathetic		
BP response to standing	The subject moves from resting supine to standing, and standing SBP is subtracted from supine SBP	Difference <10 mm Hg
BP response to sustained handgrip	The subject maintains a handgrip of 30% of the maximum handgrip squeeze for up to 5 minutes. BP is measured every minute, and the initial DBP is subtracted from the DBP just before release	Difference >16 mm Hg

Plasma Catecholamines

Accurate and sensitive techniques for measuring plasma catecholamines have existed for 3 decades, but interpretation of the data that they yield has been controversial. Normal plasma epinephrine and norepinephrine levels are typically in the range of 100 to 400 pg/mL, and they can increase sixfold or more with stress.

Plasma concentrations of epinephrine, which reflect adrenal medullary activity if not overall sympathetic activity, are labile. Significant isolated adrenal medullary secretion results from certain stressful situations, such as public speaking.[5] Moreover, venous samples may reflect epinephrine kinetics in the organ being sampled rather than in the whole body, so arterial samples may be more reliable.

The significance of the norepinephrine concentration in plasma is even more controversial. Even though the adrenal medulla secretes some norepinephrine, levels in plasma generally reflect spillover from sympathetic stimulation that was not taken

up again by the nerve terminal. Although reuptake may be tissue specific and markedly influenced by alterations in physiology or diseases, spillover in humans is 10% to 20% of the synthesis rate of norepinephrine at baseline and may be greatly enhanced in periods of sympathetic activation.[306] The most compelling argument for the use of plasma norepinephrine as a marker of sympathetic activity comes from animal studies in which plasma norepinephrine levels directly mirrored nerve stimulation. Many important studies have correlated increases in plasma catecholamines with acute and chronic stress, which has led to the concept of stress-free anesthesia. A striking relationship between mortality rates for patients with CHF and elevated plasma norepinephrine levels resulted in the use of β-adrenergic antagonists to treat ventricular dysfunction.[307,308]

The development of experimental radiotracer techniques to assess the in vivo kinetics of catecholamines has provided additional information that is of clinical importance, particularly in relation to regional kinetics. For example, studies relying only on arterial and venous catecholamines suggested that the hepatomesenteric bed contributes significantly to total-body clearance of catecholamines but only minimally (<8%) to spillover. However, later studies of regional norepinephrine kinetics demonstrated that release of norepinephrine from the gut (≤25% of the total body) was largely obscured by efficient extraction (>80%) in the liver. Similarly, selective elevations in release of norepinephrine from the heart, which may be associated with ischemia, early onset of CHF, and tachyarrhythmias, may not be apparent in measured arterial or venous levels.[309] Observations involving regional spillover led to the realization that although stress may activate a generalized sympathetic response, there may be different patterns contingent on the stimulus. It is possible that the lack of consistency of plasma norepinephrine levels in the presence of clinically significant sympathetic activation may be a function of the measurement technique or the particular stressor.

It is my belief that given the effects of age, posture, and hydration, small changes in plasma catecholamine levels correlate poorly with hemodynamic changes and merit cautious interpretation whereas significant increases (>1000 pg/mL) in levels are good markers of activation of the sympathetic nervous system.

Clinical Syndromes

Surgical Stress Response

Surgical stress, particularly that associated with major operations, results in profound metabolic and endocrine responses. The combination of autonomic, hormonal, and catabolic changes that accompany surgery has been called the surgical stress response.[310] Despite widespread clinical intuition that attenuation of the stress response is beneficial, there has been long-standing debate about whether such a strategy affects outcome. Three separate lines of evidence suggest that attenuation of the surgical stress response can lead to improved outcomes. In a series of studies, interruption of the sympathetic response to surgery markedly reduced surgical stress intraoperatively and postoperatively. The use of continuous thoracic epidural infusions of local anesthetics minimized the rise in plasma catecholamines, cortisol, and glucagon and improved outcomes. Improved outcome was independent of the patient's level of pain because metabolic and endocrine responses to surgery were not similarly reduced in patients receiving other methods of pain relief, including nonsteroidal anti-inflammatory drugs and opioids.[311] Continuation of epidural infusions well into the postoperative period was regarded as essential to improving outcome. Inflammatory and immunologic responses, which are necessary for infection control and wound healing, appear to be unaffected. With the use of similar techniques and other stress-reducing maneuvers, faster and more complete recovery was achieved in elderly patients undergoing colon resection.[312]

A separate line of evidence supporting the hypothesis that long-term attenuation of the stress response alters outcome comes from the pediatric literature. When neonates with complex congenital heart disease underwent cardiac surgery, those who received high-dose sufentanil infusions intraoperatively and for the first 24 hours postoperatively to reduce the stress response had lower β-endorphin, norepinephrine, epinephrine, glucagon, aldosterone, and cortisol levels than controls did.[310] The mortality rate in the opiate group was significantly lower than in the study or historical controls, thus demonstrating that anesthetic techniques can have profound effects on the metabolic and endocrine responses to surgery and that effective management of these reflexes can alter outcomes.

A third line of evidence involves results from the multicenter study of the Perioperative Ischemia Research Group (see "Perioperative β-Blockade").[215] The ability to alter overall survival at 2 years with a perioperative regimen of β-blockade has provided compelling evidence of the benefit of attenuating the stress response[216,217,219] and has altered clinical practice in patients at risk for cardiac morbidity. Similar results have been achieved when perioperative α_2-agonists were given to "at-risk" patients as well.[313] Presumably, the decrease in sympathetic tone that accompanied administration of the β-blocker or the α_2-agonist suppressed the stress response and improved outcomes.

Diabetes Mellitus

Diabetic autonomic neuropathy is the most common form of autonomic neuropathy and the most extensively investigated (see Chapter 35). It occurs in 20% to 40% of all insulin-dependent diabetic patients. The symptoms associated with diabetic autonomic neuropathy confer an increased risk during anesthesia and surgery by direct and secondary mechanisms. Common manifestations of diabetic autonomic neuropathy include impotence, postural hypotension, gastroparesis, diarrhea, and sweating abnormalities. Early small-fiber damage is revealed by loss or impairment of vagally controlled normal heart rate variability, decreased peripheral sympathetic tone with a subsequent increase in blood flow, and diminished sweating. In a diabetic neuropathic foot, the senses of pain and temperature are lost before touch or vibration is affected. With sympathetic denervation, the sympathetic nerves normally found supplying small arterioles are entirely absent or are abnormally distant from their effector sites. When impotence or diarrhea is the sole manifestation, there is little effect on survival; however, with postural hypotension or gastroparesis, 5-year mortality rates are greater than 50%.

Most clinicians recognize that diabetic patients with autonomic neuropathy may be at additional risk during general anesthesia.[314] Gastroparesis is probably caused by vagal degeneration and is of clinical relevance because awake or rapid-sequence intubation may be required. Systemic injury to the vasa vasorum in patients with postural hypotension increases the risk for hemodynamic instability and cardiovascular collapse in the perioperative period. Mechanisms that maintain normal standing blood

pressure are altered, and normal precapillary vasoconstriction in the foot on standing may be diminished. Baroreceptors in the carotid sinus and aortic arch are compromised by diabetic neuropathy. Diabetic patients with orthostatic hypotension usually have lower norepinephrine levels.

Even in seemingly minor surgery, diabetic autonomic neuropathy can lead to significant complications.

Diabetics with autonomic neuropathy may have a significantly greater decline in blood pressure with induction and a greater need for vasopressors than diabetic patients without autonomic dysfunction.[314] Page and Watkins[315] reported five cases of unexpected cardiorespiratory arrest in young diabetic patients, all of whom had symptoms of autonomic neuropathy. In a large, prospective study of diabetic autonomic neuropathy involving use of the five evocative clinical tests discussed earlier, parasympathetic dysfunction preceded sympathetic failure in 96% of the patients.[316] This battery of autonomic tests identifies patients with autonomic neuropathy and is highly predictive of mortality and perioperative risk.[304]

Autonomic Changes with Aging

Aging is associated with alterations in vascular reactivity manifested clinically as exaggerated changes in blood pressure—hypertension and orthostatic hypotension (see Chapter 71). Orthostatic hypotension is quite common (about 20%) in the elderly and may result largely from diminished baroreceptor responsiveness. Heart rate responses to changes in blood pressure, the Valsalva maneuver, and the respiratory cycle are blunted with aging.[317]

Resting and exercise-induced norepinephrine levels increase with age in healthy subjects (by about 13% per decade), in part because of decreased clearance.[318] Previously a matter of controversy, it now appears that besides the well-documented reduction in vagal function associated with aging,[319] the primary autonomic defect in aging is an impairment in reuptake of norepinephrine, perhaps as a function of decreased nerve density. Although there is no apparent age-dependent decrement in nerve firing rates from sympathetic efferents in skeletal muscle,[320] kinetic studies reveal selective and dramatic increases in cardiac norepinephrine spillover attributable to the decreased reuptake in elderly patients subjected to mental stress or exercise.[306] This can precipitate clinical complications (i.e., arrhythmogenesis and sudden cardiac death) in patients with cardiac disease. However, end-organ responsiveness is blunted by compensatory downregulation of β_1-adrenoreceptors (i.e., decreased receptor density and affinity) and uncoupling of β_2-adrenoreceptors through decreased G_s activity.[321] Despite increased cardiac spillover, cardiac oxygen consumption is not altered.[322]

Attenuation of presynaptic α_2-adrenoreceptor–mediated inhibition of neuronal norepinephrine release[323-325] also accounts for the increased norepinephrine levels observed with age. Reduced postsynaptic α-adrenoreceptor activity decreases contractile responses and further attenuates vasoconstrictor tone. In a seemingly vicious cycle, the increase in circulating norepinephrine levels is associated with downregulation of platelet α_2-adrenoreceptor density and responsiveness. The loss of adrenergic control through the reduction of α_2- and β-receptor–mediated responses with age causes a decrease in the sympathetic nervous system's ability to maintain cardiovascular homeostasis, thus implying a relationship with or an explanation of the increased incidence of cardiovascular disorders such as CHF in the elderly.

Autonomic Changes in Spinal Cord Transection

The most drastic of all alterations in the ANS that an anesthesiologist may encounter is complete spinal cord transection (see Chapters 46, 63, and 72). Spinal cord transection affects motor and sensory function, and it may also result in profound changes in autonomic activity that can alter anesthetic care. As is obvious from sympathetic and parasympathetic outflow anatomy, spinal cord injuries or transection can cause various degrees of autonomic dysfunction, depending on the site, extent, and timing of the lesion. Many autonomic reflexes are inhibited by the supraspinal feedback that is lost after spinal cord transection. In paraplegic patients, small stimuli can evoke exaggerated sympathetic discharges.

In patients with cervical spinal cord transection, sympathetic and parasympathetic outflow is detached from central control mechanisms. In addition to the expected motor and sensory changes, there are profound abnormalities that alter the cardiovascular, thermoregulatory, gastrointestinal, and urinary systems. The autonomic consequences of transection are not always apparent because the distal portion of the spinal cord may retain some function and thereby result in unanticipated autonomic abnormalities.

There are fundamental differences between the acute and chronic effects of spinal cord transection. Initially, a transient state of decreased excitability occurs. This phenomenon, known as spinal shock, usually takes place immediately after the lesion and may last days to weeks. In these patients, the periphery is generally atonic and the peripheral blood vessels are dilated. In patients with high thoracic lesions who have sustained recent injury, basal supine blood pressure is usually low and accompanied by plasma catecholamine levels that are approximately 35% of normal.[326] Patients with recent low spinal injuries may exhibit compensatory tachycardia from intact parts of the ANS.

Patients with chronic high spinal lesions may fail to respond to hypovolemia with an increased heart rate and may exhibit bradycardia. The only intact efferent component of the baroreflex pathways in quadriplegic patients is the vagus. Bradycardia occurs with changes in position and with Valsalva maneuvers or increased intrathoracic pressure.[327]

One aspect of care that is frequently overlooked is the effect of tracheal suctioning on patients with high spinal transection. Given that many of these patients depend on artificial respiration because of their respiratory muscle paralysis, unopposed vagal stimuli may contribute to profound bradycardia. This vagal response is particularly accentuated during hypoxemia.

Because the sympathetic nervous system may be dysfunctional in these patients, the renin-angiotensin-aldosterone system compensates for the maintenance of blood pressure. Patients with spinal cord transection may be exquisitely sensitive to ACEIs, even with modest changes in intravascular volume or posture. The release of renin may be independent of sympathetic stimulation and may be caused by the renal baroreceptor stimulation that accompanies the decline in renal perfusion pressure.

Although pressure stimuli above the lesion do not usually change blood pressure, the phenomenon of autonomic dysreflexia can occur with stimulation below the lesion. Bladder or bowel distention can elicit the so-called mass reflex. This autonomic reflex includes a dramatic rise in blood pressure, a marked reduction in flow to the periphery, and flushing and sweating in areas above the lesion. In addition, there is often contraction of the bladder and rectum, skeletal muscle spasms, and penile erection.

The patient's heart rate may decline as a reflex. Surprisingly, evidence from microneurography studies indicates that there is only a modest rise in sympathetic nerve activity during activation of the mass reflex,[328] and plasma norepinephrine levels increase only modestly. Speculation has arisen that the exaggerated blood pressure response may be caused by supersensitivity of adrenoreceptors. As anticipated, quadriplegic patients exhibit an increase in sensitivity to exogenously administered pressors.[326] Blood pressure in quadriplegic patients may increase 5- to 10-fold in response to the exogenous administration of angiotensin and to catecholamines. Impairment of the descending inhibitory reflex pathways that are activated during hypertension may contribute to the supersensitivity. This hypothesis is supported by the finding that sensitivity is rarely increased when the lesion is below T5. There is apparently a normal level of adrenoreceptors in these patients with lower spinal lesions, even those with long-standing quadriplegia.

Management of autonomic dysreflexia is of clinical importance. Although the anesthesiologist may be tempted to opt for minimal anesthesia in a patient without sensory or motor function, significant visceral reflexes can be evoked. The anesthesiologist may use spinal anesthesia, general anesthesia, or a vasodilator such as nitroprusside or nitroglycerin to attenuate this reflex, even if pain is not appreciated. There has been some enthusiasm for using clonidine prophylactically to diminish this response.

An additional problem arising from the autonomic denervation of spinal cord transection is thermogenesis. In these patients, hypothermia may result from cutaneous vasodilation and the inability to shiver. Similarly, hyperthermia can occur because the normal sweating mechanism is impaired. It is therefore important to monitor temperature assiduously in these patients during the course of anesthesia.

New Concepts in Autonomic Activity

Genetic Contributors to Autonomic Function and Drug Responsiveness

In the past 5 years there has been an explosion in the knowledge of nonmendelian genetic contributors to human physiologic and pathophysiologic function. The Human Genome Project provided a starting point for the identification of genetic abnormalities. The next logical step is to define the implications of genetic variations on physiologic and pharmacologic responses. Genetic variations as small as a single-nucleotide polymorphism (SNP) to larger genetic insertions or deletions have been identified in the genes coding for essential components of the ANS. SNPs and, to a lesser extent, larger deletion and insertion sequences have been identified in the genes that code for nearly every adrenergic and dopaminergic receptor subtype (all save the α_{1d}-receptor). Genetic coding for the muscarinic receptor subtypes, on the other hand, is remarkably well conserved.[329] In addition to variants in coding for the autonomic receptors, genetic mutations in codes for the proteins responsible for catecholamine synthesis, reuptake, and breakdown have also been identified, as have variants for the receptor-coupled G proteins.[330] Although many potential genetic contributors to autonomic-related disease states (e.g., essential hypertension, lipid and glucose metabolism, and postural tachycardia syndrome[331]) have been identified, no single genetic mutation has completely explained any of the examined autonomic dysfunctions. It is almost certainly true that abnormalities in autonomic function are polygenic in origin and also involve significant environmental input. Thus, future investigations that attempt to explain autonomic diseases will require evaluation of larger genetic sequences (not SNPs or other short-segment variants) that contain multiple associated genetic variants. Once the collection of genetic variants responsible for the majority of the autonomic findings of a given disease are identified, the impact of the combined genetic contribution on responsiveness to a given drug or class of drugs will need to be assessed through directed clinical trials.

13 Cerebral Physiology and the Effects of Anesthetic Drugs

Key Points

1. The brain has a high metabolic rate and receives approximately 15% of cardiac output. Under normal circumstances, cerebral blood flow (CBF) is approximately 50 mL/100 g/min. Gray matter receives 80% and white matter receives 20% of this blood flow.
2. Approximately 60% of the brain's energy consumption is used to support electrophysiologic function. The remainder of the energy consumed by the brain is involved in cellular homeostatic activities.
3. CBF is tightly coupled to local cerebral metabolism. When cerebral activity in a particular region of the brain increases, a corresponding increase in blood flow to that region takes place. Conversely, suppression of cerebral metabolism leads to a reduction in blood flow.
4. CBF is autoregulated and held constant over a mean arterial pressure range conservatively estimated at 65 to 150 mm Hg, given normal venous pressure. There is probably appreciable intersubject variability. CBF becomes pressure passive when mean arterial pressure is either below the lower limit or above the upper limit of autoregulation
5. CBF is also under chemical regulation. It varies directly with arterial carbon dioxide tension in the $Paco_2$ range of 25 to 70 mm Hg. With a reduction in Pao_2 to below 60 mm Hg, CBF increases dramatically. Changes in temperature affect CBF primarily by suppression of cerebral metabolism.
6. Systemic vasodilators (nitroglycerin, nitroprusside, hydralazine, calcium channel blockers) vasodilate the cerebral circulation and can, depending on mean arterial pressure, increase CBF. Vasopressors such as phenylephrine, norepinephrine, ephedrine, and dopamine do not have significant direct effects on the cerebral circulation. Their effect on CBF is dependent on their effect on systemic blood pressure. When mean arterial pressure is below the lower limit of autoregulation, vasopressors increase systemic pressure and thereby increase CBF. If systemic pressure is within the limits of autoregulation, vasopressor-induced increases in systemic pressure have little effect on CBF.
7. All modern volatile anesthetics suppress the cerebral metabolic rate (CMR) and, with the exception of halothane, can produce burst suppression of the electroencephalogram. At that level, CMR is reduced by about 60%. Volatile anesthetics have dose-dependent effects on CBF. In doses lower than the minimal alveolar concentration (MAC), CBF is not significantly altered. Beyond doses of 1 MAC, direct cerebral vasodilation results in an increase in CBF and cerebral blood volume.
8. Barbiturates, etomidate, and propofol decrease CMR and can produce burst suppression of the electroencephalogram. At that level, CMR is reduced by about 60%. Flow and metabolism coupling is preserved and therefore CBF is decreased. Opiates and benzodiazepines effect minor decreases in CBF and CMR, whereas ketamine can increase CMR (with a corresponding increase in blood flow) significantly.
9. Brain stores of oxygen and substrates are limited and the brain is exquisitely sensitive to reductions in CBF. Severe reductions in CBF (less than 10 mL/100 g/min) lead to rapid neuronal death. Ischemic injury is characterized by early excitotoxicity and delayed apoptosis.
10. Barbiturates, propofol, ketamine, volatile anesthetics, and xenon have neuroprotective efficacy and can reduce ischemic cerebral injury. Anesthetic neuroprotection is sustained only when the severity of the ischemic insult is mild; with moderate to severe injury, long-term neuroprotection is not achieved. Administration of etomidate is associated with regional reductions in blood flow, and this can exacerbate ischemic brain injury.

This chapter reviews the effects of anesthetic drugs and techniques on cerebral physiology, in particular, their effects on cerebral blood flow (CBF) and metabolism. The final section presents a brief discussion of pathophysiologic states, including cerebral ischemia, as well as discussion of cerebral protection. The chapter gives greatest emphasis to information that is of immediate relevance to the rationale for use of the anesthetic and intensive care management of patients with intracranial pathology. Chapter 63 presents the clinical management of these patients in detail. Neurologic monitoring, including the effects of anesthetics on the electroencephalogram (EEG) and evoked responses, is reviewed in Chapter 46.

Regulation of Cerebral Blood Flow

Anesthetic drugs cause dose-related and reversible alterations in many aspects of cerebral physiology, including CBF, cerebral metabolic rate (CMR), and electrophysiologic function (EEG, evoked responses). The effects of anesthetic drugs and techniques have the potential to adversely affect the diseased brain and conduct of the neurosurgical procedure and are thus of clinical importance in patients with neurosurgical disease. However, in certain instances, the effects of general anesthesia on CBF and CMR can be manipulated to improve both the operative course and the clinical outcome of patients with neurologic disorders.

The adult human brain weighs approximately 1350 g and therefore represents about 2% percent of total-body weight. However, it receives 12% to 15% of cardiac output. This high flow rate is a reflection of the brain's high metabolic rate. At rest, the brain consumes oxygen at an average rate of approximately 3.5 mL of oxygen per 100 g of brain tissue per minute. Whole-brain O_2 consumption (50 mL/min) represents about 20% of total-body oxygen utilization. Normal values for CBF, CMR, and other physiologic variables are provided in Table 13-1.

Approximately 60% of the brain's energy consumption is used to support electrophysiologic function. The depolarization-repolarization activity that occurs and is reflected in the EEG requires expenditure of energy for the maintenance and restoration of ionic gradients and for the synthesis, transport, and reuptake of neurotransmitters. The remainder of the energy consumed by the brain is involved in cellular homeostatic activities. Local CBF and CMR within the brain are very heterogeneous, and both are approximately four times greater in gray matter than in white matter. The cell population of the brain is also heterogeneous in its oxygen requirements. Glial cells make up about half the brain's volume and require less energy than neurons do. Besides providing a physically supportive latticework for the brain, glial cells are important in reuptake of neurotransmitters, in delivery and removal of metabolic substrates and wastes, and in blood-brain barrier (BBB) function.

The brain's substantial demand for substrate must be met by adequate delivery of oxygen and glucose. However, the space constraints imposed by the noncompliant cranium and meninges require that blood flow not be excessive. Not surprisingly, there are elaborate mechanisms for regulation of CBF. These mechanisms, which include chemical, myogenic, and neurogenic factors, are listed in Table 13-2.

Table 13-1 Normal Cerebral Physiologic Values

CBF	
Global	45-55 mL/100 g/min
Cortical (mostly gray matter)	75-80 mL/100 g/min
Subcortical (mostly white matter)	≈20 mL/100 g/min
$CMRO_2$	3-3.5 mL/100 g/min
CVR	1.5-2.1 mm Hg/100 g/min/mL
Cerebral venous Po_2	32-44 mm Hg
Cerebral venous So_2	55%-70%
ICP (supine)	8-12 mm Hg

CBF, cerebral blood flow; $CMRO_2$, cerebral metabolic rate of oxygen; CVR, cerebral vascular resistance; ICP, intracranial pressure.

Table 13-2 Factors Influencing Cerebral Blood Flow*

Factor	Comment
Chemical/Metabolic/Humoral	
CMR Anesthetics Temperature Arousal/seizures	CMR influence assumes intact flow-metabolism coupling, the mechanism of which is not fully understood
$Paco_2$	
Pao_2	
Vasoactive drugs Anesthetics Vasodilators Vasopressors	
Myogenic	
Autoregulation/MAP	The autoregulation mechanism is fragile, and in many pathologic states CBF is regionally pressure passive
Rheologic	
Blood viscosity	
Neurogenic	
Extracranial sympathetic and parasympathetic pathways	Contribution and clinical significance poorly defined
Intra-axial pathways

CBF, cerebral blood flow; CMR, cerebral metabolic rate; MAP, mean arterial pressure.

