The preoperative history focuses on functional capacity and cardiopulmonary symptoms. The ability of the patient to lie supine and allow airway access and management needs to be determined. Vital signs and performance of pulse oximetry are important. Auscultation for rales, decreased air entry, murmurs, and additional heart sounds and examination for edema and jugular venous distention are crucial. An ECG and chest radiograph are needed, and if patients are scheduled for spine correction surgery, a CBC and type and screen are required. An

echocardiogram may be indicated if symptoms or signs of heart failure are present. Reversible lung disease or heart failure needs to be addressed and optimized before surgery.

Raynaud's Phenomenon

Raynaud's phenomenon or disease is an exaggerated vascular response to cold or emotional stress (thought to be due to stimulation of the sympathetic nervous system) that results in color changes of the digits.[108] It can be primary (idiopathic without a known cause) or secondary (associated with connective tissue diseases, autoimmune disorders, drugs, use of vibrating tools). It is estimated that more than 95% of patients with systemic sclerosis have Raynaud's phenomenon; 20% to 30% of patients with Sjögren's syndrome or SLE have it, but less than 5% of patients with rheumatoid arthritis. Raynaud's phenomenon most often affects the hands and typically results in a sudden onset of cold digits (fingers more common than toes) with sharply demarcated pallor or cyanosis. Cutaneous vasospasm is common in other sites such as the face and ears and can cause pain and numbness. Criteria for the diagnosis of primary disease include symmetric episodic attacks, no PVD, no tissue injury or gangrene, normal nail fold capillary examination, normal erythrocyte sedimentation rate, and a negative antinuclear antibody test. Primary Raynaud's phenomenon requires no special preoperative evaluation. Secondary disease should direct the assessment for associated disease states as outlined elsewhere in this chapter. It is important to distinguish Raynaud's phenomenon from PVD because of the difference in associated comorbid conditions. Calcium channel blockers are useful in many patients and need to be continued in the perioperative period.

Cancer/Tumors in Preoperative Patients

Cancer Patients

Patients with a history of cancer may have complications related to the disease or the treatment. Typically, patients will be aware of the side effects of treatment that they have experienced or are at risk of having. Asking them if any "unexpected complications" occurred or if chemotherapy or radiotherapy had to be interrupted because of adverse effects is important. A hypercoagulable state is common in patients with cancer, particularly those with advanced disease and primary brain tumors, ovarian adenocarcinoma, and pancreatic, colon, stomach, lung, prostate, and kidney cancer. Patients with cancer have a sixfold increased risk for thromboembolic events, and active cancer accounts for 20% of new episodes of thromboembolism (see "Risk of Thromboembolism or Pulmonary Emboli").

Preoperative evaluation should focus on evaluation of the heart, lungs, and neurologic and hematologic systems. Previous head and neck irradiation may cause carotid artery disease, hypothyroidism, or difficulty with airway management.[109] In these patients, auscultation for bruits, thyroid function tests, and carotid Doppler studies are recommended.

Mediastinal, chest wall, or left breast irradiation can cause pericarditis, conduction abnormalities, cardiomyopathy, valvular abnormalities, and premature CAD, even without traditional risk factors.[110] Therefore, younger patients who might not otherwise be expected to be at risk for heart disease but who have a history of radiation therapy for cancer should be assessed for symptoms of cardiac disease as part of the preoperative history and should have a preoperative ECG.

Cardiovascular disease is the second most common cause of mortality in survivors of Hodgkin's disease. One study found that 88% of patients had echocardiographic abnormalities 5 to 20 years after treatment, most of them asymptomatic. Treatment at a younger age increases the risk. Radiation exposure is not considered in the ACC/AHA guidelines for cardiac evaluation for noncardiac surgery but can be an important predictor of CAD.[110] A preoperative ECG, echocardiography, and stress testing may be indicated. Radiation pneumonitis can occur in those who have received irradiation of the lungs, breast, or mediastinum. A chest radiograph and oxygen saturation with pulse oximetry are indicated. PFTs may be needed.

Chemotherapy with doxorubicin can cause cardiomyopathy, bleomycin can produce pulmonary toxicity, vincristine and cisplatin may cause peripheral neuropathy, and cyclophosphamide may trigger hemorrhagic cystitis. Many agents cause renal and hepatic toxicity or suppress bone marrow, which may result in pancytopenia. Anemia is most common. A chest radiograph, CBC with platelets, determination of electrolytes, BUN, and creatinine, and LFTs may be indicated based on the type of chemotherapy.

Patients with hepatocellular cancer have a high incidence of chronic liver disease (see the appropriate section). One study found that almost 25% of patients with Child's class C disease (see Table 34-5) undergoing liver resection died in the hospital and almost 20% more died within the first month after discharge.[111] A CBC with platelets, electrolyte, BUN, creatinine, and albumin levels, LFTs, and PT are needed.

Intracranial neoplasms can be primary or metastatic and can be complicated by seizures, increased intracranial pressure with mental status changes, nausea, vomiting, gait disturbances, and hemodynamic alterations or neurologic deficits. Previous therapies, including radiation, steroids, and anticonvulsants, need to be determined. If the tumor is metastatic, the primary tumor site, the course of the illness, and complications of therapy are important. Cancers that typically metastasize to the brain include breast, colorectal, and lung cancer.

Preoperative neuroimaging, an ECG, and electrolytes and glucose levels are reviewed or obtained. Steroids and anticonvulsants are continued. Breast, colorectal, lung, head, and neck tumors commonly metastasize to bone and the liver. Bone lesions can result in hypercalcemia or pancytopenia. Pancytopenia, with anemia being most common, occurs with many cancers or with treatment of these cancers. Head and neck tumors or therapy for them (surgery, radiation) may cause difficulty with airway management and thyroid dysfunction. Lung cancer can compromise pulmonary function and cause airway problems or mediastinal masses (discussed later). Computed tomography scans of the head, neck, or chest may be indicated. Paraneoplastic syndromes can complicate almost any malignancy but are commonly associated with lung cancer. Hypercalcemia, inappropriate secretion of antidiuretic hormone, Lambert-Eaton or Cushing's syndrome (discussed in this chapter), and neuropathies may occur.

Preoperative patients who are chronically receiving opioids for cancer pain are likely to require greater than usual doses of medication for postoperative pain control. They should take their usual pain therapies the day of surgery with the exception of antiplatelet agents. Patients at risk for adrenal insufficiency should

be assessed with a corticotropin (ACTH) stimulation test (see "Hypothalamic-Pituitary-Adrenal Disorders") or should be considered for additional perioperative steroids. A preoperative ECG is indicated for patients who have received mediastinal, breast, or lung irradiation or doxorubicin. All patients with cancer require a preoperative CBC with platelets and determination of electrolytes, BUN, creatinine, and calcium. Patients who are significantly malnourished benefit from 7 to 10 days of enteral or parenteral nutrition before major surgery. Surgery is delayed to allow neutropenia and thrombocytopenia to resolve if possible. Type and screening and planning blood component replacement can avoid delays on the day of surgery.

Mediastinal Masses

Lymphomas, thymomas, teratomas, metastatic disease, and goiters can occur in the anterior mediastinal space. Anterior mediastinal masses can cause obstruction of the great vessels, including the aorta, pulmonary arteries and veins, and superior vena cava, as well as the heart, trachea, and bronchi. Evaluation of patients with a mediastinal mass can be found in Chapter 59.

Von Hippel-Lindau Disease

von Hippel-Lindau disease is an inherited, autosomal dominant syndrome manifested by a variety of benign and malignant tumors. The spectrum of associated tumors includes hemangioblastoma, retinal angioma, clear cell renal cell carcinoma, pheochromocytoma, and neuroendocrine tumors of the pancreas. Preoperative evaluation of these patients focuses on evaluation of renal function and determination of symptoms or diagnoses compatible with pheochromocytomas or neuroendocrine tumors (see the section "Pheochromocytoma"). A careful history and physical examination with vital signs, an ECG, and determination of electrolytes, BUN, creatinine, and glucose is necessary in all patients. Further testing is guided by the history and laboratory findings.

Carcinoid Tumors

Carcinoid tumors are rare neuroendocrine tumors that release mediators and typically occur in the gastrointestinal tract; they are the most common neoplasm of the appendix but are also found in the pancreas and bronchi.

Preoperatively, patients with carcinoid syndrome complain of flushing, tachycardia, arrhythmias, diarrhea, malnutrition, bronchospasm, and carcinoid heart disease caused by vasoactive amines (serotonin, norepinephrine, histamine, dopamine), polypeptides (bradykinin, somatostatin, vasoactive intestinal peptide, glucagon), and prostaglandins released by the tumors. The majority of patients are asymptomatic. The liver inactivates the bioactive products of carcinoid tumors, which is why patients with gastrointestinal tumors have manifestations of carcinoid syndrome only if they have hepatic metastases. Heart disease can involve endocardial fibrosis of the pulmonic and tricuspid valves and cause stenosis and regurgitation, respectively. Right heart failure with peripheral edema and hepatomegaly can occur. Carcinoid tumors occur in MEN I.

Preoperative diagnostic tests are guided by the history and physical findings such as dyspnea, orthopnea, wheezing, edema, arrhythmias, and murmurs. Patients with diarrhea need determination of orthostatic BP, electrolytes, BUN, and creatinine. Patients with cardiac involvement need an ECG, electrolye assay, and echocardiography. Malnourished patients need orthostatic BP determination, an ECG, and electrolyte and albumin levels. Elevated urinary 5-hydroxyindoleacetic acid levels and carcinoid heart disease increase perioperative adverse events.[112] H_1 and H_2 histamine receptor blockers, ketanserin (a serotonin receptor antagonist), and octreotide may be useful to block release or the effects of mediators.

Special Issues in Preoperative Evaluation

Patients with Upper Respiratory Infections

Analysis of the literature available on patients with upper respiratory infections and anesthesia provides guidelines to help ensure patient safety while minimizing unnecessary cancellations. Although children with active and recent upper respiratory infections have been shown to be at increased risk for postoperative respiratory complications, these complications are generally manageable and have not been associated with long-term sequelae. Tait and Malviya summarized the literature on patients with upper respiratory infections and have provided a useful practice algorithm.[113] According to this algorithm, afebrile patients with symptoms of an uncomplicated upper respiratory infection, including clear secretions, should be able to undergo surgery.

The preoperative evaluation distinguishes patients with more severe symptoms, including purulent secretions, productive cough, temperature higher than 38°C, or signs of pulmonary involvement, and elective surgery should be postponed for about 4 weeks. This period was suggested because airway hyperreactivity persists for several weeks after an upper respiratory infection and patients recovering from one have been shown to have a rate of complications similar to those who have acute symptoms. Additional risk factors that should be considered include a history of asthma, need for intubation, surgery on the airway, smoking history, and a history of prematurity in pediatric patients. In patients with severe symptoms, especially those with underlying conditions (e.g., significant asthma, heart disease, and immunosuppression) that may further compromise safe anesthesia, elective surgery should be postponed for at least 4 weeks as well.[113] Preoperative laboratory testing and chest films may not be helpful in the decision; patients with viral infections may not have elevated white blood cell counts, and chest film findings typically lag behind clinical symptoms in patients with lower respiratory infections.

The risk-benefit ratio in each individual case needs to be assessed. Most would agree that surgery in patients with mild uncomplicated upper respiratory infections should not be canceled and surgery in those with more severe symptoms should be postponed for 4 weeks. Management should include awareness and prevention of potential complications.

Preoperative Evaluation of Patients with a Transplanted Organ

The number of patients with transplanted organs requiring nontransplant surgery increases yearly. These patients present special

issues for preoperative evaluation because of concerns about transplant function, allograft denervation, immunosuppression, and post-transplant physiologic and pharmacologic issues (see Chapter 67). Close interaction with the transplant team is considered one of the most important steps in the perioperative care of these patients, and clinicians performing the preoperative assessment should ensure that the transplant care providers are aware of the upcoming procedure and be given an opportunity to make recommendations.

During the preoperative evaluation, the dosage regimen of all agents should be noted and patients should be instructed to continue taking all of these medications. However, these drugs can modify the pharmacology of many agents administered during the perioperative period. Impact on agents administered during anesthesia is discussed elsewhere and has been summarized in the literature.[114,115]

There are some general preoperative considerations in all transplant patients, as well as concerns specific to the type of organ transplanted.[116] In all transplant patients, the level of function of the transplanted organ and the presence of rejection should be evaluated. Immunosuppressant therapy results in hyperglycemia and adrenal suppression (steroids); risk of infection, hypertension, and renal insufficiency (steroids, cyclosporine, tacrolimus); and myelosuppresion with anemia, thrombocytopenia, and leukopenia (azathioprine, sirolimus). Because these patients are chronically immunosuppressed, the potential for infection should be considered in any preoperative evaluation. Although these patients are at higher risk for the development of infectious complications, there is no evidence suggesting that heightened antibiotic prophylaxis has any added benefit, and the usual preoperative recommendations should be followed. The need for "stress dose" supplementation in patients taking low-dose corticosteroids is controversial, although because of the low risks involved with this therapy, it is used frequently.

Careful cardiac evaluation is important in all transplant patients because the incidence of cardiovascular disease is increased. This is due to a variety of factors, including the association of organ failure with a number of cardiovascular risk factors, as well as the role of drug regimens, transplantation, and rejection episodes in creating new and worsened cardiovascular risk factors. Patients with heart transplants periodically undergo evaluation for CAD (stress testing or catheterization) and function (echocardiogram or multiple gated acquisition [MUGA]).

Renal function should be assessed preoperatively because chronic renal insufficiency is becoming a significant problem in recipients of other solid organs secondary to long-term use of immunosuppressive regimens. Although the effects of transplantation and immunosuppressive regimens on intravascular coagulation are controversial, DVT prophylaxis should be considered in all transplant patients.

Kidney transplant recipients present some specific issues. Despite the presence of a normal creatinine level, the average GFR is generally decreased. This predisposes patients to electrolyte abnormalities and altered drug metabolism, as reviewed in the articles referenced earlier. The risk for cardiovascular disease in renal transplant recipients is approximately twice that in the general population, and careful presurgical cardiac evaluation is essential. Nephrotoxic drugs, NSAIDs, and COX-2 inhibitors should be avoided in renal transplant recipients.

Liver transplant patients require careful evaluation of pulmonary function. Hepatopulmonary syndrome, which consists of intrapulmonary shunting caused by intrapulmonary vascular dilatation, can result in hypoxemia. These patients can also have ventilation-perfusion mismatching as a result of effusion, ascites, and diaphragmatic dysfunction. Diffusion abnormalities can result from interstitial pneumonitis and impaired hypoxic pulmonary vasoconstriction. In some cases, pretransplant pulmonary disturbances do not completely resolve after transplantation.

Lung transplant patients may require months to achieve peak pulmonary functional capacity. Because of exposure to the external environment, the transplanted lung is susceptible to infection and rejection. Lung transplant patients have a high rate of pulmonary infection, and the airway anastomosis is subject to risk of injury with intubation. Loss of the cough reflex and airway hyperresponsiveness may be present. These patients are also at increased risk for pulmonary edema. Preoperative pulmonary function testing can be extremely helpful.

Most of the issues relating to heart transplant patients evolve from the absence of autonomic innervation; specific drug effects are described in detail in the items referenced. The preoperative ECG may show two P waves, one from the native atria, which is not conducted, as well as one from the donor atria. The heart transplant lacks innervation, and thus ischemia is silent and autonomic reflexes are absent (lack of chronotropic response to exercise, anemia, or hypovolemia). Conduction abnormalities are common. Permanent pacemakers are required in a significant number of patients, and their function should be confirmed during preoperative assessment.

Preoperative Evaluation of Patients with Allergies

The patient's history of allergies and adverse drug reactions should be carefully documented in the preoperative record. True anaphylactic reactions should be distinguished from adverse side effects. The patient's definition of allergy may be very different from the true clinical definition, and patients may incorrectly think that previous perioperative difficulties are due to "allergies" to anesthetic or pain medications.

The incidence of true anaphylactic and anaphylactoid reactions during anesthesia is in the range of 1 in 6000; muscle relaxants account for 69% of these reactions, followed by latex (12%) and antibiotics (8%).[117] A careful history will allow avoidance of precipitating agents; premedication with histamine blockers and steroids is not generally recommended.

Anaphylactic reactions to amide local anesthetics are extremely rare. Allergies to preservatives such as para-aminobenzoic acid used with esters are more common. Patients may perceive, especially with dental procedures, adverse side effects from epinephrine in local anesthetic solutions as allergies, and this needs to be carefully distinguished. Similarly, true allergies to opioids are rare, and opioid side effects, such as nausea and emesis, may be misinterpreted as allergies. Skin testing can be used to determine the presence of a true allergy. Allergies to muscle relaxants are more common; there are no reports of anaphylaxis to volatile anesthetics.

Penicillin is the most common cause of anaphylaxis; however, of all who report an allergy, only about 10% to 20% actually have a true allergy. There is a small risk of cross reactivity with cephalosporins, but most of these reported reactions involve

rashes and not anaphylaxis. Anaphylactic reactions to solutions such as bacitracin or providone-iodine have only rarely been reported; contact dermatitis in association with these agents is a more common reaction.

The rate of latex sensitization continues to increase; however, as better ways of identifying at-risk patients are developed, the incidence of latex-induced anaphylaxis is decreasing.[118] Diagnosis of a latex allergy during preoperative evaluation is based on a careful history. Patients at risk for latex allergy include those with a history of multiple surgical procedures, health care workers, and those with atopic histories. When latex allergy is identified during the preoperative visit, the operative team should be notified in advance to ensure that all appropriate equipment is available. The ASA task force outlines in detail intraoperative considerations for these patients.[119]

The scientific status of multiple chemical sensitivity disorder is controversial. Patients with this disorder report chronic, diffuse, nonspecific symptoms with low levels of multiple chemical substances. Symptoms involve multiple organ systems and include fatigue, headache, memory loss, palpitations, and gastrointestinal symptomatology. The symptoms are not generally accompanied by biologic test abnormalities or changes on physical examination. This disorder is frequently associated with chronic fatigue syndrome and fibromyalgia.[120] Performing a preoperative evaluation on these patients can be extremely difficult because patients have significant concerns about the multiple exposures involved during the perioperative period and the impact on their symptomatology. Cultural, historical, and behavioral issues, possibly in combination with some as yet undetermined physiologic abnormalities, may be responsible for the genesis of this disorder. There are no specific treatments and no current recommendations regarding perioperative care of these patients.

Preoperative Evaluation of Morbidly Obese Patients

A morbidly obese patient presents a special set of preoperative risks (see Chapter 64). Obesity is associated with an increased incidence of risk factors, including diabetes and cardiovascular disease. These patients have a higher incidence of difficult tracheal intubation, decreased arterial oxygenation, increased gastric volume, decreased gastric pH, postoperative wound infection, pulmonary embolism, and sudden death.[121]

Obesity is an independent risk factor for heart disease. Hypertension, stroke, hyperlipidemia, osteoarthritis, diabetes mellitus, cancer, and obstructive sleep apnea (OSA) are more common in obese people. Obese individuals have increased oxygen consumption and work of breathing but decreased lung volume and capacity. They have LVH and often decreased functional capacity. They frequently complain of dyspnea, which may be related to cardiac or pulmonary insufficiency or deconditioning. They are at risk for nonalcoholic steatohepatitis, also known as "fatty liver," which results in elevated LFT values and can progress to fibrosis.

Preoperative evaluation should be directed toward coexisting diseases. Patients with extreme obesity are at risk for heart failure and pulmonary hypertension. Obesity-hypoventilation syndrome (OHS), also known as pickwickian syndrome, is distinct from OSA. OHS is associated with awake, chronic hypoxemia (Pa_{O_2} <65 mm Hg) without a diagnosis of COPD or primary lung disease. These patients have impaired central ventilatory drive. Drugs or methods of weight reduction (purging, diuretics, laxatives, gastric bypass procedures) may result in electrolyte abnormalities, vitamin deficiencies, malnutrition, anemia, and cardiopulmonary disorders. Fenfluramine and dexfenfluramine, unavailable since 1997, caused mainly regurgitant valvular lesions and pulmonary hypertension. It is recommended that anyone ever exposed to these drugs undergo a cardiovascular evaluation. An ECG and echocardiogram (frequently done in the past) are recommended for those suspected of having dysfunction.

The preoperative history and physical examination focus on the airway, a history of snoring or daytime sleepiness, the cardiopulmonary system, and vital signs, including pulse oximetry. The BP cuff needs to have a width of approximately two thirds that of the arm and a length to adequately encircle the extremity. Neck circumference predicts difficulty with intubation. Depending on the history and physical findings, additional testing may be indicated.

These patients also have an increased incidence of OSA, which can be associated with pulmonary and systemic hypertension, left and right ventricular hypertrophy, and an increased incidence of arrhythmias, MI, and stroke.[122]

Preoperative Evaluation of Patients with Obstructive Sleep Apnea

Sleep-disordered breathing affects up to 9% of middle-aged women and 24% of middle-aged men; less than 15% of these cases have been diagnosed. Asking patients whether they snore, about the intensity of their snoring and whether it bothers others, about observed awakenings or choking, about daytime sleepiness and whether it interferes with activities, and about falling asleep while driving can identify those with probable sleep apnea. OSA, the most common serious manifestation of sleep-disordered breathing, is caused by intermittent airway obstruction. OSA is characterized by total collapse of the airway with complete obstruction for more than 10 seconds. Obstructive hypopnea is partial collapse (30% to 99%) associated with at least 4% arterial oxygen desaturation. The severity of OSA is measured with the apnea-hypoxia index, or the number of apneic and hypopneic episodes per hour of sleep. Patients with severe OSA have more than 30 episodes per hour.

Cardiovascular disease is common in patients with OSA. These patients have an increased incidence of hypertension, atrial fibrillation, bradyarrhythmias, ventricular ectopy, endothelial damage, stroke, heart failure, pulmonary hypertension, dilated cardiomyopathy, and atherosclerotic CAD.[60] Mask ventilation, direct laryngoscopy, endotracheal intubation, and even fiberoptic visualization of the airway are more difficult in patients with OSA than in healthy patients (see Chapters 50 and 64). Patients with OSA are more sensitive to the respiratory depressant effects of opioids than individuals without OSA are.

Preoperative evaluation should focus on identifying patients at risk for OSA and improving associated comorbid conditions in those with OSA. Echocardiography may be indicated if heart failure or pulmonary hypertension is suspected. Many of these patients are obese, and even if not, many of the same issues

that apply to obese patients affect those with OSA. Patients should be instructed to bring their continuous positive airway pressure devices to the hospital on the day of surgery. Postoperative pain management and monitoring are critical.

Human Immunodeficiency Virus and Acquired Immunodeficiency Syndrome

The HIV pandemic has spread to every country in the world. Acute infection with the virus causes a mononucleosis-like illness that progresses to chronic lymphadenopathy (lasting 3 to 5 years) and culminates in a cell-mediated immune deficiency characterized by opportunistic infections, malignancies such as Kaposi's sarcoma and non-Hodgkin's lymphoma, and death, usually secondary to infections, wasting, or cancer. Risk factors for HIV infection include sexual contact with an infected individual, blood-borne contamination, men who have sex with men, sexual workers, and those having contact with sexual workers. Most infection transmitted by blood exposure occurs in intravenous drug users, and infection via transfusion in the United States is rare (1 per 1.5 to 2 million blood transfusions). Mothers can transmit the disease to their infants, usually during breastfeeding or delivery.[123] Minority populations are at increased risk for HIV infection. Many patients infected with HIV are unaware of their status.

HIV can affect all organs and cause multiple complications. Myocarditis, dilated cardiomyopathy, valvular disease, pulmonary hypertension, pericardial effusions, and tamponade are possible. Antiretroviral-induced lipodystrophy causes CAD. Pulmonary infections with *Pneumocystis jiroveci*, *Mycobacterium avium* or *tuberculosis*, cytomegalovirus, and *Cryptococcus* are common and often drug resistant. Central nervous system tumors, infections, aseptic meningitis, and acquired immunodeficiency syndrome (AIDS)-related dementia occur, as well as lymphomas, Kaposi's sarcoma, cervical cancer, and lymphoid interstitial pneumonitis. Supraglottic or intraoral Kaposi's sarcoma may interfere with ventilation and intubation; non-Hodgkin's lymphoma can cause mediastinal masses. Dysphagia, diarrhea, esophagitis, and renal dysfunction can lead to malnutrition, dehydration, and electrolyte imbalance (hyponatremia and hyperkalemia are the two major electrolyte disorders). Acute tubular necrosis, glomerulonephritis, renovascular disease, and HIV-associated nephropathy with nephritic syndrome can be present. The nucleoside reverse transcriptase inhibitors (i.e., zidovudine, didanosine, stavudine, lamivudine, abacavir, emtricitabine) may cause lactic acidosis, electrolyte abnormalities, neuropathy, autonomic dysfunction, gastrointestinal upset, renal or hepatic dysfunction, and pancreatitis. Zidovudine can cause pancytopenia.

The preoperative evaluation may illicit a history of thrush, fever of unknown origin, chronic diarrhea, lymphadenopathy, or herpes zoster in more than one dermatome. In a relatively young, otherwise healthy individual, this should raise concern of HIV infection. The enzyme-linked immunosorbent assay (ELISA) is the primary screening test and is greater than 99% sensitive but has a high number of false-positive results. The Western blot technique is used to confirm ELISA results. Patients with known HIV infection will frequently require further evaluation, including an ECG, CBC with platelets, determination of electrolytes, BUN, and creatinine, LFTs, and a chest radiograph, depending on the surgical procedure. If malnourished or evidence of nephritic syndrome is present, measurement of albumin, total protein, and magnesium levels may be beneficial. Determining the $CD4^+$ lymphocyte cell count and viral load, which reflects the patient's immunologic status during the previous 3 months, can have prognostic value. A 13% mortality rate within 6 months of surgery has been reported when the $CD4^+$ count is less than $50/mm^3$ and a 0.8% mortality rate with $CD4^+$ counts greater than $200/mm^3$.[109] Antiretroviral therapy is continued perioperatively.

Evaluation of Patients with a History of Substance Abuse

A patient with a history of current or previous alcohol or drug addiction presents special challenges for the perioperative team (see Chapter 101). Although the prevalence of these addictions is significant (14% and 7%, respectively), there is limited information based on prospective clinical trials to guide perioperative management.[124]

The preoperative evaluation allows an opportunity to obtain a detailed history of addiction and recovery. Addictive disease is considered permanent, even in patients who have had long periods of abstinence. If a patient is in recovery, knowledge of the dosages and effects of medications used for maintenance of recovery is essential. Verification of all medication doses is vital. In a recovering patient, anxiety may be heightened as a result of concern about the possibility of both relapse into addiction and inadequate pain treatment because of the history of addiction. The patient should be assured during the preoperative interview that anxiety and pain will be adequately treated. Clinicians may have prejudicial attitudes and may lack the educational background to formulate appropriate plans for pain management. Pain medication may be inadequate and restricted because of concern about provoking a relapse. Identifying these at-risk patients during the preoperative evaluation and involving the acute pain service to assist in management may be helpful.

Patients who are actively abusing cocaine and amphetamines are at significant risk during anesthesia because of intraoperative hemodynamic instability. Urine testing (especially on the day of surgery) is appropriate to ensure the absence of abused substances in patients about to undergo procedures. Patients who are currently substance abusers have a variety of clinical manifestations, depending on the drug abused. Jage and Heid suggest classifying the substances into three categories: central nervous system depressors (e.g., heroin, alcohol, sedatives, hypnotics), stimulants (e.g., cocaine, amphetamines), and other psychotropic substances (e.g., cannabis).[125] The preoperative period should be used to plan for appropriate management. Heroin addicts may require substitution with methadone, and those addicted to alcohol, sedatives, or hypnotics may require stabilization with benzodiazepines. Discussion of regional techniques, avoidance of inadequate analgesia, and optimization of analgesia with nonopioids is essential. Inadequate analgesia can potentially activate addiction. All information and potential management plans should be clearly transmitted to members of the operative team.

Many addicts are polysubstance abusers, and psychiatric disorders are common comorbid conditions. Addicts may be at risk for a myriad of perioperative complications, including withdrawal, acute intoxication, altered tolerance of anesthetic and

opioid medications, infections, and end-organ damage.[126] Intravenous drug use should prompt an evaluation for cardiovascular, pulmonary, neurologic, and infectious complications such as endocarditis, abscesses, osteomyelitis, hepatitis, and HIV infection or AIDS. Alcohol abusers are specifically at risk for potentially life-threatening withdrawal with autonomic instability and hyperpyrexia. Cocaine and amphetamine addicts can have cerebrovascular accidents, cardiomyopathy, and arrhythmias. Additionally, cocaine and amphetamine inhibit the uptake of sympathomimetic neurotransmitters, increase BP, raise HR, and can cause paranoia, anxiety, seizures, angina, and MI (even in patients without CAD).[127] Long-term use causes ventricular hypertrophy, myocardial necrosis, and nasal septal perforation. Solvents can cause cardiac dysrhythmias, pulmonary and cerebral edema, diffuse cortical atrophy, and hepatic failure. Hallucinogens, including lysergic acid diethylamide (LSD), can cause autonomic dysregulation and paranoia. 3,4-Methylenedioxymethamphetamine (MDMA), commonly known as *ecstasy*, can cause excessive thirst, resulting in hyponatremia and pulmonary or cerebral edema.

Alcoholics are at risk for alcoholic hepatitis, cirrhosis, portal hypertension, cardiomyopathy, arrhythmias, seizures, neuropathies, dementia, Wernicke-Korsakoff syndrome (ataxia, cognitive dysfunction), and macrocytic anemia from vitamin deficiencies, delirium tremens, pneumonia, gastrointestinal bleeding, and coagulopathies secondary to either hepatic dysfunction or vitamin K deficiency. Marijuana can affect the cardiovascular and autonomic nervous systems and result in tachycardia, dysrhythmias, ECG abnormalities (T-wave and ST-segment changes), and increased cardiac output.

Patients who smoke marijuana are at the same risk as patients who smoke tobacco. Opioid (including heroin) users will have a tolerance to narcotics. It is important to document dosages of opioids taken, as well as any drugs to treat addiction such as methadone, clonidine, or buprenorphine (Suboxone or Subutex; with and without naloxone, respectively), a partial μ-agonist. Patients who are receiving opioid substitution therapy will experience normal pain responses to nociceptive stimuli and will require additional analgesia for control of postprocedure pain.[128]

Patients who use alcohol or prescription opioids to excess or illicit drugs may not give a reliable history. Vital signs, including temperature, are needed. Cocaine and amphetamines may raise BP and HR. Acute opioid use can slow the respiratory rate and cause lethargy and pinpoint pupils. Alcohol can often be detected by smell. Examination of venous access sites for signs of abscesses and skin and soft tissue infections is important. Auscultation for murmurs in intravenous drug users is essential. Symptoms and signs of heart failure or arrhythmias may be present in cocaine or alcohol abusers. Long-term use of alcohol causes liver dysfunction (see the appropriate section).

Preoperative testing depends on symptoms and findings from the history and physical examination. An ECG may be warranted in patients taking methadone because this drug can cause prolongation of the QT interval. It is important to ascertain whether and for how long patients can stop consuming alcohol or addictive drugs. In addition, more importantly, what happens when they do interrupt use? Does delirium tremens develop; do they have seizures or other signs of withdrawal? Ideally, patients with drug or alcohol dependence should be drug free well before elective surgery. Acute preoperative abstinence in alcoholics, however, has been associated with a poorer outcome postoperatively than if drinking is continued.[129] Preanesthesia clinic staff should be prepared to refer patients to addiction specialists or programs or prescribe medications to prevent withdrawal in the preoperative period if patients agree to abstinence.

Benzodiazepines are useful in preventing or treating alcohol withdrawal symptoms. Patients with a history of alcohol abuse who are taking disulfiram may have an altered response to sympathomimetic drugs; Hernandez and coworkers suggest that this agent be discontinued 10 days before surgery. If disulfram is continued, users can be sensitive to small amounts of alcohol (even from skin preparations or medications) and can experience flushing, nausea, and tachycardia. These authors also suggest that patients taking naltrexone for a history of alcohol or opioid abuse discontinue the drug 3 days before surgery. Patients taking SSRIs or methadone should continue maintenance doses. Marijuana users should be advised to avoid use at least 7 days before surgery because of its long half-life.[124]

Patients on methadone maintenance regimens continue the drug through the day of surgery. Because it may be difficult to overcome the analgesic agonist effect of Suboxone, it should be stopped 3 days before surgery. Patients may require substitution to avoid relapse of addiction during this period. Preoperative consultation with pain or addiction specialists (or both) may be useful for opioid abusers or patients taking methadone to combat addiction if the planned procedure will result in significant postoperative pain.

Preoperative Nutritional Evaluation

Patients who need surgery may be malnourished, either because of a chronic disease process (e.g., cancer or difficulty swallowing after a stroke) or because of a medical condition such as intermittent bowel obstruction (see Chapter 95). Malnutrition is associated with postoperative complications ranging from a prolonged hospital stay for patients undergoing total hip replacement to more major morbidity, such as wound breakdown, abscesses, infections, anastomotic breakdown, respiratory failure, and death.[130,131]

There is clear evidence that preoperative nutrition therapy in appropriate patients can reduce postoperative complications. TJC emphasizes the importance of preoperative nutritional evaluation and planning by requiring that nutritional screening be performed within 24 hours of admission, with full nutritional assessment in at-risk patients. Organizations must establish guidelines for nutrition screening and assessment that will identify patient characteristics known to be associated with nutrition problems and appropriately refer for planning. Reasonable agreement exists about predictive indicators of poor nutritional status: weight loss greater than 10% in the 6 months before surgery, change in dietary intake relative to normal, gastrointestinal symptoms that persist for longer than 2 weeks, decreased functional capacity (from lethargic to bedridden), and other physical factors such as loss of subcutaneous fat, muscle wasting, ankle edema, sacral edema, and ascites. Detsky and colleagues have incorporated these factors into the Subjective Global Assessment Scale.[132] The physical factors are rated as normal (0), mild (1+), moderate (2+), or severe (3+). Because of the high incidence of elective procedures that occur without previous admission, screening and assessment by TJC guidelines can be done either during the preoperative visit or during the first 24 hours of admission. This

makes it extremely difficult to implement preoperative nutrition support in patients who may benefit. Kudsk reported that in a group of patients undergoing gastrointestinal procedures, TJC-required assessments were performed in the vast majority of cases between 12 and 25 hours after surgery.[133] As a result, although the TJC mandate was met, the clinical team did not have the opportunity to provide preoperative nutrition support if indicated. Proper identification of at-risk patients would best be accomplished at the time of preoperative assessment and in an outpatient setting to allow time for implementation of preoperative nutrition plans.

The best places to look for loss of subcutaneous fat are the triceps region of the arms, the midaxillary line at the costal margin, the interosseous and palmar areas of the hand, and the deltoid region of the shoulder. Muscle wasting is best assessed in the quadriceps femoris and deltoid region. The nutritional status of patients can be classified A (well nourished), B (moderately malnourished; weight loss of 5% to 10% without stabilization or weight gain, poor dietary intake, and mild loss of subcutaneous tissue), or C (severely malnourished; ongoing weight loss of >10%, severe subcutaneous tissue loss, muscle wasting, and edema).

A serum albumin level of less than 3.5 g/dL in the general surgical population or less than 3.9 g/dL in patients who need total hip replacement is an accurate predictor of malnutrition.[130,131] Serum albumin less than 2.1 mg/dL was a strong predictor of mortality in veterans undergoing major noncardiac surgery.[75] The combination of history plus physical examination and serum albumin level provides slightly improved accuracy in predicting malnutrition than either indicator alone does.

When possible, nutritional status should be improved preoperatively in severely malnourished patients. Enteral nutrition is the preferred means, but if the gut cannot be used, total parenteral nutrition (TPN), though not without its own risks, is acceptable. In a Veterans Affairs study, severely malnourished patients who received TPN had fewer noninfectious complications than controls did (5% versus 43%), with no concomitant increase in infectious complications.[80]

Breastfeeding Patients

There is little science to guide recommendations for the safety of anesthetics and medications in the babies of mothers who breastfeed and receive these agents. For elective cases, women need to be advised to pump and store milk preoperatively, which can be used in the first 24 hours after administration of an anesthetic or for the duration of breast milk exposure to potentially harmful agents. The mother should discard milk produced within the first 24 hours after anesthesia and generally resume breastfeeding after this period. Very young or premature babies, especially those at risk for apnea, may have complications if the mother continues to take opioid or sedating drugs. Mothers should be advised to discuss with their child's pediatrician the safety of breastfeeding while taking medications.

Patients with Do-Not-Resuscitate Orders

Some patients scheduled for procedures will have advance directives or a do-not-resuscitate (DNR) status (see Chapter 97). In 1993 the ASA adopted guidelines for the care of these patients and updated them in 2001 (Box 34-7).[134] Frequently, in circumstances with DNR orders, care providers are focused on a procedure-directed approach (i.e., do not intubate, no resuscitative drugs), which is problematic in the perioperative period when much of anesthesia care involves this approach. It has been suggested that a better tactic would be to discuss DNR status in the context of anesthesia in a goal-directed approach (i.e., from the perspective of the patient's values and objectives, such as "quality-of-life" concerns).[135] The ideal time to discuss this emotional, complex issue is during the preoperative evaluation. It has been shown that short discussions in a preoperative clinic can foster dialogue among patients, their proxies, and physicians regarding advance directives concerning end-of-life care. A durable power of attorney was completed by 27% of intervention patients versus 10% of controls, and 87% of the intervention group discussed end-of-life care with the appropriate individuals versus 66% of the control group.[136]

Box 34-7 Do-Not-Resuscitate Orders in the Perioperative Period

Policies automatically suspending DNR orders or other directives that limit treatment before procedures involving anesthetic care may not sufficiently address a patient's rights to self-determination in a responsible and ethical manner. Such policies, if they exist, should be reviewed and revised, as necessary, to reflect the content of these guidelines.

1. Full Attempt at Resuscitation: The patient or designated surrogate may request full suspension of existing directives during anesthesia and the immediate postoperative period, thereby consenting to the use of any resuscitation procedures that may be appropriate to treat clinical events that occur during this time.
2. Limited Attempt at Resuscitation Defined with Regard to Specific Procedures: The patient or designated surrogate may elect to continue to refuse certain specific resuscitation procedures (e.g., chest compressions, defibrillation, or tracheal intubation). The anesthesiologist should inform the patient or designated surrogate about which procedures are (1) essential to the success of anesthesia and the proposed procedure and (2) which procedures are not essential and may be refused.
3. Limited Attempt at Resuscitation Defined with Regard to the Patient's Goals and Values: The patient or designated surrogate may allow the anesthesiologist and surgical team to use clinical judgment in determining which resuscitation procedures are appropriate in the context of the situation and the patient's stated goals and values. For example, some patients may want full resuscitation procedures to be used to manage adverse clinical events that are believed to be quickly and easily reversible but to refrain from treatment of conditions that are likely to result in permanent sequelae, such as neurologic impairment or unwanted dependence on life-sustaining technology.

From Committee on Ethics, American Society of Anesthesiologists: Ethical guidelines for the anesthesia care of patients with do not resuscitate orders, 2001. Available at http://www.asahq.org/publicationsAndServices/standards/09.html.

Pseudocholinesterase Deficiency

A personal or family history of pseudocholinesterase (specifically, butyrylcholinesterase) deficiency should be identified preoperatively (see Chapter 29). When patients report an "allergy to succinylcholine," one should suspect this disorder or MH. Inquiring whether the patient had to remain intubated postoperatively, was gravely ill, or required intensive care may help differentiate these disorders. Pseudocholinesterase activity may be reduced permanently because of abnormal genotypes or transiently altered because of disease, drug effects, parturition, or infancy. Patients should be educated that this enzyme also metabolizes ester-linked local anesthetics.

Preoperative records from previous anesthesia may clarify an uncertain history. A dibucaine number and plasma pseudocholinesterase, chloride, and fluoride levels should be obtained. The *dibucaine number* is a measure of the qualitative activity of pseudocholinesterase and is the percentage of inhibition of the enzyme by the local anesthetic dibucaine. Normal individuals are homozygous for the wild type, and their dibucaine number is 80 because their plasma cholinesterase is 80% inhibited by dibucaine. Those who are homozygous for the atypical genes have a dibucaine number of 20 because of 20% inhibition. Heterozygous individuals have a dibucaine number of 60 because of approximately 60% inhibition. The plasma cholinesterase level is a quantitative measure of this enzyme. Plasma cholinesterase should not be confused with cholinesterase activity, which is an assessment of erythrocyte or red blood cell cholinesterase. The combination of dibucaine number and plasma cholinesterase can differentiate genetic from nongenetic causes of prolonged apnea after the administration of succinylcholine. A transient decrease in pseudocholinesterase activity as a result of drug interactions or other identified reasons has been observed soon after episodes of suspected pseudocholinesterase deficiency, so diagnostic testing should be delayed at least 24 hours. Patients with known or suspected pseudocholinesterase deficiency should be urged to obtain proper identification (Web search for "medical alert identification").

Malignant Hyperthermia

A history of MH or a suggestion of it (hyperthermia or rigidity during anesthesia) in either a patient or family member should be clearly documented so that special arrangements can made before the day of surgery (see Chapter 37). Individuals are genetically predisposed to MH and are asymptomatic until exposed to triggering agents. Certain neuromuscular diseases are associated with a risk for MH, including Duchenne's, Becker's, and myotonic muscular dystrophies, King-Denborough syndrome, central core disease, periodic paralysis, osteogenesis imperfecta, myelomeningocele, and strabismus.

Residency Training in Preoperative Evaluation

The evolution of preoperative evaluation, as well as the anesthesiologist's role in this area, challenges training programs to educate practitioners who can function well in roles both inside and outside the operating room. Optimal preoperative assessment, as well as continued improvement, will rely on properly educating anesthesiologists in the skills of physical diagnosis and patient assessment, personnel and business management, and conducting and understanding outcome-based research in this area. It is unrealistic to expect the next generation of anesthesiologists to successfully manage administrative and clinical roles in perioperative medicine without adequate exposure during residency training. A survey of training programs published in 2001 revealed that although almost all program directors agreed that competency in preoperative evaluation was an important skill, less than half had a formal curriculum in this area, nearly 50% did not teach patient interview skills, and 39% of programs did not expose their residents to a preoperative clinic experience.[137] The American College of Graduate Medical Education (ACGME) has recognized the importance of adequate training in this area during anesthesia residency. Requirements have been amended and became effective in July 2008; requirements in preoperative education have been increased and more specifically defined.[138] During the 3 clinical anesthesia training years, 1 month must be spent in a preoperative evaluation clinic. This may occur in divided rotations not less than 1 week in length. Successive experiences must reflect increased responsibility and learning opportunities. Program objectives must include adequate training not only in the clinical aspect of preoperative assessment but also in interpersonal skills, effective communication, and business practices. Practice management, operating room management, and systems-based practice issues should be included in the curriculum.

Assessment of skills in this area requires a definition of objectives. Instruments for assessing resident performance in this area should be developed. A "Preanesthesia Consultation Scoring Checklist" has been developed that contains 37 items grouped into the domains of physician-patient relationship, medical history, physical examination, patient education, and preanesthesia records.[139] This instrument was shown to have high construct validity, moderate internal consistency, and high probability of inter-rater agreement. Analysis of the scores could reliably assess resident performance at the defined criteria. The development of similar instruments in conjunction with the institution of a specific curriculum in preoperative evaluation will be of great help in assessing resident performance, as well as in meeting ACGME requirements.

Meeting Regulatory and Reporting Requirements

Appropriate and safe clinical assessment includes elements that are considered standard of care medically, in addition to elements that are requirements mandated by outside agencies. These outside agencies may be those mandating practice for quality accreditation, such as the TJC. Agencies may mandate practice for payment, such as the Center for Medicare and Medicaid Services (CMS) or other agencies that provide payment based on practice or performance. A detailed discussion of the use of technology in the preoperative clinic to meet requirements will follow in a later section. Regulatory requirements may exist internally as well. Institutions generally develop practice guidelines or standards,

and it is incumbent on all practicing clinicians to abide by the standards of their respective institutions. A number of these standards involve preoperative care issues, and a number of requirements for accreditation by TJC involve preoperative issues. These requirements are described in detail in the TJC manual referenced and are available through the TJC website (www.jointcommission.org).

As far as the timing of preoperative assessment is concerned, TJC requires that the history and physical examination be completed within 30 days before the procedure and that a reassessment be done within the 24-hour period immediately preceding the surgery. No other TJC requirements exist regarding the timing of assessments, consents, or laboratory testing. It should be realized, however, that insurance payers might have specific requirements regarding the timing of assessments in relation to the surgical procedure and payment; providers may obtain information from their respective institutional compliance departments about the timing of assessments and payment by carrier. Hospital policies must ensure that patients have the right to refuse care, treatment, and services in accordance with the law. When the patient is not legally responsible, the surrogate decision-maker has the right to refuse care on the patient's behalf. To this end, the hospital must have a framework for ensuring that such advance directives are completed. TJC requires that the hospital document and have available to clinicians the patient's decision regarding such advance directives. The preoperative visit is an opportunity to supply the patient with information regarding advance directives, as well as to document the patient's wishes regarding such directives. TJC also requires that patients with special needs be assessed and these needs addressed. Such patients may be victims of abuse or neglect, alcohol or substance abusers, patients with significant emotional or behavioral disorders, and patients with specific nutritional needs. These assessments can be performed and documented at the time of the preoperative evaluation.

Many of these elements are documented as portions of the patient's nursing assessment, which TJC mandates be performed on each patient by a registered nurse. The preoperative history and physical examination may be performed by any licensed practitioner who is credentialed to do so. The anesthesia assessment may be performed by a physician or advanced practice nurse (nurse practitioner or certified registered nurse anesthetist) with appropriate training. TJC mandates that pain be assessed in all patients. A comprehensive pain assessment can be performed as part of the preoperative nursing or physician assessments. Establishing a baseline for the pattern of pain existing preoperatively is extremely important in formulating a postoperative care plan.

Patients who are taking significant amounts of narcotics and other pain relievers preoperatively can be identified and appropriate postoperative care plans formulated and communicated to the perioperative care team. TJC also supports a number of National Patient Safety Goals (NPSGs).[140] How an appropriate preoperative process can advance achievement of the 2007 NPSGs is illustrated in Table 34-6.

Table 34-6 Role of the Preoperative Clinic in Achieving National Patient Safety Goals

2007 National Patient Safety Goal	Preoperative Clinic Role
Improve the accuracy of patient identification	Use two patient identifiers when doing evaluation or testing; verify that all information on the operating room chart is correctly labeled
Improve the effectiveness of communication among caregivers	Communicate patient issues among multidisciplinary perioperative care providers Use a standardized list of abbreviations in the preoperative chart; eliminate the use of acronyms
Reduce the risk of health care–associated infection	Identify and transfer information to the operating room and postoperative areas regarding patients colonized with antibiotic-resistant organisms
Accurately and completely reconcile medications across the continuum of care	Begin a single accurate list of prescription and nonprescription medications and dosages that can follow the patient throughout the perioperative experience
Encourage patients' active involvement in their own care as a patient safety strategy	Perform patient and family education related to the upcoming procedure
Identify safety risks inherent in its patient population	Establish and implement a universal protocol to prevent wrong-sided procedures; verify sidedness at the time of preoperative assessment and correct errors

Preoperative Medical-Legal Issues

In a malpractice action involving preoperative professional negligence, the burden is on the plaintiff to show the generally recognized standard of medical care, deviation from that standard by the defendant, and that the deviation was the proximate cause of the patient's alleged injuries (see Chapter 10). Expert testimony is generally used to demonstrate the standard of care, as well as deviation from such standards. The ultimate decision of whether practice deviated from the standard of care should be a matter of fact, not opinion. However, in the preoperative area, many clinical "standards" are in actuality only guidelines based on general consensus or expert opinion, not on outcome data from large population-based studies. Compliance with the specific institutional guidelines, as well as with guidelines and standards set forth by credible groups such as the TJC and ASA, is heavily considered. The court generally accepts statements from these groups regarding definitions of standard of care. For example, there are a number of cases in which performance of preoperative assessment as defined by the TJC or guidelines for preoperative assessment as defined by the ASA have been placed into evidence as defining standard of care. Understanding the components of proper informed consent and establishing an effective system for obtaining consent are critical elements of the preoperative process. A review of legal decisions in this area by Raab has attempted to define appropriate parameters.[141] The absence of appropriate informed consent can result in consideration of the tort of battery. Lack of adequate informed consent has also been found to constitute the main cause of negligence, even when malpractice or substandard care cannot be proved. Courts apply either of two standards for adequate disclosure; one refers to what a reasonable clinician would consider important to the patient's decision (reasonable practitioner standard), and the other is whether the clini-

cian has disclosed what a prudent patient would need to know in order to make an intelligent decision (prudent patient standard). These are different legal concepts that are applied on a state-by-state basis. The law requires that nontrivial risks be disclosed; extremely rare complications need not be disclosed. As far as disclosure regarding risks associated with anesthesia is concerned, Raab believes that the risk of anesthesia-related death or severe injury in a patient whose health is otherwise reasonably good would be in the range of a rare consequence; however, most reasonable patients would still want to be aware of this. The signed consent form is documentation that such discussions have occurred. Raab thinks that the dilemma regarding informing patients of rare probabilities of anesthesia complications remains unsolved. With regard to surgical informed consent, a closed claims analysis has revealed that documentation of discussion in the surgeon's office notes was a significant factor in reducing indemnity risk, regardless of whether the actual consent form was signed by the surgeon, resident, or nurse practitioner.[142]

Clinicians may be concerned about liability in overordering or underordering preoperative testing. In general, clinicians are not held liable for errors in judgment; liability holds only when the testing rendered would be considered to fall below accepted standards of practice.[143] It is extremely difficult to decide what is standard of practice for routine preoperative laboratory testing because of numerous articles demonstrating lack of impact of routine preoperative screening tests on management. However, failure to order appropriate laboratory testing that would diagnose an important presurgical comorbidity would imply that the clinician had performed a substandard assessment. This emphasizes the importance of a complete and well-documented preoperative history and physical examination with testing geared toward comorbid diseases revealed by this evaluation. Routine screening batteries in the setting of inadequate evaluation would seem to put the clinician at a much greater risk of missing an important preoperative condition. A review of more than 400 diagnostic malpractice claims in the outpatient setting would support this view.[144] These investigators reported that the most common breakdowns in the diagnostic process were failure to obtain an adequate history or perform an adequate physical examination, failure to order a specific diagnostic test, failure to follow up on rest results, and incorrect interpretation of test results.

A clinician who has informed discussions with the presurgical patient and documents a proper history, physical examination, and anesthesia and nursing assessment in the chart would minimize medical-legal risk. Additionally, the clinician must provide chart evidence of discussions regarding consent, risks, and alternatives; orders of preoperative testing geared to the results of the patient's particular assessment, along with appropriate follow-up of the abnormalities documented; and notes that all the patient's questions were answered.

Information Technology and Decision Support Systems in Preoperative Evaluation

Decision support algorithms can suggest appropriate clinical management and preoperative testing based on factors documented in the patient's history and physical examination (see Chapter 4). These algorithms can be generated by clinical leadership and distributed as part of the educational and orientation process for the preoperative clinic providers. Appropriate use of clinical and testing algorithms by clinicians, even in the absence of computer-based prompts, has been demonstrated to decrease laboratory costs as a result of unnecessary or unreimbursed testing and consultations.[145]

Algorithms can be built into computer-based programs; integration with patient data stored as part of the hospital's electronic medical record would be particularly valuable. Because institutions frequently store data in programs using different platforms, there is often difficulty in attempting to integrate multiple data storage programs within a single institution and even greater difficulty in considering complete integration of patient data with commercially available systems.

Despite the potential benefits, there are a number of barriers to implementation of electronic preoperative systems. The lack of uniformity in coding medical conditions presents significant impediments to computer-based preoperative assessment systems. Coding of physician data is extremely complex, in contrast to computer recording of laboratory data. Most of the commercially available systems involve pull-down menus, which may or may not be consistent with the physician's thought processes. Pull-down menus may result in information being recorded where it "best fits" and therefore may not be completely accurate. The use of free text results in loss of the ability to generate a plan based on decision support and also prevents the use of aggregate data for reporting.

Coding needs to be recorded in such a way that the data can be used for individual patient billing, as well as in aggregate for reporting of quality performance measures. It will be difficult to demonstrate an impact of quality reporting programs on clinical outcomes until adequate physician coding through information technology can be achieved. Because of lack of this focus in coding, regulatory quality reporting programs have been shown to influence hospital improvement activities but have not been shown to have a positive impact on outcomes.[146]

Confidentiality issues in protecting computer-based data from interception are of great concern. Unlike paper-based records, computer-stored data have the potential for security risks as a result of inappropriate access to information on large numbers of patients. Proper policies and education of staff regarding privacy issues are essential. The Health Insurance Portability and Accountability Act (HIPAA) is legislation regarding the privacy of health care information and related transactions. HIPAA requirements from the Department of Health and Human Services are outlined in their website (www.hhs.gov/ocr/hipaa). Business partners of health care institutions, such as billing agencies and insurance companies, must comply with these regulations as well.

There is some concern that a change from manual to computer-based data entry during the patient visit would decrease the efficiency of established workflow patterns. The effect on the patient interview needs to be considered as well. Clinicians will need to ensure that the quality of the interview does not suffer as they divide their time between the computer terminal and the patient. The resource savings may not be demonstrated if information is merely being typed instead of written, thus again emphasizing the need for integration among platforms and reduction of requirements for free text entry. There is no evidence-

based literature demonstrating truly successful implementation, quality outcomes, and resource management with either commercially based or internally developed systems that address all of the necessary elements.

Groups such as Leapfrog and the National Surgical Quality Improvement Program have encouraged the development and use of such systems to record and report quality indicators and develop technologies to improve patient safety (www.leapfroggroup.org and www.acsnsqip.org). Because of the difficulties described with development and implementation of technology, adaption has been slow.[147] No "off-the-shelf" products are available, and no standards have been developed between vendors and institutions. Regulatory groups promote the ability of such systems to decrease errors and improve standardization and safety. Physicians are concerned about cost and the impact on workflow. The use of such systems may actually increase physician workload; one study estimated that computerized order entry would require 5% of a resident's weekly work hours.[148] Again, the ability of integration to allow medications already known in primary care and specialist's offices to be automatically entered into preoperative and order entry systems would vastly increase their appeal and efficiency.

Appropriate technology can address the TJC mandate regarding medicine reconciliation. According to this mandate, providers must enter an accurate single list of all prescription and nonprescription medications and dosages that starts at the time of entrance into the hospital for services. Development of such preoperative systems and incorporation into automated electronic perioperative information systems will aid in achieving efficient assessment before surgery. Acceptance of such systems and adequate patient and clinician use will require instruction, encouragement, and delineation of potential impact for improvement of the perioperative process.

Preoperative Involvement in Prevention of Surgical Site Infections

The preoperative visit provides an opportunity to intervene in the prevention of surgical site infections (SSIs). The Centers for Disease Control and Prevention (CDC) has used the National Nosocomial Infections Surveillance system to monitor nosocomial infections in acute care hospitals in the United States since 1970. Detailed information on this topic can be found on the CDC website (http://www.cdc.gov). In addition to considerable morbidity and mortality, SSIs significantly increase health care costs.[149] The CDC has developed standardized criteria for defining SSIs so that surveillance and comparisons can be done. Many institutions monitor the incidence of SSIs among various surgical services and procedures as a quality indicator. An analysis of one's own institutional performance and comparison with CDC benchmarks can yield extremely useful information. SSIs occurring after what would be defined by the CDC as clean surgery are probably due to certain factors, many of which can be identified during the preoperative visit (Box 34-8). The CDC recommends preoperative antiseptic showering. Preoperative showering with an antiseptic skin wash product is a well-accepted procedure for reducing skin bacteria, and showering on successive days with a skin antiseptic reduces counts progressively. However, there are no clear studies showing a direct independent relationship between preoperative antiseptic showering and a lower incidence of SSIs. Nevertheless, because of the CDC recommendation, many institutions instruct preoperative patients to perform these showers. At Brigham and Women's Hospital in Boston, patients undergoing non–mucous membrane surgery are given a skin antiseptic at the time of their preoperative clinic visit and instructed to take an antiseptic shower on each of the 2 days before the procedure. The preoperative visit can also provide an opportunity to ensure that appropriate SSI prophylaxis is ordered. If an institution establishes suggested guidelines, these algorithms can be followed and antibiotic orders written and available in the chart when the patient arrives for surgery, which would allow ample time for administration as indicated in the recommendations.

Infective Endocarditis Prophylaxis

The preoperative evaluation can also be used to identify patients in need of antibiotic prophylaxis to prevent subacute bacterial endocarditis. The recommendations by the AHA that were last published in 1997 were updated in 2006 and have included significant changes from the previous version. In this update the committee concludes that administration of antibiotics solely to prevent endocarditis is not recommended for patients undergoing a procedure on the genitourinary or gastrointestinal tract. Prophylaxis for dental procedures is recommended only for patients with underlying cardiac conditions associated with the highest risk of an adverse outcome from infective endocarditis. Infectious endocarditis is thought to be more likely to develop from frequent exposure to bacteremia associated with daily activities than from bacteremia associated with a dental, gastrointestinal, or gastrourinary procedure. The risk of antibiotic-associated adverse events and the cost-effectiveness of prophylactic therapy are such that the benefits are outweighed. Under these revised guidelines, many fewer patients will be candidates for prophylaxis.

The committee defined cardiac conditions associated with the highest risk for an adverse outcome from endocarditis. Such conditions include patients with prosthetic heart valves, unrepaired cyanotic congenital heart disease, congenital heart disease repaired with prosthetic devices for 6 months after the procedure (at which time endothelialization should have occurred), repaired congenital heart disease with residual defects, and cardiac transplantation with valvuloplasty. These are also the conditions for which prophylaxis during oral/dental procedures involving gingival manipulation or perforation of the oral mucosa are recommended, although the efficacy of such prophylaxis is unknown. Prophylaxis is recommended for the patients listed who are to undergo respiratory procedures that involve incision or biopsy of the mucosa. Prophylaxis for bronchoscopy is not recommended unless the procedure involves incision of the respiratory mucosa. Administration of prophylactic antibiotics solely to prevent endocarditis is not recommended for patients who undergo genitourinary or gastrointestinal procedures. Treatment is recommended if patients have an established infection or urinary tract colonization with enterococci. Antibiotics solely for the prevention of endocarditis are not recommended for patients with other cardiac conditions, including those with previous bypass surgeries or stents.

Prophylaxis for patients after total joint replacement was reviewed and an advisory statement issued in 2003. According to this advisory, patients with joint replacement who are undergoing high-risk procedures may need preventive antibiotics. This includes all patients during the first 2 years after joint replacement, immunocompromised/immunosuppressed patients, patients with inflammatory arthropathies such as rheumatoid arthritis and SLE, and patients with comorbid conditions, including previous prosthetic joint infections, malnourishment, hemophilia, HIV infection, insulin-dependent diabetes, and malignancy. The statements conclude that prophylaxis is not indicated for patients with pins, plates, or screws. The preoperative clinic visit can be an opportunity to identify those with joint replacements requiring prophylaxis and to ensure that appropriate orders are available at the time that the patient arrives for the procedure so that optimal timing of antibiotic administration can occur.

Recommended prophylaxis is amoxicillin, 2 g orally in adults and 50 mg/kg orally in children given 30 to 60 minutes before the procedure. This dose can be administered intravenously or intramuscularly if necessary. In patients allergic to penicillin, clindamycin (600 mg orally, intramuscularly, or intravenously in adults or 20 mg/kg orally, intramuscularly, or intravenously in children) can be used. Cephalexin (2 g orally in adults and 50 mg/kg orally in children) or cefazolin (1 g intramuscularly or intravenously in adults and 50 mg/kg intramuscularly and intravenously in children) can be used unless the patient has a history of anaphylaxis, angioedema, or urticaria with penicillin.

Preoperative Planning for Postoperative Pain Management

The preoperative evaluation provides an important opportunity to discuss and plan for the management of acute postoperative pain (see Chapter 87). Patients may be extremely concerned about this issue. Patients with chronic pain conditions need to have a plan for the management of acute pain in the setting of the chronic situation. In institutions that have an acute pain service, patients with particularly difficult management issues, patients taking large doses of analgesics, or patients with histories of analgesic abuse can be referred for consultation and appropriate perioperative managment. Patients can also be evaluated by the acute pain service postoperatively for management recommendations. In the absence of an acute pain service, the surgical service will generally be responsible for postoperative pain management.

TJC is particularly concerned that patients with pain issues be appropriately assessed and treated. A baseline pain assessment is an important part of any preoperative evaluation and is generally performed as part of the nursing assessment.[150] The preoperative pain standards in this regard state that patients have the right to appropriate assessment and management of pain and that pain must be assessed in all patients preoperatively.

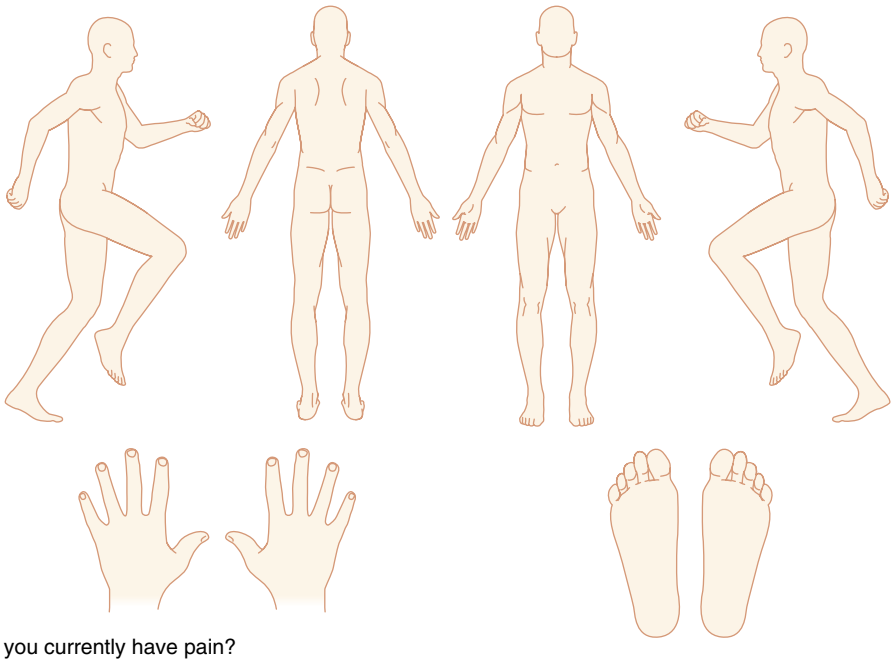
Standardization of pain measurement is difficult because of the subjective nature of the variable. Scales used fall into the categories of single-dimension scales, such as visual analog and numerical rating scales, and multidimensional scales, such as the McGill pain questionnaire.[151] Figure 34-4 shows one example used for pain assessment in a preoperative evaluation. The location of the pain is noted on the figure; the character, duration, and frequency are documented, and intensity is recorded with a numerical rating scale from 1 to 10, with 1 being no pain and 10 being the worst pain imaginable. If a numerical scale cannot be used, a scale using faces can be substituted. Use of these scales readily allows comparison when reassessments are performed postoperatively.

As part of the preoperative pain assessment, any information regarding previous and ongoing pain issues should be documented, including pain control methods that have worked or not worked in the past. Some understanding of patients' attitude toward pain medication (e.g., fear of addiction) is helpful. The exact dose of their current analgesic medications is essential. If patients take them as needed, how many are being used on average per day should be recorded.

Patients with chronic pain conditions present a special management problem. There is no reason to wean patients from pain medicine before surgery. If the patient's analgesic is an NSAID or COX-2 inhibitor, the patient may be told to discontinue use before surgery. If so, the patient may need to be given a different analgesic for pain control before the procedure. Patients should be told to take their usual morning doses of pain medicine. If the patient wears a fentanyl transdermal patch, it can be left on. It is important to inform the patient that care providers will do everything possible to maintain comfort postoperatively, but the expectation of having no pain should not be given. It should be expected that a chronic pain patient's requirement for pain medication will be increased postoperatively and should be managed accordingly. There are no useful algorithms for treatment of acute pain in chronic pain patients, and care needs to be individualized. A pain service consultation may be very useful in this situation, especially when the surgical staff is not familiar with complicated chronic pain regimens and alternative options.

Preoperative Use of Alternative and Complementary Therapies

A significant number of patients have been reported to use alternative and complementary therapies in the preoperative period (see Chapter 32). A survey of preoperative clinic patients demon-



Do you currently have pain?

☐ Yes ☐ No If Yes, location: _____

Character: ☐ sharp ☐ throbbing ☐ dull ☐ burning

Duration: _____

Frequency: _____

Intensity scale: _____

☐ Numeric

☐ Faces

What makes the pain better? _____

What makes the pain worse? _____

What is an acceptable pain level to you? _____

Figure 34-4 Pain/status/history form.

strated that 22% reported the use of herbal medications and 51% used vitamins.[152] Women and patients in the age range of 40 to 60 years were more likely to use herbal medicine. The most commonly used compounds, from highest to lowest, included echinacea, *Ginkgo biloba*, St. John's wort, garlic, and ginseng. The pediatric population has a significant amount of use as well, which varies with ethnic subgroup.[153] Use of nonprescribed dietary supplements was significantly higher in Hispanic than in white children (33% versus 9%).

Of concern is that unless specifically questioned, patients may not report the use of these nonprescription agents. In a group of patients awaiting cardiac surgery, 56% did not inform the anesthesiologists before surgery regarding the use of these products.[154] Because patients may fail to disclose the use of alternative therapies unless specifically questioned, it is difficult to make specific associations between potential drug and herb interactions. In addition, the U.S. Food and Drug Administration (FDA) does not have regulatory oversight of purity and other standards of these nonprescription medications. Many of the herbs sold are ineligible to be approved as a drug, and the FDA can take action only when a substance is determined to be unsafe.

The ASA has published two documents on dietary supplements, one for patients and one for providers.[155] Both these pamphlets are available through the ASA website. The ASA recommends discontinuation of all alternative therapies 2 weeks before elective procedures, although there are no definite data supporting this recommendation.

The impact of alternative therapies on perioperative outcome is unclear. In a Hong Kong cohort study, 80% of presurgical patients took self-prescribed traditional Chinese herbal medicines (TCHMs).[156] Despite the high use of alternative therapies in this group, there was no significant association between any type of TCHM and the occurrence of either intraoperative or postoperative events when adjusted for covariates. Patients who used TCHMs were more likely to have a preoperative event, including a prolonged aPTT and hypokalemia.

The most common potential adverse effects of herbal medicines in the perioperative period include impaired coagulation, cardiovascular side effects, electrolyte disturbances, and prolongation of the effects of anesthetic agents.[157] There is little information available about the epidemiology of perioperative events related to alternative therapies, and there is no agency currently

Box 34-9 Potential Adverse Effects of Alternative Therapies

Cardiovascular instability, including high blood pressure, tachycardia, angina, and atrial arrhythmias: saw palmetto, ginseng, black cohosh, St. John's wort

Thromboembolic events: saw palmetto, ginseng

Enhanced potential for bleeding: black cohosh, ginkgo, garlic, ginseng, ginger, chamomile, vitamin E

Prolongation of anesthesia: St. John's wort

Hypothyroidism: soy

Hyperthyroidism: triiodoacetic acid

Hepatotoxicity: echinacea, kava

Decreased effectiveness of HIV protease inhibitors: St. John's wort

Seizures: black cohosh

Enhanced effect of opioid analgesics: valerian, kava, chamomile

Inhibited effect of opioid analgesics: ginseng

responsible for overseeing manufacturing and safety, regulating sales, and reporting adverse events. Starting in 2005, TJC required that alternative therapies be considered like any other drug when documentation of patient medications is performed. Potential adverse effects of the more commonly used agents are summarized in Box 34-9. However, much of these data is based on anecdotal evidence, theoretical proposals, and case reports—not from good epidemiologic studies with large databases.[158,159] Further in vitro data, animal studies, and clinical epidemiologic studies are needed to assess the significance of these potential interactions.

A significant number of patients also report the use of nonherbal alternative therapies. The most common complementary and alternative therapies reported in a survey of preoperative patients were massage therapy (15%), herbal therapy (10%), relaxation (8%) and acupuncture (7%).[160]

Preoperative Laboratory and Diagnostic Studies

The value and outcome of preoperative diagnostic studies and testing have become a central issue in evaluating cost-effective health care in presurgical patients. It is estimated that up to $4.0 billion is spent annually in the United States on preoperative diagnostic and laboratory evaluation. The value of obtaining preoperative studies as a screening tool to detect disease and evaluate the stability of the patient's medical condition for anesthesia and surgery has been extensively published in the academic literature.[161] The concept of standardized testing in all presurgical patients regardless of age or medical condition is no longer considered medically appropriate. Unnecessary testing is inefficient and expensive, and it requires additional technical resources. Inappropriate studies may lead to costly evaluation of borderline or false-positive laboratory and diagnostic test abnormalities. This may result in unnecessary operating room delays, cancellations, and potential patient risk through additional testing and follow-up.

Patients require preoperative diagnostic and laboratory evaluation that is consistent with their medical history, the proposed surgical procedures, and the potential for intraoperative blood loss. Preoperative diagnostic and laboratory testing should be obtained for specific clinical indications that may increase perioperative risk and not simply because the patient is to undergo a surgical procedure. Consistent accuracy of diagnostic testing and the problems associated with false positives are reason enough to limit preoperative tests to specific indications. The sensitivity, specificity, reproducibility, and clinical predictive value of preoperative diagnostic studies have been comprehensively reviewed in previous editions of this chapter. It has been well documented in academic studies that routine preoperative screening tests in an asymptomatic healthy patient have no beneficial effect on surgical or anesthesia outcomes.

At many hospitals, the tradition has been that all preoperative tests and diagnostic studies be ordered by the surgeon or primary care physician. Frequently, these tests are obtained without a specific diagnostic focus other than a speculation that the anesthesiologist may "require them" to proceed with surgery and thus avoid delays and cancellations. Other reasons include routine screening for disease states, establishment of a diagnostic baseline, personal habit (using a "standard" checklist for all patients), physician reassurance, and a perceived medicolegal necessity "not to miss anything." This historical method of ordering preoperative laboratory tests as screening devices and to avoid cancellations and delays cannot be justified and is clinically inappropriate.