Chemical Regulation of Cerebral Blood Flow

Several factors, including changes in CMR, $Paco_2$, and Pao_2, cause alterations in the cerebral biochemical environment that result in adjustments in CBF.

Cerebral Metabolic Rate

Increased neuronal activity results in increased local brain metabolism, and this increase in CMR is associated with a well-matched,

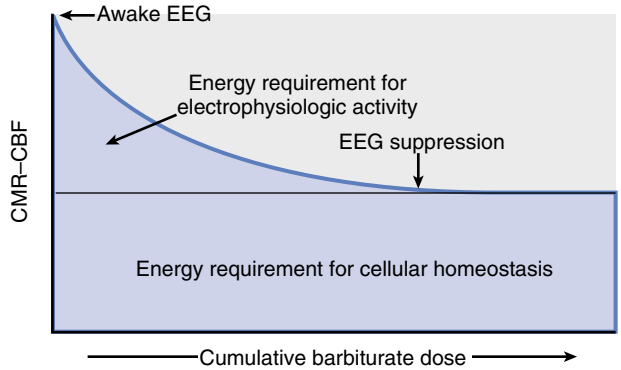

Figure 13-1 Interdependency of cerebral electrophysiologic function and cerebral metabolic rate (CMR). Administration of various anesthetics, including barbiturates, results in a dose-related reduction in the CMR of oxygen ($CMRO_2$) and cerebral blood flow (CBF). The maximum reduction occurs with the dose that results in electrophysiologic silence. At this point, the energy utilization associated with electrophysiologic activity has been reduced to zero, but the energy utilization for cellular homeostasis persists unchanged. Additional barbiturate causes no further decrease in CBF or $CMRO_2$.

proportional change in CBF and is referred to as flow-metabolism coupling. Although the precise mechanisms that mediate flow-metabolism coupling have not been defined, the data available implicate local by-products of metabolism (K^+, H^+, lactate, adenosine, and adenosine triphosphate [ATP]). Glutamate, released with increased neuronal activity, results in the synthesis and release of nitric oxide (NO), a potent cerebral vasodilator that plays an important role in coupling of flow and metabolism. More recent data have highlighted the role of glia in flow-metabolism coupling. Uptake of the glutamate released from neurons by glia triggers increased glial metabolism and lactate production. Glial processes make contact with neurons and capillaries, and hence glia may serve as a conduit for the coupling of increased neuronal activity with increased glucose consumption and regional blood flow. Nerves that innervate cerebral vessels release peptide neurotransmitters such as vasoactive intestinal peptide (VIP), substance P, cholecystokinin, somatostatin, and calcitonin gene–related peptide. These neurotransmitters may also potentially be involved in neurovascular coupling. Flow-metabolism coupling within the brain is a complex physiologic process that is regulated, not by a single mechanism, but by a combination of metabolic, glial, neural, and vascular factors.

CMR is influenced by several phenomena in the neurosurgical environment, including the functional state of the nervous system, anesthetic drugs, and temperature.

Functional State. CMR decreases during sleep and increases during sensory stimulation, mental tasks, or arousal of any cause. During epileptic activity, increases in CMR may be extreme, whereas regionally after brain injury and globally with coma, CMR may be substantially reduced.

Anesthetic Drugs. The effect of individual anesthetic drugs on CMR is presented in greater detail in the second section of this chapter. In general, anesthetic drugs suppress CMR, with ketamine and N_2O being notable exceptions. It appears that the component of CMR on which they act is that associated with electrophysiologic function. With several anesthetics, including barbiturates, isoflurane, sevoflurane, desflurane, propofol, and etomidate, increasing plasma concentrations cause progressive suppression of EEG activity and a concomitant reduction in CMR. However, increasing the plasma level beyond what is required to first achieve suppression of the EEG results in no further depression of CMR. The component of CMR required for maintenance of cellular integrity, the "housekeeping" component, is unaltered by intravenous anesthetic drugs (Fig. 13-1).

The cerebral metabolic rate of oxygen ($CMRO_2$) observed when complete suppression of the EEG is achieved with different anesthetic drugs is very similar. It should be noted, however, that anesthetic-induced EEG suppression is not a single physiologic state and is influenced by the agent that is used to produce suppression. When barbiturates are administered to the point of EEG suppression, a uniform depression in CBF and CMR occurs throughout the brain. When suppression occurs during administration of isoflurane, the relative reductions in CMR and CBF are greater in the neocortex than in other portions of the cerebrum. Electrophysiologic responsiveness also varies. Cortical somatosensory evoked responses to median nerve stimulation can readily be recorded at doses of thiopental far in excess of those required to cause complete suppression of the EEG but are difficult to elicit at concentrations of isoflurane associated with a burst-suppression pattern, such as 1.5 minimum alveolar concentration (MAC) (Fig. 13-2). In addition, the EEG characteristics of the burst-sup-

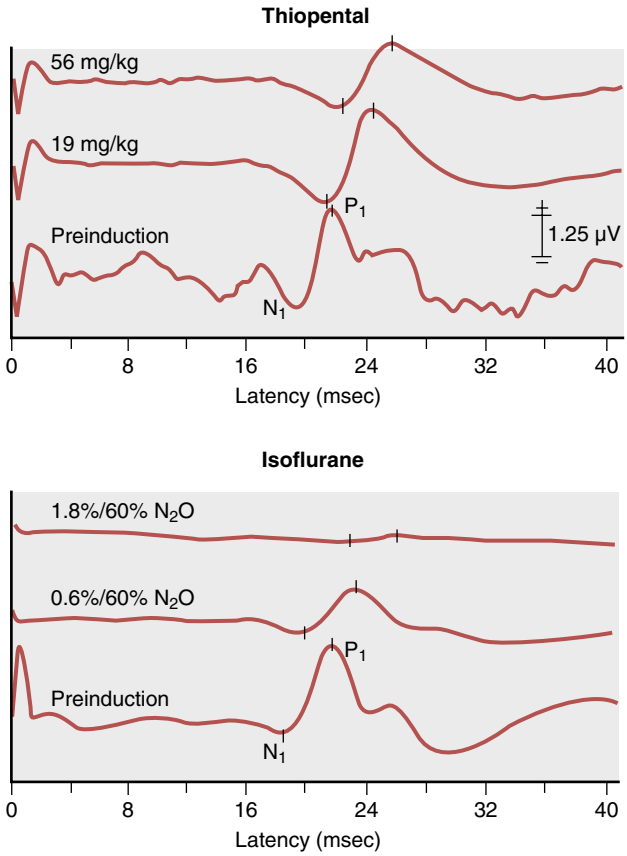

Figure 13-2 Cortical somatosensory evoked responses to median nerve stimulation in humans before induction and during anesthesia with thiopental and isoflurane/N_2O. Despite an equivalent or greater degree of reduction in the cerebral metabolic rate with thiopental, cortical evoked responses are better preserved[1] than during anesthesia with isoflurane.[2] This suggests that the electroencephalographic suppression achieved with different anesthetic drugs should not be assumed to be equivalent electrophysiologic states. The cumulative thiopental doses and expired concentrations of isoflurane and N_2O are indicated in the figure.

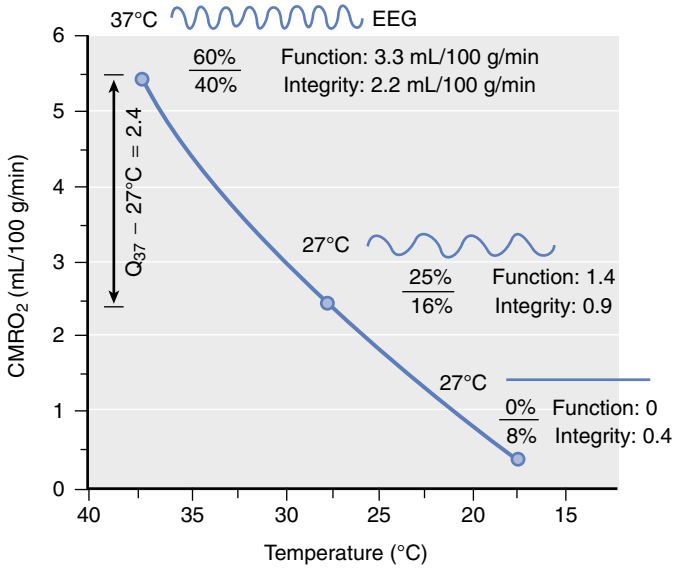

Figure 13-3 Effect of temperature reduction on the cerebral metabolic rate of oxygen ($CMRO_2$). Hypothermia reduces both of the components of cerebral metabolic activity identified in Figure 13-1: that associated with neuronal electrophysiologic activity ("Function") and that associated with maintenance of cellular homeostasis ("Integrity"). This is in contrast to anesthetics that alter only the functional component. The ratio of CMR at 37°C to that at 27°C, the Q_{10} ratio, is shown in the graph. *(Adapted from Michenfelder JD: Anesthesia and the Brain: Clinical, Functional, Metabolic, and Vascular Correlates. New York, Churchill Livingstone, 1988.)*

pression states that occur just before complete suppression differ among anesthetic drugs. These differences may be of some relevance to discussions of differences in the neuroprotective potential of drugs that can produce EEG suppression.

TEMPERATURE. The effects of hypothermia on the brain have been reviewed in detail.[3] CMR decreases by 6% to 7% per degree Celsius of temperature reduction. As is the case with some anesthetic drugs, hypothermia can also cause complete suppression of the EEG (at about 18°C to 20°C). However, in contrast with anesthetic drugs, temperature reduction beyond that at which EEG suppression first occurs *does* produce a further decrease in CMR (Fig. 13-3). This occurs because although anesthetic drugs reduce only the component of CMR associated with neuronal function, hypothermia decreases the rate of energy utilization associated with both electrophysiologic function and the basal component associated with maintenance of cellular integrity. These decreases were once assumed to be proportional. However, it has recently been demonstrated that mild hypothermia preferentially suppresses the basal component of CMR. $CMRO_2$ at 18°C is less than 10% of normothermic control values, and this probably accounts for or contributes to the brain's tolerance for moderate periods of circulatory arrest at these and lower temperatures.

Hyperthermia has an opposite influence on cerebral physiology. Between 37°C and 42°C, CBF and CMR increase. However, above 42°C, a dramatic reduction in cerebral oxygen consumption occurs, an indication of a threshold for a toxic effect of hyperthermia that may occur as a result of protein (enzyme) denaturation.

$Paco_2$. CBF varies directly with $Paco_2$ (Fig. 13-4). The effect is greatest within the range of physiologic $Paco_2$ variation. CBF changes 1 to 2 mL/100 g/min for each 1–mm Hg change in $Paco_2$ around normal $Paco_2$ values. This response is attenuated below a $Paco_2$ value of 25 mm Hg. Under normal circumstances, the sensitivity of CBF to changes in $Paco_2$ ($\Delta CBF/\Delta Paco_2$) appears to be positively correlated with resting levels of CBF. Accordingly, anesthetic drugs that alter resting CBF cause changes in the response of the cerebral circulation to CO_2. The magnitude of the reduction in CBF caused by hypocapnia is greater when resting CBF is high (as might occur during anesthesia with volatile agents). Conversely, when resting CBF is low, the magnitude of the hypocapnia-induced reduction in CBF is decreased. However, it should be noted that CO_2 responsiveness has been observed in normal brain during anesthesia with all of the numerous anesthetic drugs that have been studied.

The changes in CBF caused by $Paco_2$ are dependent on pH alterations in the extracellular fluid of the brain. NO, in particular NO of neuronal origin, is an important although not exclusive mediator of CO_2-induced vasodilation. The vasodilatory response to hypercapnia is also mediated in part by prostaglandins. The changes in extracellular pH and CBF occur rapidly after $Paco_2$ adjustments because CO_2 diffuses freely across the cerebrovascular endothelium. Note that in contrast with *respiratory* acidosis, acute systemic *metabolic* acidosis has little immediate effect on CBF because the BBB excludes hydrogen ion (H^+) from the perivascular space. The CBF changes in response to alterations in $Paco_2$ occur rapidly, but they are not sustained. Despite maintenance of an elevated arterial pH, CBF returns to normal over a period of 6 to 8 hours because the pH of cerebrospinal fluid (CSF) gradually normalizes as a result of extrusion of bicarbonate. Consequently, a patient who has had a sustained period of hyperventilation or hypoventilation deserves special consideration. Acute normalization of $Paco_2$ will result in a significant CSF acidosis (after hypocapnia) or alkalosis (after hypercapnia). The former results in increased CBF with a concomitant increase in intracranial pressure (ICP) that depends on the prevailing intracranial compliance. The latter conveys a theoretical risk for ischemia.

Pao_2. Changes in Pao_2 from 60 to greater than 300 mm Hg have little influence on CBF. Below a Pao_2 of

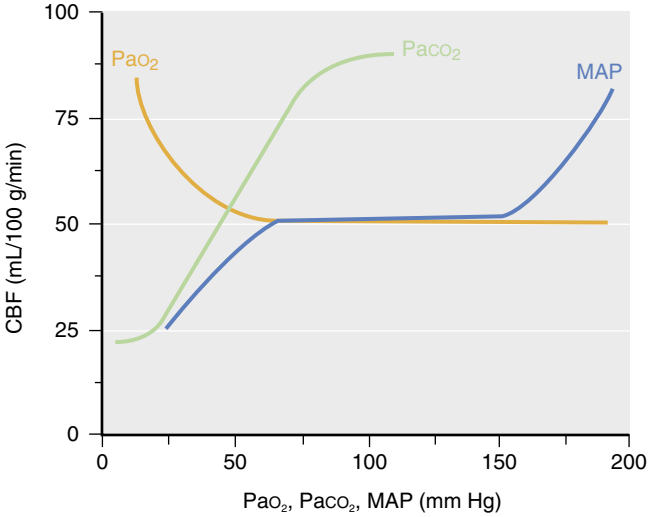

Figure 13-4 Changes in cerebral blood flow (CBF) caused by independent alterations in $Paco_2$, Pao_2, and mean arterial pressure (MAP).

60 mm Hg, CBF increases rapidly (see Fig. 13-4). The mechanisms mediating cerebral vasodilation during hypoxia are not fully understood but may include neurogenic effects initiated by peripheral and neuraxial chemoreceptors, as well as local humoral influences. At least part of the hyperemic response to hypoxia is mediated by NO of neuronal origin (see Chapter 31). Hypoxia-induced hyperpolarization of vascular smooth muscle by the opening of ATP-dependent K^+ channels also leads to vasodilation. Recent studies have indicated that the rostral ventrolateral medulla (RVM) serves as an oxygen sensor within the brain. Stimulation of the RVM by hypoxia results in an increase in CBF (but not CMR), and lesions of the RVM suppress the magnitude of the CBF response to hypoxia. The response to hypoxia is synergistic with the hyperemia produced by hypercapnia and acidosis. At high Pao_2 values, CBF decreases modestly. At 1 atm of oxygen, CBF is reduced by 12%.

Myogenic Regulation (Autoregulation) of Cerebral Blood Flow

Autoregulation refers to the capacity of the cerebral circulation to adjust its resistance to maintain CBF constant over a wide range of mean arterial pressure (MAP). In normal *human* subjects, the best available data—and they are limited—are consistent with the limits of autoregulation occurring at MAP values of approximately 70 and 150 mm Hg (see Fig. 13-4). The lower limit of autoregulation (LLA) has been widely quoted as an MAP of 50 mm Hg. Although this number may be correct for some animal species, the data available argue that the LLA is considerably higher in humans.[4] Note that the units used on the *x* axis of "autoregulation curves" will influence the correct inflection points of the curve. When the *x* axis is "mean arterial pressure", the normal average LLA is not less than 70 mm Hg (with considerable interindividual variation). Because ICP is not usually measured in normal subjects, cerebral perfusion pressure (CPP) (MAP – ICP) is rarely available. Assuming a normal ICP of 5 to 15 mm Hg in a supine subject, an LLA of 70 expressed as MAP corresponds to an LLA of 55 to 60 mm Hg expressed as CPP.

Above and below the autoregulatory plateau, CBF is pressure dependent (pressure passive) and varies linearly with CPP. Autoregulation is influenced by various pathologic processes, as well as the time course over which the changes in CPP occur. Even within the range over which autoregulation normally occurs, a rapid change in arterial pressure will result in a transient (3 to 4 minutes) alteration in CBF.

The "limits of autoregulation" are conceptual constructs for the purpose of analysis. They do not represent physiologic "all-or-none" responses. There is probably a continuum of vascular responsiveness in the knee of the both the lower and upper limits as the ability of the arteriolar bed to dilate or constrict is exhausted. Furthermore, the morphology of the autoregulation is strongly influenced by the background level of vasodilation or vasoconstriction (e.g., $Paco_2$ or anesthetic conditions).

The precise mechanism by which autoregulation is accomplished and its overlap with flow-metabolism coupling are not known. According to the myogenic hypothesis, changes in CPP lead to direct changes in the tone of vascular smooth muscle; this process appears to be passive. NO may participate in the vasodilation associated with hypotension. Autonomic innervation of cerebral blood vessels may also contribute to autoregulation of blood flow (discussed in the next section).

Neurogenic Regulation of Cerebral Blood Flow

The cerebral vasculature is extensively innervated.[5] The density of innervation declines with vessel size, and the greatest neurogenic influence appears to be exerted on larger cerebral arteries. This innervation includes cholinergic (parasympathetic and nonparasympathetic), adrenergic (sympathetic and nonsympathetic), serotonergic, and VIPergic systems of extra- and intra-axial origin. It is certain that in animals there is an extracranial sympathetic influence via the superior cervical ganglion, as well as parasympathetic innervation via the sphenopalatine ganglion. The intra-axial pathways are less well defined, although there is considerable evidence of innervation arising from several nuclei in animals, including the locus ceruleus, the fastigial nucleus, the dorsal raphe nucleus, and the basal magnocellular nucleus of Meynert. Evidence of the functional significance of neurogenic influences has been derived from studies of CBF autoregulation and ischemic injury. Hemorrhagic shock, a state of high sympathetic tone, results in a lower CBF at a given MAP than occurs when hypotension is produced with sympatholytic drugs, presumably because during shock, a sympathetically mediated vasoconstrictive effect shifts the lower end of the "autoregulatory" plateau (Fig. 13-5) to the right. It is not clear what the relative contributions of humoral and neural mechanisms are to this phe-

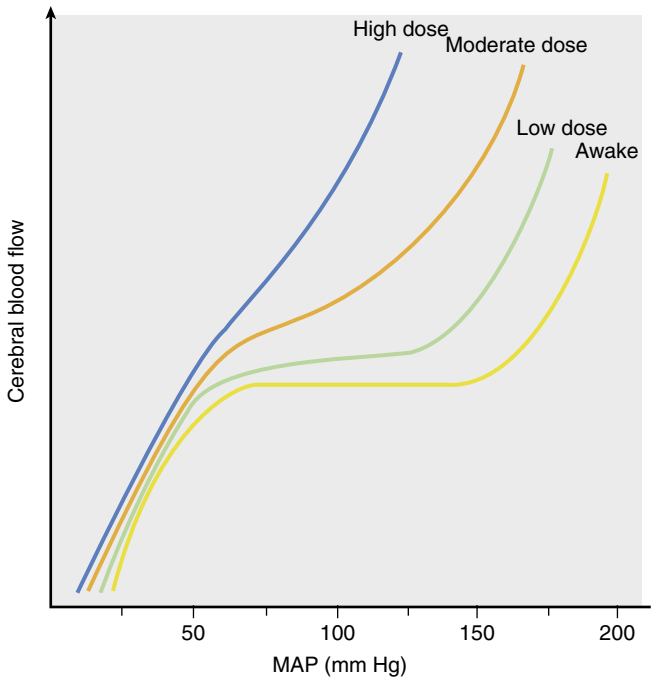

Figure 13-5 Schematic representation of the effect of increasing concentrations of a typical volatile anesthetic drug on autoregulation of cerebral blood flow. Dose-dependent cerebral vasodilation results in attenuation of autoregulatory capacity. Both the upper and lower thresholds are shifted to the left. MAP, mean arterial pressure.

nomenon; however, there is certainly a neurogenic component in some species because sympathetic denervation increases CBF during hemorrhagic shock. Moreover, sympathetic denervation produced by blockade of the stellate ganglion can increase CBF in humans.[6] Activation of cerebral sympathetic innervation also shifts the upper limit of autoregulation to the right and offers some protection against hypertensive breakthrough of the BBB. Experimental interventions that alter these neurogenic control pathways influence outcome after standardized ischemic insults, presumably by influences on vascular tone and therefore CBF. The nature and influence of such pathways in humans are not known, and their manipulation for purposes of clinical management remains to be investigated systematically.

Effects of Blood Viscosity on Cerebral Blood Flow

Blood viscosity can influence CBF. Hematocrit is the single most important determinant of blood viscosity.[7] In healthy subjects, variation of the hematocrit within the normal range (33% to 45%) probably results in only modest alterations in CBF. Beyond this range, changes are more substantial. In anemia, cerebral vascular resistance is reduced and CBF increases. However, this may result not only from a reduction in viscosity but also from reduced oxygen-carrying capacity of blood.[8] The effect of a reduction in viscosity on CBF is more obvious in the setting of focal cerebral ischemia, a condition in which vasodilation in response to impaired oxygen delivery is probably already maximal. In this situation, reducing viscosity by hemodilution results in increases in CBF in the ischemic territory. The best available information suggests that in patients with focal cerebral ischemia, a hematocrit of 30% to 34% will result in optimal delivery of oxygen. However, manipulation of viscosity in patients with acute ischemic stroke has not been shown to be of benefit in reducing the extent of cerebral injury.[9] Hence, viscosity is not a target of manipulation in patients at risk as a result of cerebral ischemia, with the possible exception of those with hematocrit values in excess of 55%.

Vasoactive Drugs

A large number of drugs with intrinsic vascular effects are used in contemporary anesthetic practice, including both anesthetic drugs and numerous vasoactive drugs used specifically for hemodynamic manipulation. This section deals with the latter. The actions of anesthetics are discussed in a later section.

Systemic Vasodilators

The majority of the drugs used to induce hypotension (including sodium nitroprusside, nitroglycerin, hydralazine, adenosine, and calcium channel blockers) also cause cerebral vasodilation. As a result, CBF either increases or is maintained at prehypotensive levels. In addition, when hypotension is induced with a cerebral vasodilator, CBF is maintained at lower MAP values than when induced by either hemorrhage or a noncerebral vasodilator. In contrast to direct vasodilators, the angiotensin-converting enzyme inhibitor enalapril does not have any significant impact on CBF.[10] Anesthetics that vasodilate the cerebral circulation simultaneously cause increases in CBV with the potential to increase ICP. The effects of these anesthetics on ICP are less dramatic when hypotension is induced slowly. This probably reflects the more effective interplay of compensatory mechanisms (shifts in CSF and venous blood) when changes occur more slowly.

Catecholamine Agonists/Antagonists

Numerous drugs with agonist and antagonist activity at catecholamine receptors (α_1, β_2, β, and dopamine) are in common use. The effects of these anesthetics on cerebral physiology are dependent on basal blood pressure, the magnitude of the systemic blood pressure changes that occur as a result of administration of the agent of interest, the status of the autoregulation mechanism, and the status of the BBB. A given agent may have direct effects on cerebral vascular smooth muscle or indirect effects mediated by the cerebral autoregulatory response to changes in systemic blood pressure (or both types of effects). When autoregulation is preserved, increases in systemic pressure would be expected to increase CBF if basal blood pressure is either below or above the lower and upper limits of autoregulation, respectively. When basal pressure is within the normal autoregulation range, an increase in systemic pressure does not affect CBF significantly because the normal autoregulatory response to a rising MAP entails cerebral vasoconstriction (an increase in cerebral vascular resistance) to maintain a constant CBF. When autoregulation is defective, CBF will vary in direct relation to systemic pressure. The information in the following paragraphs and in Table 13-3 emphasizes data obtained from investigations of pressor anesthetics in intact preparations and gives greatest weight to results obtained in humans and higher primates.

Table 13-3 Best Estimates of the Influence of Pure Catecholamine Receptor Agonists and Specific Pressor Substances on Cerebral Blood Flow and Cerebral Metabolic Rate*

Agonist	Cerebral Blood Flow	Cerebral Metabolic Rate
Pure		
α_1	0/–	0
α_2	–	0
β	+	+
β (BBB open)	+++	+++
Dopamine	++	0
Dopamine (high dose)	?–	?0
Fenoldopam	–	?0
Mixed		
Norepinephrine	0/–	0/+
Norepinephrine (BBB open)	+	+
Epinephrine	+	+
Epinephrine (BBB open)	+++	+++

*Where species differences occurred, data from primates were given preference. See text for complete discussion.
BBB, blood-brain barrier; +, increase; –, decrease; 0, no effect; the number of symbols indicates the magnitude of the effect.

α_1-Agonists. A frequently encountered clinical concern is that the administration of anesthetics with α_1-agonist effects (phenylephrine, norepinephrine) will lead to a reduction in CBF. Data derived from studies in both humans and nonhuman primates do not support this belief. Intracarotid infusion of norepinephrine in doses that significantly increase MAP result in no change in CBF. Administration of phenylephrine to patients maintained on cardiopulmonary bypass does not decrease CBF.[11] There are, however, some species differences with regard to the CBF response to α-agonists. α_1-Agonists also do not appear to cause cerebral vasoconstriction in rats but do produce modest decreases in CBF in dogs and goats; this reduction in CBF can be blocked by α_1-antagonists.

Increases in CBF have been attributed to norepinephrine. Such increases might occur if autoregulation were defective or its limit exceeded. In some instances the increases may be the result of abnormalities in the BBB. Some data suggest that β-mimetic drugs (norepinephrine has β_1 activity) cause activation of cerebral metabolism[12] with a coupled increase in CBF, and this effect is likely to be most apparent when these drugs can gain greater access to the brain parenchyma via a defective BBB (see the later section on epinephrine).

In summary, it seems likely that circulating α_1-agonists will have little direct influence on CBF in humans with the exception that norepinephrine may cause vasodilation when the BBB is defective.

β-Agonists. β-Receptor agonists, in low doses, have little direct effect on the cerebral vasculature. In larger doses and in association with physiologic stress, they can cause an increase in CMR with an accompanying increase in CBF.[13] The β_1-receptor is probably the mediator of these effects. In doses that do not result in substantial changes in MAP, intracarotid epinephrine does not change CBF in unanesthetized humans. However, with larger doses that lead to an increase in MAP, CBF and $CMRO_2$ can increase by about 20%.

There is evidence that a defect in the BBB enhances the effect of β-agonists.[14] Intracarotid norepinephrine, which does not normally affect CBF and CMR, increases CBF and CMR when BBB permeability is increased with hypertonic drugs. Artru and colleagues demonstrated that epinephrine causes an elevation in $CMRO_2$, but only when the BBB was made permeable.[14] These observations beg the interpretation that β-agonists will increase CBF and CMR *only* when the BBB is injured. However, in the human study of King and associates,[15] when epinephrine was given in doses that did not increase MAP significantly, increases in CBF/CMR occurred nonetheless. Accordingly, BBB injury may not be a necessary condition in humans for the occurrence of β-mediated increases in CBF and CMR, although it will probably exaggerate the phenomenon.

β-Blockers. β-Blockers have been variously reported to reduce or to have no effect on CBF and CMR. In two investigations in humans, propranolol, 5 mg intravenously,[16] and labetalol, 0.75 mg/kg intravenously,[17] had no effect on CBF and cerebral blood flow velocity (CBFV), respectively. Modest reductions in CBF occur after the administration of labetalol to craniotomy patients who become hypertensive during emergence from anesthesia. Esmolol has been reported to shorten seizures induced by electroconvulsive therapy (ECT), thus suggesting that it does cross the normal BBB. Catecholamine levels at the time of β-blocker administration or the status of the BBB (or both) may influence the effect of these drugs. The database with respect to these possibilities is incomplete. However, the data suggest that β-blockers are unlikely to have adverse effects on patients with intracranial pathology, other than effects secondary to changes in perfusion pressure.

Dopamine. Dopamine is widely used in the treatment of hemodynamic dysfunction. In addition, it is commonly used to augment the function of the normal cardiovascular system when an elevation in MAP is desired as an adjunct to the treatment of focal cerebral ischemia, especially in the setting of vasospasm. Nonetheless, its effects on CBF and CMR have not been defined with certainty. Taken together, the available data[18] suggest that the predominant effect of dopamine in the normal cerebral vasculature, when administered in low doses, is probably slight vasodilation with minimal change in CMR. Increased CMR in discrete regions of the brain, such as the choroid plexus and basal ganglia, has been reported. However, overall cortical blood flow is not influenced.[19] Vasoconstriction of the cerebral circulation is not observed even when dopamine is administered in doses of up to 100 μg/kg/min. In that same investigation, dobutamine was associated with 20% to 30% increases in CBF and CMR.[18] Fenoldopam is a dopamine agonist with activity at the DA_1 receptor and α_2-receptor. Administration of fenoldopam leads to systemic vasodilation and a reduction in systemic blood pressure. In humans, fenoldopam decreased systemic blood pressure to a level that was above the LLA; however, there was a modest (≈15%) reduction in CBF that did not increase to normal levels when systemic blood pressure was supported.[20] This reduction in CBF was attributed to the α_2 activity of fenoldopam. The impact of this reduction in CBF on the injured brain is not known.

α_2-Agonists. There is considerable current interest in α_2-agonists because of their analgesic and sedative effects. This class includes dexmedetomidine and clonidine, with the latter being a much less specific and less potent α_2-agonist. Two investigations in human volunteers have confirmed the ability of dexmedetomidine to decrease CBF. Dexmedetomidine dose-dependently decreased middle cerebral artery (MCA) flow velocity, with the maximum reduction being approximately 25%.[21] Dexmedetomidine (1-μg/kg loading dose and infusion at either 0.2 or 0.6 μg/kg/hr) decreased CBF by about 30%[22] in healthy human volunteers. In both these investigations, CMR was not measured and it is not clear whether the reduction in CBF was due to a direct vasoconstrictor activity of dexmedetomidine or to suppression of CMR with a corresponding reduction in CBF. In a more recent study of dexmedetomidine in which both MCA flow velocity and CMR were measured in healthy humans, dexmedetomidine decreased MCA flow velocity in parallel with a reduction in CMR.[23] These data indicate that the effects of dexmedetomidine on CBF are mediated primarily by its ability to suppress CMR. The well-know effect of dexmedetomidine to lower systemic blood pressure merits careful consideration if used in patients who are critically dependent on collateral perfusion pressure, especially in the recovery phase of an anesthetic.

Age

Aging from childhood to late adulthood is associated with a progressive reduction in CBF and $CMRO_2$.[24] This may reflect the progressive neuronal loss that occurs with age.

Effects of Anesthetics on Cerebral Blood Flow and Cerebral Metabolic Rate

This section deals with the effect of anesthetic drugs on CBF and CMR. It includes limited mention of influences on autoregulation, CO_2 responsiveness, and cerebral blood volume (CBV). Effects on CSF dynamics, the BBB, and epileptogenesis are discussed later.

In neuroanesthesia, considerable emphasis is placed on the manner in which anesthetic drugs and techniques influence CBF. The rationale is twofold. First, delivery of energy substrates is dependent on CBF, and in the setting of ischemia, modest alterations in CBF can substantially influence neuronal outcome. Second, control and manipulation of CBF are central to management of ICP because as CBF varies in response to vasoconstrictor-vasodilator influences, CBV varies with it.[25] With respect to ICP, it is CBV that is the more critical variable. In normal brain, CBV is approximately 5 mL/100 g of brain,[26] and over a $Paco_2$ range of approximately 25 to 70 mm Hg, CBV changes by about 0.049 mL/100 g for each 1–mm Hg change in $Paco_2$. In an adult brain weighing about 1400 g, this can amount to a 20-mL change in total CBV for a $Paco_2$ range of 25 to 55 mm Hg. Practically speaking, CBV is much more difficult to measure than CBF, so there is a relatively paucity of data, especially in human subjects.

Although CBV and CBF usually vary in parallel, the magnitude of change in CBV is less than the magnitude of change in CBF (Fig. 13-6); for a given increase in CBF, the increase in CBV is considerably less. In addition, CBV and CBF vary independently under some circumstances. During cerebral ischemia, for example, CBV increases whereas CBF is significantly reduced.[27] Autoregulation normally serves to prevent MAP-related increases in CBV. In fact, as the cerebral circulation constricts to maintain a constant CBF in the face of a rising MAP, CBV actually decreases.[28] When autoregulation is impaired or its upper limit (≈150 mm Hg) is exceeded, CBF and CBV then increase in parallel as arterial pressure rises (see Fig. 13-5). A declining MAP results in a progressive increase in CBV as the cerebral circulation dilates to maintain constant flow, and exaggerated increases in CBV occur as MAP falls below the LLA.[28] In normal subjects, the initial increases in CBV do not result in a significant elevation in ICP because there is latitude for compensatory adjustments by other intracranial compartments (e.g., translocation of venous blood and CSF to extracerebral vessels and the spinal CSF space, respectively). When intracranial compliance* is reduced, an increase in CBV can cause herniation or reduce CPP sufficiently to cause ischemia.

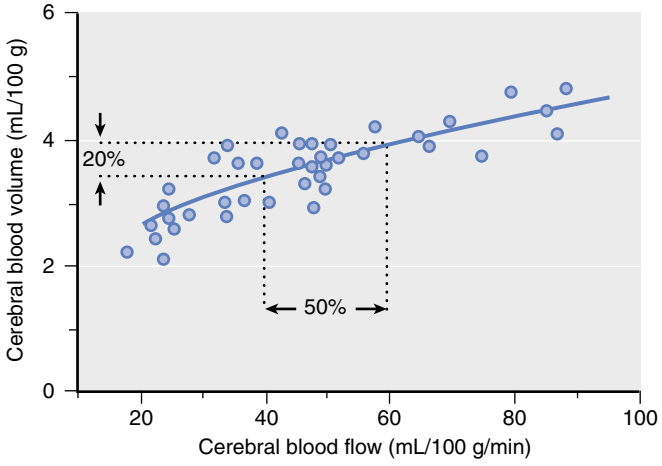

Figure 13-6 Relationship between cerebral blood flow (CBF) and cerebral blood volume (CBV). Note that although there is a linear relationship between CBF and CBV, the magnitude of the change in CBV for a given change in CBF is considerably less. In this figure, an increase in CBF of 50% results in a change in CBV of only 20%.

There have been several investigations of the effects of anesthetics on CBV in normal brain.[30,31] In general, the effects observed confirm a parallel relationship between CBF and CBV. However, the relationship is not consistently 1:1,[25,32] and CBF-independent influences on CBV may occur. It is also an unexplored possibility that anesthetic drugs may influence the venous side of the cerebral circulation. Although the intracranial veins are a largely passive compartment, there is evidence that in some species venous caliber is under active control by either neurogenic or humoral mechanisms. At present, there is no evidence that these direct effects have clinical significance. Nonetheless, the importance of blood volume on the venous side of the cerebral circulation should not be overlooked. Passive engorgement of these vessels as a result of the head-down posture, compression of the jugular venous system, or high intrathoracic pressure can have dramatic effects on ICP (see Fig. 63-5).

Intravenous Anesthetic Drugs

The general pattern of the effect of intravenous anesthetics is one of parallel alterations in CMR and CBF. The vast majority of intravenous anesthetics cause a reduction in both. Ketamine, which causes an increase in CMR and CBF, is the exception. The effects of selected intravenous anesthetic drugs on human CBF are compared in Figure 13-7.

It is probable that the changes in CBF induced by intravenous anesthetics are largely the result of effects on CMR with parallel (coupled) changes in CBF. If this were the entire explanation, the CBF/CMR ratio would be the same for all anesthetics. It is not. There are also direct effects on cerebral vascular smooth muscle (e.g., vasoconstriction, vasodilation, alteration of autoregulatory function) that make contributions to the net effect. For instance, although barbiturates are generally thought of as cerebral vasoconstrictors, some barbiturates actually cause relaxation of cerebral vascular smooth muscle in isolated vessel preparations.[45] However, a substantial reduction in CMR occurs in vivo, and the net effect at the point of EEG suppression is vasoconstriction and a substantial decrease in CBF.[46] It appears that in general,

*Note a well-entrenched misuse of terminology.[29] The "compliance" curve that is commonly drawn to describe the intracranial pressure-volume relationship (see Fig. 66-3) actually depicts the relationship $\Delta P/\Delta V$ (elastance) and not $\Delta V/\Delta P$ (compliance). What is here referred to as "reduced compliance" is more correctly described as "increased elastance." However, because the existing literature most commonly uses the "compliance" terminology, we have left the misuse uncorrected herein.

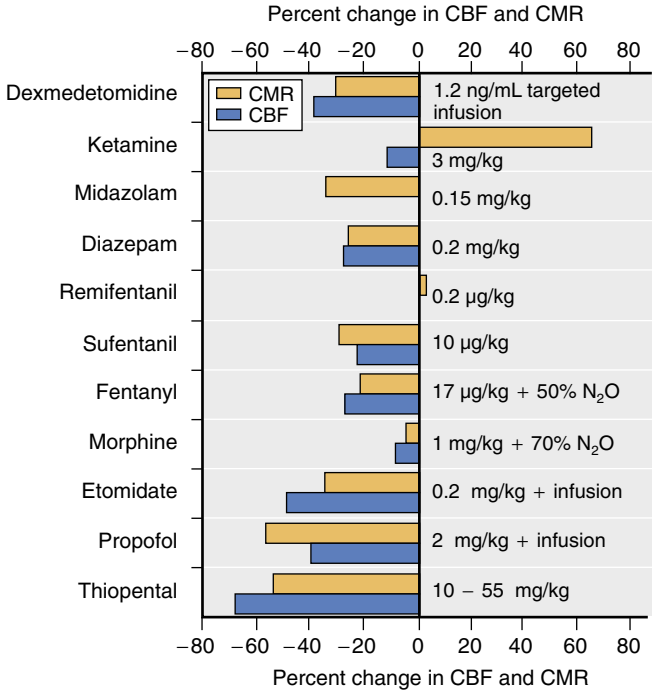

Figure 13-7 Changes in cerebral blood flow (CBF) and the cerebral metabolic rate of oxygen ($CMRO_2$) caused by intravenous anesthetic drugs. The data are derived from human investigations and are presented as percent change from unanesthetized control values. Dexmedetomidine CMR values were determined on a background of 0.5% isoflurane anesthesia. See the text for details. No data for the $CMRO_2$ effects of midazolam in humans are available. *(Data from references 22 and 33-44.)*

autoregulation and CO_2 responsiveness are preserved during administration of intravenous anesthetic drugs.

Barbiturates

A dose-dependent reduction in CBF and CMR occurs with barbiturates. With the onset of anesthesia, CBF and $CMRO_2$ are reduced by about 30%.[47] When large doses of thiopental cause complete EEG suppression, CBF and CMR are reduced by about 50%.[46,48] Further increases in the dose of barbiturate have no additional effect on CMR.[46] These observations suggest that the major effect of nontoxic doses of depressant anesthetics is a reduction in the component of cerebral metabolism that is linked to electrical brain function (e.g., neurophysiologic activity), with only minimal effects on the second component, that related to cellular homeostasis (see Fig. 13-1).

Tolerance to the CBF/CMR effects of barbiturates may develop quickly.[49] In patients with severe head injury in whom "barbiturate coma" was maintained for 72 hours, the blood concentration of thiamylal required to maintain EEG burst suppression was observed to be increased by the end of the first 24 hours and continued to increase over the next 48 hours.[50] During deep pentobarbital anesthesia, autoregulation is maintained up to arterial pressures as low as 60 mm Hg. CO_2 responsiveness also persists.

Propofol

The effects of propofol (2,6-diisopropylphenol) on CBF and CMR appear to be quite similar to those of barbiturates. Investigations in humans have revealed substantial reductions in both CBF and CMR after the administration of propofol.[51] In healthy volunteers, surgical levels of propofol reduced regional CBF by 53% to 79% in comparison with the awake state.[52,53] Alkire and coworkers assessed cerebral glucose metabolism in volunteers by positron emission tomography (PET) before and during infusion of propofol to the point of unresponsiveness.[54] The whole-brain metabolic rate decreased by 48% to 58%, with limited regional heterogeneity observed. When compared with isoflurane-fentanyl or sevoflurane-fentanyl anesthesia, a combination of propofol and fentanyl decreased subdural pressure in patients with intracranial tumors and decreased the arteriovenous oxygen content difference ($AVDO_2$).[55] Collectively, these investigations in human subjects indicate that propofol effects reductions in CMR and secondarily decreases CBF, CBV, and ICP.

Both CO_2 responsiveness and autoregulation appear to be preserved in humans during the administration of propofol,[56,57] even when administered in doses that produce burst suppression of the EEG.[58] The magnitude of the reduction in CBF during hypocapnia is decreased during propofol administration. This effect is probably due to the cerebral vasoconstriction induced by suppression of CMR, which limits further hypocapnia-mediated vasoconstriction.

Etomidate

The effects of etomidate on CBF and CMR are also similar to those of barbiturates. Roughly parallel reductions in CBF and CMR occur in humans,[33,59] and in general they are accompanied by progressive suppression of the EEG. Induction of anesthesia with either thiopental or etomidate resulted in a similar reduction in MCA flow velocity of about 27%.[60] The CBF/CMR changes are substantial. Renou and colleagues[33] gave approximately 0.2 mg/kg of etomidate to adults and observed mean reductions in CBF and CMR of 34% and 45%, respectively. As is the case with barbiturates, no further reduction in CMR occurs when additional drug is administered beyond a dose sufficient to produce EEG suppression. This latter phenomenon has not been demonstrated in humans. However, Bingham and associates[61] observed that etomidate lowered ICP when administered to severely head-injured patients in whom EEG activity was well preserved but was ineffective when there was substantial antecedent EEG suppression. The global CMR suppression attainable with etomidate is slightly less profound than that achieved with isoflurane and barbiturates. This is consistent with the observation that unlike barbiturates, which cause CMR suppression throughout the brain, the CMR suppression caused by etomidate is regionally variable and occurs predominantly in forebrain structures.

Etomidate has been shown to be effective in reducing ICP without causing a reduction in CPP in patients with intracranial tumors[62] and head-injured patients.[63] However, administration of etomidate has been shown to result in an exacerbation of brain tissue hypoxia and acidosis in patients in whom the MCA was temporarily occluded during surgery.[64] Additional concerns regarding the occurrence of adrenocortical suppression and renal injury caused by the propylene glycol vehicle[65] will probably preclude more than episodic use.

Reactivity to CO_2 is preserved in humans during the administration of etomidate.[33,59] Autoregulation has not been evaluated. Myoclonus and epileptogenesis are discussed in a later section.

Narcotics

There are inconsistencies in the information available, but it is likely that narcotics have relatively little effect on CBF and CMR in the normal, unstimulated nervous system. When changes do occur, the general pattern is one of modest reductions in both CBF and CMR. The inconsistencies in the literature probably arise largely because in many studies, the "control" states entailed paralysis and nominal sedation, often with nitrous oxide alone. In these studies, in which substantial reductions in CBF and CMR were frequently observed, the effect of the narcotic was probably a combination of the inherent effect of the drug plus a substantial component attributable to reduction of arousal. Comparable effects related to reduction of arousal may occur and can be clinically important. However, they should be viewed as nonspecific effects of sedation or pain control, or both, rather than specific properties of narcotics. The following discussion emphasizes investigations in which control measurements were unlikely to have been markedly influenced by arousal phenomena.

Morphine. When morphine (~1 mg/kg) was administered as the sole drug to humans, Moyer and associates[66] observed no effect on global CBF and a 41% decrease in $CMRO_2$. The latter is a substantial reduction, and the absence of a simultaneous adjustment in CBF is surprising. There have been no other investigations of morphine alone in humans. Jobes and coworkers gave morphine (1 and 3 mg/kg) with 70% N_2O to patients and observed no significant change in CBF or CMR.[34] The N_2O that was used might be expected to have caused a tendency toward increases in CBF and CMR. The relative absence of *net* changes in these variables from awake control measurements suggests a small to moderate depressive effect of morphine on CBF and CMR at this large dose. It should be recalled, however, that morphine can cause substantial release of histamine in individual patients. Histamine is a cerebral vasodilator that will cause an increase in CBV and a CBF effect that will vary depending on the systemic blood pressure response.

Autoregulation was observed to be intact between MAP values of 60 and 120 mm Hg in human volunteers anesthetized with morphine, 2 mg/kg, and 70% N_2O.[67]

Fentanyl. Limited human data are available. Vernhiet and colleagues[35] measured CBF and $CMRO_2$ before and during anesthesia with 12 to 30 (mean, 16) µg/kg of fentanyl and 50% N_2O in patients about to undergo cerebral angiography. Atropine and pancuronium were the only other anesthetics administered. Neither CBF nor $CMRO_2$ changed significantly from awake control values in their group of six subjects. However, one of the patients (an epileptic with normal results on computed tomography [CT]) had dramatic and unexplained increases in both CBF and $CMRO_2$. For the remaining five, CBF and $CMRO_2$ decreased by 21% and 26%, respectively ($P < .05$). The data for fentanyl/N_2O presented in Figure 13-7 are derived from these five patients, who received an average of 17 µg/kg of fentanyl. Murkin and associates measured CBF before and after induction of anesthesia with high-dose fentanyl, 100 µg/kg, and diazepam, 0.4 mg/kg.[68] CBF fell by 25%, although part of this effect may well have been a result of the benzodiazepine (see later) rather than fentanyl. Firestone and coworkers, using PET, observed a heterogeneous CBF response to 1.5 µg/kg of fentanyl in healthy volunteers. Increases occurred in the frontal, temporal, and cerebellar areas simultaneous with decreases in discreet areas associated with pain-related processing.[69] CO_2 responsiveness and autoregulation are unaffected, and the hyperemic CBF response to hypoxia remains intact.