Nonselective laboratory testing and diagnostic studies result in significant cost to the hospital and expense for the patient.[162,163] Routine presurgical screening tests are no longer supported or reimbursed by Medicare and most private insurance carriers without specific indications. Implementation of changes is necessary to reduce these costs and enhance patient care. Anesthesiologists are the perioperative medicine experts and are best qualified to establish appropriate and necessary preoperative laboratory and diagnostic tests for intraoperative anesthesia management. Providing specific guidelines and education to physician colleagues and surgical services for recommended preoperative testing reduces costs, expedites patient care, and enhances the anesthesiologist's recognition as the perioperative physician specialist.

Several academic studies have demonstrated reductions in hospital cost for preoperative diagnostic evaluation when diagnostic testing is coordinated through the anesthesia preoperative evaluation clinic.[164,165] Preoperative diagnosis-based guidelines (Table 34-7) provide basic recommendations for perioperative management of patients with medical conditions that increase operative risk. These disease-specific guidelines are not intended as absolute or standard requirements. There are no consistent recommendations or protocols in anesthesia texts or the literature or by medical/anesthesia society consensus of what constitutes recommended laboratory and diagnostic studies in an asymptomatic healthy patient at any age. After 6 years of extensive discussion, The ASA Task Force on Preanesthesia Evaluation published recommendations in 2002 that testing and consultation be done on the basis of a reasonable expectation that the patient may have an abnormal value and that such a value will have an effect on the decision whether and how to provide care during perioperative

management.[3] Specific preoperative laboratory testing will be reviewed as follows, with an emphasis on diagnosis-based/clinical indications.

Complete Blood Count, Hemoglobin, and Hematocrit

The proposed surgical procedure and potential blood loss, together with individualized clinical indications, should determine the requirement for a blood count preoperatively. Primary clinical indications include a history of increased bleeding, hematologic disorders, renal disease, chemotherapy or radiation treatment, steroid or anticoagulant therapy, poor nutrition/malabsorption status, surgical procedures with anticipated high blood loss, and trauma.

Liver Function Testing

There is no routine preoperative anesthesia requirement for liver function testing. It should be based on a history of hepatic injury and physical examination findings. Primary clinical indications include a history of viral, alcohol, or drug-induced hepatitis, jaundice, cirrhosis, portal hypertension, biliary or gallbladder disease, hepatotoxic drug exposure, infiltration of tumor, certain immunologic disorders, and bleeding disorders.

Renal Function Testing

Tests of renal function measure the degree of renal tubular dysfunction and glomerular filtration. Primary clinical indications include patients with diabetes; hypertension; cardiac disease; dehydration; nausea and vomiting; anorexia; bulimia; increase fluid overload, such as in congestive heart failure, peripheral edema, or ascites; renal, hepatic, or cardiac impairment; hematuria; nocturia; polyuria; oliguria; anuria; and a history of renal transplantation.

Coagulation Testing

Clotting studies are not indicated as a routine preoperative evaluation, even in patients undergoing regional procedures, unless there is specific indication of a known or suspected coagulopathy. A careful history that includes drug therapies and physical examination will provide guidance if coagulation testing is indicated. Primary clinical indications include a history of a bleeding disorder or previous excessive intraoperative surgical bleeding, hepatic disease, poor nutritional status, and use of anticoagulants or other drugs that affect coagulation.

Urinalysis

There is no indication during preoperative anesthesia evaluation for routine urinalysis. Primary clinical indications could include a suspected urinary tract infection or unexplained fever or chills.

Pregnancy Test

Pregnancy testing is often determined by individual group practice protocols and can be based on the history and specific questions. Clinical indications can include the date of the last menstrual period, sexual activity, type or absence of birth control method, and patient or physician intuition.

The Electrocardiogram

The ECG is used to determine a previous history of MI, conduction/rhythm disturbances, ischemia, chamber hypertrophy, and metabolic/electrolyte disorders. Primary clinical indications preoperatively include a history of CAD or MI, hypertension, diabetes, congestive heart failure, chest pain, palpitations, abnormal valvular murmurs, peripheral edema, syncope, dizziness, dyspnea on exertion, shortness of breath, paroxysmal nocturnal dyspnea, and cerebrovascular disease. The ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation provide additional recommendations for preoperative resting ECGs (see Box 34-3).[7]

The Chest Radiograph

There is no routine indication to obtain a chest radiograph in preoperative evaluation. The chest radiograph should be used to assess concerned abnormalities that are present by history or physical examination. Primary clinical indications for a preoperative chest radiograph include auscultation of rales or rhonchi, advanced COPD and blebs, pulmonary edema, suspected pneumonia, pulmonary or mediastinal masses, tracheal deviation, aortic aneurysm, atelectasis, cardiomegaly, pulmonary hypertension, or dextrocardia.

Preoperative Pulmonary Function Assessment

PFTs are not considered routine for patients with a history of asthma, emphysema, or COPD. Patients with pulmonary diseases have often undergone pulmonary function testing through their primary care physician, obtainable as needed. Clinical examination and a careful history will indicate the patient's current respiratory status and the potential for anesthesia/surgical pulmonary compromise.

Preoperative PFTs can assess potential respiratory complications in patients undergoing surgical resection of the lung. PFTs determine the patient's pulmonary reserve and whether the patient may require postoperative chronic ventilation support. The specifics of preoperative pulmonary function testing in patients undergoing lung resection are reviewed in another section of this chapter.

The Preoperative Evaluation Clinic

Many anesthesia groups and major medical centers have developed preoperative evaluation programs and clinics with the goal

of enhancing operating room efficiency and the quality of patient care.[166,167] There are many variations in the staffing, structure, financial support, and daily operations of preoperative programs; however, all have a common goal of avoiding cancellations, delays, and adverse patient outcomes that could have been addressed before the day of surgery.

The development and implementation of a preoperative evaluation clinic depend on the daily volume of patients, the predominant medical patient acuity, the availability of facilities, the demographics of distance of the patient from the hospital, and a perioperative staff, hospital administrative, and anesthesia departmental commitment that supports changes.

It is essential that the anesthesiologist develop the leadership and management position in the preoperative evaluation program. When internal medicine departments and other medical specialties develop preoperative programs within hospitals, the anesthesiologist's role and expertise in perioperative patient management often become secondary. This can result in significant interdepartmental conflict and disagreement concerning a patient's evaluation, risk stratification, and optimal stability to proceed with anesthesia.

When patients are "cleared for surgery" by other specialties, this is often considered by the surgeon as evidence that the patient is appropriate and suitable for anesthesia. Unfortunately, this clearance is frequently provided with limited knowledge of current anesthesia practice and intraoperative patient management. The preoperative history, physical examination, and assessment by a medical specialist may not address specific anesthesia concerns of risk assessment[168,169] and patient optimization, thus providing the framework for potential surgical delays and cancellations. Additionally, patients may have had medications preoperatively withdrawn, changed, or added to their treatment in preparation for surgery, which further complicates intraoperative anesthesia management.

When cases are delayed or canceled by the assigned anesthesiologist on the day of surgery, it often creates significant frustration in the surgeon and patient. The anesthesiologist is the only specialist who can make the final determination of whether the patient is appropriate for anesthesia and whether the patient is stable to proceed. It is advantageous to accentuate this fact to hospital administrators and those who plan the development of a preoperative clinical program but remain uncertain regarding which speciality to support. Clinical studies have demonstrated that the anesthesiologist's leadership and direct clinical responsibility in a preoperative program will reduce hospital costs by decreasing operating room delays, cancellations,[164,170] and potential adverse intraoperative patient events.

Good outcomes depend strongly on awareness and planning. Anesthesia groups with a predominantly healthy outpatient and to-be-admitted population and hospital facilities with limited resources and staffing may be unable to evaluate all patients preoperatively before the day of surgery. This requires a means of screening patients and triaging them from the preoperative program in a manner that ensures a high level of accuracy in determining the patient's current health status. Accurate triaging results in time savings and avoidance of costly cancellation and delays on the day of surgery without compromising patient quality of care and outcomes.

One process of triaging involves having an anesthesia questionnaire (see Fig. 34-1) available in the surgeon's office, which could be filled out by the patient during the initial assessment by the surgeon. The questionare would be faxed to the group's anesthesia location before the surgical date. Reviewing the patient's medical history before the day of surgery, even by paper, reduces unresolved or unexpected medical concerns. A decision could then be made of whether the patient requires a formal preoperative consultation or could be evaluated on the day of surgery. A phone call by an anesthesiologist to a patient with a questionable medical history could clarify issues of concern. Another method of triaging patients to reduce the impact of unnecessary clinic evaluations would be to provide patients at the initial surgical visit with an anesthesia department Internet address where patients could fill out their medical questionnaire online for review.

Anesthesia groups with a larger number of medically complex presurgical patients may benefit from a more formal preoperative facility with multiple examination rooms, dedicated staffing, and a full-time operational system. The following sections describe the development and implementation of an anesthesia preoperative evaluation clinic with a focus on the necessary protocols, policies, and requirements for recognition, accomplishment, and success. Not every aspect of what is described becomes necessary. Various modifications and adaptations for individual practices, facility expansion, and financial support are expected.

Establishment of a successful anesthesia preoperative evaluation clinic requires interdepartmental commitment, collaboration, and financial support of several hospital disciplines.[164,171] The departments of anesthesia, surgery, nursing, and hospital administration must agree that a centralized preoperative clinic has value for the hospital, and each discipline must firmly support the necessary changes and operational goals of a preoperative evaluation clinic (Box 34-10).

Collaboration, Commitment, and Teamwork

The preoperative evaluation clinic is a visible partnership and collaboration between the departments of anesthesia, surgery, nursing, and hospital administration in achieving common goals as illustrated in Figure 34-5. It conveys the important concept that the development of this new clinical program is an integrated enterprise and requires obligation, sharing of endeavor, and financial responsibility.

Initially, surgeons may be reluctant to send patients to a newly developed anesthesia preoperative evaluation clinic. This hesitation stems from an unclear understanding of the supportive process, significance, and enhanced outcomes of a medical evaluation by an anesthesiologist. A surgeon's hesitation to send patients to the preoperative evaluation clinic can be reduced by identifying the clinical advantages of the preoperative program.

For example, informal assurances should be given to the surgical services that if a patient is evaluated in the preoperative program, the case will proceed to surgery without cancellation or delay by the assigned anesthesiologist, the only exception being illness or an adverse medical event between the time of evaluation and the time of the planned surgery. Cancellations and delays on the day of surgery can be a prominent source of aggravation and even antagonism for surgeons and patients and results in loss of revenue. Additionally, patients are often billed for hospital services although their actual surgical procedure was not performed.

Box 34-10 Operational Goals for a Preoperative Evaluation Clinic

Improve the client's perception of the preoperative evaluation experience by increasing personalized patient care, comfort, and convenience.

Provide a centralized site for preoperative evaluation.

Institute an anesthesia scheduling system for timely patient access and flow.

Ensure the presence of an anesthesiologist on site when patients are present.

Appoint a medical director to coordinate all activities.

Ensure the availability of medical records and surgical notes at the time of preoperative evaluation.

Decrease logistic shuffling of patients to multiple hospital service areas.

Integrate and coordinate services through on-site facilities for admission/registration, insurance authorization, laboratory tests, and electrocardiographic studies.

Improve the education of patients and families about the elements of their surgical procedure and the proposed anesthesia care, including postoperative pain control options.

Educate patients about what to expect regarding postoperative feeding and discharge needs.

Ensure and coordinate cost-effective ordering of preoperative laboratory and diagnostic studies.

Provide an anesthesia medical consultation service for evaluation of medically complex inpatients and outpatients.

Decrease the number of cancellations and delays in operative procedures on the day of surgery.

Enlist the skills of a nurse practitioner to assist in preoperative evaluation and patient/family education.

Develop protocols, policies, and clinical pathways.

Perform quality assurance reviews.

Maximize efficiency in operating room function and turnover time by coordinating all preoperative information at one location in the anesthesia preoperative evaluation clinic.

Enhance patient and surgeon satisfaction.

It is of paramount importance that anesthesia departmental practitioners discuss and agree on individual practice variations. Differences, such as at what fasting blood glucose level a surgical case would be canceled or what degree of preoperative hypertension is acceptable, require departmental clarification and agreement. If half the anesthesiologists would perform a particular surgical case with increased patient risk and the other half would cancel the case, the inconsistency demonstrated to the surgeon would foster a lack of support and reluctance to have patients evaluated, and essentially the clinic would be unsuccessful.

The anesthesia preoperative evaluation clinic can become a valued perioperative and hospital asset by providing consistent quality patient management and cost-effective outcomes that decrease surgical delays and cancellations. If a special medical concern related to anesthesia is identified before surgery, the preoperative program coordinates collecting the medical data, managing any additional workup or consultations, and discussing the case with the surgeon and the assigned anesthesiologist before the date.

Financial Concerns in Developing a Preoperative Clinic

Health care reforms have resulted in closer evaluation of the cost-benefit ratio and operational efficiency of many hospital programs.[172,173] Economic changes have decreased reimbursement and reduced the patient's length of stay in the hospital. At the same time there has been rapid advancement in outpatient services, especially in ambulatory surgery. The percentage of surgical patients entering the hospital as outpatients or admitted on the same day as surgery continues to increase and challenge perioperative personnel, especially the anesthesiologist.

Physicians are the primary decision-makers concerning the utilization of health care services. In preparing a patient for surgery, physicians are directly responsible for ordering virtually all of the patient's evaluations, including preoperative diagnostic testing and referral to specialists. Although health care continues to be in an active state of reform, it is frequently difficult for an individual physician or group to change the manner or routine of clinical practice patterns. There is increasing demand from hospitals and insurance carriers that providers demonstrate veri-

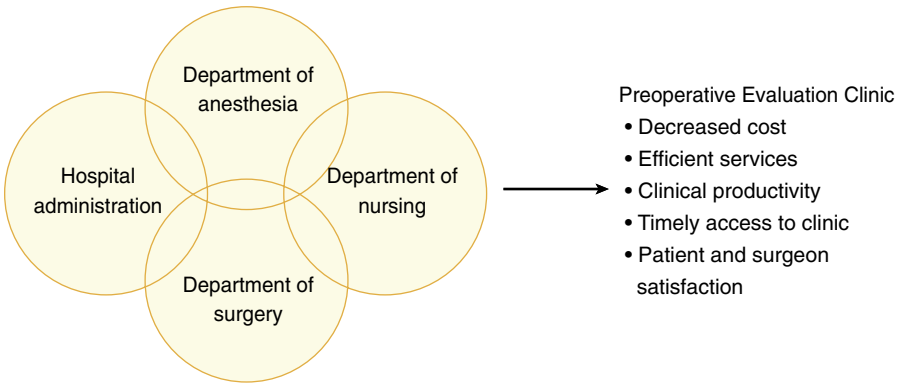

Figure 34-5 The anesthesia preoperative evaluation clinic is a constructive partnership toward common goals. Sharing of resources and budgetary costs is apportioned.

fiable evidence of decreasing costs while maintaining productivity and a high level of quality patient care.

Hospital support and financial contribution for a preoperative evaluation clinic will focus on price, quality, and value. Economic analysis of a proposed preoperative evaluation clinic is imperative to align administrative, operational, and financial support. It requires a documented comparison between the current preoperative resource utilization, costs, and outcomes (operating room delays, cancellations) with the projected preoperative evaluation clinic and anticipated operational improvements (decreased operating room delays, cancellations, enhanced operating room efficiency, etc.)

This document must be comprehensive and focused on opportunities for improvement. It is presented for hospital financial analysis in a business plan (Box 34-11) linked with academic publications demonstrating cost-effectiveness and outcomes in the preoperative clinic model. A preoperative clinic that offers no improvement and an increase in cost is unsuitable and economically detrimental to the hospital. Financial support for the anesthesia medical director is derived from both the department of anesthesia and hospital administration because the preoperative evaluation clinic is a hospital improvement–based program and can reduce hospital costs.

Facility Restructuring and Modernization

Focusing all preoperative clinical services into one hospital location establishes a center of visibility, competitiveness, and efficiency. The preoperative clinic should be regarded as a long-term investment for the hospital, physicians, and patients.

Facilities that have been developed at Stanford University Hospital are listed in Box 34-12 and are provided as an example of an extensive facility already in need of expansion because of increasing patient volume. However, not all hospital centers have the facilities or funding to construct a formal preoperative evaluation clinic. A compromise of sharing the preoperative clinic space with another medical specialty clinic could be beneficial in terms of staffing and reducing costs. The simplest of preoperative evaluation areas might be a private space in the presurgical holding area or the postanesthesia care unit as patient census decreases later in the day. Cross-trained staff from available resources such as the operating room or recovery room can assist in the preoperative evaluation program during downtime/low patient volume to process preliminary paperwork, obtain medical and outside records, record vital signs, collect laboratory specimens, and perform ECGs, for example.

The predominant costs of operating a preoperative evaluation clinic are essentially the number of staff per diem. Facility renovation can be costly or nominal. Material and supplies are usually minimal. A preoperative facility with a comfortable, low-stress patient waiting area is a positive investment in patient relationships. Patients often express their primary complaint with hospital services as waiting for excessive periods. A thoughtfully designed clinic facility enhances the patient's anesthesia experience.

Hospital administrators, surgeons, and other physicians will monitor performance of the preoperative evaluation clinic in terms of outcome measurements, personal observations, and value analysis. Achievement and success are often linked to renewed or additional financial support.

Quality assurance measurements and clinical benchmark indicators for the preoperative clinic should be entered into a database, which can then be used to determine performance standards and areas in need of improvement.[174,175] This information could measure, for example, operating room cancellation and delays, the specific causes, cost, and resource time loss. It provides the basis for operational changes and improvements in hospital service. Figure 34-6 is an example of a quality and service indicator form for a preoperative evaluation clinic.

Preoperative Standardization and Accuracy of Documentation

Standardization of the preoperative process is essential for both clinical and administrative reasons. Important reasons to encourage standardization in process and documentation are listed in Box 34-13.

Standardization maximizes reimbursement by ensuring accurate coding for the diagnosis-related group (DRG) and for preoperative testing. In many institutions, nonclinical personnel are used to review the preoperative history and physical assessment, from which comorbid conditions are coded to define the appropriate reimbursement level based on the surgical diagnosis and procedure. In some cases, a variety of clinicians in outside offices may be submitting preoperative history and physical assessments in nonstandard ways, thus making coding difficult. These assessments may focus on the surgical diagnosis and may not appropriately list all existing comorbid conditions. If an institution does not have a standardized process for preoperative recording of the history and physical examination, appropriate reimbursement for these issues may not be attained. This can be a major source of institutional revenue loss. In addition, a standardized process allows the clinician to accurately code for preoperative laboratory testing by diagnoses that can be reimbursed, as opposed to screening laboratory tests, which are no longer reimbursed by the CMS.

Standardization maximizes reimbursement by standardizing coding and data collection regarding pay-for-performance measures. Numerous strategies, including pay-for-performance measures, are being instituted across the country in an attempt to improve quality. Standardizing preoperative processes will allow the development and implementation of protocols so that the measures are met and appropriately documented. This is particularly important if implementation of these protocols is required before the day of the procedure. Presently, this could include implementing some of the national Surgical Care Improvement Project measures (e.g., appropriate perioperative β-blocker therapy).

Standardization allows the implementation of clinical algorithms based on best practice, which will optimize preoperative medical management and potentially reduce complications and ensure the best possible outcomes. Preoperative risk factors have been shown to be effective predictors of hospital cost.[176] Therefore, preoperative intervention to reduce risk could lead to significant cost savings. For example, despite the existing evidence, a significant number of patients who would be candidates for perioperative β-blockade are not receiving it at the time of the preoperative visit. There is inconsistent application of these guidelines by surgeons and referring physicians, thus again leading to

Box 34-11 Outline of a Business Plan for an Anesthesia Preoperative Evaluation Clinic (APEC)

The business plan provides or describes the following items:

I. An Executive Summary
One-paragraph summary of the proposed APEC program

II. Description of the APEC
Objective or mission of the APEC

Names of the proposed APEC medical director, department chair

Location within the hospital designated for the APEC (define an area, even if currently occupied)

Development stage (is there an existing preoperative program?)

Services of the APEC (see operational goals, Box 34-10)

Anesthesiology specialty information (i.e., anesthesiologists are the experts in operating room medicine and preoperative evaluation)

III. Analysis of General Factors Affecting Viability of the APEC
Volume and medical condition of preoperative patients (present a graph for past years)

Anticipated growth trends

Vulnerability to economic factors (e.g., fee-for-service payment is decreasing, managed care is increasing, hospitals need to decrease cost)

Technologic factors (e.g., anesthesia and surgical procedures are increasingly becoming more complex)

Regulatory issues (the APEC conforms to all local, state, and federal policies)

Financial considerations

IV. Definition of Target Markets
All outpatient and same-day admissions (i.e., increased smooth flow of a healthy patient through the health care system and educational processes, often starting in the surgical office)

Medically complex patient undergoing anesthesia and surgery

V. Discussion of Factors Relating to Competition
Competitive position of the APEC (the anesthesiologist is the operating room and preoperative medicine expert)

Barriers to entry (primary care physicians/consultants believe that they have sufficient specialty knowledge to clear patients for anesthesia and surgery)

Future competition

VI. Description of Effective Marketing Strategies
Increased visibility, which increases viability of the APEC

Use of hospital/health system news media to explain who anesthesiologists are and what they do

Formation of strategic partnerships with the departments of nursing and surgery and with the hospital/health system administration

Informal assurance that cases will be facilitated by anesthesia if seen in the APEC

Presentations at surgical, medical, gynecologic, pediatric, and administrative grand rounds (as well as others) and conferences

VII. Description of Operational Aspects of the APEC
Facilities (e.g., examination rooms, phlebotomy/electrocardiography room)

Equipment and supplies

Variable labor requirements (e.g., nurse practitioner, anesthesiologist)

Daily anticipated operations and flow

Quality assurance and utilization review

Management information systems

VIII. Description of Management and Organization of the APEC
Clinical and administrative director

Inclusion of the department of nursing and hospital administration

Organization management (presented in a flow chart)

IX. Description of the Developmental Goals of the APEC
Short-term goals (changes in clinical practice)

Long-term goals (e.g., renovation of facilities)

A time line (demonstrates a developmental plan)

The growth strategy (projection of 6-month, 1-year, and 5-year goals)

Evaluation of risk

X. Discussion of Financial Matters
Income statement (consider a facility fee, anesthesia medical consultation charge, projected hospital/health system cost savings, and market share enrichment)

Variable expenditures (e.g., APEC personnel and resources, facility housekeeping and supplies)

Balance sheet

Box 34-12 Facilities of the Anesthesia Preoperative Evaluation Clinic at Stanford University Hospital

- Five combination office and examination rooms
- A patient and family education room (preoperative teaching)
- A patient-centered media and video room
- A phlebotomy and electrocardiography room
- An on-site office for the medical director
- A registration and reception area
- On-site restroom facilities
- A large, comfortable patient lounge
- An area for admitting and financial services
- Approximately 2200 square feet for facilities
- Conference room and shared chart and computer support room

the question of accountability for the preoperative process. An anesthesia preoperative clinic can develop and standardize clinical presurgical evaluation policies and guidelines to coordinate the process of implementing appropriate protocols before the day of surgery. This could result in decreased cost for prolonged hospitalizations caused, for example, by perioperative cardiac complications. Providing algorithms for clinical practice in areas where outcome-based data are unavailable may result in the use of arbitrary parameters based on consensus opinion. An algorithm provided to clinical staff performing preoperative assessment is provided in Box 34-14.

A second example in which implementation of a preoperative protocol may reduce postoperative complications is protocols that address reduction of SSIs. A standardized preoperative process provides a means for instruction in this regard; for example, at the time of the preoperative visit, patients can be given antiseptic agents to shower with before surgery.

Standardized processes allow more accurate data collection for quality reporting. Hospitals may be contributing data on their operational results to organizations such as TJC, the National Surgical Quality Improvement Program, or the Institution for Health Care Improvement. In addition, state law may mandate reporting requirements. For example, in the state of Massachusetts, information on the preoperative, operative, and postoperative factors and outcomes of cardiac surgical patients must be collected in a standardized fashion and reported to the state.

Standardized processes help minimize complications caused by communication errors. Recent work shows that serious communication breakdowns occur throughout the continuum of surgical care.[177] In a review of surgical malpractice claims, 81 communication breakdowns occurred in a total of 444 cases. Of these breakdowns, 38% involved problems with communication of preoperative information. Ambiguity about responsibility was a commonly associated factor. Standardization of documentation would improve transfer of care from preoperative clinicians to the operative team. Responsibility for dealing with abnormalities identified during the preoperative assessment could be clearly delineated.

Information Management and Centralization

For a patient's surgery to proceed without delay, all required paperwork and information must be present. At many hospitals, the surgeon's history and physical examination, operation consent form, laboratory test results, nursing operating room admission form, and anesthesia preoperative notes must be present in the patient's chart before entering the operating room.

The preoperative evaluation clinic can coordinate, process, and centralize all patient presurgical information in the medical chart. A simple checklist of required content can reduce delays and increase operating room efficiency by correcting problems before the day of surgery.

Because patients from out of the local area may be staying in hotels or with family or friends, it is important that a "day before surgery" local/cellular phone number be recorded in the presurgical chart so that the patient can be contacted before surgery. The preoperative staff telephones patients on the evening before surgery to ensure compliance with arrival time, to reinforce instructions, and to answer any questions. This contact by telephone avoids day-of-surgery delays and potential cancellations.

Accuracy of preoperative records is imperative, with multiple health care professionals, regulatory agencies, and occasionally the legal profession reading and reviewing medical entries. Preoperative issues that result in misinterpretation of intended documentation or physician orders can be a factor in adverse patient outcome and potential legal responsibility. Box 34-15 reviews preoperative evaluation documentation fundamentals and concerns.

Box 34-13 Importance of Preoperative Process Standardization

- Standardization maximizes reimbursement by diagnosis-related group and for preoperative testing by standardization and accuracy of documentation in the preoperative assessment.
- Standardization maximizes reimbursement by standardizing coding and data collection regarding pay-for-performance measures.
- Standardization allows the implementation of clinical algorithms based on best practice, which will optimize preoperative medical management and potentially reduce complications and ensure the best possible outcomes.
- Standardized care protocols and optimization of clinical care with a potential impact on reduction of complications can reduce the cost of admission and length of stay.
- Standardized processes allow more accurate data collection for quality reporting.
- Standardized processes help minimize complications caused by communication errors.

Visit time in: _____

Visit time out: _____

If No, cause of delay in preop program:

☐ No chart

☐ Outside records/tests did not arrive with patient
Time to find old/recent: ☐ ECG ☐ Chest X-ray ☐ MUGA ☐ PFTs ☐ ECHO ☐ Stress test ☐ Lab work

☐ Complex history, No H&P, start from the beginning for history

☐ Lab order problems/changes ☐ Call resident

☐ Wait to clear patient's ECG

☐ Consult with medical director

☐ Medical director not available, find appropriate person

☐ Contact outside source for additional information

☐ Patient arrived after 5:00 P.M.

☐ Patient had surgery recently, chart not available, start all over with information

☐ Clinical complication that could postpone or cancel surgery

☐ Language barrier w/interpreter ☐ Language barrier w/NO interpreter

☐ Physical disabilities

☐ Teaching

☐ Nursing assessment forms

☐ Solved problems unrelated to anesthesia; explain: _____

☐ Cardiac surgical team not available

Comments: _____

Figure 34-6 Preoperative program quality and service indicator form. ECG, electrocardiogram; ECHO, echocardiography.

Structure and Activities of the Preoperative Evaluation Clinic

The daily operations of an anesthesia preoperative clinic will vary according to patient volume, acuity of the patient's medical conditions, availability of facilities, and employee resources. However, a generalized operational structure can be suggested by examining several preoperative clinic models currently in practice.

Centers with a large volume of patients should have their patients formally scheduled in the clinic before the day of evaluation so that medical records and appropriate outside information would be available. The surgeon's office should schedule the anesthesia clinic appointment at the same time that the operating room case is booked. Flexibility in scheduling appointments is needed in the clinic to accommodate patients with urgent surgical requirements and those residing outside the local hospital area.

The anesthesia evaluator interviews and examines the patient, obtains historical medical information and outside records (via facsimile and phone as needed), and determines the appropriate diagnostic, laboratory, ECG, and other evaluation requirements. Phlebotomy, ECG, and hospital admitting/insurance registration are available in the preoperative clinic. Such centralization of multiservices provides a significant convenience to patients, who no longer must search for multiple hospital locations to complete preoperative requirements. It also centralizes all

Box 34-14 Algorithm for Preoperative Clinical Assessment

A. Assess Surgical Risk:

High risk (>5%)
- Aortic surgery
- Major vascular surgery
- Peripheral vascular surgery
- Prolonged procedures with fluid shifts*

Moderate risk (1% to 5%)
- Head and neck surgery
- Intraperitoneal and intrathoracic surgery
- Carotid endarterectomy
- Orthopedic surgery
- Prostate surgery

Low risk (1%)
- Superficial procedures
- Cataract surgery
- Breast surgery

B. Assess Functional Status

Low functional status: METs less than 4, unable to climb two flights of stairs, or inability to assess functional status

Acceptable functional status: METs greater than 4 or able to climb two flights of stairs without symptoms

C. Assess Stability

1. Does the patient have shortness of breath that is not due to pulmonary disease?
2. Does the patient have a history of syncope that has not been investigated?
3. Does the patient have a change in the pattern of chest pain or a history of chest pain that has not been investigated?
4. Does the patient have an increase in leg swelling, rales on lung examination, or new leg swelling that has not been investigated?
5. Does the patient have a history of paroxysmal nocturnal dyspnea or orthopnea that has not been investigated or has worsened?

D. Decision for Referral Based on A, B, C:

With a "yes" answer to any of the questions in C, consider referral to the PCP or cardiology regardless of functional status or surgical risk

If the answer to questions 1 to 5 is "no" and functional status is low, consider referral to cardiology only if the surgery is very high risk

If the answer to questions 1 to 5 is "no" and functional status is adequate, the patient does not warrant referral based on stability

Consider Cardiology Evaluation:
- Pacemaker not checked within 6 months
- Automatic implanted cardioverter-defibrillator not checked within 3 months
- History of positive exercise tolerance test without follow-up (Bruce <6 minutes, >4 segments with perfusion abnormalities)
- New left bundle branch block
- Atrial fibrillation (new or old) with a ventricular rate greater than 120 beats/min
- New T-wave inversions or new ST elevations or depressions greater than 2 mm
- New atrial fibrillation
- Second-degree atrioventricular block with a wide QRS complex (not investigated)
- New pathologic Q waves consistent with myocardial infarction
- Prolonged QT (>520 msec)

Consider Primary Care Evaluation
- New anemia (hematocrit less than 30% with unknown cause)
- Diastolic blood pressure greater than 110 mm Hg
- Glycohemoglobin greater than 8.5
- Wheezing on physical examination
- Potassium less than 3.2
- Platelet count less than 100,000, cause unknown or not investigated
- New hyperthyroidism
- Abnormal urinalysis suggestive of urinary tract infection
- Unexplained coagulation abnormalities
- New murmur

*Mastectomy with reconstruction, major bowel resection with colectomy, major lung resection procedures, hip revision, major back surgery, pelvic debulking.
METs, metabolic equivalents of the task; PCP, primary care provider.

hospital data into one chart, which remains in the preoperative evaluation clinic area until the time of surgery.

The patient's ECG is assessed during the clinic visit, and laboratory test results are evaluated at the end of each clinic day, with follow-up of abnormal findings as needed. In this manner, significant abnormalities can be addressed immediately, and if needed, cancellation of a surgical case would occur before the day of surgery.

One of the fundamental goals of the preoperative evaluation clinic is patient perioperative education to increase awareness and comfort by decreasing anxiety and fear. A nurse educator specifically trained in perioperative teaching discusses in detail the forthcoming surgical/hospital process with each patient and family member.

Enhanced Operating Room Efficiency and Outcomes

Appropriate utilization of perioperative services yields net benefits to the hospital and achieves a cost-benefit framework. Unnecessary surgical delays result in increased cost to the hospital and reduce operating room efficiency. The preoperative evaluation

Box 34-15 Preoperative Documentation and Concerns

Legibility of records. Poor handwriting results in misinterpretation or failure to implement important orders preoperatively.

Entries that are not signed or the signature is illegible. Print your last name and beeper/contact number.

All preoperative evaluation entries must be dated and timed in the document.

Do not black-out, obliterate, or white-out an error. Place one line through the entry, initial, and write "error."

Document all phone calls, time, and date to consulting physicians with their name and specifically what was discussed.

Note HIPAA* guidelines regarding unapproved abbreviations, which can result in patient medication and treatment errors.

If the patient has an abnormal diagnostic test result, document it and indicate what follow-up is planned. If you order a laboratory test, chest radiograph, electrocardiogram, or any test, you are responsible for knowing the results, follow-up, or referral if needed. Document it in the chart.

*Health Insurance Portability and Accountability Act.

program focuses on patient management and preparation for a smooth transition to surgery.

In one study on start times of the first case of the day, 91% of patients evaluated in the preoperative evaluation clinic entered the operating room by 6:50 AM for 7:30 AM start times. Delays were considered the exception rather than the customary occurrence. The operating room day ends earlier with decreased cost and overtime staffing when delays and problems are minimized. The preoperative evaluation clinic can establish a standard of efficient clinical services, including a contribution to on-time starts, decreased delays, and increased patient and surgeon satisfaction.

Although there are defined costs in developing and maintaining a preoperative evaluation clinic, a comparison with previous outcomes clearly demonstrates the clinic's utility, performance, and an improvement in operating room efficiency in terms of energy, time, and money.

Patient Education and Patient Satisfaction

The benefits of an effective preoperative evaluation process on efficiency have been well documented; however, there is limited information on the benefit of these clinics to the patient's experience. The use of patient satisfaction has been advocated as a unique clinical end point and as an indicator of the quality of the health care provided. Fung and Cohen believed that this outcome could be more insightful than the use of rare major outcomes such as death or common minor outcomes such as pain and nausea, which can be influenced by many other factors. Patient education and patient satisfaction with the preoperative process are closely linked. In work using an internally generated patient satisfaction questionnaire to assess satisfaction with all elements of the preoperative evaluation, the subscale that involved information and communication had the highest correlation with the overall satisfaction subscale.[178] Providing good patient education may facilitate patients' involvement in their care, give them a sense of control over the process, and contribute to increased patient satisfaction. Consumerism and transparency in quality measures, with patient satisfaction being one of these quality measures, are becoming ever more important issues in health care. Measuring patient satisfaction with the various elements of the preoperative process is essential to evaluate success and plan process improvement. Although health care leaders realize the importance of feedback systems, they often do not use the information they receive to pinpoint opportunities for change and correction.[166,179] Gail Scott provides tools and techniques that would allow feedback on the preoperative process to drive improvement.[179] These techniques are summarized in Box 34-16.

Most currently available surveys used by hospitals, such as the commonly used Press Ganey survey, reflect the overall perioperative experience. These standard questions are not effective at discerning patient satisfaction with particular elements of the preoperative process. For this reason, studies have developed internal questionnaires to measure this. Studies using this questionnaire (Box 34-17) show successful evaluation of preoperative process improvement. As noted, in this study the subscale that involved information and communication had the highest correlation with the overall satisfaction subscale. The authors conclude that the clinical and functional aspects of the preoperative evaluation visit have a significant impact on patient satisfaction, with information and communication versus the total amount of time

Box 34-16 Using Feedback to Drive Preoperative Process Improvement

Raise awareness; make sure that everyone in the organization understands the focus of process improvement.

Create measurable targets and goals (e.g., decreasing wait time).

Set service expectations and standards of behavior.

Allow direct service providers (frontline staff) access to hear feedback and input into problem solving.

Develop skills. Teach staff members customer service skills such as interviewing, dealing with difficult people, and conflict management.

Identify and remove barriers. Policies that do not make sense need to be eliminated.

Develop and support teams and relationships.

Listen to your customers: surveys, interviews, comments, shadowing.

Do not forget internal customers; obtain feedback from other teams and departments in the organization.

Share feedback in ways that teach. Eliminate an environment of blame.

Box 34-17 Sample Preoperative Satisfaction Questionnaire

Your feedback is important to us in assessing our services and helping us make changes. Please rate the quality of the services you received during your visit to the Pre-Admitting Test Center. To indicate your answer, just fill in the circle. *Please do not "check" or "X" circles.*

What Type of Surgery Are You Having?

○ Orthopedic	○ Neurosurgery	**Use these ratings:**
○ Thoracic	○ Ear, nose, throat/ophthalmology	*Poor*
○ Cardiac	○ Gynecology	*Fair*
○ General surgery	○ Urology	*Good*
○ Plastic	○ Other/Don't know	*Very Good*
		Excellent

Please rate the following about your visit to the Weiner Center for Preoperative Evaluation (CPE):

1. Explanation of the CPE process by your surgeon's office _____.
2. Ease of locating the CPE in the hospital _____.
3. How clearly the CPE receptionist explained what would happen during your visit _____.
4. Courtesy and efficiency of the CPE receptionist _____.
5. Length of time you spent waiting to be seen _____.
6. If you called the CPE, how promptly and efficiently were your questions answered _____.

Visit with the Anesthesia Care Provider

1. Courtesy and respect you were given by your anesthesia provider _____.
2. Explanation of your options and plan for anesthesia _____.
3. Amount of time spent with the anesthesia provider _____.

Visit with a Nurse or Nurse Practitioner

1. Courtesy and respect you were given by your nurse/nurse practitioner_____.
2. Explanation of your planned operation _____.
3. Amount of time spent with the nurse/nurse practitioner _____.
4. Explanation of how you should prepare for your surgery _____.

Visit with Laboratory/X-Ray Technicians

1. Courtesy and respect you were given by the lab and x-ray technicians _____.
2. Skill of the lab and x-ray technicians _____.

Other

1. Overall, how would you rate the care and service you received in the CPE? _____.
2. To what degree were your questions answered clearly and completely? _____.
3. After your CPE visit, how prepared do you feel for your surgery? _____.
4. If you submitted information to the CPE over the Internet, such as medical history, how would you rate the service? _____.

spent being the most positive and negative components, respectively. Of note is that after the preoperative visit, the vast majority of patients felt appropriately prepared for their upcoming procedure regarding education and communication of information (Box 34-17).

It is the role of the preoperative staff to educate the patient about issues regarding anesthesia, surgery, and the perioperative experience and to address specific patient anxieties about the procedure. A variety of ways to provide this have been evaluated, including direct communication, written information, videos, and websites. When comparing a face-to-face interview with an interview plus a brochure or a video, patients in the group receiving an interview plus a video had the highest scores in patient satisfaction and information gain.[167] An Internet tool may be a viable way for patients to receive information about their particular upcoming procedure, as well as to express concerns and formulate questions without the pressure of a rushed preoperative visit. Past studies have shown that patients may in fact be more likely to provide more information and reveal more problems, especially social and psychiatric issues, at a computer interface instead of to a health care provider.[180] By being aware of patient concerns, the visit can be tailored to better meet the needs of the patient. Time that would otherwise be spent trying to extract information from the patient can be used instead to answer patient questions more comprehensively, build rapport, and decrease stress.

How best can education be provided and patient concerns addressed? To answer this requires some understanding of what concerns patients have regarding their anesthetic and surgical experience. A number of studies have been reviewed to understand this information. Failure to wake up from an anesthetic has

consistently been shown to be a major concern. Younger patients and women tend to express more anxiety regarding their anesthesia. Some practitioners believe that informing patients of all possible risks in detail will serve only to increase anxiety. Several studies have shown that more information does not necessarily decrease anxiety. It may be more important to identify subgroups of patients and focus the information toward the patient's coping style. A British study showed that although there was no correlation between the level of information provided preoperatively and patient anxiety, there was a strong correlation between patients' satisfaction with the amount of information provided and decreased anxiety. Identifying patient subgroups that may benefit from specific educational methodologies and providing this education to these subgroups in a cost-effective manner remain a challenge. In addition, optimal skills in the practitioner providing the patient education must be ensured. Diverse levels of educator experience can result in inconsistent patient information. Skill levels and core competencies in providing patient education must be established.

Preoperative patient education has been demonstrated to be a factor in reducing postoperative pain. Egbert found reduced narcotic requirements and reduced length of stay in patients who had intensive preoperative instruction about pain. Reduction in length of stay and postoperative medication was also shown in patients undergoing spinal surgery for back pain who received teaching sessions before surgery. In patients undergoing CABG, the group receiving information plus coping preparations had a lower incidence of postoperative hypertension, although this study did not show a decrease in length of stay or postoperative narcotic requirements.

In addition, patients who are taught to use a pain scale during the preoperative visit can more effectively self-report pain postoperatively.[181] Preoperative education can also provide an opportunity for intervention to improve patient lifestyle, such as an introduction to smoking cessation programs.

Optimal preoperative patient education can influence a number of factors that affect overall operating room efficiency. For example, appropriate preoperative fasting and medication orders can be given, thereby preventing delays and cancellations. An adequate discussion of informed consent during the clinic visit prevents delays in the preoperative holding area to address these issues. The preoperative visit can ensure that the patient receives adequate bowel preparation and stoma care instructions, and patients undergoing day surgery can be educated regarding the requirement for transportation home.

Preoperative Fasting Status

Preoperative fasting recommendations have been made to reduce the occurrence of pulmonary aspiration. The ASA has published practice guidelines for preoperative fasting based on the evidence available.[5] The task force supports a fasting period of 2 hours for clear liquids in all patients. The volume of liquid ingested is less important than the type of liquid ingested. A fasting period of 4 hours for neonates and infants receiving breast milk and 6 hours for those receiving formula and solids is recommended. For noninfants, a fasting period of 6 hours after a light meal and 8 hours after a meal that includes fried or fatty foods is recommended. These guidelines recommend that the preoperative evaluation include assessment of factors that may increase the risk for aspiration, including gastrointestinal motility disorders, the potential for difficult airway management, and diabetes mellitus. Separate fasting guidelines are not provided for patients with these and other conditions that may increase the risk of regurgitation and pulmonary aspiration. There is great diversity among institutions in the current practice patterns for preoperative fasting, with many being more conservative than the ASA guidelines would suggest.[182]

There is agreement among most institutions in this study that ingestion of clear fluids up to 2 to 3 hours before anesthesia is acceptable. There is diversity regarding solids, with many institutions still restricting intake of solids after midnight.

Role of the Medical Consultant in Preoperative Evaluation

The use of medical consultation for preoperative patients will vary by institution, depending on the level of expertise in perioperative medicine of the clinicians performing preoperative assessments. The comfort level of the preoperative staff in interpreting ECGs and in ordering and interpreting stress testing and echocardiograms will have a major influence on the amount of consultation requested, as demonstrated by Tsen and colleagues. Park has summarized the recommendations for preoperative cardiology consultation in a 2003 review.[183] This analysis suggests that anesthesiologists need consultation for a significant number of patients with cardiac disease who are undergoing noncardiac surgery.[184] However, as Kleinman states in the accompanying editorial, the level of expertise of the cardiology consultant over and beyond that of the requesting anesthesiologist is related to the immediate management of acute coronary syndromes.

As a perioperative physician, the anesthesiologist should have adequate expertise to quantify and manage perioperative risk. For example, in the one generally accepted effective intervention of perioperative β-blockade, a cardiologist is not needed to provide this therapy. In Kleinman's opinion, the cardiologist's major role is in the perioperative management of acute coronary syndromes and in long-term management of chronic medical conditions. There seems to be little agreement among cardiologists, anesthesiologists, and surgeons regarding the purposes and utility of consultation; a review of 55 consecutive cardiology consultations suggests that most give little advice that truly affects management.[169] When requesting a cardiology or any specialty consultation, the anesthesiologist should ask specific questions regarding the information desired to increase the value of the consultation and perioperative management.

The anesthesiologist is the final physician who questions and determines the patient's appropriateness and stability for surgery. There can be considerable frustration and tension in the presurgical holding area when a patient's surgery is delayed or canceled just before entering the operating room. Essential diagnostic studies such as a cardiac stress test or specific laboratory tests may not have been obtained. A perioperative risk concern may not have been evaluated by the specialty consultation. To avoid day-of-surgery delays and cancellations by the anesthesiol-

ogist, some surgeons have developed a pattern of obtaining more medical specialty consultations than are necessary or appropriate. When the anesthesiologist is involved in the determination of whether a medical consultation is needed, overall numbers of specialty consultations decrease—a substantial savings in cost and time.[164]

Role of the Preoperative Clinic in Guiding Intraoperative Management Choices

The role of preoperative evaluation is to provide data and guidance so that the team managing the case on the day of the procedure can make appropriate choices. It is inappropriate for clinic providers or any preoperative consultant to make ultimate decisions regarding a specific type of anesthesia to be provided. Possible options that depend on the type of procedure, patient comorbid conditions, and patient preference should be discussed. Documentation in the final anesthesia assessment should include a statement that the options have been discussed with the patient and any patient preference noted. The patient should be informed that the final decision regarding the anesthetic plan would be made by the team managing the case. The preoperative clinician should provide ample opportunity for the patient to have any questions or concerns regarding anesthetic options addressed. Patients are often concerned that they are not speaking with the anesthesia clinician who will be providing their care. They should be reassured that all information obtained in the clinic is transferred and reviewed by the team and that they will have a chance to speak with their actual care providers on the day of surgery if additional questions arise.

Additionally, should a high-risk case warrant the skills of a specialty anesthesiologist, this assessment and request can be facilitated through the preoperative evaluation clinic before the day of surgery. A personal discussion the day before surgery between the preoperative evaluator and anesthesiologist assigned a difficult case or airway enhances the perioperative management plan and avoids operating room delays, cancellations, and potential adverse outcomes.

Summary

The practice of anesthesiology has changed.[185,186] The expanding role of the anesthesiologist outside the operating room has redefined our specialty in the hospital and with our physician colleagues with regard to our clinical expertise, effectiveness, and contribution to quality patient care.

Anesthesiologists have noticeably evolved from a specialty practicing only inside the operating rooms to an acknowledged position as perioperative medicine specialists who comprehensively evaluate and manage patients preoperatively, intraoperatively, and through their postoperative pain requirements. Frequently this occurs in formalized hospital service programs or anesthesia preoperative/pain management clinics. The anesthesiologist's visibility and leadership position in perioperative patient management has enhanced hospital opportunities, leadership recognition, and the viability of our specialty.

Anesthesiologists need to be clinically knowledgeable and skilled in assessing patients in the preoperative period, whether it be in an evaluation clinic setting before the day of surgery or at the bedside immediately before induction of anesthesia. Preparation for anesthesia and surgery can be straightforward or complex and difficult. Medicine is increasingly fragmented and extremely specialized. Patients are getting older and living longer with chronic diseases. Surgical technologies, procedures, and settings where anesthesia is administered, as well as regulatory requirements, are constantly changing and requiring anesthesiologists to accept expanding perioperative responsibilities.

Guidelines and evidence-based medicine practices are being developed and updated frequently. Virtually all disease states have an impact on perioperative patients and their care. Anesthesiologists can collaborate with primary care providers, physician extenders, and specialists, but none can truly evaluate the risks associated with anesthesia, discuss these risks with patients, or manage them perioperatively other than a physician trained in anesthesiology.

Although health care changes, regulatory issues, consensus guidelines, and medical developments will occur, the primary purpose of preoperative evaluation will never change. The anesthesia preoperative evaluation is the clinical foundation and framework of perioperative patient management and can potentially reduce operative morbidity and enhance patient outcome.

35 Anesthetic Implications of Concurrent Diseases

Key Points

1. The history and physical examination most accurately predict the risks and the likelihood of changes in monitoring or therapy.
2. For diabetic patients, end-organ dysfunction and the degree of glucose control in the perioperative and periprocedural periods are the critical issues with regard to risk.
3. The key to managing blood glucose levels in diabetic patients perioperatively is to set clear goals and then monitor blood glucose levels frequently enough to adjust therapy to achieve these goals.
4. Obesity is associated with multiple comorbid conditions, including diabetes, hyperlipidemia, and cholelithiasis, but the primary concern is derangements of the cardiopulmonary system.
5. Obstructive sleep apnea is important to recognize because of the increased sensitivity to and the consequence of depressing the effects of hypnotics and opioids on airway muscle tone and respiration, as well as the difficulty with laryngoscopy and mask ventilation.
6. Although no controlled, randomized prospective clinical studies have been performed to evaluate the use of adrenergic receptor blocking drugs in patients undergoing resection of pheochromocytoma, the preoperative use of such drugs is generally recommended.
7. For patients with hypertension, we recommend the routine administration of all drugs preoperatively except angiotensin-converting enzyme inhibitors and angiotensin II antagonists.
8. Evaluation of a patient with cardiovascular disease depends on clinical risk factors, the extent of surgery, and exercise tolerance.
9. In patients with pulmonary disease, the following should be assessed: dyspnea, coughing and the production of sputum, recent respiratory infection, hemoptysis, wheezing, previous pulmonary complications, smoking history, and physical findings.
10. In patients with pulmonary disease, several strategies have been suggested, including cessation of smoking 8 weeks or more before surgery.
11. Risk factors for perioperative renal dysfunction include advanced age, congestive heart failure, previous myocardial revascularization, diabetes, and elevated baseline creatinine.
12. The main concern for a patient with renal disease is making it worse and thereby increasing the chance for renal failure, coma, and death.
13. Mild perioperative anemia may be significant only in patients with ischemic heart disease.
14. Careful management of chronic drug administration can include questions about the effects and side effects of alternative as well as prescription drugs.

This chapter reviews many conditions requiring special preoperative and preprocedure evaluation, intraoperative or intraprocedure management, or postprocedure care with particular focus on preprocedure care for those with increased waist size (see Chapter 64). Patients undergoing surgery move through a continuum of medical care to which a primary care physician, an internist or pediatrician, an anesthesiologist, and a surgeon, radiologist, or obstetrician-gynecologist contribute to ensure the best outcome possible. No aspect of medical care requires greater cooperation among physicians than does performance of a surgical operation or complex procedure involving multiple specialists and the perioperative care of a patient. Moreover, nowhere else can counseling make so huge a difference in so many lives. Because over 40% of medical costs are occasioned by tobacco use, physical inactivity, and poor food choices, the anesthesiologist has an important role in initiating change while assessing and ameliorating risk. We spend twice as much as developed Europe on medical care, largely because we in the United States have twice the incidence of chronic disease.[1] However, costs in the United States and the world will increase dramatically if we and other physicians do not

use preoperative and other similar situations to influence patient lifestyle choices. The importance of integrating physicians' expertise is even greater within the context of the increasing life span of our population.[2] As the number of the elderly and the very old (those >85 years) grows, so does the need of surgical patients for preoperative consultation to help plan for comorbidity and multiple drug regimens, knowledge of which is crucial to successful patient management (also see Chapter 71). At a time when medical information is encyclopedic, it is difficult, if not impossible for even the most conscientious anesthesiologist to keep abreast of the medical issues relevant to every aspect of perioperative or periprocedure patient management. This chapter reviews such issues with primary emphasis on the anesthesiologist providing preoperative evaluation and care rather than transferring these responsibilities to other providers.

As with "healthy" patients (also see Chapter 34), it is the history and physical examination that most accurately predict not only the associated risks but also the likelihood that a monitoring technique or change in therapy will be beneficial or necessary for survival. This chapter emphasizes instances in which specific information should be sought in history taking, physical examination, or laboratory evaluation. Although controlled studies designed to confirm that optimizing a patient's preoperative or preprocedure physical condition would result in lower morbidity have not been performed for most diseases, it is logical to assume that such is the case. Studies showing the benefits of optimizing specific preprocedure conditions are highlighted. The fact that such preventive measures would cost less than treating the morbidity that would otherwise occur is an important consideration in a cost-conscious and soon cost-restricted environment.

Minimally invasive procedures such as cataract extraction, magnetic resonance imaging (MRI), or diagnostic arthroscopy, performed in conjunction with the best current anesthetic practices, may pose no greater risk than daily living does and thus might not be considered an opportunity for special evaluation. Nonetheless, preanesthetic and preprocedure evaluations have provided information that has led to changes in health care plans for more than 15% of all American Society of Anesthesiologists (ASA) class I and II patients (and for >20% of all patients in general) at the University of Florida (Gibby GL, et al., personal communication). Although these changes in care plans were attributable to data found by history taking and observation (the most common being gastric reflux, diabetes mellitus requiring insulin, asthma, and suspected difficult endotracheal intubation), no data show that patient outcome was improved by such changes. Nevertheless, logic caused practitioners to alter plans for such patients in ways that would optimize operating room schedules and decrease costs. Examples would be administering a β-adrenergic blocking drug, aspirin, or a statin (or any combination) the night before rather than delaying surgery to do so on the morning of surgery; administering a histamine type 2 (H_2) antagonist 1 to 2 hours before and an oral antacid immediately before entry into the operating room; ensuring the availability of equipment to measure blood glucose levels; obtaining a history of the patient's diabetic course and treatment from the primary care doctor, as well as from the patient; and performing a fiberoptic laryngoscopic examination or procuring additional skilled attention. Counseling to begin walking even 5 days in advance of surgery anecdotally reduces perioperative complications and speeds return to typical behavior. Thus, even if preoperative and preprocedure evaluation might not alter the outcome in an important way, its ability to decrease cost by reducing unwarranted laboratory testing and delays in obtaining treatment and equipment perceived to be beneficial (and medicolegally required) would be substantial and would warrant its use.

The following conditions are discussed in this chapter:

1. Diseases involving the endocrine system and disorders of nutrition (we have put this first because of its increasing importance to care)
2. Diseases involving the cardiovascular system
3. Disorders of the respiratory and immune system (including a tobacco cessation counseling plan—Breathe Free)
4. Diseases of the central nervous system (CNS), neuromuscular diseases, and mental disorders
5. Diseases involving the kidney, infectious diseases, and disorders of electrolytes
6. Diseases involving the gastrointestinal (GI) tract or the liver
7. Diseases involving hematopoiesis and various forms of cancer
8. Diseases of aging or those that occur more commonly in the aged, as well as chronic and acute medical conditions requiring drug therapy (also see Chapter 71).

Role of the Primary Care Physician or Consultant

The role of the primary care physician or consultant is not to select or suggest anesthetic or surgical methods but rather to optimize the patient's preoperative and preprocedure status regarding conditions that increase the morbidity and mortality associated with surgery and to alert the anesthesia care team about these conditions.

Quotations and a box in a Medical Knowledge Self-Assessment Program published by the leading organization representing internists, the American College of Physicians, highlight this role for the consultant[2]:

> *Effective interaction with colleagues in other specialties requires a thorough grounding in the language and science of these other disciplines as well as an awareness of basic guidelines for consultation [Box 35-1]. The consulting internists' role in perioperative care is focused on the elucidation of medical factors that may increase the risks of anesthesia and surgery. Selecting the anesthetic technique for a given patient, procedure, surgeon, and anesthetist is highly individualized and remains the responsibility of the anesthesiologist rather than the internist.*

Optimizing a patient's preoperative and preprocedure condition and counseling a patient about needed future lifestyle changes such as walking, food choices, and tobacco cessation are cooperative ventures between the anesthesiologist and the internist, pediatrician, surgeon, or family physician. If the primary care physician cannot affirm that the patient is in the very best physical state attainable (for that patient), the anesthesiologist and physician should do what is necessary to optimize that condition. Failure to consult with the primary care physician preoperatively

Box 35-1 Guidelines for Consultation Practice

Complete a prompt, thorough, generalist-oriented evaluation.

Respond specifically to the question or questions posed.

Indicate clearly the perioperative importance of any observations and recommendations outside the area of initial concern.

Provide focused, detailed, and precise diagnostic and therapeutic guidance.

Emphasize verbal communication with the anesthesiologist and surgeon, particularly to resolve complex issues.

Avoid chart notations that unnecessarily create or exacerbate regulatory or medicolegal risk.

Use frequent follow-up visits in difficult cases to monitor clinical status and compliance with recommendations.

From American College of Physicians: Medical consultation. *In* Medical Knowledge Self-Assessment Program IX, Part C, Book 4. Philadelphia, American College of Physicians, 1992, p 939.

or before a complex procedure is as risky as not checking the oxygen in the spare tanks. In fact, statements that describe the preoperative and preprocedure physical condition of the patient (e.g., "This patient is in optimum shape" and "I believe the mitral stenosis is more severe than the slight degree of mitral insufficiency") are much more useful to the anesthesiologist than statements that suggest overall clearance ("cleared for surgery") or perioperative procedures ("prevent hypoxia and hypotension"). Knowing the patient's waist size and exercise capacity is much more important than learning that his T waves did not flip by the time he completed his stress test (knowing his maximum metabolic equivalents of the task [METs] and heart rate recovery from a stress test are very useful).

Primary care physicians can prepare and treat a patient to provide optimal conditions for daily life. However, they do not have the depth of understanding of the anesthesiologist regarding the physiologic changes brought on by surgery and the manipulations in function that must be made to facilitate surgery and procedures and optimize perioperative and periprocedure outcomes. One example would be the induction of some degree of prerenal azotemia in a patient with congestive heart failure (CHF) by the primary care physician. The intravascular volume depletion associated with prerenal azotemia may make a cardiac patient more comfortable in daily life but would predispose that patient to hypovolemic problems during and after surgery and complex procedures. Thus, even though it would be desirable for the primary care physician to start the process of preparing the patient for the needs of surgery or complex procedures, this activity would not be compatible with the current state of knowledge or functioning of the vast majority of primary care physicians. Although such education is more readily available and of better quality than in previous decades[3-5] and although Fleisher, Goldman, Charlson, and their coworkers and even cardiologic organizations have provided considerable data regarding the importance of this aspect of care,[6-8] the training, knowledge, and ability of primary care physicians are still very deficient in this aspect of consultation. Without understanding the physiologic changes that occur perioperatively, it is difficult to prescribe the appropriate therapy. It is therefore part of the anesthesiologist's job to instruct the patient's consultants about the type of information needed from the preoperative and preprocedure consultation.

Diseases Involving the Endocrine System and Disorders of Nutrition

Pancreatic Disorders

Preoperative and Preprocedure Diabetes Mellitus

This section makes nine major points regarding diabetes:

1. The number of people known to be diabetic has more than tripled in 17 years in the United States to 25 million and is increasing substantially in the world. This growth has been fueled by the rise in type 2 diabetes caused by waist gain in the adult and now pediatric population (also see Chapter 82).
2. Diabetes itself may not be as important to perioperative outcome as its end-organ effects are (see point 4 for exceptions). Although the presence of diabetes has long been assumed to increase perioperative risk, results from epidemiologic studies may not support this assumption in patients not requiring management in the intensive care unit (ICU). These studies segregated the effects of diabetes per se on the organ system from the effects of the complications of diabetes (e.g., cardiac, nervous system, renal, and vascular disease) and the effects of old age and the accelerated aging that diabetes causes. Even in patients requiring ICU management, long-standing diabetes does not appear to be as important an issue as the end-organ dysfunction that exists and the degree of glucose control in the perioperative/periprocedure and ICU periods.[9-14]
3. Because diabetes represents at least two disease processes, its perioperative management may differ between these processes.
4. The Diabetes Control and Complication Trial for type 1 diabetics, the U.K. Prospective Diabetes Study for type 2 diabetics, The Advance Studies, and the Kumamoto studies all show that chronic tight control of blood sugar and blood pressure (BP), along with physical activity, results in a major delay in microvascular complications and perhaps indefinite postponement in type 2 diabetic patients.[15,16] However, current debate centers on the benefit associated with tight control in the perioperative period and on the benefit-risk ratio. Evidence indicates that tight control of blood glucose might be of benefit for pregnant diabetics (and their future offspring) (also see Chapter 69), for diabetics undergoing cardiopulmonary bypass (also see Chapter 60), for those with (global) CNS ischemia (also see Chapters 13 and 63), and for patients requiring postoperative or postprocedure care in an ICU. Little evidence indicates that perioperative tight control is of substantial benefit to any other group; moreover, the benefit-risk ratio of tight control has not been examined for any other group of patients.[9-14]

5. Different regimens permit almost any degree of perioperative control of blood glucose levels, but the tighter the control desired, the more frequently blood glucose levels must be monitored. Three treatment regimens are outlined later.
6. The major risk factors for diabetics undergoing surgery are the end-organ diseases associated with diabetes: cardiovascular dysfunction, renal insufficiency, joint collagen tissue abnormalities (limitation in neck extension,[17] poor wound healing), inadequate granulocyte production, and neuropathies.[9-19] Thus, a major focus of the anesthesiologist should be the preoperative and preprocedure evaluation and treatment of these diseases to ensure optimal preoperative and preprocedure conditions.
7. Regional anesthesia may be indicated to facilitate some procedures (also see Chapter 52). The following considerations should be kept in mind regarding the use of regional anesthesia for diabetic patients. Local anesthetic requirements are lower and the risk of nerve injury is higher in diabetic patients.[20] In addition, combining local anesthetics with epinephrine may pose an even greater risk for ischemic or edematous nerve injury (or both) in diabetics.
8. Nosocomial infection rates are probably decreased with outpatient surgery; the frequency of complications may be decreased in diabetics most at risk by either tight control of blood glucose or intense postoperative care, or both.
9. Both forms of diabetes cause accelerated aging (also see Chapter 71). Thus, the risks involved in caring for someone with diabetes are similar to those for someone much older, that is, someone who has a much higher physiologic age (or "RealAge").[21-23]

Non–insulin-dependent (type 2) diabetics account for more than 95% of the over 25 million diabetics in the United States. At the current rate of growth, there will be 300 million diabetics in the world in 2010. These individuals tend to be overweight, relatively resistant to ketoacidosis, and susceptible to the development of a hyperglycemic-hyperosmolar nonketotic state. The diagnosis of diabetes is made with a fasting blood glucose level greater than 110 mg/dL (6.1 mmol/L), and impaired glucose tolerance is diagnosed if the fasting level is less than 110 mg/dL (6.1 mmol/L) but greater than 100 (5.5). Plasma insulin levels are normal or increased in type 2 diabetics but are relatively low for the level of blood glucose. This hyperinsulinemia by itself is postulated to cause accelerated cardiovascular disease.

Diabetes mellitus is a heterogeneous group of disorders that have the common feature of a relative or absolute lack of insulin. The disease is characterized by a multitude of hormone-induced metabolic abnormalities, by diffuse microvascular lesions, and by long-term end-organ complications. Diabetes can be divided into two very different diseases that share these end-organ abnormalities. Type 1 diabetes is associated with autoimmune diseases and has a concordance rate of 40% to 50% (i.e., if one of a pair of monozygotic twins had diabetes, the likelihood that the other twin would have diabetes is 40% to 50%). In type 1 diabetes, the patient is insulin deficient and susceptible to ketoacidosis if insulin is withheld. In type 2, the concordance rate is 100% (i.e., genetic material is both necessary and sufficient for the development of type 2 diabetes). How markedly the aging and end-organ effects of these genes are expressed is based on lifestyle choices of food and physical activity. These patients are not susceptible to the development of ketoacidosis in the absence of insulin, and they have peripheral insulin resistance. Gestational diabetes develops in more than 3% of all pregnancies and increases the risk for type 2 diabetes to 17% to 63% within 15 years.

Type 1 and type 2 diabetes differ in other ways as well. Contrary to long-standing belief, patient age does not allow a firm distinction between type 1 and type 2 diabetes; type 1 diabetes can develop in an older person, and clearly, type 2 diabetes can develop in overnourished children. A diabetes-producing variant of Coxsackie B4 virus has been isolated from the pancreas of a patient who died of diabetic ketoacidosis (type 1 diabetes). This virus was also recovered from mice bred to be diabetes prone after inoculation of the virus had produced hyperglycemia and pancreatic beta cell necrosis coincident with rising antibody titers. Thus, the intrinsic genetic "vulnerability" in insulin-dependent type 1 diabetes mellitus may consist of a diminished capacity of beta cells to survive exposure to potentially damaging extrinsic agents. Type 1 diabetes is associated with a 15% prevalence of other autoimmune diseases, including Graves' disease, Hashimoto's thyroiditis, Addison's disease, and myasthenia gravis.

The common orally administered drugs can be classified into six groups in the sulfonylurea class of antidiabetic medications: tolazamide (Tolinase), tolbutamide (Orinase), and the newer sulfonylureas glyburide (Micronase), glipizide (Glucotrol), gliclazide (Diamicron), and glimepiride (Amaryl). Some of these medications have a longer blood glucose–lowering effect that persists for 24 hours or more and fewer drug-drug interactions. Oral hypoglycemic drugs may produce hypoglycemia for as long as 50 hours after intake (chlorpropamide [Diabinese] has the longest half-life). Other drugs and drug classes that fit into the category of hypoglycemic agents include the biguanide metformin, which decreases hepatic glucose output and may increase peripheral responsiveness to glucose (and is associated with lactic acidosis if the patient becomes dehydrated); the α-glucosidase inhibitors acarbose and miglitol, which decrease glucose absorption; the thiazolidinediones (such as pioglitazone), which increase peripheral responsiveness to insulin; and meglitinides and other noninsulin secretagogues such as repaglinide (Prandin), nateglinide (Starlix), and sitagliptin (Januvia). Recent experience with rosiglitazone (Avandia) for control of blood sugar makes one question whether examination of the mechanism or end-organ effects may lead to the best outcome for patients. Nevertheless, physicians advocating tight control of blood sugar levels usually give insulin to "maturity-onset" insulin-dependent diabetic patients twice a day or even more frequently.

Insulin-dependent diabetics tend to be young, nonobese, and susceptible to the development of ketoacidosis. Plasma insulin levels are low or nonmeasurable, and therapy requires insulin replacement. Patients with insulin-dependent diabetes experience an increase in their insulin requirements in the postmidnight hours, which may result in early-morning hyperglycemia (dawn phenomenon). This accelerated glucose production and impaired glucose utilization are due to nocturnal surges in secretion of growth hormone (GH). Normal patients and diabetics taking insulin have steady-state levels of insulin in their blood. (Unfortunately, traditional values for insulin pharmacokinetics are derived from studies designed as though the diabetic received only one shot of insulin in a lifetime.) Absorption of insulin is highly variable and dependent on the type and species of insulin, the site of administration, and subcutaneous blood flow. Nevertheless, attainment of a steady state is dependent on periodic

administration of the preparations received by the patient. Thus, it seems logical to perioperatively continue the combinations of preparations that the patient had been receiving chronically after examining the patient's blood glucose monitoring logbook for the degree of control. (In our clinical experience, erratic control can foreshadow perioperative hypoglycemia.)

Acute complications in diabetic patients include hypoglycemia and diabetic ketoacidosis, as well as hyperglycemic, hyperosmolar, nonketotic coma. Diabetic patients are also subject to a series of long-term complications that lead to considerable morbidity and premature mortality, including cataracts, neuropathies, retinopathy, and angiopathy involving peripheral and myocardial vessels. The leading cause of the blindness associated with renal failure in the United States is diabetes. Many of these complications will bring the diabetic patient to surgery. The evidence that hyperglycemia itself accelerates these complications or that tight control of blood sugar levels decreases the rapidity of progression of microangiopathic disease is becoming more definitive.[24]

Glucose itself may be toxic because high levels can promote nonenzymatic glycosylation reactions leading to the formation of abnormal proteins that may decrease elastance and wound-healing tensile strength. The decrease in elastance is responsible for the stiff joint syndrome and for the fixation of the atlanto-occipital joint that makes intubation difficult. Furthermore, elevations in glucose may increase the production of macroglobulins by the liver, thereby increasing blood viscosity, and may promote intracellular swelling by favoring the production of nondiffusible, large molecules (e.g., sorbitol). Newer drug therapies (e.g., aldose reductase inhibitors) aim to decrease intracellular swelling by inhibiting the formation of such large molecules.

Studies on the long-term outcome of type 1 and type 2 diabetics indicate that tight control of blood glucose and blood sugar substantially prevents such complications (Table 35-1).[15,16]

Perioperative management of a diabetic patient may affect the surgical outcome. Physicians advocating tight control of blood glucose levels point to the evidence of increased wound-healing tensile strength and decreased wound infections in animal models of diabetes (type 1) under tight control and the development of infections, renal failure, other serious complications, and death in patients requiring intensive care.[9-14]

Infections account for two thirds of postoperative complications and about 20% of perioperative deaths in diabetic patients. Experimental data suggest that many factors can make a diabetic patient vulnerable to infection. Many alterations in leukocyte function have been demonstrated in hyperglycemic diabetics, including decreased chemotaxis and impaired phagocytic activity of granulocytes, as well as reduced intracellular killing of pneumococci and staphylococci.[25] Keeping glucose levels in the vicinity of 150 mg/dL appears to maintain the ability of immunoglobins to form complexes. When diabetic patients are treated aggressively and blood glucose levels are kept below 270 mg/dL, the phagocytic function of granulocytes is improved and intracellular killing of bacteria is restored to nearly normal levels.[25]

Diabetic patients experience more infections in clean wounds than nondiabetics do. In a review of 23,649 surgical patients, the rate of wound infection in clean incisions was 10.7% for diabetics versus 1.8% for nondiabetics.[26] In addition, hyperglycemia may worsen the neurologic outcome after intraoperative cerebral ischemia.

Blood glucose levels may affect neurologic recovery after a global ischemic event. In a study of 430 consecutive patients resuscitated after out-of-hospital cardiac arrest, mean blood glucose levels were higher in patients who never awakened (341 ± 13 mg/dL) than in those who did awaken (262 ± 7 mg/dL).[27] Among patients who awakened, those with persistent neurologic deficits had higher mean glucose levels (286 ± 15 mg/dL) than those without deficits did (251 ± 7 mg/dL). These results are consistent with the finding that hyperglycemia during a stroke is associated with poorer short- and long-term neurologic outcomes. Although several questions remain, the likelihood that blood glucose is a determinant of brain damage after global ischemia is supported by the vast majority of animal studies after global CNS ischemia and by most, but not all studies after focal CNS ischemia. The preponderance of data after CNS ischemia indicates that levels of glucose higher than 150 or 250 mg/dL have an adverse effect on CNS recovery. Until better data are available, many will argue that a diabetic patient about to undergo surgery in which hypotension or reduced cerebral blood flow may occur should have a blood glucose level below 200 mg/dL during a period of cerebral ischemia. Some special situations may also influence how tightly one should manage a patient's glucose level, such as surgery requiring cardiopulmonary bypass, surgery in pregnant patients, and emergency surgery in patients with diabetic ketoacidosis or hyperosmolar nonketotic coma.