These data, taken together, suggest that fentanyl will cause a moderate global reduction in CBF and CMR in the normal quiescent brain and will, like morphine, cause larger reductions when administered during arousal.

Alfentanil. McPherson and associates[70] administered alfentanil, 320 µg/kg, to pentobarbital-anesthetized dogs. They observed no changes in CBF, CMR, CO_2 responsiveness, autoregulation, or the CBF response to hypoxia. There have been no studies of the effects of alfentanil on CMR in humans. Schregel and colleagues administered 25 to 50 µg/kg of alfentanil to patients receiving 60% N_2O after induction of anesthesia with thiopental.[71] CBFV decreased transiently. A Doppler measure of MCA diameter was simultaneously unchanged, thus suggesting that the reduction in CBFV was indicative of a decrease in CBF. Mayberg and coworkers also observed no change in CBFV in response to 25 to 50 µg/kg of alfentanil given to patients during maintenance of anesthesia with isoflurane-N_2O.[72]

Although there are fewer data, the general pattern is similar and the conclusions should be the same as for sufentanil (see the next paragraph).[73-77] Alfentanil was included with fentanyl and sufentanil in two of the investigations of conditions in the surgical field mentioned in connection with sufentanil.[78,79] No adverse effects were noted.

Sufentanil. The majority of investigations in both animals[80,81] and humans indicate that sufentanil causes, depending on the dose, either no change or a reduction in CBF and CMR. Stephan and colleagues[36] measured CBF and $CMRO_2$ in patients before and after induction of anesthesia with 10 µg/kg of sufentanil. They observed a 29% reduction in CBF and a 22% reduction in $CMRO_2$. Murkin and coworkers, in a study involving the same dose of sufentanil and a similar design, made essentially identical observations.[82] Mayer and associates gave 0.5 µg/kg of sufentanil to volunteers and observed no change in CBF.[83] Weinstabl and coworkers observed reductions in CBFV when 1.0 and 2.0 µg/kg of sufentanil were given to intensive care unit (ICU) patients with increased ICP.[84] Neither Weinstabl and colleagues[84] nor Mayer and associates,[83] who administered sufentanil to healthy volunteers, observed changes in CBFV after 0.5 µg/kg of sufentanil.

The data from the aforementioned studies led to anticipation of no change or a reduction in ICP as a result of administration of either sufentanil or alfentanil. With respect to sufentanil, the bulk of the data derived in humans[84-88] has revealed no change in ICP after its administration. However, in some investigations in humans, sufentanil was associated with modest increases in intracranial pressure.[73,89] Subsequent investigations appear to indicate that the increases in ICP associated with sufentanil are at least in large part the consequence of a normal autoregulatory response to the sudden reduction in MAP that can occur as a consequence of sufentanil administration.[90] Based on these data, sufentanil (and for that matter fentanyl as well[87]) are best administered in a manner that does not produce sudden reduction of MAP. MAP reduction will clearly reduce CPP and may increase ICP, each of which, in sufficient extreme, may be deleterious. However, it should be noted that the ICP increases attributed to sufentanil have been small. Furthermore, four investigations[78,79,91,92] that compared conditions in the surgical field, including pressure under brain retractors,[78] identified no adverse influences attribut-

able to sufentanil. Accordingly, sufentanil need not be viewed as in any way contraindicated, although it should be used with attention to its effect on MAP.

Remifentanil. Investigations of moderate doses of remifentanil in patients have revealed minimal effects that are very similar to those of the other synthetic narcotics (with the exception of its substantially shorter duration of action). In patients undergoing craniotomy for supratentorial space-occupying lesions, 1 μg/kg of remifentanil caused no change in ICP.[93] In a second investigation in craniotomy patients, approximately 0.35 μg/kg/min of remifentanil resulted in CBF values comparable to those observed with moderately deep anesthesia with either isoflurane/N_2O or fentanyl/N_2O,[94] and CO_2 responsiveness was preserved. Greater doses of remifentanil may have more substantial effects. CBFV in the MCA decreased 30% in response to 5 μg/kg followed by 3 μg/kg/min of remifentanil at a constant MAP in patients being anesthetized for bypass surgery.[37] A lower dose of 2 μg/kg followed by an infusion of 3 μg/kg/min, however, did not affect CBFV. Quantitatively similar observations were made after a large dose of sufentanil in patients undergoing cardiac anesthesia (see earlier).[36]

It should be noted that in the previously mentioned studies, remifentanil was administered with other drugs that might influence cerebral hemodynamics. More recent studies in human volunteers have demonstrated that the infusion of *low* (*sedative*) doses of remifentanil can increase CBF. A PET study in human subjects to whom remifentanil, 0.05 and 0.15 μg/kg/min, was administered revealed increases in CBF in the prefrontal, inferior parietal, and supplementary motor cortices; reductions in CBF were observed in the cerebellum, superior temporal lobe, and midbrain gray matter.[95] The relative increase in CBF was greater with administration of the higher dose of remifentanil. Similar data were obtained by Lorenz and colleagues, who used magnetic resonance imaging for determination of CBF.[96] In a PET investigation in human volunteers, Kofke and coworkers observed remifentanil-induced increases in regional CBF within the limbic system.[97] Although the underlying mechanisms of the increases in CBF are not clear, disinhibition produced by the low-dose remifentanil infusion, or perhaps the sensation of side effects (warmth, comfort, pruritus),[96] may have contributed. It should be noted that when combined with N_2O, CBF and CO_2 reactivity are similar in patients given remifentanil or fentanyl.[98] In aggregate, the available human data indicate that in low sedative doses, administration of remifentanil alone can effect minor increases in CBF. With higher doses or with the concomitant administration of anesthetic adjuvants, CBF is either unaltered or modestly reduced.

Benzodiazepines

Benzodiazepines cause parallel reductions in CBF and CMR in humans. CBF and $CMRO_2$ decreased by 25% when 15 mg of diazepam was given to head-injured patients.[38] The effects of midazolam on CBF (but not CMR) have also been studied in humans. Forster and associates observed a 30% to 34% reduction in CBF[39,99] after the administration of 0.15 mg/kg of midazolam to awake healthy human volunteers. Veselis and coworkers, using PET, observed a global 12% reduction in CBF after a similar dose and noted that the decreases occurred preferentially in the brain regions associated with arousal, attention, and memory.[100] CO_2 responsiveness was preserved.[101]

The foregoing studies indicate that benzodiazepines should cause a moderate reduction in CBF in humans and suggest that the effect may be metabolically coupled. The extent of the maximal CBF/CMR reduction produced by benzodiazepines is probably intermediate between the decreases caused by narcotics (modest) and barbiturates (substantial). It appears that benzodiazepines should be safe to administer to patients with intracranial hypertension, provided that respiratory depression and an associated increase in $Paco_2$ do not occur.

Flumazenil

Flumazenil is a highly specific, competitive benzodiazepine receptor antagonist. It had no effect on CBF when administered to unanesthetized human volunteers.[99,102] However, flumazenil reverses the CBF-, CMR-, and ICP-lowering effects of midazolam. Whereas Knudsen and colleagues[103] observed no change in either CBF or CMR when patients were aroused from midazolam anesthesia with flumazenil at the conclusion of craniotomy for brain tumor resection, Chiolero and coauthors[104] reported severe increases in ICP when flumazenil was given to midazolam-sedated head injury patients in whom ICP was poorly controlled before the administration of flumazenil. These latter observations are consistent with animal investigations in which flumazenil not only reversed the CBF and CMR effects of midazolam but also caused a substantial, though short-lived overshoot above premidazolam levels in both CBF (by 44% to 56%) and ICP (by 180% to 217%). CMR did not rise above control levels, thus indicating that the increase in CBF was not metabolically coupled. The CBF overshoot effect is unexplained, but it may be a neurogenically mediated arousal phenomenon. Flumazenil should be used very cautiously to reverse benzodiazepine sedation in patients with impaired intracranial compliance.

Droperidol

There have been no human investigations of the CBF/CMR effects of droperidol in isolation. However, the information available from animal investigations and combination drug administration in humans,[105,106] taken together, suggests that droperidol is not a cerebral vasodilator and probably has little effect on CBF and CMR in humans. The occasional increases in ICP that have been observed[105] probably reflect normal autoregulation-mediated vasodilation in response to an abrupt fall in MAP.

Ketamine

Among the intravenous anesthetics, ketamine is unique in its ability to cause increases in both CBF and CMR.[107] Animal studies indicate that the changes in CMR are regionally variable. In rats, substantial increases occur in limbic system structures with modest changes or small decreases in cortical structures.[108] PET studies in humans have demonstrated that subanesthetic doses of ketamine (0.2 to 0.3 mg/kg) can increase global CMR by about 25%.[109] The greatest increase in CMR occurred in the frontal and anterior cingulated cortex. A relative reduction in CMR in the cerebellum was also observed. Commercially available formulations of ketamine contain both the (*S*)- and (*R*)-ketamine enantiomers. The (*S*)-ketamine enantiomer increases CMR substantially, whereas the (*R*) enantiomer tends to decrease CMR, particularly in the temporomedial cortex and in the cerebellum.[110] These changes in CMR are accompanied by corresponding changes in CBF.[111] Increases in global (as well as regional) CBF in humans

that were not accompanied by similar increases in $CMRO_2$ after the administration of (*S*)-ketamine have been observed. However, the majority of investigations indicate that autoregulation is maintained during ketamine anesthesia[112]; the observed effects of ketamine on cerebral hemodynamics indicate that ketamine increases CMR and secondarily increases CBF. CO_2 responsiveness is preserved.

The anticipated ICP correlate of the increase in CBF has been confirmed to occur in humans. However, anesthetic drugs (diazepam, midazolam, isoflurane/N_2O, propofol) have been shown to blunt or eliminate the increases in ICP or CBF associated with ketamine.[113-115] In fact, decreases in ICP have been reported in response to relatively large doses of ketamine (1.5 to 5 mg/kg) administered to propofol-sedated head-injured patients.[116] Accordingly, although ketamine is probably best avoided as the sole anesthetic agent in patients with impaired intracranial compliance, it may be reasonable to use it cautiously in patients who are simultaneously receiving the other drugs mentioned earlier.

Lidocaine

Lidocaine produces a dose-related reduction in $CMRO_2$ in experimental animals.[117] In dogs, 3 mg/kg lowered $CMRO_2$ by 10% and 15 mg/kg reduced it by 27%. When very large doses (160 mg/kg) were given to dogs maintained on cardiopulmonary bypass, the reduction in $CMRO_2$ was apparently greater than that seen with high-dose barbiturates.[118] This may occur because the membrane-stabilizing effect of lidocaine also reduces the energy required for maintenance of membrane integrity. In unanesthetized human volunteers, Lam and colleagues observed reductions in CBF and CMR of 24% and 20%, respectively, after the administration of 5 mg/kg of lidocaine over a 30-minute period, followed by infusion of 45 µg/kg/min.[119]

Bedford and coworkers[120] compared the effectiveness of bolus doses of thiopental, 3 mg/kg, and lidocaine, 1.5 mg/kg, in controlling the acute increase in ICP that occurred after the application of a pin head holder or skin incision in craniotomy patients. The two regimens were equally effective in causing a reduction in ICP. However, the decrease in MAP was greater with thiopental. Accordingly, a bolus dose of lidocaine is a reasonable adjunct to the prevention or treatment of acute elevations in ICP and has been recommended for preventing increases in ICP associated with endotracheal suctioning. Note that large doses of lidocaine can produce seizures in humans and some experimental animals. Lidocaine-induced seizures have not been reported in anesthetized humans. Nonetheless, it seems appropriate to restrict lidocaine doses to amounts that achieve serum levels less than the seizure threshold (>5 to 10 µg/mL) in awake humans. After a 2-mg/kg bolus, peak serum concentrations of 6.6 to 8.5 µg/mL are below this seizure threshold. Bolus doses of 1.5 to 2.0 mg/kg therefore seem appropriate.

Inhaled Anesthetics

Volatile Anesthetics

The pattern of volatile anesthetic effects on cerebral physiology is a striking departure from that observed with the intravenous anesthetics, which generally cause parallel reductions in CMR and CBF. All volatile anesthetics, similar to intravenous sedative-hypnotic drugs, suppress cerebral metabolism in a dose-related manner.[121-125] Volatile anesthetics also possess intrinsic cerebral vasodilatory activity as a result of direct effects on vascular smooth muscle. The net effect of volatile anesthetics on CBF is therefore a balance between a reduction in CBF caused by CMR suppression and augmentation of CBF caused by the direct cerebral vasodilation. When administered at a dose of 0.5 MAC, CMR suppression–induced reduction in CBF predominates, and net CBF decreases in comparison to the awake state. At 1.0 MAC, CBF remains unchanged; at this dose, CMR suppression and vasodilatory effects are in balance. Beyond 1.0 MAC, the vasodilatory activity predominates, and CBF increases significantly even though CMR is substantially reduced.

The increase in CBF produced by volatile anesthetics at doses greater than 1.0 MAC has been interpreted as evidence of uncoupling of flow and metabolism. However, there is considerable evidence that coupling (CBF adjustments paralleling changes in CMR) persists during anesthesia with volatile agents.[126-129] Accordingly, it is probably more accurate to say that the CBF/CMR ratio is altered (increased) by volatile anesthetics. This alteration is dose related, and under steady-state conditions there is a positive correlation between MAC multiples and the CBF/$CMRO_2$ ratio[123,130]; that is, higher MAC levels cause greater "luxury" perfusion.

The important clinical consequences of administration of volatile anesthetics are derived from the increases in CBF and CBV—and consequently ICP—that can occur. Of the commonly used volatile anesthetics, the order of vasodilating potency is approximately halothane >> enflurane > desflurane ≈ isoflurane > sevoflurane.

Effects on Cerebral Blood Flow. Volatile anesthetics possess intrinsic vasodilatory activity, and they not only modify cerebral autoregulation but also produce dose-dependent reductions in systemic blood pressure. Hence, their effects on CBF and CMR are best evaluated when arterial pressure is supported to a common level. In addition, the cerebrovascular effects of volatile anesthetics are modulated by the simultaneous administration of other central nervous system (CNS)-active drugs. It is therefore important to understand the control state (awake, sedated, or anesthetized) against which the CBF and CMR effects of volatile anesthetics are compared. The best information about the cerebrovascular effects of volatile anesthetics is obtained in studies in which a nonanesthetized awake control state is used.

Data on the cerebrovascular effects of halothane and enflurane are limited. Initial studies in humans demonstrated that administration of 1 MAC halothane significantly increases CBF, even when systemic blood pressure is substantially reduced, in comparison to preanesthetic CBF.[131] The same investigators subsequently showed that in humans, when MAP is maintained at 80 mm Hg, 1.1 MAC levels of halothane increase CBF by as much as 191% and decrease CMR by about 10% (Fig. 13-8).[131,132] When compared with awake values, 1.2 MAC enflurane also increase CBF and decrease CMR by 45% and 15%, respectively.[136] The dramatic increases in CBF with a simultaneous modest reduction in CMR attest to the cerebral vasodilatory properties of halothane and enflurane. Isoflurane, by contrast, does not increase CBF as much as halothane or enflurane does. Human studies have shown that at doses of 1.1 MAC, isoflurane increases CBF by about 19% when systemic pressure is maintained within the normal range. CMR is reduced by about 45%.[129]

More recent investigations have shown that both sevoflurane and desflurane can significantly reduce CBF in humans

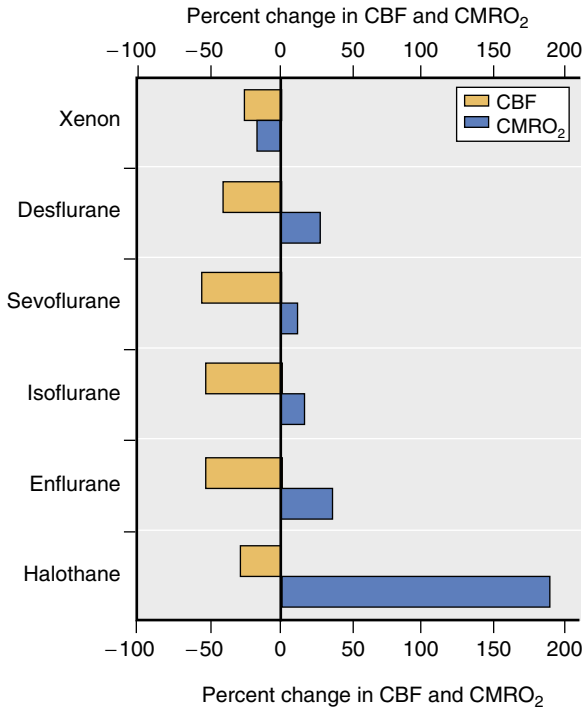

Figure 13-8 Estimated changes in cerebral blood flow (CBF) and the cerebral metabolic rate of oxygen ($CMRO_2$) caused by volatile anesthetics. The CBF data for halothane, enflurane, and isoflurane were obtained during anesthesia (with blood pressure support) at 1.1 minimum alveolar concentration (MAC) in humans[132] and are expressed as percent change from awake control values. The $CMRO_2$ data for halothane, enflurane, and isoflurane were obtained in the cat[123,133] and are expressed as percent change from N_2O-sedated control values. The data for sevoflurane were obtained during 1.1 MAC anesthesia in the rabbit and are expressed as percent change from a morphine/N_2O-anesthetized control state.[125] CBF values were obtained in patients who received 1 MAC sevoflurane anesthesia.[134] Desflurane data were obtained in patients to whom 1 MAC desflurane was administered.[135]

when compared with CBF in awake, nonanesthetized patients. At 1.0 MAC concentrations, sevoflurane[134] and desflurane[136] decreased CBF by 38% and 22% and CMR by 39% and 35%, respectively. These results, which suggest that the cerebral vasodilation produced by isoflurane is greater than that produced by sevoflurane and desflurane, were obtained with CBF measured by the inert gas technique. This technique measures CBF primarily within the cortex and therefore may have substantially underestimated global CBF. PET studies in healthy humans have shown that sevoflurane dose-dependently suppresses $CMRO_2$ and CBF; at 1 MAC levels, the reduction in CBF and $CMRO_2$ is approximately 50% and 50% to 60%, respectively.[52,53] In addition, other investigations in humans, most using measurement of MCA flow velocity by transcranial Doppler, indicate that differences in the effects of isoflurane, desflurane (Fig. 13-9), and sevoflurane are, at best, modest.[137,138,151] It should be noted that a strictly quantitative comparison between these volatile anesthetics is not possible given the variations in blood pressure among study group patients. In addition, there is some discrepancy among studies in the literature regarding the magnitude of the effects of volatile anesthetics on CBF. Much of this may occur as a result of the interaction of regionally selective CBF methods with the heterogeneity within the cerebrum of the CBF effects of volatile anesthetics. See the later section "Distribution of Changes in Cerebral Blood Flow/Cerebral Metabolic Rate."

There is considerable interest in use of the inert gas xenon in the modern practice of anesthesia. The anesthetic properties of xenon were recognized several decades ago, but it is only now that the agent is being evaluated for possible use in patients. The MAC

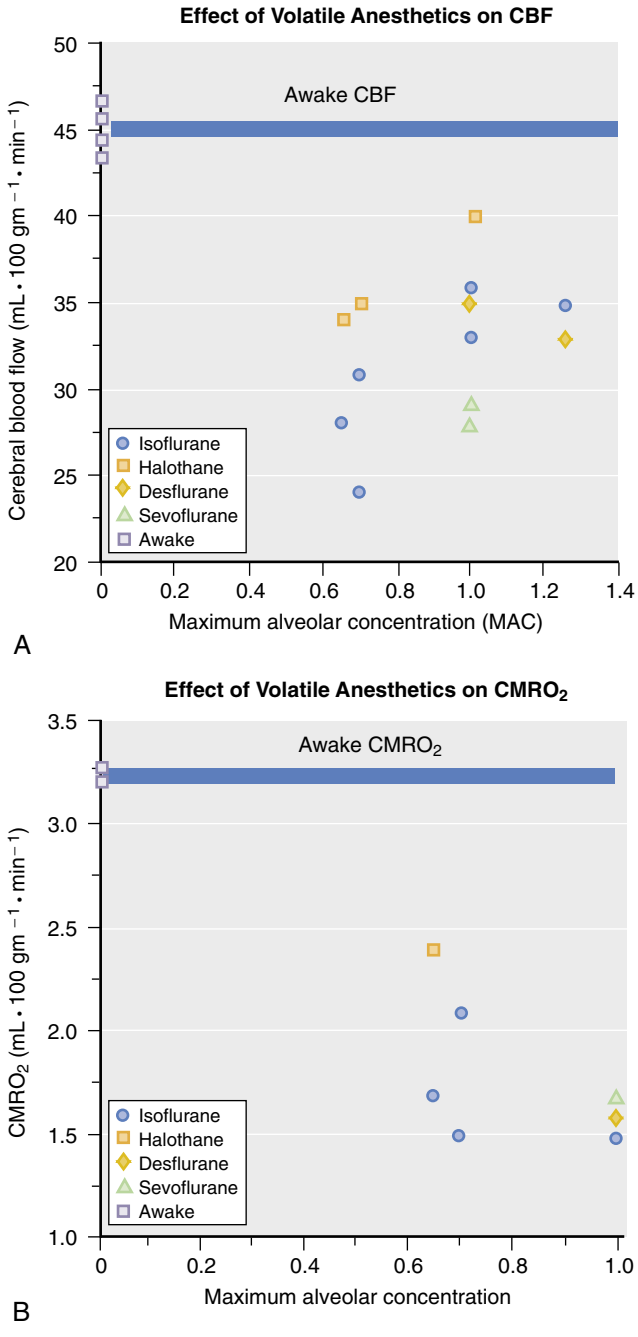

Figure 13-9 Effect of volatile anesthetics on cerebral blood flow (CBF) (**A**) and the cerebral metabolic rate of oxygen ($CMRO_2$) (**B**) in humans. The results are a composite of CBF and $CMRO_2$ values obtained from a number of separate investigations.[54,96,134,135,138-150] In these studies, $Paco_2$ was maintained in the normocapnic range (~35 to 40 mm Hg) and mean arterial pressure was supported. In most of the investigations, CBF was measured by the inert gas technique. This technique measures primarily cortical CBF and, as such, might underestimate global CBF.

of xenon has been estimated to be 63% to 71%, with females having significantly lower MAC values (51%).[152] Xenon is thought to exert its anesthetic effect primarily via noncompetitive antagonism of the *N*-methyl-D-aspartate (NMDA) receptor,[153] although activation of the TREK two-pore K^+ channel might also play a role.[154] In healthy humans, administration of 1 MAC xenon resulted in a reduction in CBF by approximately 15% in the cortex and by 35% in the cerebellum; interestingly, CBF in white matter increased by 22%.[155] This reduction in CBF is accompanied by a parallel reduction of 26% in the CMR of glucose (CMRg).[156] Cerebral autoregulation and CO_2 reactivity are preserved during xenon anesthesia in animals.[157] Under background pentobarbital anesthesia in an experimental model of increased ICP, administration of xenon did not increase ICP, and the response to both hypocapnia and hypercapnia was preserved.[158] Diffusion of xenon into air-containing spaces such as the bowel does occur, although the magnitude of air expansion is considerably less than that with N_2O.[159] Accordingly, caution will have to be exercised with the use of xenon in patients with intracranial air. Although the use of xenon in neurosurgical patients has not been evaluated, the data available suggest that it has a favorable profile for neuroanesthesia.