Diabetics undergoing coronary artery bypass grafting (CABG) in 1980 had a perioperative mortality rate of 5% versus 1.5% for nondiabetics.[28] In this study and in most other studies of diabetic patients undergoing CABG, important additional risk factors or confounding variables were not considered, including the incidence and extent of hypertension, ventricular dysfunction, and CHF or the severity of coronary artery disease.

The aforementioned study of 340 diabetics and 2522 nondiabetics undergoing CABG in 1980 demonstrated only a moderate increase in operative mortality for diabetics (1.8% versus 0.6%).[28] In the postbypass phase, patients with diabetes were found to require inotropic therapy and intra-aortic balloon

Table 35-1 Tight Control of Blood Glucose Levels Reduces Chronic Complications in Type 1 Diabetic Patients

	Type 1 Diabetic Patients	
Measure and Results	**Group Undergoing Intensive Control of Blood Glucose**	**Control Group**
Measurement of blood glucose levels	≥4/day	1/day
Insulin injections	≥3/day or an insulin pump was used	1-2/day
Diet	Special diet	Usual diabetic diet
Physician office visits	1-4/mo	Once every 3 mo
Results after 6 yr		
Diabetic retinopathy	70% less than control	
Treatment needed for retinopathy	50% less than control	
Significant nephropathy	50% less than control	
Neuropathy	60% less than control	

Modified from Reichard P, Nilsson BY, Rosenqvist U: The effect of long-term intensified insulin treatment on the development of microvascular complications of diabetes mellitus. N Engl J Med 329:304-309, 1993.

pump support five times more frequently than nondiabetics did. This increased need for therapy in diabetics is due to several possible factors. Diabetics with angina have more extensive coronary artery disease than nondiabetic patients do. They are also more likely to have hypertension, cardiomegaly, diffuse hypokinesis, and previous myocardial infarction (MI). Insulin-dependent diabetics with coronary artery disease, impaired stress responses, and autonomic nerve dysfunction appear to have stiffer ventricles with a large increase in left ventricular end-diastolic pressure than matched nondiabetic controls do.[29] During cardiopulmonary bypass, hypothermia and stress reactions decrease the response to insulin and result in marked hyperglycemia (even when the perfusate and intravenous solutions do not contain glucose) (also see Chapter 60). Administration of washed cells has been advocated for small individuals because acid citrate dextrose– or adenine-supplemented blood can result in significant hyperglycemia. These changes are exaggerated in diabetic patients, and administration of insulin may have little effect until rewarming is achieved. Inotropic drugs are ineffective in maintaining cardiac contractility, although filling pressures, sinus rhythm, serum electrolytes, and arterial blood gases were adequate. Blood sugar levels were elevated in each case. After intravenous infusion of insulin, effective myocardial contractions returned and allowed easy and rapid weaning from bypass. The effect of glucose levels on neurologic outcome during cardiopulmonary bypass is both unclear and controversial.

Many diabetics requiring emergency surgery for trauma or infection have significant metabolic decompensation, including ketoacidosis. Frequently, little time is available for stabilization of the patient, but even a few hours may be sufficient for correction of any fluid and electrolyte disturbances that are potentially life threatening. It is futile to delay surgery in an attempt to eliminate ketoacidosis completely if the underlying surgical condition will lead to further metabolic deterioration. The likelihood of intraoperative cardiac arrhythmias and hypotension resulting from ketoacidosis will be reduced if intravascular volume depletion and hypokalemia are at least partially treated.

Insulin therapy is initiated with a 10-unit intravenous bolus of regular insulin, followed by continuous insulin infusion. The rate of infusion is determined most easily if one divides the last serum glucose value by 150 (or 100 if the patient is receiving steroids, has an infection, or is considerably overweight [body mass index ≥35]). The actual amount of insulin administered is less important than regular monitoring of glucose, potassium, and pH. Because the number of insulin binding sites is limited, the maximum rate of decline in glucose is fairly constant and averages 75 to 100 mg/dL/hr, regardless of the dose of insulin.[30] During the first 1 to 2 hours of fluid resuscitation, the glucose level may fall more precipitously. When serum glucose reaches 250 mg/dL, the intravenous fluid should include 5% dextrose.

The volume of fluid required for therapy varies with the overall deficit; it ranges from 3 to 5 L and may be as high as 10 L. Despite losses of water in excess of losses of solute, sodium levels are generally normal or reduced. Factitious hyponatremia caused by hyperglycemia or hypertriglyceridemia may result in this seeming contradiction. The plasma sodium concentration decreases by about 1.6 mEq/L for every 100-mg/dL increase in plasma glucose above normal. Initially, normal saline is infused at a rate of 250 to 1000 mL/hr, depending on the degree of volume depletion and cardiac status. Some measure of left ventricular volume should be monitored in diabetics who have a history of myocardial dysfunction. About a third of the estimated fluid deficit is corrected during the first 6 to 8 hours and the remaining two thirds over the next 24 hours.

The degree of acidosis is determined by measurement of arterial blood gases and detection of an increased anion gap (also see Chapter 49):

$$Na^+ - (Cl^- + HCO_3^-)$$

Acidosis with an increased anion gap (≥16 mEq/L) in an acutely ill diabetic may be caused by ketones in ketoacidosis, lactic acid in lactic acidosis, increased organic acids from renal insufficiency, or all three problems. In ketoacidosis, plasma levels of acetoacetate, β-hydroxybutyrate, and acetone are increased. Plasma and urinary ketones are measured semiquantitatively with Ketostix and Acetest tablets. The role of bicarbonate therapy in diabetic ketoacidosis is controversial. Myocardial function and respiration are known to be depressed at a blood pH below 7.0 to 7.10, yet rapid correction of acidosis with bicarbonate therapy may result in alterations in CNS function and structure. These alterations may be caused by (1) paradoxical development of cerebrospinal fluid and CNS acidosis from rapid conversion of bicarbonate to carbon dioxide and diffusion of the acid across the blood-brain barrier, (2) altered CNS oxygenation with decreased cerebral blood flow, and (3) the development of unfavorable osmotic gradients. After treatment with fluids and insulin, β-hydroxybutyrate levels decrease rapidly, whereas acetoacetate levels may remain stable or even increase before declining. Plasma acetone levels remain elevated for 24 to 42 hours, long after blood glucose, β-hydroxybutyrate, and acetoacetate levels have returned to normal; the result is continuing ketonuria.[30] Persistent ketosis with a serum bicarbonate level less than 20 mEq/L in the presence of a normal glucose concentration is an indication of the continued need for intracellular glucose and insulin for reversal of lipolysis.

The most important electrolyte disturbance in diabetic ketoacidosis is depletion of total-body potassium. Deficits range from 3 to 10 mEq/kg body weight. Serum potassium levels decline rapidly and reach a nadir within 2 to 4 hours after the start of intravenous insulin administration. Aggressive replacement therapy is required. The potassium administered moves into the intracellular space with insulin as the acidosis is corrected. Potassium is also excreted in urine because of the increased delivery of sodium to the distal renal tubules that accompanies volume expansion. Phosphorus deficiency in ketoacidosis as a result of tissue catabolism, impaired cellular uptake, and increased urinary losses may give rise to significant muscular weakness and organ dysfunction. The average phosphorus deficit is approximately 1 mmol/kg body weight. Replacement is needed if the plasma concentration decreases below 1.0 mg/dL.[30]

Glucotoxicity

Chronic tight control of blood glucose has been motivated by a theoretical concern about four potential glucotoxicities, plus the results from three major randomized outcome studies involving diabetic patients.[9-17]

1. Glucose itself may be toxic because high levels can promote nonenzymatic glycosylation reactions that lead to the formation of abnormal proteins. These proteins may weaken endothelial junctions and decrease elastance, which is responsible for the stiff joint syndrome (and difficult intu-

bation secondary to fixation of the atlanto-occipital joint), as well as decrease wound-healing tensile strength.
2. Furthermore, elevations in glucose may increase macroglobulin production by the liver (which would increase blood viscosity) and promote intracellular swelling by favoring the production of nondiffusible, large molecules (such as sorbitol). Some drug therapies (e.g., aldose reductase inhibitors) endeavor to decrease intracellular swelling by inhibiting the formation of such large molecules.
3. Glycemia also disrupts autoregulation. Glucose-induced vasodilation prevents target organs from protecting against increases in systemic BP. A glycosylated hemoglobin level of 8.1% is the threshold at which the risk for microalbuminuria increases logarithmically. A person with type 1 diabetes who has microalbuminuria of greater than 29 mg/day has an 80% chance of experiencing renal insufficiency. The threshold for glycemic toxicity differs for various vascular beds. For example, the threshold for retinopathy is a glycosylated hemoglobin value of 8.5% to 9.0% (12.5 mmol/L or 225 mg/dL), and that for cardiovascular disease is an average blood glucose value of 5.4 mmol/L (96 mg/dL). Thus, different degrees of hyperglycemia may be required before different vascular beds are damaged, or certain degrees of glycemia are associated with other risk factors for vascular disease. Another view is that perhaps severe hyperglycemia and microalbuminuria are simply concomitant effects of a common underlying cause. For instance, diabetics in whom microalbuminuria develops are more resistant to insulin, insulin resistance is associated with microalbuminuria in first-degree relatives of type 2 diabetics, and persons who are normoglycemic but subsequently have clinical diabetes are at risk for atherogenesis before the onset of disease.

Tight control retards all these glucotoxicities and may have other benefits in retarding the severity of diabetes itself.[9-17,31]

Thus, management of intraoperative glucose might be influenced by specific situations, such as the type of operation, pregnancy,[32] and the expected global CNS insult; the bias of the patient's primary care physician; or the type of diabetes. Type 1 diabetic patients definitely need insulin and might be considered candidates for tight control of blood glucose levels. Type 2 diabetic patients have insulin, and current data indicate that they do not benefit from tight perioperative control unless they need intensive care.[9-14]

The key to managing blood glucose levels perioperatively in diabetic patients is to set clear goals and then monitor blood glucose levels frequently enough to adjust therapy to achieve these goals. Three regimens that afford various degrees of perioperative control of blood glucose levels are discussed in the following sections.

Classic "Non–Tight Control" Regimen

Aim: To prevent hypoglycemia, ketoacidosis, and hyperosmolar states.

Protocol:

1. On the day before surgery, the patient should be given nothing by mouth (NPO) after midnight; a 13-oz glass of clear orange juice should be at the bedside or in the car for emergency use.
2. At 6 AM on the day of surgery, infuse a solution of intravenous fluids containing 5% dextrose through plastic cannulas at a rate of 125 mL/hr/70 kg body weight.
3. After starting the intravenous infusion, give half the usual morning insulin dose (and the usual type of insulin) subcutaneously.
4. Continue 5% dextrose solutions through the operative period and give at least 125 mL/hr/70 kg body weight.
5. In the recovery room, monitor blood glucose concentrations and treat on a sliding scale.

Such a regimen has been found to meet its goals.

"Tight Control" Regimen 1

Aim: To keep plasma glucose levels at 79 to 120 mg/dL. Maintenance of such levels may improve wound healing and prevent wound infections, improve neurologic outcome after global or focal CNS ischemic insults, or improve weaning from cardiopulmonary bypass.

Protocol:

1. On the evening before surgery, determine the preprandial blood glucose level.
2. Through a plastic cannula, begin an intravenous infusion of 5% dextrose in water at a rate of 50 mL/hr/70 kg body weight.
3. "Piggyback" an infusion of regular insulin (50 units in 250 mL or 0.9% sodium chloride) to the dextrose infusion with an infusion pump (Fig. 35-1). Before attaching this piggyback line to the dextrose infusion, flush the line with 60 mL of infusion mixture and discard the flushing solution. This approach saturates insulin binding sites on the tubing.

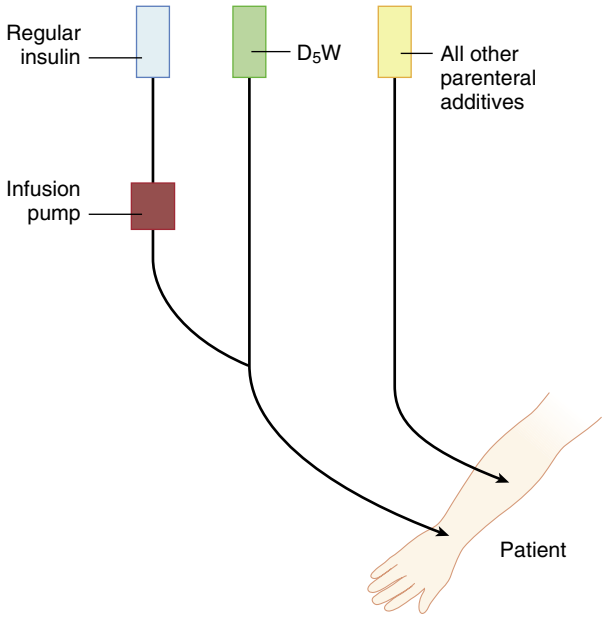

Figure 35-1 Arrangement of intravenous lines for infusion of regular insulin in a regimen tightly controlling blood glucose levels in diabetic patients undergoing surgery. D_5W, 5% dextrose in water.

4. Set the infusion rate by using the following equation: Insulin (U/hr) = plasma glucose (mg/dL)/150. (*Note*: The denominator should be 100 if the patient is taking corticosteroids, e.g., 10 mg of prednisolone a day or its equivalent, not to include inhaled steroids, or has a body mass index of ≥35.)
5. Repeat blood glucose measurements every 4 hours as needed, and adjust insulin appropriately to obtain blood glucose levels of 100 to 200 mg/dL.
6. On the day of surgery, intraoperative fluids and electrolytes are managed by continued administration of non–dextrose-containing solutions, as described in steps 3 and 4.
7. Determine the plasma glucose level at the start of surgery and every 1 to 2 hours for the rest of the 24-hour period. Adjust the insulin dosage appropriately.

Although we have not found it necessary to treat hypoglycemia (i.e., blood glucose levels <50 mg/dL), we have been prepared to do so with 15 mL of 50% dextrose in water. In such circumstances, the insulin infusion would be terminated. This regimen has been found to accomplish its objectives, with the exception of such tight goals for blood glucose, even in very "brittle" diabetics (i.e., those extremely resistant to treatment) given high doses of steroids.

"Tight Control" Regimen 2

Aim: Same as for Tight Control Regimen 1.

Protocol:

1. Obtain a "feedback mechanical pancreas" and set the controls for the desired plasma glucose regimen.
2. Institute two appropriate intravenous lines.

This last regimen may well supersede all others if the cost of a mechanical pancreas can be reduced and if control of hyperglycemia is shown to make a meaningful difference perioperatively; it has superseded all others in many ICUs and for good reason (Table 35-2).[11-13]

Table 35-2 Therapy for 1548 Postsurgical Diabetics in the Leuven Intensive Care Unit Study*

	Intensive Glucose Therapy (80-110 mg/dL)	Conventional Glucose Therapy (180-200 mg/dL)
Death in the ICU	4.6%	8.0%
After 5 days in the ICU	10.6%	20.2%
First 5 ICU days	1.7%	1.8%
All deaths	7.2%	10.9%
>14 days in the ICU	11.4%	15.7%
>14 days ventilated	7.5%	11.9%
Rx dialysis	4.8%	8.2%
Polyneuropathy	28.7%	51.9%

*Decreased complication rates and improved survival were observed in the group treated by tight control.

Diabetes and Accelerated Physiologic Aging

Adverse perioperative outcomes have repeatedly and substantially correlated with the age of the patient,[6,7,21-23,33] and diabetes does cause physiologic aging. When one translates the results of the Diabetes Control and Complications Trials into age-induced physiologic changes, a type 1 diabetic who has poor control of blood sugar ages approximately 1.75 years physiologically for every chronologic year of the disease and 1.25 years if blood sugar has been controlled tightly.[21-23] A type 2 diabetic ages about 1.5 years for every chronologic year of the disease and about 1.06 years with tight control of blood sugar and BP.[16,21-23,34] Thus, when providing care for a diabetic patient, one must consider the associated risks to be those of a person who is much older physiologically. That is, a diabetic's physiologic age ("RealAge") is considerably higher than that person's calendar age just by virtue of having the disease.[2]

The increased prevalence of obesity and lack of physical exercise seem to be major contributors to the increased prevalence of type 2 diabetes. As with type 1 diabetes, tight control of blood sugar, increased physical activity, and reduction in weight appear to reduce the accelerated aging associated with type 2 diabetes and even to substantially delay appearance of the disease and aging from it (Box 35-2).[21-23,34] Although such a reduction in aging should reduce the perioperative risk for diabetic patients, no controlled trials have confirmed this theory.

Other Conditions Associated with Diabetes

Diabetes is associated with microangiopathy (in retinal and renal vessels), peripheral neuropathy, autonomic dysfunction, and infection. Diabetics are often treated with angiotensin-converting enzyme (ACE) inhibitors, even in the absence of gross hypertension, in an effort to prevent the effects of disordered autoregulation, including renal failure.[15,16,35]

Before surgery, assessment and optimization of treatment of the potential and potent end-organ effects of diabetes are at least as important as assessment of the diabetic's current overall metabolic status. The preoperative evaluation of diabetics is also discussed in Chapter 34.

If one is to believe the few studies we have, the presence of autonomic neuropathy makes the operative period more hazardous and the postoperative period crucial to survival. Evidence of autonomic neuropathy might be routinely sought before surgery. Patients with diabetic autonomic neuropathy are at increased risk for gastroparesis (and consequent aspiration) and for intraoperative and postoperative cardiorespiratory arrest. Data indicate that diabetics who exhibit signs of autonomic neuropathy, such as early satiety, lack of sweating, lack of pulse rate change with inspiration or orthostatic maneuvers, and impotence, have a very high incidence of painless myocardial ischemia[19,36] and gastroparesis. Some investigators have successfully used 10 mg of metoclopramide preoperatively to facilitate gastric emptying of solids (Fig. 35-2). Interference with respiration or sinus automaticity by pneumonia or by anesthetics, pain medications, or sedative drugs appears to be the precipitating cause in most cases of sudden cardiorespiratory arrest. Measuring the degree of sinus arrhythmia or beat-to-beat variability provides a simple, accurate test for significant autonomic neuropathy. The difference between the maximum and minimum heart rate on deep inspiration is normally 15 beats/min but is 5 beats/min or less in all patients who sustained cardiorespiratory arrest.[19,36]

Box 35-2 The YOU Docs Plan for Reversing the Aging from Type 2 Diabetes and Metabolic Syndrome*

We or you have told us of tests and measurements that indicate you have type 2 diabetes or metabolic syndrome. Don't be alarmed; you can control the genes that predispose you to such so that this syndrome will not be as much problem to you in the future. BUT YOU HAVE TO DO IT—it is not your docs or your mother, IT IS UP TO YOU TO CONTROL YOUR GENES.

Because you have been diagnosed with type 2 diabetes or these syndromes, you can begin getting healthier by reducing your weight. Without a doubt, diabetes can be as damaging to your health as an annoyed anaconda. However, if you can hit these goals and even gradually decrease your waist size and your weight (aim for 2 pounds a week for the first 4 weeks, then 1 pound a week for 4 weeks, then 1 pound every month—after all you didn't get this big all at once), you'll decrease the aging effects of diabetes or metabolic syndrome by 80%, perhaps even more. Here's what has worked for our typical patient with your physique and tests and how to lose the weight and waist:

1. Avoid all white food—we're talking icing and white bread, not cauliflower.
2. Walk 30 minutes a day, no matter what.
3. Get a buddy and a plan for making YOU-turns: If you can walk 30 minutes every day and call (or e-mail) a support person each day after you've walked, you can lose the weight and have the waist you want, at least that's what review of weight and waist loss from over 190,000 buddy pairs tells us. So get a buddy you tell you walked daily and who will call you to check up if you do not call her within 15 minutes of your usual time (her's work better as buddies than him's). Have a plan for when you slip up—because you will. Here's a three-step approach for getting back on the right path:
   - Relax and say something positive to steer yourself back on course. Be confident that you can overcome the slip.
   - Do something physical right away—for instance, take a brisk walk or do a yoga pose. I recommend the downward-facing dog posture. This will help you refocus, take a deep breath, and remind yourself of your goals.
   - Eat something nutritious. Certain foods—such as carrots and apples—can help counteract stress, probably because they're crunchy and a touch sweet. You could choose a crisp vegetable, too. Whatever it is, make this the nutritious food "YOU-turn" to whenever you're stressed.
4. Once you have walked 30 minutes a day for 30 consecutive days, learn to lift weights and then integrate a resistance training program for 20 minutes three times a week into your weekly routine (you can download one for free at www.realage.com/youdocs); start with the beginner level no matter what your age.
5. Measure your waist around your belly button every Sunday. Suck in (you will anyway). Aim to lose an inch a month.
6. Get a blood pressure monitor and take it every Sunday. Your goal is 115/75.
7. Avoid the five aging foods: all added sugars and syrups, including all high-fructose corn syrup; saturated fats (four-legged plus palm or coconut oil) and *trans*-fats (blends or partially hydrogenated fats); and any grain except 100% whole grain, especially if it's one of the first five ingredients listed on a label.
8. Have as much fruit—whole, not fruit mixes or canned—and veggies as you want. By the way, Fruit Loops doesn't cut it.
9. Eat half an ounce of nuts—6 walnut halves, 12 almonds, or 20 peanuts—8 minutes before each meal, followed by a glass of water 4 minutes later.
10. Make eating automatic. I know I've said this before, but if you can train yourself—over 2 weeks or longer—to eat the right foods and make the right activity choices, you'll reprogram your body so that gradually eating right and exercising becomes a habit, one you'll do automatically. One tip for making your eating automatic is to have the same foods every day for two meals, say breakfast and lunch, and vary only one meal, such as dinner. Perhaps you're thinking "No one could do that." In fact, I practice what I preach by eating steel cut oatmeal for breakfast everyday. You can even prepare a week's worth of oats in advance to save time.
11. Inform and work with your primary care doctor. Keep taking your antidiabetic medications (and all others such as anti–high blood pressure medications), but follow your blood sugar and blood pressure closely. Our typical patients have to reduce antidiabetic medications and insulin after about 2 weeks and gets rid of them by the time they have lost 15% to 20% of the excess waist and weight they have gained since age 18 (women) or age 21 (men). Moreover, that reduction in medications occurs for their anti–high blood pressure medications too.

*The Type II Diabetes Disease Reversal plan is copywritten by the YOU Docs in *YOU On a Diet: The Owner's Manual for Waist Management* (Free Press, 2006 in the United States), reprinted here by permission of the copyright owner and offered to all who want to use it—feel free to copy and hand to patients (as long as credit is given).

Other characteristics of patients with autonomic neuropathy include postural hypotension with a decrease in BP of more than 30 mm Hg, resting tachycardia, nocturnal diarrhea, and dense peripheral neuropathy. Diabetics with significant autonomic neuropathy may have impaired respiratory responses to hypoxia and are particularly susceptible to the action of drugs that have depressant effects. These patients may warrant very close, continuous cardiac and respiratory monitoring for 24 to 72 hours postoperatively, although such logical treatment has not been tested in a rigorous, controlled trial.[19] In the absence of autonomic neuropathy, we would favor outpatient surgery for a diabetic (Table 35-3).

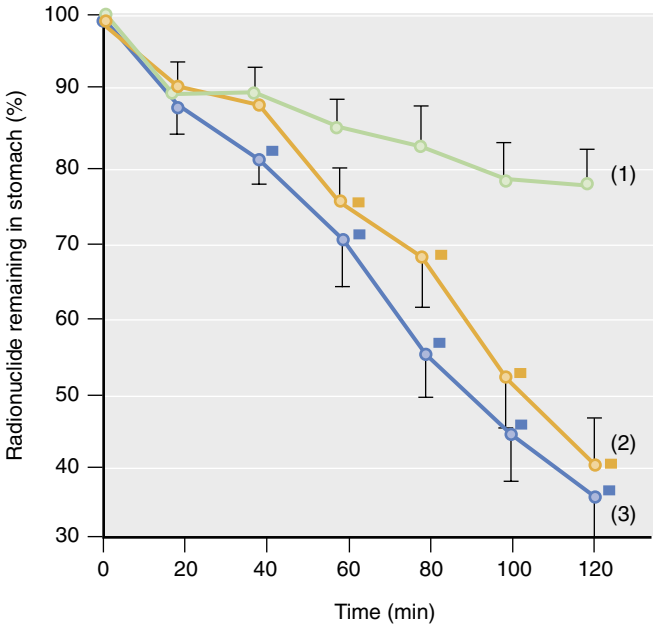

Figure 35-2 Gastric emptying time (mean ± SD) of a solid test meal in three groups of patients: diabetics (line 1), diabetics given metoclopramide (10 mg intravenously) 1.5 hours before the test meal (line 2), and nondiabetics (line 3). *(From Wright RA, Clemente R, Wathen R: Diabetic gastroparesis: An abnormality of gastric emptying of solids. Am J Med Sci 289:240, 1985.)*

Anticipated Newer Treatments of Diabetes

At least three major changes in the care of diabetic patients have made it to the clinical trial stage:

- Implanted (like a pacemaker) glucose analyzer with electronic transmission to a surface (watch) monitor
- New islet transplantation medication that makes islet cell transplants much more successful and rejection medication less hazardous
- Medications such as INGAP (islet neogenesis–associated protein) peptide, which may cause regrowth of normally functioning islet cells (without needing transplantation)

One can imagine how some of these treatments may radically change the therapies used in the perioperative period. If regrowth of islets becomes common, type 1 diabetes could all but disappear; if implanted minute-to-minute glucose reading is possible, tight control may be much easier and more expected.

Insulinoma and Other Causes of Hypoglycemia

Hypoglycemia in persons not treated for diabetes is rare. Hypoglycemia in nondiabetics can be caused by such diverse entities as pancreatic islet cell adenoma or carcinoma, large hepatoma, large sarcoma, alcohol ingestion, use of β-adrenergic receptor blocking drugs, haloperidol therapy, hypopituitarism, adrenal insufficiency, altered physiology after gastric or gastric bypass surgery, hereditary fructose intolerance, ingestion of antidiabetic drugs, galactosemia, or autoimmune hypoglycemia.[37] The last four entities cause postprandial reactive hypoglycemia. Because restriction of oral intake prevents severe hypoglycemia, the practice of keeping the patient NPO and infusing small amounts of a solution containing 5% dextrose greatly lessens the possibility of perioperative postprandial reactive hypoglycemia. The other causes of hypoglycemia can cause serious problems during the perioperative period.[37]

Symptoms of hypoglycemia fall into two groups: adrenergic excess (tachycardia, palpitations, tremulousness, or diaphoresis) and neuroglycopenia (headache, confusion, mental sluggishness, seizures, or coma). All these symptoms may be masked by anesthesia, so blood glucose levels should be determined frequently in such patients to ensure that hypoglycemia is not present. Because manipulation of an insulinoma can result in massive insulin release, this tumor should probably be operated on only at centers equipped with a mechanical pancreas. Perioperative use of the somatostatin analog octreotide, which suppresses insulin release from such tumors, appears to make the perioperative period a logarithm safer in anecdotal experience.

Disorders of Nutrition, Including Obesity

Hyperlipoproteinemia, Hyperlipidemia, and Hypolipidemia

Hyperlipidemia may result from obesity, estrogen or corticoid therapy, uremia, diabetes, hypothyroidism, acromegaly, alcohol ingestion, liver disease, inborn errors of metabolism, or pregnancy. Hyperlipidemia may cause premature coronary or peripheral vascular disease or pancreatitis.

Data showing that coronary events can be reduced by treating individuals with even normal levels of low-density cholesterol (LDL) cholesterol with the "statins"—drugs that raise high-density cholesterol (HDL) and lower LDL cholesterol levels—resulted from a decade of rapid progress in preventing reinfarction in high-risk patients.[38-40] Secondary prevention efforts were successful when these high-risk patients stopped smoking, reduced their BP, controlled stress, increased physical activity, and used aspirin, folate, β-blocking drugs, angiotensin inhibitors, diet, and other drugs to reduce their levels of LDL and increase their levels of HDL.

Table 35-3 Should a Diabetic Be an Outpatient or a Morning Admittance Patient?

Outpatient If	Morning Admittance Patient If
Can evaluate the history in advance	Cannot evaluate the history
End-organ disease does not require monitoring	End-organ disease requires invasive monitoring
Prehydration is available	Needs careful prehydration or is unnecessary
No CNS ischemia or planned cardiopulmonary bypass	CNS ischemia is present or cardiopulmonary bypass is planned
Not pregnant	Pregnant
Patient or vested home "mate" can determine blood glucose level	Patient cannot determine blood glucose level
Has vested home "mate"	No vested individual
Can take temperature or look for "red" wound	Cannot take temperature or look for "red" wound
Plan higher admission rate (no data)	Social care network is unsuitable

Although controlling the diet remains a major treatment modality for all types of hyperlipidemia, the drugs fenofibrate and gemfibrozil, which are used to treat hypertriglyceridemia, can cause myopathy, especially in patients with hepatic or renal disease; clofibrate is also associated with an increased incidence of gallstones. Cholestyramine binds bile acids, as well as oral anticoagulants, digitalis drugs, and thyroid hormones. Nicotinic acid causes peripheral vasodilation and should probably not be continued through the morning of surgery. Probucol (Lorelco) decreases the synthesis of apoprotein A-I; its use is associated on rare occasion with fetid perspiration or prolongation of the QT interval (or both) and sudden death in animals.

The West of Scotland Coronary Prevention Study and its congeners produced convincing evidence that drugs in the "statin" class (3-hydroxy-3-methylglutaryl–coenzyme A [HMG-CoA] reductase inhibitors) prevent the morbidity and mortality related to arterial aging and vascular disease, as well as their consequences, such as coronary artery disease, stroke, and peripheral vascular insufficiency.[39] Thus, the statins—lovastatin (Mevacor), pravastatin (Pravachol), simvastatin, fluvastatin, atorvastatin (Lipitor), and rosuvastatin (Crestor)—are mainstays of therapy.

However, the report of Downs and coworkers[39] from the Air Force/Texas Coronary Atherosclerosis Prevention Study went further. It showed a 37% reduction in the risk for first acute major coronary events in patients who had no risk factors and normal (average) LDL cholesterol levels. In this study lovastatin did not alter mortality rates, but that had been true for many early short-term trials with the statins. Although much of the effect of the statins has been attributed to their lipid-lowering effects, at least 40% of the effect of statins is modification by them of endothelial function, inflammatory responses, plaque stability, and thrombogenicity (Steven Nissen, MD, personal communcation). The report of Downs and colleagues broadened the use of statins, and they remain mainstays of therapy for hyperlipidemia. Statins are drugs that block HMG-CoA reductase, the rate-limiting enzyme of cholesterol synthesis. Their use is occasionally accompanied by liver dysfunction, CNS dysfunction, and severe depression not related to the high cost of each drug and its cogeners. Other drugs that reduce LDL and increase HDL cholesterol and decrease triglycerides are docosahexaenoic acid (DHA, an ω-3 fatty acid) and niacin. Recent data indicate that statins also provide the substantial benefit of reversing inflammation in arteries, as evidenced by their ability to decrease highly specific C-reactive protein and pull cholesterol from plaque.[41]

Hypolipidemic conditions are rare diseases often associated with neuropathy, anemia, and renal failure. Although anesthetic experience with hypolipidemic conditions has been limited, some specific recommendations can be made: continuation of caloric intake and intravenous administration of protein hydrolysates and glucose throughout the perioperative period.

Obesity

Although many conditions associated with obesity (diabetes, hyperlipidemia, cholelithiasis, gastroesophageal reflux disease, cirrhosis, degenerative joint and disk disease, venous stasis and thrombotic/embolic disease, sleep disorders, and emotional and altered body image disorders) contribute to chronic morbidity in the obese, the main concerns for the anesthesiologist have been the same for more than 4 decades—derangements of the cardiopulmonary system (also see Chapter 64).

Morbid obesity with minimal or no coexisting pulmonary conditions (e.g., no obesity-hypoventilation syndrome or chronic obstructive pulmonary disease [COPD]) will be referred to as "simple" obesity. In simple obesity, the pathophysiology of mild alterations in daytime gas exchange and pulmonary function may also result from compression and restriction of the chest wall and diaphragm by excess adipose tissue.[42] Typically, in the obese, the expiratory reserve volume and functional residual capacity are most affected and reduced to 60% and 80% of normal, respectively. Morbid obesity and its perioperative implications are also discussed in Chapters 34 and 64.

Other Eating Disorders: Anorexia Nervosa, Bulimia, and Starvation

Many endocrine and metabolic abnormalities occur in patients with anorexia nervosa, a condition characterized by starvation to the point of 40% loss of normal weight, hyperactivity, and a psychiatrically distorted body image. Many anorectic patients exhibit impulsive behavior, including suicide attempts, and intravenous drug use is much more common than in the general population. Acidosis, hypokalemia, hypocalcemia, hypomagnesemia, hypothermia, diabetes insipidus, and severe endocrine abnormalities mimicking panhypopituitarism need attention before anesthesia and surgery. Similar problems occur in bulimia (bulimorexia), a condition that may affect as many as 50% of female college students[43] and is even unintentionally present in many elderly.[44] As in severe protein deficiency (kwashiorkor), anorexia nervosa and bulimia may be accompanied by alterations on the electrocardiogram (ECG), including a prolonged QT interval, atrioventricular (AV) block, and other arrhythmias; sensitivity to epinephrine; and cardiomyopathy.[43] Total depletion of body potassium makes the addition of potassium to glucose solutions useful; however, fluid administration can precipitate pulmonary edema in these patients. Esophagitis, pancreatitis, and aspiration pneumonia are more frequent in these patients, as is delayed gastric emptying. Thus, invasive monitoring (radial artery and pulmonary artery catheterization) may be indicated for anorectic, bulimic, and malnurtured patients requiring emergency surgery. Elective surgery should probably be delayed until the abnormalities are treated.

Hyperalimentation (Total Parenteral or Enteral Nutrition)

Hyperalimentation (i.e., total parenteral nutrition [TPN]) consists of concentrating hypertonic glucose calories in the normal daily fluid requirements (also see Chapter 95). The solutions contain protein hydrolysates, soybean emulsions (i.e., Intralipid), or synthetic amino acids (or any combination of these ingredients). The major benefits of TPN or enteral nutrition have been fewer complications postoperatively and shorter hospital stays for patients scheduled to have no oral feeding for 7 days or who were malnourished preoperatively.[45,46] Starker and colleagues[47] found that the response to TPN, as monitored by serum albumin levels, predicted the postoperative outcome. The group demonstrating a rise in serum albumin with TPN had diuresis, weight loss, and fewer complications (1 of 15 patients) than did the group that gained weight and had a decrease in serum albumin (8 of 16 patients had 15 complications) (Fig. 35-3). These data are echoed by those in the Veterans Administration (VA) studies, which

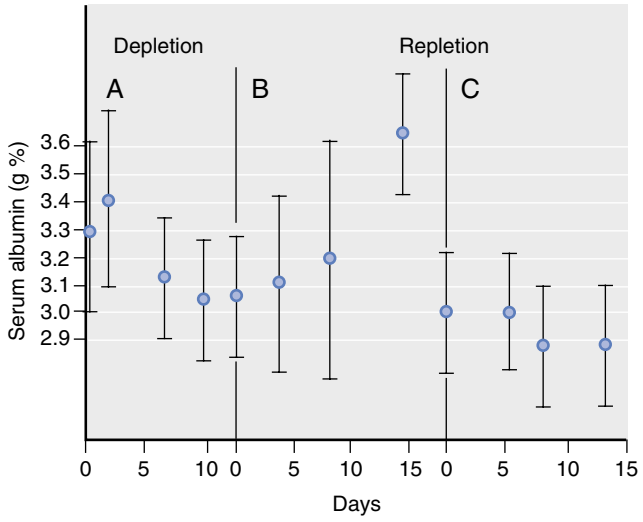

Figure 35-3 The response to hyperalimentation A, (repletion), as measured by variation in serum albumin levels, predicted the outcome of surgery. Patients who responded (B) to nutritional support with increased albumin levels had a significantly better outcome than did those whose albumin level did not increase (C). See the text for a more complete explanation. *(Adapted from Starker PM, Group FE, Askanazi J, et al: Serum albumin levels as an index of nutritional support. Surgery 91:194, 1982.)*

reported that the serum albumin level was one of the most powerful predictors of perioperative outcome.[45]

The major complications of hyperalimentation are sepsis and metabolic abnormalities. The central lines used for TPN require application with an absolutely aseptic technique and should not be used routinely as an intravenous route for drug administration. Major metabolic complications of TPN relate to deficiencies and the development of hyperosmolar states. Complications of hypertonic dextrose can develop if the patient has insufficient insulin (diabetes mellitus) to metabolize the sugar or if insulin resistance occurs (e.g., because of uremia, burns, or sepsis).

A gradual decrease in the infusion rate of TPN prevents the hypoglycemia that can occur on abrupt discontinuance. Thus, the infusion rate of TPN should be decreased the night before anesthesia and surgery or be continued throughout the operation at its current rate. The main reason for slowing or discontinuing TPN before anesthesia is to avoid intraoperative hyperosmolarity secondary to accidental rapid infusion of the solution or hypoglycemia if the infusion is discontinued because of high levels of endogenous insulin and lower levels of glucose present in the usual crystalloid solutions.[45] Hypophosphatemia is a particularly serious complication that results from the administration of phosphate-free or phosphate-depleted solutions for hyperalimentation. The low serum phosphate level causes a shift of the oxygen dissociation curve to the left. The resulting low 2,3-diphosphoglycerate and adenosine triphosphatase levels mean that cardiac output must increase for oxygen delivery to remain the same. Hypophosphatemia of less than 1.0 mg/dL of blood may cause hemolytic anemia, cardiac failure, tachypnea, neurologic symptoms, seizures, and death. In addition, long-term TPN is associated with deficiencies in trace metals such as copper (refractory anemia), zinc (impaired wound healing), and magnesium.

For these reasons, one author (M.F.R.) has adopted the following practices. Infusion of TPN or enteral nutrition is reduced beginning the night before surgery, and a 5% or 10% dextrose solution is substituted preoperatively. If serum glucose, phosphate, and potassium concentrations (measured preoperatively) are abnormal, they are restored to within normal limits. Strict asepsis is maintained. Conversely, one should continue infusing the TPN solution by using a pump system or enteral nutrition while strictly maintaining its normal rate and asepsis, administering all fluids through a different intravenous site, and performing a rapid-sequence induction of anesthesia (for those who received enteral nutrition).

Adrenocortical Malfunction

Three major classes of hormones—androgens, glucocorticoids, and mineralocorticoids—are secreted by the adrenal cortex. For each class, an excess or a deficiency of hormone produces a characteristic clinical syndrome. The widespread use of steroids can also make the adrenal cortex unable to respond normally to the demands placed on it by surgical trauma and subsequent healing. The increase in unindicated (scanning) computed tomography (CT) abdominal imaging procedures has meant that many adrenal masses have unfortunately been discovered only incidentally. These adrenal "incidentalomas," as they are termed because they were initially thought a nuisance discovered by unindicated body scans, have proved more serious. As many as 30% are hormonally active; in one recent review of 2000 such masses, 82% were not hormonally active, 5.3% proved to be cortisone-secreting adenomas, 5.1% were pheochromocytomas, 4.7% were adrenal carcinomas, 2.5% were unsuspected metastatic disease, and 1% were aldosterone-secreting adenomas. Incidentalomas may therefore require serious pursuit. Several points relative to adrenal cortical management deserve attention.

Controlled comparisons of the perioperative management of patients who have disorders of adrenal function are lacking, although we use steroids more and more commonly, with the results of some controlled trials available for specific uses. However, a review of the possible pathophysiologic changes in the adrenal cortex and techniques for their management should enable us to improve the perioperative care of patients with adrenal abnormalities.

Physiologic Properties of Adrenocortical Hormones

Androgens

Androstenedione and dehydroepiandrosterone, weak androgens arising from the adrenal cortex, constitute major sources of androgen in women (and have gained prominence for their use or abuse by baseball players seeking to hit more home runs). Excess secretion of androgen causes masculinization, pseudopuberty, or female pseudohermaphroditism. With some tumors, androgen is converted to an estrogenic substance, in which case feminization results. No special anesthetic evaluation is needed for such patients. Some congenital enzyme defects that cause androgen abnormalities also result in glucocorticoid and mineralocorticoid abnormalities that should be evaluated before surgery. Most of these patients are treated with exogenous glucocorticoids and mineralocorticoids and consequently require supplementation of these hormones perioperatively (see later).

Glucocorticoids

The principal glucocorticoid, cortisol, is an essential regulator of carbohydrate, protein, lipid, and nucleic acid metabolism. Cortisol exerts its biologic effects through a sequence of steps initiated by binding of hormone to stereospecific intracellular cytoplasmic receptors. This bound complex stimulates nuclear transcription of specific mRNA molecules. These molecules are then translated to give rise to proteins that mediate the ultimate effects of hormones.

Most cortisol is bound to corticosterone-binding globulin (CBG, transcortin). It is the relatively small amounts of unbound cortisol that enter cells to induce actions or to be metabolized. Conditions that induce changes in the amount of CBG include liver disease and nephrotic syndrome, both of which result in decreased circulating levels of CBG, and estrogen administration and pregnancy, which result in increased CBG production. Total serum cortisol levels may become elevated or depressed under conditions that alter the amount of bound cortisol, and yet the unbound, active form of cortisol is present in normal amounts. The most accurate measure of cortisol activity is the level of urinary cortisol—that is, the amount of unbound, active cortisol filtered by the kidney.

The serum half-life of cortisol is 80 to 110 minutes. However, because cortisol acts through intracellular receptors, pharmacokinetic data based on serum levels are not good indicators of cortisol activity. After a single dose of glucocorticoid, serum glucose is elevated for 12 to 24 hours; improvement in pulmonary function in patients with bronchial asthma can still be measured 24 hours after glucocorticoid administration. Treatment schedules for glucocorticoid replacement are therefore based not on the measured serum half-life but on the well-documented prolonged end-organ effect of these steroids. Hospitalized patients requiring chronic glucocorticoid replacement therapy are usually treated twice daily, with a slightly higher dose given in the morning than in the evening to simulate the normal diurnal variation in cortisol levels. For patients who require parenteral "steroid coverage" during and after surgery (see later paragraphs), administration of glucocorticoid every 12 hours is appropriate.[48] The relative potencies of glucocorticoids are listed in Table 35-4. Cortisol is inactivated primarily in the liver and is excreted as 17-hydroxycorticosteroid. Cortisol is also filtered and excreted unchanged into urine.

The synthetic glucocorticoids vary in their binding specificity in a dose-related manner. When given in supraphysiologic doses (>30 mg/day), cortisol and cortisone bind to mineralocorticoid receptor sites and cause salt and water retention and loss of potassium and hydrogen ions. When these steroids are administered in maintenance doses of 30 mg/day or less, patients require a specific mineralocorticoid for electrolyte and volume homeostasis. Many other steroids do not bind to mineralocorticoid receptors, even at high doses, and have no mineralocorticoid effect (see Table 35-4).

Secretion of glucocorticoids is regulated by pituitary adrenocorticotropic hormone (ACTH). ACTH is synthesized from a precursor molecule (pro-opiomelanocortin) that is metabolized to form an endorphin (β-lipotropin) and ACTH. Episodic secretion of ACTH has a diurnal rhythm that is normally greatest during the early morning hours in men, later in women, and is regulated at least in part by light-dark cycles. Its secretion is stimulated by release of corticotropin-releasing factor (CRF) from the hypothalamus. (An abnormality in the diurnal rhythm of corticoid secretion has been implicated as a cause of so-called jet lag.) Cortisol and other glucocorticoids exert negative feedback at both the pituitary and hypothalamic levels to inhibit the secretion of ACTH and CRF. If the CRF- or ACTH-producing cells are destroyed, the adrenal gland takes more than 30 days to atrophy to the point where acute administration of exogenous ACTH will cause almost no adrenal responsiveness.

Table 35-4 Relative Potencies and Equivalent Doses for Commonly Used Glucocorticoids

Steroids	Relative Glucocorticoid Potency	Equivalent Glucocorticoid Dose (mg)
Short Acting		
Cortisol (hydrocortisone)	1.0	20.0
Cortisone	0.8	25.0
Prednisone	4.0	5.0
Prednisolone	4.0	5.0
Methylprednisolone	5.0	4.0
Intermediate Acting		
Triamcinolone	5.0	4.0
Long Acting		
Betamethasone	25.0	0.60
Dexamethasone	30.0	0.75

Data from Axelrod L: Glucocorticoid therapy. Medicine (Baltimore) 55:39, 1976.

Mineralocorticoids

Aldosterone, the major mineralocorticoid secreted in humans, comes from the zona glomerulosa of the adrenal cortex and causes reabsorption of sodium and secretion of potassium and hydrogen ions, thereby contributing to electrolyte and volume homeostasis. This action is most prominent in the distal renal tubule but also occurs in the salivary and sweat glands. The major regulator of aldosterone secretion is the renin-angiotensin system. Juxtaglomerular cells in the cuff of renal arterioles are sensitive to decreased renal perfusion pressure or volume and, consequently, secrete renin. Renin splits the precursor angiotensinogen (from the liver) into angiotensin I, which is further converted by a converting enzyme, primarily in the lung, to angiotensin II. Angiotensin II binds to specific receptors to increase mineralocorticoid secretion, which is also stimulated by an increased potassium concentration and, to a lesser degree, by ACTH.

Adrenocortical Hormone Excess

Glucocorticoid Excess

Glucocorticoid excess (Cushing's syndrome) resulting from either endogenous oversecretion or chronic treatment with glucocorticoids at higher than physiologic doses produces a moon-faced plethoric individual with a centripetal distribution of fat (truncal obesity and skinny extremities), thin skin, easy bruising, and striae. Muscle wasting is common, but the heart and diaphragm are usually spared. A test for this syndrome is to ask the patient

Table 35-5 Clinical Features of Hyperadrenalism (Cushing's Syndrome) and Hypoadrenalism

Cushing's Syndrome	Hypoadrenalism
Central obesity	Weight loss
Proximal muscle weakness	Weakness, fatigue, lethargy
Osteopenia at a young age	Muscle and joint pain and back pain
Hypertension	Postural hypotension and dizziness
Headache	Headache
Psychiatric disorders	Anorexia, nausea, abdominal pain, constipation, diarrhea
Purple striae	
Spontaneous ecchymoses	
Plethoric facies	
Hyperpigmentation	Hyperpigmentation
Hirsutism	
Acne	
Hypokalemic alkalosis	Hyperkalemia, hyponatremia
Glucose intolerance	Occasional hypoglycemia
Kidney stones	Hypercalcemia
Polyuria	Prerenal azotemia
Menstrual disorders	
Increased leukocyte count	

to get up from a chair without using the hands. An inability to do so indicates proximal muscle weakness consistent with Cushing's syndrome. These patients often have osteopenia as a result of decreased formation of bone matrix and impaired absorption of calcium. Fluid retention and hypertension (because of increases in renin substrate and vascular reactivity caused by glucocorticoid) are common. Such patients may also have hyperglycemia and even diabetes mellitus from inhibition of peripheral use of glucose, as well as anti-insulin action and concomitant stimulation of gluconeogenesis (Table 35-5).

The most common cause of Cushing's syndrome is the administration of glucocorticoids for such conditions as arthritis, asthma, and allergies.[49] In these conditions, the adrenal glands atrophy and cannot respond to stressful situations (e.g., the preoperative and preprocedure period) by secreting more steroid. Thus, additional glucocorticoids may be required perioperatively (see the later section "Patients Taking Steroids for Other Reasons"). Spontaneous Cushing's syndrome may be caused by pituitary production of ACTH (65% to 75% of all spontaneous cases), which is usually associated with pituitary microadenoma, or by nonendocrine ectopic ACTH production (principally by tumors of the lung, pancreas, or thymus).[50] Ten percent to 20% of cases of spontaneous Cushing's syndrome are caused by an ACTH-independent process, either an adrenal adenoma or carcinoma.

Special preoperative and preprocedure considerations for patients with Cushing's syndrome include regulating diabetes and hypertension and ensuring that intravascular fluid volume and electrolyte concentrations are normal. Ectopic ACTH production may cause marked hypokalemic alkalosis. Treatment with the aldosterone antagonist spironolactone will stop the potassium loss and help mobilize excess fluid. Because of the high incidence of severe osteopenia and the risk of fractures, meticulous attention must be paid to positioning of the patient. In addition, glucocorticoids are lympholytic and immunosuppressive and thus increase the patient's susceptibility to infection. The tensile strength of healing wounds decreases in the presence of glucocorticoids, an effect that is at least partially reversed by the topical administration of vitamin A.

Specific considerations pertain to the surgical approach for each cause of Cushing's syndrome. For example, nearly three fourths of cases of spontaneous Cushing's disease result from a pituitary adenoma that secretes ACTH. One author's (M.F.R.) perioperative treatment of patients who have Cushing's disease and a pituitary microadenoma differs from that of patients who have a pituitary adenoma associated with amenorrhea and galactorrhea. A patient with Cushing's disease is inclined to bleed more easily and (on the basis of anecdotal evidence) tends to have higher central venous pressure (CVP). Thus, during transsphenoidal tumor resection in such patients, the practice is to routinely monitor CVP and maintain it at the low end of the normal range. In other cases of transsphenoidal resection of microadenoma, such monitoring is needed only infrequently.

Ten percent to 15% of patients with Cushing's syndrome exhibit adrenal overproduction of glucocorticoids from an adrenal adenoma or carcinoma. If either unilateral or bilateral adrenal resection is planned, we normally begin administering glucocorticoids at the start of resectioning of the tumor. Despite the absence of definitive studies, we normally give 100 mg of hydrocortisone hemisuccinate or hydrocortisone phosphate every 24 hours intravenously. We reduce this amount over a period of 3 to 6 days until a maintenance dose is reached. Beginning on day 3, the surgeons that we have worked with most also give a mineralocorticoid, 9α-fluorocortisol (0.05 to 0.1 mg/day). In certain patients, both steroids may require several adjustments. This therapy continues if the patient has undergone bilateral resection. For a patient who has undergone unilateral adrenal resection, therapy is individualized according to the status of the remaining adrenal gland. The incidence of pneumothorax in open adrenal resection approaches 20%; the diagnosis of pneumothorax is sought and treatment is begun before the wound is closed. This problem has almost vanished with use of the laparoscopic technique, which means that patients who need open resection merit even closer postoperative scrutiny.

Bilateral adrenalectomy in patients with Cushing's syndrome is associated with a high incidence of postoperative complications and a perioperative mortality rate (greater than that of even cardiac surgery) of 5% to 10%; it often results in permanent mineralocorticoid and glucocorticoid deficiency. Ten percent of patients with Cushing's syndrome who undergo adrenalectomy have an undiagnosed pituitary tumor. After reduction of high levels of cortisol by adrenalectomy, the pituitary tumor enlarges. These pituitary tumors are potentially invasive and may produce large amounts of ACTH and melanocyte-stimulating hormone, thereby increasing pigmentation.

Adrenal tumors are at least 85% incidentalomas—that is, discovered incidentally during screening (and largely unindicated) CT scans. Nonfunctioning adrenal adenomas are found in patients on autopsy, ranging from 1% to 32% in different series. Functioning adenomas are generally treated surgically; often, the

contralateral gland resumes functioning after several months. Frequently, however, the effects of carcinomas are not cured by surgery. In such cases, administration of inhibitors of steroid synthesis, such as metyrapone or mitotane (*o,p′*-DDD[2,2-bis(2-chlorophenyl4-chlorophenyl)-1,1-dichloroethane]), may ameliorate some symptoms but may not improve survival. These drugs and specific aldosterone antagonists may aid in reducing symptoms in the case of ectopic ACTH secretion if the primary tumor proves unresectable. Patients given these adrenal suppressants are also prescribed chronic glucocorticoid replacement therapy (i.e., the goal of therapy is complete adrenal suppression). These patients should be considered to have suppressed adrenal function, and glucocorticoid replacement should be increased perioperatively.

Mineralocorticoid Excess

Excess mineralocorticoid activity (common with glucocorticoid excess because most glucocorticoids have some mineralocorticoid properties) leads to potassium depletion, sodium retention, muscle weakness, hypertension, tetany, polyuria, inability to concentrate urine, and hypokalemic alkalosis. These symptoms constitute primary hyperaldosteronism, or Conn's syndrome (a cause of low-renin hypertension because renin secretion is inhibited by the effects of the high levels of aldosterone).

Primary hyperaldosteronism is present in 0.5% to 1% of hypertensive patients who have no other known cause of hypertension. Primary hyperaldosteronism most often results from unilateral adenoma, although 25% to 40% of patients have been found to have bilateral adrenal hyperplasia. Intravascular fluid volume, electrolyte concentrations, and renal function should be restored to within normal limits preoperatively by administering the aldosterone antagonist spironolactone. The effects of spironolactone are slow in onset and increase for 1 to 2 weeks. A patient who has a serum potassium level of 2.9 mEq/L may have a total-body potassium deficit of as little as 40 mEq or as much as 400 mEq. Frequently, at least 24 hours is required to restore potassium equilibrium. A normal serum potassium level does not necessarily imply correction of a total-body deficit of potassium. In addition, patients with Conn's syndrome have a high incidence of hypertension and ischemic heart disease; hemodynamic monitoring should be appropriate for the degree of cardiovascular impairment.

A retrospective anecdotal study indicated that intraoperative hemodynamic status was more stable when BP and electrolytes were controlled preoperatively with spironolactone than when other antihypertensive drugs were used. However, the efficacy of optimizing the perioperative status of patients who have disorders of glucocorticoid or mineralocorticoid secretion has not been clearly established. We have assumed that gradual restoration of a normal condition is good medicine and that it would decrease perioperative morbidity and mortality.

Adrenocortical Hormone Deficiency

Glucocorticoid Deficiency

Withdrawal of steroids or suppression of synthesis by steroid therapy is the leading cause of underproduction of corticosteroids. Management of this type of glucocorticoid deficiency is discussed in the later section "Patients Taking Steroids for Other Reasons." Other causes of adrenocortical insufficiency include defects in ACTH secretion and destruction of the adrenal gland by autoimmune disease, tuberculosis, hemorrhage, or cancer; some forms of congenital adrenal hyperplasia (see previous discussion); and administration of cytotoxic drugs.

Primary adrenal insufficiency (Addison's disease) is associated with local destruction of all zones of the adrenal cortex and results in both glucocorticoid and mineralocorticoid deficiency if the insufficiency is bilateral; common symptoms and signs are listed in Table 35-5. Autoimmune disease is the most common cause of primary (nonexogenous) bilateral ACTH deficiency in the United States, whereas tuberculosis is the most common cause worldwide. Tuberculosis is associated with decreased adrenal function but large adrenal glands, as is also common in sarcoidosis, histoplasmosis, amyloidosis, metastatic malignancy, and adrenal hemorrhage. Destruction or partial destruction by trauma and by human immunodeficiency virus (HIV) and other infections, such as cytomegalovirus, mycobacteria, and fungi, is being recognized more frequently.

An increasingly common cause of adrenal insufficiency associated with large adrenal glands is heparin-induced thrombocytopenia, which might be considered in every patient who has received heparin and has hypotension.

Autoimmune destruction of the adrenals may be associated with other autoimmune disorders, such as some forms of type 1 diabetes and Hashimoto's thyroiditis. Enzymatic defects in cortisol synthesis also cause glucocorticoid insufficiency, compensatory elevations in ACTH, and congenital adrenal hyperplasia. Because adrenal insufficiency usually develops slowly, such patients are subject to marked pigmentation (from excess ACTH trying to stimulate an unproductive adrenal gland) and cardiopenia (apparently secondary to chronic hypotension).

Secondary adrenal insufficiency occurs when ACTH secretion is deficient, often because of a pituitary or hypothalamic tumor. Treatment of pituitary tumors by surgery or radiation therapy may result in hypopituitarism and subsequent adrenal failure.

If unstressed, glucocorticoid-deficient patients usually have no perioperative problems. However, acute adrenal crisis (addisonian crisis) can occur when even a minor stress is present (e.g., upper respiratory infection). Preparation of such a patient for anesthesia and surgery should include treatment of hypovolemia, hyperkalemia, and hyponatremia. Because these patients cannot respond to stressful situations, it was traditionally recommended that they be given a stress dose of glucocorticoids (about 200 mg hydrocortisone/70 kg body weight/day) perioperatively. However, Symreng and colleagues[51] gave 25 mg of hydrocortisone phosphate intravenously to adults at the start of the operative procedure, followed by 100 mg intravenously over the next 24 hours. Because using the minimum drug dose that would produce an appropriate effect is desirable, this latter regimen seems attractive. Such a regimen has proved to be as successful as a regimen using maximum doses (about 300 mg hydrocortisone per 70 kg body weight per day—see the later section "Patients Taking Steroids for Other Reasons"). Thus, we now recommend giving 100 mg of hydrocortisone phosphate intravenously every 24 hours.

Mineralocorticoid Deficiency

Hypoaldosteronism, a less common condition, can be congenital or can occur after unilateral adrenalectomy or prolonged administration of heparin. In addition, it can also be a consequence of long-standing diabetes and renal failure. Nonsteroidal inhibitors of prostaglandin synthesis may also inhibit renin release and exacerbate this condition in patients with renal insufficiency.

Plasma renin activity is below normal and fails to increase appropriately in response to sodium restriction or diuretic drugs. Most symptoms are caused by hyperkalemic acidosis rather than hypovolemia; in fact, some patients are hypertensive. These patients can have severe hyperkalemia, hyponatremia, and myocardial conduction defects. These defects can be treated successfully by administering mineralocorticoids (9α-fluorocortisol, 0.05 to 0.1 mg/day) preoperatively. Doses must be carefully titrated and monitored to avoid an increase in hypertension.

Patients Taking Steroids for Other Reasons

Perioperative Stress and the Need for Corticoid Supplementation

Many experimental studies and other reports (mostly anecdotal) concerning the adrenal responses of normal patients to the perioperative period, as well as the responses of patients taking steroids for other diseases, indicate the following:

1. Perioperative stress is related to the degree of trauma and the depth of anesthesia. Deep general or regional anesthesia causes the usual intraoperative glucocorticoid surge to be postponed to the postoperative period.
2. A few patients with suppressed adrenal function will have perioperative cardiovascular problems if they do not receive supplemental steroids perioperatively.
3. Although on occasion a patient who chronically takes steroids becomes hypotensive perioperatively, only rarely has this event been documented sufficiently to implicate glucocorticoid or mineralocorticoid deficiency as the cause.
4. Acute adrenal insufficiency occurs only rarely but can be life-threatening.
5. There is little risk in giving these patients steroid coverage equivalent to 100 mg of hydrocortisone hemisuccinate perioperatively.

In a well-controlled study of glucocorticoid replacement in primates, the investigators clearly defined the life-threatening events that can be associated with inadequate perioperative corticosteroid replacement.[48] This study further defined the physiologic and hemodynamic consequences of inadequate cortisol replacement; an alternative dose regimen is suggested that has stood the test of a decade and has altered management methods to possibly improve patient safety. In this study, adrenalectomized primates and sham-operated controls were maintained on physiologic doses of steroids for 4 months. The animals were then randomly allocated to groups that received subphysiologic (a 10th of the normal cortisol production), physiologic, or supraphysiologic (10 times the normal cortisol production) doses of cortisol for 4 days preceding abdominal surgery (cholecystectomy). Hemodynamic variables were measured by means of arterial and pulmonary artery catheters. The animals were maintained on their randomized dosage schedules during and after surgery. The group given subphysiologic doses of steroid perioperatively had a significant increase in postoperative mortality. Death rates for the physiologic and supraphysiologic replacement groups were the same and did not differ from the rate for sham-operated controls. Death in the subphysiologic replacement group was related to severe hypotension associated with a significant decrease in systemic vascular resistance and a reduced left ventricular stroke work index. Filling pressures of the heart were unchanged when compared with those in control animals. There was no evidence of hypovolemia or severe CHF. Despite the low systemic vascular resistance, the animals did not become tachycardic. All these responses are compatible with the previously documented interaction of glucocorticoids and catecholamines and thus suggest that glucocorticoids mediate catecholamine-induced increases in cardiac contractility and maintenance of vascular tone.

The investigators used a sensitive measure of wound healing involving accumulation of hydroxyproline. All treatment groups, including the group given supraphysiologic doses of glucocorticoids, had the same capacity for wound healing. Furthermore, perioperative administration of supraphysiologic doses of corticosteroids produced no adverse metabolic consequences.

This well-conducted study confirms several long-standing intuitive impressions concerning patients who have inadequate adrenal function as a result of either underlying disease or administration of exogenous steroids. Inadequate replacement of corticosteroids perioperatively can lead to addisonian crisis and death. Administration of supraphysiologic doses of steroids for a short time perioperatively caused no discernible complications. However, at least theoretical negative consequences can occur when large doses of steroids are given (see later). It is clear that inadequate corticosteroid coverage can cause death. What is not so clear is what dose of steroid should be recommended for replacement therapy. The authors of the previously discussed study on monkeys were reluctant to recommend simple physiologic steroid replacement doses for human patients perioperatively.[48] We never supplement perioperatively with a dose lower than what the patient has already been receiving.

Which patients definitely need supplementation? If in doubt, how can a patient's need for glucocorticoid supplementation be determined? Because the risk is low, we normally provide supplementation for any patient who has received steroids within a year.[48,51] Data indicate that topical application of steroids (even without the use of occlusive dressings) can suppress normal adrenal responses for as long as 9 months to 1 year (Table 35-6).

How can one determine when adrenal responsiveness has returned to normal? The morning plasma cortisol level does not reveal whether the adrenal cortex has recovered sufficiently to ensure that cortisol secretion will increase adequately to meet the demands of stress. Inducing hypoglycemia with insulin has been advocated as a sensitive test of pituitary-adrenal competence but is impractical and probably a more dangerous practice than simply administering glucocorticoids. If the plasma cortisol concentration is measured during acute stress, a value of greater than 25 μg/dL assuredly (and a value >15 μg/dL probably) indicates normal pituitary-adrenal responsiveness. In another test of pituitary-adrenal sufficiency, the baseline plasma cortisol level is determined. Then, 250 μg of synthetic ACTH (cosyntropin) is given, and plasma cortisol is measured 30 to 60 minutes later. An increase in plasma cortisol of 6 to 20 μg/dL or more is normal.[52,53] A normal response indicates recovery of pituitary-adrenal axis function. A lesser response usually indicates pituitary-adrenal insufficiency, possibly requiring perioperative supplementation with steroids.

It is unusual for laboratory data defining pituitary-adrenal adequacy to be available before surgery. Rather than delay surgery or test most patients, we assume that any patient who has taken steroids at any time during the preceding year has sup-

Table 35-6 Recovery of Hypothalamic-Pituitary-Adrenal Function after Withdrawal of Steroids

Recovery Time (mo)	Plasma 17-Hydroxycorticoid Values	Plasma ACTH Values	Adrenal Response to Exogenous ACTH	Response to Metyrapone
1	Low*	Low	Low	Low
2-5	Low	High†	Low	Low
6-9	Normal	Normal	Low	Low
>9	Normal	Normal	Normal	Normal

*Various subjective manifestations of mild adrenal insufficiency occur during this stage.

ACTH, adrenocorticotropic hormone.
Data from Graber AL, Ney RI, Nicholson WE, et al: Natural history of pituitary-adrenal recovery following long-term suppression with corticosteroids. J Clin Endocrinol Metab 25:11, 1965.

pressed pituitary-adrenal function and will require perioperative supplementation.

Under perioperative conditions, the adrenal glands secrete 116 to 185 mg of cortisol daily. Under maximum stress, they may secrete 200 to 500 mg/day. Good correlation exists between the severity and duration of the operation and the response of the adrenal gland. "Major surgery" would be represented by procedures such as laparoscopic colectomy and "minor surgery" by procedures such as herniorrhaphy. In one study of 20 patients during major surgery, the mean maximal concentration of cortisol in plasma was 47 µg/dL (range, 22 to 75 µg/dL). Values remained above 26 µg/dL for a maximum of 72 hours after surgery. During minor surgery, the mean maximal concentration of cortisol in plasma was 28 µg/dL (range, 10 to 44 µg/dL).

Although the precise amount required has not been established, we usually intravenously administer the maximum amount of glucocorticoid that the body manufactures in response to maximal stress (i.e., approximately 200 mg/day of hydrocortisone phosphate per 70 kg body weight). For minor surgical procedures, we usually give hydrocortisone phosphate intravenously, 100 mg/day per 70 kg body weight. Unless infection or some other perioperative complication develops, we decrease this dose by approximately 25% per day until oral intake can be resumed. At this point, the usual maintenance dose of glucocorticoids can be administered.

Risks of Supplementation

Rare complications of perioperative steroid supplementation include aggravation of hypertension, fluid retention, inducement of stress ulcers, and psychiatric disturbances. Although data are not available to assess the incidence of the following risks, two common complications of short-term perioperative supplementation with glucocorticoids are described in the literature: abnormal wound healing and an increased rate of infections. This evidence is inconclusive, however, because it relates to acute glucocorticoid administration and not to chronic administration of glucocorticoids with increased doses at times of stress. In contrast to some studies that suggest a deleterious effect of perioperative glucocorticoid administration on wound healing in rats, a study involving primates suggests that high doses of glucocorticoids, administered perioperatively, do not impair sensitive measures of wound healing.[48] Other data are not conclusive regarding a short-term increase in supplementation. However, an overall assessment of these results suggests that short-term perioperative supplementation with steroids has a small, but definite deleterious effect on wound healing that is perhaps partially reversed by topical administration of vitamin A.

Information regarding the risk of infection from perioperative glucocorticoid supplementation is also unclear. In many studies of chronic patient use and supplementation, no increased risk of serious infections was reported with chronic use alone. Data indicate that the risk of infection in a patient chronically taking steroids is real, but these data are inadequate to conclude that perioperative supplementation with steroids increases that risk.

Adrenal Cortex Function in the Elderly

Production of androgens by the adrenal gland progressively decreases with age (also see Chapter 71). This decrease in androgen activity has no known implications for anesthesia. Plasma levels of cortisol are unaffected by increasing age. Levels of CBG are also unaffected by age, which suggests that a normal fraction of free cortisol (1% to 5%) is present in elderly patients. Several investigators have noted a progressively impaired ability of aged patients to metabolize and excrete glucocorticoids. In normal individuals, the quantity of 17-hydroxycorticosteroids excreted is reduced by half by the seventh decade. This decreased excretion undoubtedly reflects the reduced renal function that occurs with aging. When excretion of cortisol metabolites is expressed as a function of creatinine clearance, the age difference disappears. Further reductions in cortisol clearance may be due to impaired hepatic metabolism of circulating cortisol.

The rate of secretion of cortisol is 30% lower in the elderly. This reduced secretion may be an appropriate compensatory mechanism for maintaining a normal cortisol level in the face of decreased hepatic and renal clearance of cortisol. It is important to the anesthesiologist that the reduced cortisol production can be overcome during periods of stress and that even the very elderly (those older than 100 years) display an entirely normal adrenal response to the administration of ACTH and to stresses such as hypoglycemia.

Both underproduction and overproduction of glucocorticoids are generally considered diseases of younger individuals. The highest incidence of Cushing's disease of either pituitary or adrenal origin occurs during the third decade of life. The most common cause of spontaneous Cushing's disease is benign pituitary adenoma. However, in patients older than 60 years in whom Cushing's disease develops, the most likely cause is adrenal carcinoma or ectopic ACTH production from tumors usually located in the lung, pancreas, or thymus.

Adrenal Medullary Sympathetic Hormone Excess: Pheochromocytoma

Less than 0.1% of all cases of hypertension are caused by pheochromocytomas, or catecholamine-producing tumors derived from chromaffin tissue.[54] Nevertheless, these tumors are clearly important to the anesthetist inasmuch as 25% to 50% of hospital deaths in patients with pheochromocytoma occur during induction of anesthesia or during operative procedures for other causes.[55] Though usually found in the adrenal medulla, these vascular tumors can occur anywhere, such as in the right atrium, the spleen, the broad ligament of the ovary, or the organs of Zuckerkandl at the bifurcation of the aorta. Malignant spread, which occurs in less than 15% of pheochromocytomas, usually proceeds to venous and lymphatic channels with a predisposition for the liver. This tumor is occasionally familial or part of the pluriglandular-neoplastic syndrome known as multiple endocrine adenoma type IIa or type IIb and is manifested as an autosomal dominant trait. Type IIa consists of medullary carcinoma of the thyroid, parathyroid adenoma or hyperplasia, and pheochromocytoma. What used to be called type IIb is now often called pheochromocytoma in association with phakomatoses such as von Recklinghausen's neurofibromatosis and von Hippel-Lindau disease with cerebellar hemangioblastoma. Frequently, bilateral tumors are found in the familial form. Localization of tumors can be achieved by MRI or CT, metaiodobenzylguanidine (MIBG) nuclear scanning, ultrasonography, or intravenous pyelography (in decreasing order of combined sensitivity and specificity).

Symptoms and signs that may be solicited before surgery or procedures and are suggestive of pheochromocytoma are excessive sweating; headache; hypertension; orthostatic hypotension; previous hypertensive or arrhythmic response to induction of anesthesia or to abdominal examination; paroxysmal attacks of sweating, headache, tachycardia, and hypertension; glucose intolerance; polycythemia; weight loss; and psychological abnormalities. In fact, the occurrence of combined symptoms of paroxysmal headache, sweating, and hypertension is probably a more sensitive and specific indicator than any one biochemical test for pheochromocytoma (Table 35-7). Despite more than 2000 articles in the literature about pheochromocytoma, little is known about what factors in care affect perioperative morbidity.[56,57]

Although no controlled, randomized, prospective clinical studies have investigated the value of preoperative and preprocedure use of adrenergic receptor blocking drugs, the use of such drugs is generally recommended before surgery. These drugs probably reduce the complications of hypertensive crisis, the wide BP fluctuations during manipulation of the tumor (especially until venous drainage is obliterated), and the myocardial dysfunction that occurs perioperatively. A reduction in mortality associated with resection of pheochromocytoma (from 40% to 60% to the current 0% to 6%) occurred when α-adrenergic receptor blockade was introduced as preoperative and preprocedure preparatory therapy for such patients.[56-60]

α-Adrenergic receptor blockade with prazosin or phenoxybenzamine restores plasma volume by counteracting the vasoconstrictive effects of high levels of catecholamines. This re-expansion of fluid volume is often followed by a decrease in hematocrit. Because some patients may be very sensitive to the effects of phenoxybenzamine, it should initially be given in doses of 20 to 30 mg/70 kg orally once or twice a day. Most patients usually require 60 to 250 mg/day. The efficacy of therapy should be judged by the reduction in symptoms (especially sweating) and stabilization of BP. For patients who have carbohydrate intolerance because of inhibition of insulin release mediated by α-adrenergic receptor stimulation, α-adrenergic receptor blockade may reduce fasting blood sugar levels. For patients who exhibit ST-T changes on the ECG, long-term preoperative and preprocedure α-adrenergic receptor blockade (1 to 6 months) has produced ECG and clinical resolution of catecholamine-induced myocarditis.[56,57,59-63]

β-Adrenergic receptor blockade with propranolol is suggested for patients who have persistent arrhythmias or tachycardia[56,57,59-63] because these conditions can be precipitated or aggravated by α-adrenergic receptor blockade. β-Adrenergic receptor blockade should not be used without concomitant α-adrenergic receptor blockade lest the vasoconstrictive effects of the latter go unopposed and thereby increase the risk for dangerous hypertension.

The optimal duration of preoperative therapy with phenoxybenzamine has not been studied. Most patients require 10 to 14 days, as judged by the time needed to stabilize BP and ameliorate symptoms. On the basis of our experience, this is a minimal period.[59,60,63] Because the tumor spreads slowly, little is lost by waiting until medical therapy has optimized the patient's preop-

Table 35-7 Characteristics of Tests for Pheochromocytoma

			Likelihood Ratio	
Test/Symptoms	**Sensitivity (%)**	**Specificity (%)**	**Positive Result***	**Negative Result†**
Vanillylmandelic acid excretion	81	97	27.0	0.20
Catecholamine excretion	82	95	16.4	0.19
Metanephrine excretion	83	95	16.6	0.18
Abdominal computed tomography	92	80	4.6	0.10
Concurrent paroxysmal hypertension, headache, sweating, and tachycardia‡	90	95	18.0	0.10

*The ratio representing the likelihood of a positive result is obtained by dividing the sensitivity by 1 and then subtracting the specificity.
†The ratio representing the likelihood of a negative result is obtained by subtracting the sensitivity from 1 and then dividing by the specificity.
‡Data for concurrent paroxysmal symptoms are best estimates from available data.
Modified from Pauker SG, Kopelman RI: Interpreting hoofbeats: Can Bayes help clear the haze? N Engl J Med 327:1009, 1992.

erative condition. Accordingly, we recommend using the following criteria:

1. No in-hospital BP reading higher than 165/90 mm Hg should be evident for 48 hours before surgery. We often measure arterial BP every minute for 1 hour in a stressful environment (our postanesthesia care unit). If no BP reading is greater than 165/90, this criterion is considered satisfied.
2. Orthostatic hypotension should be present, but BP on standing should not be lower than 80/45 mm Hg.
3. The ECG should be free of ST-T changes that are not permanent.
4. No more than one premature ventricular contraction (PVC) should occur every 5 minutes.

Other drugs, including prazosin, calcium channel blocking drugs, clonidine, dexmedetomidine, and magnesium, have also been used to achieve suitable degrees of α-adrenergic blockade before surgery.

Although specific anesthetic drugs have been recommended, we believe that optimal preoperative preparation, gentle induction of anesthesia, and good communication between the surgeon and anesthesiologist are most important. Virtually all anesthetic drugs and techniques (including isoflurane, sevoflurane, sufentanil, remifentanil, fentanyl, and regional anesthesia) have been used with success. In fact, all drugs studied are associated with a high rate of transient intraoperative arrhythmias.[59] One author (M.F.R.) has avoided desflurane because it may precipitate non-neurogenic catecholamine release. No good data indicate that these biases are appropriate.

Because of ease of use, there is a preference to give phenylephrine hydrochloride (Neo-Synephrine) or dopamine for hypotension and nitroprusside for hypertension. Phentolamine (Regitine) has too long an onset and duration of action. Occasionally (five times in >80 pheochromocytoma resections), we have used a β-adrenergic blocking agent (esmolol is now the preferred agent) for severe tachycardia without hypertension or volume depletion. Painful or stressful events such as intubation often cause an exaggerated stress response in less than perfectly anesthetized patients who have pheochromocytoma. This response is caused by release of catecholamines from nerve endings that are "loaded" by the reuptake process. Such stresses may result in catecholamine levels of 200 to 2000 pg/mL in normal patients. For a patient with pheochromocytoma, even simple stress can lead to blood catecholamine levels of 2000 to 20,000 pg/mL. However, infarction of a tumor, with release of products onto peritoneal surfaces, or surgical pressure causing release of products can result in blood levels of 200,000 to 1,000,000 pg/mL—a situation that should be anticipated and avoided (ask for a temporary stay of surgery, if at all possible, while the rate of nitroprusside infusion is increased). Once the venous supply is secured and if intravascular volume is normal (as measured by pulmonary wedge pressure or echocardiography), normal BP usually results. However, some patients become hypotensive and occasionally require massive infusions of catecholamines. On rare occasion, patients remain hypertensive intraoperatively. Postoperatively, about 50% remain hypertensive for 1 to 3 days—and initially have markedly elevated but declining plasma catecholamine levels—at which time all but 25% become normotensive. It is important to interview other family members and perhaps advise them to inform their future anesthetist about the potential for such familial disease.

Hypofunction or Aberration in Function of the Sympathetic Nervous System (Dysautonomia)

Disorders of the sympathetic nervous system include Shy-Drager syndrome, Riley-Day syndrome, Lesch-Nyhan syndrome, Gill's familial dysautonomia, diabetic dysautonomia, and the dysautonomia of spinal cord transection.

Although individuals can function well without an adrenal medulla, a deficient peripheral sympathetic nervous system occurring late in life poses major problems for many facets of life; nevertheless, perioperative sympathectomy or its equivalent has been recommended by some.[64-70] A primary function of the sympathetic nervous system appears to be regulation of BP and intravascular fluid volume during changing of body position. Common features of all the syndromes of hypofunctioning of the sympathetic nervous system are orthostatic hypotension and decreased beat-to-beat variability in heart rate. These conditions can be caused by deficient intravascular volume, deficient baroreceptor function (as also occurs in carotid artery disease[71]), abnormalities in CNS function (as in Wernicke or Shy-Drager syndrome), deficient neuronal stores of norepinephrine (as in idiopathic orthostatic hypotension[72] and diabetes), or deficient release of norepinephrine (as in traumatic spinal cord injury[73]). These patients may have an increased number of available adrenergic receptors (a compensatory response) and an exaggerated response to sympathomimetic drugs. In addition to other abnormalities, such as retention of urine or feces and deficient heat exchange, hypofunctioning of the sympathetic nervous system is often accompanied by renal amyloidosis. Thus, electrolyte and intravascular fluid volume status should be evaluated preoperatively. Because many of these patients have cardiac abnormalities, intravascular fluid volume might be assessed preoperatively with a Swan-Ganz catheter or intraoperatively via transesophageal echocardiography rather than measurement of CVP.

Inasmuch as functioning of the sympathetic nervous system is not predictable in these patients, we generally use slow, gentle induction of anesthesia and treat sympathetic excess or deficiency by infusing, with careful titration, drugs that directly constrict (phenylephrine) or dilate (nitroprusside) blood vessels or that stimulate (isoproterenol) or depress (esmolol) the heart rate. We prefer these drugs to agonists or antagonists, which may indirectly release catecholamines. A 20% perioperative mortality rate for 2600 patients after spinal cord transection has been reported, thus indicating that such patients are difficult to manage and deserve particularly close attention.

After reviewing 300 patients with spinal cord injuries, Kendrick and coworkers[74] concluded that autonomic hyperreflexia syndrome does not develop if the lesion is below spinal dermatome T7. If the lesion is above that level (splanchnic outflow), 60% to 70% of patients experience extreme vascular instability. The trigger to this instability, or a mass reflex involving noradrenergic and motor hypertonus,[75] can be a cutaneous, proprioceptive, or visceral stimulus (a full bladder is a common initiator). The sensation enters the spinal cord and causes a spinal reflex, which in normal persons is inhibited from above. Sudden increases in

Table 35-8 Biochemical Measurements of Thyroid Function That Account for Variation in Production of Thyroid-Binding Globulin

	Examples of Normal Thyroid Status					
	FT_4E	=	**T_4**	×	**THBR**	**TSH**
Normal	0.19 (0.12-0.25)	=	0.6 (0.4-0.9)	×	31% (25%-35%)	0.2 (0.2-0.8)
During use of oral contraceptives	0.19	=	1.3	×	15%	0.3
During use of corticosteroids	0.18	=	0.3	×	60%	0.3

FT_4E is the free T_4 (thyroxine) estimate. It is usually obtained by multiplying the total T_4 concentration (the free amount and the amount bound to protein) by the thyroid hormone–binding ratio (THBR, formerly called the resin T_3 uptake). THBR is a measure of the bound thyroid hormone–binding protein. TSH is the thyroid-stimulating hormone secreted by the pituitary in the negative feedback loop. (TSH increases when FT_4E is low in hypothyroidism.)

BP are sensed in the pressure receptors of the aorta and carotid sinus. The resulting vagal hyperactivity produces bradycardia, ventricular ectopia, or various degrees of heart block. Reflex vasodilation may occur above the level of the lesion and result in flushing of the head and neck. Two new techniques to help reduce acute injury or aid in repair (high-dose DHA and acute cooling) may also have anesthetic implications, but reports of these effects, if any, have not been published.

Depending on the length of time since spinal cord transection, other abnormalities may occur. Acutely (i.e., <3 weeks from the time of spinal injury), retention of urine and feces is common and, by elevating the diaphragm, may impair respiration. Disimpaction of the intestine alleviates this respiratory problem. Hyperesthesia is present above the lesion; reflexes and flaccid paralysis are present below the lesion. The intermediate period (3 days to 6 months) is marked by a hyperkalemic response to depolarizing drugs.[76] The chronic phase is characterized by return of muscle tone, a Babinski sign, and frequently, the occurrence of hyperreflexia syndromes (e.g., mass reflex, see earlier).

Thus, in addition to meticulous attention to perioperative intravascular volume and electrolyte status, the anesthesiologist should know—by history taking, physical examination, and laboratory data—the status of the patient's myocardial conduction (as revealed by the ECG), the status of renal functioning (by noting the ratio of creatinine to blood urea nitrogen [BUN]), and the condition of the respiratory muscles (by determining the ratio of forced expiratory volume in 1 second [FEV_1] to forced vital capacity [FVC]) (also see Chapter 44). The anesthesiologist may also obtain a chest radiograph if atelectasis or pneumonia is suspected on the basis of history taking or the physical examination. Temperature control, the presence of bone fractures or decubitus ulcers, and normal functioning of the urination and defecation systems must be assessed. Confirmation of the latter prevents postoperative pneumonia or atelectasis caused by high positioning of the diaphragm.

Thyroid Dysfunction

The major thyroid hormones are thyroxine (T_4), a prohormone product of the thyroid gland, and the more potent 3,5,3-triiodothyronine (T_3), a product of both the thyroid and extrathyroidal enzymatic deiodination of T_4. Under normal circumstances, approximately 85% of T_3 is produced outside the thyroid gland. Production of thyroid secretions is maintained by secretion of thyroid-stimulating hormone (TSH) in the pituitary, which in turn is regulated by secretion of thyrotropin-releasing hormone (TRH) in the hypothalamus. Secretion of TSH and TRH appears to be negatively regulated by T_4 and T_3. Many believe that all effects of thyroid hormones are mediated by T_3 and that T_4 functions only as a prohormone.

Because T_3 has greater biologic effect than T_4 does, one would expect the diagnosis of thyroid disorders to be based on levels of T_3. However, this is not usually the case. The diagnosis of thyroid disease is confirmed by one of several biochemical measurements: levels of free T_4 or total serum concentrations of T_4 and the "free T_4 estimate." This estimate is obtained by multiplying total T_4 (free and bound) by the thyroid-binding ratio (formerly called resin T_3 uptake) (Table 35-8). Free T_4 can be accurately measured by many laboratories. Direct measurement of free T_4 obviates the need to account for changes in binding protein synthesis and affinity caused by other conditions. The T_3-binding ratio measures the extra quantity of serum protein-binding sites. This measurement is necessary because thyroxine-binding globulin (TBG) is abnormally high during pregnancy, hepatic disease, and estrogen therapy (all of which would elevate the total T_4 level) (Box 35-3). Reliable interpretation of measurements of the total hormone concentration in serum necessitates

data on the percentage of bound hormone. The thyroid hormone–binding ratio test provides this information. In this test, I-labeled T_3 is added to a patient's serum and allowed to reach an equilibrium binding state. A resin is then added that binds the remaining radioactive T_3. Resin uptake is greater if the patient has fewer TBG-binding sites. In normal patients, resin T_3 uptake (the thyroid hormone–binding ratio) is 25% to 35%. When serum TBG is elevated, the thyroid hormone–binding ratio is diminished (see Table 35-8). When serum TBG is diminished, as in nephrotic syndrome, in conditions in which glucocorticoids are increased, or in chronic liver disease, the thyroid hormone–binding ratio is increased.

The free T_4 estimate and the free T_3 estimate are frequently used as measures of a patient's serum T_4 and T_3 hormone concentration. To obtain these estimates, the concentration of total serum T_4 or total serum T_3 is multiplied by the measured thyroid hormone–binding ratio. Values of these two indices are normal in the event of a primary alteration in binding but not with an alteration in secretion of thyroid hormone.

Hyperthyroidism can be diagnosed by measuring levels of TSH after the administration of TRH. Although administering TRH normally increases TSH levels in blood, even a small increase in the T_4 or T_3 level in blood abolishes this response. Thus, a subnormal or absent serum TSH response to TRH is a very sensitive indicator of hyperthyroidism. In one group of disorders involving hyperthyroidism, serum TSH levels are elevated in the presence of elevated levels of free thyroid hormone.

Measurement of the α-subunit of TSH has been helpful in identifying the rare patients who have a pituitary neoplasm and who usually have increased α-subunit concentrations. Some patients are clinically euthyroid in the presence of elevated levels of total T_4 in serum. Certain drugs, notably gallbladder dyes, propranolol, glucocorticoids, and amiodarone, block the conversion of T_4 to T_3, thereby elevating T_4 levels. Severe illness also slows this conversion. Levels of TSH are often high in situations in which the rate of conversion is decreased. In hyperthyroidism, cardiac function and responses to stress are abnormal; return of normal cardiac function parallels the return of TSH levels to normal.

Hyperthyroidism

Although hyperthyroidism is usually caused by the multinodular diffuse enlargement in Graves' disease (also associated with disorders of the skin or eyes, or both), it can also occur with pregnancy, thyroiditis (with or without neck pain), thyroid adenoma, choriocarcinoma, or TSH-secreting pituitary adenoma. Five percent of women have thyrotoxic effects 3 to 6 months postpartum and tend to have recurrences with subsequent pregnancies. Major manifestations of hyperthyroidism are weight loss, diarrhea, warm moist skin, weakness of large muscle groups, menstrual abnormalities, osteopenia, nervousness, jitteriness, intolerance to heat, tachycardia, cardiac arrhythmias, mitral valve prolapse, and heart failure. When the thyroid is functioning abnormally, the entity most threatened is the cardiovascular system. When diarrhea is severe, dehydration should be corrected preoperatively. Mild anemia, thrombocytopenia, increased serum alkaline phosphatase, hypercalcemia, muscle wasting, and bone loss frequently occur in hyperthyroidism. Muscle disease usually involves the proximal muscle groups; it has not been reported to cause respiratory muscle paralysis. In the apathetic form of hyperthyroidism (seen most commonly in persons older than 60 years), cardiac effects dominate the clinical picture. Signs and symptoms include weight loss, anorexia, and cardiac effects such as tachycardia, irregular heart rhythm, atrial fibrillation (in 10%), heart failure, and occasionally, papillary muscle dysfunction.

Although β-adrenergic receptor blockade can control the heart rate, its use is fraught with hazard in a patient already experiencing CHF. However, a decreasing heart rate may improve heart-pumping function. Thus, hyperthyroid patients who have fast ventricular rates, who are in CHF, and who require emergency surgery are given esmolol guided by changes in pulmonary artery wedge pressure and their condition. If slowing the heart rate with a small dose of esmolol (50 μg/kg) does not aggravate the heart failure, we administer more esmolol. We believe that we should aim to avoid imposing surgery on any patient whose thyroid function is clinically abnormal. Therefore, we believe that only "life or death" emergency surgery should preclude making the patient pharmacologically euthyroid, a process that can take 2 to 6 weeks. Evaluation of hyperthyroidism is also covered in Chapter 34. Antithyroid medications include propylthiouracil and methimazole, both of which decrease the synthesis of T_4 and may enhance remission by reducing TSH receptor antibody levels (the primary pathologic mechanism in Grave's disease). Propylthiouracil also decreases the conversion of T_4 to the more potent T_3. However, the literature indicates a trend toward preoperative preparation with propranolol and iodides alone.[77] This approach is quicker (i.e., 7 to 14 days versus 2 to 6 weeks); it shrinks the thyroid gland, as does the more traditional approach; it decreases conversion of the prohormone T_4 into the more potent T_3; and it treats symptoms but may not correct abnormalities in left ventricular function. Regardless of the approach, antithyroid drugs should be administered chronically and on the morning of surgery. If emergency surgery is necessary before the euthyroid state is achieved, if subclinical hyperthyroidism progresses without adequate treatment, or if hyperthyroidism gets out of control during surgery, intravenous administration of esmolol, 50 to 500 μg/kg, could be titrated to restore a normal heart rate (assuming the absence of CHF) (see earlier). In addition, intravascular fluid volume and electrolyte balance should be restored. However, administering propranolol or esmolol does not invariably prevent "thyroid storm."

No controlled study has demonstrated clinical advantages of any anesthetic drug over another for surgical patients who are hyperthyroid. A review of cases performed at the University of California, San Francisco, from 1968 to 1982 revealed that virtually all anesthetic drugs and techniques[78] have been used without adverse effects even remotely being attributable to the drug or technique. Furthermore, although some investigators have recommended that anticholinergic drugs (especially atropine) be avoided inasmuch as they interfere with the sweating mechanism and cause tachycardia, atropine has been given as a test for the adequacy of antithyroid treatment. Because patients are now subjected to operative procedures only (or almost only) when euthyroid, the traditional "steal" of a heavily premedicated hyperthyroid patient (so commonly found in the iodine-deficient locales surrounding the Lahey, Mayo, and Cleveland clinics) in the operating room has vanished.

A patient with a large goiter and an obstructed airway can be handled in the same way as any other patient with problematic airway management. Preoperative medication should avoid excessive sedation, and an airway should be established, often with the patient awake. A firm armored endotracheal tube is preferable

and should be passed beyond the point of extrinsic compression. It is most useful to examine CT scans of the neck preoperatively to determine the extent of compression. Maintenance of anesthesia usually presents little difficulty. Postoperatively, extubation should be performed under optimal circumstances for reintubation in the event that the tracheal rings have been weakened and the trachea collapses.

Of the many possible postoperative complications (nerve injury, bleeding, and metabolic abnormalities), "thyroid storm" (discussed later), bilateral recurrent nerve trauma, and hypocalcemic tetany are the most feared. Bilateral recurrent laryngeal nerve injury (secondary to trauma or edema) causes stridor and laryngeal obstruction as a result of unopposed adduction of the vocal cords and closure of the glottic aperture. Immediate endotracheal intubation is required, usually followed by tracheostomy to ensure an adequate airway. This rare complication occurred only once in more than 30,000 thyroid operations at the Lahey Clinic. Unilateral recurrent nerve injury often goes unnoticed because of compensatory overadduction of the uninvolved cord. However, we often test vocal cord function before and after this surgery by asking the patient to say "e" or "moon." Unilateral nerve injury is characterized by hoarseness and bilateral nerve injury by aphonia. Selective injury to the adductor fibers of both recurrent laryngeal nerves leaves the abductor muscles relatively unopposed, and pulmonary aspiration is a risk. Selective injury to the abductor fibers leaves the adductor muscles relatively unopposed, and airway obstruction can occur. Bullous glottic edema, an additional cause of postoperative respiratory compromise, has no specific cause or known preventive measure.

The intimate involvement of the parathyroid gland with the thyroid gland can result in inadvertent hypocalcemia during surgery for thyroid disease. Complications related to hypocalcemia are discussed in the later section "Hypocalcemia."

Because postoperative hematoma can compromise the airway, neck and wound dressings are placed in a crossing fashion (rather than vertically or horizontally) and should be examined for evidence of bleeding before a patient is discharged from the recovery room.

Thyroid Storm

"Thyroid storm" is the name for the clinical diagnosis of a life-threatening illness in a patient whose hyperthyroidism has been severely exacerbated by illness or surgery. Thyroid storm is characterized by hyperpyrexia, tachycardia, and striking alterations in consciousness. It can thus be manifested very similarly to malignant hyperthermia, pheochromocytoma, or neuroleptic malignant syndrome. No laboratory tests are diagnostic of thyroid storm, and the precipitating (nonthyroidal) cause is the major determinant of survival. Therapy can include blocking the synthesis of thyroid hormones by administering antithyroid drugs, blocking the release of preformed hormone with iodine, meticulous attention to hydration and supportive therapy, and correcting the precipitating cause. Blocking the sympathetic nervous system with reserpine, α- and β-receptor antagonists, or α_2-agents may be exceedingly hazardous and requires skillful management and constant monitoring of the critically ill patient.

Thyroid dysfunction, either hyperthyroidism or hypothyroidism, develops in more than 10% of patients treated with the antiarrhythmic agent amiodarone.[79] Approximately 35% of the drug's weight is iodine, and a 200-mg tablet releases about 20 times the optimal daily dose of iodine. This iodine can lead to reduced synthesis of T_4 or increased synthesis. In addition, amiodarone inhibits the conversion of T_4 to the more potent T_3.

Patients receiving amiodarone might be considered to be in need of special attention preoperatively and may even require special attention to anesthesia, not just because of the arrhythmia that led to such therapy but also to ensure that no perioperative dysfunction or surprises occur because of unsuspected thyroid hyperfunction or hypofunction.[80] Many patients with amiodarone-induced thyrotoxicosis receive steroids for a period, another area of questioning that might be triggered by the use of amiodarone in a preoperative patient.

Hypothyroidism

Hypothyroidism is a common disease that has been detected in 5% of a large population in Great Britain, in 3% to 6% of a healthy older population in Massachusetts, and in 4.5% of a medical clinic population in Switzerland. The apathy and lethargy that often accompany hypothyroidism frequently delay its diagnosis, so the perioperative period may be the first opportunity to spot many such hypothyroid patients. However, hypothyroidism is usually subclinical, serum concentrations of thyroid hormones are in the normal range, and only serum TSH levels are elevated. The normal range of TSH is 0.3 to 4.5 mU/L, and TSH values of 5 to 15 mU/L are characteristic of this entity. In such cases, hypothyroidism may have little or no perioperative significance. However, a retrospective study of 59 mildly hypothyroid patients found that more hypothyroid patients than control subjects required prolonged postoperative intubation (9 of 59 versus 4 of 59) and had significant electrolyte imbalances (3 of 59 versus 1 of 59) and bleeding complications (4 of 59 versus 0 of 59).[81] Because only a small number of charts were examined, these differences did not reach statistical significance. In another study, overt hypothyroidism later developed in a high percentage of patients with a history of subclinical hypothyroidism.[82,83] Thus, a previous history of subclinical hypothyroidism may indicate the need to search for and be concerned about the possibility of overt hypothyroidism.

In the less frequent occurrences of overt hypothyroidism, the relative lack of thyroid hormone results in slow mental functioning, slow movement, dry skin, arthralgias, carpal tunnel syndrome, periorbital edema, intolerance to cold, depression of the ventilatory responses to hypoxia and hypercapnia, impaired clearance of free water with or without hyponatremia, "hung-up reflexes," slow gastric emptying, sleep apnea,[84] and bradycardia. In extreme cases, cardiomegaly, heart failure, and pericardial pleural effusions are manifested as fatigue, dyspnea, and orthopnea. Hypothyroidism is often associated with amyloidosis, which may produce an enlarged tongue, abnormalities of the cardiac conduction system, and renal disease. Hypothyroidism decreases the anesthetic requirement slightly. The tongue may be enlarged in a hypothyroid patient even in the absence of amyloidosis, and such enlargement may hamper endotracheal intubation.

A rising TSH level is the most sensitive indicator of failing thyroid function. Ideal preoperative and preprocedure management of hypothyroidism consists of restoring normal thyroid status: we routinely administer the normal dose of levothyroxine the morning of surgery, even though these drugs have long half-lives (1.4 to 10 days). (Levothyroxin is the preferred therapy because it allows the controlling enzyme systems to regulate TSH secretion, as well as conversion to T_3.) Reduced GI absorption of levothyroxine may occur with the coadministration of cholestyramine or aluminum hydroxide, iron, a high-bran meal, or sucral-

fate or colestipol. For patients in myxedema coma requiring emergency surgery, liothyronine can be given intravenously (with fear of precipitating myocardial ischemia, however) while supportive therapy is undertaken to restore normal intravascular fluid volume, body temperature, cardiac function, respiratory function, and electrolyte balance.

Treating hypothyroid patients with symptomatic coronary artery disease poses special problems and may require compromises in the general practice of preoperatively restoring euthyroidism with drugs. Although both levothyroxine and esmolol may be given, adequate amelioration of both ischemic heart disease and hypothyroidism may be difficult to achieve. The need for thyroid therapy must be balanced against the risk of aggravating the anginal symptoms. One review suggested early consideration of coronary artery revascularization.[85] It advocated initiating thyroid replacement therapy in the ICU soon after the patient's arrival from the operating room and myocardial revascularization surgery. However, several deaths from arrhythmia and CHF, as well as cardiogenic shock with infarction, have occurred while patients who were not given thyroid therapy were awaiting surgery. Thus, true emergency coronary artery revascularization should be considered in patients with both severe coronary artery disease and significant hypothyroidism.

In hypothyroidism, respiratory control mechanisms do not function normally. However, the response to hypoxia and hypercapnia and clearance of free water become normal with thyroid replacement therapy. Drug metabolism is anecdotally reported to be slowed, and awakening times from sedatives are reported to be prolonged during hypothyroidism. However, few formal studies and none in humans of the pharmacokinetics and pharmacodynamics of sedatives or anesthetic drugs have been published. These concerns disappear when thyroid function is normalized preoperatively. Addison's disease (with its relative steroid deficiency) is more common in hypothyroidism, and some endocrinologists routinely treat noniatrogenic hypothyroid patients with stress doses of steroids perioperatively because both conditions are commonly caused by autoimmune responses. The possibility that this steroid deficiency exists should be considered if the patient becomes hypotensive perioperatively. Body heat mechanisms are inadequate in hypothyroid patients, so temperature should be monitored and maintained, especially in patients requiring emergency surgery. Because of an increased incidence of myasthenia gravis in hypothyroid patients, it may be advisable to use a peripheral nerve stimulator to guide administration of muscle relaxants (see Chapter 29).

Thyroid Nodules and Carcinoma

More than 90% of thyroid nodules are benign, yet identifying malignancy in a solitary thyroid nodule is a difficult and important procedure. Male patients and patients with previous radiation therapy to the head and neck have an increased likelihood of malignant disease in their nodules. Often, needle biopsy and scanning are sufficient for the diagnosis, but occasionally, excisional biopsy is needed. Papillary carcinoma accounts for more than 70% of all thyroid carcinomas. Simple excision of lymph node metastases appears to be as efficacious for patient survival as radical neck procedures. Follicular carcinoma accounts for about 15% of thyroid carcinomas, is more aggressive, and has a less favorable prognosis.

Medullary carcinoma, the most aggressive form of thyroid carcinoma, is associated with a familial occurrence of pheochromocytoma, as are parathyroid adenomas. For this reason, a history might be obtained from patients who have a surgical scar in the thyroid region so that the possibility of occult pheochromocytoma can be ruled out.

Disorders of Calcium Metabolism

The three substances that regulate serum concentrations of calcium, phosphorus, and magnesium—parathyroid hormone (parathyrin, PTH), calcitonin, and vitamin D—act on bone, kidney, gut, and their own receptors (the last has led to an important advance in treatment in the last few years). Calcium excess in blood is due to either malignancy or hyperparathyroidism in more than 90% of patients.[86] PTH stimulates bone resorption, inhibits renal excretion of calcium, and increases conversion to active vitamin D, three conditions that lead to hypercalcemia. Calcitonin can be considered an antagonist to PTH. Through its metabolites, vitamin D aids in the absorption of calcium, phosphate, and magnesium from the gut and facilitates the bone resorptive effects of PTH. Secretion of PTH is modulated through the calcium-sensing receptor on the cell surface of parathyroid cells. An increase in ionized calcium stimulates this receptor, which causes a decrease in PTH secretion. Recognition of this effect has led to re-evaluation of the therapy for hyperparathyroidism inasmuch as a drug upregulating this receptor's sensitivity reduces PTH levels and the presence of increased calcium in over 60% of people who have elevated calcium levels from this cause.[87]

Hyperparathyroidism and Hypercalcemia

Primary hyperparathyroidism occurs in about 0.1% of the population, most commonly begins in the third to fifth decades of life, and occurs two to three times more frequently in women than men. Primary hyperparathyroidism usually results from enlargement of a single gland, commonly an adenoma and very rarely a carcinoma. Hypercalcemia almost always develops.

Calcium is the chief mineral component of the body; it provides structure to the skeleton and performs key roles in neural transmission, intracellular signaling, blood coagulation, and neuromuscular functioning. Ninety-nine percent of the 1000 g of calcium present in the average human body is stored in the bone mineral reservoir. The normal total serum calcium level is 8.6 to 10.4 mg/dL, as measured in most laboratories. Fifty percent to 60% is bound to plasma proteins or is complexed with phosphate or citrate. The value is dependent on the albumin level, with a decline of 0.8 mg/dL for each 1-g/dL drop in albumin. Binding of calcium to albumin is dependent on pH: binding decreases with acidic pH and increases with alkaline pH. It should be noted that serum calcium and not ionized calcium decreases with decreases in albumin levels. Although ionized calcium is the clinically significant fraction, the cost and technical difficulties of stabilizing the electrodes used for measurement have limited the available assays. Nevertheless, PTH and vitamin D_3 work to keep the level stable within 0.1 mg/dL in any individual.

Many of the prominent symptoms of hyperparathyroidism are a result of the hypercalcemia that accompanies it. Regardless of the cause, hypercalcemia can produce any of a number of symptoms, the most prominent of which involve the renal, skeletal, neuromuscular, and GI systems—anorexia, vomiting, constipation, polyuria, polydipsia, lethargy, confusion, formation of renal calculi, pancreatitis, bone pain, and psychiatric abnormalities. Free intracellular calcium initiates or regulates muscle con-

traction, release of neurotransmitters, secretion of hormones, enzyme action, and energy metabolism.

Nephrolithiasis occurs in 60% to 70% of patients with hyperparathyroidism. Sustained hypercalcemia can result in tubular and glomerular disorders, including proximal (type II) renal tubular acidosis. Polyuria and polydipsia are common complaints.

Skeletal disorders related to hyperparathyroidism are osteitis fibrosa cystica, simple diffuse osteopenia, and osteoporosis. The rate of bone turnover is five times higher in patients with hyperparathyroidism than in normal controls. Patients may have a history of frequent fractures or complain of bone pain, the latter especially in the anterior margin of the tibia.

Because free intracellular calcium initiates or regulates muscle contraction, neurotransmitter signaling, hormone secretion, enzyme action, and energy metabolism, abnormalities in these end organs are often symptoms of hyperparathyroidism. Patients may experience profound muscle weakness, especially in proximal muscle groups, as well as muscle atrophy. Depression, psychomotor retardation, and memory impairment may occur. Lethargy and confusion are frequent complaints.

Peptic ulcer disease is more common in these patients than in the rest of the population. Production of gastrin and gastric acid is increased. Anorexia, vomiting, and constipation may also be present.

Approximately a third of all hypercalcemic patients are hypertensive, but the hypertension usually resolves with successful treatment of the primary disease. Neither hypertension nor minimally invasive surgery seems to alter the perioperative risk associated with surgery in such patients in comparison to the usual hypertensives.[88,89] Even octogenarians with asymptomatic hyperparathyroidism can be operated on without mortality and with morbidity no different from that in younger individuals, thus encouraging the use of parathyroidectomy as preventive therapy.[89,90] Long-standing hypercalcemia can lead to calcifications in the myocardium, blood vessels, brain, and kidneys. Cerebral calcifications may cause seizures, whereas renal calcifications lead to polyuria that is unresponsive to vasopressin.

The most useful confirmatory test for hyperparathyroidism is a radioimmunoassay for PTH. In fact, two recent changes have radically reduced anesthesia involvement in the care of patients with primary hyperparathyroidism. One, the drug class that modulates the calcium-sensitive PTH cell receptor and thereby decreases calcium levels, the calcimimetics, has been discussed (earlier) and its use emphasized in older individuals (see later). The other is to use minimally invasive approaches after imaging procedures with just local anesthesia or a cervical plexus block—as with thyroidectomy.[91,92] Most surgeons now performing minimally invasive parathyroid removal monitor PTH levels intraoperatively to determine whether they have resected the causative adenoma. In hyperparathyroid patients, hormone levels are abnormal for a given level of calcium. The level of inorganic phosphorus in serum is usually low, but it may be within normal limits. Alkaline phosphatase is elevated if considerable skeletal involvement is present.

Glucocorticoid administration reduces the level of calcium in blood in many other conditions that cause hypercalcemia, but not usually in primary hyperparathyroidism. In sarcoidosis, multiple myeloma, vitamin D intoxication, and some malignant diseases, all of which can cause hypercalcemia, administration of glucocorticoids may lower serum calcium levels through an effect on GI absorption. This effect occurs to a lesser degree in primary hyperparathyroidism.

Hypercalcemia may also occur as a consequence of secondary hyperparathyroidism in patients who have chronic renal disease. When phosphate excretion decreases as a result of lower nephron mass, serum calcium levels fall because of deposition of calcium and phosphate in bone. Secretion of PTH subsequently increases, which causes the fraction of phosphate excreted by each nephron to increase. Eventually, the chronic intermittent hypocalcemia of chronic renal failure leads to chronically high levels of serum PTH and hyperplasia of the parathyroid glands—one of the entities termed secondary hyperparathyroidism.

What should be done for asymptomatic patients with primary hyperparathyroidism or even ones with secondary hyperparathyroidism? This question has become the subject of a major controversy, for which no definitive answer exists. Symptomatic primary hyperparathyroidism in those younger than 50 years or with serum calcium levels more than 1 mg/dL above the upper limit of normal, a 30% or greater reduction in the glomerular filtration rate (GFR), or severe bone demineralization is usually treated surgically. If the patient refuses surgery or if other illnesses make surgery inadvisable, medical management with the new calcimimetic cinacalcet has made management much more feasible. The difficulty with such management is that the hyperfunctioning parathyroid glands secrete more hormone as the serum calcium concentration is lowered—as though the calcium set point for feedback regulation of PTH secretion had been raised.

Patients with moderate hypercalcemia who have normal renal and cardiovascular function present no special preoperative and preprocedure problems. The ECG can be examined preoperatively and intraoperatively for shortened PR or QT intervals (Fig. 35-4). Because severe hypercalcemia can result in hypovolemia, normal intravascular volume and electrolyte status should be restored before commencement of anesthesia and surgery.

Management of hypercalcemia preoperatively should include (even in urgent or emergency situations) treatment of the underlying cause—a frequent strategy in malignancy-associated hypercalcemic patients coming to surgery. Antitumor therapy preoperatively for both malignant and nonmalignant causes of hypercalcium can include hydration and diuresis to increase urinary calcium excretion. Restoration of intravascular volume, augmentation and excretion of urinary sodium (with saline infusion), and administration of diuretics (furosemide is commonly used) generally increase urinary calcium excretion substantially. Infusion rates of 200 to 400 mL/hr preoperatively are commonly used, but monitoring is needed to avoid fluid overload, especially since many patients have compromised cardiac pumping ability. Other complications of these interventions include hypomagnesemia and hypokalemia.

In emergency situations, vigorous expansion of intravascular volume usually reduces serum calcium to a safe level (<14 mg/dL); administration of furosemide is also often helpful in these situations. Phosphate should be given to correct hypophosphatemia because it decreases calcium uptake into bone, increases calcium excretion, and stimulates breakdown of bone. Hydration and diuresis, accompanied by phosphate repletion, suffice in the management of most hypercalcemic patients. Other measures to decrease reabsorption of bone include the bisphosphonates pamidronate sodium (90 mg intravenously) and zoledronate

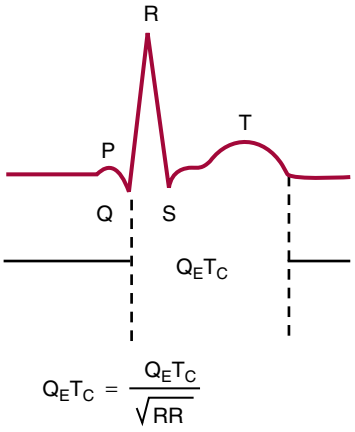

Figure 35-4 Measurement of the QTc interval (properly termed Q_ET_c to indicate that it begins with the start of the Q wave, lasts throughout the QT interval, ends with the end of the T wave, and is corrected for heart rate). RR is the RR interval in seconds. *(From Hensel P, Roizen MF: Patients with disorders of parathyroid function. Anesthesiol Clin North Am 5:287, 1987.)*

(4 mg intravenously), salmon calcitonin (100 to 400 units every 12 hours), and plicamycin (15 to 25 µg/kg intravenously).

Calcitonin lowers serum calcium levels through direct inhibition of bone resorption. It can decrease serum calcium levels within minutes after intravenous administration. Side effects include urticaria and nausea. It is so rapid acting that it can be used to reduce calcium levels while waiting for hydration and a bisphosphonate to take effect. Dialysis can also be used when appropriate.

It is especially important to know whether the hypercalcemia has been chronic because serious cardiac, renal, or CNS abnormalities may have resulted.

Hypocalcemia

Hypocalcemia (caused by hypoalbuminemia, hypoparathyroidism, hypomagnesemia, hypovitaminosis D, hungry bones after correction of hyperparathyroidism, anticonvulsant therapy, citrate infusion, or chronic renal disease) is not usually accompanied by a clinically evident cardiovascular disorder. The most common cause of hypocalcemia is hypoalbuminemia. In true hypocalcemia (i.e., when the free calcium concentration is low), myocardial contractility is affected. That is, myocardial contractility varies directly with levels of blood ionized calcium, although contractility decreased only 20% when ionized calcium levels changed from 1.68 to 1.34 mmol/L. The clinical signs of hypocalcemia are clumsiness; convulsions; laryngeal stridor; depression; muscle stiffness; paresthesia (oral and perioral); parkinsonism; tetany; Chvostek's sign; dry scaly skin, brittle nails, and coarse hair; low serum concentrations of calcium; prolonged QT intervals; soft tissue calcifications; and Trousseau's sign.

Hypocalcemia delays ventricular repolarization, hence increasing the QTc interval (normal, 0.35 to 0.44 second). With electrical systole prolonged, the ventricles may fail to respond to the next electrical impulse from the sinoatrial node, and a 2:1 heart block results. Prolongation of the QT interval is a moderately reliable ECG sign of hypocalcemia, not for the population as a whole, but for the individual patient.[93] Thus, monitoring the QT interval as corrected for the heart rate (see Fig. 35-4) is a useful, but not always accurate means of monitoring hypocalcemia in any individual patient. CHF may also occur with hypocalcemia, but this is rare. Because CHF in patients with coexisting heart disease is reduced in severity when calcium and magnesium ion levels are restored to normal, these levels may be normalized before surgery in a patient with impaired exercise tolerance or signs of cardiovascular dysfunction; normalization can be achieved intravenously over a 15-minute period if absolutely necessary.[94,95] Sudden decreases in blood levels of ionized calcium (as with chelation therapy) can result in severe hypotension.

Patients with hypocalcemia may have seizures. They may be focal, jacksonian, petit mal, or grand mal in appearance, indistinguishable from such seizures in the absence of hypocalcemia. Patients may also have a type of seizure called cerebral tetany, which consists of generalized tetany followed by tonic spasms. Therapy with standard anticonvulsants is ineffective and may even exacerbate these seizures (by an anti–vitamin D effect). In long-standing hypoparathyroidism, calcifications may appear above the sella; these calcifications represent deposits of calcium in and around small blood vessels of the basal ganglia. They may be associated with a variety of extrapyramidal syndromes.

The most common cause of acquired hypoparathyroidism is surgery on the thyroid or parathyroid glands. Other causes include autoimmune disorders, therapy with iodine 131, hemosiderosis or hemochromotosis, neoplasia, and granulomatous disease. Idiopathic hypoparathyroidism has been divided into three categories: an isolated persistent neonatal form, branchial dysembryogenesis, and autoimmune candidiasis related to multiple endocrine deficiency.

Pseudohypoparathyroidism and pseudopseudohypoparathyroidism are rare hereditary disorders characterized by short stature, obesity, rounded face, and shortened metacarpals. Patients with pseudohypoparathyroidism have hypocalcemia and hyperphosphatemia despite high serum levels of PTH. These patients have a deficient end-organ response to PTH as a result of abnormalities in G-protein function.

Because treatment of hypoparathyroidism is not surgical, hypoparathyroid patients who come to the operating room are those who require surgery for an unrelated condition. Their calcium, phosphate, and magnesium levels should be measured both preoperatively and postoperatively. Patients with symptomatic hypocalcemia might be treated with intravenous calcium gluconate before surgery. Initially, 10 to 20 mL of 10% calcium gluconate may be given at a rate of 5 mL/min. The effect on serum calcium levels is of short duration, but a continuous infusion with 10 mL/min of 10% calcium gluconate in 500 mL of solution over a period of 6 hours helps keep serum calcium at adequate levels. Magnesium and phosphate levels may require normalization as well to normalize cardiovascular and nervous system function.

The objective of therapy is to bring the symptoms under control before surgery and anesthesia. For patients with chronic hypoparathyroidism, the objective is to keep the serum calcium level in the lower half of the normal range. A preoperative and preprocedure ECG is useful for maintaining the QTc interval. The preoperative and preprocedure QTc value may be used as a guide to the serum calcium level if rapid laboratory assessment is not possible. Changes in the calcium level may alter the duration of muscle relaxation, so such alterations might be monitored by using a twitch monitor in these (as well as all other) patients.

The intimate involvement of the parathyroid gland with the thyroid gland can result in unintentional hypocalcemia during

surgery for diseases of either organ. Because of the affinity of their bones for calcium, this relationship is crucial in patients with advanced osteitis. Internal redistribution of magnesium, calcium, or both ions may occur (into "hungry bones") after parathyroidectomy and cause hypomagnesemia, hypocalcemia, or both conditions. Because the tendency to tetany increases with alkalosis, hyperventilation is usually assiduously avoided. The most prominent manifestations of acute hypocalcemia are distal paresthesias and muscle spasm (tetany). Potentially fatal complications of severe hypocalcemia include laryngeal spasm and hypocalcemic seizures. The clinical sequelae of magnesium deficiency include cardiac arrhythmias (principally ventricular tachyarrhythmias), hypocalcemic tetany, and neuromuscular irritability independent of hypocalcemia (tremors, twitching, asterixis, and seizures).

In addition to monitoring total serum calcium or ionized calcium postoperatively, one can test for the Chvostek and Trousseau signs. (Note that serum calcium and not ionized calcium is dependent on the albumin level, with a decline of about 0.8 mg/dL for each 1-g/dL drop in serum albumin level.) Because the Chvostek sign can be elicited in 10% to 15% of patients who are not hypocalcemic, an attempt should be made to elicit it preoperatively to ensure that its appearance is meaningful. The Chvostek sign is a contracture of the facial muscles produced by tapping the ipsilateral facial nerves at the angle of the jaw. The Trousseau sign is elicited by applying a BP cuff at a level slightly above the systolic level for a few minutes. The resulting carpopedal spasm, with contraction of the fingers and inability to open the hand, stems from the increased muscle irritability in hypocalcemic states, aggravated by ischemia produced by the BP cuff.

Osteoporosis

Fifty percent of women older than 65 years sustain an osteoporotic fracture. (Because men are living longer, osteoporosis has become an increasing problem for them too, and recent reports indicate a 15% per decade hip fracture rate for men older than 65 years).[93] Men with COPD (even without steroid treatment) are at high risk for vertebral fractures and thus might be allowed to position and move themselves onto and off surgical tables. Furthermore, in either gender, each vertebral fracture is associated with a 10% decrease in lung capacity. Diagnosis and treatment of these conditions have increased with routine use of dual-energy x-ray absorptiometry (DEXA) or quantitative ultrasonography. Because "T" and "Z" scores were developed to relate changes in white postmenopausal women to those at age 21, care must be used in interpreting the results. Known risk factors include age, relative lifetime estrogen deficiency (late menarche, amenorrhea, early menopause, nulliparity), deficiency of dietary calcium, tobacco use, increased aerobic exercise in combination with decreased weight-bearing exercise, decreased weight-bearing exercise by itself, use of soft drinks, and Asian or white ancestry. Although therapy for osteoporosis (use of biphosphates, bone mineral depositors, weight-bearing exercises, calcium, vitamin D, estrogen, and now designer estrogens that may be useful for men such as Evista) does not have major known implications for anesthesia care,[96-98] bone fractures in such patients have occurred on movement to and from an operating table. Recombinant PTH and calcitonin are also used, but again, no reports of perioperative interactions have been prominent. Thus, the precautions mentioned earlier for hyperparathyroid patients relative to self-positioning and careful positioning may be useful.

Pituitary Abnormalities

Anterior Pituitary Hypersecretion

The anterior pituitary gland (or master endocrine gland) consists of five identifiable types of secretory cells (and the hormones that they secrete): somatotrophs (GH), corticotrophs (ACTH), lactotrophs (prolactin), gonadotrophs (luteinizing hormone [LH] and follicle-stimulating hormone [FSH]), and thyrotrophs (TSH). Secretion of these pituitary hormones is largely regulated by a negative-feedback loop by hypothalamic regulatory hormones and by signals that originate from the target site of pituitary action. Six hypothalamic hormones have been characterized: dopamine, the prolactin-inhibiting hormone; somatostatin, the GH release– inhibiting hormone; GH-releasing hormone (GHRH); corticotropin-releasing hormone (CRH); gonadotropin-releasing hormone (GnRH or LHRH); and TRH. Most pituitary tumors (>60%) are hypersecretory and are classified according to the excess production of a specific anterior pituitary hormone.

The three most common disorders of pituitary hypersecretion are those related to excesses of prolactin (amenorrhea, galactorrhea, and infertility), ACTH (Cushing's syndrome), or GH (acromegaly). In addition to knowing the pathophysiologic processes of the disease involved, the anesthesiologist must determine whether the patient recently underwent air pneumoencephalography (almost obsolete, but still used rarely). If so, nitrous oxide should not be used to lessen the risk of intracranial hypertension from gas collection. CT or MRI of the sella has largely replaced neuroencephalography, but as stated, the latter is still performed.

Preoperative evaluation of patients with acromegaly is found in Chapter 34. More than 99% of cases of acromegaly are attributable to pituitary adenoma (or use of recombinant GH for unapproved aging prevention, which it does not do as of current data). Thus, the primary treatment of acromegaly is transsphenoidal surgery (or withdrawal of drug) and symptomatic treatment of the carpal tunnel or other syndromes provoked. If the pituitary tumor is not totally removed, patients are often offered external pituitary irradiation. In the case of suprasellar extension, conventional transfrontal hypophysectomy is often performed. The dopaminergic agonist bromocriptine can lower GH levels, but the long-term follow-up with this drug is not favorable. Octreotide, a long-acting analog of somatostatin, now given in depot form about once a month, produces effective palliation in 50% of patients. Other medical therapies such as pegvisomant or somatostatin analogs are also medications that have been tried before surgery.

Difficulty with endotracheal intubation should be anticipated in an acromegalic patient; lateral neck films or CT scans of the neck and direct or indirect visualization can identify patients with subglottic stenosis or an enlarged tongue, mandibles, epiglottis, or vocal cords. If placement of an arterial line is necessary, a brachial or femoral site may be preferable to a radial site.[99]

Anterior Pituitary Hypofunction

Anterior pituitary hypofunction results in deficiency of one or more of the following hormones: GH, TSH, ACTH, prolactin, or gonadotropin. Preoperative and preprocedure preparation of patients who are chronically deficient in ACTH and TSH is dis-

cussed in Chapter 34. No special preoperative and preprocedure preparation is required for a patient deficient in prolactin or gonadotropin; deficiency in GH, however, can result in atrophy of cardiac muscle, a condition that may necessitate preoperative and preprocedure cardiac evaluation. Nonetheless, anesthetic problems have not been documented in patients with isolated GH deficiency. Acute deficiencies are another matter.

Acute pituitary deficiency is often caused by bleeding into a pituitary tumor. In surgical specimens of resected adenomas, as many as 25% show evidence of hemorrhage. These patients often have acute headache, visual loss, nausea or vomiting, ocular palsy, disturbances of consciousness, fever, vertigo, or hemiparesis. In such patients, rapid transsphenoidal decompression should be accompanied by consideration of replacement therapy, including glucocorticoids, and treatment of increased intracranial pressure.

Obstetric anesthesiologists are often aware of these pituitary failure problems (also see Chapter 69); Sheehan's syndrome is the clinical manifestation of pituitary infarction associated with hypotension after or during obstetric hemorrhage. Conditions that strongly suggest this diagnosis are failure to start postpartum lactation, increasing fatigue, cold intolerance, and especially hypotension unresponsive to volume replacement and pressors.

Posterior Pituitary Hormone Excess and Deficiency

Secretion of vasopressin or antidiuretic hormone (ADH) is enhanced by increased serum osmolality or the presence of hypotension. Inappropriate secretion of vasopressin, without relation to serum osmolality, results in hyponatremia and fluid retention. This inappropriate secretion can result from a variety of CNS lesions; from drugs such as nicotine, narcotics, chlorpropamide, clofibrate, vincristine, vinblastine, and cyclophosphamide; and from pulmonary infections, hypothyroidism, adrenal insufficiency, and ectopic production from tumors. Preoperative and preprocedure management of a surgical patient with inappropriate secretion of vasopressin includes appropriate treatment of the causative disorders and restriction of water. Occasionally, drugs that inhibit the renal response to ADH (e.g., lithium or demeclocycline) should be administered preoperatively to restore normal intravascular volume and electrolyte status.

Most of the clinical features associated with the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) are related to hyponatremia and the resulting brain edema; such features include weight gain, weakness, lethargy, mental confusion, obtundation, and disordered reflexes and may culminate in convulsions and coma. This form of edema rarely leads to hypertension.

Recently, it has been recognized that 10% to 20% of long-distance and marathon runners have SIADH with increased vasopressin secretion. Because such people not infrequently undergo surgical treatment of injuries, SIADH symptoms and laboratory evaluation might be routine for that group as well.

SIADH should be suspected in any patient with hyponatremia who excretes urine that is hypertonic relative to plasma. The following laboratory findings further support the diagnosis:

1. Urinary sodium >20 mEq/L
2. Low serum levels of BUN, creatinine, uric acid, and albumin
3. Serum sodium <130 mEq/L
4. Plasma osmolality <270 mOsm/L
5. Urine hypertonic relative to plasma

Noting the response to water loading is a useful way of evaluating patients with hyponatremia. Patients with SIADH are unable to excrete dilute urine even after water loading. Assay of ADH in blood can confirm the diagnosis. Too vigorous treatment of chronic hyponatremia can result in disabling demyelination.[100,101] The increase in serum sodium should not be greater than 1 mEq/L/hr[100,101] (see discussion of hyponatremia in the later section "Electrolyte Disorders").

Patients with mild to moderate symptoms of water intoxication (and worse outcomes are seen in children, those with hypoxic episodes, and menstruant women) can be treated with restriction of fluid intake to about 500 to 1000 mL/day. Patients with severe water intoxication and CNS symptoms may need vigorous treatment consisting of intravenous administration of 200 to 300 mL of a 5% saline solution over a period of several hours, followed by fluid restriction.

Treatment should be directed at the underlying problem. If SIADH is drug induced, use of the drug should be withdrawn. Inflammation should be treated with appropriate measures, and neoplasms should be managed by surgical resection, irradiation, or chemotherapy, whichever is indicated.

No drugs are available that can suppress release of ADH from the neurohypophysis or from a tumor. Phenytoin (Dilantin) and narcotic antagonists such as naloxone and butorphanol have some inhibiting effect on physiologic ADH release but are clinically ineffective in patients with SIADH. Drugs that block the effect of ADH on renal tubules include lithium, which is rarely used because its toxicity often outweighs its benefits, and demethylchlortetracycline in doses of 900 to 1200 mg/day. The latter drug interferes with the ability of the renal tubules to concentrate urine, thereby causing excretion of isotonic or hypotonic urine and lessening the hyponatremia. Demethylchlortetracycline can be used in ambulatory patients with SIADH when it is difficult to restrict fluids.

When a patient with SIADH comes to the operating room for any surgical procedure, fluids are managed by measuring central volume status by CVP, pulmonary artery lines, or the cross-sectional left ventricular area at end-diastole on transesophageal echocardiography and by frequent assays of urine osmolarity, plasma osmolarity, and serum sodium, including the period immediately after surgery. Despite the common impression that SIADH is frequently seen in elderly patients in the postoperative period, studies have shown that the patient's age and the type of anesthetic used have no bearing on the postoperative development of SIADH. It is not unusual to see several patients in the neurosurgical ICU suffering from this syndrome. The diagnosis is usually one of exclusion. Patients with SIADH generally require only fluid restriction; very rarely is hypertonic saline needed.

Lack of ADH, which results in diabetes insipidus, is caused by pituitary disease, brain tumors, infiltrative diseases such as sarcoidosis, head trauma (including trauma after neurosurgery), or lack of a renal response to ADH. The last can occur as a result of such diverse causes as hypokalemia, hypercalcemia, sickle cell anemia, obstructive uropathy, and renal insufficiency. Preoperative or preprocedure treatment of diabetes insipidus consists of restoring normal intravascular volume by replacing urinary

losses, administering desmopressin nasally, and giving daily fluid requirements intravenously.

Perioperative management of patients with diabetes insipidus is based on the extent of the ADH deficiency. Management of a patient with complete diabetes insipidus and a total lack of ADH does not usually present any major problem as long as the side effects of the drug are avoided and the presence of the condition is known before surgery. Just before surgery, the patient is given the usual dose of DDAVP (desmopressin acetate) intranasally or an intravenous bolus of 100 mU of aqueous vasopressin, followed by a constant infusion of 100 to 200 mU/hr.[2] The dose is usually adjusted to permit the daily breakthrough polyuria that avoids the iatrogenic syndrome of SIADH. We have found it useful to continue that dosing regimen perioperatively in all ambulatory patients who can take fluid orally in the postoperative period. All the intravenous fluids given intraoperatively should be isotonic to reduce the risk of water depletion and hypernatremia. Plasma osmolality should be measured every hour, both intraoperatively and immediately after surgery. If plasma osmolality rises well above 290 mOsm/L, hypotonic fluids can be administered; the rate of the intraoperative vasopressin infusion can be increased to greater than 200 mU/hr.

For patients who have a partial deficiency of ADH, it is not necessary to use aqueous vasopressin perioperatively unless plasma osmolality rises above 290 mOsm/L. Nonosmotic stimuli (e.g., volume depletion) and the stress of surgery usually cause the release of large quantities of ADH perioperatively. Consequently, these patients require only frequent monitoring of plasma osmolality during this period.

Because of side effects, the dose of vasopressin should be limited to that necessary for control of diuresis. The oxytoxic and coronary artery–constricting properties of vasopressin make this limit especially applicable to patients who are pregnant or have coronary artery disease.

Another problem for anesthesiologists is the care of patients who come to the operating room with a vasopressin drip for the treatment of bleeding from esophageal varices. This treatment is less common since the advent of laser therapy for varices. However, when vasopressin is given, the vasoconstrictive effect of vasopressin on the splanchnic vasculature is used to decrease bleeding. Such patients are often volume depleted and may have concomitant coronary artery disease. Because vasopressin has been shown to markedly decrease oxygen availability, primarily as a result of decreased stroke volume and heart rate, monitoring of tissue oxygen delivery may be useful. In patients with a history of angina pectoris who received a combination of cimetidine and vasopressin for esophageal varices, bradyarrhythmias and AV block have occurred. This effect indicates that the combination of cimetidine and vasopressin could be deleterious to the heart because of the combined negative inotropic and arrhythmogenic effects of the two drugs.

Diseases Involving the Cardiovascular System

Hypertension

Analysis of the perioperative treatment of hypertension is important because of the prevalence of the condition (30% of the general population in the United States), the great risk in perioperative care of a hypertensive patient, and the high cost of unnecessary delays in surgery (also see Chapter 34). The controversy centers around two issues. Does inadequate control of hypertension result in complications that could be prevented with some control? How much control of BP is needed and for how long? That is, does overzealous control just create unnecessary postponements of elective surgery or, worse, predispose the patient to exaggerated adverse drug reactions and greater hemodynamic instability than not so zealous control does?

Because of the controversy regarding the appropriateness of preoperative treatment of hypertension, the original articles that stimulated this controversy have been evaluated fully in previous editions.

Several schools of thought exist, the two oldest represented by studies conducted by Prys-Roberts and colleagues[102] in 1971 and by Goldman and Caldera[103] in 1979. Several other studies (Bedford and Feinstein,[104] Asiddao et al.,[105] Stone et al.,[106] Flacke et al.,[107] Ghignone et al.,[108] Tuman et al.,[109] Ellis et al.,[110] Mangano et al.,[111] Pasternack et al.[112]) have also been cited. Weksler and colleagues[113] studied 989 chronically treated hypertensive patients who underwent noncardiac surgery with diastolic BP between 110 and 130 mm Hg and no previous MI, unstable or severe angina pectoris, renal failure, pregnancy-induced hypertension, left ventricular hypertrophy, previous coronary revascularization, aortic stenosis, preoperative dysrhythmias, conduction defects, or stroke.[113] The control group had their surgery postponed and remained in the hospital for control of BP, and the study patients received 10 mg of nifedipine intranasally. No statistically significant differences in postoperative complications were observed, thus suggesting that this subset of patients without significant cardiovascular comorbid conditions can proceed with surgery despite elevated BP the day of surgery.

Only one study has directly assessed the relationship between cardiovascular disease and preoperative isolated systolic hypertension. In a multicenter study of patients undergoing CABG, the presence of isolated systolic hypertension has been associated with a 30% increased incidence of perioperative cardiovascular complications when compared with normotensive individuals, but no study has addressed the importance of isolated systolic hypertension in noncardiac surgery.[114] Unfortunately, each of these studies has deficiencies that prevent the establishment of a definitive answer to this question.

Recommendations

Although preoperative systolic BP is a significant predictor of postoperative morbidity, no data definitively establish whether preoperative treatment of hypertension reduces perioperative risk. Until a definitive study is performed (and that would unfortunately be extremely difficult to do), we recommend letting the weight of evidence guide preoperative treatment of a patient with hypertension. Such treatment would be based on three general beliefs: (1) the patient should be educated regarding the importance of lifelong treatment of hypertension, even isolated systolic hypertension; (2) perioperative hemodynamic fluctuations occur less frequently in treated than in untreated hypertensive patients (as demonstrated by Prys-Roberts and colleagues[102] and confirmed by Goldman and Caldera[103] and Mangano and associates,[111]); and (3) hemodynamic fluctuations have some relationship to morbidity. The data of Pasternack and colleagues[112] and Weksler and associates[113] imply that rapid correction of BP or prevention of increases in heart rate may be all that is needed. However, data from animals that had declining renal function with acute reduc-

tions in arterial BP accentuate the risks of such reductions.[115] Even though other epidemiologic data confirm these risks,[116,117] the hazards of BP fluctuations and acute hypertension may be serious in an untreated hypertensive subject.[118] Modern drug therapy for hypertension appears to reduce these risks but does so for many with a decrement in quality of life that causes many patients to avoid such medications.[119] Specific racial differences need to be considered before treatment (African Americans respond less well to β-adrenergic receptor blocking drugs and ACE inhibitors but as well to calcium channel antagonists as whites do).[120]

We use preoperative data to determine the individualized range of values that we consider tolerable by a particular patient during and after surgery. That is, if BP is 180/100 mm Hg and the heart rate is 96 beats/min on admission with no signs or symptoms of myocardial ischemia, we feel confident that the patient can tolerate these levels during surgery. If during the night BP decreases to 80/50 mm Hg and the heart rate to 48 beats/min and the patient does not wake with signs of a new cerebral deficit, we believe that the patient can safely tolerate such levels during anesthesia. Therefore, on the basis of preoperative data, we derive an individualized set of values for each patient. We then try to keep cardiovascular variables within that range and, in fact, plan before induction what therapies to use to accomplish that goal (e.g., administration of more/less anesthesia, nitroglycerin or nitroprusside/dopamine, dobutamine, phenylephrine, propranolol/isoproterenol, or atropine). We believe that this type of planning is especially important for a patient with suspected cardiovascular disease and relatively unimportant for a totally healthy patient. We do not know for certain that keeping cardiovascular variables within an individualized range of acceptable values improves the surgical outcome, but we do believe that such a plan reduces morbidity. For example, the POISE study demonstrated that acute β-blocker administration resulted in an increased incidence of stroke and death that was associated with an increased rate of hypotension.[121]

Preoperative Administration of All Antihypertensive Drugs

We routinely administer all antihypertensive drugs preoperatively, except ACE inhibitors or angiotensin II antagonists (AIIAs), which we tailor to the individual patient. Coriat and colleagues[122] found that ACE inhibitors were associated with hypotension in 100% of patients during induction versus about 20% in whom ACE inhibitors were withheld on the morning of surgery. Bertrand and coworkers performed a prospective randomized study in which it was demonstrated that more severe hypotensive episodes requiring vasoconstrictor treatment occur after induction of general anesthesia in patients chronically treated with an AIIA and receiving the drug on the morning before surgery than in those in whom AIIAs were discontinued on the day before surgery.[123] Kheterpal and colleagues performed a propensity-matched analysis of 12,381 noncardiac surgery cases.[124] Patients with chronic ACE inhibitor/angiotensin receptor blocker and diuretic therapy showed more periods with a mean arterial BP lower than 70 mm Hg, periods with a 40% decrease in systolic BP, periods with a 50% decrease in systolic BP, and vasopressor boluses than patients receiving diuretic therapy alone did. If these drugs are continued, vasopressin is the drug of choice for refractory hypotension. Although the long-term adverse effects of withholding therapy on the morning of surgery were not assessed, we withhold therapy until either oral fluid is able to be consumed (ambulatory patients) or we can convert to intravenously or nasogastrically administered alternatives (patients who remain NPO postoperatively). We even administer the patient's chronic diuretics on the morning of surgery because the major effect of diuretics after 1 week of therapy is arteriolar vasodilation and assessment of urine output may be inaccurate if the diuretic is abruptly discontinued on the morning of surgery.

Ischemic Heart Disease

Preoperative evaluation of a patient with ischemic heart disease (also see Chapter 60) and a discussion of the American Heart Association/American College of Cardiology (AHA/ACC) guidelines can be found in Chapter 34.[125]

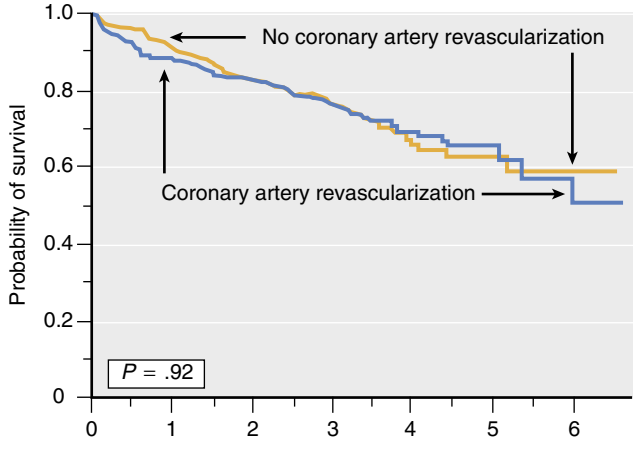
Role of Coronary Artery Bypass Graft or Percutaneous Coronary Interventions before Noncardiac Surgery

Coronary revascularization has been suggested as a means of reducing perioperative risk before noncardiac surgery. Previous retrospective evidence has shown that prior successful preoperative revascularization may decrease postoperative cardiac risk twofold to fourfold in patients undergoing elective vascular surgery.[126,127] The strongest retrospective evidence comes from the Coronary Artery Surgery Study (CASS) registry, which enrolled patients from 1978 to 1981. Operative mortality in patients with CABG performed before noncardiac surgery was 0.9% but was significantly higher at 2.4% in patients without previous CABG. However, there was a 1.4% mortality rate associated with the CABG procedure itself. Eagle and colleagues reported on a long-term analysis of patients entered into CASS.[128] They studied patients assigned to medical or surgical therapy for coronary artery disease for over 10 years who subsequently underwent 3368 noncardiac operations in the years after assignment of coronary treatment. Intermediate-risk surgery such as abdominal, thoracic, or carotid endarterectomy was associated with a combined morbidity and mortality rate of 1% to 5% and a small but significant improvement in outcome in patients who had previously undergone revascularization. The most significant improvement in outcome occurred in patients who underwent major vascular surgery such as abdominal or lower extremity revascularization. However, this observational study did not randomize patients and was undertaken in the 1970s and 1980s, before significant advances in medical, surgical, and percutaneous coronary strategies.[128] Landesberg and coauthors retrospectively reviewed long-term outcomes in 578 major vascular procedures.[129] By multivariate analysis, age, type of vascular surgery, presence of diabetes, previous MI, and moderate to severe ischemia on preoperative thallium scanning (PTS) independently predicted mortality, and preoperative coronary revascularizaton predicted improved survival. Long-term survival after major vascular surgery was significantly improved if patients with moderate to severe ischemia on PTS underwent selective coronary revascularization.

The benefit of percutaneous coronary intervention (PCI) before noncardiac surgery has also been examined in several cohort studies. Posner and colleagues used an administrative data set of patients who underwent PCI and noncardiac surgery in Washington State.[130] They matched patients with coronary disease who were undergoing noncardiac surgery with and without previous PCI and looked at cardiac complications. In this nonrandomized design, they noted a significantly lower rate of 30-day

cardiac complications in patients who underwent PCI at least 90 days before the noncardiac surgery. Importantly, however, PCI within 90 days of noncardiac surgery did not improve outcome. Although the explanation for these results is unknown, they may support the notion that PCI performed "to get the patient through surgery" may not improve perioperative outcome because cardiac complications may not occur in patients with stable or asymptomatic coronary stenosis. PCI may actually destabilize coronary plaque, which becomes manifest in the days or weeks after noncardiac surgery. Godet and associates studied a cohort of 1152 patients after abdominal aortic surgery in which 78 patients underwent PCI.[131] In the PCI group, the observed percentages of patients with a severe postoperative coronary event (9.0%; 95% confidence interval [CI], 4.4 to 17.4) or death (5.1% [95% CI, 2.0 to 12.5]) were not significantly different from the expected percentages (8.2% and 6.9%, respectively), which was confirmed by propensity analysis. PCI did not seem to significantly limit cardiac risk or death after aortic surgery.

Several randomized trials have now addressed the value of testing and CABG or PCI (or both) in a subset of patients. McFalls and colleagues reported the results of a multicenter randomized trail in the VA Health System in which patients with documented coronary artery disease on coronary angiography, excluding those with left main disease or a severely depressed ejection fraction (<20%), were randomized to CABG (59%) or percutaneous transluminal coronary angioplasty (PTCA) (41%) versus routine medical therapy.[132] At 2.7 years after randomization, mortality in the revascularization group was not significantly different (22%) from that in the no-revascularization group (23%) (Fig. 35-5). Within 30 days after the vascular operation, postoperative MI, defined by elevated troponin levels, occurred in 12% of the revascularization group and 14% of the no-revascularization group (P = .37). The authors suggested that coronary revascularization is not indicated in patients with stable coronary artery disease, and their results further support the lack of efficacy of PCI or CABG for single- or double-vessel disease before noncardiac surgery. However, in a follow-up analysis, Ward and coauthors reported improved outcome in the subset who underwent CABG versus PCI.[133] Poldermans and colleagues randomized 770 patients about to undergo major vascular surgery and considered to have intermediate cardiac risk, defined as the presence of one or two cardiac risk factors, to either undergo further risk stratification with stress imaging or proceed directly to surgery.[134] All patients received bisoprolol with a targeted heart rate of 60 to 65 beats/min initiated before and continued after surgery. The 30-day incidence of cardiac death and nonfatal MI was similar in both groups (1.8% in the no-testing group versus 2.3% in the tested group). The conclusion of the authors was that further risk stratification in this group of patients considered to be at intermediate risk based on clinical history alone was unnecessary as long as perioperative β-blockers were used and that testing only delayed necessary vascular surgery. In a pilot study, Poldermans and associates tested patients with more than three risk factors; 101 (23%) showed extensive ischemia and were randomly assigned to revascularization (n = 49) or no revascularization.[135] Revascularization did not improve 30-day outcome; the incidence of the composite end point was 43% versus 33% (odds ratio [OR], 1.4; 95% CI, 0.7 to 2.8; P = .30). In addition, no benefit during 1-year follow-up was observed after coronary revascularization (49% versus 44%; OR, 1.2; 95% CI, 0.7 to 2.3; P = .48).