Effects on Cerebral Metabolic Rate. All of the volatile anesthetics cause reductions in CMR. The degree of reduction in $CMRO_2$ that occurs at a given MAC level is less with halothane than with the other four anesthetics (see Fig. 19-8). Sevoflurane's effect on $CMRO_2$ is very similar to that of isoflurane. The available information, derived in separate investigations, suggests that desflurane causes slightly less suppression of $CMRO_2$ than isoflurane does, especially at concentrations above 1.0 MAC.[124] Although a direct comparison of the $CMRO_2$ effects of all of the volatile anesthetics has not been performed in humans, collation of data from a number of investigations has shown that at doses of 1.0 MAC, isoflurane, sevoflurane, and desflurane reduce $CMRO_2$ ($AVDO_2$ in arterial and jugular bulb blood samples) by 25%,[139] 38%,[134] and 22%,[160] respectively. PET studies in humans have also shown that halothane (0.9 MAC) and isoflurane (0.5 MAC) can decrease CMRg by 40% and 46%, respectively.[54,140] The reduction in $CMRO_2$ is dose related. With isoflurane (and almost certainly desflurane and sevoflurane as well), the maximal reduction is attained simultaneously with the occurrence of EEG suppression.[124] This occurs at clinically relevant concentrations, such as 1.5 to 2.0 MAC in humans. In dogs, additional isoflurane up to 6.0% end-tidal volume results in no further reduction in CMR and no indication of metabolic toxicity. Halothane presents a contrast to this pattern. Halothane concentrations in excess of 4.0 MAC are required to achieve EEG isoelectricity in dogs, and additional halothane causes a further reduction in $CMRO_2$ in concert with alterations in energy charge. The latter changes, which are reversible, suggest interference with oxidative phosphorylation. These data indicate that unlike isoflurane, halothane can produce reversible toxicity when administered in very high concentrations.

There is some nonlinearity in the CBF and CMR dose-response relationships for volatile anesthetics. The initial appearance of an EEG pattern associated with the onset of anesthesia with halothane, enflurane, and isoflurane is accompanied by a precipitous decline in $CMRO_2$.[47] Thereafter, $CMRO_2$ declines in a slower dose-dependent manner. Such an effect has also been demonstrated for sevoflurane. In a dose escalation study in humans, the greatest reduction in entropy (a measure of anesthetic depth) was observed with 1 MAC sevoflurane anesthesia, with lesser reductions occurring at increasing concentrations.[161] Other studies during anesthetic induction with halothane found marked increases in CBF before any alteration in CMR. This suggests that the direct effect of a volatile agent on smooth muscle may develop more rapidly than influences related to depression of CMR.

Distribution of Changes in Cerebral Blood Flow/Cerebral Metabolic Rate. The regional distribution of anesthetic-induced changes in CBF and CMR differs markedly with halothane and isoflurane. Halothane produces relatively homogeneous changes throughout the brain. CBF is globally increased and CMR is globally depressed. The changes caused by isoflurane are more heterogeneous. Increases in CBF are greater in subcortical areas and hindbrain structures than in the neocortex.[128,162,163] For CMR the converse is true, with a greater reduction in the neocortex than in the subcortex.[164] In humans, 1.0 MAC sevoflurane (Fig. 13-10) results in a reduction in CBF within the cortex and an increase in CBF within the cerebellum.[141] These effects of sevoflurane are similar to those produced by isoflurane.[141,163] Desflurane has not been submitted to similar local CBF studies. However, given the similarity of its effects on the EEG (suggesting similar cortical CMR and CBF effects), the interim assumption of similar heterogeneity in CBF distribution seems reasonable. These distribution differences may explain certain apparent contradictions in reported CBF effects in the existing literature for isoflurane. Methods that assess global hemodynamic effects reveal greater changes than those that emphasize the cortical compartment. For instance, Eintrei and coworkers found no increase in CBF by surface Xe washout when isoflurane was administered to patients undergoing craniotomy,[165] yet others[166-168] have reported that administration of isoflurane to normocapnic subjects with intracranial pathology can result in increases in CSF pressure.

Cerebral Vasodilation by Volatile Anesthetics—Clinical Implications. Isoflurane, desflurane, and sevoflurane may have a modest cerebral vasodilating effect in the human cortex when administered at doses of 1 MAC or less. In fact, administration of volatile anesthetics can effect net decreases in CBF (see Fig. 13-9). These data, however, should be interpreted with considerable caution because the critical variable that is of interest in the clinical sphere is CBV. Although there is a direct correlation between CBF and CBV, as noted earlier, the relationship is not strictly 1:1. The magnitude of the changes in CBV is significantly less than the magnitude of the changes in CBF, and modest reduction in CBF may not necessarily be accompanied by reductions in CBV. This is exemplified by clinical investigations in which a significant increase in ICP (and by extension, CBV) was observed in patients to whom isoflurane was administered at doses that would be expected to effect a reduction in CBF.[166,168] Although induction of hypocapnia mitigated the increase in ICP in these studies, other investigations have revealed that hyperventilation may not be effective in blunting isoflurane-induced increases in ICP in patients with intracranial tumors.[167] In experimental investigations of cerebral injury, volatile anesthetics increased ICP significantly, and this rise in ICP was not ameliorated by hypocapnia.[169] Collectively, these data suggest that volatile anesthetics will have minimal effects on cerebral hemodynamics in patients with normal intracranial compliance. However, in patients with abnormal intracranial compliance, the potential for volatile agent–induced increases in CBV and ICP exists. Accordingly, there should be discretion in the use of volatile anesthetics in the setting of large or rapidly expanding mass lesions, unstable

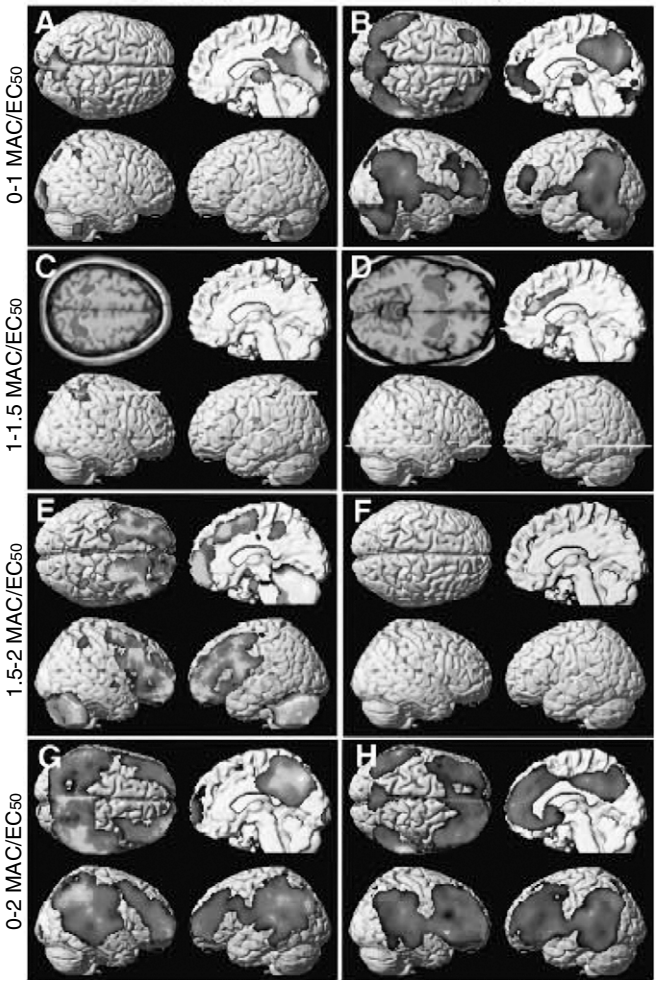

Figure 13-10 Dose-dependent redistribution of cerebral blood flow (CBF) in humans. **A** to **H**, Positron emission tomography (PET) scans demonstrate a dose-dependent reduction in CBF in both sevoflurane-anesthetized (*left*) and propofol-anesthetized (*right*) subjects. During sevoflurane anesthesia, an increase in concentration from 1.5 to 2.0 minimum alveolar concentration (MAC) leads to an increase in CBF within the subcortex, particularly in the cerebellum. There was a gradual reduction in mean arterial pressure (MAP) with increasing concentrations of sevoflurane, and MAP was not supported. The CBF values would be expected to be considerably greater had blood pressure been maintained within the normal range. Therefore, the CBF values represented in the figure probably *underestimate* true CBF during sevoflurane anesthesia. In propofol-anesthetized subjects, CBF was uniformly decreased and redistribution of CBF was not observed. *(Data from Kaisti K, Metsahonkala L, Teras M, et al: Effects of surgical levels of propofol and sevoflurane anesthesia on cerebral blood flow in healthy subjects studied with positron emission tomography. Anesthesiology 96:1358-1370, 2002.)*

ICP, or other significant derangements of cerebral physiology in which CO_2 responsiveness and flow-metabolism coupling may be impaired. When they occur (a somnolent, vomiting patient with papilledema, a large mass, and compressed basal cisterns), the clinician may well be advised to use a predominantly intravenous technique until such time as the cranium and dura are open and the effect of the anesthetic technique can be assessed directly. Such circumstances will be relatively rare in elective neurosurgery.

Situations in which there has been substantial antecedent lowering of CMR by drug administration or disease processes should also justify caution in the use of volatile anesthetics. If a volatile agent has a substantial direct vasodilating effect on the cerebral vasculature that is normally offset by an opposing metabolically mediated vasoconstricting influence, it might be surmised that when near-maximal reduction of CMR has occurred, introduction of the volatile agent will have a predominantly vasodilating effect.[58,127] There are data to support this prediction. Maekawa and colleagues[164] measured CBF and local CMRg in rats both awake and during anesthesia with increasing concentrations of isoflurane. One MAC isoflurane resulted in an average decrease in CMRg of 54% of the awake control value in five cortical areas and no change in average CBF. An additional 1.0 MAC (i.e., a total of 2.0 MAC) caused a further reduction in CMRg of only 20% of the control value, and CBF simultaneously increased by 70% (Fig. 13-11). These data together suggest that isoflurane is a significant cerebral vasodilator when administered in concentrations at and above those associated with near-maximal CMR suppression or, perhaps, when administered in situations in which the component of CMR that is associated with electrophysiologic function is already suppressed by other drugs[58,127] or pathologic processes, such as traumatic brain injury.

The net vasodilating effect of equi-MAC concentrations of isoflurane, desflurane, and sevoflurane is less in humans than that of halothane, and the former are probably therefore preferable if a volatile agent is to be used in the setting of impaired intracranial compliance. That is not to say that halothane is contraindicated in these circumstances. It has been clearly demonstrated that when hypocapnia is established before the introduction of halothane, the increases in ICP that might otherwise occur in a nor-

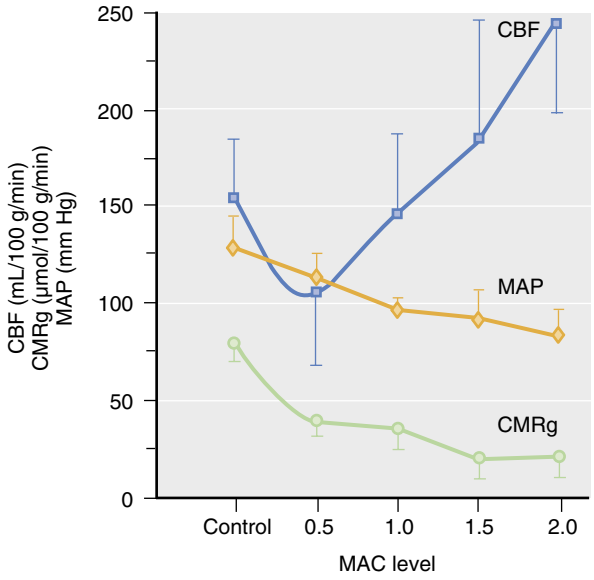

Figure 13-11 Relationship between changes in the cerebral metabolic rate of glucose (CMRg) and cerebral blood flow (CBF) in the motor-sensory cortex in rats during isoflurane anesthesia. The majority of the suppression in CMR caused by isoflurane has occurred by 1.0 minimum alveolar concentration (MAC), and in this concentration range CBF is not increased. Thereafter, additional isoflurane causes little further reduction in CMR, and cerebral vasodilation occurs. These data (±SD), from Maekawa and colleagues,[164] suggest the importance of metabolic coupling in determining the effects of isoflurane on CBF. MAP, mean arterial pressure.

mocapnic patient with poor intracranial compliance can be prevented or greatly attenuated. Nonetheless, most clinicians will prefer isoflurane, desflurane, or sevoflurane because the margin for error is probably wider than with halothane.

Time Dependence of Cerebral Blood Flow Effects. The effect of volatile anesthetic drugs on CBF has been shown to be time dependent in animal investigations. After an initial increase, CBF falls substantially and reaches a steady state near pre–volatile agent levels between 2½ and 5 hours after exposure.[162,170,171] The mechanism of this effect is not understood, and the phenomenon was not evident in humans studied during 3- or 6-hour exposure to halothane, isoflurane, desflurane, or sevoflurane.[151,172]

Cerebral Blood Volume. The extensive investigation of the influence of volatile anesthetics on CBF has been based primarily on the concern that the cerebral vasodilation produced by volatile anesthetics might increase ICP. It should be noted, however, that it is CBV and not CBF per se that influences ICP. The vast majority of intracranial blood is within the cerebral venous circulation, and although there is a reasonable correlation between vasodilation-induced increases in CBF and CBV, the magnitude of changes in CBF is considerably greater than that in CBV (see Fig. 13-6). Hence, changes in CBF do not reliably predict changes in CBV and, by extension, in ICP. Nonetheless, the available data do indicate that CBV is considerably greater during isoflurane anesthesia than during propofol or pentobarbital anesthesia.[25] In human volunteers, 1 MAC sevoflurane reduced regional CBF but not regional CBV; by contrast, propofol reduced both regional CBF and regional CBV (Fig. 13-12).[53] In addition, CBV responds to changes in $Paco_2$ by a reduction in CBV with hypocapnia and an increase in CBV with hypercapnia. The magnitude of the change in CBV is, however, less than the change in CBF. In aggregate, these data indicate clearly that although the effect of anesthetics and interventions on CBF may parallel the effect on CBV, there may well be substantial qualitative and quantitative differences.

CO_2 Responsiveness and Autoregulation. CO_2 responsiveness is well maintained during anesthesia with all of the volatile anesthetics.[142,173,174] As with all vasodilators, CBF is preserved up to lower MAP values during the administration of volatile anesthetics with no evidence of differences among the various anesthetics. Direct comparisons of CBF with isoflurane, desflurane, and sevoflurane anesthesia during hypotension are not available. By contrast, autoregulation of CBF in response to rising arterial pressure is impaired. This impairment appears to be most apparent with the anesthetics that cause the greatest cerebral vasodilation and is dose related (see Fig. 13-5). Sevoflurane may cause less impairment of autoregulation than other volatile anesthetics do. Recent studies surprisingly reported no change in CBFV in response to phenylephrine-induced increases in MAP during anesthesia with 1.2 to 1.5 MAC sevoflurane[175,176] or in CBF during hemorrhagic hypotension.[177] The autoregulatory response to rising pressure may be pertinent during acute episodes of hypertension, such as during laryngoscopy or mismatch of surgical stimulation to anesthetic depth. There may be some relevance to hyperemic states after carotid endarterectomy or resection of arteriovenous malformations (see Chapter 63).

Nitrous Oxide

The available data indicate that N_2O can cause increases in CBF, CMR, and ICP. At least a portion of the increases in CBF and CMR may be the result of a sympathoadrenal-stimulating effect of N_2O. The magnitude of the effect varies considerably according to the presence or absence of other anesthetic drugs (Fig. 13-13). When N_2O is administered alone, very substantial increases in CBF and ICP can occur. In sharp contrast, when N_2O is administered in combination with intravenous drugs, including barbiturates, benzodiazepines, narcotics, and propofol, its cerebral-vasodilating effect is attenuated or even completely inhibited. The addition of N_2O to anesthesia established with a volatile agent will result in moderate increases in CBF.

N_2O Administered Alone. The most dramatic reported increases in ICP or CBF in humans[181] and experimental animals[182] have occurred when N_2O was administered alone or with minimal background anesthesia. For instance, Henriksen and Jorgensen[181] recorded ICP before and during spontaneous breathing of 66% N_2O by patients with intracranial tumors. Mean ICP rose from

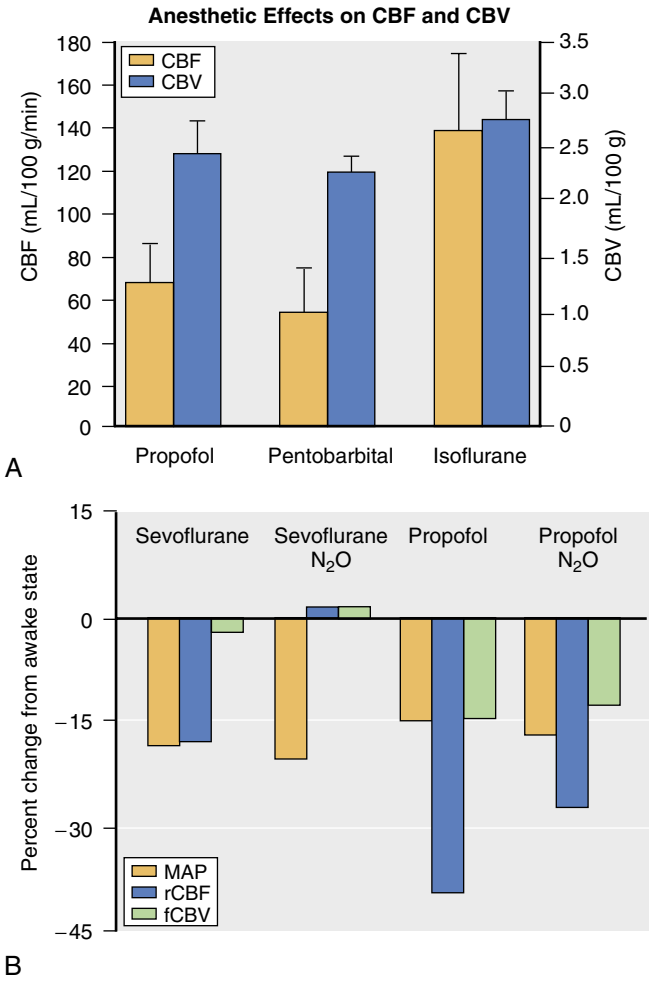

Figure 13-12 Effect of anesthetic drugs on cerebral blood flow (CBF) and cerebral blood volume (CBV). **A,** When compared with isoflurane, propofol and pentobarbital effected substantial reductions in CBF. However, reductions in CBV were more modest.[156] **B,** Although sevoflurane effected a significant reduction in regional CBF (rCBF), regional CBV (rCBV) was unchanged; had blood pressure been supported to normal levels, rCBV may have been greater than the awake state. By contrast, propofol effected a significant reduction in both rCBF and rCBV. These data indicate that the magnitude of the effect of anesthetics on rCBF is substantially greater than on rCBV. Hence, a reduction in rCBF may not lead to equivalent reductions in rCBV. MAP, mean arterial pressure.

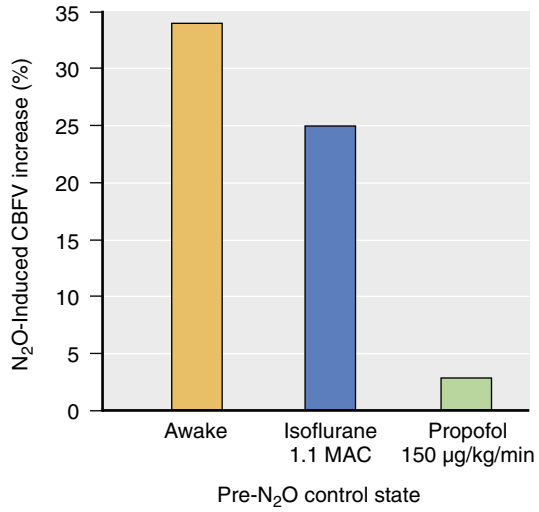

Figure 13-13 Mean percent increases in cerebral blood flow velocity (CBFV) in the middle cerebral artery of normocapnic subjects exposed to 60% N_2O after control recording in three conditions: awake[178]; 1.1 minimum alveolar concentration (MAC) of isoflurane[179]; and propofol, 150 µg/kg/min.[180]

13 to 40 mm Hg. The increases in CBF observed in humans are more modest than those observed in animals but are still substantial.[178] Whether these substantial increases represent the effects of N_2O per se or whether they reflect the nonspecific effects of a "second-stage" arousal phenomenon is not known.

N_2O Administered with Intravenous Anesthetics. When N_2O is administered in conjunction with certain intravenous anesthetics, its CBF effect may be considerably attenuated. Phirman and Shapiro[183] observed that a reproducible increase in ICP that had occurred in response to administration of 70% N_2O to a comatose patient was prevented by the previous administration of a combination of thiopental and diazepam despite no change in baseline ICP. In an investigation of patients with intracranial tumors and poor intracranial compliance (mean preinduction ICP, 27 mm Hg),[184] 50% N_2O introduced during barbiturate anesthesia and after the induction of hypocapnia had a negligible effect on ICP. Jung and associates compared lumbar CSF pressure in patients with brain tumors during administration of 0.7% isoflurane or 70% N_2O after induction of anesthesia with a barbiturate. Lumbar CSF pressure was modestly but significantly greater with N_2O.[185] That the increase was less dramatic than those cited earlier for N_2O alone may reflect the presence of residual barbiturate. Benzodiazepines administered alone have been shown to blunt the CBF response to N_2O in both animals and humans.[96] Narcotics appear to have a similar effect. Jobes and coauthors[34] reported that anesthesia with 1 mg/kg of morphine plus 70% N_2O resulted in no change in CBF from awake control values. Because of the very minor effect of morphine on CBF, these data suggest that N_2O did not cause substantial cerebral vasodilation. Although the addition of N_2O to propofol anesthesia in children increased MCA flow velocity,[186] such increases have not been demonstrated by other investigators.[180]

N_2O Administered with Volatile Anesthetics. In the majority of investigations, including several in humans, in which N_2O has been added to an anesthetic of 1.0 MAC or greater, substantial increases in CBF have been recorded.[179-187-190] Algotsson and associates[143] examined the effect of an approximately equi-MAC substitution of N_2O for isoflurane. They compared CBF in patients anesthetized with 1.5 MAC isoflurane and 0.75 MAC isoflurane with 65% N_2O. They observed 43% greater CBF with the latter, again consistent with a substantial vasodilating effect of N_2O in the presence of a volatile agent. Similar observations were made by Lam, Strebel, and their colleagues.[179,190] Several investigations have confirmed that CBF will be less with 1.0 MAC isoflurane than with a 1.0 MAC combination achieved with 50% to 65% N_2O and isoflurane.[143,144,191]

The result of an investigation in humans indicates that this vasodilating effect of N_2O may be positively correlated with the concentration of inhaled drug[190] and suggests that in general, the increase in CBF caused by N_2O is exaggerated at higher concentrations of both halothane and isoflurane. Of importance, however, is the observation of Reinstrup and coworkers, who demonstrated that administration of 50% N_2O to healthy volunteers did not significantly alter CBV.[192] In support of this observation, Kaisti and colleagues did not observe any effect of N_2O on CBV when added to a background of 1 MAC sevoflurane anesthesia.[53] These data indicate that although N_2O can increase CBF, its effect on CBV is modest at best.

Effects of N_2O on Cerebral Metabolic Rate. There is no uniform agreement about the effect of N_2O on CMR. Parallel changes in CBF and CMR,[182] increases in CBF without alteration of CMR,[193] and CMR alteration occurring without changes in CBF[194] have all been reported. This is doubtless the product of differences in species, methods, depth of background anesthesia, and interactions with simultaneously administered anesthetics. In a recent investigation in humans, administration of 70% N_2O on a background of either sevoflurane or propofol anesthesia resulted in modest increases in $CMRO_2$, thus indicating that N_2O does indeed increase cerebral metabolism.[53]

The CBF response to CO_2 is preserved during administration of N_2O.[195]

Clinical Implications. Despite the inconsistencies that are evident, data indicate that the vasodilatory action of N_2O can be clinically significant in neurosurgical patients with reduced intracranial compliance. However, it appears that N_2O-induced cerebral vasodilation can be considerably blunted by the simultaneous administration of intravenous anesthetics, although not all anesthetics have been evaluated and the dose-response relationships are not well defined. By contrast, addition of N_2O to a volatile drug–based anesthetic can increase cerebral metabolism and blood flow modestly. N_2O has been widely used in neurosurgery, and banishing it is inconsistent with the experience accumulated. Nonetheless, in circumstances wherein ICP is persistently elevated or the surgical field is persistently "tight," N_2O should be viewed as a potential contributing factor. Because N_2O rapidly enters a closed gas space, it should be avoided or omitted when a closed intracranial gas space may exist or intravascular air is a concern.

Muscle Relaxants

Nondepolarizing Relaxants

The only recognized effect of nondepolarizing relaxants on the cerebral vasculature occurs via the release of histamine (see Chapter 29). Histamine can result in a reduction in CPP because of the simultaneous increase in ICP (caused by cerebral vasodilation) and decrease in MAP.[196] It is not entirely clear, when the BBB

is intact, whether histamine directly causes cerebral vasodilation or whether it is a secondary (autoregulatory) response to a reduction in MAP. D-Tubocurarine is the most potent histamine releaser among available muscle relaxants. Metocurine, atracurium, and mivacurium also release histamine in lesser quantities. This effect is likely to be clinically inconsequential unless these anesthetics are administered in the large doses necessary to achieve intubating conditions rapidly. Of this group of drugs, cisatracurium has the least histamine-releasing effect. No evidence of histamine release was seen after the administration of 0.15 mg/kg (three times the ED_{95} for twitch depression) of cisatracurium to neurosurgical ICU patients.[197]

Vecuronium, in relatively large doses of 0.1 to 0.14 mg/kg, had no significant effect on cerebral physiology in patients with brain tumors.[198] Pipecuronium and rocuronium have not been studied but should similarly be without direct effect, and no adverse events have been reported.

The indirect actions of relaxants may also have effects on cerebral physiology. Pancuronium given as a large bolus dose can cause an abrupt increase in arterial pressure. This might elevate ICP in patients with impaired intracranial compliance and defective autoregulation; however, no significant clinical event has ever been reported. Muscle relaxation may reduce ICP because coughing and straining are prevented, and this results in lowering of central venous pressure with a concomitant reduction in cerebral venous outflow impedance.

A metabolite of atracurium, laudanosine, may be epileptogenic. However, although large doses of atracurium caused an EEG arousal pattern in dogs, CBF, CMR, and ICP were unaltered.[199] In rabbits, administration of laudanosine did not increase the severity of the epileptoid activity caused by direct application of a cephalosporin to the cortical surface.[200] It appears highly unlikely that epileptogenesis will occur in humans with atracurium.[201]

In summary, vecuronium, pipecuronium, rocuronium, atracurium, mivacurium, cisatracurium, metocurine, and pancuronium (if acute MAP increases are prevented with the latter) are all reasonable muscle relaxants for use in patients with or at risk for intracranial hypertension. Doses of metocurine, atracurium, and mivacurium should be limited to ranges not associated with hypotension.

Succinylcholine

Succinylcholine can produce modest increases (~5 mm Hg) in ICP in lightly anesthetized humans. This effect appears to be the result of cerebral activation (as evidenced by EEG changes and increases in CBF) caused by afferent activity from the muscle spindle apparatus.[202] Note, however, that there is poor correlation between the occurrence of visible muscle fasciculations and an increase in ICP. As might be expected with what appears to be an arousal phenomenon, deep anesthesia has been observed to prevent succinylcholine-induced increases in ICP in the dog. In humans, the increase in ICP is also blocked by paralysis with vecuronium and by "defasciculation" with metocurine, 0.03 mg/kg.[198] The efficacy of other defasciculating anesthetics has not been examined in humans.

Although succinylcholine *can* produce increases in ICP, it need not be viewed as contraindicated in circumstances in which its use for rapid attainment of paralysis is otherwise seen as appropriate. Kovarik and coauthors observed no change in ICP after the administration of succinylcholine, 1 mg/kg, to 10 nonparalyzed, ventilated neurosurgical ICU patients, 6 of whom had sustained a head injury.[203] Their observations are very relevant because it is in precisely this population of patients that the issue of the use of succinylcholine arises most frequently. Given that the ICP effects of succinylcholine may be an arousal phenomenon caused by increased afferent traffic from muscle spindles,[202] it is not unreasonable that disease processes that substantially blunt the level of consciousness might similarly blunt this response. As with many anesthetics, the concern should be not whether it is used but how it is used. If administered with proper attention to control of carbon dioxide tension, blood pressure, and depth of anesthesia and after defasciculation, little hazard should attend its use.

Other Effects of Anesthetics on Cerebral Physiology

Cerebrospinal Fluid Dynamics

There is approximately 150 mL of CSF in the adult human, half within the cranium and half in the spinal CSF space. CSF, which is formed in the choroid plexuses and to a lesser extent in the brain's interstitium with transependymal diffusion into the ventricular system, is replaced about three to four times per day. It functions both as a cushion for the CNS and as an excretory pathway. Anesthetics have been shown to influence both the rate of formation and the rate of reabsorption of CSF. Table 13-3 provides nonquantitative information about the direction of the influences of common anesthetic drugs. All the information has been derived from animals,[30,204-209] and these processes have not been examined in humans. Of the volatile anesthetics, halothane decreases secretion of CSF, isoflurane has no effect, and enflurane and desflurane increase secretion. Absorption of CSF is reduced by halothane and enflurane, unchanged by desflurane, and increased by isoflurane. Though probably of minimal relevance to clinical practice, a theoretical concern might be in the setting of a prolonged closed-cranium procedure in a patient with poor intracranial compliance. The most deleterious potential combination of effects in a patient with poor intracranial compliance is increased CSF production and decreased reabsorption. In the dog this pattern occurs with enflurane, which is perhaps another reason (in addition to the potential for epileptogenesis in the presence of cerebral injury and hypocapnia) for omission of enflurane in this circumstance.

Blood-Brain Barrier

In the majority of the body's capillary beds, there are fenestrations approximately 65 Å in diameter between endothelial cells. In the brain, with the exception of the choroid plexus, the pituitary, and the area postrema, tight junctions reduce this pore size to approximately 8 Å. As a result, large molecules and most ions are prevented from entering the brain's interstitium. There is little evidence that anesthetics alter the function of this "blood-brain

barrier" in most circumstances. However, acute hypertension can breach the barrier, and certain anesthetics facilitate this phenomenon.[210] Forster and colleagues[211] observed that extravasation of Evan blue into rabbit brain was greater when acute hypertension occurred during anesthesia with halothane than with thiopental. It is likely that the effect is a nonspecific result of cerebral vasodilation rather than a specific effect of halothane. These results were obtained in the setting of extreme, abrupt hypertension in animals with an initially normal BBB. To our knowledge, no peer-reviewed investigation has attempted a comparison of anesthetic effects on BBB function during anesthesia in normotensive humans.

Epileptogenesis

An extensive review of the convulsant and anticonvulsant effects of anesthetics and adjuvants is available.[212,213] Several commonly used anesthetics have some epileptogenic potential, particularly in predisposed individuals. A concern is that seizure activity may go unrecognized in an anesthetized and paralyzed patient and result in neuronal injury if substrate demand (CMR) exceeds supply for a prolonged period.[214] A second concern is that the epileptogenic effect will persist in the postanesthesia period when seizures may occur in less well controlled circumstances than exist in the operating room. In practice, it appears that spontaneous seizures during or after anesthesia have been extremely rare events. Nonetheless, in patients with processes that might predispose to seizures, it seems prudent to avoid the use of potentially epileptogenic drugs in situations in which there are reasonable alternatives.

Volatile Anesthetics

Enflurane is potentially epileptogenic in the clinical setting. Of particular relevance to neuroanesthesia is the observation that hypocapnia potentiates seizure-type discharges during enflurane anesthesia.[215] A 50% decrease in $CMRO_2$ was noted in human volunteers anesthetized with 3% enflurane, but with the onset of seizure activity, $CMRO_2$ returned to normal,[216] thus indicating preservation of flow-metabolism coupling. Note that there is no evidence that this type of EEG activity is deleterious when oxygen delivery is maintained during the event. However, because seizure activity can elevate brain metabolism by as much as 400%, the use of enflurane, especially at high doses and with hypocapnia, should probably be avoided in patients predisposed to seizures or with occlusive cerebrovascular disease.

The EEG-activating property of enflurane has been used intraoperatively to activate and identify seizure foci that are to be surgically resected, and in this situation spike activity not present preoperatively has been observed to persist after surgery.[217] There have also been two reports of seizures in the immediate postoperative period after enflurane anesthesia in both predisposed[218] and non-predisposed individuals.[219] No permanent sequelae appeared to occur as a result of these events, and in fact, this association is not a rigorously proven one. At worst, such occurrences are extremely uncommon.

Isoflurane can cause EEG spiking and myoclonus, but in the experimental setting it has not been associated with the frank epileptoid activity induced by enflurane. The clinical experience with isoflurane is very large, and unexplained "seizure-like activity" has been reported in only two patients. One occurrence was intraoperative[220] and the other immediately postoperative.[221] It therefore appears that epileptogenesis is not a clinical concern with isoflurane. In fact, isoflurane has been successfully used to control EEG seizure activity in refractory status epilepticus.[222]

Seizures occur during induction of anesthesia with high concentrations of sevoflurane in children, including those without a recognized seizure diathesis.[223] In two healthy human subjects, EEG burst suppression with 2 MAC sevoflurane was accompanied by epileptiform discharges that were observed during EEG monitoring.[224] These discharges were associated with a significant increase in CBF, thus demonstrating that flow-metabolism coupling was preserved. In patients with temporal lobe epilepsy, administration of 1.5 MAC sevoflurane elicited widespread paroxysmal interictal EEG activity. Of note was the observation that paroxysmal activity was not restricted to the ictal focus and that the administration of sevoflurane was not of any assistance in localization of the epileptogenic region of the brain.[225] The development of tonic-clonic movements indicative of seizure activity has also been reported in otherwise healthy patients on emergence from sevoflurane anesthesia.[226,227] In all of the reported cases of seizure activity attributable to sevoflurane anesthesia, untoward sequelae have not been documented. These reports highlight sevoflurane's ability, albeit small, to evoke epileptiform activity, and accordingly, the use of sevoflurane in patients with epilepsy should be undertaken with appropriate caution.

Methohexital

Myoclonic activity is sometimes observed with methohexital, and this agent has been used to activate seizure foci during cortical mapping.[224,228] In neurosurgical patients to whom larger doses of methohexital were administered to produce burst suppression of the EEG, refractory seizures have occurred.[229] Accordingly, it appears that patients with seizures of temporal lobe origin, typically of the psychomotor variety, or those to whom high doses are administered are at risk for seizure activation by methohexital. However, it should be noted that prolonged seizure activity after single-dose methohexital administration has not been reported in patients who undergo ECT.

Ketamine

Ketamine can elicit seizures in patients with an epileptic diathesis.[230] Depth electrode recordings in epileptic patients have revealed the occurrence of isolated subcortical seizure activity originating in the limbic and thalamic areas during ketamine anesthesia and demonstrated that this subcortical activation may not be reflected in surface EEG recordings.[231] Seizures have also been reported to occur after ketamine anesthesia in neurologically normal subjects on only two occasions,[232,233] and in one of these instances seizure thresholds may have been lowered by aminophylline.

Etomidate

Etomidate frequently produces myoclonus that is not associated with epileptiform activity on the EEG.[234] A single instance of severe, sustained myoclonus immediately after anesthesia with etomidate by infusion has been reported.[235] Etomidate has also been shown to precipitate generalized epileptic EEG activity in epileptic patients,[236] and its use in this population should probably be avoided. However, it has been used electively, in low doses, to activate seizure foci for the purposes of intraoperative EEG

localization.[237] In our experience (unpublished), selective activation of a quiescent focus can be achieved with 0.1 mg/kg. Larger doses are more likely to lead to generalized activation.

Etomidate is also associated with longer seizures in response to ECT than occur after methohexital or propofol. Remarkably, etomidate, in the dose range of 0.15 to 0.3 mg/kg, does not cause dose-related seizure inhibition during ECT as is readily demonstrated with the other two drugs.

The preceding information not withstanding, there are no convincing reports to indicate epileptogenesis in normal subjects, and use of etomidate need not be restricted on this basis. In fact, it has been used to control refractory status epilepticus.

Propofol

Seizures and opisthotonos have been reported to occur after propofol anesthesia. However, systematic studies in both humans[238] and animals,[239] though identifying the occurrence of occasional dystonic and choreiform movements, have failed to confirm the notion that propofol is proconvulsant. In fact, propofol appears to be anticonvulsant in mice.[239] Furthermore, ECT seizures were shorter after induction with propofol than after induction with methohexital,[240] which is more consistent with an *anticonvulsant* effect. In addition, propofol sedation has been widely used during "awake" resection of seizure foci and other intracranial lesions. Although pronounced high-amplitude β-frequency activity in the EEG has been observed,[241] there has not been an unexpected incidence of seizures.

Narcotics

Seizures or limbic system hypermetabolism (or both) can be readily elicited in some animal species with narcotics. Although an increase in CBF in deep brain structures associated with pain processing has been observed in human volunteers,[69] humans do not have a clinically apparent correlate of the hypermetabolism effect seen in animals. Several anecdotal accounts, unaccompanied by EEG recordings, have reported the occurrence of grand mal convulsions in patients who received both high and low doses of fentanyl. However, systematic investigations of EEG changes during the administration of relatively large doses of fentanyl, sufentanil, and alfentanil in humans have *not* documented neuroexcitatory activity,[242-244] and the "seizures" may have been an exaggerated rigidity phenomenon. There are exceptions. Tempelhoff and coauthors reported on induction of anesthesia with fentanyl for secondary craniotomy and anterior temporal lobectomy in patients with partial complex seizures. Eight of the nine patients displayed electrical seizure activity at a range of clinically relevant fentanyl doses (mean, 26 μg/kg).[245] Another study found that alfentanil, 50 μg/kg, augmented temporal lobe spike activity in patients with temporal lobe epilepsy.[246] Note that untreated rigidity may itself also have important CNS consequences. ICP elevation can occur during narcotic-induced rigidity, probably as a consequence of cerebral venous congestion.

Atracurium

See discussion regarding the atracurium metabolite laudanosine in the section on nondepolarizing muscle relaxants.

Neonatal Anesthetic Neurotoxicity

This subject is covered in detail in Chapter 82.

Cerebral Physiology in Pathologic States

Cerebral Ischemia—Pathophysiology

Critical Cerebral Blood Flow Thresholds

The brain has a high rate of energy utilization and very limited energy storage capacity. It is therefore extremely vulnerable in the event of interruption of substrate (oxygen, glucose) supply. Under normal circumstances, global CBF is maintained at approximately 50 mL/100 g/min. In the face of a declining CBF and therefore oxygen supply, neuronal function deteriorates progressively rather than in an all-or-none fashion (Fig. 13-14). There is a substantial reserve below normal CBF levels, and it is not until CBF has fallen to approximately 20 mL/100 g/min that EEG evidence of ischemia begins to appear. At a CBF level of approximately 15 mL/100 g/min, the cortical EEG is isoelectric. However, only when CBF is reduced to about 6 mL/100 g/min are indications of potentially irreversible membrane failure (elevated extracellular potassium[247] and loss of the direct cortical response) rapidly evident. As CBF decreases in the flow range between 15 and 10 mL/100 g/min, a progressive deterioration in energy supply occurs and eventually leads, with a time course that may last hours rather than minutes, to membrane failure and neuronal death. The brain regions falling within this CBF range (6 to 15 mL/100 g/min) encompass brain tissue in which neuronal dysfunction is temporarily reversible but within which neuronal death will occur if flow is not restored; such regions are referred to as the ischemic penumbra.[247,251] Studies defining progression to cerebral infarction within the penumbra have been performed principally in the cerebral cortex of primates, and the actual CBF levels at which the various decrements in function occur may vary with both anesthetic[250] and species. However, in humans anesthetized with halothane and

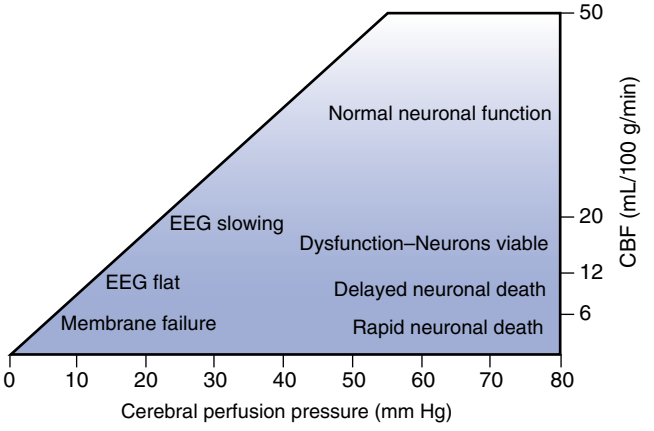

Figure 13-14 Relationships between cerebral perfusion, cerebral blood flow (CBF), the electroencephalogram (EEG), and the functional status/viability of neurons. Note that in the approximate CBF range of 6 to 12 mL/kg/min, the energy supply is insufficient to support electrophysiologic activity (i.e., EEG flat) but can prevent complete membrane failure and neuronal death for extended periods (see Fig. 13-15). These areas are referred to as the ischemic penumbra.[247] The data are derived from studies on the cerebral cortex of barbiturate-anesthetized baboons[247,248] and unanesthetized monkeys.[249] The CBF and mean arterial pressure thresholds may vary with anesthetic and species.[250]

N_2O, the CBF threshold for the initial EEG change[252] is similar to that observed in the animal investigations.

Models of Cerebral Ischemia

Much has been made of the difference between complete cerebral ischemia, as occurs during cardiac arrest, and incomplete cerebral ischemia, as may occur during occlusion of a major cerebral vessel or severe hypotension. However, from the clinician's vantage, the important difference is that the residual blood flow during incomplete ischemia may result in enough delivery of oxygen to allow some generation of ATP and thereby stave off the catastrophic irreversible membrane failure that occurs within minutes during normothermic complete cerebral ischemia. This difference in the rate of failure of the energy supply[253,254] (Fig. 13-15) can result in much greater apparent tolerance for focal or incomplete ischemia than for complete global ischemia (e.g., cardiac arrest).

Energy Failure and Excitotoxicity

Energy failure is the central event that occurs during cerebral ischemia.[255] ATP is required for maintenance of the normal membrane ionic gradient, and energy failure is rapidly attended by membrane depolarization and influx of sodium and calcium into the neuron. Voltage-dependent calcium channels are then activated and calcium gains entry into the cytosol. Depolarization of presynaptic terminals also results in the release of massive quantities of excitatory neurotransmitters, particularly glutamate, into the synaptic cleft. Activation of glutamatergic receptors, the NMDA and α-amino-3-hydroxy-5-methyl-4-isoxazopropionic acid (AMPA) receptors, adds to the influx of Na^+ and Ca^{2+} (Fig. 13-16). Initiation of cellular signaling by activation of metabotropic receptors leads to the release of stored Ca^{2+} from the endoplasmic reticulum via inositol 1,4,5-triphosphate (IP_3) receptors. Ionic influx is accompanied by influx of water, and neuronal swelling occurs rapidly after membrane depolarization. The injury that is initiated by excessive glutamate receptor activity is referred to as excitotoxicity.

Calcium is a ubiquitous second messenger in cells, and it is a cofactor required for the activation of a number of enzyme systems. The rapid, uncontrolled increase in cytosolic Ca^{2+} levels initiates the activation of a number of cellular processes that contribute to injury. Cytoskeletal proteins such as actin are cleaved

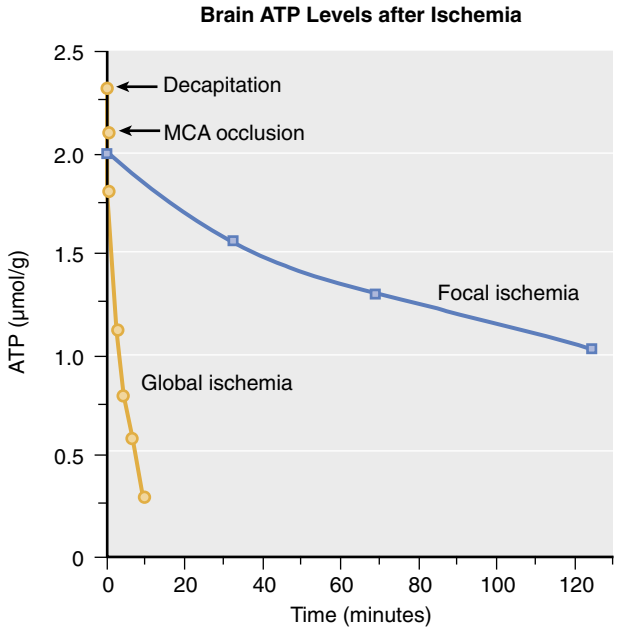

Figure 13-15 Comparison of rates of failure of energy supply (adenosine triphosphate) in complete global ischemia (produced by decapitation in dogs[254]) and in incomplete focal ischemia (middle cerebral artery [MCA] occlusion in monkeys[253]). In the presence of residual CBF, energy supply failure is substantially delayed.