Years	1	2	3	4	5	6
No. at risk						
Revascularization	226	175	113	65	18	7
No revascularization	229	172	108	55	17	12

Figure 35-5 Long-term survival in patients randomized to coronary revascularization or routine care in patients with coronary artery disease on angiography and undergoing major vascular surgery in the Coronary Artery Revascularization Prophylaxis trial. *(Reproduced with permission from McFalls EO, Ward HB, Moritz TE, et al: Coronary-artery revascularization before elective major vascular surgery. N Engl J Med 351:2795-2804, 2004.)*

One issue in interpreting the results is that the length of time between coronary revascularization and noncardiac surgery most likely has an impact on its protective effect and potential risks. Back and coworkers studied 425 consecutive patients undergoing 481 elective major vascular operations at an academic VA Medical Center.[136] Coronary revascularization was classified as recent (CABG <1 year; PTCA <6 months) in 35 cases (7%), prior (CABG >1 year and ≤5 years; PTCA >6 months and ≤2 years) in 45 cases (9%), and remote (CABG ≥5 years; PTCA ≥2 years) in 48 cases (10%). Outcomes in patients with previous PTCA were similar to those after CABG (P = .7). Significant differences in adverse cardiac events and mortality were found between patients with CABG performed within 5 years or PTCA within 2 years (6.3%, 1.3%, respectively), individuals with remote revascularization (10.4%, 6.3%), and nonrevascularized patients stratified at high risk (13.3%, 3.3%) or intermediate/low risk (2.8%, 0.9%). The authors concluded that previous coronary revascularization (CABG <5 years; PTCA <2 years) may provide only modest protection against adverse cardiac events and mortality after major arterial reconstruction.

PCI using coronary stenting poses several special issues. Kaluza and associates reported on the outcome of 40 patients who underwent prophylactic coronary stent placement less than 6 weeks before major noncardiac surgery requiring general anesthesia.[137] There were seven MIs, 11 major bleeding episodes, and 8 deaths. All deaths and MIs, as well as 8 of the 11 bleeding episodes, occurred in patients subjected to surgery less than 14 days after stenting. Four patients expired after undergoing surgery 1 day after stenting. Wilson and colleagues reported on 207 patients who underwent noncardiac surgery within 2 months of stent placement.[5] Eight patients died or suffered an MI, all of whom were among the 168 patients who had surgery 6 weeks after stent placement. Vincenzi and coworkers studied 103 patients and reported that the risk of suffering a perioperative cardiac event

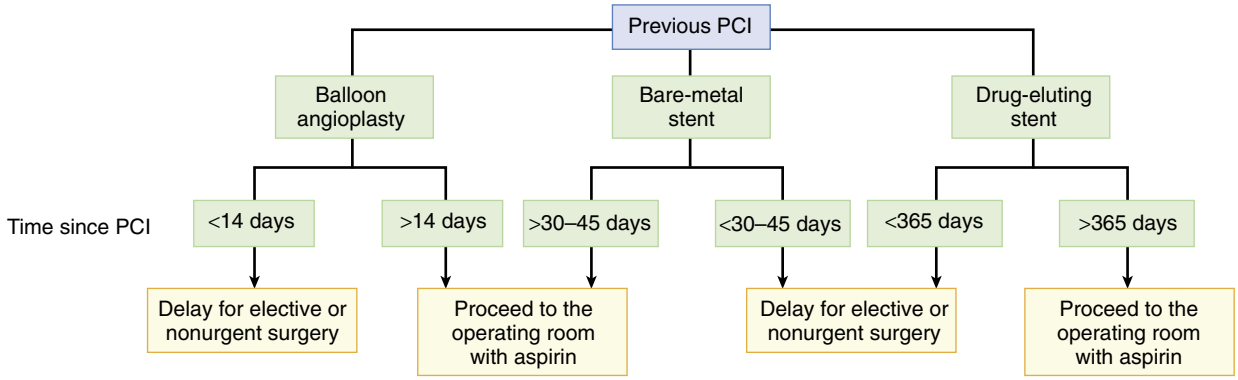


Figure 35-6 Recommendation for management of a patient with a previous percutaneous coronary intervention (PCI) from the American Heart Association/American College of Cardiology. *(Reproduced with permission from Fleisher LA, Beckman JA, Brown KA, et al: ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the 2002 Guidelines on Perioperative Cardiovascular Evaluation for Noncardiac Surgery): Developed in collaboration with the American Society of Echocardiography, American Society of Nuclear Cardiology, Heart Rhythm Society, Society of Cardiovascular Anesthesiologists, Society for Cardiovascular Angiography and Interventions, Society for Vascular Medicine and Biology, and Society for Vascular Surgery. Circulation 116(17): e418-e499, 2007.)*

was 2.11-fold greater in patients with recent stents (<35 days before surgery) than in those who underwent PCI more than 90 days before surgery.[138] Leibowitz and associates studied a total of 216 consecutive patients who underwent PCI within 3 months of noncardiac surgery (PTCA, 122; stent, 94).[139] A total of 26 patients (12%) died, 13 in the stent group (14%) and 13 in the PTCA group (11%), a nonsignificant difference. The incidence of acute MI and death within 6 months was not significantly different (7% and 14% in the stent group and 6% and 11% in the PTCA group, respectively). Significantly more events occurred in the two groups when noncardiac surgery was performed within 2 weeks of PCI. Based on the accumulating data, elective noncardiac surgery after PCI, with or without stent placement, should be delayed for 4 to 6 weeks.

Drug-eluting stents may represent an even greater problem during the perioperative period based on case reports. Nasser and coauthors described two patients with in-stent thrombosis occurring 4 and 21 months after the implantation of sirolimus-eluting stents.[140] Several reports suggest that drug-eluting stents may represent an additional risk over a prolonged period (up to 12 months), particularly if antiplatelet agents are discontinued.[141] The new guidelines suggest continuing aspirin therapy in all patients with a coronary stent and discontinuing clopidogrel for as short an interval as possible for patients with bare-metal stents in place for less than 30 days or drug-eluting stents for less than 1 year (Fig. 35-6).

Summary of Preoperative and Intraoperative Factors That Correlate with Perioperative Morbidity

Summarizing a large number of studies, we list the following preoperative findings as conditions that correlate with perioperative morbidity and that can be corrected before surgery:

Table 35-9 Cardiovascular Disease Classification Chart

Class	New York Heart Association Functional Classification	Canadian Cardiovascular Society Functional Classification
I	Patients have cardiac disease but without the resulting limitations of physical activity. Ordinary physical activity does not cause undue fatigue, palpitation, dyspnea, or anginal pain.	Ordinary physical activity such as walking or climbing stairs does not cause angina. Angina with strenuous or rapid prolonged exertion at work or recreation
II	Patients have cardiac disease resulting in slight limitation of physical activity. They are comfortable at rest. Ordinary physical activity results in fatigue, palpitation, dyspnea, or anginal pain.	Slight limitation of ordinary activity. Ordinary walking or climbing stairs rapidly, walking uphill, and walking or stair climbing after meals or in the cold, in wind, under emotional stress, or only for a few hours after awakening. Walking more than two blocks on a level surface or up more than one flight of stairs at a normal pace and under normal conditions
III	Patients have cardiac disease resulting in marked limitation of physical activity. They are comfortable at rest. Less than ordinary physical activity causes fatigue, palpitation, dyspnea, or anginal pain.	Marked limitation of ordinary physical activity. Walking one or two blocks on a level surface and climbing more than one flight of stairs under normal conditions
IV	Patients have cardiac disease resulting in inability to carry on any physical activity without discomfort. Symptoms of cardiac insufficiency or of the anginal syndrome may be present even at rest. If any physical activity is undertaken, discomfort is increased.	Inability to carry out physical activity without discomfort—anginal syndrome *may* be present at rest

Modified from Wong DH, Weber EC, Schell MJ, et al: Factors associated with postoperative pulmonary complications in patients with severe COPD. Anesth Analg, 80: 276, 1995.

1. Recent MI[91,119,142-144]
2. Severe CHF (i.e., sufficiently severe to produce rales, an S_3 gallop, or distention of the jugular vein)[91,111,130,137,142,145-164]
3. Severe angina (see Table 35-9 for classification of the severity of angina)[137,142,145-152]
4. Heart rhythm other than sinus[142,145,153,154]
5. Premature atrial contractions[142]
6. More than five PVCs per minute (although unconfirmed in later studies)[142]
7. Chronic renal insufficiency
8. BUN levels higher than 50 mg/dL or potassium levels below 3.0 mEq/L[142,148,149,155]

Preoperative factors that correlate with perioperative risk but cannot be altered include (1) old physiologic or chronologic age (perioperative risk increases with age),* (2) significant aortic stenosis,[142,155,169] (3) emergency surgery,[91,142,145,147,153-155,165] (4) cardiomegaly,[142,145,147,153-156] (5) history of CHF,[91,142,145-147,153-158,160-163,170,171] (6) angina (or a history of angina or ischemia) on the ECG,[91,111,142,145-147,153,154,157-162,170,172] (7) abnormal ST-segment or inverted or flat T waves on the ECG,[8,142,145,154] or abnormal QRS complex on the ECG,[142] and (8) a significant mitral regurgitant murmur.[142,155]

Significant intraoperative factors that correlate with perioperative risk and that may be avoided or altered are (1) unnecessary use of vasopressors,[173,174] (2) unintentional hypotension[120,142,175] (this point is controversial, however, because some investigators have found that unintentional hypotension does not correlate with perioperative morbidity[174]), (3) hypothermia,[176] (4) too low or too high a hematocrit,[177,178] and (5) lengthy operations.[142]

Significant intraoperative factors that correlate with perioperative morbidity and probably cannot be avoided are (1) emergency surgery and (2) thoracic or intraperitoneal surgery or above-the-knee amputations.[142,145-147,153-155,157-159,161,162,168,170,171]

Although the evidence for these factors is fairly substantial, virtually no data are derived from prospective randomized studies indicating that treatment of the aforementioned conditions reduces perioperative risk in patients with ischemic heart disease. Nevertheless, all logic dictates that such treatment does reduce risk. Thus, the goal in giving anesthesia to patients with ischemic heart disease is to achieve the best preoperative condition obtainable by treating conditions that correlate with perioperative risk. The next step is to intraoperatively monitor for conditions that correlate with perioperative risk and, by careful attention to detail, avoid circumstances that lead to perioperative risk. Although local anesthesia may reduce perioperative risk, epidemiologic studies do not indicate any significant differences in perioperative morbidity in patients with ischemic heart disease who are given local anesthesia as opposed to general anesthesia.

Preoperative and Preprocedure Therapy

The only way known to increase oxygen supply to the myocardium of patients with coronary artery stenosis is to maintain diastolic BP, hemoglobin concentration (Fig. 35-7), and oxygen saturation. The main goal of anesthesia practice for these patients has been to decrease the determinants of myocardial oxygen demand, heart rate, ventricular wall tension, and contractile performance and improve plaque stabilization. Thus, medical management designed to preserve all viable myocardial tissue may include the following:

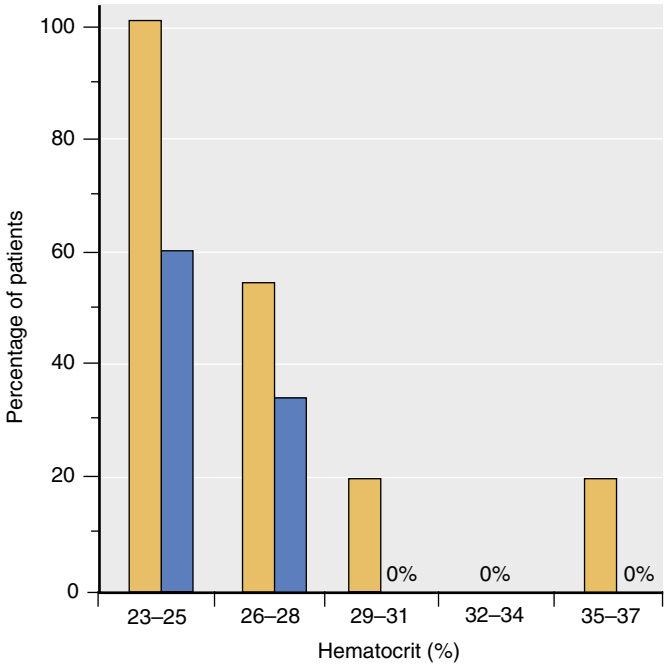

Figure 35-7 Relationship of postoperative myocardial ischemia (*yellow bars*) and morbid cardiac events (*blue bars*) to hematocrit for 27 high-risk patients undergoing infrainguinal arterial bypass. *(Data from Nelson AH, Fleisher LA, Rosenbaum SH: The relationship between postoperative anemia and cardiac morbidity in high risk vascular patients in the ICU. Crit Care Med 21:860, 1993.)*

1. Continuation of β-adrenergic receptor blocking drugs (propranolol, atenolol, esmolol, or metoprolol) to avoid β-blocker withdrawl leading to increased contractility and heart rate. Multiple studies have demonstrated improved outcome in patients given perioperative β-blockers, especially if the heart rate is controlled.[179,180] However, newer studies have demonstrated that β-blockers may not be effective if the heart rate is not well controlled or in lower-risk patients.[181-183] Recently, the POISE trial was published in which 8351 high-risk β-blocker–naive patients were randomized to high-dose continuous-release metoprolol versus placebo.[121] There was a significant reduction in the primary outcome of cardiovascular events along with a 30% reduction in the MI rate, but a significantly increased rate of 30-day all-cause mortality and stroke. The current ACC/AHA guidelines on perioperative β-blockade advocate that perioperative β-blockade is a class I indication and should be used in patients previously taking β-blockers and those with a positive stress test undergoing major vascular surgery, although acute administration without titration may be associated with harm (Table 35-10).
2. Vasodilation (with nitroglycerin or its "long-acting" analogs nitroprusside, hydralazine, or prazosin) to decrease ventricular wall tension may be beneficial, although there are currently no randomized trials that support the prophylactic use of these agents.[110-112] The use of Swan-Ganz catheters[159,184] and transesophageal echocardiography for this type of patient is described in Chapters 40 and 41, and the

Circulation 116(17):e418-e499, 2007.

intraoperative management of patients with ischemic heart disease is discussed in further detail in Chapters 60 and 62 and in recent guidelines.[125]

3. Aspirin, statins, exercise, and diet. These choices seem to be indicated in many patients. Briefly, we believe that drugs given chronically (e.g., antihypertensive medications and some ACE inhibitors) should be continued through the morning of surgery (see earlier). The topic of chronic drug therapy is discussed in more detail in the last section of this chapter.

Valvular Heart Disease

Major alterations in the preoperative management of patients with valvular heart disease have been made regarding the use of anticoagulant therapy and are now based on the causes of the disease. Preoperative and intraoperative management of patients with valvular heart disease is discussed in Chapters 34 and 60.

The prognosis and, presumably, the perioperative risk for patients with valvular heart disease depend on the stage of the disease. Although stenotic lesions progress faster than regurgitant lesions do, regurgitant lesions secondary to infective endocarditis, rupture of the chordae tendineae, or ischemic heart disease can be rapidly fatal. Left ventricular dysfunction is common in the late stage of valvular heart disease.

Preoperative maintenance of drug therapy can be crucial; for example, a patient with aortic stenosis can deteriorate rapidly with the onset of atrial fibrillation or flutter because the atrial contribution to left ventricular filling can be critical in maintaining cardiac output. One of the most serious complications of valvular heart surgery and valvular heart disease before surgery is cardiac arrhythmia. Conduction disorders and chronic therapy with antiarrhythmic and inotropic drugs are discussed elsewhere in this chapter. The reader is referred elsewhere in this book (Chapter 83) or to other sources[185] for discussion of the management of a child with congenital heart disease who is undergoing noncardiac surgery.

Preoperative Antibiotic Prophylaxis for Endocarditis

Patients who have any form of valvular heart disease, as well as those with intracardiac (ventricular septal or atrial septal defects) or intravascular shunts, should be protected against endocarditis at the time of a known bacteremic event. Endocarditis has occurred in a sufficiently significant number of patients with hypertrophic cardiomyopathy (subvalvular aortic stenosis, asymmetric septal hypertrophy) and mitral valve prolapse to warrant the inclusion of these two conditions in the prophylaxis regimen.

Is endotracheal intubation associated with bacteremia? Bacteremia occurs after the following events: dental extraction, 30% to 80%; brushing of teeth, 20% to 24%; use of oral irrigation devices, 20% to 24%; barium enema, 11%; transurethral resection of the prostate (TURP), 10% to 57%; upper GI endoscopy, 8%; nasotracheal intubation, 16% (4 of 25 patients); and orotracheal intubation, 0% (0 of 25 patients). There are new guidelines from the AHA that are substantially different from those published in 2006.[186] There is also an update in 2008 from the AHA/ACC on endocarditis in patients with valvular heart disease, with changes from the 2006 document shown in Table 35-11.[187]

Cardiac Valve Prostheses and Anticoagulant Therapy and Prophylaxis for Deep Venous Thrombosis

In patients with prosthetic valves, the risk of increased bleeding during a procedure in a patient receiving antithrombotic therapy has to be weighed against the increased risk of thromboembolism caused by stopping the therapy. Common practice in patients undergoing noncardiac surgery with a mechanical prosthetic valve in place is cessation of anticoagulant therapy 3 days before surgery. This timeframe allows the international normalized ratio to fall to less than 1.5 times normal. The oral anticoagulants can then be resumed on postoperative day 1. Using a similar protocol, Katholi and colleagues found no perioperative episodes of thromboembolism or hemorrhage in 25 patients.[188] An alternative approach in patients at high risk for thromboembolism is conversion to heparin during the perioperative period. The heparin can then be discontinued 4 to 6 hours before surgery and resumed shortly thereafter. Current prosthetic valves may have a lower

Table 35-11 Changes Related to Endocarditis Prophylaxis: AHA/ACC Guidelines on Valvular Heart Disease

2006 VHD Guideline Recommendations	2008 VHD Focused Update Recommendations	Comments
Class I	**Class IIa**	
1. Prophylaxis against infective endocarditis is recommended for the following patients: • Patients with prosthetic heart valves and patients with a history of infective endocarditis (*level of evidence: C*) • Patients who have complex cyanotic congenital heart disease (e.g., single-ventricle states, transposition of the great arteries, tetralogy of Fallot) (*level of evidence: C*) • Patients with surgically constructed systemic pulmonary shunts or conduits (*level of evidence: C*) • Patients with congenital cardiac valve malformations, particularly those with bicuspid aortic valves, and patients with acquired valvular dysfunction (e.g., rheumatic heart disease) (*level of evidence: C*) • Patients who have undergone valve repair (*level of evidence: C*) • Patients who have hypertrophic cardiomyopathy when there is latent or resting obstruction (*level of evidence: C*) • Patients with MVP and auscultatory evidence of valvular regurgitation and/or thickened leaflets on echocardiography* (*level of evidence: C*)	1. Prophylaxis against infective endocarditis is reasonable for the following patients at highest risk for adverse outcomes from infective endocarditis who undergo dental procedures that involve manipulation of either gingival tissue or the periapical region of teeth or perforation of the oral mucosa: • Patients with prosthetic cardiac valves or prosthetic material used for cardiac valve repair (*level of evidence: B)* • Patients with previous infective endocarditis (*level of evidence: B*) • Patients with CHD (*level of evidence: B*) • Unrepaired cyanotic CHD, including palliative shunts and conduits (*level of evidence: B*) • Completely repaired congenital heart defect repaired with prosthetic material or device, whether placed by surgery or by catheter intervention, during the first 6 months after the procedure (*level of evidence: B*) • Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (both of which inhibit endothelialization) (*level of evidence: B*) • Cardiac transplant recipients with valve regurgitation as a result of a structurally abnormal valve (*level of evidence: C*)	Modified recommendation (changed class of recommendation from I to IIa, changed text). There are no class I recommendations for infective endocarditis prophylaxis
Class III		
1. Prophylaxis against infective endocarditis is not recommended for the following patients: • Patients with isolated secundum atrial septal defect (*level of evidence: C*) • Patients 6 or more months after successful surgical or percutaneous repair of atrial septal defect, ventricular septal defect, or patent ductus arteriosus (*level of evidence: C*) • Patients with MVP without MR or thickened leaflets on echocardiography* (*level of evidence: C*) • Patients with physiologic, functional, or innocent heart murmurs, including patients with aortic valve sclerosis as defined by focal areas of increased echogenicity and thickening of the leaflets without restriction of motion and a peak velocity of less than 2.0 m/sec (*level of evidence: C*) • Patients with echocardiographic evidence of physiologic MR in the absence of a murmur and with structurally normal valves (*level of evidence: C*) • Patients with echocardiographic evidence of physiologic TR and/or pulmonary regurgitation in the absence of a murmur and with structurally normal valves (*level of evidence: C*)	1. Prophylaxis against infective endocarditis is not recommended for nondental procedures (such as transesophageal echocardiography, esophagogastroduodenoscopy, or colonoscopy) in the absence of active infection (*level of evidence: B*)	Modified recommendation (changed text)

*This footnote is obsolete. Please see 2006 VHD Guideline (3) for footnote text.
CHD, congestive heart disease; MR, mitral regurgitation; MVP, mitral valve prolapse; TR, tricuspid regurgitation; VHD, valvular heart disease.
From Nishimura RA, Carabello BA, Faxon DP, et al: ACC/AHA 2008 guideline update on valvular heart disease: Focused update on infective endocarditis: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines: Endorsed by the Society of Cardiovascular Anesthesiologists, Society for Cardiovascular Angiography and Interventions, and Society of Thoracic Surgeons. Circulation 118:887-896, 2008.

incidence, and the risk associated with heparin may outweigh its benefit in the perioperative setting. According to the AHA/ACC guidelines, heparin can usually be reserved for those who have had a recent thrombus or embolus (arbitrarily within 1 year), those with demonstrated thrombotic problems when previously off therapy, those with a Björk-Shiley valve, and those with more than three risk factors (atrial fibrillation, previous thromboembolism, hypercoagulable condition, and mechanical prosthesis).[189] A lower threshold for recommending heparin should be considered in patients with mechanical valves in the mitral position, in whom a single risk factor would be sufficient evidence of high risk. Subcutaneous low-molecular-weight heparin offers an alternative outpatient approach.[190] It is appropriate for the surgeon and cardiologist to discuss the optimal perioperative manage-

ment for such a patient, including a review of the most recent guidelines.[191]

Regional anesthetic techniques might be avoided, although this issue is controversial.[192] Many practitioners do not hesitate to use regional anesthesia in the face of prophylaxis for deep venous thrombosis.[193-195] However, epidural hematoma has been associated with anticoagulant therapy in many reports. Large retrospective reviews of outcome after epidural or spinal anesthesia, or both, during or shortly before initiation of anticoagulant therapy with heparin have not reported neurologic dysfunction related to hematoma formation in any patient.[196,197] This paucity of damaging epidemiologic evidence, though reassuring, does not reduce the need for frequent evaluation of neurologic function and a search for back pain in the perioperative period after regional anesthesia in any patient receiving any clotting function inhibitor, including aspirin.[192,198-200] The risk of regional anesthesia concurrent with prophylaxis for deep venous thrombosis with heparin is greater with the use of low-molecular-weight heparin. (Heparin-induced thrombocytopenia has been treated successfully with intravenous immunoglobulin.[194]) The American Society of Regional Anesthesia and Pain Management has issued a consensus statement on the use of regional anesthesia in anticoagulated patients.[201] They suggest that the decision to perform spinal or epidural anesthesia/analgesia and the timing of catheter removal in a patient receiving antithrombotic therapy should be made on an individual basis, with the small though definite risk of spinal hematoma weighed against the benefits of regional anesthesia for a specific patient.

Deep venous thrombosis is so common in postoperative patients that almost 1% of postsurgical patients die of fatal pulmonary embolism (Table 35-12).[202] Because of this high mortality risk, prophylaxis against deep venous thrombosis has attained widespread acceptance; thus, prophylaxis often begins with 5000 units of heparin given subcutaneously 2 hours before surgery.[202-204] Other trials have shown equal effect with external pneumatic compression.[203,205] Persuading surgeons to use this technique may provide greater assurance in using regional anesthesia. Such an option, however, is not available for patients

with a prosthetic valve. New recommendations are available from the American College of Chest Physicians for prophylaxis against venous thromboembolism.[235a]

Another problem that can arise is managing a pregnant patient with a prosthetic valve during delivery. It is recommended that warfarin be replaced by subcutaneous heparin during the peripartum period. During labor and delivery, elective induction is advocated with discontinuance of all anticoagulant therapy, as indicated for the particular valve prosthesis (discussed earlier).[206]

Auscultation of the prosthetic valve should be performed preoperatively to verify normal functioning (Fig. 35-8).[207] Abnormalities in such sounds warrant preoperative consultation and verification of functioning.

Cardiac Conduction Disturbances: Cardiac Arrhythmias

Bradyarrhythmias, especially if profound or associated with dizziness or syncope, are generally managed with pacemakers (also see Chapters 34, 43, and 61). However, chronic bifascicular block (right bundle branch block with a left anterior or posterior hemiblock or a left bundle branch block with combined left anterior and posterior hemiblocks), even when only a first-degree heart block is present, can progress to complete heart block and sudden perioperative death on rare occasion. In six studies, less than 2% of the approximately 266 patients with bifascicular block progressed to complete heart block perioperatively.[208] On the other hand, these patients have a high 5-year mortality rate (160 of 554 patients, or 29%). Most of the deaths were related to tachyarrhythmias or MI—events not usually preventable by traditional pacemakers.[209] Thus, the presence of a bifascicular block on the ECG should make the anesthesiologist more worried about associated coronary artery disease or left ventricular dysfunction. Nevertheless, these patients rarely have complete heart block perioperatively. Therefore, prophylactic preoperative insertion of temporary pacing wires for bifascicular block does not seem warranted. However, a central route can be established in advance in the event that a temporary pacemaker needs to be inserted (most operating rooms do not rely on transthoracic pacing, although such might be attempted if available).[210] The actual pacemaker equipment and appropriate personnel should be immediately available and tested regularly because symptomatic heart block does occur perioperatively in more than 1% of patients. One study appears to have confirmed this rate of at least 1% for patients undergoing cardiac surgery.[211] One percent of patients in whom a pacing pulmonary artery catheter was not inserted preoperatively subsequently required pacing before cardiopulmonary bypass. By contrast, 19% of patients who had such a catheter in place underwent cardiac pacing before cardiopulmonary bypass. Predictors of the need for pacing included previous symptomatic bradyarrhythmia, a history of transient complete AV block, and aortic valve disease.

More than five PVCs per minute on preoperative examination correlates with perioperative cardiac morbidity.[142,147,153,154] To the classic criteria for treating PVCs (the presence of R-on-T couplets, the occurrence of more than three PVCs per minute,

Prosthesis Type	Mitral Prosthesis	Acoustic Characteristics	Aortic Prosthesis	Acoustic Characteristics
Ball valves		1) A_2–MO Interval 0.07–0.11 sec. 2) MV > MC 3) II-III/VI Systolic ejection murmur (SEM) 4) No diastolic murmur		1) S_1–AO Interval 0.07 sec. 2) AO > AC 3) II/VI harsh SEM 4) No diastolic murmur

and multifocality of PVCs) must be added frequent (>10/hr over a 24-hour period) and repetitive ventricular beats. Electrophysiologic and programmed ventricular stimulation studies are being used to indicate and guide treatment of patients with ischemic heart disease or recurrent arrhythmias and survivors of out-of-hospital cardiac arrest. Although such patients are often treated with antiarrhythmic therapy, attention to their underlying condition should be a focus of our preoperative management. Chronic antiarrhythmic therapy is discussed in the last section of this chapter. Torsades de pointes is an arrhythmia characterized by episodes of alternating electrical polarity such that the major vector of the QRS complex seems to alternate around an isoelectric line. The hallmark enabling differential diagnosis from ventricular tachycardia is the unusual response of this arrhythmia to commonly used antiarrhythmic drugs. That is, the use of drugs that prolong the QT interval (e.g., quinidine, procainamide, disopyramide, some of the antihistamines, and the antipsychotic phenothiazines) may well make the arrhythmia more frequent or of longer duration. Reports of the sudden occurrence of torsades de pointes during surgery have been rare in the anesthesia literature. Immediate therapy consists of the administration of magnesium or electrical cardioversion, followed by overdrive cardiac pacing or the administration of β-adrenergic agonists and discontinuation of drugs that prolong the QT interval.

Premature atrial contractions and cardiac rhythm other than sinus also correlate with perioperative cardiac morbidity.[142,153] These arrhythmias may be more a marker of poor cardiovascular reserve than a specific cause of perioperative cardiac complications.

Pre-excitation syndrome is the name for supraventricular tachycardias associated with AV bypass tracts.[212] Successful treatment, which is predicated on an understanding of the clinical and electrophysiologic manifestations of the syndrome, consists of either catheter ablation techniques[209] or surgery using preoperative and intraoperative techniques that avoid release of sympathetic and other vasoactive substances and therefore tachyarrhythmias.[213,214] Anesthesia for electrophysiologic procedures is discussed in Chapter 61.

Disorders of the Respiratory and Immune Systems

General Preoperative and Preprocedure Considerations

Pulmonary complications after procedures requiring anesthesia are as common as cardiovascular complications—even more common if deep venous thrombosis is included. Moreover, pulmonary complications are equally or more important to the patient and health system in terms of morbidity, mortality, length-of-stay extension, and cost.

Although little may seem to have changed in the preoperative preparation of patients with respiratory disease, this impression is not true. Major changes in drug therapy have occurred, and appreciation of the effects of smoking and sleep apnea on perioperative and chronic care has increased.[215-232] (Preoperative and preprocedure identification and perioperative care of patients with sleep apnea are discussed in the earlier section on obesity and in Chapter 64.)

The main purpose of preoperative testing is to identify patients at risk for perioperative complications so that appropriate perioperative therapy can be instituted to foster return to functional status. Preoperative assessment can also establish baseline function and the feasibility of surgical intervention. Whereas numerous investigators have used pulmonary function tests to define inoperability or high-risk versus low-risk groups for pulmonary complications, few have been able to demonstrate that the performance of any specific preoperative or intraoperative measure, save perhaps smoking cessation and physical activity such as a walking program, reliably decreases perioperative pulmonary morbidity or mortality. Because routine preoperative pulmonary testing and care are discussed extensively in Chapters 44 and 59, the current discussion is limited to an assessment of the effectiveness of this type of care.

In fact, few randomized prospective studies indicate an outcome benefit of preoperative preparation, and we do not even have such for smoking cessation or walking—only epidemiologic data; a larger cohort has implied a benefit of intraoperative and postoperative pain therapy techniques (usually planned preoperatively).[227-232] Stein and Cassara[228] randomly allocated 48 patients to undergo preoperative therapy (cessation of smoking, administration of antibiotics for purulent sputum, and use of bronchodilating drugs, postural drainage, chest physiotherapy, and ultrasonic nebulizer) or no preoperative therapy. The no-treatment group had a mortality of 16% and morbidity of 60%, as opposed to 0% and 20%, respectively, for the treatment group. In addition, the treatment group spent an average of 12 postoperative days in the hospital as compared with 24 days for the 21 survivors in the no-treatment group.

Collins and colleagues[233] prospectively examined the benefits of preoperative antibiotics, perioperative chest physiotherapy and therapy with bronchodilating drugs, and routine postoperative analgesia (morphine) on postoperative respiratory complications in patients with COPD. Of these therapies, only preoperative treatment with antibiotics had a beneficial effect.

Warner and coworkers[234] collected data retrospectively about smoking history and prospectively (concurrently) about pulmonary complications for 200 patients undergoing CABG. These investigators documented that 8 weeks or more of smoking cessation was associated with a 66% reduction in postoperative pulmonary complications. Smokers who stopped for less than 8 weeks actually had an increase (from 33% for current smokers to 57.1% for recent quitters) in the rate of one or more of the six complications surveyed: purulent sputum with pyrexia; need for respiratory therapy care; bronchospasm requiring therapy; pleural effusion or pneumothorax (or both) necessitating drainage; segmental pulmonary collapse, as confirmed by radiography; or pneumonia necessitating antibiotic therapy. Others have found that both shorter and longer periods of cessation of smoking were needed before achieving cardiovascular[235] and hematologic benefit.[236] Of note, Bluman and associates[237] performed a retrospective chart review of 410 patients undergoing noncardiac surgery at a VA hospital. Current smoking was associated with a nearly sixfold increase in risk for a postoperative pulmonary complication. Reduction in smoking within 1 month of surgery was not associated with a decreased risk for postoperative pulmonary complications. Nakagawa and coauthors also reported higher pulmonary complication rates in patients undergoing pulmonary

surgery who quit within 4 weeks of surgery than in current smokers or those who had stopped smoking for more than 4 weeks.[238] The fact that anesthesiologists rarely see their patients 4 weeks or more before surgery presents a dilemma: if one is unable to advise the patient to stop smoking 8 weeks or more before surgery, is it preferable for the patient to continue smoking? Perhaps these data will further support the implementation of preoperative and preprocedure assessment clinics in which anesthesiologists are able to advise and counsel patients about risk reduction.

At the Cleveland Clinic we have embarked on an active campaign motivated by several articles[239,240] and the ASA's efforts to use the preprocedure time of heightened awareness of health to try to motivate each patient who smokes to quit smoking as soon as recovery from surgery has begun. In the first 7 months we referred more than 1000 patients (of about 5000 admitted smokers) to a "breath free" clinic that follows a low-cost Web-based doctor-supervised process (Box 35-4) and succeeded in helping over 50% of those who kept their initial appointment successfully quit. Although that rate is lower than rates in patients self-referred and self-reported to websites that use the same protocol (Oprah.com and Real Age.com—where we have more than 120,000 self-reported successful quitters), we consider the effort worthwhile. Many fewer patients (about 100) have decided to quit before surgery (L. Skolaris and I. Hasan, personal communication).

When Skolnick and coworkers[226] studied 602 children prospectively, exposure to passive smoking (as measured by urinary cotinine, the major metabolite of nicotine) correlated directly with airway complications. Children with the least exposure to passive smoke had the fewest complications. Second-hand smoke may be a model for particulate air pollution with PM 2.5 particles, which have immediate and long-term effects in increasing lung dysfunction and inflammatory stimuli throughout the body.[241,242] In this sense, reducing particulate and diesel exhaust exposure in the 2 weeks before surgery might make sense, but such a hypothesis has not been tested (and outpatient surgery centers off busy freeways might prove to make such subtle inhibition of healing secondary to diesel particles an appropriate site to study).

As for things to do, Celli and associates[243] performed a randomized prospective controlled trial of intermittent positive-pressure breathing (IPPB) versus incentive spirometry and deep-breathing exercises in 81 patients undergoing abdominal surgery. The groups exposed to a respiratory therapist (regardless of the treatment given) had more than a 50% lower incidence of clinical complications (30% to 33% versus 88%) and shorter hospital stays than the control group did. Thus, this third prospective study indicates that outcome improves when there is any concern about

Box 35-4 You Tool: Breathe Free Program

Smoking Cessation Plan*

One of the most powerful addictions isn't bridal reality shops; it's cigarette smoking. Here, in our Breathe Free Program, developed with Daniel Seidman, MD, and the Cleveland Clinic team, we're going to teach you how to stop the addiction so that you can gain back the 8 to 13 years you've taken off your life (half in length and half in disability and illness) through those nasty sticks. Yes, you get a do-over here too and can make yourself younger even if you've burned your fingers with 20 cigarettes every day.

Step 1: Assess Yourself

Answer the following questions to see if you've lost control of your smoking behavior and it's turned into a full-fledged dependence.

1. **Have you smoked every day for at least the past several weeks?**
2. **Do you experience any of the following withdrawal symptoms after you stop or reduce your amount of smoking ("withdrawal symptoms can begin within a few hours of cessation")?**
   - Depressed mood
   - Insomnia
   - Irritability, frustration, or anger
   - Anxiety
   - Difficulty concentrating
   - Restlessness
   - Decreased heart rate
   - Increased appetite or weight gain
3. **Do you experience significant distress because of the symptoms in Question 2? Do you avoid social or work obligations—or leave in the middle of these obligations—because of significant distress or discomfort from not smoking?**

   If you answer "yes" to Question 1, "yes" to at least four of the symptoms in Question 2, and/or "yes" to Question 3, then you have a problem and may even meet the psychiatric definition for nicotine withdrawal. Knowing this can help build your commitment to change and to learning to breathe free.
4. **In the past year, was there a day you didn't smoke at all—not even a puff?**

   If you answered "yes," think about how you did it and how you then went back to smoking. Try to learn from what worked and what didn't.

   If you answered "no," don't despair. The movie in your head about how impossible breaking free from smoking will be probably is greatly exaggerated. With proper use of medicines and a good behavioral plan, it's possible to break free of smoking. We know, we helped over 700 people individually and over 80,000 using our Web-based programs (see oprah.com or realage.com). If you follow our plan and have a buddy to help, we believe your chance of success is over 60% each time you try—so three tries will get you to over a 90% chance of success.

*The Breath Free plan is copywritten by the YOU Docs in *YOU Being Beautiful: The Owner's Manual to Outer and Inner Beauty* (Free Press, 2008, United States), reprinted here by permission of the copyright owner and offered to all who want to use it—feel free to copy and hand to patients (as long as credit is given).

Box 35-4 You Tool: Breathe Free Program—cont'd

5. **Do you continue to smoke despite having a tobacco-caused medical problem such as bronchitis or COPD (chronic obstructive pulmonary disease)?**

   If you answered "yes," consider that almost all smokers are well aware of the medical problems associated with smoking. After all, they are listed on every pack you smoke. Even when told it is a matter of life and death, many continue to smoke after having a heart attack, lung surgery, or oral cancer removed. This behavior mystifies your loved ones and even leaves you, the smoker, bewildered, yet this is a hallmark of addiction and distinguishes it from "bad habits," which also involve automatic behavior. The difference is that bad habits predictably don't cause real and serious life consequences—a 20-can-a-day diet cola habit doesn't invariably result in troubles, nor does picking your nose.

6. **Do you get less of an effect—of pleasure or satisfaction—from the same number of cigarettes each day?**

7. **Do you continue to smoke, even though you enjoy only 10% to 20% of the cigarettes you light up?**

   If you answered "yes" to Questions 6 and 7, know that many people get sick of their addiction over time, especially after age 40. What was social and fun becomes rote habit with less pleasure than advertised. Keeping this in mind can motivate you to move forward with breathing free.

8. **Do you still enjoy smoking most or all of the time?**

   If you answered "yes," ask yourself if it would be nice to shed the burden of guilt and shame you carry from smoking? Remember, this is your body, and there is only one available for each customer. So even with all the new replacement parts available, you still can't protect your body from all the pollution in the cigarette smoke.

9. **Do you feel anxious and nervous, and has this continued every day for the past 2 weeks?**

   If you answered "yes," you may have more anxiety about getting through your breathe-free day—the day you go completely tobacco free. In that case, you may need to pay extra attention to the next step—working on preparation, confidence building, and motivation.

10. **Do you feel sad and blue, and has this continued every day for the past 2 weeks?**

    If you answered "yes," you may have more emotional discomfort after getting through your breathe-free day. You may also need to carefully review with your doctor nicotine withdrawal symptoms and the use of successful strategies to learn to live well without tobacco.

Step 2: Do the Prep Work

You're about to make a big change, one that requires some planning. Give yourself a month (31 days) to do all the prep work.

- **Promise yourself**: Make a personal pact with yourself to quit.
- **Set a quit date:** Make it at least a month from today
- **Take the Breathe Free Pledge:** See below.

As of _____, my official "Quit Date," I pledge to commit to breathing free!

My reasons for quitting smoking: _____ _____.

I have found a buddy I will call daily: _____ _____.

I recognize that this may be one of the greatest challenges of my life, but I also know that breathing free is the best decision I can make to protect and improve my health. Upon signing this contract, I make a commitment to myself to breathe free and free myself from the limitations placed on me by my addiction.

I don't know what will happen or how difficult it will be, but I can get help from _____ _____, and I have decided to (check one):

___ 1. Walk for 30 days and try nicotine patches (21 or 22 mg if I smoke a pack a day or so) and bupropion (100 mg twice a day—a reduced dose of Zyban) plus my buddy

___ 2. Use nicotine patches (or nicotine gum or nicotine oral inhaler) alone (plus my buddy)

___ 3. Use varenicline (Chantix) alone (plus my buddy)

I also know that staying smoke free (not having "just one") after the initial breathe-free period is important, and I have asked my friends and family to support me and not smoke around me. I will also continue to talk daily to my buddy for at least 6 months, and then I'll become a buddy to others.

By committing to a life of breathing free, I will ensure a healthier future for myself, and I will protect the well-being of my loved ones and everyone around me who will no longer be exposed to the dangers of second-hand smoke. I know that I am not only motivated but also committed and willing to make the effort to become a nonsmoker.

I deserve to give myself the healthiest life possible and breathe free!

- **Think of the three biggest reasons why you're quitting**: Write them on a card that you can carry with you and look at several times each day.
- **Be restrictive**: Eliminate smoking in two or three situations that usually prompt you to smoke.
- **Cut back**: Reduce the number of cigarettes you smoke to one pack a day or less.
- **Go cheap**: Change to a less desirable brand of cigarettes.
- **Need a light**: Discard your lighter and matches.
- **Misplace your cigarettes:** Carry them in a different place than you usually do.
- **Role-play**: Spend a little time each day imagining yourself in stressful situations in which you are not smoking.

(Continued)

Box 35-4 You Tool: Breathe Free Program—cont'd

Do the following four things, which will make quitting easier and could be the keys to your success.

- **Start walking 30 minutes a day—every day.**

Before you actually stop smoking, you have to establish another behavior—walking 30 minutes a day, every day—in its place. No excuses—you miss a day, you reset the clock to day 0. That is because another behavior takes at least 30 days to form. However, after a month of walking, you'll have two of the things you need to stick with our plan: more physical stamina and greater mental discipline.

- **Find a quitting buddy**.

Don't quit alone. We know from experience that everyone needs to be encouraged by someone—and your buddy is that someone. However, you shouldn't be the only one relying on other people; try to find a support partner who needs you as much as you need him or her.

- **See if you're covered**.

More and more insurance plans are offering some level of coverage for quit-smoking efforts. Ask your insurance company about its coverage. If your aren't insured, ask your HR department—many cover the cost (about $600 for 6 months—it really is cheaper than a pack a day, but we know dollars spent for medical expenses and smoking are usually segregated in smokers' minds and hearts).

- **Schedule a checkup.**

Quitting smoking is physically and mentally stressful, and you want to be sure you have no conditions that might interfere with the tools, techniques, and medications suggested in this program. So talk to your doctor about the following prescriptions to help you stop smoking:

1. Bupropion (Zyban or Wellbutrin) in 100-milligram tablets—one twice a day. Bupropion is an anticraving drug (it's also an antidepressant at higher doses) that can help you make the transition from smoker to quitter. It can interact with other medications, so make sure your doctor's aware of any drugs you're taking, particularly for high blood pressure or seizure disorders.
2. Nicotine patches. Talk with your doctor to figure out what strength would be best for you—for a one-pack-a-day habit it's usually 22 milligrams.

Quitting day is almost here—it's time to start getting your body ready to fight future cravings.

- **Start taking bupropion.** On day 30, 2 days before you'll actually stop smoking, take one tablet in the morning.
- **Keep taking bupropion**. On day 31, take one bupropion tablet in the morning.

Step 3: Break the Habit

Today's the day you stop smoking. If you've done the prep work, you're ready.

- **On day 32, QUIT**: Throw away all your cigarettes, and get rid of all ashtrays and any other smoking-related objects.
- **Put on a nicotine patch**. Place one on your arm, chest, or thigh (you'll be doing this daily for a while).
- **Take your bupropion**: One in the morning and one at night.

Here are your daily to-do's for days 33 through 61.

- **Take two**: Increase your bupropion to two tablets a day—one in the morning and another in the evening.
- **Patch up**: Put on a new one every day (and don't forget to take the old one off).
- **Keep walking**: Every day for 30 minutes.
- **Reach out**: Check in with your buddy.
- **Drink up**: Have as much coffee or water as you wish.

Step 4: Enjoy Life as an Ex-Smoker

Making it through a month without smoking is a huge accomplishment. It's time to celebrate the new YOU! Here are some to-do's for day 62 and beyond.

- **Breathe in**: Enjoy how quitting has made your lungs happier.
- **Push yourself**: Use your newfound vitality to start a strength-building routine. But take it slow; don't increase your physical activity by more than 10% a week.
- **Love life without the patch**: Every 2 months, decrease the dose of your nicotine patch by a third. Your goal is to be patch free after 6 months.
- **Say bye-bye bupropion**: But make it a slow goodbye. At 5 months, decrease your bupropion to one tablet in the evening, and aim to be off it entirely by your 8-month anniversary. Tip: Just in case you feel a craving, for the rest of your life carry one bupropion tablet with you at all times so that you can take it if you need to.

lung function on the part of someone knowledgeable in maneuvers designed to clear lung secretions.

Bartlett and coworkers[244] randomly assigned 150 patients undergoing extensive laparotomy to one of two groups. One group received preoperative instruction in and postoperative use of incentive spirometry (10 times per hour). The other group received similar medical care but no incentive spirometry. Only 7 of 75 patients using incentive spirometry had postoperative pulmonary complications, as opposed to 19 of 75 in the control group. However, other studies have not shown a benefit for specific treatments or have been too contaminated with bias to have a clear result emerge. Lyager and colleagues[245] randomly assigned 103 patients undergoing biliary or gastric surgery to receive either incentive spirometry with preoperative and postoperative chest physiotherapy or only preoperative and postoperative chest physiotherapy. No difference in the postoperative course or pulmonary complications was found between the two groups. Other studies have shown a specific benefit (i.e., above that provided by routine care) for chest physiotherapy and IPPB. These studies are usually poorly controlled, not randomized, or retrospective in design (or any combination of the three); these deficiencies probably substantially bias the results toward finding a benefit in

Table 35-13 Grade of Dyspnea Caused by Respiratory Problems (Assessed In Terms of Walking on a Level Surface at a Normal Pace)

Category	Description
0	No dyspnea while walking on a level surface at a normal pace
I	"I am able to walk as far as I like, provided I take my time"
II	Specific (street) block limitation ("I have to stop for a while after one or two blocks")
III	Dyspnea on mild exertion ("I have to stop and rest while going from the kitchen to the bathroom")
IV	Dyspnea at rest

Modified from Boushy SF, Billing DM, North LB, et al: Clinical course related to preoperative pulmonary function in patients with bronchogenic carcinoma. Chest 59:383, 1971.

reducing postoperative pulmonary complications. Although randomized prospective studies showed no benefit or actual harm from chest physiotherapy and IPPB on the resolution of pneumonia or postoperative pulmonary complications, the four studies cited earlier[228,233,243,244] and numerous retrospective studies strongly suggest that preoperative evaluation and treatment of patients with pulmonary disease actually decrease perioperative respiratory complications, even if only by causing a change in anesthetic techniques.

Recent meta-analyses have suggested a benefit of anesthetic and pain management with respect to respiratory outcomes. Rodgers and associates reviewed 141 trials involving 9559 patients who had been randomized to receive neuraxial blockade or general anesthesia. Overall mortality was significantly lower in the neuraxial blockade group (2.1% versus 3.1%). The relative risk of pneumonia in the neuraxial group was 0.61 (CI, 0.48 to 0.81), and the relative risk of respiratory depression was 0.41 (CI, 0.23 to 0.73).[227]

Not all studies demonstrate beneficial effects of pretreatment. In afebrile outpatient ASA class I and II children with no lung disease or findings who underwent noncavitary, nonairway surgery lasting less than 3 hours, neither albuterol nor ipratropium premedication decreased adverse events.[246]

Evaluation of dyspnea is especially useful and thus warrants discussion here (for a review of specific pulmonary function tests that identify high-risk groups, see Chapter 44). Boushy and coworkers[247] found that grades of preoperative dyspnea correlated with postoperative survival. (Grades of respiratory dyspnea are provided in Table 35-13.) Mittman[248] demonstrated an increased risk of death after thoracic surgery, from 8% in patients without dyspnea to 56% in patients who were dyspneic. Similarly, Reichel[249] found that no patients died after pneumonectomy if they were able to complete a preoperative treadmill test for 4 minutes at the rate of 2 mph on level ground. Other studies have found that the history and physical examination of an asthmatic subject can also predict the need for hospitalization.[217] Wong and colleagues[250] found that the risk index (Table 35-14) correlated with postoperative pulmonary complications. Other than dyspnea, what preoperative conditions make postoperative respiratory complications more likely? (See also Chapter 34.)

Arozullah and associates developed the first validated multifactorial risk index for postoperative respiratory failure, defined as mechanical ventilation for more than 48 hours after surgery or reintubation and mechanical ventilation after postoperative extubation.[251] In a prospective cohort study of 181,000 male veterans as part of the National Veterans Administration Surgical Quality Improvement Program, seven factors independently predicted risk (Table 35-15). With increasing numbers of risk factors present, the rate of complications increased from 0.5% (class 1) to 26.6% (class 4). Arozullah and colleagues subsequently developed a risk index for postoperative pneumonia by using data on 160,805 patients undergoing major noncardiac surgery and validated the index by using data on an additional 155,266 patients.[252] Patients were divided into five risk classes by using risk index scores (Table 35-16). Pneumonia rates were 0.2% in those with 0 to 15 risk points, 1.2% in those with 16 to 25 risk points, 4.0% in those with 26 to 40 risk points, 9.4% in those with 41 to 55 risk points, and 15.3% in those with more than 55 risk points.

Preoperative evaluation of patients with pulmonary disease can be found in Chapters 34 and 44. Despite the lack of definitive data establishing the efficacy of preoperative pulmonary testing and therapy, we recommend the following approach:

1. Eradicate acute infections and suppress chronic infections by using appropriate diagnostic measures and antibiotic treatment.
2. Relieve bronchospasm by using inhaled corticosteroids and bronchodilating drugs and document such relief with measurements of FEV_1 (also see Chapter 44).

Table 35-14 Classification of Risk of Pulmonary Complications for Thoracic and Abdominal Procedures

Category	Points*
I. Expiratory spirogram	
A. Normal (% FVC + [% FEV_1/FVC] > 150)	0
B. % FVC + (% FEV_1/FVC) = 100-150	1
C. % FVC + (% FEV_1/FVC) < 100	2
D. Preoperative FVC > 20 mL/kg	3
E. Postbronchodilator FEV_1/FVC < 50%	3
II. Cardiovascular system	
A. Normal	0
B. Controlled hypertension, myocardial infarction without sequelae for more than 2 yr	0
C. Dyspnea on exertion, orthopnea, paroxysmal nocturnal dyspnea, dependent edema, congestive heart failure, angina	1
III. Nervous system	
A. Normal	0
B. Confusion, obtundation, agitation, spasticity, discoordination, bulbar malfunction	1
C. Significant muscular weakness	1
IV. Arterial blood gases	
A. Acceptable	0
B. $Paco_2$ >50 mm Hg or Pao_2 <60 mm Hg on room air	1
C. Metabolic pH abnormality >7.50 or <7.30	1
V. Postoperative ambulation	
A. Expected ambulation (minimum, sitting at bedside) within 36 hr	0
B. Expected complete bed confinement for ≥36 hr	1

Modified from Wong DH, Weber EC, Schell MJ, et al: Factors associated with postoperative pulmonary complications in patients with severe COPD. Anesth Analg 80:276, 1995.

Table 35-15 Preoperative Predictors of Postoperative Respiratory Failure

Variable	Odds Ratio (95% Confidence Interval)
Type of surgery	
Abdominal aortic aneurysm	14.3 (12.0-16.9)
Thoracic	8.14 (7.17-9.25)
Neurosurgery, upper abdominal, or peripheral vascular	4.21 (3.80-4.67)
Neck	3.10 (2.40-4.01)
Other surgery*	1.00 (reference)
Emergency surgery	3.12 (2.83-3.43)
Albumin <0.30 g/L	2.53 (2.28-2.80)
Blood urea nitrogen >0.30 mg/dL	2.29 (2.04-2.56)
Partially or fully dependent status	1.92 (1.74-2.11)
History of COPD	1.81 (1.66-1.98)
Age (yr)	
≥70	1.91 (1.71-2.13)
60-69	1.51 (1.36-1.69)
<60	1.00 (reference)

*Other surgeries include ophthalmologic, ear, nose, mouth, lower abdominal, extremity, dermatologic, spine, and back surgery.
COPD, chronic obstructive pulmonary disease.
From Arozullah AM, Daley J, Henderson WG, et al: Multifactorial risk index for predicting postoperative respiratory failure in men after major noncardiac surgery. The National Veterans Administration Surgical Quality Improvement Program. Ann Surg 232:242-253, 2000, with permission.

3. In patients with bronchial asthma, consider the administration of corticosteroids beginning at least 48 hours before surgery in patients with a significant history of bronchospastic disease to achieve the maximal effect at the time of surgery. No randomized data support such an approach, but studies have not shown an increase in the risk for respiratory infection or wound complications.[253]
4. Institute measures to improve sputum clearance and familiarize the patient with respiratory therapy equipment (incentive spirometry) and postural drainage maneuvers. Initiate practice coughing and deep-breathing exercises.
5. Treat uncompensated right ventricular heart failure and heart rate with digoxin, diuretics, oxygen, and drugs that decrease pulmonary vascular resistance (e.g., hydralazine).[254]
6. The use of low-dose heparin prophylactically to decrease the incidence of venous thrombosis (and pulmonary emboli) has been the standard.[255,256] More recently, the use of low-molecular-weight heparin and intermittent compression stockings has become the standard for high-risk patients.[235a,255,256]
7. Identify and treat suspected or diagnosed sleep apnea with continuous positive airway pressure (CPAP), biphasic positive airway pressure (BiPAP), or other measures as indicated earlier (in the section "Disorders of Nutrition, Including Obesity").
8. Encourage reduction or cessation of smoking at least 4 weeks and preferably 8 weeks or more before surgery.[234,239,240]

Specific Diseases

Pulmonary Vascular Diseases

Pulmonary vascular diseases include pulmonary hypertension secondary to heart disease (postcapillary disorders), parenchymal lung disease (pulmonary precapillary disorders), pulmonary embolism, and cor pulmonale from COPD.[257] Optimal preoperative management of these conditions requires treatment of the underlying disease.[257-259] Because pulmonary embolism can be particularly difficult to diagnose, it is crucial to be especially alert to the possibility of this disease. The clinical findings of pulmonary emboli are not always present or specific for the diagnosis. The history may include tachypnea, dyspnea, palpitations, syncope, chest pain, or hemoptysis. Physical examination can reveal a pleural rub, wheezing, rales, a fixed and split second heart sound, right ventricular lift, or evidence of venous thrombosis, none of which are present in most patients. If the ECG shows an

From Arozullah AM, Khuri SF, Henderson WG, et al: Development and validation of a multifactorial risk index for predicting postoperative pneumonia after major noncardiac surgery. Ann Intern Med 135:847-857, 2001, with permission.

S_1Q_3 pattern, spiral CT or lung perfusion scans can be obtained to rule out the diagnosis of pulmonary emboli. A high degree of suspicion is necessary to warrant angiography and anticoagulation or fibrinolytic therapy. If possible, the reactivity of the pulmonary vasculature should be determined, for it may be enhanced or decreased by such drugs as nifedipine, hydralazine, nitroglycerin, prazosin, tolazoline, phentolamine, sildenafil citrate, and nitric oxide. Monitoring of pulmonary artery pressure is often required; preoperative measures should be undertaken to ensure that the patient is not exposed to conditions that elevate pulmonary vascular resistance (e.g., hypoxia, hypercapnia, acidosis, lung hyperinflation, hypothermia)[260] or that decrease blood volume (prolonged restriction of fluid intake) or systemic vascular resistance.

Infectious Diseases of the Lung

Preoperative evaluation and treatment should follow the basic guidelines outlined in the introduction to this section and Chapter 34; treatment of the underlying disease should be completed before all but emergency surgery is performed.

Even though elective surgery should be postponed whenever infectious diseases of the lung are present, patients undergoing emergency surgery often have nosocomial infections and immunocompromised systems. The predominant pathogens for nosocomial pneumonia are gram-negative bacilli, *Staphylococcus aureus*, *Haemophilus influenzae*, anaerobes, and pneumococci. Furthermore, tuberculosis increased rapidly in the late 1980s and in the 1990s, probably because of reactivation in patients infected with HIV. Increased funding and directly observed antituberculosis therapy have more than offset immigrant and travel risk to cause it to decrease recently. Tuberculosis leads to chronic pulmonary and systemic symptoms. Affected patients may have malaise, headache, fever, hemoptysis, and extrapulmonary diseases affecting the skin, cervical lymph nodes, kidneys, pericardium, and meninges. Active disease is treated with four-drug therapy: isoniazid, pyrazinamide, ethambutol or streptomycin, and rifampin for 9 months. Therapy should probably be started before surgery. Management of these emergency patients (many of whom have adult respiratory distress syndrome) before they are brought to the operating room might include initiation of anti-infective therapy, optimization of fluid status and gas exchange, and therapy for the underlying pathophysiologic process.

Chronic Diseases of the Lung

Treatment of COPD (reactive airways) may include the use of β-adrenergic drugs, parasympatholytic agents (especially for exercise-induced asthma), systemic or inhaled corticosteroids, and leukotriene antagonists. An estimated 5% of the population has bronchospasm. Some investigators recommend using inhaled bronchodilators as first-line drugs and reducing the dose of inhaled steroids, such as beclomethasone dipropionate, budesonide, mometasone, or fluticasone, which are inactivated after absorption. However, in large doses, these "inhaled" steroids can suppress adrenal function, and supplemental systemic corticosteroids may be needed at times of stress (see earlier discussion under the section "Adrenocortical Malfunction"). Preoperative assessment must include gaining knowledge of drug regimens and their effects and education of the patient regarding proper use of an inhaler (Box 35-5) because these drugs can interact dangerously with anesthetics (see the last section of this chapter) or can be used inappropriately and therefore produce side effects without maximum benefit.[215-225] No known interaction between the inhaled anticholinergic ipratropium bromide and muscle relaxants has been reported. Patients can feel fine at rest but must be tested by exercise or spirometry to document the degree of current bronchospasm. Furthermore, a symptomatic response to bronchodilators in an asymptomatic patient may not predict whether the patient responds to bronchodilator therapy. An estimated 10% of asthmatic patients exhibit sensitivity to aspirin and may react not only to compounds containing aspirin but also to tartrazine, yellow dye No. 5, indomethacin, other nonsteroidal anti-inflammatory drugs, and aminopyrine.[261]

Box 35-5 Procedures for Correct Use of a Metered-Dose Inhaler

Remove the cap and hold the inhaler upright.

Shake the inhaler.

Tilt the head back slightly and exhale steadily to functional residual capacity.

Position the inhaler by using a spacer between the actuator and the mouth.

Press down on the inhaler while taking a slow, deep breath (3 to 5 seconds).

Hold the full inspiration for at least 5 and up to 10 seconds, if possible, to allow the medication to reach deeply into the lungs.

Repeat inhalations as directed. Waiting 1 minute after inhalation of the bronchodilator may permit subsequent inhalations to penetrate more deeply into the lungs and is necessary to ensure proper delivery of the dose. Rinse your mouth and expectorate after using the inhaler.

Cystic fibrosis is characterized by dilatation and hypertrophy of the bronchial glands, mucous plugging of the peripheral airways, and frequently, bronchitis, bronchiectasis, and bronchiolectasis. For all these conditions, the measures recommended earlier in this section, as well as appropriate hydration to allow mobilization of secretions, constitute optimal preprocedure therapy.

Surgical resection is the primary therapy for non–small cell carcinomas (e.g., adenocarcinoma, squamous cell carcinoma, and large cell carcinoma). These carcinomas account for 75% of all lung carcinomas, 12% of all malignant tumors, and 20% of all cancer deaths in the United States.[262] Success of surgery can be predicted by the stage of the tumor.

The combination of chemotherapy and radiation therapy is the current treatment of choice for small cell carcinomas of the lung.[263] Oat cell (small cell) carcinoma of the lung and bronchial adenomas are known for their secretion of endocrinologically active substances, such as ACTH-like hormones. Squamous cell cancers in the superior pulmonary sulcus produce Horner's syndrome, as well as characteristic pain in areas served by the eighth cervical nerves and first and second thoracic nerves. These tumors are now treated with preoperative radiation; surgical resection leads to an almost 30% "cure" rate.

Anaphylaxis, Anaphylactoid Responses, and Allergic Disorders Other Than Those Related to Lung Diseases and Asthma

Anaphylactic and Anaphylactoid Reactions

Anaphylaxis is a severe life-threatening allergic reaction. *Allergic* applies to immunologically mediated reactions, as opposed to those caused by pharmacologic idiosyncrasy, by direct toxicity or drug overdosage, or by drug interaction.[264-266] Anaphylaxis is the typical immediate hypersensitivity reaction (type I). Such reactions are produced by immunoglobulin E (IgE)-mediated release of pharmacologically active substances. These mediators in turn produce specific end-organ responses in the skin (urticaria), the respiratory system (bronchospasm and upper airway edema), and the cardiovascular system (vasodilation, changes in inotropy, and increased capillary permeability). Vasodilation occurs at the level of the capillary and postcapillary venule and leads to erythema, edema, and smooth muscle contraction. This clinical syndrome is called *anaphylaxis*. By contrast, *anaphylactoid reaction* denotes an identical or very similar clinical response that is not mediated by IgE or (usually) an antigen-antibody process.[265,266]

In anaphylactic reactions, an injected or inhaled (or injested) substance—usually drugs, food, or insect venom—can serve as the allergen itself. Low-molecular-weight agents are believed to act as haptens that form immunologic conjugates with host proteins. The offending substance, regardless of whether it is a hapten, may be the parent compound, a nonenzymatically generated product, or a metabolic product formed in the patient's body. When an allergen binds immunospecific IgE antibodies on the surface of mast cells and basophils, histamine and eosinophilic chemotactic factors of anaphylaxis are released from storage granules in a calcium- and energy-dependent process.[265,266] Other chemical mediators are rapidly synthesized and subsequently released in response to cellular activation. These mediators include slow-reacting substance of anaphylaxis, which is a combination of three leukotrienes; other leukotrienes[265,266]; kinins; platelet-activating factors; adenosine; chemotactic factors; heparin; tryptase; chymase; and prostaglandins, including the potent bronchoconstrictor prostaglandin D_2, eosinophil growth and activating factors, mast cell growth factors, and proinflammatory and other factors that contribute to the IgE isotype switch.

The end-organ effects of the mediators produce the clinical syndrome of anaphylaxis. Usually, a first wave of symptoms, including those caused by vasodilation and a feeling of impending doom, is quickly followed by a second wave as the cascade of mediators amplifies the reactions. In a sensitized patient, onset of the signs and symptoms caused by these mediators is usually immediate but may be delayed 2 to 15 minutes or, in rare instances, as long as 2.5 hours after the parenteral injection of antigen.[267,268] After oral administration, manifestations may occur at unpredictable times.

Mast cell proliferation, together with severe progressive inflammation, contributes to the worsening of symptoms that occurs even after an allergen load is no longer present. The antigen present in cells and lymphocytes, as well as activated mast cells, starts to induce the production of cytokines. These proinflammatory cytokines recruit more inflammatory cells, which leads to tissue edema and mediates a second wave of mast cell degranulation. This second wave can promote the recurrence of severe symptoms 6 to 8 hours later and necessitates, some believe, at least 8 hours of continued ICU-like observation.

In addition, there are multiple effector processes by which biologically active mediators can be generated to produce an anaphylactoid reaction. Activation of the blood coagulation and fibrinolytic systems, the kinin-generating sequence, or the complement cascade can produce the same inflammatory substances that result in an anaphylactic reaction. The two mechanisms known to activate the complement system are called classical and alternative. The classical pathway can be initiated through IgG or IgM (transfusion reactions) or plasmin. The alternative pathway can be activated by lipopolysaccharides (endotoxin), drugs (Althesin), radiographic contrast media,[269] membranes (nylon tricot membranes for bubble oxygenators), cellophane membranes of dialyzers, vascular graft material,[270] latex or latex-containing products,[271,272] and perfluorocarbon artificial blood. The most common agents responsible for intraoperative anaphylaxis are muscle relaxants.[272] However, latex accounts for a significant number of these reactions, and the incidence of intraoperative anaphylaxis caused by latex is increasing. It is now probably the second most important cause of intraoperative anaphylaxis. In addition, histamine can be liberated independent of immunologic reactions.[273] Mast cells and basophils release histamine in response to chemicals or drugs. Most narcotics can release histamine[273] and produce an anaphylactoid reaction, as can radiographic contrast media,[269] *d*-tubocurarine, and thiopental. What makes some patients susceptible to release of histamine in response to drugs is unknown, but hereditary and environmental factors may play a role.

Intravenous contrast material is probably the most frequently used agent that causes anaphylactoid reactions. Because diagnostic (skin and other) tests are helpful only in IgE-mediated reactions, pretesting is not useful for contrast reactions. Pretreatment with diphenhydramine, cimetidine (or ranitidine), and corticosteroids has been reported to be useful in preventing or ameliorating anaphylactoid reactions to intravenous contrast material[269,274] and perhaps to narcotics. Unfortunately, very large doses of steroids (1 g of methylprednisolone intravenously) may be necessary to obtain a beneficial effect.[275] The efficacy of large-dose steroid therapy has not been confirmed. Other common substances associated with anaphylactic or anaphylactoid reactions that might merit preoperative therapy include antibiotics, volume expanders, and blood products (Table 35-17).[265] The anesthesiologist should be prepared preoperatively to treat an anaphylactic or anaphylactoid response.

In some cases, a patient with a history of an anaphylactic or anaphylactoid reaction must receive a substance suspected of producing such a reaction (e.g., iodinated contrast material). In addition, some patients have a higher than average likelihood of having a reaction, thus warranting well-planned pretreatment and therapy for possible anaphylactic and anaphylactoid reactions.[269]

Minimizing Risks Preoperatively

Although virtually all evidence on this subject is merely anecdotal, enough consistent thought recurs through the literature to justify proposing an optimal approach to these problems. First, predisposing factors should be sought; patients with a history of atopy or allergic rhinitis should be suspected of being at risk. Because anaphylactic and anaphylactoid reactions to contrast media occur 5 to 10 times more frequently in patients with a previously suspected reaction, consideration should be given to the administration of low-osmotic agents and both H_1 and H_2 receptor antagonists for 16 to 24 hours before exposing these

Table 35-17 Incidence of Anaphylactic or Anaphylactoid Reactions to Some Common Agents

Agent	Incidence
Plasma protein	
Plasma protein derivative	0.019
Human serum albumin	0.011
Dextran 60/75	0.069
Dextran 40	0.007
Hydroxyethyl starch	0.085
Penicillin	0.002*
Chymopapain	0.3-1.5

*Fatal reactions.
Data modified from Levy JH, Roizen MF, Morris JM: Anaphylactic and anaphylactoid reactions: A review. Spine 11:282, 1986; and Moss J, McDermott DJ, Thisted RA, et al: Anaphylactic/anaphylactoid reactions in response to Chymodiactin (chymopapain). Anesth Analg 63:253, 1984.

patients to a suspected allergen. H_1 receptor antagonists appear to require this much time to act on the receptor. Volume status can be optimized,[265] and perhaps large doses of steroids (1 g of hydrocortisone) should also be administered before exposing patients to agents associated with a high incidence of anaphylactic or anaphylactoid reactions.[275] Older patients and patients taking β-adrenergic blocking drugs present special problems; they are at higher risk of having complications from both pretreatment (especially vigorous hydration) and therapy for anaphylactic reactions (glucagon is useful here) and are less responsive to treatment regimens.[276] One approach is to avoid drugs likely to trigger anaphylactic or anaphylactoid reactions or alter the treatment protocol for this group. Drawing blood for later analysis, especially of tryptase, can be useful in clarifying the diagnosis.[277]

With the increasing incidence of latex hypersensitivity, attempts have been made to make much of the operating room environment latex free; however, costs and preferences have resulted in the continued use of latex-containing gloves in many hospitals. Nonetheless, more hospitals are totally latex free. In allergic patients, care should be taken to ensure that no latex-containing products are present in the operating room.

Primary Immunodeficiency Diseases

Primary immunodeficiency diseases are usually manifested early in life as recurrent infections. Along with survival achieved with antibiotic and antibody treatment have come new prominent features: cancer and allergic and autoimmune disorders. Hereditary angioneurotic edema is an autosomal dominant genetic disease characterized by episodes of angioneurotic edema involving the subcutaneous tissues and submucosa of the GI tract and airway and often manifested as abdominal pain. These patients have a functionally impotent inhibitor or deficiency of an inhibitor to complement component C1. Treatment of an acute attack is supportive because epinephrine, antihistamines, and corticosteroids often fail to work. Plasma transfusions have been reported to resolve attacks or make them worse (theoretically by supplying either C1 esterase inhibitor or previously depleted complement components). The severity of attacks can be prevented or decreased by drugs that are either plasmin inhibitors (e.g., ε-aminocaproic acid [EACA] and tranexamic acid) or androgens (e.g., danazol). Because trauma can precipitate acute attacks, prophylactic therapy with danazol, intravenous EACA, plasma, or all three is recommended before elective surgery. Reports have also described the successful use of a partially purified C1 esterase inhibitor in two patients.

Most of the 1 in 700 persons who have selective IgA deficiency (i.e., <5 mg/dL) have repeated serious infections or connective tissue disorders. These infections commonly involve the respiratory tract (e.g., sinusitis, otitis) or GI tract (manifested as diarrhea, malabsorption, or both). If the patient has rheumatoid arthritis, Sjögren's syndrome, or systemic lupus erythematosus, the anesthetist should consider the possibility of isolated IgA deficiency. However, patients with this disorder can be otherwise healthy. Because antibodies to IgA may develop in these patients if previously exposed to IgA (as might occur from a previous blood transfusion), subsequent blood transfusions can cause anaphylaxis, even when they contain washed erythrocytes. Transfusions should therefore consist of blood donated by another IgA-deficient patient.

Many immunomodulators are now being given to augment cancer treatments[278]; no interactions between these modulators, no effects on the incidence of immune reactions during anesthesia, and no interactions with anesthetic effects have been reported except those regarding immune-suppressing drugs (see the last section of this chapter).

Immunonutrition[271] is increasingly being used preprocedurally by patients and prescribed by providers to decrease inflammatory responses. Whereas excellent data on the benefits of probiotics in changing the intestinal mileau to decrease inflammation can be found, limited data are available on their effects on periprocedural recovery or outcomes.