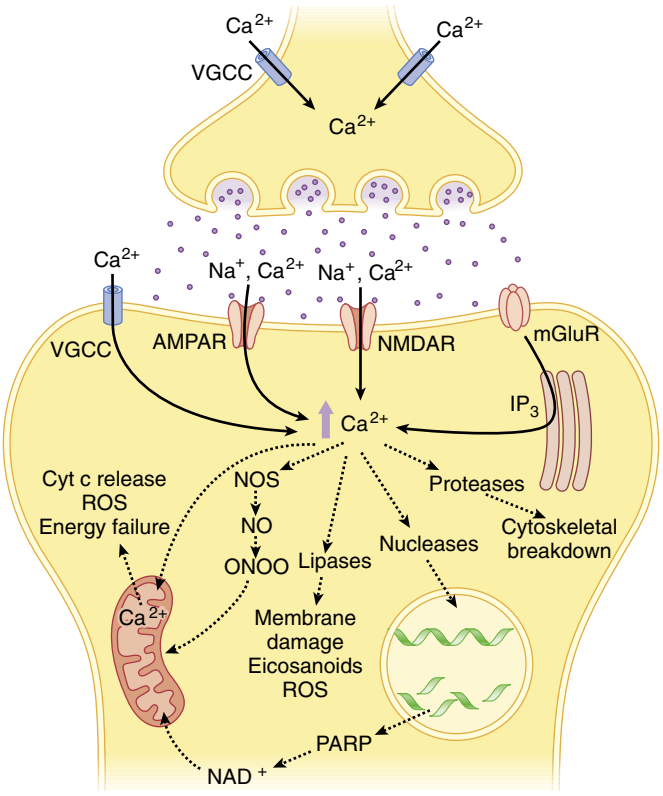

Figure 13-16 During ischemia, depletion of adenosine triphosphate leads to neuronal depolarization and the subsequent release of supranormal quantities of neurotransmitters, especially glutamate. Excessive stimulation of ligand-gated channels and the simultaneous opening of voltage-dependent Ca^{2+} channels permit rapid entry of Ca^{2+} into neurons. Stimulation of metabotropic glutamate receptors generates inositol 1,4,5-triphosphate (IP_3), which causes release of Ca^{2+} from the endoplasmic reticulum (ER)/mitochondria. Activation of the α-amino-3-hydroxy-5-methyl-4-isoxazopropionic acid receptor (AMPAR)-gated subset of glutamate receptors also permits excessive entry of sodium (Na^+). Excessive free Ca^{2+} results in activation of numerous enzymes: protease activation causes breakdown of the cytoskeleton of the neuron; lipases damage plasma membrane lipids and release arachidonic acid, which is metabolized by cyclooxygenases and lipooxygenases to yield free radicals and other mediators of cell injury; activation of nitric oxide synthase (NOS) leads to release of nitric oxide (NO) and, in turn, the generation of peroxynitrite (ONOO), a highly reactive free radical; and activated endonucleases damage DNA, thereby rendering the neuron susceptible to apoptosis. Injury to mitochondria leads to energy failure, generation of free radicals, and release of cytochrome *c* (Cyt c) from the mitochondria; the latter is one of the means by which neuronal apoptosis is initiated. mGluR, metabotropic glutamate receptor; NAD^+, oxidized form of nicotinamide adenine dinucleotide; NMDAR, *N*-methyl-D-aspartate receptor; PARP, poly-ADP-ribose polymerase; ROS, reactive oxygen species; VGCC, voltage-gated calcium channels.

by activated proteases. These enzymes also degrade a number of the protein constituents of the neuron. Lipases attack cellular lipids and produce membrane damage. An important lipase, phospholipase A_2, releases fatty acids such as arachidonic acid from membranes. Metabolism of arachidonic acid to prostaglandins and leukotrienes by cyclooxygenase and lipoxygenase is accompanied by the generation of superoxide free radicals. The latter, in combination with other free radicals generated in response to mitochondrial injury, can lead to lipid peroxidation and membrane injury. Prostaglandins and leukotrienes also evoke an inflammatory response and are powerful chemotactic drugs. Activation of platelets within cerebral microvessels, as well as influx of white blood cells into damaged areas, aggravates ischemic injury by occluding the vasculature.

DNA damage is also an important event during ischemic neuronal injury. Generation of free radicals from arachidonic acid metabolism, from injured mitochondria, and from the production of peroxynitrite from NO leads to oxidative injury to DNA. Activation of endonucleases also produces DNA strand breaks. Under normal circumstances, DNA injury results in the activation of poly-ADP-ribose polymerase (PARP), an enzyme that participates in DNA repair. With excessive DNA injury, PARP activity increases dramatically, and this can lead to the depletion of nicotinamide adenine dinucleotide (NAD), a substrate of PARP. NAD is also an important coenzyme in energy metabolism, and its depletion further exacerbates energy failure.

Lactate formation is an additional element of the pathophysiologic process. Lactic acid is formed as a result of the anaerobic glycolysis that takes place after failure of the supply of oxygen. The associated decline in pH contributes to deterioration of the intracellular environment. An increased preischemic serum glucose level may accelerate this process by providing additional substrate for anaerobic glycolysis.

NO, which has emerged as a probable mediator of CBF changes in many normal physiologic states (see the preceding sections), is also of relevance to the pathophysiology of ischemia. NO is, in fact, a weak free radical that in turn leads to the generation of a more reactive species (peroxynitrite), and it is a "killer substance" used by macrophages. In cerebral ischemia, NO is probably both friend and foe. It is likely that during a period of focal ischemia, the vasodilating effect of NO (probably constitutively elaborated NO of endothelial origin) serves to augment collateral CBF. However, in the postischemic phase, NO (probably derived from neurons or macrophages) contributes to neuronal injury.

Collectively, the simultaneous and unregulated activation of a number of cellular pathways overwhelms the reparative and restorative processes within the neuron and ultimately leads to neuronal death.

Nature of Neuronal Death

Neuronal death that occurs in response to these processes has been categorized as necrotic or apoptotic in nature (see Chapter 98). Necrotic death of neurons, mediated by excitotoxic injury, is characterized by rapid cellular swelling, condensation and pyknosis of the nucleus, and swelling of the mitochondria and endoplasmic reticulum. A characteristic of these necrotic neurons is the presence of acidophilic cytoplasm.[256] Necrotic neuronal death results in local infiltration of the brain by inflammatory cells. A consequence of this inflammation is a considerable amount of collateral damage.

Neuronal apoptosis, a form of cellular suicide, has also been demonstrated in a variety of models of cerebral ischemia. Apoptosis is characterized by chromatin condensation, involution of the cell membrane, swelling of mitochondria, and cellular shrinkage. In the later stages of apoptosis, neurons fragment into several apoptotic bodies, which are then cleared from the brain.[256] The lack of a substantial inflammatory response to apoptotic death limits injury to surrounding neurons that have survived the initial ischemic insult.

A number of biochemical pathways that lead to apoptosis have been described. Initiation of apoptosis by the release of cytochrome *c* from injured mitochondria has been studied the most (Fig. 13-17). Cytochrome *c* is restricted from the cytoplasm by the outer mitochondrial membrane.[257] When mitochondria are injured, pores within the outer membrane allow cytochrome *c* to be released into the cytoplasm, where it interacts with procaspase-9 and apoptosis-activating factor (APAF) to produce an apoptosome. Procaspase-9 undergoes activation by proteolytic cleavage. Activated caspase-9 then activates caspase-3. The latter serves as an executor of apoptosis by cleaving a number of protein substrates that are essential in DNA repair (such as PARP). Activation of caspase-3 can also occur by inflammatory signaling via tumor necrosis factor-α (TNF-α) and activation of caspase-8.[258] It should be noted that the neuronal injury that occurs in response to ischemia cannot easily be divided into necrosis or apoptosis. The

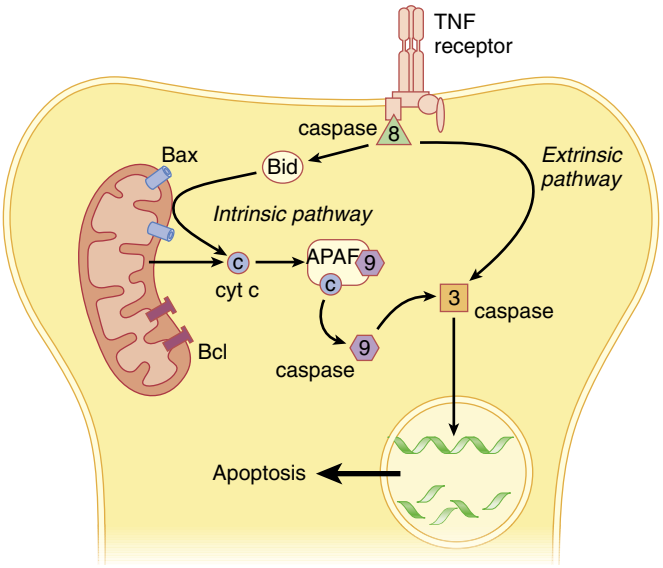

Figure 13-17 Cellular processes that lead to neuronal apoptosis. Cytochrome *c* (cyt c), which is normally restricted to the space between the inner and outer mitochondrial membranes, is released in response to mitochondrial injury. Cytochrome *c*, in combination with apoptosis-activating factor (APAF), activates caspase-9 by proteolytic cleavage. Activated caspase-9 then leads to activation of caspase-3. This enzyme cleaves a number of substrates, including those necessary for DNA repair. Within the mitochondria, Bax augments and Bcl prevents the release of cytochrome *c*. Release of cytochrome *c* can also be initiated by Bid, a substance that is activated by caspase-8 via tumor necrosis factor (TNF) signaling. In addition, caspase-8 can directly activate caspase-3. Excessive activation of poly-ADP-ribose polymerase (PARP), an enzyme integral to DNA repair, depletes cellular stores of oxidized nicotinamide adenine dinucleotide (NAD^+). Depletion of NAD^+ further exacerbates the energy failure because of its critical role in energy metabolism.

nature of neuronal death probably encompasses a spectrum in which some neurons undergo necrosis or apoptosis whereas others undergo cell death that has features of both necrosis and apoptosis.

Timing of Neuronal Death

The traditional concept of ischemic injury was that neuronal death was restricted to the time of ischemia and during the early reperfusion period. However, more recent data indicate that postischemic neuronal injury is a dynamic process in which neurons continue to die for a long period after the initiating ischemic insult (Fig. 13-18).[259] This delayed neuronal death, which was first demonstrated in models of global cerebral ischemia, has been demonstrated during focal ischemia as well. The extent of delayed neuronal death depends on the severity of the ischemic insult. With severe ischemia, most neurons undergo rapid death. With more moderate insults, neurons that survive the initial insult undergo delayed death. This ongoing neuronal loss contributes to the gradual expansion of cerebral infarction after focal ischemia. In experimental studies, evidence of cerebral inflammation, which can theoretically contribute to further injury, has been demonstrated even 6 to 8 months after the primary ischemia.

The occurrence of delayed neuronal death has important implications for the evaluation of studies in which neuroprotective strategies are being investigated. A wide variety of interventions have shown neuroprotective efficacy in studies in which the extent of injury is evaluated within 3 to 4 days after ischemia. However, this neuroprotective efficacy may not be sustained. Recent data indicate that cerebral infarction undergoes gradual expansion and that a reduction in injury attributed to a particular therapeutic intervention is no longer apparent when the injury is evaluated after a long postischemic recovery period.[259] Long-term (>1 month) evaluation of the efficacy of a particular intervention is therefore important.

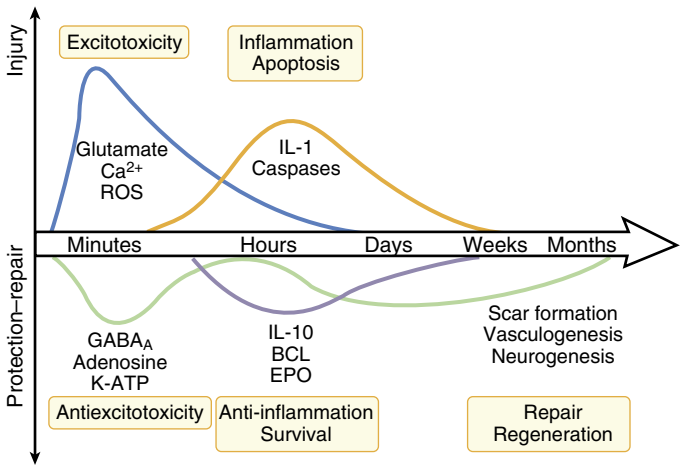

Figure 13-18 Time course of neuronal death. Excitotoxic (glutamate-mediated) injury results in neuronal death within the first few hours after the onset of ischemia. Brain tissue injury elicits an inflammatory response, an important process in removal of injured tissue and in healing, that leads to a substantial amount of collateral damage. Inflammation-mediated neuronal death can continue for several days. Neuronal apoptosis can occur in injured neurons that survived the initial insult. Apoptotic neuronal death has been demonstrated to occur for many days after the initiating ischemic insult. It is now apparent that ischemic neuronal death is a dynamic process in which neurons continue to die for a long period. *(Adapted from Dirnagl U, Iadecola C, Moskowitz M: Pathobiology of ischaemic stroke: An integrated view. Trends Neurosci 22:391-397, 1999.)*

Brain Protection

The literature on cerebral ischemia and brain protection is vast, and a detailed discourse on this topic is beyond the scope of the present discussion. A number of excellent recent reviews on the subject are available.[256,260-262]

Considerations Relevant to Complete Global Ischemia (Cardiac Arrest)

Maintenance of adequate perfusion pressure after cardiac arrest is of considerable importance. Hypotension developing after resuscitation from cardiac arrest may aggravate the microcirculatory and vasospastic processes occurring at this time and increase brain damage. A late phase of intracranial hypertension may occur and is due to the development of extensive cerebral edema, probably both vasogenic and cytotoxic in etiology, associated with brain necrosis. Attempts to control this type of intracranial hypertension with osmotherapy usually fail. ICP monitoring is not generally used because the patients in whom these delayed increases in ICP develop have sustained massive tissue damage.

Both barbiturates and calcium channel blockers have been administered after cardiac arrest. The former are ineffective.[263] In a small cohort (51 patients) of cardiac arrest victims, nimodipine was shown to improve CBF but not neurologic outcome.[264] In a second trial in approximately 150 cardiac arrest victims, no overall benefit in neurologic outcome was observed.[265] However, a subset of patients in whom initiation of advanced life support was delayed for more than 10 minutes demonstrated improved survival. This single study cannot serve as justification for the administration of nimodipine after cardiac arrest, especially in the face of the unequivocally negative results of the multicenter lidoflazine cardiac arrest study.[266] Once again, the important therapeutic objectives are maintenance of normocapnia and normotension, normalization of systemic pH, avoidance of hyperthermia, and prevention and treatment of seizures.

Induced mild hypothermia is effective in reducing mortality and morbidity in patients who sustain a cardiac arrest.[267] Induction of mild hypothermia in the range of 32°C to 34°C for a period of about 24 hours improved neurologic outcome and survival 6 months after cardiac arrest in comparison to a normothermic group. Mild hypothermia was induced without difficulty. Passive rewarming of patients was accomplished slowly over a period of 8 hours. The incidence of complications was similar to that in the control normothermic group. This important study is one of the first to demonstrate the feasibility and efficacy of induced hypothermia as a treatment to prevent injury from global ischemia. Undoubtedly, induced hypothermia will now be added to the armamentarium for the treatment of cerebral complications of cardiac arrest.

Considerations Relevant to Focal (Incomplete) Ischemia

Before discussing individual anesthetics, it should be noted that a general theme that can be extracted from the protection-by-anesthetics literature, in particular for anesthesia with volatile anesthetics, is that anesthesia per se is protective. It appears that for undefined reasons, reducing the level of systemic stress associated with a standardized experimental insult results in an

improved outcome.[268,269] In reviewing the protection-by-anesthetics literature, readers should be conscious of the possibility that the protective benefit ascribed to an intervention with an anesthetic drug may in fact be the product of exaggeration of the injury in a high-stress control state, such as N_2O "sedation."

Barbiturates. There have been numerous demonstrations of the protective efficacy of barbiturates in focal cerebral ischemia in animals[270-272] and a single demonstration of effectiveness in a human.[273] The effect has been attributed principally to suppression of CMR. However, the effects of CBF redistribution and free radical scavenging[274] have been suggested to contribute, and there is evidence that CMR suppression is not the sole mechanism.[275] Suppression of CMR might logically be expected to be of benefit to brain regions in which oxygen delivery is inadequate to meet normal demands but is sufficient to allow energy consumption by some on-going electrophysiologic activity (i.e., in which the EEG was abnormal but not flat). Such regions are likely to be limited in size in the setting of focal ischemia, yet several of the animal investigations suggest a very substantial protective effect.[270,271] Review of these experiments reveals that the methods used to monitor and maintain temperature, though accepted at the time, were below the standards that have evolved from more recent understanding of the effects of both deliberate[276,277] and inadvertent hypothermia. Unrecognized cerebral hypothermia may well have been a factor in some of the cited investigations, and it is therefore possible that the protective efficacy of barbiturates may have been overestimated. Although more recent publications involving suitable temperature control methods do in fact indicate a protective effect by barbiturates,[275,278,279] the magnitude of that effect was modest when compared with the results of earlier studies. Barbiturate-induced EEG suppression in an already anesthetized patient may still be logical therapy when it can be applied before or early in the course of a period of temporary focal ischemia (e.g., temporary occlusion during aneurysm surgery). However, the decision to institute such therapy should be made only after consideration of the risk of the occlusive event, the patient's cardiovascular status, and the physician's willingness to accept the possible prolongation of arousal, together with an objective view of the probable magnitude of the protective effect.

Numerous investigations in animals and humans have failed to demonstrate any protective effect of barbiturates in the setting of global cerebral ischemia (e.g., cardiac arrest).[263]

Because CMR suppression has been the presumed mechanism of effect, barbiturates have traditionally been administered to produce maximal reduction of CMR (which is nearly complete when EEG burst suppression has been achieved). However, data presented by Warner and colleagues[275] demonstrated that the same protective benefit (expressed as reduction of infarct volume) could be achieved with a third of the burst-suppression dose. This raises a clinically important issue. The various barbiturates (thiopental, thiamylal, methohexital, pentobarbital) have similar effects on CMR and have generally been assumed to have equal protective efficacy. However, if the mechanism of protection is a pharmacologic effect other than reduction in CMR, is it reasonable to assume equivalence among the barbiturates? Recent data suggest that the neuroprotective efficacy of barbiturates is not similar. In a direct comparison of three clinically used barbiturates, methohexital and thiopental, but not pentobarbital, reduced injury in an animal model of focal ischemia.[280] These data suggest that mechanisms other than or at least in addition to metabolic suppression may contribute to the protective effect of barbiturates.

Volatile Anesthetics. Isoflurane is also a potent suppressant of CMR in the cerebral cortex, and EEG evidence suggestive of a protective effect in humans has been reported.[250] In comparison to the awake or N_2O-fentanyl–anesthetized state, isoflurane is neuroprotective in models of hemispheric,[281] focal,[282] and nearly complete ischemia.[283,284] Of interest is the recent observation that isoflurane's neuroprotective efficacy is not sustained.[285] When injury is evaluated 2 days after ischemia, a robust reduction in injury is observed with isoflurane anesthesia. However, by 14 days this reduction in injury was not apparent. These data indicate that neuronal injury continues well into the postischemic recovery period and that the neuroprotection that is evident shortly after ischemia may not persist for the long term. More recent data have shown that long-term neuroprotection with isoflurane is achievable under conditions in which the severity of ischemia is limited and restoration of blood flow after ischemia is complete.[286] The neuroprotective effect of isoflurane is not substantially different from that of other volatile anesthetics. Sevoflurane reduces ischemic injury in animal models of focal[287] and hemispheric ischemia[288]; its efficacy is not different from that of halothane. Desflurane also reduces neuronal injury to the same extent that isoflurane does.[289] The available data therefore suggest that adequate anesthesia per se may have a protective effect[268,269] versus the awake state, but there does not appear to be any difference in neuroprotective efficacy among the volatile anesthetics.

Xenon. The inert gas xenon exerts its anesthetic action by noncompetitive blockade of NMDA receptors. As such, it is logical to suspect that it might provide neuroprotection against excitotoxic injury. The neuroprotective efficacy of xenon has been demonstrated against oxygen-glucose deprivation in vitro,[290] focal ischemia in vivo in mice,[291] and cardiopulmonary bypass–induced cognitive dysfunction in rats.[292] Of interest are observations that simultaneous administration of *subanesthetic* doses of xenon in combination with either hypothermia[293] or isoflurane[294] significantly reduces neuronal injury and improves neurologic function in a neonatal rodent model of hypoxia-ischemia; this protective effect was apparent as late as 30 days after injury. Moreover, administration of xenon has been shown to have a preconditioning effect on the brain[295]; previous exposure reduces the vulnerability of the brain to ischemic injury. Anesthetic drugs that have activity at NMDA receptors (ketamine) and γ-aminobutyric acid type A ($GABA_A$) receptors (volatile anesthetics, barbiturates, benzodiazepines, propofol) have been shown to cause neuronal injury in rodent neonatal pups during the critical period of synaptogenesis.[296] Although xenon has antagonist activity at NMDA receptors, the evidence to date suggests that it does not lead to apoptosis in the developing brain.[297] Note should be made, however, that long-term neuroprotection with xenon has not yet been demonstrated in adult experimental subjects. The specific use of xenon for the purpose of neuroprotection awaits results from outcome studies in humans.

Propofol. EEG suppression can also be achieved with clinically feasible doses of propofol. Anecdotal information suggests that it is being used to provide "protection" during both aneurysm surgery[298] and carotid endarterectomy. In experimental models of cerebral ischemia, the extent of neurologic injury in propofol-anesthetized animals was similar to that in halothane-anesthetized animals.[299] Given the previous demonstration that

halothane can reduce injury, these data provide indirect evidence of propofol's neuroprotective efficacy. In a more recent investigation, cerebral infarction was significantly reduced in propofol-anesthetized animals in comparison to awake animals.[300] Direct comparison of propofol to pentobarbital has also demonstrated that cerebral injury after focal ischemia is similar in animals anesthetized with the two drugs.[301] Similar to the situation with volatile anesthetics, initial investigations revealed that propofol protection is not sustained.[302] Durable protection with propofol is achievable if the severity of the ischemic insult is mild.[303] Collectively, these data are consistent with the premise that propofol can reduce ischemic cerebral injury.

Etomidate. Etomidate was proposed as a potential protective anesthetic in the setting of aneurysm surgery.[304] It too produces CMR suppression to an extent equivalent to barbiturates, and like the barbiturates, etomidate is an agonist at the (inhibitory) $GABA_A$ receptor. To the contrary, in an experimental model of focal ischemia, the volume of injury was not reduced by etomidate relative to a 1.2 MAC halothane-anesthetized control group. In fact, the volume of injury with etomidate was significantly larger than that in the control group. In patients subjected to temporary intracranial vessel occlusion, administration of etomidate results in greater tissue hypoxia and acidosis than equivalent desflurane anesthesia does. The aggravation of injury produced by etomidate (an imidazole) may be related to direct binding of NO as a consequence of etomidate-induced hemolysis[305] combined with direct inhibition of the NO synthase enzyme by etomidate. Therefore, there is no scientific support for the current use of etomidate for "cerebral protection."