Diseases of the Central Nervous System, Neuromuscular Diseases, and Psychiatric Disorders

Evaluation of a patient with neurologic or psychiatric disease can be found in Chapter 34. Information gathered from the history that would warrant further investigation includes a previous need for postoperative ventilation in a patient without inordinate lung disease, which would indicate the possibility of metabolic neurologic disorders such as porphyria, alcoholic myopathy, other myopathies, neuropathies, and neuromuscular disorders such as myasthenia gravis. Other historical information warranting further investigation would be the use of drugs such as steroids; guanidine; anticonvulsant, anticoagulant, and antiplatelet drugs; lithium; tricyclic antidepressants; phenothiazines; and butyrophenones.

Although preoperative treatment of most neurologic disorders has not been reported to lessen perioperative morbidity, knowledge of the pathophysiologic characteristics of these disorders is important in planning intraoperative and postoperative management. Thus, preoperative knowledge about these disorders and their associated conditions (e.g., cardiac arrhythmias with Duchenne's muscular dystrophy or respiratory and cardiac muscle weakness with dermatomyositis) may reduce perioperative morbidity. A primary goal of neurologic evaluation is to determine the site of the lesion in the nervous system. Such localization to one of four levels (supratentorial compartment, poste-

rior fossa, spinal cord, peripheral nervous system) is essential for accurate diagnosis and appropriate management. (Disorders accompanied by increased intracranial pressure and cerebrovascular disorders are discussed in Chapters 13 and 63.)

Coma

Little is known about specific anesthetic or perioperative or periprocedural choices that alter outcome for a comatose patient, but as for all other conditions, it is imperative to know the cause of the coma so that drugs can be avoided that might worsen the condition or that might not be metabolized because of organ dysfunction. First, the patient should be observed. Yawning, swallowing, or licking of the lips implies a "light" coma with major brainstem function intact. If consciousness is depressed but respiration, pupillary reactivity to light, and eye movements are normal and no focal motor signs are present, metabolic depression is likely. Abnormal pupillary responses may indicate hypoxia, hypothermia, local eye disease, or drug intoxication with belladonna alkaloids, narcotics, benzodiazepines, or glutethimide; pupillary responses may also be abnormal, however, after the use of eye drops. Other metabolic causes of coma include uremia, hypoglycemia, hepatic coma, alcohol ingestion, hypophosphatemia, myxedema, and hyperosmolar nonketotic coma. Except in extreme emergencies, such as uncontrolled bleeding or a perforated viscus, care should be taken to render the patient as metabolically normal as possible before surgery. This practice and documenting the findings on the chart preoperatively lessen any confusion regarding the cause of intraoperative and postoperative problems. However, too rapid correction of uremia or hyperosmolar nonketotic coma can lead to cerebral edema, a shift of water into the brain as a result of a reverse osmotic effect caused by dysequilibrium of the urea concentration.

The physical examination can be extremely helpful preoperatively in assessing the prognosis. Arms flexed at the elbow (i.e., decorticate posture) imply bilateral hemisphere dysfunction but an intact brainstem, whereas extension of the legs and arms (bilateral decerebrate posture) implies bilateral damage to structures at the upper brainstem or deep hemisphere level. Seizures are often seen in patients with uremia and other metabolic encephalopathies. Hyperreflexia and upward-pointing toes suggest a structural CNS lesion or uremia, hypoglycemia, or hepatic coma; hyporeflexia and downward-pointing toes with no hemiplegia generally indicate no structural CNS lesion.

Epileptic Seizures

Epileptic seizures result from paroxysmal neuronal discharges of abnormally excitable neurons. Six percent to 10% of individuals younger than 70 years will experience a seizure at some time during their lifetime. Fifty percent to 70% of patients with one seizure will never have another. However, 70% of people with two seizures will have an epileptic focus, be candidates for antiseizure medications, and be subject to withdrawal seizures after anesthesia if such medications are not continued.[279] A seizure is the term for the clinical event defined as a paroxysmal alteration in neurologic function caused by a synchronous, rhythmic depolarization of brain cortical neurons. Epilepsy is the condition manifested by recurrent, unprovoked seizures. Sometimes syncopal episodes can be mistaken for seizures, especially when interviews are compressed in the short timeframe of a preoperative visit. We believe that each patient who gives a history of recent undiagnosed syncope or seizure should be seen by a specialist in this field before proceeding with anesthesia because anesthesia can provoke these conditions (see later).[280] Twenty-five percent of patients with a seizure have a normal electroencephalogram (EEG) when interictal. Thus, a negative EEG does not indicate that someone with a seizure will not have a withdrawal seizure when emerging from anesthesia. Seizures can be generalized (arising from deep midline structures in the brainstem or thalamus, usually without an aura or focal features during the seizure), partial focal motor, or sensory (the initial discharge comes from a focal unilateral area of the brain, often preceded by an aura). As with cerebrovascular accidents and coma, knowing the origin may be crucial to understanding the pathophysiologic processes of the disease and to managing the intraoperative and postoperative course.

Epileptic seizures can arise from discontinuation of sedative-hypnotic drugs or alcohol, use of narcotics, uremia, traumatic injury, neoplasms, infection, congenital malformation, birth injury, drug use (e.g., amphetamines, cocaine), hypercalcemia or hypocalcemia, blood in the ventricle or hypoxia, and vascular disease and vascular accidents. Thirty percent of epileptic seizures have no known cause. Most partial seizures are caused by structural brain abnormalities (secondary to tumor, trauma, stroke, infection, and other causes).

An epileptic patient requires no special anesthetic management other than that for the underlying disease. Most authorities believe that anticonvulsant medications should be given in the therapeutic range[279-281] and continued through the morning of surgery, even in pregnant women; they should also be given postoperatively, even in mothers who plan to breast-feed, according to guidelines published by the American Academy of Neurology. Many of the epileptic drugs, including phenytoin, carbamazepine, and phenobarbiturate, alter the hepatic metabolism of many drugs and induce cytochrome P450 enzyme activity. Drug-drug interactions are much less problematic with the newer epileptic drugs such as gabapentin and topirimate.[279] Appropriate treatment of status epilepticus may include general anesthesia.[281] In one controlled trial, phenobarbital was more rapidly effective in controlling status epilepticus than was diazepam followed by phenytoin.[281] The frequency of side effects and required tracheal intubation was similar for both regimens. High concentrations of enflurane (especially with hyperventilation) can be associated with EEG evidence of epileptic activity and tonic-clonic movements. These seizures, however, do not appear to have serious sequelae. Enflurane anesthesia does not seem to increase seizure activity in patients with a history of convulsive disorders, and it even suppresses seizures induced by electroshock, pentylenetetrazole, strychnine, picrotoxin, or bemegride. Thus, other than the use of current drug therapy and heeding precautions taken for the underlying disease, no known changes in perioperative management seem to be indicated.

Infectious Diseases of the Central Nervous System, Degenerative Disorders of the Central Nervous System, and Headache

Many degenerative CNS disorders have been traced to slowly developing viral diseases or even the presence of certain proteins

or viral particles ("prions"). No special perioperative anesthetic considerations appear to apply for infectious disorders of the CNS other than those for increased intracranial pressure and avoidance of occupational exposure and transmission of disease to health care workers (also see Chapter 101). The appropriate prophylactic measures to take if one comes in contact with meningococcal disease or other infectious CNS diseases are still not well established. The use of *H. influenzae* type b vaccine has made meningitis an adult disease.[282]

Parkinson's disease is a degenerative disorder of the CNS that may or may not be caused by a virus. Clinically, Parkinson's disease, chronic manganese intoxication, phenothiazine or butyrophenone toxicity, Wilson's disease, Huntington's chorea, traumatic boxing injury, the effects of street drug toxins such as methylphenyltetrahydropyridine (MPTP), and carbon monoxide encephalopathy all have similar initial features: bradykinesia, muscular rigidity, and tremor.

Newer therapies have been developed to arrest or even reverse the progression of Parkinson's disease. Therapy is directed at (1) increasing the neuronal release of dopamine or the receptor's response to dopamine, (2) stimulating the receptor directly with bromocriptine and lergotrile, (3) implanting dopaminergic tissue, or (4) decreasing cholinergic activity. New therapies using the monoamine oxidase inhibitor (MAOI) deprenyl or adrenal medullary transplants to slow the progression of disease appear promising,[283,284] and even treatment with high-dose coenzyme Q10 seems to be strikingly beneficial.[22] Experience with deprenyl in the perioperative milieu is insufficient to make proscriptions about its use. Anticholinergic agents have been the initial drugs of choice because they decrease tremor more than muscle rigidity. Dopamine does not pass the blood-brain barrier, so its precursor L-dopa (levodopa) is used. Unfortunately, L-dopa is decarboxylated to dopamine in the periphery and can cause nausea, vomiting, and arrhythmia. These side effects are diminished by the administration of α-methylhydrazine (carbidopa), a decarboxylase inhibitor that does not pass the blood-brain barrier. Refractoriness to L-dopa develops, and it is now debated whether the drug should be used only when symptoms cannot be controlled with other anticholinergic medications. "Drug holidays" have been suggested as one means of restoring the effectiveness of these compounds, but cessation of such therapy may result in a marked deterioration of function and need for hospitalization. Therapy for Parkinson's disease should be initiated before surgery and be continued through the morning of surgery; such treatment seems to decrease drooling, the potential for aspiration, and ventilatory weakness.[285,286] Reinstituting therapy promptly after surgery is crucial,[280,283-287] as is avoiding drugs such as the phenothiazines and butyrophenones (droperidol), which inhibit the release of dopamine (and perhaps alfentanil) or compete with dopamine at the receptor.[285] Carbidopa/levodopa in low doses (20 to 200 mg nightly versus the usual 60 to 600 mg/day for Parkinson's disease) is commonly used in the nonparkinsonian restless leg syndrome of the elderly (present in 2% to 5% of individuals older than 60 years). This drug too should be given the night before and the night immediately after surgery. Clozapine (a benzodiazepine) does not appear to worsen the movement disorders of Parkinson's disease and has been used postoperatively to stop levodopa-induced hallucinations.

Dementia, a progressive decline in intellectual function, can be caused by treatable infections (e.g., syphilis, cryptococcosis, coccidioidomycosis, Lyme disease, tuberculosis), depression (a trial of antidepressants is indicated in most patients), side effects of medications (digitalis has slowed brain function more than the heart rate), myxedema, vitamin B_{12} deficiency, chronic drug or alcohol intoxication, metabolic causes (liver and renal failure), neoplasms, partially treatable infections (HIV), untreatable infections (Creutzfeldt-Jakob syndrome), or decreased acetylcholine in the cerebral cortex (Alzheimer's disease). This last condition occurs in more than 0.5% of Americans.[288-291] Although these patients are often given cholinergic agonists, controlled trials of these drugs have not as yet shown major significant benefit.[289,290,292] Gingko has been advocated and has improved subjective symptoms in 37% of patients versus 23% of those given placebo. Although later controlled trials have failed to confirm its benefit in early Alzheimer's disease or in healthy elderly individuals, gingko is still popular. However, the prevalence of Alzheimer's disease and the desperation of the patients and their families have now widened such therapies. Cholinergic medications have been shown to improve functioning in patients with Alzheimer's disease.[293] These families often desire surgery, but the interactions of these drugs and therapies with perioperative analgesic and anesthetic drug therapies are not well established. There is one case report of intraoperative bradycardia in such patients with two cholinergic drugs.[294] Based on basic science research, there is some concern about a link between Alzheimer's disease, postoperative cognitive dysfunction, and inhaled agents.[295] Several investigators have demonstrated β-amyloid deposition in animals exposed to inhaled anesthetics.[296-298] Further research is required to determine whether this link is clinically relevant in humans. Most reversible dementias are either drug-induced delirium or depression.[289,290,299] At present, early results with stimulation at "threshold testing" are promising and seem to stimulate dendritic regrowth and may reverse some or much of the cognitive decline. Such computer programs and games are in early testing. Creutzfeldt-Jakob disease has been transmitted inadvertently by surgical instruments and corneal transplants; the causative virus or protein particle is not inactivated by heat, disinfectants, or formaldehyde.

More than 90% of patients with chronic recurring headaches are categorized as having migraine, tension, or cluster headaches. The mechanism of tension or cluster headaches may not differ qualitatively from that for migraine headaches; all may be manifestations of labile vasomotor regulation.[300] A headache is said to be migraine if it is characterized by four of the following five "POUNDing" conditions: if it is Pulsating, if it lasts One day or more, if it is Unilateral, if there is Nausea, and if it Disturbs daily activities.[301]

Treatment of cluster and migraine headaches centers on the use of serotonin drugs such as sumatriptan or ergotamine and its derivatives.[300-302] Other drugs that may be effective are propranolol, calcium channel inhibitors, cyproheptadine, prednisone, antihistamines, tricyclic antidepressants, phenytoin, and diuretic drugs, as well as biofeedback. Giant cell arteritis, glaucoma, and all the meningitides, including Lyme disease, are other causes of headache that might benefit from treatment before surgery.[303] No other special treatment is indicated preoperatively for a patient who has a well-delineated cause for the headaches. Acute migraine attacks can sometimes be terminated by ergotamine tartrate aerosol or by injection of sumatriptan or dihydroergotamine mesylate intravenously; general anesthesia has also been used. We normally continue all prophylactic headache medicine, although the decision to continue aspirin through the morning of surgery is usually left to the surgeon.

Back Pain, Neck Pain, and Spinal Canal Syndromes

Acute spinal cord injury is discussed earlier in the section on autonomic dysfunction. Although it is a common problem, little is written about the anesthetic management of syndromes related to herniated disks, spondylosis (usually of advancing age), and the congenital narrowing of the cervical and lumbar canal that gives rise to symptoms of nerve root compression. One report stresses the importance of the vascular component in the mechanism of damage to the spinal cord and, hence, the theoretical desirability of slight hypertension perioperatively.[304] Another report suggests the use of awake intubation, a fiberoptic bronchoscope, and monitoring of evoked potentials.[305] Other than the commonsense approach of seeking neurologic consultation or, if necessary, using awake positioning of patients in a comfortable position before emergency root decompression procedures, no special procedures appear to be necessary.

Demyelinating Diseases

Demyelinating diseases constitute a diffuse group of diseases ranging from those with uncertain cause (e.g., multiple sclerosis, where genetic, epidemiologic, and immunologic factors are probably all involved and interferon beta appears to be a promising treatment[306]) to those that follow infection, vaccination (e.g., Guillain-Barré syndrome), or antimetabolite treatment of cancer. Therefore, demyelinating diseases can have very diverse symptoms. Apparently, there is a risk of relapse of these diseases immediately after surgery. Because relapse may occur as a result of rapid electrolyte changes in the perioperative period, such changes might be avoided. In addition, perioperative administration of steroids has been advocated as a protective measure.[99] Although there are concerns about the use of neuraxial anesthesia in these patients, epidural anesthesia has been administered without problems.[307] Multiple sclerosis and demyelinating diseases in general are the most common cause of nontraumatic disability in young adults. The age-adjusted survival rate is 80% of that of unaffected individuals, or put another way, the average patient with multiple sclerosis ages 1.2 years for every year with the disease. However, the variability of the disease makes this average rate of aging almost meaningless. Thus far, no mode of treatment has been shown to alter most of these disease processes, although ACTH, steroids, interferon beta, glatiramer acetate (Copaxone), and plasmapheresis may ameliorate or abbreviate a relapse, even alter disease progression, especially progression of multiple sclerosis and (if started within 2 weeks of onset) Guillain-Barré syndrome.[308] Such an effect is consonant with the hypothesis of an immunologic disorder being the cause of these diseases. Care should be taken to avoid succinylcholine in these patients because of the risk of hyperkalemia

Sleep apnea may be considered a demyelinating or degenerative CNS disease or a peripheral disease of obesity, depending on its etiology. Both types (central and peripheral causes) appear to be increasingly common and are present in more than 5% of elderly African Americans. Preprocedure and preoperative identification of patients and therapy for sleep apnea are discussed in Chapter 64.

Metabolic Diseases

Included in the category of metabolic diseases is nervous system dysfunction secondary to porphyrias, alcoholism, uremia, hepatic failure, and vitamin B_{12} deficiency. The periodic paralysis that can accompany thyroid disease is discussed under "Neuromuscular Disorders" (see later).

Alcoholism or heavy alcohol intake is associated with acute alcoholic hepatitis (also see Chapter 66), the activity of which declines as alcohol is withdrawn; with myopathy and cardiomyopathy, which can be severe; and with withdrawal syndromes. Within 6 to 8 hours of withdrawal, the patient may become tremulous, a state that usually subsides within days or weeks. Alcoholic hallucinosis and withdrawal seizures generally occur within 24 to 36 hours. These seizures are generalized grand mal attacks; when focal seizures occur, other causes should be sought. Delirium tremens usually appears within 72 hours of withdrawal and is often preceded by tremulousness, hallucinations, or seizures. These three symptoms, combined with perceptual distortions, insomnia, psychomotor disturbances, autonomic hyperactivity, and in a large percentage of cases, another potentially fatal illness (e.g., bowel infarction or subdural hematoma), are components of delirium tremens. This syndrome is now treated with benzodiazepines. Nutritional disorders of alcoholism include alcoholic hypoglycemia and hypothermia, alcoholic polyneuropathy, Wernicke-Korsakoff syndrome, and cerebellar degeneration. In alcoholic patients (i.e., those who drink at least two six packs of beer or 1 pint of whiskey per day or the equivalent), emergency surgery and anesthesia (despite alcoholic hepatitis) are not associated with worsening abnormalities in liver enzymes. In addition, about 20% of alcoholic patients also have COPD. A patient who has a history of alcohol abuse therefore warrants careful examination of many systems for quantification of preoperative physical status.

Although hepatic failure can lead to coma with high-output cardiac failure, unlike uremia, it does not lead to chronic polyneuropathy. Uremic polyneuropathy is a distal symmetric sensorimotor polyneuropathy that may be improved by dialysis. The use of depolarizing muscle relaxants in patients with polyneuropathies has been questioned (also see Chapter 29). We believe that patients who have a neuropathy associated with uremia should not be given succinylcholine because of a possible exaggerated hyperkalemic response.

Pernicious anemia caused by vitamin B_{12} deficiency may result in subacute combined degeneration of the spinal cord; the signs are similar to those of chronic nitrous oxide toxicity. Both pernicious anemia and nitrous oxide toxicity are associated with peripheral neuropathy and disorders of the pyramidal tract and posterior column (which governs fine motor skills and the sense of body position). Combined-system disease can also occur without anemia, as can nitrous oxide toxicity in dentists and nitrous oxide abusers. Patients with vitamin B_{12} deficiency and anemia, if treated with folate, improve hematologically but progress to dementia and severe neuropathy. It may thus be prudent to give an intramuscular injection of 100 μg of vitamin B_{12} or 800 μg orally before giving folate to a patient who has signs of combined-system degeneration.[309]

The porphyrias are a constellation of metabolic diseases that result from an autosomally inherited lack of functional enzymes active in the synthesis of hemoglobin. Figure 35-9 sche-

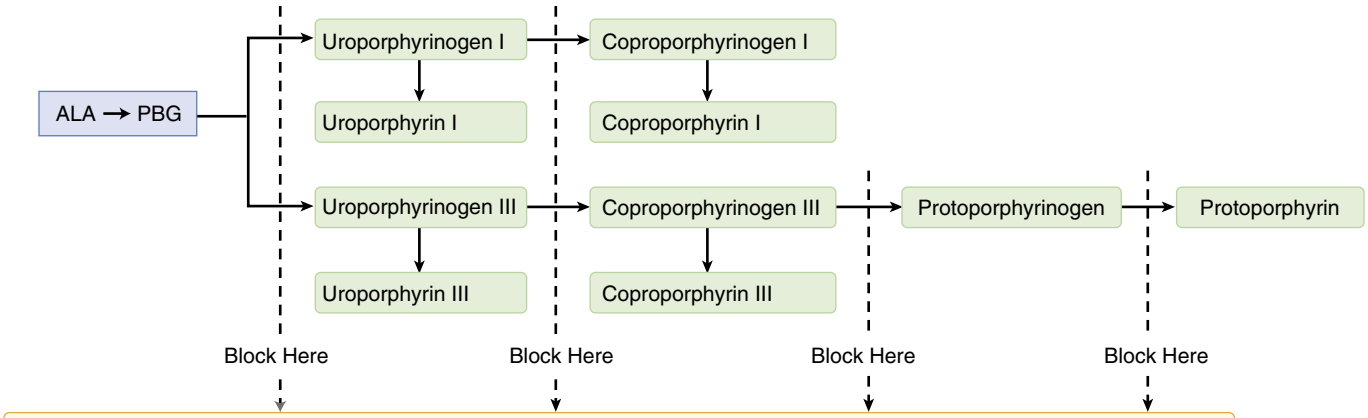
matically depicts the abnormalities that result from these enzyme deficits. It is important to note that type 1, 3, and 4 porphyrias can cause life-threatening neurologic abnormalities. These conditions are characterized by the presence of aminolevulinic acid (ALA) or porphobilinogen (or both) in urine; these substances do not occur in porphyria cutanea tarda, a disease that does not incur neurologic sequelae.[310] In acute intermittent porphyria, the typical pattern consists of acute attacks of colicky pain, nausea, vomiting, severe constipation, psychiatric disorders, and lesions of the lower motor neuron that can progress to bulbar paralysis. Certain drugs can induce the enzyme ALA synthetase and thereby exacerbate the disease process.[311-313] Such sensitizing drugs include barbiturates, meprobamate, chlordiazepoxide, glutethimide, diazepam, hydroxydione, phenytoin, imipramine, pentazocine, birth control pills, ethyl alcohol, sulfonamides, griseofulvin, and ergotamine preparations. Patients often have attacks during infection, fasting, or menstruation. Administration of glucose suppresses ALA synthetase activity and prevents or ablates acute attacks. Drugs used in anesthetic management that are reported to be safe for patients with porphyria include neostigmine (Prostigmin), atropine, gallamine, succinylcholine, *d*-tubocurarine, pancuronium, nitrous oxide, procaine, propofol, propanidid, etomidate, meperidine, fentanyl, morphine, droperidol, promazine, promethazine, and chlorpromazine.[311-313] Although ketamine has been used, postoperative psychoses attributable to the disease may be difficult to distinguish from those possibly caused by ketamine. In addition, although ketamine and etomidate are reported to be safe in humans, they seem to be porphyrinogenic in rats. Propofol has been used without provoking porphyria in at least two susceptible patients.[311,312]

Neuromuscular Disorders

Neuromuscular disorders consist of conditions affecting any major component of the motor unit: motor neuron, peripheral nerve, neuromuscular junction, and muscle. Neuropathies may involve all components of the nerve, thereby producing sensory, motor, and autonomic dysfunction, or only one component. Myopathies may involve only the proximal or distal muscles, or both.

Myasthenia gravis (also see Chapter 34) is a disorder of the muscular system caused by partial blockade or destruction of nicotinic acetylcholine receptors by IgG antibodies. The severity of the disease correlates with the ability of antibodies to decrease the number of available acetylcholine receptors.[314] Treatment of myasthenia is usually begun with anticholinesterase drugs, but in moderate and severe disease, treatment progresses to steroids and thymectomy.[314,315] Immunosuppressive drugs and plasmapheresis are initiated if the more conservative measures fail, and intravenous immunoglobulin, a rapid-onset therapy, is reserved for acute exacerbations and myasthenic crises.[314,315]

One major problem for the anesthesiologist involves the use of muscle relaxants and their reversal.[316] Because much of the care of myasthenia gravis patients involves tailoring the amount



Diagnosis:	Acute intermittent porphyria	Porphyria cutanea tarda	Coproporphyria (hereditary porphyria)	Variegate porphyria
In urine:	ALA PBG	Uroporphyrin	ALA PBG	ALA PBG
Neurologic sequelae:	Yes	No	Yes	Yes
Drug sensitization:	Yes	No	Yes	Yes

Figure 35-9 Schematic depiction of the functional enzyme deficits that occur in some of the porphyrias. ALA, aminolevulinic acid; PBG, porphobilinogen.

of anticholinesterase medication to the maximal muscle strength of the patient, derangement of the course of the patient during surgery could necessitate reassessment of the drug dosage. For that reason, several researchers recommend withholding all anticholinergic drugs for 6 hours before surgery and reinstituting medication postoperatively with extreme caution because the sensitivity of these patients to such drugs may have changed. In addition, there has been some concern that anticholinergic drugs may lead to a high incidence of bowel anastomotic leaks in patients who have undergone bowel anastomosis. Small doses of succinylcholine can be used to facilitate endotracheal intubation; tiny doses of nondepolarizing drugs can be used for intraoperative relaxation not achieved by regional anesthesia or volatile anesthetics. Controlled ventilation is frequently required for at least 24 to 48 hours postoperatively, although immediate extubation has become more common.[315-317] Postoperative ventilation is especially important in cases involving myasthenia gravis of more than 6 years' duration, COPD, a daily pyridostigmine requirement of 750 mg in association with significant bulbar weakness, and vital capacity of less than 40 mL/kg.[317]

Lambert-Eaton syndrome (myasthenic syndrome) is characterized by proximal limb muscle weakness and is associated with antibodies directed against the voltage-gated calcium channels in presynaptic nerve terminals. Strength or reflexes may increase with repetitive effort. Affected patients exhibit decreased release of acetylcholine at the neuromuscular junction. Guanidine therapy enhances the release of acetylcholine from nerve terminals and improves strength. Men with this syndrome generally have small cell carcinoma of the lung or other malignancy, whereas women often have malignancy, sarcoidosis, thyroiditis, or a collagen-related vascular disease. In addition, these patients have increased sensitivity to both depolarizing and nondepolarizing muscle relaxants.[318] Lambert-Eaton syndrome is also associated with an autonomic nervous system defect manifested by gastroparesis, orthostatic hypotension, and urinary retention.

Dermatomyositis and polymyositis are characterized by proximal limb muscle weakness with dysphagia. These conditions are associated with malignancy or collagen-related vascular disease and often involve respiratory and cardiac muscle.

Periodic paralysis is another disease in which sensitivity to muscle relaxants increases. Periodic weakness starts in childhood or adolescence and is precipitated by rest after exercise, sleep, cold, surgery, or pregnancy. Hypokalemic and hyperkalemic forms exist and are associated with cardiac arrhythmias. Like thyrotoxic periodic paralysis, these hypokalemic and hyperkalemic forms usually spare the respiratory muscles. Anesthetic management consists of minimizing stress and maintaining normal fluid and electrolyte status and body temperature.[318-321]

Muscular dystrophy patients now survive into their late twenties or early thirties, and their preoperative evaluation is reviewed in Chapter 34. Because the disease involves the muscles themselves and not their innervation, conduction anesthesia cannot produce adequate relaxation of tonic muscles. Gastric dilation has also been reported to be a problem, as has malignant hyperthermia. As with the other forms of muscular dystrophy, most problems in myotonic dystrophy arise from cardiac arrhythmias and inadequacy of the respiratory muscles.[322] For all the forms of muscular dystrophy, as for all the neuropathies (discussed earlier), there have been problems related to exaggerated release of serum potassium after the administration of depolarizing muscle relaxants (also see Chapter 29).

Malignant hyperthermia (also see Chapter 37) in the patient or in a relative of the patient merits careful history taking and at least consideration of performing a test for susceptibility to the condition. Prophylaxis with intravenous dantrolene sodium (Dantrium) may also be warranted. In some cases, malignant hyperthermia has been associated with recognizable musculoskeletal abnormalities such as strabismus, ptosis, myotonic dystrophy, hernias, kyphoscoliosis, muscular dystrophy, central core disease, and marfanoid syndrome. Appropriate preparation for a patient with previous masseter spasm, or trismus, is a matter of considerable debate. We prepare for malignant hyperthermia (i.e., we ensure a contaminant-free machine, use nontriggering agents, and have a malignant hyperthermia cart in the room) but do not routinely perform muscle biopsy or prescribe dantrolene prophylaxis.[323,324] Malignant hyperthermia occurs most frequently in children and adolescents, the incidence being 1 in 14,000 administrations of anesthetic. The incidence increases to 1 in 2500 patients requiring squint surgery.

Down Syndrome

Down syndrome (trisomy 21) occurs once in 1000 live births. It is associated with congenital cardiac lesions such as endocardial cushion defects (40%), ventricular septal defects (27%), patent ductus arteriosus (12%), and tetralogy of Fallot (8%), and prophylactic antibiotics should be used before predictable bacteremic events. Down syndrome is also associated with upper respiratory infections, with atlanto-occipital instability (in about 15% of patients,[325-328] in whom it is asymptomatic in most cases, but it is recommended that all patients be treated as though they have atlanto-occipital instability) and laxity of other joints, with thyroid hypofunction (50%), with an increased incidence of subglottic stenosis, and with enlargement of the tongue (or a decreased oral cavity size for a normal-sized tongue).[327,329] No abnormal responses to anesthetics or anesthetic adjuvants have been substantiated. A reported sensitivity to atropine has been disproved, although administration of atropine to any patient given digoxin for atrial fibrillation should be done with extreme care.[329] Examination for the conditions associated with Down syndrome should precede surgery.

Preoperative Prediction of Increased Intracranial Pressure during Neurosurgery

Symptoms and signs of increased intracranial pressure include morning headache or headache made worse by coughing, nausea, vomiting, disturbances in consciousness, history of large tumors, tumors involving the brainstem, neck rigidity, and papilledema. Patients with these signs, large ventricles (as seen on radiography or images of the brain), or edema surrounding supratentorial tumors should be considered at risk for intraoperative intracranial hypertension. These patients may benefit from preoperative treatment or anesthetic management that assumes this possibility (also see Chapter 63).[330]

Other preoperative considerations for patients with neurologic disease that can cause intracranial hypertension are the associated hypoventilation and hypoxia in patients who have severe hemiplegia and the presence of subarachnoid bleeding or other forms of intracranial hemorrhage (especially likely in

women given heparin who have two or more cerebral infarcts noted on CT). Many strokes or transient ischemic attacks have a possible cardiac origin (59 of 184 patients).[331,332] The drugs used to prevent cerebral arterial spasm—calcium channel blockers—are discussed in the last section of this chapter.

Mental Disorders

Perhaps the most important preoperative consideration for patients with mental disorders, in addition to developing rapport, is understanding their specific drug therapy and its effects and side effects. More than 15% of all adult patients undergoing surgery are taking one of these therapies or have recently been taking one of these therapies. Lithium, tricyclic antidepressants, selective serotonin reuptake inhibitors (SSRIs), other antidepressants that defy classification such as bupropion, phenothiazines, butyrophenones, and MAOIs are used in these patients.[333] These drugs have potent effects and side effects that are discussed in the last section of this chapter.

Renal Disease, Infectious Diseases, and Electrolyte Disorders

One may ask why preoperative preparation of a patient with renal disease is discussed in the same section as preoperative preparation of a patient with an infectious disease. Although it is commonly recommended that no surgery except emergency or curative (e.g., drainage of an abscess) operations be performed in patients with infectious disease, it has become evident that renal insufficiency can be caused by antimicrobial drugs[334] and that sepsis, not shock, is probably the leading cause of acute postoperative renal failure. The anesthesiologist has an important role to play in preventing the onset and consequences of renal failure and its initiators. The linking of renal failure to electrolyte disorders is more obvious: the kidney is the primary organ for regulating body osmolality and fluid volume and has a major role in excretion of the end products of metabolism. In performing these functions, the kidney becomes intimately involved in the excretion of electrolytes.

A patient with renal insufficiency whose own kidneys are still functioning is distinct not only from a patient with end-stage renal disease whose renal functions are provided by dialysis but also from a patient who has a transplanted kidney. These three groups of patients require very different preoperative preparation. In addition, acute changes in renal function present quite a different problem than do chronic alterations in function. Certain renal diseases require different preoperative preparation than others, but generally, renal disease of any origin presents the same preoperative problems (also see Chapters 18, 34, and 45).

Renal Disease

Causes and Systemic Effects of Renal Disorders

Nephrotic syndrome may develop in patients with glomerular diseases without disturbing tubular function. The soundness of tubular function is an important consideration because tubular dysfunction with attendant uremia presents quite different problems than glomerular disease with only nephrotic syndrome does. This is not to minimize the adverse effects of glomerular disease; nephrotic syndrome consists of massive proteinuria and consequent hypoalbuminemia. The resulting reduction in plasma oncotic pressure diminishes plasma volume and calls forth compensatory mechanisms that result in retention of sodium and water. As a result, a common clinical finding in nephrotic syndrome is edema. Thus, patients with nephrotic syndrome may have excess total-body water and decreased intravascular volume. In addition, diuretics are often given in an attempt to decrease edema. Although serum creatinine and creatinine clearance estimations have limitations as indices of the GFR (inulin clearance is still the gold standard), these measurements are, for now, the most readily available to the anesthesiologist. Plasma creatinine levels reflect endogenous muscle catabolism and dietary intake, as well as urinary excretion. Urinary excretion depends on both filtration and secretion by the kidney. Drugs that are commonly used in the preoperative and perioperative periods can distort this measure of glomerular filtration: cimetidine and trimethoprim interfere with secretion by increasing plasma creatinine and decreasing creatinine clearance without altering filtration. It should also be remembered that the commonly used methods for measuring creatinine have a 95% confidence limit of greater than 20% for a GFR higher than 30 mL/min. Thus, a normal creatinine level of 1.3 mg/dL might give a measured value ranging from 1.0 to 1.5 mg/dL.

Furthermore, in patients with nephrotic syndrome in whom renal tubular function has been preserved, hypovolemia appears to be a significant cause of deteriorating tubular renal function.[335-337] Consequently, we advocate the same intense preoperative, intraoperative, and postoperative fluid management for patients with nephrotic syndrome as we do for patients with diminished tubular function. Admittedly, no randomized study has shown that close control of intravascular volume status in these groups of patients preserves renal tubular function (or any other measure of perioperative morbidity) to a greater degree than less rigid control does.

Uremia, the end result of renal tubular failure (i.e., failure of the concentrating, diluting, acidifying, and filtering functions) is manifested in many ways. Changes occur in the cardiovascular, immunologic, hematologic, neuromuscular, pulmonary, and endocrine systems, as well as in bone. These alterations are ascribed either to the toxic end products of protein metabolism or to an imbalance in functioning of the kidney. As the number of functioning nephrons diminishes, the still-functioning nephrons attempt to increase some solute and body composition preservation functions at the expense of other functions, such as excretion of phosphate. The accumulation of phosphate increases PTH levels, which in turn produces osteodystrophy. Osteodystrophy can be managed by (1) restriction of dietary phosphate, (2) the use of gels (e.g., aluminum hydroxide or carbonate) that bind with intestinal phosphate, (3) calcium supplementation, or (4) parathyroidectomy.

Certain alterations in patients with uremia, such as neuropathy, are most logically attributed to an accumulation of toxic metabolites. Peripheral neuropathy is most often sensory and involves the lower extremities, but it may also be motor; peripheral neuropathies are frequently improved with hemodialysis and can be dramatically reversed with transplantation. The use of

depolarizing muscle relaxants in patients with peripheral neuropathy is controversial and is discussed in the section on neuropathies. Tubular function is commonly assessed by acidifying and concentrating capabilities.[338] Although such tests are crude, these capabilities are usually readily assessed by measuring urine pH and specific gravity. Better assessment of renal blood flow, for the purpose of improving renal blood flow and its distribution, is promised by the use of contrast-enhanced ultrasound in the operating room.[339] Along with the altered volume status and cardiac complications in uremic patients, autonomic neuropathy may contribute to hypotension during anesthesia. Atherosclerosis is often accelerated in uremic patients; hypertension, with its attendant consequences, is very common.

Cardiac failure (especially episodic failure) frequently occurs in uremic patients because of the presence of many adverse conditions: anemia with increasing myocardial work, hypertension, atherosclerosis, and altered volume status. Pericarditis can be manifested by pericardial rub alone or by pain (with or without hemorrhage). Cardiac tamponade should be ruled out on the basis of clinical features and by echocardiography if this diagnosis is seriously suspected preoperatively. In addition, cardiac tamponade should be treated or planned for preoperatively.

If anemia is present, its severity generally parallels the degree of uremia; chronically uremic patients seem to adapt well to anemia. No hard data have substantiated the need to give a preoperative blood transfusion to a chronically uremic patient, even when the preoperative hematocrit is as low as 16 or 18 vol%. Even in nonuremic patients in an ICU, a randomized trial was unable to demonstrate improved outcome with a liberal transfusion strategy,[340] and transfusions increase the risk for immune system compromise (also see Chapter 55).[341] Thus, one of the major historical reasons for not transfusing blood in patients with end-stage renal disease has been disproved by this finding: data show that the more blood transfusions a transplant recipient receives before transplantation, the greater the chance that the transplant will function successfully.[342] This immunosuppressive effect of transfusions is now routinely used in transplantation. However, the development of recombinant human erythropoietin has obviated the need for transfusions in chronically uremic patients. Balancing of the immunosuppressive use of blood transfusions versus the benefits of erythropoietin and the risks of transfusion remains to be determined. In uremic patients, coagulation and platelet adhesiveness may be abnormal and factor III activity decreased. Even uremic patients not given corticosteroids or immunosuppressive drugs may demonstrate abnormal immunity, perhaps warranting increased attention regarding procedures that lessen patient cross-contamination.

Uremic patients exhibit a wide variety of metabolic and endocrinologic disorders in addition to hyperparathyroidism, including impaired carbohydrate tolerance, insulin resistance, type IV hyperlipoproteinemia, autonomic insufficiency, hyperkalemia, and anion-gap acidosis (caused by an inability of the kidneys to reabsorb filtered bicarbonate and excrete sufficient ammonium into urine). Furthermore, the excretion and pharmacokinetics of drugs are different in uremic patients than in normal patients. In addition, complications of hemodialysis include nutritional deficiencies, electrolyte and fluid imbalances, and mental disorders. Because these conditions can lead to serious perioperative morbidity, they should be evaluated before surgery. No data, however, have substantiated the hypothesis that preoperative optimization of these metabolic and endocrinologic disorders reduces perioperative risk in uremic patients.

As with uremic patients, preoperative optimization of volume status is paramount in patients with kidney stones, and both are affected by carbohydrate intolerance.[343,344] Seventy-five percent of all kidney stones are composed of calcium oxalate. Patients with these stones frequently take diuretic drugs, consume calcium- and citrate-rich foods, and restrict salt intake. Prevention of dehydration by institution of intravenous fluid therapy along with restricted oral intake of protein may be as important for these patients as it is for those with struvite or uric acid stones. Struvite stones often result from urinary infection. Uric acid stones can be prevented by treatment with allopurinol, by preoperative hydration, or by alkalization of urine. Acidosis may contribute to stone formation. Again, optimal intravascular volume status is important in preventing stones and preserving renal function. More thorough discussion of renal function and physiology is provided in Chapter 18. Chapter 65 deals with the complexities of managing patients for renal surgery and other urologic procedures.

Creatinine clearance in conjunction with free water clearance appears to be the most accurate way of quantifying, for pharmacokinetic purposes, the degree of decreased renal function (also see Chapter 18).[344] For a patient with stable renal function, creatinine clearance, which is a rough estimate of GFR, can be approximated by noting the serum creatinine level: a doubling of the creatinine level represents a halving of the GFR. Thus, a patient with a stable serum creatinine level of 2 mg/dL would have a GFR of approximately 60 mL/min. A stable serum creatinine level of 4 mg/dL would accompany a GFR of approximately 30 mL/min, and a stable serum creatinine level of 8 mg/dL would accompany a GFR of 15 mL/min or less. When pregnancy and considerable edema are not present and the serum creatinine level is stable, the following formulas can be used to estimate creatinine clearance and free water clearance.[344-346]

$$\text{Creatinine clearance} = \frac{(140 - \text{Age}[\text{yr}]) \times \text{Body weight}\,(\text{kg})}{72 \times \text{Serum creatinine}\,(\text{mg/dL})}$$

$$\text{Free water clearance} = \text{Urine flow}\,(\text{mL/hr}) - \frac{\text{Urine osmolality}\,(\text{mOsm/L}) \times \text{Urine flow}\,(\text{mL/hr})}{\text{Plasma osmolality}\,(\text{mOsm/L})}$$

Note that renal function must be stable. Unstable renal function is often associated with changes in serum creatinine levels that lag by several days. Although knowing the serum creatinine level is more useful than knowing the BUN level, the latter provides some information, as discussed in the next section.

Free water clearance is a measure of renal concentrating ability and is normally −25 to +100 mL/hr; it becomes more positive in renal insufficiency states. It may also become more positive in patients who have a head injury or high blood alcohol levels or in those undergoing aggressive fluid infusion or administration of diuretics.[345]

Patients with Insufficient but Functioning Kidneys

One of the greatest challenges for the anesthesiologist is presented by patients with insufficient renal function whose renal function

must be preserved during surgery. Additionally, the presence of chronic renal failure is associated with higher rates of perioperative cardiac morbidity, which may warrant further evaluation for the presence of occult coronary artery disease.[346] The many uremic symptoms and great perioperative morbidity associated with uremia can probably be avoided by attention to detail in the preoperative and perioperative management of patients with insufficient, but still functioning kidneys.[335-337]

First, studies demonstrate that acute postoperative renal failure is associated with an extremely high mortality rate.[347] There are multiple risk factors for the development of perioperative renal dysfunction, the most important of which include preexisting renal disease, heart surgery involving cardiopulmonary bypass or aortic surgery involving cross-clamping of the thoracic or abdominal aorta, and ongoing sepsis. In a systematic review of 28 studies by Novis and colleagues, preoperative renal risk factors such as increased serum creatinine, increased BUN, and preoperative renal dysfunction were repeatedly found to predict postoperative renal dysfunction.[345] Mangano and coworkers performed a prospective cohort study of 2222 patients with or without concurrent vascular surgery.[347] They identified five independent preoperative predictors of renal dysfunction: age 70 to 79 years (relative risk [RR], 1.6; 95% CI, 1.1 to 2.3) or age 80 to 95 years (RR, 3.5; CI, 1.9 to 6.3), CHF (RR, 1.8; CI, 1.3 to 2.6), previous myocardial revascularization (RR, 1.8; CI, 1.2 to 2.7), type 1 diabetes mellitus (RR, 1.8; CI, 1.1 to 3.0) or preoperative serum glucose levels exceeding 16.6 mmol/L (RR, 3.7; CI, 1.7 to 7.8), and preoperative serum creatinine levels of 124 to 177 µmol/L (RR, 2.3; CI, 1.6 to 3.4).

Moreover, acute perioperative renal failure is most likely to occur in patients who have renal insufficiency before surgery, are older than 60 years, and have preoperative left ventricular dysfunction.[345,347] Proper hydration before surgery probably decreases the mortality after acute renal failure induced by radiocontrast agents.[337] Clues regarding the presence of hypovolemia or hypervolemia should be sought from the history and physical examination (e.g., weight loss or gain, thirst, edema, orthostatic hypotension and tachycardia, flat neck veins, dry mucous membranes, decreased skin turgor). In seriously ill patients, insertion of a pulmonary artery catheter will permit more precise monitoring of intravascular fluid volume. Other causes of deterioration in function in chronic renal insufficiency are low cardiac output or low renal blood flow (in prerenal azotemia, whether because of cardiac failure or fluid depletion from diuretic drugs, BUN often increases disproportionately to increases in creatinine), urinary tract infection, use of nephrotoxic drugs, hypercalcemia, and hyperuricemia. These conditions and drugs should be avoided; if any of these conditions exist, they should be treated preoperatively.

To preserve normal renal function, infusion of saline, mannitol, furosemide, or low-dose dopamine has been recommended.[348-350] However, these therapies should be initiated with caution because saline infusions and mannitol can lead to fluid overload and myocardial damage; in addition, diuretic drugs given intraoperatively can produce postoperative hypovolemia, which worsens renal function. Very high concentrations of mannitol may also cause acute renal failure.[351] A meta-analysis of 58 trials involving the use of dopamine for renal protection/treatment, only 17 of which were randomized, was unable to demonstrate any benefit from the use of low-dose dopamine.[352] Maintenance of normal intravascular fluid volume can be guided by pulmonary capillary wedge pressure and has prevented impairment of renal function after open abdominal aortic reconstruction, even when urinary volumes were low.[353] Fenoldopam is a dopamine analog that causes natriuresis and increases renal blood flow and urine output. Several small studies have reported renoprotective effects of fenoldopam in patients undergoing cardiopulmonary bypass and infrarenal aortic aneurysm repair.[354-356]

Anesthetic drugs have been studied in patients with renal insufficiency. In a randomized trial, general anesthesia with desflurane or isoflurane did not exacerbate renal insufficiency.[357] Despite concern that sevoflurane leads to the production of compound A, which impairs renal functioning, a randomized trial of low-flow sevoflurane versus low-flow isoflurane anesthesia in patients with stable renal insufficiency did not demonstrate any difference in any measured renal function parameter.[358]

Patients Undergoing Dialysis

Patients with chronic (and at times acute) renal failure require renal replacement therapy, including conventional intermittent hemodialysis, peritoneal dialysis, and continuous renal replacement therapy (CRRT). CRRT includes a wide variety of techniques whose perioperative management has recently been reviewed (Table 35-18).[359] Although the primary indication for CRRT is acute renal failure, it can also be used for fluid clearance, correction of electrolyte abnormalities, and management of metabolic acidosis. It can be used in surgical patients without significant hemodynamic abnormalities. These patients may return to the operating room and their assessment and management may be complicated by the underlying disease and the use of systemic anticoagulation to prevent filter and circuit clotting. In patients undergoing intermittent treatment with hemodialysis or peritoneal dialysis, the procedure is discontinued before entering the operating room. For CRRT, the anesthesiologist must determine the appropriateness of discontinuing the therapy. With short procedures, the therapy can almost always be stopped and the arterial and venous ends of the circuit connected and run in the bypass mode. CRRT can also be used to manage fluids during surgery by changing the dialysate. If CRRT is continued, its effect on drug dosing must be recognized. In addition to effects on renal elimination of drugs, there are effects from changes in protein binding and volume of distribution, as well as drug removal effects from membrane permeability, membrane surface area, the ultrafiltration rate, and the dialysate flow rate.

Because a patient undergoing dialysis has already lost natural renal functioning, the emphasis in preoperative assessment shifts toward protecting other organ systems and optimally maintaining vascular access sites for cannulation. Usually, this does not require invasive monitoring. Emphasis is placed on intravascular fluid volume and electrolyte status, which can be ascertained by knowing when the patient last underwent dialysis, how much weight was normally gained or lost with dialysis, whether the fluid loss was peritoneal or intravascular, and what electrolyte composition the blood was dialyzed against. Although preoperative dialysis may benefit patients who have hyperkalemia, hypercalcemia, acidosis, neuropathy, and fluid overload, the resulting dysequilibrium between fluid and electrolytes can cause problems. Because hypovolemia induced by dialysis can lead to intraoperative hypotension, we try to avoid weight and fluid

Table 35-18 Characteristics of Renal Replacement Therapy

Renal Replacement Therapy	Blood Pump	Replacement Fluid (RF)/Dialysate (D)	Intraoperative Use
Conventional intermittent hemodialysis	Yes	D	No
Peritoneal dialysis	No	D	No
Slow continuous ultrafiltration	Yes/no	None	Yes
Continuous arteriovenous hemodialysis	No	D	No
Continuous arteriovenous hemodiafiltration	No	RF/D	No
Continuous venovenous hemofiltration	Yes	RF	Yes
Continuous venovenous hemodialysis	Yes	D	Yes
Continuous venovenous hemodiafiltration	Yes	RF/D	Yes

From Petroni KC, Cohen NH: Continuous renal replacement therapy: Anesthetic implications. Anesth Analg 94:1288-1297, 2002, with permission.

reduction in patients undergoing preoperative dialysis. In addition, hypopnea has been found to occur during and after dialysis when the dialysate contained acetate. Avoiding an acetate bathing solution may prevent this cause of hypoventilation.

Patients Who Have Received a Renal Transplant

More than 175,000 patients have received renal transplants (versus 300,000 currently undergoing dialysis in the United States). Approximately 50% are still alive, although a third must undergo dialysis (approximately 60,000 patients are now awaiting transplantation).[360] When these patients have subsequent surgery, the status of their renal function must be determined (i.e., whether they have normal renal function, insufficient but still functioning kidneys, or end-stage renal disease requiring hemodialysis). Descriptions of side effects from immunosuppressive drugs should also be sought. The drugs used preoperatively and intraoperatively to prevent acute rejection themselves have serious side effects that encourage close monitoring of blood glucose and cardiovascular function.[342,361] Because renal transplantation greatly increases the risk of infection, it is very important to avoid invasive monitoring and prevent patient cross-contamination.

Drugs in Patients with Renal Failure

Patients with renal azotemia have a threefold or higher risk of having an adverse drug reaction than those with normal renal function do.[362-364] The risk is increased by two conditions. (1) Excessive pharmacologic effects result from high levels of a drug or its metabolite (e.g., the metabolite of meperidine) in blood because of physiologic changes in target tissues induced by the uremic state. An example would be excessive sedation in a uremic patient with standard blood levels of sedative-hypnotic drugs. (2) Excessive administration of electrolytes with drugs also increases the risk of having an adverse drug reaction. For example, penicillin standardly has 1.7 mEq of potassium per 1 million units.[362-364] Administration of standard doses of drugs that depend on renal excretion for their elimination can result in drug accumulation and enhanced pharmacologic effect. Bennett and associates[362] have provided dosing guidelines for many drugs used by anesthesiologists for patients with and without renal failure. For example, patients with end-stage renal disease required significantly higher propofol doses to achieve the clinical end point of hypnosis than patients with normal renal function did.[364]

Infectious Disease

Because it is commonly recommended that no surgery except emergency or essential surgery (e.g., drainage of an abscess) be performed when an acute infectious disease is present and because renal insufficiency can be caused by antimicrobial drugs,[334,336,337] renal function and organ damage from renal insufficiency should be assessed preoperatively when infectious disease is present. Prophylactic administration of antibiotics (see Table 35-11) helps prevent sepsis from bacteremic interventions.[365] If therapeutic levels of an antibiotic are achieved and a reduction in fever occurs (presumably because of decreased levels of interleukin-2 released), spinal anesthesia might be considered by the anesthesiologist (using benefit-risk judgments) when an acute infectious disease is present.[366]

Sepsis is a leading cause of postoperative morbidity,[334,337] probably through a decrease in systemic vascular resistance related to activation of the complement system and other mediators. Thus, attention to the effects of antibiotic drugs must be supplemented by attention to intravascular volume status.[334-337,367,368] The degree of impairment of the infected organ and its effect on anesthesia should be assessed. For instance, endocarditis merits examination of volume status; antibiotic and other drug therapy and side effects[369]; myocardial function; and renal, pulmonary, neurologic, and hepatic function—organ systems that can be affected by endocarditis.

Although all surgery except emergency or essential operations is proscribed when an acute infectious disease is present (also see the section on upper respiratory infections in the pulmonary section of this chapter), many such diseases (e.g., influenza and pneumococcal pneumonia) and even inflammatory conditions are becoming less frequent because of successful immunization recommendations and programs.[370] Furthermore, even though acute infections are less common, surgery in patients with chronic viral diseases such as hepatitis and HIV infection is more frequent. Many of these patients may also harbor opportunistic infections such as tuberculosis or may have other systemic problems. Whether anesthesia or surgery, or both, exacerbates these infections or their systemic manifestations is not clear.

At least two other considerations merit preoperative consideration: patient isolation to prevent contamination of the

patient and health care providers. Both concerns are real and are the focus of at least several published volumes. Nosocomial infection is a major source of postsurgical morbidity and has been radically reduced by consistent practices such as hand washing.[371,372] Acquired immunodeficiency syndrome (AIDS) and many forms of hepatitis (A, B, and C) appear to be due to viral infections but require direct contact with blood or body fluids. Screening for specific viruses or for the chronic end-organ effects of these viruses[373] is now being done to reduce the risk of infection to both recipients and health care personnel during blood transfusions. The usual precautions appear to be largely effective, but the risk is considerable if these precautions are not followed meticulously.[374]

Electrolyte Disorders

Disorders of calcium, magnesium, and phosphate balance were discussed in the section on diseases involving the endocrine system and disorders of nutrition (also see Chapters 34 and 49).

Hyponatremia and Hypernatremia

Electrolyte disorders are usually detected by determining the levels of electrolytes in serum. These concentrations reflect the balance between water and electrolytes. The osmolality of all body fluids is normally maintained within the narrow physiologic range of 285 to 290 mOsm/kg H_2O by integration of three key processes: thirst, release of ADH, and responsiveness of the medullary collecting ducts to ADH. Because of the permeability of biologic membranes, intracellular osmolality and extracellular osmolality are almost always equal and can be estimated by the following formula:

$$2[NA^+](mEq/L) + \frac{[Glucose](mg/dL)}{18} + \frac{[BUN](mg/dL)}{2.8} = mOsm/kg$$

This formula will become easier to calculate when we convert fully to the Système International d'Unités (metric system) because millimoles (mmol) can be substituted for mg/(factor) in the above formula to read

$$2[Na^{2+}] + [Glucose] + [BUN] = mOsm/kg$$

with concentrations expressed in millimoles per liter (mmol/L). Although secretion of ADH is tightly controlled by osmotic stimuli at 285 to 290 mOsm/kg, the osmotic threshold for thirst is high (300 mOsm/kg), thus making this sign an important guide to volume deficiency.

Hyponatremia is perhaps the third most common fluid electrolyte abnormality in hospitalized patients. (Magnesium deficiency occurs in as many as 25% [see Chapter 54] and potassium deficiency, discussed later in this section, in as many as 10%.) Hyponatremia can occur in isotonic, hypertonic, or hypotonic forms. For example, isotonic hyponatremia can develop in protein or liquid accumulation states such as myeloma. Hypertonic hyponatremia can be present with hyperglycemia or with infusions of glycine (as in the TURP syndrome[375]). Hypotonic hyponatremia is the largest classification and is subdivided according to the status of the extracellular fluid into hypovolemic, isovolumic, or hypervolemic hypotonic hyponatremia. All three types require that excretion of renal water be impaired despite continued intake of dilute fluid. Common causes of hypovolemic hypotonic hyponatremia (Box 35-6) are GI losses[376] (vomiting, diarrhea), third-space losses (diuretics or salt-wasting nephropathy), or adrenal insufficiency. Hypervolemic hypotonic hyponatremic states complicate severe cardiac failure,[377] cirrhosis, nephrotic syndrome, or renal failure and are characterized by retention of sodium with disproportionately larger amounts of water.

The more common isovolumic hypotonic hyponatremia is caused by retention of water without sodium. Because edema is not usually clinically apparent, such patients appear isovolumic. Edema is most often caused by SIADH, which in turn may be caused by CNS or pulmonary tumors or dysfunction. Secretion of ADH increases with age, thus rendering the elderly more prone to hyponatremia. Drugs that potentiate the secretion of ADH (tricyclic antidepressants and vincristine) or its effects on the medullary collecting duct system in the kidney (nonsteroidal anti-inflammatory drugs and chlorpropamide) or that have similar effects (oxytocin) may be more likely to cause hyponatremia in the elderly. To establish the diagnosis of SIADH, the physician should determine that the patient is free of renal and cardiac dysfunction, has normal adrenal and thyroid function, and is normovolemic. Urine osmolality would then be found to exceed 100 mOsm/kg, serum osmolality would be low, and urine sodium excretion would be higher than 20 mEq/L (20 mOsm/L).

Disturbances in serum sodium therefore reflect alterations in glucose metabolism, renal function, or accumulation of body water. The last can be affected by disturbances in thirst, release of ADH, and renal function. Thus, hyponatremia reflects a relative excess of free water and can occur when total-body sodium

Box 35-6 Types and Causes of Hypotonic Hyponatremia*

increases (as in edematous disorders), when total-body sodium is normal (as in excess of free water because of SIADH), or when total-body sodium decreases (as occurs with too aggressive use of diuretic drugs). Definition of the cause defines the treatment. For instance, water restriction is the mainstay of therapy for SIADH. Administration of demeclocycline is another option that corrects SIADH by inducing a reversible nephrogenic diabetes insipidus. The anesthesiologist is faced with the question of what levels of electrolytes require treatment before anesthesia. Although slowly developing hyponatremia usually produces few symptoms, the patient may be lethargic and apathetic. Chronic hyponatremia is better tolerated than acute hyponatremia because of mechanisms regulating intracellular fluid volume that alleviate brain edema; the loss of other solutes from cells decreases the osmotic movement of water into cells. Nonetheless, severe chronic hyponatremia (i.e., serum sodium levels <123 mEq/L) can cause brain edema.

By contrast, acute hyponatremia may be manifested by severe symptoms requiring emergency treatment: profound cerebral edema with obtundation, coma, convulsions, and disordered reflexes and thermoregulatory control.[99,100,378] Depending on the cause and relative total sodium and water content, treatment can range from the administration of hypertonic saline or mannitol (with or without diuretic drugs) to restriction of fluids or administration of other drugs.[99,100,378] Because neurologic damage may develop if the serum sodium concentration is increased too rapidly, the rate of increase should not exceed 1 mEq/L/hr.[99,100,378] After the serum sodium concentration has reached 125 mEq/L, therapy may consist of water restriction; more rapid correction may result in CNS demyelination.[99,100,378] In hyponatremic patients who have excess total-body water secondary to SIADH, serum levels can be corrected by giving furosemide, 1 mg/kg, and hypertonic saline to replace the loss of electrolytes in urine.[99,100,378] The diagnosis of SIADH is discussed earlier in this chapter (see the section "Pituitary Abnormalities").

Neither acute nor chronic hyponatremia necessitates restoration of serum sodium to normal levels; brain swelling usually disappears at a serum sodium level of 130 mEq/L. This leaves us with the question of what levels of serum sodium make anesthesia more risky. Because no data exist to answer this question, to allow for some error in caring for patients, we have arbitrarily chosen a flexible concentration of 131 mEq/L as the lower sodium limit for elective surgery.

Hypernatremia occurs much less commonly than hyponatremia. It is often iatrogenic in origin (e.g., it can be caused by failure to provide sufficient free water to a patient who is unconscious or who has had a recent stroke-induced deficit of the thirst mechanism) and can occur in the presence of low, normal, or excess total-body sodium. The primary symptoms of hypernatremia relate to brain cell shrinkage. Because too rapid correction of hypernatremia can lead to cerebral edema and convulsions, correction should be made gradually. Again, with no data to support this stance, we believe that all patients undergoing surgery should have serum sodium concentrations of less than 150 mEq/L before anesthesia.

Hypokalemia and Hyperkalemia

Hypokalemia and hyperkalemia are also discussed in Chapters 34 and 54. The relationship between the measured potassium concentration in serum and total-body potassium stores can best be described with a scattergram. Only 2% of total-body potassium is stored in plasma (4200 mEq in cells and 60 mEq in extracellular fluid). In normal persons, 75% of the 50 to 60 mEq/L of total-body potassium is stored in skeletal muscle, 6% in red blood cells, and 5% in the liver. Thus, a 20% to 25% change in potassium levels in plasma could represent a change in total-body potassium of 1000 mEq or more if the change were chronic or as little as 10 to 20 mEq if the change were acute.

As with serum sodium levels,[99,100,378] acute changes in serum potassium levels appear to be less well tolerated than chronic changes. Chronic changes are relatively well tolerated because of the equilibration of serum and intracellular stores that takes place over time to return the resting membrane potential of excitable cells to nearly normal levels.

Hyperkalemia can result from factitious elevation of potassium (as in red blood cell hemolysis); excessive exogenous potassium from sources such as salt substitutes or, in large amounts, bananas; cellular shifts in potassium (as a result of metabolic acidosis, tissue and muscle damage after burns, use of depolarizing muscle relaxants, or intense catabolism of protein); and decreased renal excretion (as occurs in renal failure, renal insufficiency with trauma, and therapy with potassium-sparing diuretic drugs, especially when combined with ACE inhibitors or mineralocorticoid deficiency).[379-381] Factitious hyperkalemia can occur when a tourniquet is left on too long or even by simple fist clenching.[382]

The major danger in anesthetizing patients who have disorders in potassium balance appears to be abnormal cardiac function—that is, both electrical disturbance[379] and poor cardiac contractility. Hyperkalemia lowers the resting membrane potential of excitable cardiac cells and decreases the duration of the myocardial action potential and upstroke velocity. This decreased rate of ventricular depolarization, plus the beginning of repolarization in some areas of the myocardium while other areas are still undergoing depolarization, produces a progressively widening QRS complex that merges with the T wave into a sine wave on the ECG.

Above a potassium level of 6.7 mEq/L, the degree of hyperkalemia and the duration of the QRS complex correlate well.[379] This correlation is even better than the correlation between the serum potassium level and T-wave changes. Nevertheless, the earliest manifestations of hyperkalemia are narrowing and peaking of the T wave. Though not diagnostic of hyperkalemia, T waves are almost invariably peaked and narrow when serum potassium levels are 7 to 9 mEq/L. When serum potassium levels exceed 7 mEq/L, atrial conduction disturbances appear, as manifested by a decrease in P-wave amplitude and an increase in the PR interval. Supraventricular tachycardia, atrial fibrillation, PVCs, ventricular tachycardia, ventricular fibrillation, or sinus arrest may all occur.

The ECG and cardiac alterations associated with hyperkalemia are potentiated by low serum levels of calcium and sodium. Intravenous administration of saline, bicarbonate, glucose with insulin (1 U/2 g glucose), and calcium can reverse these changes by shifting some extracellular potassium into the cell.

β-Adrenergic stimuli also cause redistribution of potassium into the cell. Indeed, the plasma potassium concentration measured in samples immediately before surgery is usually 0.2 to 0.8 mEq/L lower than that measured during the less stressful period 1 to 3 days before surgery.[383] β-Adrenergic receptor blocking drugs such as propranolol can be used to prevent such an

effect preoperatively. A β-adrenergic receptor stimulating agent (20 mg of nebulized albuterol for a 70-kg patient) can be used to treat hyperkalemia when it occurs; it decreases potassium levels 1.0 mEq/L within 30 minutes, and its effect lasts 2 hours.[384] Although nebulized β_2-agonists effectively lower plasma potassium concentrations by stimulating sodium- and potassium-dependent adenosine triphosphatase, this therapy should be used as an adjunct to rather than a substitute for more established measures. Kayexalate (sodium polystyrene sulfonate) enemas can be given to bind potassium in the gut in exchange for sodium. Dialysis against a hypokalemic solution will also decrease serum potassium levels. However, in a hyperkalemic patient, hypoventilation can be dangerous during anesthesia because each 0.1 change in pH can produce a 0.4- to 1.5-mEq/L change in serum potassium levels in the opposite direction. For example, if pH decreases from 7.4 to 7.3, serum potassium levels could increase from 5.5 to 6.5 mEq/L.

Hypokalemia can be caused by inadequate intake of potassium, excessive GI loss (through diarrhea, vomiting, nasopharyngeal suctioning, chronic use of laxatives, or ingestion of cation exchange resins, as in certain wines), excessive renal loss (because of the use of diuretic drugs, renal tubular acidosis, chronic chloride deficiency, metabolic alkalosis, mineralocorticoid excess, excessive ingestion of licorice, use of antibiotics, ureterosigmoidostomy, and diabetic ketoacidosis), and shifts of potassium from extracellular to intracellular compartments (as occurs in alkalosis, insulin administration, administration of a β-adrenergic agonist or stress, barium poisoning, and periodic paralysis). As with hyperkalemia, knowledge of the cause of the potassium deficiency and appropriate preoperative evaluation and treatment of that cause may be as important as treatment of the deficiency itself. Also like hyperkalemia, hypokalemia may reflect small or vast changes in total-body potassium. Acute hypokalemia may be much less well tolerated than chronic hypokalemia. The major worrisome manifestations of hypokalemia pertain to the circulatory system, both the cardiac and peripheral components. In addition, chronic hypokalemia results in muscle weakness, hypoperistalsis, and nephropathy.

Cardiovascular manifestations of hypokalemia include autonomic neuropathy, which results in orthostatic hypotension and decreased sympathetic reserve; impaired myocardial contractility; and electrical conduction abnormalities, which can result in sinus tachycardia, atrial and ventricular arrhythmias, and disturbances in intraventricular conduction that can progress to ventricular fibrillation. In addition to arrhythmias, the ECG shows widening of the QRS complex, ST-segment abnormalities, progressive diminution of the T-wave amplitude, and a progressive increase in the U-wave amplitude. Surawicz[379] found these changes to be invariably present when serum potassium levels decreased to below 2.3 mEq/L. Although U waves are not specific for hypokalemia, they are sensitive indicators of the condition. Replenishing the total-body potassium deficit for a depletion reflected by a serum deficit of 1 mEq/L (e.g., from 3.3 to 4.3 mEq/L) may require 1000 mEq of potassium. Even if this amount could be given instantaneously (and it should not be replenished at a rate exceeding 250 mEq/day), it would take 24 to 48 hours to equilibrate in all tissues. Potassium-depleted myocardium is unusually sensitive to digoxin, calcium, and most important, potassium. Rapid potassium infusion in a hypokalemic patient can produce arrhythmias as severe as those produced by hypokalemia itself.[385] One potential strategy to prevent hypokalemia from anxiety and stress includes premedication with clonidine.[386]

Thus, the decision to proceed with surgery and anesthesia in the face of acute or chronic depletions or excesses of potassium depends on many factors.[387-392] It is essential to know the cause and treatment of the underlying condition creating the electrolyte imbalance and the effect of that imbalance on perioperative risk and physiologic processes. The urgency of the operation, the degree of electrolyte abnormality, the medications given, the acid-base balance, and the suddenness or persistence of the electrolyte disturbance are all considerations. For example, one small study of patients undergoing vascular access procedures with preoperative potassium levels of greater than 6 mmol/L demonstrated no adverse outcomes.[390] Similarly, in a cohort study in which 38 patients had a preoperative potassium level higher than 5.5 mEq/L, there were no dysrhythmias or major morbidity associated with the use of succinylcholine.[391]

Retrospective epidemiologic studies attribute significant risk to the administration of potassium (even chronic oral administration).[387] In one study, 1910 of 16,048 consecutive hospitalized patients were given oral potassium supplements. Of these 1910 patients, hyperkalemia contributed to death in 7, and the incidence of complications of potassium therapy was 1 in 250. Armed with such data, many internists do not prescribe oral potassium therapy for patients given diuretic drugs. Yet these patients frequently become moderately hypokalemic.[393] Modest hypokalemia occurs in 10% to 50% of patients given diuretic drugs. Should surgery be delayed to subject such patients to the risks of potassium therapy?

Three studies investigated whether modest hypokalemia was a problem by prospectively seeking arrhythmias on the ECGs of patients who had various preoperative levels of potassium.[388,389,392] No difference in the incidence of arrhythmias occurred in 25 normokalemic ($K > 3.4$ mEq/L) patients, 25 moderately hypokalemic ($K = 3$ to 3.4 mEq/L) patients, and 10 severely hypokalemic ($K < 2.9$ mEq/L) patients.[388] Wahr and coauthors studied 2402 patients undergoing elective CABG and reported that a serum potassium level less than 3.5 mmol/L was a predictor of serious perioperative arrhythmia (OR, 2.2; 95% CI, 1.2 to 4.0), intraoperative arrhythmia (OR, 2.0; 95% CI, 1.0 to 3.6), and postoperative atrial fibrillation/flutter (OR, 1.7; 95% CI, 1.0 to 2.7).[392] The inability of the eye to pick up these changes—or even the inability of Holter recordings for short periods (which seem not to have been used in this study)—points to the need for confirming studies.

Other studies indicate that modest hypokalemia can have severe consequences.[393,394] Holland and coworkers[394] treated 21 patients with 50 mg of hydrochlorothiazide twice a day for 4 weeks. These patients had a history of becoming hypokalemic during diuretic therapy; none of them had cardiac disease or was taking other medications. Before and after diuretic therapy, 24-hour ambulatory ECGs were recorded. This study is also subject to the limitations of Holter monitoring. Ventricular ectopy, including complex ventricular ectopy (multifocal PVCs, ventricular couplets, ventricular tachycardia), developed in 7 of the 21 patients (33%). Potassium repletion decreased the number of ectopic ventricular beats per patient from 71.2 to 5.4/hr. Apparently, some patients are sensitive to even minor potassium depletion. In the Multiple Risk Factor Intervention Trial involving 361,662 patients, more than 2000 of whom were treated for hypertension with

diuretics, the reduction in serum potassium after diuretic therapy was greater in those with PVCs.[393] Although we recommend that hypokalemic patients be given potassium supplements, the merit of this practice is unclear.

Our personal criteria for preoperative potassium therapy are as follows. As a rule, all patients undergoing elective surgery should have normal serum potassium levels. However, we do not recommend delaying surgery if the serum potassium level is above 2.8 mEq/L or below 5.9 mEq/L, if the cause of the potassium imbalance is known, and if the patient is in otherwise optimal condition. This range of safe potassium levels is arbitrary and has changed from 3.3 in 1979, to 3.1 in 1986, to 2.9 in 1990 on the lower side and from 5.6 in 1979, to 5.7 in 1986, to 5.9 in 1990 on the upper side as more data have become available on the safety of preoperative hypokalemia and the dangers of replacing potassium in a hospital environment.[387] We subject all patients with end-stage renal failure to dialysis (using the same arbitrary safe range) before all surgical procedures except truly emergency ones (as in instances of imminent exsanguination). In studies on dogs in 1978, Tanifuji and Eger[395] determined the relationships between electrolyte status and anesthetic requirements that may require intraoperative consideration: hyponatremia and hypoosmolality decreased the minimum alveolar concentration (MAC), hypernatremia increased MAC, and hyperkalemia did not affect the anesthetic requirement.

Gastrointestinal and Liver Diseases

Gastrointestinal Disease

Preoperative Search for Diverse Associated Disorders in Gastrointestinal Disease

Although preoperative preparation of the GI tract is usually the responsibility of the surgeon and although the GI tract frequently does not need to be extensively evaluated by the anesthesiologist, GI disease can and often does cause derangements in many or all other systems. Such disturbances can affect the safety of anesthesia for the patient. Thus, the anesthesiologist may need to not only optimize the patient's condition through extensive preoperative preparation but also have knowledge of disease processes and their effects to guide the patient smoothly through the perioperative period. The major advances of correcting fluid and electrolyte disorders and optimizing nutritional status before surgery now allow surgery to be performed in patients with GI disease previously deemed to be at too great a risk and may have lessened the risk for others.[45-47,396] Still, in patients with GI disease, thorough assessment of intravascular fluid volume, electrolyte concentrations, and nutrition is essential, including an evaluation of the supervening side effects of these therapies (e.g., hypophosphatemia from parenteral nutrition, hyperkalemia or cardiac arrhythmias from too vigorous treatment of hypokalemia, and CHF from too rapid or too vigorous treatment of hypovolemia).