Calcium Channel Blockers. It is now established clinical practice to administer nimodipine orally (the intravenous preparation is not approved for clinical use in North America) for 21 days beginning as soon as possible after subarachnoid hemorrhage.[306] However, it has not yet become standard practice to administer nimodipine or any other calcium channel blocker routinely after neurologic stroke occurring in the operating room or in any other environment. Despite favorable results in small trials, not all investigations in stroke victims have confirmed the benefits of nimodipine.[307]

Other Anesthetics. A remarkable number of anesthetics have shown neuroprotective efficacy in animal studies. However, to date, large-scale randomized trials of a variety of anesthetics in patients with stroke have not demonstrated neuroprotection for any drug. With the exception of tissue plasminogen activator (tPA) for thrombolysis and the calcium channel blockers nimodipine and nicardipine for the management of subarachnoid hemorrhage, pharmacologic neuroprotective anesthetics are not available for the treatment of patients with cerebral ischemia. Details about drugs that have undergone clinical trials and those that are currently being investigated in humans can be found at the Stroke Trials Registry (www.strokecenter.org/trials/TrialDetail.aspx?tid=338) of Washington University, St. Louis, MO.

Cerebral Ischemia: Influence of Physiologic Variables

Cerebral Perfusion Pressure. Measures designed to augment CBF (an important determinant of energy supply) are also important. In the "ischemic penumbra" (described earlier), small improvements in CBF have the potential to prolong neuronal survival substantially. Maintenance of high-normal CPP can augment collateral perfusion pressure and maintain CBF[308] and has been shown to result in improvement in various neurophysiologic parameters, including neurologic function.[309,310] By contrast, hypotension can reduce CBF and exacerbate injury. In trials of nimodipine in patients with acute stroke, a reduction in blood pressure of 10% to 20% increased the probability of an adverse outcome (either death or dependency) fourfold,[311] thus emphasizing the adverse impact of blood pressure reduction on an injured brain. Therefore, in patients with cerebral ischemia, hypotension should be treated promptly and normotension restored. Although it is quite obvious that the target MAP should be based on knowledge of a patient's preexisting blood pressure, there are insufficient data in humans to provide specific guidelines. In the majority of patients, maintenance of MAP in the 70– to 80–mm Hg range should be adequate. The available data provide support for reducing blood pressure to less than 180/105 mm Hg in patients with stroke who have been treated with tPA in the hope of reducing the incidence of hemorrhage into the ischemic brain.[312] In addition, blood pressure augmentation to a systolic pressure of 180 to 220 mm Hg in patients with subarachnoid hemorrhage–induced vasospasm and to a CPP of greater than 60 mm Hg in patients with traumatic brain injury is reasonable.[312] Note, however, that augmentation of CPP in the high-normal range carries the inadequately explored risks of increased edema and hemorrhagic infarction if used as support during more than brief periods of ischemia, particularly when several hours has elapsed since the onset of ischemia.

Carbon Dioxide Tension. Hypercapnia has the potential to cause intracerebral steal and may worsen intracellular pH. Despite some support for the occurrence of a favorable so-called Robin Hood or inverse steal,[313] hypocapnia has not generally proved effective in either laboratory or clinical settings.[314-316] Pending further information and in the absence of a means of verifying the perfusion response to manipulation of $Paco_2$, normocapnia remains standard practice.

Temperature. Hypothermia is firmly and justifiably established as the principal cerebral protective technique for circulatory arrest procedures (see Chapter 48). It unequivocally enhances cerebral tolerance for episodes of ischemia. For deep hypothermia, this effect has been presumed to be largely a function of the reduction in CMR. Although pharmacologic drugs such as barbiturates reduce only the component of CMR associated with electrophysiologic "work" (about 60% of $CMRO_2$ in the awake state), hypothermia causes a reduction in both electrophysiologic energy consumption and the energy utilization related to maintenance of cellular integrity, and mild hypothermia may preferentially suppress the latter.[317,318] Recently, there has been a surge of interest in *mild* hypothermia as a cerebral protective technique. A substantial number of laboratory studies have demonstrated that mild degrees of hypothermia (2°C to 4°C) during an episode of ischemia can confer substantial protection as measured histologically.[276,277] In addition, there is also evidence from animal studies that hypothermia initiated in the immediate postischemic period confers a protective benefit.[319,320]

In light of this dramatic protective effect of mild hypothermia, its use in the operating room setting has been advocated. Proponents of its use argue that hypothermia is readily achieved and not accompanied by significant myocardial depression or arrhythmias. In addition, the patient can easily be rewarmed in the operating room after the risk of ischemia has subsided. Results of a pilot study clearly demonstrated a trend toward improved

neurologic outcome in hypothermic patients undergoing intracranial aneurysm clipping.[321] Unfortunately, the subsequent definitive trial did not demonstrate any improvement in outcome that could be attributable to hypothermia.[322] However, it should be noted that the majority of the patients in that study had subarachnoid hemorrhage of grades I, II, and III. In addition, the number of patients who had temporary clips applied in excess of 20 minutes was quite small (five to six patients). Consequently, an argument has been made that mild hypothermia may well be of benefit in patients with high-grade aneurysms or in those in whom the complexity of the aneurysm clipping is such that prolonged temporary clipping may be required. Given that temperature reduction takes some time, the decision to induce hypothermia must be made in advance. Therefore, the therapeutic use of hypothermia may be considered in such "high-risk" patients.

The application of mild hypothermia after head injury reduced ICP[323] and improved neurologic outcome[324] in pilot trials. Of note is the finding that complications attributable to hypothermia were not observed. A subsequent multicenter trial of hypothermia in head-injured patients, however, failed to confirm the findings of the pilot studies.[325] Induction of mild hypothermia did not improve long-term neurologic outcome. Note should be made, however, of the post hoc finding that outcome in patients younger than 45 years who were initially hypothermic was worse if these patients were rewarmed; these data suggest that such patients should be rewarmed over a prolonged period.

A number of clinical trials of induced hypothermia in a limited number of stroke patients have been conducted. To date, these trials have demonstrated the feasibility of inducing hypothermia in the range of 33°C to 35°C, even in patients who are not subjected to endotracheal intubation and mechanical ventilation.[326] Hypothermia was associated with improved ICP and CPP. However, complications, particularly thrombocytopenia, bradycardia, ventricular ectopy, hypotension, and infection, are frequent. In addition, an intractable increase in ICP can occur during rewarming, even if the elevation in temperature is gradual and accomplished over a period of several hours. These side effects attest to the need to conduct proper randomized trials to properly evaluate the efficacy of mild hypothermia in stroke patients. Such trials are currently under way.

Data regarding the application of mild hypothermia in survivors of cardiac arrest are more positive. Two recent trials have demonstrated that induction of hypothermia (32°C to 34°C) after successful resuscitation from cardiac arrest resulted in a significantly better neurologic outcome 6 months after the arrest.[267,327] These studies demonstrate the clinical efficacy of hypothermia for purposes of reducing ischemic cerebral injury and provide support for the use of intraoperative hypothermia in patients who are considered to be at high risk.

By contrast, increases in brain temperature during and after ischemia aggravate injury.[328] An increase of as little as 1°C can dramatically increase injury. Ischemia that normally results in scattered neuronal necrosis produces cerebral infarction when body temperature is elevated. It therefore seems prudent to avoid hyperthermia in patients who have suffered an ischemic insult or in those who are risk for cerebral ischemia. In the operating room, hyperthermia is seldom a problem (witness our efforts to prevent hypothermia). One situation in which body temperature is often allowed to increase is during rewarming after hypothermic cardiopulmonary bypass. In that situation, hyperthermia (core body temperature in excess of 38°C) is not uncommon. The suggestion that increases in temperature in excess of 37°C to 38°C are detrimental has some merit given the recent information regarding the deleterious effect of hyperthermia.

Glucose. Withholding of glucose-containing solutions in situations in which cerebral ischemia may occur is now an established practice. The practice is based on numerous demonstrations in animal models of brain and spinal cord ischemia that elevation of plasma glucose before episodes of either complete or incomplete ischemia results in aggravation of neurologic injury. However, it should be noted that the majority of investigations have involved adult animals and that there is less certainty about the adverse effects of hyperglycemia in immature subjects, such as neonates.[329] Furthermore, it should be noted that only some[330,331] and not all[332] of the investigations in humans have provided confirmation of an independent effect of serum glucose on neurologic outcome. Nonetheless, in long-term outcome studies, hyperglycemia (diabetic and nondiabetic) has been shown to be an independent predictor of poor outcome.[331] In the National Institutes of Health–sponsored recombinant tPA stroke trial, hyperglycemia was associated with significantly lower odds for desirable clinical outcomes and a higher incidence of intracranial hemorrhage.[333] These data prompted a randomized clinical trial of the efficacy of insulin administration to patients with acute stroke. Although the trial was underpowered, the results showed that administration of insulin to control blood glucose levels in stroke patients did not improve outcome 3 months after stroke.[334] A recurrent theme in the discussion of these studies is that glucose elevation may be the *result* of the stress associated with a severe insult, either ischemic or traumatic, rather than its *cause.* In addition, the inevitable questions of whether and how quickly immediate prerisk treatment of an elevated plasma glucose level with insulin reduces risk to normoglycemic levels have not been examined thoroughly. It is our opinion that at this juncture, acute insulin administration (with its attendant risk of hypoglycemia) in patients with modest glucose elevation (~150 mg/dL) in the operating room setting is not yet justified.

By contrast, hypoglycemia is also associated with cerebral injury. With a gradual reduction in blood glucose values of about 40 mg/dL, a shift in EEG frequencies from α and β toward δ and θ occurs.[335] Below a blood glucose level of 20 mg/dL, suppression of the EEG (flat) is observed. Persistence of this level of hypoglycemia results in seizure activity and neuronal injury, particularly to the hippocampus.

Seizures, pH. Normalization of systemic pH, prevention and treatment of seizures, which dramatically increase CMR, and control of ICP and CPP are all, though mundane and lacking in appeal of the pharmacologic silver bullet, important elements of brain protection and resuscitation.

Volume/Hematocrit Manipulation. Although hemodilution has not proved effective in studies of human stroke, both laboratory and human data support the practice, and it is an established part of management of the ischemia associated with vasospasm. However, the data do not currently justify routine hemodilution (a hematocrit of 30% to 35% is the theoretical optimum) in patients in whom focal ischemia *might* occur in the operating room.[336] On the other hand, the potentially deleterious effects of hemoconcentration should help further suppress the out-of-date notion that neurosurgical patients should be "run dry." An elevated hematocrit, because of viscosity effects, reduces CBF.[7] It is our unsubstantiated opinion that in anticipation of a

procedure wherein incomplete ischemia might occur, such as carotid endarterectomy, a hematocrit in excess of 55% should be lowered by preoperative phlebotomy.

Summary of Anesthetics and Neuroprotection

In comparison to the awake or lightly sedated state, the vulnerability of the brain to ischemic injury is reduced under anesthesia. Volatile anesthetics, barbiturates, propofol, xenon, and ketamine have all been shown to reduce injury in experimental models, and there is support for the premise that administration of any of these anesthetics reduces injury in comparison to a pure nitrous oxide–narcotic anesthetic. However, direct comparison has not demonstrated the superiority of any one agent (or combination) over another. Therefore, based on the available data, use of a specific anesthetic or anesthetic regimen for the purpose of brain protection in the clinical setting cannot be advocated. A possible exception is barbiturate administration. In the setting of cardiac surgery under cardiopulmonary bypass, administration of barbiturates has been shown to reduce cerebral injury in humans.[273] The cardiovascular depression and hemodynamic instability attendant on the use of barbiturates have significantly restricted their use clinically. Of considerable importance is the observation that the neuroprotective efficacy of anesthetic drugs is achieved only by strict attention to maintenance of physiologic homeostasis; in fact, the potential for exacerbation of cerebral injury, either traumatic or ischemic, with physiologic mismanagement is significantly greater than the modest protection afforded by pharmacologic drugs. Accordingly, with respect to brain protection, efforts should be focused on maintenance of physiologic parameters (perfusion pressure, oxygenation, normocapnia, temperature management, control of hyperglycemia, and seizure prophylaxis) within the appropriate range and less on pharmacologic or anesthetic drugs to reduce cerebral injury.

Deferring Elective Procedures after Stroke

The risk of extension of cerebral infarction in the event of subsequent anesthesia and surgery has not been studied systematically. In patients who have suffered a stroke, CBF undergoes marked changes. Areas of both high and low CBF occur, and stabilization of regional CBF and CMR is apparent after about 2 weeks.[337] Loss of normal vasomotor responses (CO_2 responsiveness, autoregulation) in the early postinsult period is very common,[338-340] and these changes persist beyond 2 weeks in a small percentage of stroke victims.[339,340] BBB abnormalities, as reflected by accumulation of CT contrast material or brain scan isotopes, are still present 4 weeks after the insult,[341] and the histologic resolution of large infarcts is not complete for several months. The information available does not allow a definite statement regarding how long elective procedures should be deferred. A 6-week delay should give some assurance of the probable recovery of autoregulation, CO_2 responsiveness, and BBB integrity. However, the size and location of the infarction should be weighed. A small infarction in silent cortex may give wider latitudes than a large lesion that has resulted in a paresis that is still resolving. A small prospective study suggested that in patients with nondisabling stroke, early carotid endarterectomy can be safely performed within 2 weeks of the stroke.[342] However, in patients with larger strokes, pending other information, it seems reasonable to defer elective surgery for at least 4 weeks after a cerebral vascular accident and preferably for 6 weeks from the point at which a stable postinsult neurologic state has been achieved.

Chronic Arterial Hypertension

A recurrent concern is that of acceptable levels of blood pressure reduction in chronically hypertensive patients. Firm guidelines have not been established. However, from the vantage of cerebral well-being, limiting elective MAP reduction to 30% to 35% of resting mean levels seems appropriate for both hypertensive and normotensive patients. It is reasonable that the same guidelines might apply in both populations because in chronic hypertension, both the lower and upper limits of autoregulation are shifted to the right with apparently little distortion.[343]

The rationale for a limit of 30% to 35% is as follows. It has been demonstrated that MAP reductions of 50% in nonanesthetized patients, both normotensive and hypertensive, will commonly produce reversible symptoms of cerebral hypoperfusion.[343-345] Although even greater reductions will probably be tolerated provided that exposures are brief, the hematocrit is reasonable, and the cerebral vasculature is patent, we counsel against it. A reduction in MAP of this magnitude will significantly increase the probability of CPP being close to or below the LLA, thereby reducing cerebrovascular reserve. It has been demonstrated that a 25% reduction in MAP will bring both normotensive and hypertensive patients to the LLA.[343] As the reduction in MAP exceeds 25% of baseline, CBF values will be below normal, albeit in subjects free of occlusive vascular disease, but above the threshold for neurophysiologic dysfunction or injury (see Fig. 13-4). However, physiologic reserve is being encroached upon, thereby leaving little margin for error or for other causes of impaired cerebral oxygen delivery (low hematocrit, unrecognized cerebrovascular disease).

It has been demonstrated in animals that treatment of chronic hypertension can restore the LLA to normal.[346,347] A similar phenomenon has been observed in humans by Strandgaard, although restoration was incomplete and had failed to occur after as long as 12 months of treatment in some subjects.[343] It is an unexplored possibility that the extent of restoration of the LLA with antihypertensive therapy is agent dependent. Some may restore the LLA more effectively than others do. In particular, angiotensin-converting enzyme inhibitors have been shown to decrease the LLA acutely in both normotensive and hypertensive subjects.[348,349]

Intracranial Hypertension

Control of intracranial hypertension is discussed in detail in Chapter 63.

Brain Tumors

There are few data regarding the physiology of intracranial tumors. Arbit and colleagues[350] measured CBF in cerebral tumors with laser-Doppler technology. In general, they found that tumors had lower CBF than normal brain did. Autoregulation was occasionally apparent. Vascular responsiveness to changes in Pao_2[351] and $Paco_2$[352] are generally preserved in patients with gliomas. However, in some circumstances, hyperventilation can at times be associated with paradoxical increases in MCA flow velocity ipsilateral to the tumor.[353] Measurement of regional CBF in the area of the tumor might also be a useful predictor of the grade of intracranial gliomas; both regional CBF and regional CBV are

greater with higher-grade gliomas.[354] There is often considerable edema in association with intracranial tumors, and the radiologic extent of the edema (which presumably represents the extent of abnormal vessel leakiness) correlates with the severity of the elevation in ICP that occurs in association with intubation-related hypertension.[355] Edema formation in the peritumoral region can be characterized as either vasogenic with leakage of plasma proteins from the vascular space, hydrocephalic secondary to obstruction of CSF flow, or static as a result of venous obstruction by tumor.[356] Although the precise mechanisms by which edema formation occurs are not clear, loss of integrity of the tight junctions of components of the BBB, increased permeability induced by vascular endothelial growth factor expressed by tumors, and increased expression of leukotriene C_4 in peritumoral fluid probably play a role.[357] Osmotherapy with mannitol will effect a reduction in edema; however, with a permeable BBB, mannitol can diffuse into the peritumoral space and lead to rebound edema formation.[356] For acute reduction of ICP in the operating room, this is not a significant concern. Dexamethasone remains the mainstay of treatment of tumor edema; it causes a reduction in edema formation with little effect on edema reabsorption, a reduction in permeability of the BBB that can be seen as rapidly as 1 hour after administration,[358] and a modest reduction in tumor size. See Chapter 63 for a complete discussion.

Coma and Epilepsy

Regardless of its etiology, coma is associated with reductions in brain metabolism. In the case of lesions occurring in the reticular activating system, the reduction in CMR probably represents a normal physiologic adjustment to reduced functional activity. During generalized seizure activity, CMR and CBF may increase dramatically.[200] The intensive motor and brain activity associated with generalized seizures leads to the development of systemic and cerebral acidosis, often accompanied by a reduction in arterial oxygenation, an increase in $Paco_2$, and peripheral lactic acidosis. If generalized seizure activity continues unabated, arterial hypotension ensues. With muscular relaxation and measures ensuring adequate oxygenation and ventilation, the systemic acidosis and hypotension can be avoided and the severity of the cerebral acidosis diminished. During relatively brief episodes of continuous seizures, the brain seems able to meet the high metabolic demands.[214] However, even with effective ventilation and maintenance of perfusion pressure, when seizures continue for a prolonged period, they can lead to the development of irreversible neuronal damage.[359] Therapy aimed at interrupting the seizure and restoring a normal balance between cerebral metabolic demand and blood flow is indicated. Barbiturates, benzodiazepines, or other potent anticonvulsants are appropriate. Adequate ventilation, oxygenation, and maintenance of blood pressure are important adjunctive measures. Muscle relaxants must be viewed as purely symptomatic therapy because they do not alter the abnormal cerebral electrical activity.

The potentially injurious nature of seizures justifies attention to prevention. Practices vary. However, patients who have sustained a severe head injury or subarachnoid hemorrhage and any patient in whom a substantial cortical incision is planned are at risk, and prophylactic anticonvulsants should be considered.

14 Neuromuscular Physiology and Pharmacology

Key Points

1. The neuromuscular junction provides a rich array of receptors and substrates for drug action. Several drugs used clinically have multiple sites of action, and muscle relaxants are not exceptions to the rule that most drugs have more than one site or mechanism of action. The major actions seem to occur by the mechanisms and at the sites described for decades: agonistic and antagonistic actions at postjunctional receptors for depolarizing and nondepolarizing relaxants. This description of neuromuscular drug action is a simplistic one. Neuromuscular transmission is impeded by nondepolarizers because they prevent access of acetylcholine to its recognition site on the postjunctional receptor.
2. If the concentration of nondepolarizer is increased, another, noncompetitive action—block of the ion channel—is superimposed. The paralysis is also potentiated by prejunctional actions of the relaxant, which prevents release of acetylcholine. The latter can be documented as fade that occurs with increased frequency of stimulation. A more accurate description of the effects of relaxants recognizes that the neuromuscular junction is a complex and dynamic system in which the phenomena produced by drugs are composites of actions that vary with drug, dose, activity in the junction and muscle, time after administration, presence of anesthetics or other drugs, and the age and condition of the patient.
3. Inhibition of postjunctional acetylcholinesterase by anticholinesterases increases the concentration of acetylcholine, which can compete with and displace the nondepolarizer and thus reverse the paralysis. These anticholinesterases also have other effects, including those on nerve terminals and on the receptor, by an allosteric mechanism. Cyclodextrins are a new class of compounds that reverse paralysis of only steroidal muscle relaxants by directly binding to them.
4. Depolarizing compounds initially react with the acetylcholine recognition site and, like the transmitter, open ion channels and depolarize the end-plate membrane. Unlike the transmitter, they are not subject to hydrolysis by acetylcholinesterase and therefore remain in the junction. Soon after administration of the drug, some receptors are desensitized and, although occupied by an agonist, they do not open to allow current to flow to depolarize the area.
5. If the depolarizing relaxant is applied in high concentration and allowed to remain at the junction for a long time, other effects occur, including entry of the drug into the channel to obstruct it or to pass through it into the cytoplasm. Depolarizing relaxants also have effects on prejunctional structures, and the combination of prejunctional and postjunctional effects plus secondary ones on muscle and nerve homeostasis results in the complicated phenomenon known as phase II blockade.
6. Intense research in the area of neuromuscular transmission continues at a rapid pace. Newer observations on receptors, ion channels, membranes, and prejunctional function reveal a much broader range of sites and mechanisms of action for agonists and antagonists.
7. Some of the other drugs used clinically (e.g., botulinum toxin) have effects on the nerve and therefore indirectly on muscle. Systemic infection with clostridial toxins (*Clostridium tetanus*, *Clostridium botulinum*) can lead to systemic paralysis as a result of decreased release of acetylcholine from the nerve terminal. Nondepolarizing muscle relaxants administered even for 12 hours or for prolonged periods can have effects on the postsynaptic receptor and simulate denervation (chemical denervation). In recognizing these sites and mechanisms, we begin to bring our theoretical knowledge closer to explaining the phenomena observed when these drugs are administered to living humans.
8. The most recent work seems to be focused on the postjunctional membrane and control of acetylcholine receptor expression in normal and diseased states. The presence or absence of mature and immature isoforms seems to complicate matters further. In certain pathologic states (e.g., stroke, sepsis, burns, immobilization, chronic use of relaxants), acetylcholine

receptors are upregulated, usually with expression of the immature isoform. More recently, another isoform of the acetylcholine receptor, previously described in neuronal tissues only, the α7 neuronal acetylcholine receptor, has been identified in muscle. These receptors have different functional and pharmacologic properties than conventional muscle postsynaptic receptors do. The altered functional and pharmacologic characteristics of the immature (γ-subunit) and neuronal (α7-subunit) receptors result in increased sensitivity to succinylcholine with hyperkalemia and resistance to nondepolarizers.

9. An area of increasing attention is control of the expression of mature versus the other two receptor isoforms. Re-expression of the immature γ and α7 receptors is probably related to aberrant growth factor signaling. Mutations in the acetylcholine receptor that result in prolonged open-channel time, similar to that seen with the immature receptor, can lead to a myasthenia-like state, even in the presence of normal receptor numbers. The weakness is usually related to the prolonged open-channel time. The role of the immature isoform of the receptor in the muscle weakness associated with critical illness such as burns is unknown.
10. Despite the fact that the neuromuscular junction is the most studied receptor, complete knowledge of its workings has not been achieved. This is an area of continuing interest for many researchers worldwide.