In addition to the vast alterations in fluids, electrolytes, and nutrition that can occur with such diverse GI diseases as neoplasms and pancreatitis, patients with GI disorders can have gastroesophageal reflux disease,[397] bowel obstruction, vomiting, or hypersecretion of acid. These effects may merit rapid induction of anesthesia with the application of cricoid pressure or awake endotracheal intubation, preoperative nasogastric suctioning, or preoperative use of histamine receptor blocking agents. Clotting abnormalities may need to be corrected because fat-soluble vitamin K (often malabsorbed) is necessary for the synthesis of factors V, VII, IX, and X in the liver (also see Chapter 56). Liver disease is often associated with GI disease and, if severe enough, can also result in a deficiency of clotting factors synthesized by the liver.

Other factors should be remembered in the perioperative management of any patient with GI disease. First, closed spaces containing gas expand by absorbing nitrous oxide. Such expansion can lead to ischemic injury, rupture of GI viscera, or both. Second, GI surgery predisposes the patient to sepsis; sepsis and decreased peripheral vascular resistance can lead to massive fluid requirements, cardiac failure, and renal insufficiency. Recently, the surgical site infection rate has been declining. This decrease may be attributable to the use of better technique, more appropriate prophylactic timing and use of antibiotics, better nutrition, less invasive (laparoscopic and endoscopic) surgery, maintenance of normothermia, or surgical resection of even solid tumors.[398-402] Third, patients with GI disease may have many other associated disorders not directly related to the GI tract. For example, they may be anemic from deficiencies in iron, intrinsic factor, folate, or vitamin B_{12}. They may also manifest neurologic changes from combined-system disease. Respiration may be impaired because of heavy cigarette smoking, peritonitis, abscess, pulmonary obstruction, previous incisions, aspiration, or pulmonary embolism (as occurs with ulcerative colitis or with thrombophlebitis in the bedridden). These patients may also have hepatitis, cholangitis, side effects from antibiotic drugs or other medications, massive bleeding with anemia and shock, or psychological derangements.

Because GI disease can be accompanied by so many diverse associated disorders, the clinician must clearly search for involvement of other systems and preoperatively assess and treat such disorders appropriately. Discussion of two specific diseases, ulcerative colitis and carcinoid tumor, will highlight the importance of involvement of other systems in GI disease.

Ulcerative Colitis and Carcinoid Tumors as Examples of Gastrointestinal Disease Affecting Other Systems

Patients with ulcerative colitis often have psychological problems. They may also have phlebitis; deficiencies in iron, folate, or vitamin B_{12}; anemia; or clotting disorders caused by malabsorption. They may be malnourished or dehydrated or have electrolyte abnormalities. In addition, ulcerative colitis can be accompanied by massive bleeding, bowel obstruction or perforation or toxic megacolon causing respiratory compromise, hepatitis, arthritis, iritis, spondylitis, or diabetes secondary to pancreatitis.

The site of origin of carcinoid tumors in more than 75% of patients is the GI tract. Within the GI tract, carcinoid tumors have been documented to occur from the esophagus to the rectum. The most frequent site is the appendix, but carcinoids in this location rarely, if ever metastasize or produce carcinoid syndrome. Tumors arising in the ileocecal region have the highest incidence of metastases. Carcinoid tumors originating from sites other than the GI tract, such as the head and neck, lung, gonads, thymus, breast, and urinary tract, have also been reported. Cardiac involvement, though frequently reported, is usually limited to right-sided valvular and myocardial plaque formation.[403]

Not all patients with carcinoid tumors have symptoms attributable to secretion of hormone by the tumor. Some can, however, and unexpected carcinoid can be manifested during surgery by hypersecretion of gastric fluid. The most comprehensive series in the literature indicates that only 7% of patients have carcinoid syndrome, which typically consists of flushing, diarrhea, and valvular heart disease. Of those with the syndrome, approximately 74% have cutaneous flushing; 68%, intestinal hypermotility; 41%, cardiac symptoms; and 18%, wheezing. Factors influencing symptoms include the location of the tumor and the specific hormones produced and secreted. Although it is generally believed that if patients do not exhibit carcinoid syndrome, the tumors are not producing serotonin (5-hydroxytryptamine [5-HT]), but such may not be the case. Approximately 50% of patients with carcinoid tumors of the GI tract demonstrate evidence of 5-HT production as manifested by elevated urinary levels of 5-hydroxyindoleacetic acid (5-HIAA), a metabolic product of 5-HT. Carcinoid syndrome is usually associated with ileal carcinoid tumors that have metastasized to the liver. Presumably, the liver clears mediators released from the tumor. Impairment of this clearing ability by the metastatic tumor results in carcinoid syndrome.

Most patients with carcinoid tumors and increased urinary 5-HIAA have typical carcinoid tumors originating from the midgut (ileum or jejunum). These patients excrete only small amounts of 5-hydroxytryptophan (5-HTP). Patients with atypical carcinoid tumors that originate in the foregut (bronchus, stomach, and pancreas) excrete large amounts of 5-HT and 5-HTP, as well as moderately higher amounts of 5-HIAA.

Although it is generally agreed that 5-HT is responsible for the diarrhea experienced by patients with carcinoid tumors, other neurohumoral agents may contribute to the flushing and hypotension, including dopamine, histamine, and some of the neuropeptides such as substance P, neurotensin, vasoactive intestinal peptide, and somatostatin.

The net physiologic effect of circulating 5-HT represents a composite of both direct action (mediated by 5-HT receptors) and indirect action (mediated through modulation of adrenergic neurotransmission). The existence of several subtypes of 5-HT receptors may account for the different effects of 5-HT on various serotonin-sensitive tissue beds. Indirect actions are effected through alterations in catecholamine release and depend on the level of circulating 5-HT.

5-HT has little if any direct effect on the heart. With elevated levels, however, positive chronotropic and inotropic myocardial effects may occur, mediated by the release of noradrenaline (norepinephrine). Effects of serotonin on the vasculature include both vasoconstriction and vasodilation.

Alterations in GI function attributed to 5-HT include increased motility and net intestinal secretion of water, sodium chloride, and potassium. 5-HT reportedly causes bronchoconstriction in many animals, but rarely in humans. Asthmatics are a possible exception. Carcinoid tumors are frequently manifested as diarrhea with fluid and electrolyte abnormalities. Because these tumors secrete vasoactive substances, patients can exhibit hypotension or hypertension along with the flush associated with release of vasoactive substances. Vasoactive substances can be released from the tumor by any number of substances, including catecholamines. Until the 1990s, management of patients with this tumor was a real challenge for the anesthesiologist. Thus, anesthesiologists of that era had to tread a fine line between avoiding substances known to release 5-HT (e.g., *d*-tubocurarine and morphine) and inducing anesthesia so light that painful stimuli activate a sympathetic stress response.[404] The anesthesiologist also needed to be ready and able to treat hypotension, decreased peripheral vascular resistance, bronchospasm, and hypertension. α-Adrenergic receptor blockade with the phenothiazines, butyrophenones, or phenoxybenzamine and β-adrenergic receptor blockade with propranolol have been advocated to prevent catecholamine-mediated release of vasoactive substances. These practices, however, can lead to hypotension. Nevertheless, the difficulty in managing carcinoid syndrome seemed to change with the availability of a somatostatin analog. In fact, somatostatin is now such a powerful inhibitor of the release of peptides from carcinoid tumors and an inhibitor of the peptic effects on receptor cells that it is the therapy of choice for preoperative, intraoperative, and postoperative management of carcinoid symptoms and crises.[404,405] In cardiac surgical patients there has been a reduction in mortality over time, and vasopressors were shown to be safe in conjunction with octreotide.[406] However, the ease of management of most patients[404,405,407-410] should not lull the anesthesiologist into being unprepared—in fact, somatostatin has caused problems of its own and has failed to prevent severe hypotension and bronchospasm.[411,412]

In patients with severe hypotension that is not treatable with somatostatin, the drug of choice is either angiotensin or vasopressin. (Angiotensin is not commercially available in the United States.) However, the vasoactive substances released by carcinoid tumors cause fibrosis of the heart valves that often results in pulmonic stenosis or tricuspid insufficiency. To increase cardiac output in a patient with tricuspid insufficiency, the anesthesiologist should avoid drugs or situations that increase pulmonary vascular resistance (e.g., angiotensin, vasopressin, acidosis, hypercapnia, hypothermia). In addition, the production of large amounts of 5-HT (equal to 200 mg/day of 5-HIAA) can lead to the development of niacin deficiency with pellagra (as occurs with diarrhea, dermatitis, and dementia).

Acute elevation of plasma kinin activity in carcinoid patients has been postulated for many years as the explanation for the symptoms of carcinoid syndrome. The physiologic effects of kinins are known to include vasodilation of smaller resistance vessels and stimulation of the release of histamine from mast cells. The latter action potentiates their own vasodilating properties and further reduces systolic and diastolic BP. In addition, increases in vascular permeability may lead to edema. Kinins are not known to affect the myocardium directly.

Steroids have been effective in treating the symptoms of bronchial carcinoid tumors. Although prophylactic preoperative administration and intraoperative therapeutic use have been described, controlled studies of beneficial effects are lacking. Aprotinin, like steroids, inhibits the kallikrein cascade. This drug is capable of blocking the proteinase activity of kallikrein, and some reports have described a dramatic clinical response.

A subset of patients with symptoms of carcinoid syndrome excrete histamine at increased levels in their urine. Histamine causes vasodilation of small blood vessels, which leads to flushing and decreased total peripheral resistance. Histamine is known to cause bronchoconstriction, particularly in patients with bronchial asthma and other pulmonary diseases. Its role in carcinoid bronchospasm, if any, is uncertain. Histamine receptor blocking drugs have been used with some success in alleviating the flushing associated with carcinoid syndrome. H_2 antagonism alone was

found to be just as effective as combination therapy in preventing symptoms; pure H_1 antagonism, however, was ineffective. These therapies have been relegated to a second-line defense since the use of somatostatin.

Catecholamines aggravate the symptoms of carcinoid syndrome, presumably by stimulating release of hormone by the tumor. The mechanism by which this release occurs remains obscure. Adrenergic receptors have not been demonstrated in carcinoid tumors, nor do these tumors usually have neural innervation. Perhaps adrenergic stimuli work through their mechanical effects on the gut and vessels to stimulate the release of tumor products. Treatment of patients with carcinoid tumors by means of α- and β-adrenergic antagonists has been beneficial in ameliorating flushing in some instances but ineffective in others.

The results of prospective studies on somatostatin to ameliorate the symptoms of carcinoid syndrome have been dramatic. Somatostatin appears to be a major advancement in the treatment of carcinoid syndrome.

It might logically be concluded that preoperative preparation of a patient with carcinoid syndrome would be similar to that for a patient with pheochromocytoma: titration of adrenergic, histaminic, and serotonergic receptor blocking drugs to maximum effect while monitoring intravascular volume status and adding somatostatin before surgery. Although this approach is logical, preoperative symptoms do not correlate with perioperative symptoms, and only the last two therapeutic options (optimization of intravascular fluid status and administration of somatostatin) are most effective.

Bronchospasm with or without flushing also develops in many patients when vasoactive substances are released. Thus, a patient with carcinoid tumor may be well or may be severely incapacitated by pulmonary, neurologic, nutritional, fluid, electrolytic, or cardiovascular disturbances. Therefore, although the GI system in itself may not require extensive preoperative preparation, GI disease can cause disturbances in any or all other systems that require extensive preoperative preparation to optimize the patient's condition plus preoperative knowledge of physiology and the effects of diseases to guide patients through the perioperative period smoothly. In addition, the anesthesiologist's understanding of the nature of the surgery probably aids in determining the system involvement caused by the GI disorder.

Another perioperative consideration is that patients with GI diseases (perhaps even more so than those with other diseases) have had to endure the psychosocial trauma of having to live with their disease for long periods or the necessity of facing such a prospect.[413] They need emotional support and holistic kindnesses as much as, if not more than others, without sacrificing scientific rigor in the treatment of their condition. Obtaining relevant psychological data while gathering medical information, sitting (not standing) while taking the history, and empathizing with the patient about how difficult it must be to accomplish tasks with this disease (stressing accomplishments, we have found) legitimize the physician's interests in and support of the patient's pain and other psychosocial issues. The time spent sitting and talking with the patient also allows the anesthesiologist to discuss options for pain therapy with the patient, why systemic morphine might be avoided in a patient with a fresh bowel anastomosis,[414] and other issues that show the anesthesiologist to be both a competent physician and particularly concerned with that patient's well-being. In addition to an appreciation of the organic effects of their disease, attention to emotional support of these patients perioperatively presents opportunities to use one's full skills as a physician to bring about healing.

Liver Disease

What are the risks of giving anesthesia to patients with acute liver disease who require emergency surgery? What are the risks of giving anesthesia to patients with chronic impairment of liver function? What can be done to minimize these risks? Although one might think that the experiences gained from providing anesthesia for liver transplantation would answer many of these questions, there is a substantial difference between optimizing cardiovascular function to meet the needs of a new liver (e.g., supply of nutrients) and maintaining liver function in a diseased liver. Because hepatic function and physiology are discussed in Chapter 17 and the preoperative evaluation is reviewed in Chapter 34, we will mention only that the liver performs many functions: it synthesizes substances (e.g., proteins, clotting factors), detoxifies the body of both drugs and the products of normal human metabolism, excretes waste products, and stores and supplies energy.

Hematologic Disorders and Oncologic Disease

Hematologic Disorders

Anemia and Polycythemia

Chapters 55 and 57 discuss the evidence that normovolemic anemia or polycythemia increases perioperative morbidity. The results indicate that knowledge and pretreatment of polycythemia might decrease perioperative morbidity and mortality.

Except for patients with ischemic heart disease (see later), no such evidence exists for normovolemic anemia.[415] Thus, there are no specific preoperative routines for anemia itself, except regarding patients who have or are likely to have ischemic heart disease (as determined by risk factors).[416-418] For these patients, hematocrits above or below 29% to 34% were found in two separate studies to be associated with increased episodes of myocardial ischemia after vascular surgery (Fig. 35-10).[178] For patients at risk for current ischemic heart disease, data indicate that transfusion to a hematocrit level of 29% to 34% may be appropriate (also, see the earlier section on cardiovascular diseases).[419,420] It should be remembered that anemia is a reduction in circulatory erythrocyte mass below the range of values considered normal for persons of the same sex at the same location (age older than 6 months, race, and ethnic background do not explain anemia). Each erythrocyte lives for approximately 120 days; therefore, replacement of 15 to 20 mL of senescent cells needs to be accomplished in the absence of diseases that destroy or cause loss of blood cells. Moreover, the symptoms of anemia—headache, weakness, exertional dyspnea, and loss of endurance—do not provide much information about the severity, rapidity of onset, and cardiorespiratory effects of the underlying cause of the anemia.

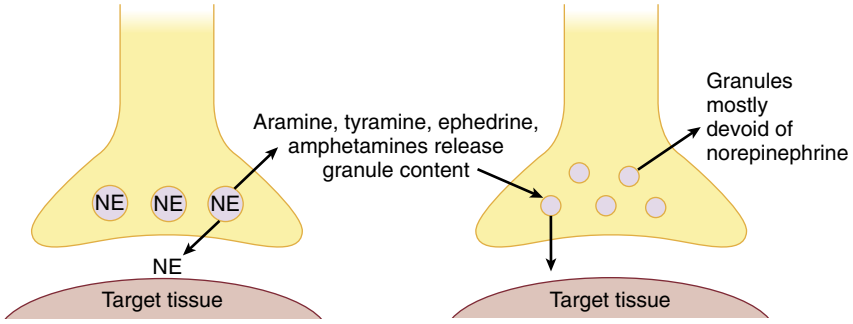

Figure 35-10 Antihypotensive drugs such as metaraminol (Aramine), tyramine, and ephedrine create their effect by releasing catecholamines from granules of the nerve terminal. Therefore, when treatment with drugs such as methyldopa, reserpine, or guanethidine depletes store of norepinephrine (NE) in the granules, little NE remains for release, and the antihypotensive drugs have been rendered ineffective.

Furthermore, because anemia can be a hallmark of many other diseases possibly affecting perioperative anesthetic management, the preoperative presence of anemia requires a search for and treatment of the underlying cause. For instance, anemia could indicate renal insufficiency or a drug reaction, both of which could alter anesthetic management. For this reason, the cause of the anemia should be known preoperatively. Similarly, polycythemia can be a primary disease (e.g., polycythemia vera), or it can be secondary to smoking, the use of diuretic drugs, chronic use of androgens, hypoxia, or other forms of chronic lung/heart disease. Phlebotomies are quite effective for patients with mild polycythemia. Cerebral blood flow improves when the hematocrit is kept below 45%. No prospective controlled study has been performed on humans regarding a possible decrease in perioperative morbidity or wound healing[178,416-418] as a result of perioperative treatment of anemia or polycythemia, although a National Institutes of Health–sponsored trial in hip fracture patients is ongoing. The time of most danger to the patient may be the early recovery room period, during which time oxygen delivery to the lungs is perhaps at its worst.[178] Options for alternatives to blood therapy are discussed in Chapters 55 and 57.

Erythropoietin is one of the substances necessary for normal production of red blood cells. Production and secretion of erythropoietin from the peritubular cells of the kidney are stimulated by tissue hypoxia. Signal transduction of this hypoxic stimulus depends on a heme-containing oxygen-sensing protein that mediates changes in the stability of messenger RNA from chromosome 7 in erythropoietin-producing cells. Erythropoietin triggers quiescent, early erythroid progenitor cells into cycle by acting like a mitogen and facilitating differentiation into late committed erythroid progenitor cells. In normoxic individuals, synthesis of erythropoietin is not stimulated until the concentration of hemoglobin falls below 10.5 g/dL. In severe anemia, erythropoietin levels can increase more than 1000-fold. Iron, folic acid, and vitamin B_{12} are also needed for normal maturation of erythrocytes. Several forms of anemia present special situations, such as sickle cell anemia, hereditary spherocytosis, and the autoimmune hemolytic anemias.

Sickle Cell Anemia and Related Hemoglobinopathies

The sickle cell syndromes constitute a family of hemoglobinopathies caused by abnormal genetic transformation of amino acids in the heme portion of the hemoglobin molecule. The sickle cell syndromes arise from a mutation in the β-globin gene that changes the sixth amino acid from valine to glutamic acid. A major pathologic feature of sickle cell disease is the aggregation of irreversibly sickled cells in blood vessels. The molecular basis of sickling is the aggregation of deoxygenated hemoglobin B molecules along their longitudinal axis.[421] This abnormal aggregation distorts the cell membrane and thereby produces a sickle shape. Irreversibly sickled cells become dehydrated and rigid and can cause tissue infarcts by impeding blood flow and oxygen to tissues.[421-424] Some have challenged this hypothesis, with several studies showing enhanced adhesion of sickled erythrocytes to vascular endothelium.[425] Some other abnormal hemoglobins interact with hemoglobin S to various degrees and give rise to symptomatic disease in patients heterozygous for hemoglobin S and one of the other hemoglobins such as the hemoglobin of thalassemia (hemoglobin C).

Three tenths of 1% of the African American population in the United States have sickle cell–thalassemia disease (hemoglobin SC); these patients also have end-organ disease and symptoms suggestive of organ infarction. For these patients, perioperative considerations should be similar to those for patients with sickle cell disease (hemoglobin SS), discussed later.

Whereas 8% to 10% of African Americans have the sickle cell trait (hemoglobin AS), 0.2% are homozygous for sickle cell hemoglobin and have sickle cell anemia. Sickle cell trait is a heterozygous condition in which the individual has one βS globin gene and one βA globin gene, which results in the production of both hemoglobin S and hemoglobin A, with a predominance of hemoglobin A. Sickle cell trait should not be considered a disease because hemoglobin AS cells begin to sickle only when the oxygen saturation of hemoglobin is below 20%. No difference has been found between normal persons (those with hemoglobin AA) and those with hemoglobin AS regarding survival rates or the incidence of severe disease, with one exception: patients with hemoglobin AS have a 50% increase in pulmonary infarction. However, single case reports of a perioperative death and a perioperative brain infarct in two patients with hemoglobin AS disease do exist, and a report of death believed to be due to aortocaval compression during general anesthesia that resulted in a sickling crisis does exist.[426] The need for exchange transfusion before cardiac surgery has been debated.[427,428] Frequent measurement of oxygen

saturation (pulse oximetry) in multiple areas of the body is recommended, including the ear and toe in pregnant patients.[426] A retrospective review of exercise in military recruits showed that soldiers with sickle cell trait had a higher risk for sudden death after extreme exertion during basic training than did black soldiers with only hemoglobin A—32 per 100,000 versus 1 per 1,000,000.[429] Although this magnitude of increase may not seem great, the vasoactive responses of the perioperative period can be similar to those of moderate to extreme exertion.

The pathologic end-organ damage that occurs in sickle cell states is attributable to three processes: the sickling or adhesion (or both) of cells in blood vessels, which causes infarcts and subsequent tissue destruction secondary to tissue ischemia; hemolytic crisis secondary to hemolysis; and aplastic crises that occur with bone marrow exhaustion, which can rapidly result in severe anemia. Logic dictates that patients currently in crisis not undergo surgery except for extreme emergencies, and then only after an exchange transfusion.[423,425-429]

Because sickling is increased with lowered oxygen tensions, acidosis, hypothermia, and the presence of more desaturated hemoglobin S, current therapy includes keeping the patient warm and well hydrated, giving supplemental oxygen, maintaining high cardiac output, and not creating areas of stasis with pressure or tourniquets. Meticulous attention to these practices in periods when we do not usually pay most careful attention (i.e., waiting in the preinduction area) or when gas exchange may be most unmatched to the cardiovascular-metabolic demands (early postoperative period) may be important in lessening morbidity. Even following these measures routinely, with no special emphasis placed on the periods described, succeeded in reducing mortality to 1% in several series of patients with sickle cell syndromes.[426,429,430] Retrospective review of patient charts led the authors of those studies to conclude that at most, a 0.5% mortality rate could be attributed to the interaction between sickle cell anemia and anesthetics.

Can this rate be decreased?[422,430] Several investigators have advocated using partial exchange transfusions perioperatively. In children with sickle cell anemia and acute lung syndromes, partial exchange transfusion improved clinical symptoms and blood oxygenation. In addition, serum bilirubin levels decreased in patients with acute liver injury. Clinical improvement of pneumococcal meningitis and cessation of hematuria in papillary necrosis also accompanied exchange transfusion.[422] The goal of exchange transfusion is to increase the concentration of hemoglobin A to 40% and the hematocrit to 35%. The 40% figure is an arbitrary one because no controlled studies have established a threshold ratio of hemoglobin A to hemoglobin S that would render blood unable to sickle in vivo. To achieve the 40% ratio in a 70-kg adult, about 4 units of washed erythrocytes would have to be exchanged; the system is inexpensive but efficient.

The possible decrease in preoperative morbidity after partial exchange transfusion has not been compared with the risks of exchange, except in two studies,[424,431] in which the risks of exchange were found to exceed the benefits. In the first study, a retrospective review of 82 surgical procedures performed between 1978 and 1986 in 60 patients, no advantage was noted for preoperative exchange transfusion, as measured by a decrease in postoperative complications.[431] (However, only the sickest may have received exchange transfusions because patients were not randomly allocated to exchange or nonexchange groups.) A slight increase in postoperative atelectasis requiring treatment was seen in patients given preoperative transfusions. More than 50% of the patients given transfusions had a postoperative complication. Patients who began with a hematocrit higher than 36% had a lower rate of complications.[431] In the second study, a randomized comparison of aggressive versus conservative transfusion practices in 551 patients (604 operations), perioperative sickling complications were not different between groups, and transfusion-related complications were substantially less in the conservative group.[424] Therefore, our recommendation is to pay meticulous attention to preventing conditions that increase sickling or that cause infection and to limit exchange transfusion to crisis situations. Perhaps giving higher concentrations of enriched oxygen to patients undergoing laparoscopic procedures should also become routine. Induction of hyponatremia has been shown to abort acute sickle cell crisis; however, this treatment has not gained widespread acceptance. Other conditions are common in sickle cell syndromes: pulmonary dysfunction with increased shunting, renal insufficiency, gallstones, small MIs, priapism, stroke, aseptic necrosis of bones and joints, ischemic ulcers, retinal detachment as a result of neovascularization, and complications of repeated transfusions.

In thalassemia, globin structures are normal, but because of gene deletion, the rate of synthesis of either the α- or β-chains of hemoglobin (α- and β-thalassemia, respectively) decreases.[432-434] Two copies of the gene that codes for the α-globin chain are located on chromosome 16. Deletion of all four of these genes causes cell death in utero, and three deletions cause severe chronic hemolysis and a shortened life span. "α-Thalassemia-1 (trait)" occurs when two genes have been deleted and mild anemia results; "α-thalassemia-2 (silent)" occurs when the two genes have been deleted but no mild anemia or microcytosis results. In α-thalassemia trait, the hemoglobin A_2 level is normal. β-Thalassemia is associated with an excess of α-chains, which denature developing erythrocytes, thereby leading to their premature death in marrow or to shortened survival in the circulation. An elevated hemoglobin A_2 level is the hallmark of β-thalassemia trait, a common cause of mild anemia and microcytosis. Bone marrow transplantation and pharmacologic manipulation of hemoglobin F synthesis are being tried in these hemoglobinopathies, as is direct gene replacement therapy. These therapies seem to be promising in even reversing liver failure from previous iron overload.[435] These syndromes are common in Southeast Asia, India, and the Middle East and in people of African descent.

In thalassemia, facial deformity from erythropoietin-stimulated ineffective erythropoiesis (ineffective because of a genetic inability to produce useful hemoglobin) has been reported to make endotracheal intubation difficult.[432,433] This one case report[433] has not been amplified, and there are no reports of this complication in patients with sickle cell anemia. However, the anemia associated with these syndromes often produces a compensatory hyperplasia of the erythroid marrow, which in turn is associated with severe skeletal abnormalities.[432-434]

Cytoskeletal Anemias (Hereditary Spherocytosis and Elliptocytosis), Enzyme-Deficient Anemias, and Autoimmune Hemolytic Anemias

Congenital abnormalities of the erythrocyte membrane are becoming better understood. In elliptocytosis and hereditary spherocytosis, the membrane is more permeable to cations and more susceptible to lipid loss when cell energy is depleted than is the membrane of a normal red blood cell. Both hereditary sphe-

rocytosis (present in 1 in 5000 people) and hereditary elliptocytosis are inherited as autosomal dominant traits. In both disorders, defects in the membrane are thought to result from a mutation of spectrin, a structural protein of the membrane cytoskeleton.[436] Although the therapeutic role of splenectomy in these diseases is not fully defined, in severe disease, splenectomy is known to improve the shortened life span of the red blood cell 100% (from 20 to 30 days to 40 to 70 days). Because splenectomy predisposes the patient to gram-positive septicemia (particularly pneumococcal), perhaps patients should be given pneumococcal vaccine preoperatively before predictable bacteremic events. No specific problems related to anesthesia have been reported for these disorders.

Glucose-6-phosphate dehydrogenase (G6PD) deficiency (a gender-linked recessive trait) is also reported to occur in approximately 8% of African American men.[437] Young cells have normal activity, but older cells are grossly deficient when compared with normal cells. A deficiency in G6PD results in hemolysis of the erythrocyte and the formation of Heinz bodies. Red cell hemolysis can also occur with intercurrent infections or after the administration of drugs that produce substances requiring G6PD for detoxification (e.g., methemoglobin, glutathione, and hydrogen peroxide). Drugs to be avoided are sulfa drugs, quinidine, prilocaine, lidocaine, antimalarial drugs, antipyretic drugs, nonnarcotic analgesics, vitamin K analogs, and perhaps sodium nitroprusside.

The autoimmune hemolytic anemias include cold antibody anemia, warm antibody anemia (idiopathic), and drug-induced anemia.[438-440] Cold antibody hemolytic anemias are mediated by IgM or IgG antibodies, which at room temperature and below cause red blood cells to clump. When these patients are given blood transfusions, the cells and all fluid infusions must be warm, and body temperature must be meticulously maintained at 37°C if hemolysis is to be prevented. Warm antibody (or "idiopathic") hemolytic anemia is a difficult management problem characterized by chronic anemia, the presence of antibodies active against red blood cells, a positive Coombs test, and difficulty crossmatching blood. For patients undergoing elective surgery, autologous transfusions, predeposit of blood with or without erythropoietin stimulation,[441] and blood from rare Rh-negative red blood cell donors or the patient's first-degree relatives (or both) can be used. In emergency situations, the possibility of autotransfusion, splenectomy, or corticosteroid treatment should be discussed with a hematologist knowledgeable in this area.

Drug-induced anemias have three mechanisms. In receptor-type hemolysis, a drug (e.g., penicillin) binds to the membrane of the red blood cell, and the complex stimulates the formation of an antibody against the complex. In "innocent bystander" hemolysis, a drug (e.g., quinidine, sulfonamide) binds to a plasma protein, thereby stimulating an antibody (IgM) that cross-reacts with an erythrocyte. In autoimmune hemolysis, the drug stimulates the production of an antibody (IgG) that cross-reacts with the erythrocyte. Drug-induced hemolytic anemias generally cease when therapy with the drug ends. In emergency situations, the least incompatible cells available should be used for blood transfusion.

Granulocytopenia

Granulocyte mechanisms have undergone experimental elaboration in the last decade, partly because of the molecular biologic revolution: in addition to erythropoietin (discussed earlier), more than 14 hemolymphopoietic growth factors or cytokines have been characterized biochemically and cloned genetically. These growth factors interact with cell-surface receptors to produce their major actions (Table 35-19).[442] Use of the colony-stimulating factors has permitted more intense oncologic treatment. The few reports related to their perioperative effects detail the unfavorable adverse consequences that such therapies can have on gas exchange when adverse immunologic effects occur.[443]

In patients who have fewer than 500 granulocytes per milliliter of blood and established sepsis, the use of growth factor and granulocyte transfusion has been shown to prolong life.[444-446] Although bone marrow transplantation is being used increasingly, complications usually occur after transplantation, not on harvesting of cells (at which time the anesthesiologist who is not involved in critical care is most frequently involved). Abnormal results on pulmonary function testing before bone marrow transplantation seem to predict complications after transplantation, but not so strongly as to preclude transplantation.[447]

Platelet Disorders

Although inherited platelet disorders are rare, acquired disorders are quite common and affect at least 20% of all patients in medical and surgical ICUs, with infections and drug therapies being the leading causes (also see Chapter 55).[448] Both acquired and inherited platelet conditions cause skin and mucosal bleeding, whereas defects in plasma coagulation produce deep tissue bleeding or delayed bleeding. Perioperative treatment of inherited platelet disorders (e.g., Glanzmann's thrombasthenia, Bernard-Soulier syndrome, Hermansky-Pudlak syndrome) consists of platelet transfusions. EACA has recently been used successfully (experimentally, 1 g/70 kg four times daily) to decrease perioperative bleeding in thrombocytopenic patients. The much more common acquired disorders may respond to one of several therapies (see Chapter 55). Immune thrombocytopenias, such as those associated with lupus erythematosus, idiopathic thrombocytopenic purpura, uremia, hemolytic-uremic syndrome, platelet transfusions, heparin, and thrombocytosis, may respond to steroids, splenectomy, plateletpheresis, eradication of *Helicobacter pylori*, or alkylating agents or may require platelet transfusions, plasma exchange, whole blood exchange, or transfusion; sometimes these disorders do not respond to anything.[194,449,450] Traditionally, splenectomy is performed when steroid therapy fails or reaches a dosage that poses unacceptable risks of toxicity. Newer agents such as anti-D immune globulin and rituximab may induce desirable remissions in idiopathic thrombocytopenic purpura without splenectomy.

Thrombotic thrombocytopenic purpura is a rare disorder of unknown cause. Despite various therapies, this disorder carries a very high mortality rate. However, the introduction of plasmapheresis has improved response rates dramatically in patients with this disease. One uncontrolled study implies that the benefit lies not only in improvement of the hematologic picture but also in prevention of adult respiratory distress syndrome, a leading cause of death in these patients.[450] In that study, early institution of plasmapheresis improved oxygenation.

By far the largest number of platelet abnormalities consists of drug-related defects in the aggregation and release of platelets. Aspirin irreversibly acetylates platelet cyclooxygenase, the enzyme that converts arachidonic acid to prostaglandin endoperoxidases. Because cyclooxygenase is not regenerated in the circulation within the life span of the platelet and because this enzyme is

Table 35-19 Major Effects of Hemolymphopoietic Growth Factors/Cytokines

Cytokine	Other Names	Biologic Effects
Erythropoietin		Erythrocyte production
Interleukin-3 (IL-3)	Multicolony-stimulating factor Stem cell–activating factor Persisting cell-stimulating factor Hemopoietin-2	Stimulates proliferation and differentiation of granulocyte, macrophage, eosinophil, mast cell, megakaryocyte, and T- and B-cell lineage and early myeloid stem cells. Interacts with erythropoietin to stimulate erythroid colony formation, stimulates proliferation of AML blasts, and stimulates histamine release by mast cells
Granulocyte colony-stimulating factor (G-CSF)	Differentiation factor MGI-2	Stimulates granulocyte lineage proliferation and differentiation. Acts on early myeloid stem cells, especially in association with other factors; synergizes with IL-3 to stimulate megakaryocyte colony formation. Increases neutrophil phagocytes and antibody-dependent cell-mediated cytotoxicity. Releases neutrophils from bone marrow and is chemotactic for neutrophils and monocytes. Enhances phagocytosis and antibody dependent cell-mediated cytotoxicity and oxidative metabolism of neutrophils. Stimulates monocyte killing of *Mycobacterium avium-intracellulare* and *Candida* species, tumoricidal activity of monocytes, antibody-dependent cell-mediated cytotoxicity, and expression of cell-surface proteins
Granulocyte-macrophage colony-stimulating factor (GM-CSF)		Stimulates granulocyte, macrophage, and megakaryocyte proliferation and differentiation, early myeloid stem cells, and—in the presence of erythropoietin—erythropoiesis. Enhances the cytotoxic and phagocytic colony-stimulating factor activity of neutrophils against bacteria, yeast, parasites, and antibody-coated tumor cells. Increases surface expression of neutrophil adhesion proteins and enhances eosinophil cytotoxicity, macrophage phagocytosis, and basophil histamine release. Amplifies IL-2–stimulated T-cell proliferation and stimulates B-cell lines to proliferate
Colony-stimulating factor-1	Macrophage colony-stimulating factor	Stimulates predominantly macrophage-monocyte proliferation and differentiation with lesser effects on granulocytes. Acts synergistically with other factors on earlier myeloid stem cells. Stimulates macrophage phagocytosis, killing, migration, antitumor activity, and metabolism. Stimulates secretion of plasminogen activator, G-CSF, interferon, IL-3, or tumor necrosis factor by peritoneal macrophages
Interleukin-1 (α and β)	Endogenous pyrogen Hemopoietin-1 Osteoclast-activating factor Lymphocyte-activating factor	Induces synthesis of acute-phase proteins by hepatocytes. Activates resting T cells, cofactor for T- and B-cell proliferation. Chemotactic for monocytes and neutrophils. Induces production of growth factors, including G-CSF, GM-CSF, IL-6, CSF-1, IL-3, and interferon by many cells. Radioprotective in mice
Interleukin-2	T-cell growth factor	Growth factor for T cells, activates cytotoxic T lymphocytes, promotes synthesis of other cytokines, enhances natural killer cell function
Interleukin-4	B-cell–stimulating factor-1 B-cell differentiation factor (BCDF) IgG induction factor	Enhances antibody production (IgG and IgE) and upregulates class II MHC molecules and Fc receptors on B cells. Costimulant with anti-IgM antibodies for induction of DNA synthesis in resting B cells. Stimulates growth of activated T cells. In the presence of IL-3, enhances mast cell growth; with G-CSF, enhances granulocytes of GM colony formation; and with erythropoietin and/or IL-1, stimulates erythroid and megakaryocyte colony formation
Interleukin-5	Eosinophil differentiation factor (EDF) T-cell–replacing factor (TRF) B-cell growth factor-II (BCGF-II) B-cell differentiation factor (BCDF)	Enhances antibody production (IgA). Promotes proliferation and IgG secretion by B-cell lines and induces hapten-specific IgG secretion in vitro by in vivo–primed B cells. Promotes differentiation by normal B cells. Stimulates eosinophil production and differentiation (GM-CSF and IL-3 act synergistically with IL-5 to stimulate eosinophil proliferation and differentiation). Enhances synthesis of IL-2 receptors
Interleukin-6	B-cell–stimulating factor-2 (BSF-2) Interferon-β_2 T-cell activation factor Hybridoma growth factor	B-cell differentiation and IgG secretion. T cells activated to cytotoxicity. Synergizes with IL-3 on early marrow myeloid stem cells and stimulates proliferation and differentiation of granulocytes, macrophages, eosinophils, mast cells, and megakaryocytes, as well as platelet production (may be a thrombopoietin)
Interleukin-7	Lymphopoietin-1	Stimulates pre–B-cell production. Stimulates T-cell proliferation
Interleukin-8*	Neutrophil-activating factor T-cell chemotactic factor	Inflammatory mediator; stimulates activation of neutrophils
Interleukin-9		Stimulates erythroid colony formation and proliferation of a megakaryocyte cell line
Interleukin-10	Cytokine synthesis– inhibiting factor	Inhibits cytokine production by T_H1 cells
Interleukin-11		Stimulates B-cell, megakaryocyte, and mast cell lineages
C-kit ligand	Mast cell factor Stem cell factor Hemolymphopoietic growth factor-1	Acts on relatively early stem cells synergistically with other cytokines. Stimulates pre-B cells

*Not considered a true growth factor but included here for completeness.
AML, acute myeloblastic leukemia; MHC, major histocompatibility complex; T_H1, first of the thymus-derived cells.
Modified from Quesenberg PJ, Schafer AI, Schreiber AD, et al: Hematology. *In* American College of Physicians: Medical Knowledge Self-Assessment. Philadelphia, American College of Physicians, 1991, p 374.

essential for the aggregation of platelets, one aspirin tablet may affect platelet function for a week. All other drugs that inhibit platelet function (e.g., vitamin E, indomethacin, sulfinpyrazone, dipyridamole, tricyclic antidepressant drugs, phenothiazines, furosemide, steroids) do not inhibit cyclooxygenase function irreversibly; these drugs disturb platelet function for only 24 to 48 hours. If emergency surgery is needed before the customary 8-day period for platelet regeneration after aspirin therapy or if the 2-day period for other drugs has not elapsed, administration of 2 to 5 units of platelet concentrates will return platelet function in a 70-kg adult to an adequate level and platelet-induced clotting dysfunction to normal. Only 30,000 to 50,000 normally functioning platelets per milliliter is needed for normal clotting. Because low-dose aspirin therapy (<650 mg/day) allows aspirin to be gone from the body 24 hours after the last dose and because the body makes 70,000 platelets/mL blood per day, a 48-hour period after the last aspirin in minidose therapy should be sufficient time for platelet aggregation to become normal. This may be the period that must pass to avoid platelet transfusions and their associated risks. One platelet transfusion will increase the platelet count from 4000 to 20,000/mL blood; the platelet half-life is about 8 hours.

Heparin-induced thrombocytopenia can develop within hours on re-exposure to heparin in a previously sensitized patient. Lepirudin and argatroban are direct thrombin inhibitors effective as therapy for heparin-induced thrombocytopenia.[451]

Major risk factors for thrombosis include factor V Leiden and prothrombin 20210A mutations, elevated plasma homocysteine, and the antiphosphoid antibody syndrome.[452,453] Clinicians facing these challenging patients might seek expert local consultation for help with management. This issue is discussed more fully in Chapter 56.

Hemophilia and Related Clotting Disorders

Abnormalities in blood coagulation as a result of defects in plasma coagulation factor are either inherited or acquired. Inherited disorders include X-linked hemophilia A (a defect in factor VIII activity), von Willebrand's diseases (defect in the von Willebrand component of factor VIII), hemophilia B (a sex-linked deficiency of factor IX activity), and other less common disorders. The sex-linked origin of some of these disorders means that hemophilia occurs almost exclusively in the male offspring of female carriers; men do not transmit the disease to their male offspring.

In elective surgery, levels of the deficient coagulation factor should be assayed 48 hours before surgery and the level restored to 40% of normal before surgery. One unit of factor concentrate per kilogram of body weight normally increases the factor concentration by 2%. Thus, in an individual essentially devoid of activity, administration of 20 U/kg body weight would be required as an initial dose. Because the half-life is 6 to 10 hours for factor VIII and 8 to 16 hours for factor IX, approximately 1.5 U/hr/kg of factor VIII or 1.5 U/2 hr/kg of factor IX should be given. Additional administration of factors VIII and IX should be guided by the activity of the clotting factors for about 6 to 10 days postoperatively.[454-456]

These factors are available in various preparations; the newer genetically engineered von Willebrand factor, cryoprecipitate, which contains 20 U/mL, is obtained from regular donors (the risk of hepatitis being 1 in 200 for 5-mL lots) or from fresh frozen plasma (which contains 1 U/mL). Some risk of transmitting hepatitis and AIDS accompanies transfusion but, with better testing, much less than formerly.[457-460] Current screening of blood for aspartate or alanine aminotransferase levels is believed to result in a much lower risk of hepatitis C and even AIDS from transfusion. Theoretically, antigenic testing for HIV should further decrease the risk of transmission by blood products. Heat treatment is also reported to reduce the risk substantially. Factor IX, but not factor VIII is contained in prothrombin complex concentrates; however, these concentrates may contain activated clotting factors, which can lead to disseminated intravascular coagulation (DIC) and a high risk for hepatitis. In addition, although EACA or tranexamic acid is sometimes administered as a fibrinolytic inhibitor, these substances carry with them a significant risk for DIC. Additional hazards of modern therapy include acute and chronic hepatitis, AIDS, hypersensitivity reactions, psychic trauma, chronic pain with narcotic addiction, and inhibition of factors, especially VIII.

An antibody that inactivates factor VIII or IX (fresh frozen plasma fails to increase clotting factor activity after incubation with the patient's plasma) develops in approximately 10% of patients with either hemophilia A or B. These acquired anticoagulants are usually composed of IgG, are poorly removed by plasmapheresis, and are variably responsive to immunosuppressive drugs. The use of prothrombin complex concentrates can be lifesaving but carries the risk of DIC and hepatitis.

Vitamin K deficiency is discussed in the section on liver disease. To review, vitamin K–dependent clotting factors (II, VII, IX, and X) require vitamin K for the postsynthetic addition of γ-carboxyl groups to glutamate residues; administration of vitamin K or fresh frozen plasma can correct these deficiencies.

Patients who come to the operating room after having received many units of blood (as in massive GI bleeding) may have deficient clotting. This impaired clotting is initially caused by depletion of platelets, which occurs after approximately 10 to 15 units of blood has been given, and later, by depletion of coagulation factors (see Chapter 56). Treatment of these deficiencies can be corrected with platelet concentrates—each concentrate is normally suspended in 50 mL of fresh plasma; thus, coagulation factors are also replaced.

Urokinase, streptokinase, and tissue plasminogen activator (t-PA) have been used to treat pulmonary embolism, deep venous thrombosis, stroke, and arterial occlusive disease. These drugs accelerate the lysis of thrombi and emboli, in contrast to heparin, which may prevent, but not dissolve a thrombus. Bleeding complications associated with these fibrinolytic agents are the result of dissolution of hemostatic plugs and can be quickly reversed by discontinuing the medication and replenishing plasma fibrinogen with cryoprecipitate or plasma. However, cryoprecipitate and plasma are seldom needed preoperatively because the fibrinolytic activity of urokinase and streptokinase usually dissipates within 1 hour of discontinuing their administration. Nonetheless, insufficient data have accumulated to prescribe the ideal preoperative preparation and intraoperative management of hemostasis in patients recently treated with urokinase, streptokinase, or t-PA. Postponing surgery for three half-lives of the drug (increases in plasmin activity in blood can be assayed for ≥4 to 8 hours) may not be possible, and meticulous observation of the operative field for hemostasis may not suffice.[461,462] The process may be even more complex in a vascular or cardiac patient who requires heparin administration intraoperatively. To correct the fibrinogen deficiency in these patients, some clinicians administer fibrinogen

before surgery and EACA at heparin administration. We usually delay or avoid giving EACA until heparin is administered in an effort to minimize the risk for thrombosis.

Desmopressin is now being tried in operations associated with high blood loss as a routine measure to decrease bleeding and transfusion requirements. Desmopressin therapy began as treatment of platelet dysfunction in von Willebrand's disease but has since expanded to routine use in patients undergoing cardiovascular surgery and frequent use in other high–blood loss operations. This increased use was prompted by the finding that desmopressin decreases bleeding and transfusion requirements.[463] Whether the side effects of desmopressin exceed its benefits remains to be determined and will probably influence how routine its administration becomes.

The problem of patients taking oral anticoagulants is discussed in the cardiovascular section of this chapter.[193-200,202-205] Regional anesthetic techniques might be avoided in patients given anticoagulant drugs.[193-200,202-205] Whether these regional techniques should also be avoided in patients treated prophylactically with low-dose subcutaneous heparin has not been studied. The effects of heparin sulfate can be reversed by titrating protamine, with the activated clotting time used as a guide.

Pharmacologic research is searching for specific molecular subtypes of heparin that have different anticoagulant potencies, binding affinities for antithrombin III, antithrombotic effects, and platelet-aggregating effects (see the pulmonary section in this chapter on prophylaxis for deep venous thrombosis). The search is on for a "new" heparin preparation that will block thrombosis without causing clinical bleeding (see earlier). Such a development might change our ways of monitoring clotting function. As of now, the new heparins appear to increase the risk for epidural hematoma. Determining the bleeding time, platelet count, partial thromboplastin time, and prothrombin time will identify almost all problems in patients with a suspected clotting or bleeding disorder (also see Chapter 56). As explained in Chapter 34, these screening tests should probably not be obtained for asymptomatic patients.

Oncologic Disease

Patients with malignant tumors may be otherwise healthy or may be desperately ill with nutritional, neurologic, metabolic, endocrinologic, electrolyte, cardiac, pulmonary, renal, hepatic, hematologic, or pharmacologic disabilities. Thus, determining the other disabilities accompanying malignant tumors requires evaluation of all systems. Abnormalities frequently accompanying such tumors include hypercalcemia either by direct bone invasion or by ectopic elaboration of PTH or other bone-dissolving substance, uric acid nephropathy, hyponatremia (especially with small cell, or oat cell, carcinoma of the lung), nausea, vomiting, anorexia and cachexia, fever, tumor-induced hypoglycemia, intracranial metastases (10% to 20% of all cancers), peripheral nerve or spinal cord disorders, meningeal carcinomatosis, toxic neuropathies secondary to anticancer therapy, and paraneoplastic neurologic syndromes (dermatomyositis, Eaton-Lambert syndrome, myopathies, and distal neuropathies).

Many patients with malignant tumors are given large doses of analgesics and should be kept comfortable during the perioperative period. Avoiding drug dependence is of no practical importance in terminally ill patients.[464] Marijuana (tetrahydrocannabinol) depresses the CNS vomiting center and may be more effective than the phenothiazines or butyrophenones in suppressing the nausea associated with cancer and its therapy; marijuana decreases anesthetic requirements 15% to 30%. Immunomodulators, stimulating factors or cytokines, gene identification,[465,466] and drugs for treating side effects (e.g., midazolam or ondansetron) have given new hope for safer, more effective therapy with fewer limiting side effects. The effect of ondansetron in preventing vomiting and the effect of midazolam in preventing "memory-stimulated vomiting" have been important additions. The NK-1 antagonists have also been approved for treatment in oncologic patients."

The toxicity of cancer chemotherapy is related to the drugs used and the dose. For radiation therapy, damage occurs when the following doses are exceeded: lungs, 1500 rad; kidneys, 2400 rad; heart, 3000 rad; spinal cord, 4000 rad; intestine, 5500 rad; brain, 6000 rad; and bone, 7500 rad. The toxicities of biologic and immunomodulating therapies are related to the change in immune function that they cause. Alkylating agents cause bone marrow depression, including thrombocytopenia, as well as alopecia, hemorrhagic cystitis, nausea, and vomiting. The alkylating agents, including cyclophosphamide and mechlorethamine, can act as an anticholinesterase and prolong neuromuscular blockade.[467] The antineoplastic alkaloid vincristine produces peripheral neuropathy and SIADH, and vinblastine produces myelotoxicity. Cisplatin is also associated with peripheral neuropathy and severe nausea. Nitrosoureas can produce severe hepatic and renal damage, as well as bone marrow toxicity, myalgia, and paresthesia. Folic acid analogs such as methotrexate have been linked to bone marrow depression, ulcerative stomatitis, pulmonary interstitial infiltrates, GI toxicity, and occasionally, severe liver dysfunction. Fluorouracil and floxuridine, both pyrimidine analogs, cause bone marrow toxicity, megaloblastic anemia, nervous system dysfunction, and hepatic and GI alterations. Purine analogs (mercaptopurine, thioguanine) have bone marrow depression as their primary toxic effect. Anthracycline antibiotics (doxorubicin, daunorubicin, mithramycin, mitomycin C, bleomycin) can all cause pulmonary infiltrates; cardiomyopathy (especially doxorubicin and daunorubicin); myelotoxicity; and GI, hepatic, and renal disturbances.

The wisdom of anesthetizing patients given bleomycin has been questioned. A retrospective study by Goldiner and coauthors[468] reported postoperative deaths in five consecutive patients given bleomycin. All five patients died of postoperative respiratory failure. Using the same anesthetic technique, Goldiner and coworkers[468] then anesthetized 12 patients, limited the inspired oxygen concentration to 22% to 25% perioperatively, and replaced much of the blood loss with colloids rather than crystalloids. None of the 12 patients died. These investigators postulated that bleomycin caused epithelial cell edema that progressed to necrosis of type I alveolar cells, leakage of fluid into the alveolar space, and the formation of "hyaline membranes" similar to that associated with oxygen toxicity. Goldiner and colleagues[468] believe that this pathophysiologic similarity indicates a possible synergistic relationship between oxygen and bleomycin. However, LaMantia and coworkers[469] retrospectively analyzed the changes in 16 patients undergoing surgery after bleomycin therapy. Thirteen patients were given oxygen at inspired concentrations of 37% to 45%. No instances of postoperative respiratory failure occurred. Animal data do not support this effect of bleomycin in altering the toxicity of hyperoxia.[470] Thus, data are currently available to

support all practices regarding administration of oxygen to patients given bleomycin. We prefer to keep inspired oxygen concentrations at the lowest level that provides adequate tissue oxygenation. When in doubt about side effects in patients undergoing cancer chemotherapy, our practice is to seek advice from two experts.

Patients Given Drug Therapy for Chronic and Acute Medical Conditions

A steadily increasing number of potent drugs are being used to treat disease, and the average hospitalized patient receives more than 10 drugs. Many drugs have side effects that might make anesthesia more risky or patient management more difficult. Knowing the pharmacologic properties and potential side effects of commonly used drugs helps the anesthesiologist avoid pitfalls during anesthesia and surgery.

The first step in avoiding these pitfalls is to obtain a drug history from the patient, including vitamins, herbs, and supplements.[21-23,471,472] Then, for every drug, medicine, and over-the-counter preparation that the patient is using, the anesthesiologist should know the name, classification of drug, diseases and conditions for which it is prescribed, and common side effects. Having this knowledge before surgery helps the anesthesiologist avoid making mistakes that might turn minor side effects into life-threatening situations. If necessary, the anesthesiologist should return to the patient's bedside (or telephone outpatients) to search for signs or symptoms of these effects. Unnecessary drugs should be discontinued for at least three and preferably five half-lives of the drugs. This period should be longer if metabolites of the drug have activity and longer half-lives. For essential or beneficial drugs, the optimal dose should be determined in consultation with the treating physician; the optimal dose is that maximizing the ratio of therapeutic value to the risk of drug toxicity. Side effects should be sought and either corrected preoperatively or at least planned for in anesthetic management. For instance, if a patient is made hypokalemic with diuretic drugs, hypokalemia might be corrected before surgery; an additional tactic would be to avoid hyperventilation during surgery (see the earlier section on hypokalemia). This line of reasoning and planning is best done at least 1 week before surgery. Ideally, the surgeon, internist, primary care practitioner, and anesthesiologist should communicate regarding these topics well in advance of surgery. Understanding the side effects of chronic drug therapy that affect the sympathetic nervous system requires some knowledge of the basic pharmacologic characteristics of the sympathetic nervous system (see Chapter 12).

Pharmacologic Processes in the Sympathetic Nervous System

It is important to remember several points related to the pharmacology of the sympathetic nervous system when considering chronic drug therapy.

Norepinephrine, dopamine, and epinephrine exert their physiologic effect by interacting with an appropriate receptor at the target tissue. The primary receptor acts through intermediary messenger systems (including cyclic 3′,5′-adenosine monophosphate [cAMP] or G-stimulatory or G-inhibitory proteins, or both) or can change the conformation (and hence the affinity for ligands) of bordering or neighboring receptors. These bordering or neighboring receptor effects may account for many of the multitude of effects associated with catecholamines.

The action of sympathomimetic substances is terminated through an unusual process: the nerve ending uses an active reuptake system to recapture most of the norepinephrine from the target tissue (see Chapter 12). Obviously, blockage of this system permits more norepinephrine to remain free to produce physiologic effects. In addition to this reuptake system, two enzymes transform catecholamines metabolically: monoamine oxidase (MAO) and catechol-*O*-methyltransferase (COMT).

Antihypertensive Drugs

Many antihypertensive drugs and almost all mind-altering drugs affect sympathetic neuronal storage, uptake, metabolism, or release of neurotransmitters. For instance, the antihypertensive drug reserpine depletes the granules of norepinephrine, epinephrine, and dopamine in both the brainstem and periphery. Depletion of transmitters in sympathetic nerve endings renders drugs such as ephedrine and metaraminol ineffective because these drugs act primarily by releasing catecholamines (see Fig. 35-10). Guanethidine and guanadrel deplete granular norepinephrine and affect only the peripheral sympathetic system. In amounts used clinically, reserpine decreases MAC by 20% to 30%, whereas guanethidine has no effect on anesthetic requirements. In addition to causing a lack of response to indirect-acting vasopressors, reserpine can cause denervation supersensitivity and hyperresponsiveness (with hypertension or tachycardia, or both) to the usual doses of direct-acting sympathetic amines such as phenylephrine (Neo-Synephrine), isoproterenol, norepinephrine, epinephrine, and dopamine.[471,472] Thus, in patients who have been treated with drugs that alter sympathetic neurotransmitter release, uptake, metabolism, or receptor function, some problems may occur: hypotension, hypertension, and bradycardia should be treated by titrating doses of direct-acting vasoconstrictors such as phenylephrine, vasodilators such as nitroprusside, or chronotropic drugs such as atropine, isoproterenol, or dopamine.

Another group of antihypertensive drugs consists of "false neurotransmitters." False neurotransmitters replace norepinephrine in the granules at the nerve ending. α-Methyldopa (Aldomet) becomes α-methyldopamine, which is further metabolized to α-methylnorepinephrine (Fig. 35-11). In some nerve endings and for some receptors, α-methyldopamine or α-methylnorepinephrine is more potent than dopamine or norepinephrine as dopaminergic or α-adrenergic receptor stimulants. However, at most nerve endings, the false neurotransmitters are less potent stimulants; this lower degree of stimulation is one means by which their antihypertensive action is produced. Alternatively, α-methyldopa may act by stimulating the brainstem sympathetic nervous system. When this system antagonizes the peripheral sympathetic nervous system, the activity of the latter decreases and BP is reduced. Through its central effect, α-methyldopa decreases anesthetic requirements 20% to 40%.

In addition to altering the response to exogenously administered vasopressors, these neurotransmitter-depleting drugs can

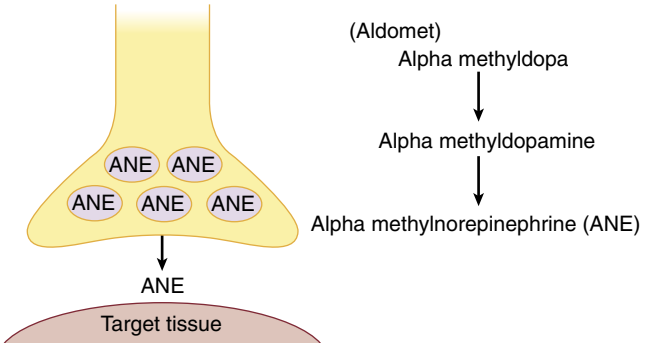

Figure 35-11 In the granules of the nerve terminal, α-methyldopa (Aldomet) is converted enzymatically to α-methyldopamine by the same enzyme that converts dopa to dopamine. α-Methyldopamine is converted to α-methylnorepinephrine by the same enzyme that converts dopamine to norepinephrine.

also produce side effects: psychic depression, nightmares, drowsiness, nasal stuffiness, diarrhea, bradycardia, and orthostatic hypotension with impotence (reserpine).[473-475] Guanethidine and guanadrel can cause orthostatic hypotension, bradycardia, asthma, diarrhea, and inhibition of ejaculation. α-Methyldopa is associated with drowsiness, orthostatic hypotension, bradycardia, diarrhea, acute or chronic hepatitis, cirrhosis, and autoimmune hemolytic anemia (i.e., a positive Coombs test result).[472] Because of these side effects, ACE inhibitors (captopril, enalapril, lisinopril, enalaprilat, and ramipril) and angiotensin II receptor blockers are being used increasingly as first-line drugs and appear to improve the quality of life of patients taking antihypertensive drugs. One of the angiotensin II receptor blockers—valsartan—when combined with a diuretic, actually increases libido in both men and women while decreasing BP. However, ACE inhibitors and angiotensin II receptor blockers may be associated with more peripheral vasodilation and hypotension on induction of anesthesia than sympatholytics are. Added to this group are the ACE receptor blocking agents. These last two classes of drugs are associated with such severe hypotension with standard anesthetic induction that we discontinue or at least consider discontinuing the use of these drugs preoperatively (see earlier).

Catecholamine or sympathetic receptor blocking drugs affect the three major types of catecholamine receptors: α-adrenergic, β-adrenergic, and dopaminergic. The existence of subdivisions (e.g., β_1 and β_2) suggested the possibility that some drugs would be found to affect only one set of receptors. For example, terbutaline is used more frequently than isoproterenol because terbutaline is said to exert a preferential effect on α_2-receptors (i.e., dilation of bronchial smooth muscle), thereby avoiding the cardiac stimulation produced by drugs that stimulate β_1-receptors. In fact, the selectivity is dose related. At a certain dose, a direct β_2-receptor stimulating drug will affect only those receptors but, at a higher dose, will stimulate both β_1- and β_2-receptors. The effect of a given dose varies with each patient. A certain dose may stimulate β_1- and β_2-receptors in one patient but neither receptor in another patient. More and more selective blocking drugs are being developed in hope of widening the margin between β_1- and β_2- and α-adrenergic effects. Ultimately, however, even more selectivity is desired. It would be advantageous to be able to decrease the heart rate without changing myocardial contractility or to increase contractility without changing the heart rate. Such is the goal of much drug research and the development of dobutamine and fenoldopam. However, to date, all such selectivity appears to be dose related, even for dobutamine.

Metoprolol (Lopressor) and atenolol (Tenormin) (both β_1-adrenergic receptor blocking drugs) and propranolol, betaxolol, timolol, esmolol, pindolol, oxprenolol, acebutolol, carteolol, penbutolol, and nadolol are widely available β-adrenergic receptor blocking drugs used for chronic therapy in the United States. Because nadolol has poor lipid solubility, it has a long elimination half-life (17 to 24 hours) and does not cross the blood-brain barrier readily. Although selective β-adrenergic receptor blocking drugs should be more appropriate in patients with increased airway resistance or diabetes, this advantage is apparent only when low doses are used. The use of β-adrenergic receptor blocking drugs has become widespread because these drugs treat everything from angina and hypertension to priapism and stage fright. These drugs appear to decrease morbidity and mortality in patients who have initially survived MI[476,477] and may increase perioperative survival in selected patients (see the earlier section on cardiovascular disease).

Smulyan and colleagues[478] studied the problems of long-term propranolol hydrochloride therapy in adult patients who must undergo abdominal surgery. Because these patients cannot take oral medications postoperatively for many days, they must be protected against perioperative sympathetic stimulation and the propranolol withdrawal syndrome. It is therefore common to develop intravenous β-blocker protocols for patients chronically taking these agents, although it is important to recognize the risk of β-blockers. The hypotensive and bradycardic effects of propranolol and general anesthesia appear to be additive. Because of its shorter half-life (3 to 10 minutes), esmolol has replaced propranolol in critical care (including anesthesia) settings because errors in therapy or side effects, such as increased airway resistance, vanish much more quickly than if propranolol were administered.[479] Propranolol does not affect anesthetic requirements, and one would expect the same lack of effect from other "pure" β-adrenergic receptor blocking drugs.

α-Adrenergic receptor blocking drugs include phentolamine, prazosin, terazosin, doxazosin, phenoxybenzamine, the phenothiazines, and the butyrophenones (e.g., droperidol). Dopaminergic receptor antagonists include the antischizophrenic drugs (phenothiazines and butyrophenones) and metoclopramide. The receptor blocking drugs inhibit the action of sympathomimetic drugs at the receptor in a dose-related fashion. Thus, propranolol lowers BP by blocking the tendency of norepinephrine and epinephrine to increase the rate and force of contractions of the heart (and perhaps their tendency to increase the secretion of renin as well). To overcome this blockade, one need only provide more β-receptor stimulating drug. Thus, high doses of vasopressors may be needed to increase BP in a patient given large doses of propranolol.

When administration of β-adrenergic receptor blocking drugs is terminated, sympathetic stimulation often increases, as though the body had responded to the presence of these drugs by increasing sympathetic neuron activity. Thus, propranolol and nadolol (to name just two) withdrawal can be accompanied by a hyper–β-adrenergic condition that increases myocardial oxygen

demands. Administering propranolol or metoprolol can cause bradycardia, CHF, fatigue, dizziness, depression, psychoses, bronchospasm, and Peyronie's disease. The POISE study emphasizes the concerns that inadequate titration of these agents can lead to stroke or increased mortality.[121] Side effects of dopaminergic receptor blocking drugs are discussed later in this chapter. Prazosin (Minipress), terazosin, and oxazocin are α_1-adrenergic receptor blocking drugs used to treat hypertension, ischemic cardiomyopathy, receding hairlines, and benign prostatic hypertrophy because they dilate both veins and arteries and reduce sphincter tone. These drugs are associated with vertigo, palpitations, depression, dizziness, weakness, and anticholinergic effects.

Some sympathomimetic drugs stimulate α-adrenergic receptors in the brainstem. Clonidine (Catapres), a drug with a half-life of 12 to 24 hours, guanabenz, and guanfacine (Tenex) are α_2-adrenergic receptor stimulants. Presumably, α_2-adrenergic agonists, including clonidine, guanabenz, and guanfacine, chronically lower BP through the central brainstem adrenergic stimulation referred to previously. They may also be used chronically to treat opiate, cocaine, food, and tobacco withdrawal. Occasionally, withdrawal from clonidine can precipitate a sudden hypertensive crisis, analogous to that occurring on withdrawal from propranolol, and cause a hyper–β-adrenergic condition. The degree of hypertensive crisis after clonidine withdrawal is now being debated. (Although intravenous clonidine is not available in the United States, a skin patch of clonidine is being used preoperatively to ablate sympathomimetic responses perioperatively.) Tricyclic antidepressant drugs and presumably phenothiazines and the butyrophenones interfere with the action of clonidine. Although administration of a butyrophenone (e.g., droperidol) to a patient taking clonidine, guanabenz, or guanfacine chronically could theoretically precipitate a hypertensive crisis, none has been reported. Clonidine administration can be accompanied by drowsiness, dry mouth, orthostatic hypotension, bradycardia, and impotence. Acute clonidine or dexmedetomidine administration decreases anesthetic requirements by at least 40% to 60%; chronic administration decreases requirements by 10% to 20%.[480,481] Because of the relative safety of these drugs and their ability to decrease anesthetic requirements, block narcotic-induced muscle rigidity, and provide pain relief, their popularity preoperatively, intraoperatively, and in ICU sedation is increasing dramatically.[480-484]

Three other classes of antihypertensive drugs affect the sympathetic nervous system indirectly: diuretics, arteriolar dilators, and slow (calcium) channel blocking agents. Thiazide diuretic drugs are associated with hypochloremic alkalosis, hypokalemia, hyperglycemia, hyperuricemia, and hypercalcemia. The potassium-sparing diuretic drug spironolactone is associated with hyperkalemia, hyponatremia, gynecomastia, and impotence. All diuretic drugs can cause dehydration. The thiazide diuretics and furosemide appear to prolong neuromuscular blockade. The arteriolar dilator hydralazine can cause a lupus-like condition (usually with renal involvement), nasal congestion, headache, dizziness, CHF, angina, and GI disturbances. Such a syndrome is nonexistent with the other direct vasodilator on the U.S. market, minoxidil.

The slow-channel calcium ion antagonists ("calcium channel blocking drugs") inhibit the transmembrane influx of calcium ions into cardiac and vascular smooth muscle. Such inhibition reduces the heart rate (negative chronotropy); depresses contractility (negative inotropy); decreases conduction velocity (negative dromotropy); and dilates coronary, cerebral, and systemic arterioles (Fig. 35-12).[485] Verapamil, diltiazem, and nifed-

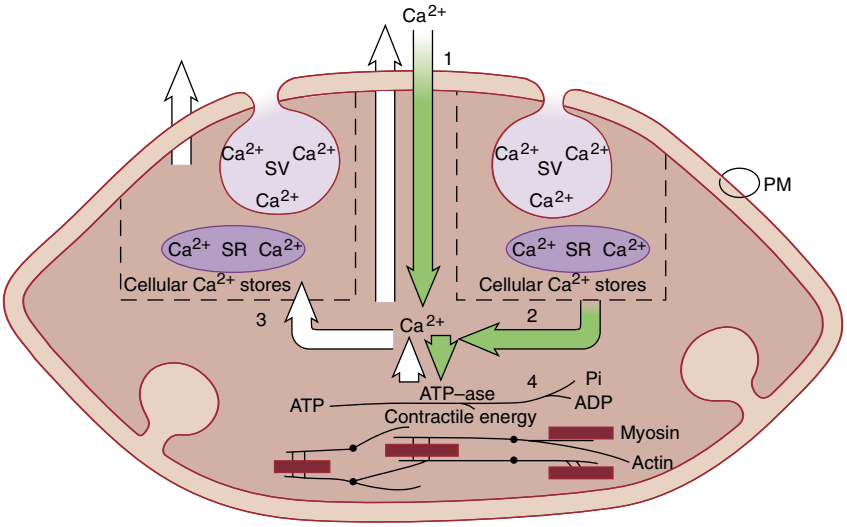

Figure 35-12 Schematic drawing of a smooth muscle cell showing calcium flux and possible sites of interference by halothane and nifedipine. The concentration of calcium (Ca^{2+}) in the cytoplasm increases (*green arrows*) because of entry through the plasma membrane (PM) and release from surface vesicles (SV) or the sacroplasmic reticulum (SR). When the concentration of cytoplasmic Ca^{2+} is sufficiently high, adenosine triphosphate (ATP) is activated. Splitting of ATP by adenosine triphosphatase (ATPase) into phosphatidylinositol (Pi) and adenosine diphosphate (ADP) provides the interaction and contraction of actin filaments and myosin particles constituting muscle fibers. The concentration of cytoplasmic Ca^{2+} decreases (*white arrows*) with the return of Ca^{2+} to cellular stores and the extracellular transport of Ca^{2+}. Both halothane and nifedipine probably (1) inhibit the entry of Ca^{2+} and (2) may also interfere with cytoplasmic Ca^{2+} flux by reducing the release of Ca^{2+} by the SR, by (3) reducing storage and reuptake, or by (4) blocking ATPase or the contractile mechanism (or both). *(Redrawn from Tosone SR, Reves JG, Kissin I, et al: Hemodynamic responses to nifedipine in dogs anesthetized with halothane. Anesth Analg 62:903, 1983.)*

ipine all produce such effects, but to varying degrees and apparently by similar, but different mechanisms. These mechanisms relate to the three different classes of calcium channel antagonists that they represent: the phenylalkyl amines, the benzothiazepines, and the dihydropyridines, respectively. Nifedipine is the most potent of the three as a smooth muscle dilator, whereas verapamil and diltiazem have negative dromotropic and inotropic effects and vasodilating properties. Diltiazem has weak vasodilating properties when compared with nifedipine and has less of an AV conduction effect than verapamil does. Thus, verapamil and diltiazem can increase the PR interval and produce AV block. In fact, reflex activation of the sympathetic nervous system may be necessary during the administration of diltiazem, and especially during verapamil therapy, to maintain normal conduction. Clearly, verapamil and diltiazem must be titrated very carefully when a patient is already taking a β-adrenergic receptor blocking drug or when adding β-blocking drugs to a patient already taking verapamil or diltiazem.

The use of calcium channel blocking drugs has several important implications for anesthetic management.[485-487] First, the effects of inhaled and narcotic anesthetics and nifedipine in decreasing systemic vascular resistance, BP, and contractility may be additive. Similarly, verapamil and anesthetics (inhaled anesthetics, nitrous oxide, and narcotics) increase AV conduction times and additively decrease BP, systemic vascular resistance, and contractility. Second, verapamil and presumably the other calcium channel blocking drugs have been found to decrease anesthetic requirements by 25%. These drugs can produce neuromuscular blockade, potentiate both depolarizing and nondepolarizing neuromuscular blocking drugs, and in at least one type of myopathy (Duchenne's muscular dystrophy), even precipitate respiratory failure. Finally, because slow-channel activation of calcium is necessary to cause spasms of cerebral and coronary vessels, bronchoconstriction, and normal platelet aggregation, these drugs may have a role in treating ischemia of the nervous system, bronchoconstriction, and unwanted clotting disorders perioperatively. All three drugs are highly protein bound and may displace or be displaced by other drugs that are also highly protein bound (e.g., lidocaine, bupivacaine, diazepam, disopyramide, and propranolol). Adverse consequences can be minimized by titrating the inhaled or narcotic drug to the hemodynamic and anesthetic effects. By monitoring for side effects, the anesthetist can prevent them from becoming serious (S. Slogoff and coworkers, personal communication). Hemodynamic, but not electrophysiologic changes can usually be reversed by administering calcium. Reversal of the electrophysiologic effects may occur if "industrial" doses of β-adrenergic agonists are given.

Mood-Altering Drugs

Mood-altering drugs are the most frequently prescribed medications in the United States.[474,475] They include MAOIs, SSRIs, phenothiazines, tricyclic antidepressant drugs, other antidepressants that fail previous drug category classification such as bupropion, and drugs of abuse such as cocaine. MAOIs, which include isocarboxazid (Marplan), phenelzine (Nardil), pargyline (Eutonyl), tranylcypromine (Parnate), and deprenyl, bind irreversibly to the enzyme MAO, thereby increasing intraneuronal levels of amine neurotransmitters (serotonin, norepinephrine, dopamine, epinephrine, octopamine). This increase is associated with an antidepressant effect, an antihypertensive effect, an antinarcoleptic effect, elevation of liver enzymes, and delayed onset of Parkinson's disease (deprenyl). Because two forms of the enzyme (MAO-A and MAO-B) are selective in vitro for substrate (MAO-A is selective for serotonin, dopamine, and norepinephrine; MAO-B for tyramine and phenylethylamine), presumably MAOIs selective for MAO-A or MAO-B would have different effects.[488] This is not known for certain inasmuch as deprenyl (selegiline [Eldepryl]), an MAO-B–selective drug, improves a dopamine deficiency state, parkinsonism.

Interactions between MAOIs and a variety of foods and drugs containing indirect-acting sympathomimetic substances such as ephedrine or tyramine (found especially in aged cheeses) can occur for as long as 2 weeks after the last dose of MAOI is given. The most serious effects of this interaction are convulsions and hyperpyrexic coma (particularly after narcotics).

Anesthetic management of a patient given an MAOI can be chaotic; for this reason it is widely accepted practice to discontinue MAOIs at least 2 to 3 weeks before any planned operation.[474,475,488-492] An alternative point of view has been expressed regarding severely psychotic patients or emergency surgery.[488,493-495] Clearly, the risk of discontinuing MAOIs must be weighed against the risk of suicidal tendencies in some patients deprived of MAOIs. There are no reported experiences of interactions between narcotics and deprenyl, so judgments about possible worsening of Parkinson's disease and continuing MAOIs have no basis in data. It should be noted that severe reactions have occurred when too short an interval existed between the administration of MAOIs and tricyclic antidepressants. Emergency surgery on patients given MAOIs can be punctuated by hemodynamic instability. A regional block can be attempted as treatment of postoperative pain to avoid having to give narcotics. Cases of hyperpyrexic coma after the administration of most narcotics have been reported in humans, and animal studies document a 10% to 50% incidence of hyperpyrexic coma in animals pretreated with MAOIs and then given a variety of narcotics.[474,475,488-492] These reactions appear to be treated best by therapy supporting vital functions.

Alternative drugs for the treatment of severe depression include the tricyclic antidepressant drugs: amitriptyline (Elavil, Endep), imipramine (Tofranil, Presamine), desipramine (Norpramin), doxepin (Adapin, Sinequan), nortriptyline (Aventyl), fluoxetine (Prozac), trazodone (Desyrel), bupropion (Wellbutrin), and others.[474,475] Tricyclic antidepressant drugs also block the reuptake of neurotransmitters and cause their acute release. Given chronically, these drugs decrease stores of noradrenergic catecholamines. Tricyclic antidepressant drugs also produce side effects similar to those of atropine (dry mouth, tachycardia, delirium, urinary retention) and can cause changes on the ECG (changes in the T wave, prolongation of the QRS complex, bundle branch block or other conduction abnormalities, or PVCs). Although arrhythmias induced by tricyclic antidepressants have been treated successfully with physostigmine, bradycardia has sometimes occurred.[474,475] Drug interactions with tricyclic antidepressants include those related to blockade of the reuptake of norepinephrine (such as interference with the action of guanethidine) and fatal arrhythmias after halothane and pancuronium.[496,497] Such interactions, though predictable for a population of patients, may not alter a patient's threshold for arrhythmias. The newer antidepressants (the SSRIs) can also have serious side effects. Fluoxetine, a tricyclic that also has an SSRI effect, causes nausea,

vomiting, headaches, nervousness, and possibly paranoia and ideas of suicide more commonly than the other tricyclics do[474,475]; however, it is less likely to cause anticholinergic effects or orthostatic hypotension. Bupropion may cause nausea, vomiting, seizures, agitation, tremor, excitement, and increased motor activity, but it only rarely causes anticholinergic effects or orthostatic hypotension. Discontinuing drugs can cause withdrawal symptoms or precipitate recurrence of psychiatric illness. Switching between drugs for depression can cause hyperpyrexia and coma. Thus, switching before surgery should not be requested casually.[474,475]

The effectiveness of phenothiazines and butyrophenones in schizophrenia suggests a dopamine receptor blocking action. In addition, these drugs possess varying degrees of parasympathetic stimulation and ability to block α-adrenergic receptors. The phenothiazines include chlorpromazine (Thorazine, Chlor-PZ), promazine (Sparine), triflupromazine (Vesprin), fluphenazine (Prolixin), trifluoperazine, prochlorperazine (Compazine), and many others. The butyrophenones include droperidol and haloperidol (Haldol). Both the phenothiazines and butyrophenones produce sedation, depression, and antihistaminic, antiemetic, and hypothermic responses. They are also associated with cholestatic jaundice, impotence, dystonia, and photosensitivity. Other side effects associated with phenothiazines include orthostatic hypotension (partly as a result of α-adrenergic blockade) and abnormalities on the ECG such as prolongation of the QT or PR intervals, blunting of T waves, depression of the ST segment, and on rare occasion, PVCs and torsades de pointes.[474,475,496,497] Although few data are available on the antidepressant drugs selective for serotonin (the SSRIs), occasional case reports of severe hypotension and cardiac arrest with severe bradycardia have been presented in abstract form.

Several important drug interactions are noteworthy for the phenothiazine derivatives. The effects of CNS depressants (especially narcotics and barbiturates) are enhanced by the concomitant administration of phenothiazines. In addition, the CNS seizure threshold is lowered by the administration of phenothiazines, which should be avoided in patients who are epileptic or withdrawing from any drug that depresses the CNS. The antihypertensive effects of guanethidine and guanadrel are blocked by tricyclic antidepressant drugs and the phenothiazines.[472] Lithium carbonate is used to treat manic depression, but it is more effective in preventing mania than relieving depression. In excitable cells, lithium mimics sodium and decreases the release of neurotransmitters both centrally and peripherally. Lithium prolongs neuromuscular blockade and may decrease anesthetic requirements because it blocks brainstem release of norepinephrine, epinephrine, and dopamine.

Psychoactive drugs such as the amphetamines (including methamphetamines and their smokable derivative in crystal form known as "ice") and cocaine acutely release norepinephrine, epinephrine, and dopamine and block their reuptake. Taken chronically, they deplete nerve endings of these neurotransmitters.

Drugs that appear to increase central α-adrenergic release increase anesthetic requirements, whereas drugs that appear to decrease central α-adrenergic release decrease anesthetic requirements. (This may not be the mechanism by which they alter anesthetic requirements, but it is a convenient way of remembering the alteration.) Drugs that affect only the β-adrenergic receptors do not alter anesthetic requirements.

Sympathomimetic Drugs

Many antiasthmatic drugs (bronchodilators) such as terbutaline, aminophylline, and theophylline are sympathomimetic drugs that can interact with volatile anesthetics to cause cardiac arrhythmias (also see Chapter 16). Halothane (and to some degree most other volatile anesthetics) sensitizes the myocardium to exogenous catecholamines.[498,499] Sensitization means that the minimum dose of exogenous epinephrine administered intravenously that is needed to produce PVCs would be lower in patients anesthetized with halothane than in awake patients.

How much epinephrine is safe to give when halothane is the anesthetic? Katz and Bigger[498] reported that the administration of 0.15 mL/kg of a 1:100,000 epinephrine solution per 10-minute period (not to exceed 0.45 mL/kg of a 1:100,000 solution per hour) was safe. Several studies have shown that lidocaine given with epinephrine affords extra protection and that enflurane and isoflurane are less sensitizing than halothane. Xanthines are effective bronchodilators because they produce β-adrenergic stimulation in two ways: they cause the release of norepinephrine[500,501] and also inhibit the breakdown of cAMP,[502] the mediator of many of the actions of β-adrenergic receptor agonists. Phosphodiesterase catalyzes the breakdown of cAMP. Thus, inhibition of phosphodiesterase by theophylline increases the concentration of cAMP. Marcus and associates[500] and Westfall and Flemming[501] showed that at least 40% of the inotropic effects of aminophylline are due to its ability to release norepinephrine directly.

Plasma theophylline levels of 5 mg/L are needed to reduce abnormally high airway resistance. No further beneficial effects are obtained when levels exceed 20 mg/L; instead, toxic effects appear. Theophylline (aminophylline is a combination of 85% theophylline and 15% ethylenediamine) is metabolized largely by the liver, with less than 10% being excreted unchanged in urine. The average half-life is 4.4 ± 1.15 hours in adults, and clearance is 1.2 mL/min/kg. Significant liver disease or pulmonary edema can decrease clearance of the drug by half and by a third, respectively.

An interaction between aminophylline and halothane appears to be a frequent, predictable occurrence: of 16 dogs anesthetized with 1% halothane and given high-dose bolus injections of aminophylline, 12 had ventricular arrhythmias and 8 had ventricular tachycardia or fibrillation. Thus, it is advisable to wait three drug half-lives after the last dose of aminophylline is given (i.e., approximately 13 hours in normal individuals) before using halothane to anesthetize an asthmatic patient. Using another anesthetic that is a bronchodilator but is less likely to predispose the patient to catecholamine-induced arrhythmias (e.g., enflurane, isoflurane, or sevoflurane) or using inhaled or systemic steroids started several days in advance might be alternatives in patients requiring aminophylline or other exogenous sympathomimetic drugs before or during surgery.

Other Drugs

Drugs other than those discussed earlier in this chapter have implications for anesthetic management. The therapies that have been discussed include anticoagulants and fibrinolytics (in the hematologic section), endocrinologic preparations excluding

birth control pills but including corticosteroids (in the section on endocrinologic disease), antihypertensive drugs (earlier in this section and in the section on cardiovascular diseases), anticonvulsant drugs (in the section on neurologic disorders), and cancer chemotherapeutic agents (in the section on oncology).

Antiarrhythmic Drugs

Antiarrhythmic drugs include local anesthetics (lidocaine, procaine), anticonvulsant (phenytoin) or antihypertensive (propranolol) drugs, calcium channel blocking drugs, or primary antiarrhythmic drugs. These drugs are classified into five major categories: local anesthetics that alter phase 0 and phase 4 depolarization (quinidine, procainamide, and flecainide), local anesthetics that affect only phase 4 depolarization (lidocaine, tocainide, phenytoin, encainide), β-adrenergic receptor antagonists, antiadrenergic drugs (bretylium, disopyramide, amiodarone), and calcium entry blockers. These drugs are discussed elsewhere in this chapter. A useful reference with suggestions about drug therapy for cardiac arrhythmias and monitoring of side effects was published by the *Medical Letter on Drugs and Therapeutics*.[503] A lack of adverse reports does not indicate that all these drugs should be continued through the time of surgery; pharmacokinetic studies have not yet determined whether anesthesia (or anesthesia with specific agents) alters the volume of distribution or clearance of these drugs to an extent sufficient to warrant changing the dosage or dosage schedule in the perioperative period. The dearth of reports on this subject may be due to a lack of significant drug interaction or to a lack of awareness that untoward events could be caused by such an interaction.

The pharmacologic characteristics of the various antiarrhythmic drugs can affect anesthetic management. Disopyramide is similar to quinidine and procainamide in its antiarrhythmic effectiveness. Disopyramide is excreted mainly by the kidneys, but hepatic disease increases its half-life. This drug often produces anticholinergic effects, including tachycardia, urinary retention, and psychosis. Hepatitis has also been reported to have occurred after its use.[503] Little is known of the interaction of bretylium with anesthetics. Because bretylium blocks the release of catecholamines, chronic therapy with this drug has been associated with hypersensitivity to vasopressors.[503] Quinidine is dependent on the kidneys for excretion, can produce vagolytic effects that can decrease AV block, and is associated with blood dyscrasias and GI disturbances.[503] Most of the antiarrhythmic drugs enhance nondepolarizing neuromuscular blockade. Reports have confirmed this enhancement for quinidine, phenytoin, lidocaine, procainamide, and propranolol.[504-512] Amiodarone, an antiadrenergic drug used to treat recurrent supraventricular and ventricular tachycardia, causes thyroid dysfunction as a result of the large amount of iodine in its structure (see the section on thyroid disorders earlier in this chapter), as well as peripheral neuropathy, and has been associated with hypertension, bradyarrhythmias, and reduced cardiac output during anesthesia.[513] The drug has a half-life of 29 days, and its pharmacologic effects persist for over 45 days after discontinuance.[514] No data document such an effect for depolarizing muscle relaxants.

Antibiotics

Many antibacterial agents are nephrotoxic or neurotoxic (or both), and many prolong neuromuscular blockade (also see Chapter 29).[506-512] The only antibiotics devoid of neuromuscular effects appear to be penicillin G and the cephalosporins.[511] Most enzyme-inducing drugs do not increase the metabolism of enflurane or isoflurane. However, isoniazid appears to induce the microsomal enzymes responsible for the metabolism of at least enflurane, thereby increasing the possibility of fluorine-associated renal damage after enflurane.[515] Appropriate antibiotic prophylaxis for surgery requires a knowledge of the probability of infection for that type of surgical procedure and, if the incidence of infection warrants, the use of a drug regimen directed against the most likely infecting organisms.[516]

Digitalis

Digitalis preparations have a limited margin of safety, and the risk of toxicity increases with hypokalemia.[517] Although there is good rationale for administering digoxin prophylactically before surgery,[518] we generally avoid doing so because potassium concentrations can fluctuate widely during anesthesia as a result of fluid shifts, ventilatory acid-base derangements, and adjuvant treatments and because intraoperative arrhythmias caused by digitalis toxicity may be difficult to differentiate from those having other sources. Digitalis intoxication can be manifested by such diverse cardiac arrhythmias as junctional escape rhythm, PVCs, ventricular bigeminy or trigeminy, junctional tachycardia, paroxysmal atrial tachycardia with or without block, sinus arrest, sinus exit block, Mobitz type I or II block, or ventricular tachycardia.[517] However, anesthetics appear to protect against digitalis toxicity, at least in animal studies.[519-522] A titrated cardioversion technique using at first 10- and then 20-, 30-, 40-, 50-, 75-, 100-, 150-, and 200-J doses resulted in safe cardioversion in the presence of digitalis and propofol or midazolam hypnosis.[523] For patients in atrial fibrillation, the ventricular response should guide the choice of dose of digitalis.

Medications for Glaucoma

Medications for glaucoma include two organophosphates: echothiophate and isoflurophate (also see Chapter 75). These drugs inhibit serum cholinesterase, which is responsible for the hydrolysis and inactivation of succinylcholine and ester-type local anesthetics such as procaine, chloroprocaine, and tetracaine.[524,525] These ester-type local anesthetics should be avoided in patients treated with eye drops containing organophosphate. Table 35-20 lists other medications related to anesthesia and their side effects (from the National Registry for Drug-Induced Ocular Side Effects, Oregon Health Sciences University, 3181 SW Sam Jackson Park Road, Portland, OR 97201; 503-279-8456).

Magnesium, Cimetidine, and Oral Contraceptives

Although information on drugs long used in therapy is old, it is still pertinent and useful to review for these old "standby" drugs. Magnesium is given to treat eclampsia; it can cause neuromuscular blockade by itself and potentiates neuromuscular blockade by both nondepolarizing and depolarizing muscle relaxants. Cimetidine reduces hepatic blood flow and inhibits enzymatic degradation of drugs by the liver. Thus, higher blood levels and prolonged elimination half-lives may result when drugs that are metabolized by the liver (e.g., lidocaine, procaine, some narcotics, and propranolol) are given to patients taking cimetidine chronically or acutely.[526,527] The risk of postoperative venous thrombosis increases when oral contraceptives are used preoperatively. Although some authorities recommend changing from oral con-

Table 35-20 Common Ophthalmologic Drugs and Their Anesthetically Important Interactions

Drug (Trade Name)	Toxicities and Specific Treatments
Glaucoma: Primary goal is to reduce IOP by Miotics and epinephrine: increase outflow of aqueous humor β-Blockade and carbonic anhydrase inhibitors: reduce production of aqueous humor Osmotic drugs: transiently decrease volume	
Miotics Parasympathomimetics Pilocarpine (Adsorbocarpine, Isopto Carpine, Pilocar, Pilocel) Carbachol	
Acetylcholinesterase inhibitors Physostigmine Demecarium Isoflurophate (Floropryl) Echothiophate (Echodide, Phospholine)	Tox: Hypersalivation, sweating, N/V, bradycardia, hypotension, bronchospasm, CNS effects, coma, respiratory arrest, death Rx: Atropine, pralidoxime (Protopam) Ix: Succinylcholine—prolonged apnea (drugs must be discontinued 4 wk before)
Epinephrine (Epitrate, Murocoll, Mytrate, Epifrin, Glaucon, Epinal, Eppy)	Tox: (rare) Tachycardia, PVCs, HTN, headache, tremors Ix: Avoid drugs that sensitize to catecholamines, e.g., halothane
β-Blockers Timolol (Timoptic) Betaxolol (Betoptic) Levobunolol (Betagan)	Tox: J-blockade with bradycardia, exacerbation of asthma, CNS depression, lethargy, confusion Synergy noted with systemic drugs
Carbonic anhydrase inhibitors Acetazolamide (Diamox) Dichlorphenamide (Daranide, Oratrol) Ethoxzolamide (Cardrase, Ethamide) Methazolamide (Neptazane)	Tox: Anorexia, GI disturbances, "general miserable feeling" and malaise, paresthesias, diuresis, hypokalemia (transient), renal colic and calculi, hyperuricemia, thrombocytopenia, aplastic anemia, acute respiratory failure in patients with COPD
Osmotic drugs Glycerin (Glyrol, Osmoglyn) Isosorbide (Ismotic) Urea (Urevert, Ureaphil) Mannitol (Osmitrol)	Tox: Dehydration, hyperglycemia, nonketotic hyperosmolar coma (rare). Fatalities with mannitol secondary to CHF or intracranial bleeding Urea may cause thrombosis
Intraocular acetylcholine (Miochol)	Tox: Hypotension, bradycardia Rx: Atropine
Mydriatics and cycloplegics: Provide pupillary dilatation and paralysis of accommodation Anticholinergics block muscarinic receptors; paralyzing in iris α-Adrenergics contract the dilator of the iris	
Anticholinergics Atropine (Atropisol, Bufopto, Isopto Atropine) Cyclopentolate, alone (Cyclogyl) or with phenylephrine-homatropine (Cyclomydril) Scopolamine tropicamide (Homatrocel, Isopto Homatropine, Isopto Hyoscine, Murocoll #19, Mydriacyl)	Tox: Dry mouth, flushing, thirst, tachycardia, seizure, hyperactivity, transient psychosis, rare coma, and death Rx: Physostigmine
α-Adrenergics Phenylephrine (Efricel, Mydfrin, Neo-Synephrine) Hydroxyamphetamine (Paredrine)	Tox: Tachycardia, HTN, PVCs, myocardial ischemia, agitation

CHF, congestive heart failure; CNS, central nervous system; COPD, chronic obstructive pulmonary disease; GI, gastrointestinal; HTN, hypertension; IOP, intraocular pressure; Ix, interaction; N/V, nausea and vomiting; PVCs, premature ventricular contractions; Rx, treatment; Tox, toxicity.

traceptives to topical methods of birth control 2 to 4 weeks before surgery, no controlled study has determined whether birth control pills should be discontinued before surgery or the resulting incidence of pregnancy. Moreover, year-long pellets make discontinuation impractical for some. Other authorities recommend preventing venous thromboembolism by using low-dose heparin, guided by a determination of efficacy and cost-effectiveness. In addition, estrogens with micronized progestins are effective at reducing all-cause mortality for at least the first 10 years after menopause.[22,23,528] Thus, the uncertainty surrounding prophylaxis

for heart disease (created by the dilemma of long-term benefit versus the short-term risk of thromboembolism) needs better data for resolution.

Interrupting a Drug Regimen before Surgery

If a drug is needed for treatment preoperatively, it should be continued through surgery. One of us (M.F.R.) provides patients and other professionals with a detailed list (Box 35-7) that we supply through our preanesthesia and preprocedure assessment clinic. It must often be specifically requested because many patients and nurses perceive the NPO directive to include drugs.[529,530] The only exception to this general rule of not altering preoperative drug therapy might pertain to (1) MAOIs, (2) anticoagulants and fibrinolytic drugs (e.g., clopidogrel [Plavix]) if surgical hemostasis is needed, (3) nicotinic acid, (4) dosage adjustments for insulin and corticosteroids, (5) ACE inhibitors and receptor antagonists (angiotensin II receptor blocking drugs), and (6) drugs for erectile dysfunction (i.e., sildenafil [Viagra], vardenafil [Levitra], tadalafil [Cialis], or similar drugs). These recommendations require that the anesthesiologist be aware of the pharmacologic characteristics, interactions, and anesthetic implications of drugs described earlier in this chapter.

When in doubt about a disease or a drug, we consult the following textbooks: *Harrison's Principles of Internal Medicine*; *Anesthesia and Uncommon Diseases: Pathophysiologic and Clinical Correlations*; *Anesthesia and Co-Existing Disease*; *Essence of Anesthesia Practice*; *Anesthetic Implications of Congenital Anomalies in Children*; *Pharmacology and Physiology in Anesthetic Practice*; and *Goodman and Gilman's The Pharmacologic Basis of Therapeutics*. It is then wise to consult two experts on the drug or disease and determine who is best able to care for the patient. The

Box 35-7 Preoperative and Preprocedure Medication Instruction Guidelines (PPAC Form 5)

Instruct patients to take the following medications with a small sip of water EVEN IF OTHERWISE NPO:

Antihypertensive medications—Continue on the day of the operation or procedure

Diuretics—Continue on the day of the operation or procedure

Cardiac medications (e.g., digoxin)—Continue on the day of the procedure

Antidepressant, antianxiety, and psychiatric medications—Continue on the day of the operation or procedure

Thyroid medications—Continue on the day of the operation or procedure

Birth control pills—Continue on the day of the operation or procedure

Eye drops—Continue on the day of the operation or procedure

Heartburn or reflux medications (e.g., Prilosec, Zantac)—Continue on the day of the operation or procedure

Narcotic pain medications—Continue on the day of the operation or procedure

Antiseizure medications—Continue on the day of the operation or procedure

Asthma medications—Continue on the day of the operation or procedure

Steroids (oral and inhaled)—Continue on the day of the operation or procedure

Statins (e.g., Zocor, Lipitor)—Continue on the day of the operation or procedure

Aspirin—Usually continue; discontinue 7 days before plastic surgery and surgery on the retina

COX-2 inhibitors—Continue on the day of the operation or procedure unless the surgeon specifies (usually concerned about bone healing)

NSAIDs—Usually continue; discontinue 48 hours before plastic surgery and surgery on the retina

Vitamins, iron, Premarin—Discontinue on the day of the operation or procedure

Topical medications (e.g., creams and ointments)—Discontinue on the day of the operation or procedure

Oral hypoglycemic drugs—Discontinue on the day of the operation or procedure

Insulin—For all patients, discontinue all regular or combination (70/30 preparations) insulin on the day of the operation or procedure. Type 2 diabetics should discontinue all insulins of any type. Type 1 diabetics should take a small amount (usually a third) of their usual AM long-acting insulin (e.g., Lente or NPH) on the day of the operation or procedure. Type 1 diabetics should not take any short-acting insulin, such as regular insulin, on the day of the procedure. Patients with an insulin pump should continue their basal rate only.

Viagra, Levitra, Cialis, or similar drugs—Discontinue 36 hours before surgery

Warfarin (Coumadin)—Discontinue 4 days before surgery except for patients undergoing cataract surgery without a bulbar block

Plavix (clopidogrel)—Discontinue 7 days before surgery except for vascular patients or those undergoing cataract surgery

Herbals and nonvitamin supplements—Discontinue 7 days before surgery

MAOIs—Patients taking these antidepressant medications need an anesthesia consultation before surgery (preferably 3 weeks before surgery)

COX, cyclooxygenase; MAOIs, monoamine oxidase inhibitors; NPO, nothing by mouth; NSAIDs, nonsteroidal anti-inflammatory drugs.

expert who is best qualified should be observed while attending to the patient, not only preoperatively and intraoperatively but also postoperatively. It is important to remember that few prospective controlled studies have shown that any preoperative technique, treatment, or management decreases perioperative risk. However, common sense and foreknowledge of potential pitfalls, as well as diligence in avoiding these pitfalls, should reduce avoidable perioperative complications.

36 Patient Positioning and Anesthesia

Key Points

1. Patient positioning is a major responsibility that is shared by the entire operating room team. A balance between optimal surgical positioning and patient well-being is sometimes required.
2. Many patient positions that are used for surgery result in undesirable physiologic consequences, including significant cardiovascular and respiratory compromise. Anesthetics blunt natural compensatory mechanisms, rendering surgical patients vulnerable to positional changes.
3. Peripheral nerve injury, although rare, accounted for 18% of cases in the 1990-1994 American Society of Anesthesiologists (ASA) Closed Claims Database, second only to death. Peripheral nerve injury is often a result of patient positioning. The mechanisms of injury are stretching, compression, and ischemia.
4. Ulnar neuropathy is the most common postoperative nerve injury, followed by injury to the brachial plexus, lumbosacral nerve roots, and spinal cord.
5. Not all postoperative neuropathies, including ulnar neuropathy, are currently explainable and may not be entirely preventable. Many postoperative ulnar nerve deficits do not seem to be related to intraoperative patient position because they appear days after surgery.
6. The ASA issued a Practice Advisory in 2000 for the prevention of perioperative peripheral neuropathies. Only 6 of 509 studies reviewed met the standard, however, for a scientifically proven relationship between intervention and outcome.
7. Postoperative visual loss is a rare but devastating complication that is associated with the prone position. The causes are multifactorial and incompletely understood.
8. Anesthetics administered outside classic operating rooms present special challenges with regard to patient positioning because of equipment limitations and differences in the work environment and culture.

Anesthesiologists share a critical responsibility for the proper positioning of patients in the operating room. Positions deemed optimal for surgery often result in undesirable physiologic changes, such as hypotension from impaired venous return to the heart or oxygen desaturation owing to ventilation-perfusion mismatching. In addition, peripheral nerve injuries during surgery remain a significant source of perioperative morbidity.[1-3]

Proper positioning requires the cooperation of anesthesiologists, surgeons, and nurses to ensure patient well-being and safety while providing surgical exposure. During anesthesia care, whenever possible, patients should be placed in a position that they would tolerate when awake. Jewelry and hair ornaments are removed. Padded surfaces, lumbar support, and natural joint position are optimal. The head should remain midline without substantial extension or flexion whenever possible. At no time should pressure on the eyes occur. Because surgeons wish to have optimal exposure, and positions may be maintained for long periods, prevention of complications often requires compromise and judgment. The duration of more extreme positions, if such are necessary, should be limited as much as possible. Expected tilting of the operating room table during surgery should be anticipated before draping, and the patient should be secured accordingly. Use of safety straps and prevention of a patient fall are fundamental.

Cardiovascular Concerns

Complex arterial, venous, and cardiac physiologic responses have evolved to blunt the effects of positional changes on arterial blood pressure and maintain perfusion to vital organs. Central, regional, and local mechanisms are involved. This is particularly important for humans who maintain an upright posture, owing to the vertical distance from the heart to the brain and its need for constant perfusion.

Normally, as an individual reclines from an erect to a supine position, venous return to the heart increases as pooled blood from the lower extremities redistributes toward the heart. Preload, stroke volume, and cardiac output are augmented. The resultant

increase in arterial blood pressure activates afferent baroreceptors from the aorta (via the vagus nerve) and within the walls of the carotid sinuses (via the glossopharyngeal nerve) to decrease sympathetic outflow and increase parasympathetic impulses to the sinoatrial node and myocardium. The result is a compensatory decrease in heart rate, stroke volume, and cardiac output. Mechanoreceptors from the atria and ventricle also are activated to decrease sympathetic outflow to muscle and splanchnic vascular beds. Lastly, atrial reflexes are activated to regulate renal sympathetic nerve activity, plasma renin, atrial natriuretic peptide, and arginine vasopressin levels.[4] As a result, systemic arterial blood pressure is maintained within a narrow range during postural changes in the unanesthetized setting.

General anesthesia, muscle relaxation, positive-pressure ventilation, and neuraxial blockade interfere with venous return to the heart, arterial tone, and autoregulatory mechanisms, rendering patients under anesthesia especially vulnerable to relatively uncompensated circulatory effects of changes in position. The use of spinal or epidural anesthesia causes a significant sympathectomy across all affected dermatomes, independent of the presence of general anesthesia, reducing preload and potentially blunting cardiac response if the sympathetic output to the heart is affected (see Chapter 51). Positive-pressure ventilation increases mean intrathoracic pressure, diminishing the venous pressure gradient from peripheral capillaries to the right atrium. Because small pressure gradients are active in the venous circulation, this may significantly affect cardiac filling and consequently cardiac output. Positive end-expiratory pressure increases mean intrathoracic pressure further, as do conditions associated with low lung compliance, such as airways disease, obesity, ascites, and light anesthesia. Venous return and cardiac output may be compromised further.[5]

For these reasons, arterial blood pressure is often particularly labile immediately after the initiation of anesthesia and during patient positioning. It is crucial for the anesthesiologist to anticipate, monitor, and treat these effects, and to assess the safety of positional changes for each patient. Blood pressure should be measured frequently after induction of anesthesia or initiation of neuraxial blockade. It is often necessary to increase intravenous fluid administration, adjust the level of anesthesia, or administer vasopressors during this hemodynamic transition. Temporary use of head-down positions may be helpful. Sometimes a delay in repositioning of the patient for surgery may be necessary until systemic blood pressure reaches an acceptable level of homeostasis. Interruptions in monitoring to facilitate positioning or turning of the operating room table must be minimized during this dynamic period. Patient positioning is always secondary to patient safety.

Pulmonary Concerns

Anesthetized patients who are breathing spontaneously have a reduced tidal volume and functional residual capacity and an increased closing volume compared with the nonanesthetized state. Positive-pressure ventilation with muscle relaxation may ameliorate ventilation-perfusion mismatches under general anesthesia by maintaining adequate minute ventilation and limiting atelectasis. The diaphragm assumes an abnormal shape, however, owing to the loss of muscle tone, and is displaced less in the dependent portions of the lung.[6] This decreases ventilation-perfusion matching and consequently arterial Po_2. Patients undergoing neuraxial anesthesia lose abdominal and thoracic muscle function in affected dermatomes, but diaphragmatic function is retained if general anesthesia and muscle relaxation are not concurrently administered. In addition to these effects of anesthesia, patient position has distinct effects on pulmonary function. In particular, any position that limits movement of the diaphragm, chest wall, or abdomen may increase atelectasis and intrapulmonary shunt.

Spontaneous ventilation results from small negative intrathoracic pressure shifts during inspiration owing to diaphragmatic displacement and chest wall expansion. This pressure decrease also promotes venous return to the thorax by reducing the pressure in the great veins and right atrium compared with the periphery. Normal distribution of ventilation is determined by the excursion of the diaphragm, movement of the chest wall, and compliance of the lung. When an individual shifts from standing to supine, functional residual capacity decreases owing to cephalad displacement of the diaphragm. The relative contribution to ventilation of the chest wall compared with the diaphragm decreases from 30% to 10%. With spontaneous ventilation in either position, diaphragmatic movement is greatest adjacent to the most dependent portions of the lung, helping to bring new ventilation to the zones of the lung that are preferentially perfused. The preferential perfusion of the dependent portions is dominated by gravity; however, other factors, such as pulmonary vascular length, also may be important. Perfusion seems to follow a central-to-peripheral spectrum in each lobe that is maintained with changes in cardiac output.[7-9]

The prone position has been used to improve respiratory function in patients with adult respiratory distress syndrome.[10] In anesthetized patients, the prone position has advantages over the supine position with regard to lung volumes and oxygenation without adverse effects on mechanics,[11,12] including obese[13] and pediatric patients (see Chapter 82).[14] When patients are prone, weight should be distributed to the thoracic cage and bony pelvis, allowing the abdomen to move with respiration, as outlined subsequently.

Specific Positions

Supine

The most common position for surgery is the supine, or dorsal decubitus position (Fig. 36-1). Because the entire body is close to the level of the heart, hemodynamic reserve is best maintained. Because compensatory mechanisms are blunted by anesthesia, however, even a few degrees of head-down (Trendelenburg) position or head-up (reverse Trendelenburg) position are sufficient to cause significant cardiovascular changes.

Associated Arm Position

In a supine patient, one or both arms may be abducted out to the side or adducted (tucked) alongside the body. It is recommended that upper extremity abduction be limited to less than 90 degrees to minimize the likelihood of brachial plexus injury by caudad pressure in the axilla from the head of the humerus.[15] The hand

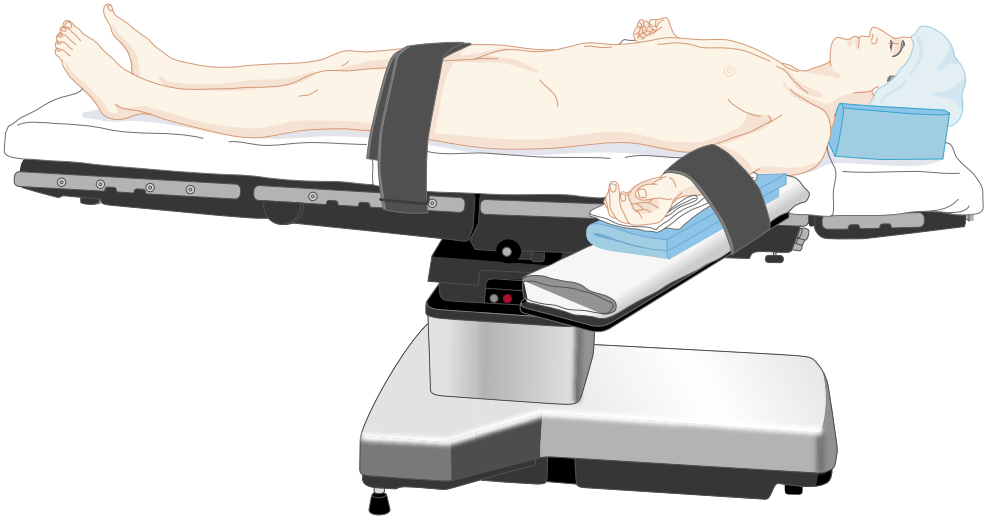

Figure 36-1 Supine position. Note the asymmetry of the base of the table, placing the patient's center of gravity over the base if positioned in the usual direction.

and forearm are either supinated or kept in a neutral position with the palm toward the body to reduce external pressure on the spiral groove of the humerus and the ulnar nerve (Fig. 36-2).[16-18] When the arms are adducted, they are usually held alongside the body with a "draw sheet" that passes under the body and over the arm, and is then tucked directly under the torso (not the mattress) to ensure that the arm remains properly placed next to the body. Alternatively, in surgeries in which access to the chest or abdomen is not necessary, curved arm cradles may be used. In all cases, the arms are placed in a neutral position.[16] The elbows and any protruding objects, such as intravenous fluid lines and stopcocks, are padded (Fig. 36-3).

Variations of the Supine Position

Several variations of the supine position are frequently used. The *lawn chair position,* in which the hips and knees are slightly flexed (Fig. 36-4), reduces stress on the back, hips, and knees, and is better tolerated by patients who are awake or undergoing monitored anesthesia care. In addition, because the legs are slightly above the heart, venous drainage from the lower extremity is facilitated. Also, the xiphoid to pubic distance is decreased, reducing the tension on the ventral abdominal musculature and easing closure of laparotomy incisions. Proper positioning of the patient's hips on the operating room table and several modifications to the table are required to achieve this position. Typically, the back of

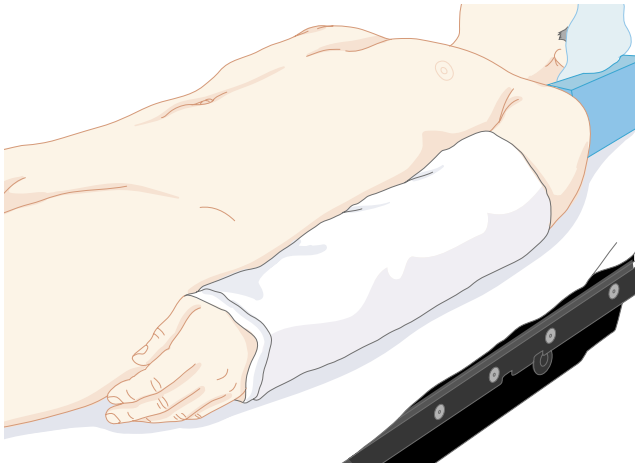

Figure 36-3 Arm tucked at patient's side. Arm in neutral position with palm to hip. The elbow is padded, and one needs to ensure that the arm is supported.

the bed is raised, the legs below the knees are lowered to an equivalent angle, and a slight Trendelenburg tilt is used to level the hips with the shoulders, if desired. These modifications reduce venous pooling in the legs and permit an arm board or table to be parallel with the floor if desired for upper extremity surgery.

The *frog-leg position,* in which the hips and knees are flexed, and the hips are externally rotated with the soles of the feet facing each other, allows access to the perineum, medial thighs, genitalia, and rectum. Care must be taken to minimize stress and postoperative pain in the hips and prevent dislocation by supporting the knees appropriately.

Tilting a supine patient head down, the *Trendelenburg position* (Fig. 36-5), is often used to increase venous return during hypotension, to improve exposure during abdominal and laparoscopic surgery, and to prevent air emboli and facilitate cannulation during central line placement. It is linked by name to a 19th century German surgeon, Trendelenburg, who described its use for abdominal surgery. Nonsliding mattresses are recommended to prevent the patient from sliding cephalad. Shoulder braces are not recommended because of considerable risk of compression injury to the brachial plexus.

The Trendelenburg position has significant cardiovascular and respiratory consequences. The head-down position increases central venous, intracranial, and intraocular pressures. Prolonged head-down position also can lead to swelling of the face, conjunctiva, larynx, and tongue with an increased potential for postoperative upper airway obstruction. The cephalic movement of abdominal viscera against the diaphragm also decreases functional residual capacity and pulmonary compliance. In spontaneously ventilating patients, the work of breathing increases. In mechanically ventilated patients, airway pressures must be higher to ensure adequate ventilation. The stomach also lies above the glottis. Endotracheal intubation is often preferred to protect the airway from pulmonary aspiration related to reflux and to reduce atelectasis. Because of the risk of edema to the trachea and mucosa surrounding the airway during surgeries in which patients have been in the Trendelenburg position for prolonged periods, it may be prudent to verify an air leak around the endotracheal tube or visualize the larynx before extubation.

Reverse Trendelenburg position (head-up tilt) (see Fig. 36-5) is often employed to facilitate upper abdominal surgery by shifting the abdominal contents caudad. This position is increasingly popular because of the growing number of laparoscopic surgeries. Caution is advised to prevent patients from slipping on the table, and more frequent monitoring of arterial blood pressure may be prudent to detect hypotension owing to decreased venous return. In addition, the position of the head above the heart reduces perfusion pressure to the brain and should be taken into consideration when determining optimal blood pressure.

In all positions in which the head is at a different level than the heart, the effect of the hydrostatic gradient on cerebral arterial and venous pressures should be carefully considered in terms of cerebral perfusion pressure. Careful documentation of any potential arterial pressure gradients is especially prudent.

Figure 36-4 Lawn chair position. Flexion of the hips and knees decreases tension on the back.

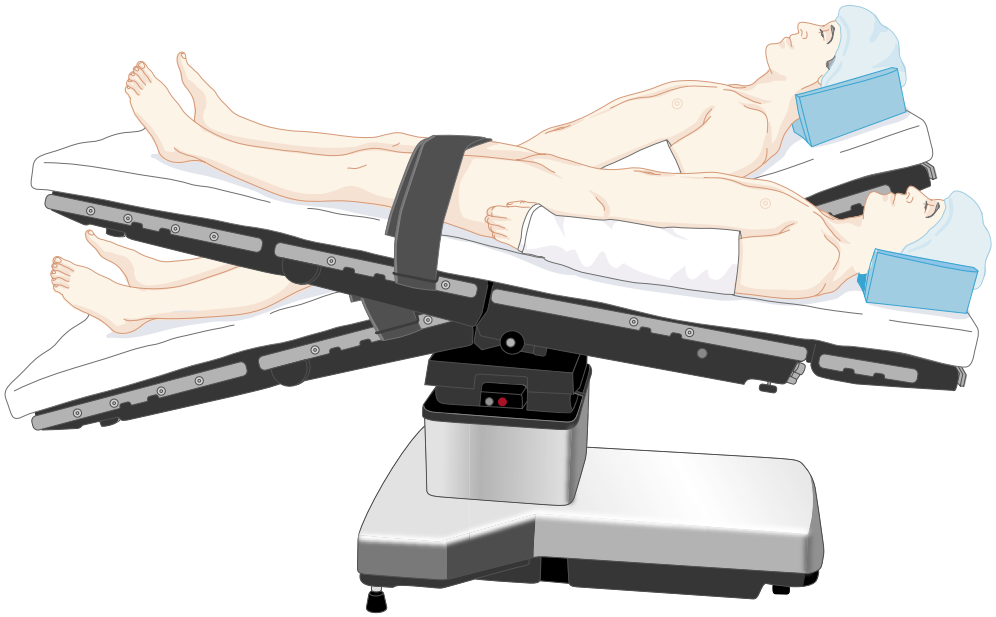

Figure 36-5 Trendelenburg position and reverse Trendelenburg position. Shoulder braces should be avoided to prevent brachial plexus compression injuries.

Complications

Pressure alopecia resulting from ischemic hair follicles is related to prolonged immobilization of the head with its full weight falling on a limited area, usually the occiput. Lumps, such as those caused by monitoring cable connectors, should not be placed under head padding because they may create focal areas of pressure. Hypothermia and hypotension during surgery, such as during cardiopulmonary bypass, may increase the incidence of this complication. Consequently, it is prudent to cushion the head well, and if possible during prolonged surgery, periodic rotation of the head to redistribute the weight may be considered.

Backache may occur in the supine position as the normal lumbar lordotic curvature, particularly the tone of the paraspinous musculature, is lost during general anesthesia with muscle relaxation or a neuraxial block. Consequently, patients with extensive kyphosis, scoliosis, or a previous history of back pain may require extra padding of the spine or slight flexion at the hip and knee. Tissues overlying all bony prominences, such as the heels and sacrum, must be padded to prevent soft tissue ischemia owing to pressure, especially during prolonged surgery.[19]

Peripheral nerve injury (discussed in detail subsequently) is a complex phenomenon with a multifactorial etiology. The American Society of Anesthesiologists (ASA) published a practice advisory in 2000 to help prevent perioperative neuropathies.[16] Ulnar neuropathy is the most common lesion. Although there is no direct evidence that positioning or padding alone can prevent perioperative ulnar neuropathies, the committee has recommended, as mentioned earlier, to limit arm abduction in a supine patient to less than 90 degrees at the shoulder with the hand and forearm either supinated or kept in a neutral position. Regardless of the position of the upper extremities, maintaining the head in a relatively midline position can help minimize the risk of stretch injury to the brachial plexus.[20]

When patients are very heavy, caution is advised when placing them in reverse axis on the operating room table (see Chapter 64). The base of the operating room table is asymmetric, with the torso over the foot of the table. Patients are often positioned with the torso over the open side of the table, however, to improve surgical access or to permit use of equipment such as C-arm x-ray devices. This positioning places the heaviest part of the body and the patient's center of gravity opposite the weighted foot of the table, with substantial leverage. The operating room table can tilt and tip over if sufficient weight is placed away from the base, particularly if extensions are used, or the bed is tilted in the Trendelenburg position. Operating room table weight limits differ substantially with regard to normal and reverse positioning and should be strictly observed.

Lithotomy

The classic lithotomy position is frequently used during gynecologic, rectal, and urologic surgeries. The hips are flexed 80 to 100 degrees from the trunk, and the legs are abducted 30 to 45 degrees from the midline. The knees are flexed until the lower legs are parallel to the torso, and the legs are held by supports or stirrups, usually "candy cane," knee crutch, or calf support style (Figs. 36-6, 36-7, and 36-8). The foot section of the operating room table is lowered. If the arms are on the operating table alongside the patient, the hands and fingers may lie near the open edge of the lowered section of the table. When raising the foot of the table at the end of surgery, strict attention to the position of the hand must be paid to avoid a potentially disastrous crush injury to the fingers (Fig. 36-9). For this reason, positioning the arms on armrests far from the table hinge point is recommended at all times when patients are in the lithotomy position.

Initiation of the lithotomy position requires coordinated positioning of the lower extremities by two assistants to avoid torsion of the lumbar spine. Both legs should be raised together, flexing the hips and knees simultaneously. The lower extremities should be padded to prevent compression against the stirrups. After the surgery, the patient must be returned to the supine posi-

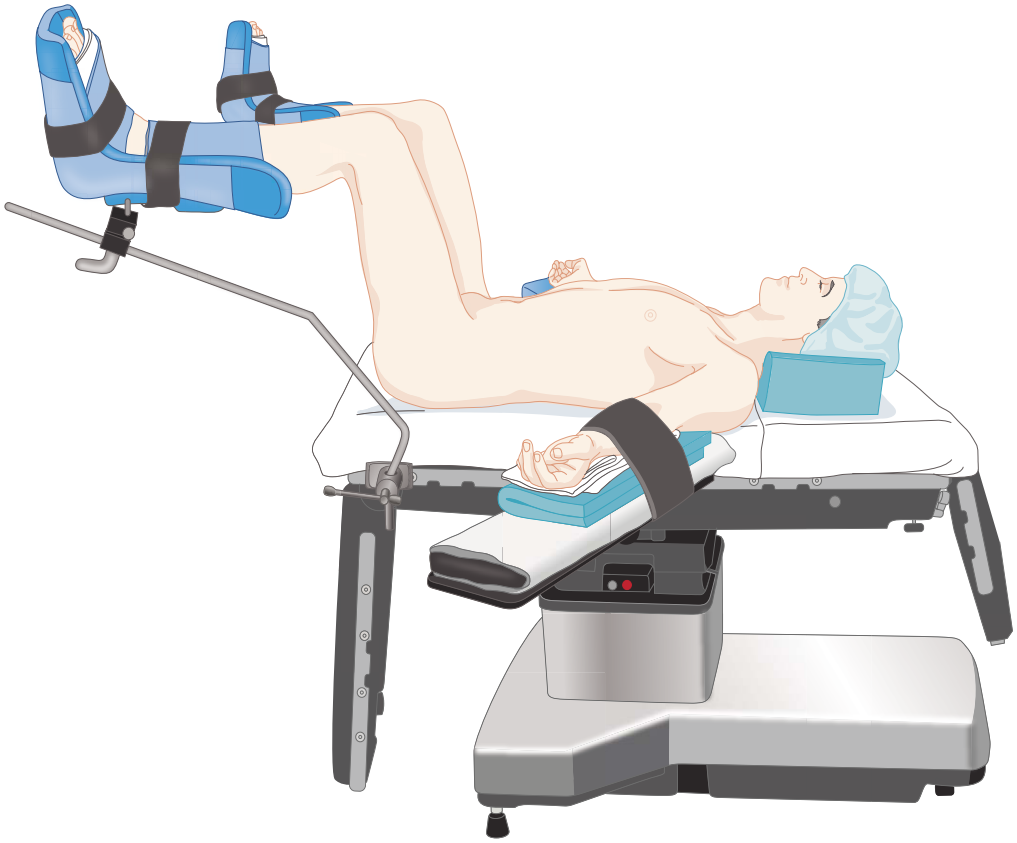

Figure 36-6 Lithotomy position. Hips are flexed 80 to 100 degrees with lower leg parallel to body. Arms are on armrests away from hinge point of foot section.

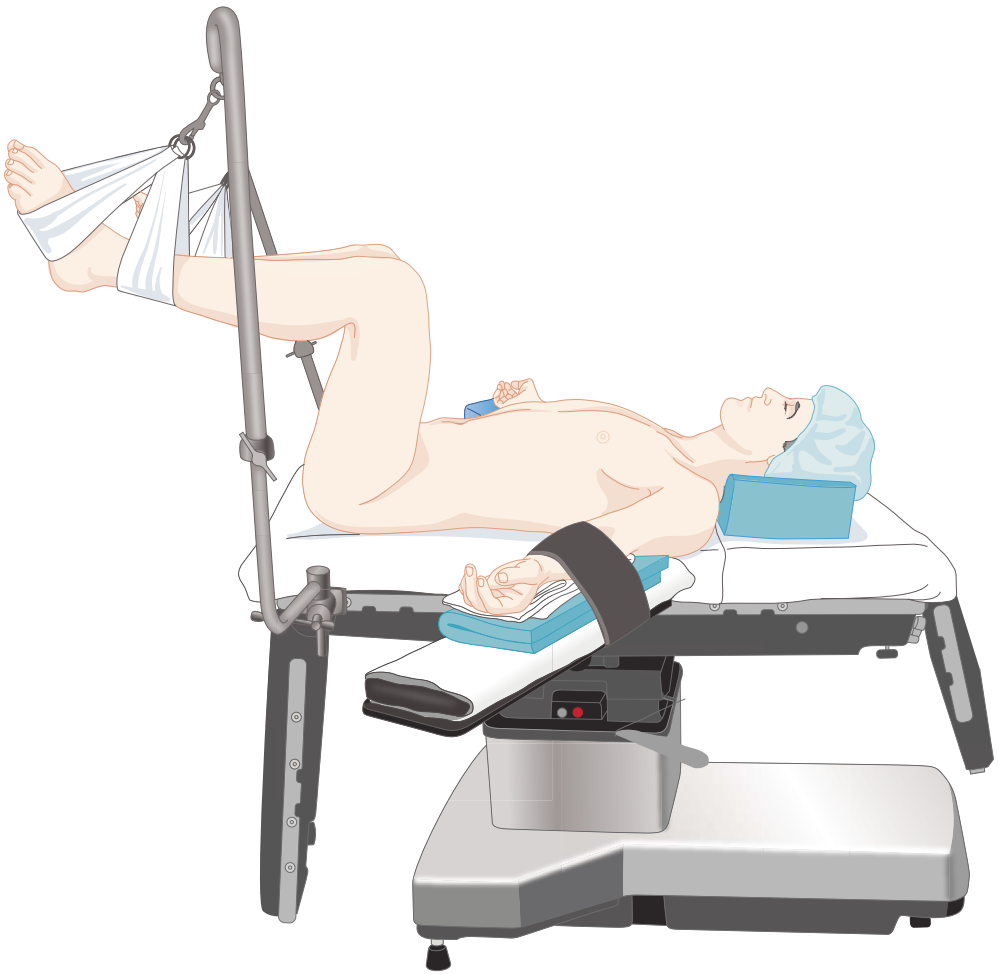

Figure 36-7 Lithotomy position with “candy cane” supports.

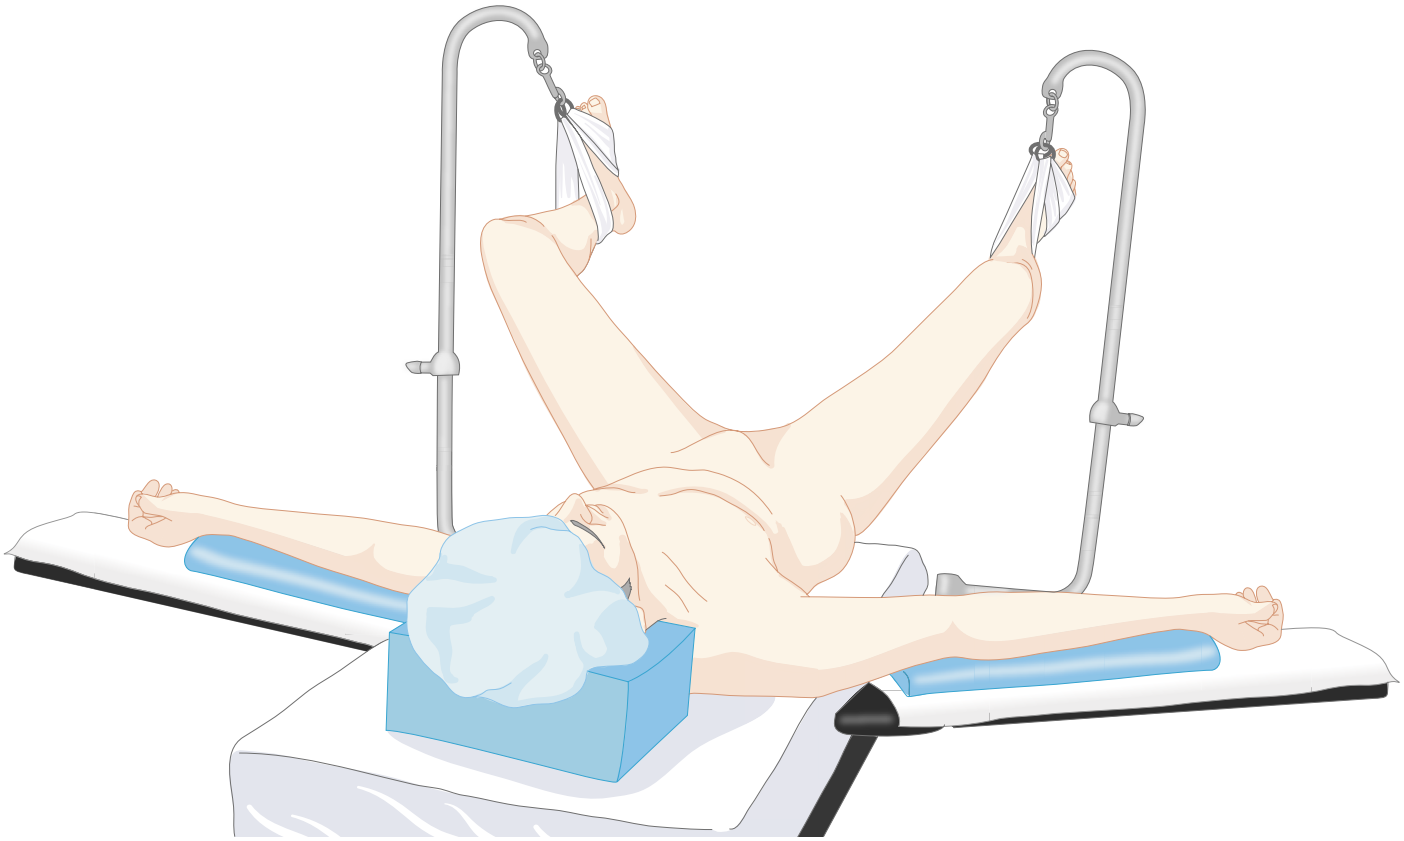

Figure 36-8 Lithotomy position with correct position of "candy cane" stirrups well away from lateral fibular head.

tion in a coordinated manner. As mentioned, the hands should be positioned to prevent entrapment in any moving or articulating sections of the operating room table. The legs should be removed from the holders simultaneously, knees brought together in the midline, and the legs slowly straightened and lowered onto the operating room table.

The lithotomy position also may cause significant physiologic changes. When the legs are elevated, preload increases, causing a transient increase in cardiac output and, to a lesser extent, cerebral venous and intracranial pressure in otherwise healthy patients. In addition, the lithotomy position causes the abdominal viscera to displace the diaphragm cephalad, reduc-

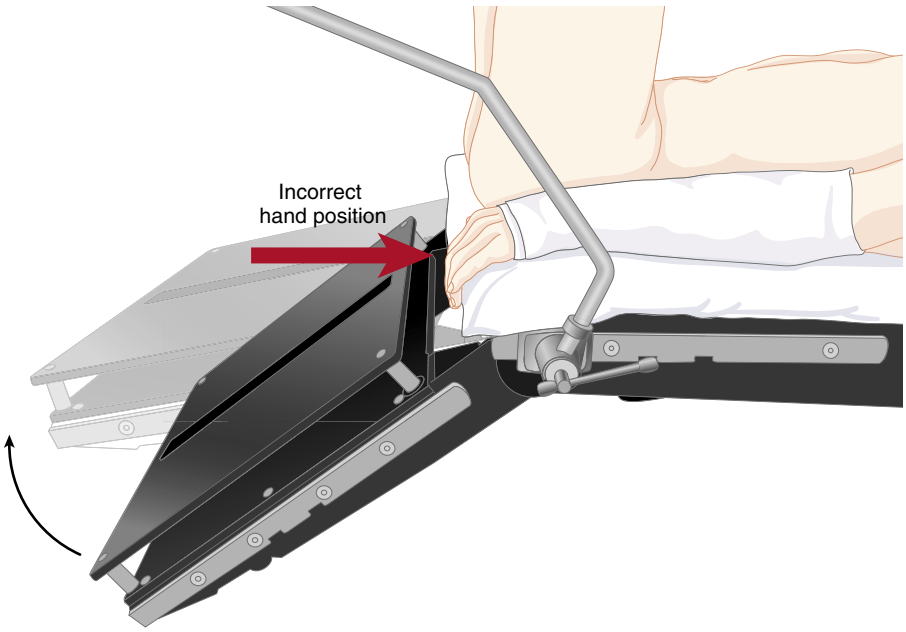

Figure 36-9 Improper position of arms in lithotomy position with fingers at risk for compression when the lower section of the bed is raised.

Figure 36-10 Lateral decubitus position. Note flexion of lower leg, padding between legs, and proper support of both arms.

ing lung compliance and potentially resulting in a decreased tidal volume. If obesity or a large abdominal mass is present (tumor, gravid uterus), abdominal pressure may increase significantly enough to obstruct venous return to the heart. Lastly, the normal lordotic curvature of the lumbar spine is lost in the lithotomy position, potentially aggravating any previous lower back pain.[21]

In a retrospective review of 198,461 patients undergoing surgery in the lithotomy position from 1957 to 1991, injury to the common peroneal nerve was the most common lower extremity motor neuropathy, representing 78% of nerve injuries. A potential cause of the injury was the compression of the nerve between the lateral head of the fibula and the bar holding the legs. When the candy cane stirrups are used, special attention must be paid to avoid compression (see Fig. 36-8). The injury was more common with patients who had low body mass index, recent cigarette smoking, or prolonged duration of surgery.[22] In a prospective review of 991 patients undergoing surgery in the lithotomy position from 1997 to 1998, there were no motor neuropathies in the lower extremity, although paresthesias in the distribution of the obturator, lateral femoral cutaneous, sciatic, and peroneal nerves were found.[23]

Lower extremity compartment syndrome is a rare complication associated with the lithotomy position. It occurs when perfusion to an extremity is inadequate, resulting in ischemia, edema, and extensive rhabdomyolysis from increased tissue pressure within a fascial compartment. In a large retrospective review of 572,498 surgeries, the incidence of compartment syndromes was higher in the lithotomy (1 in 8720) and lateral decubitus (1 in 9711) positions compared with the supine (1 in 92,441) position. Long surgical procedure time was the only distinguishing characteristic of the surgeries in which patients developed lower extremity compartment syndromes.[24] Compartment pressures have been studied in the lithotomy position and found to increase over time. It is recommended to lower the legs to the level of the body periodically if surgery extends beyond several hours.[25-27]

Lateral Decubitus

The lateral decubitus position (Fig. 36-10) is used most frequently for surgery involving the thorax, retroperitoneal structures, or hip. The patient rests on the nonoperative side and is balanced with anterior and posterior support, such as bedding rolls or a deflatable beanbag, and a flexed dependent leg. The arms usually are positioned in front of the patient. The dependent arm rests on a padded arm board perpendicular to the torso. The nondependent arm is often supported over folded bedding or suspended with an armrest or foam cradle. If possible, the arm should not be abducted more than 90 degrees. For some high thoracotomies, the nondependent arm may need to be elevated above the shoulder plane for exposure; however, vigilance is warranted to prevent neurovascular compromise.

The act of positioning a patient in the lateral decubitus position requires the cooperation of the entire operating room staff to prevent potential injuries. The patient's head must be kept in a neutral position to prevent excessive lateral rotation of the neck and stretch injuries to the brachial plexus. Additional head support may be required (Fig. 36-11). The dependent ear should be checked to avoid folding and undue pressure. It is advised to verify that the eyes are securely taped before repositioning if the patient is asleep. The dependent eye must be checked frequently for external compression.

To avoid compression injury to the dependent brachial plexus or vascular compression, an "axillary roll" (generally a liter bag of intravenous fluid) is frequently placed just caudal to the dependent axilla (Fig. 36-12). This roll should never be placed *in* the axilla. Its purpose is to ensure that the weight of the thorax is borne by the chest wall caudal to the axilla and avoid compression of the axillary contents. Many practitioners do not use a roll if the deflatable beanbag is used to cradle the torso. Regardless of the technique, the pulse should be monitored in the dependent arm for early detection of compression to axillary neurovascular structures. Vascular compression and venous engorgement in the dependent arm may affect the pulse oximetry reading, and a low

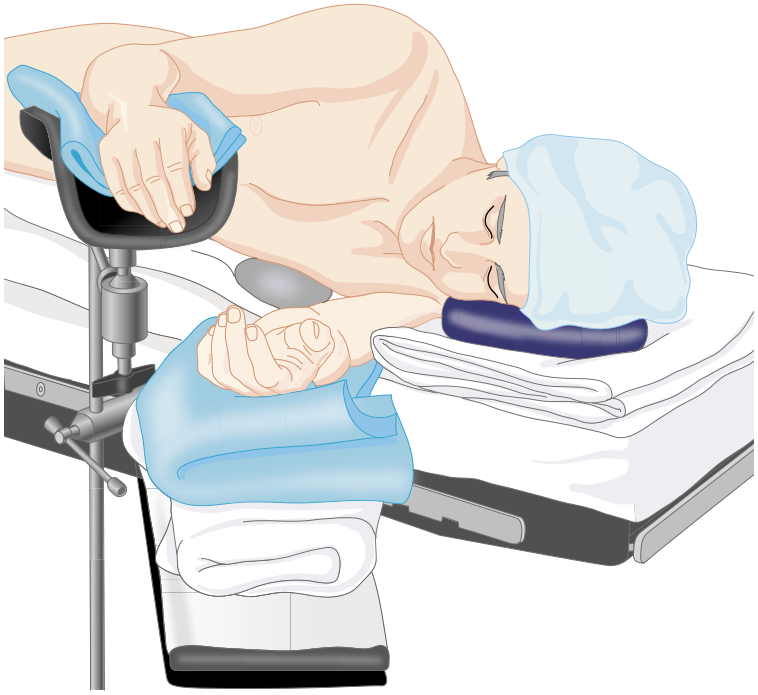

Figure 36-11 Lateral decubitus position showing placement of arms and head. Note additional padding under headrest to ensure alignment of head with spine. Headrest should be kept away from dependent eye.

saturation reading may be an early warning of compromised circulation. Hypotension measured in the dependent arm may be due to axillary arterial compression, so it is useful to retain the ability to measure blood pressure in both arms. When a kidney rest is used, it must be properly placed under the dependent iliac crest to prevent inadvertent compression of the inferior vena cava. Finally, a pillow or other padding is generally placed between the knees with the dependent leg flexed to minimize excessive pressure on bony prominences and stretch of low extremity nerves.

The lateral decubitus position also is associated with pulmonary compromise.[28] In a patient who is mechanically ventilated, the combination of the lateral weight of the mediastinum and disproportionate cephalad pressure of abdominal contents on the dependent lung favors overventilation of the nondependent lung. At the same time, pulmonary blood flow to the underventilated, dependent lung increases owing to the effect of gravity. Consequently, ventilation-perfusion matching worsens, potentially affecting gas exchange and ventilation.

The lateral decubitus position is preferred during pulmonary surgery and one-lung ventilation. The minute ventilation of the dependent lung is usually increased when the nondependent lung is collapsed. The increase in minute ventilation combined with decreased compliance owing to positioning may exacerbate further the airway pressure required to achieve adequate ventilation. Head-down tilt in the lateral position

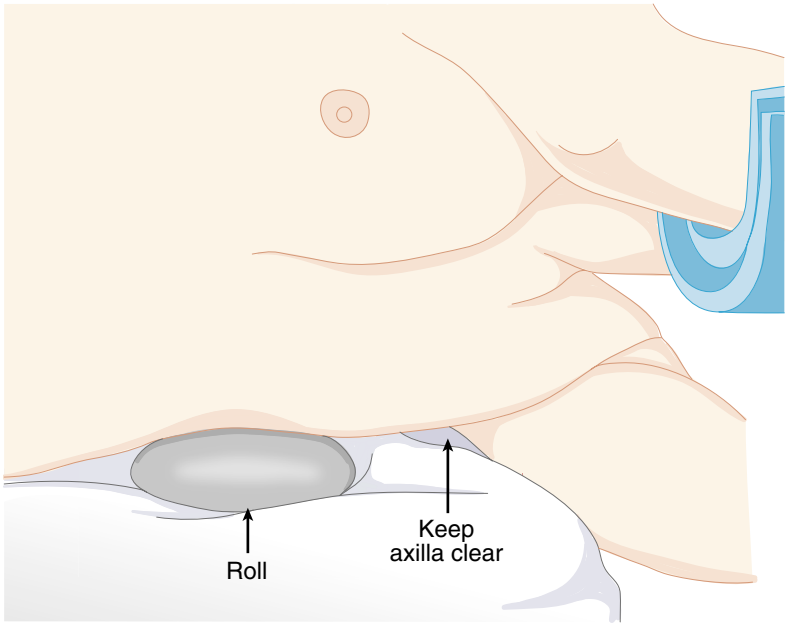

Figure 36-12 Use of axillary roll in lateral decubitus position. Roll, in this case a bag of intravenous fluid, is placed well away from axilla to prevent compression of the axillary artery and brachial plexus.

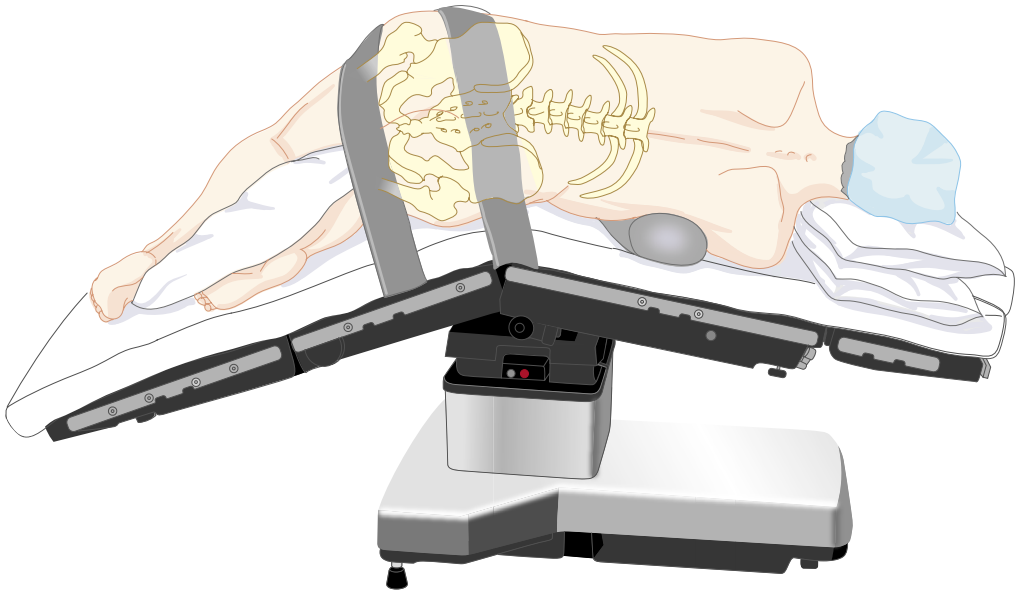

Figure 36-13 Flexed lateral decubitus position. Point of flexion should lie under iliac crest, rather than the flank or lower ribs, to optimize ventilation of the dependent lung.

worsens pulmonary function still further, increasing shunt fraction.[29]

Patients may be flexed while in the lateral position to spread the ribs during thoracotomies or improve exposure of the retroperitoneum for renal surgeries. The point of flexion, and the kidney rest if raised, should lie under the iliac crest rather than the flank or ribcage to minimize compression of the dependent lung (Fig. 36-13). This position is often accompanied by a component of reverse Trendelenburg positioning, creating the potential for venous pooling in the lower body. For these reasons, use of the flexed, lateral position is discouraged when not actively needed for surgical exposure.

Prone

The prone or ventral decubitus position (Fig. 36-14) is used primarily for surgical access to the posterior fossa of the skull, the posterior spine, the buttocks and perirectal area, and the lower extremities. As with the supine position, if the legs are in plane with the torso, hemodynamic reserve is maintained; however, if there is any significant lowering of the legs or tilt of the entire table, venous return may be decreased or augmented accordingly. Pulmonary function may be superior to the supine or lateral decubitus positions if there is no significant abdominal pressure, and the patient is properly positioned.[30,31] The legs should be

Figure 36-14 Prone position with Wilson frame. Arms are abducted less than 90 degrees whenever possible. Pressure points are padded, and chest and abdomen are supported away from the bed to minimize abdominal pressure and preserve pulmonary compliance. Soft head pillow has cutouts for eyes and nose and a slot to permit endotracheal tube exit. Eyes must be checked frequently.

padded and flexed slightly at the knees and hips. The head may be supported face-down with its weight borne by the bony structures or turned to the side.

Both arms may be positioned to the patient's sides and tucked in the neutral position as described for a supine patient, or placed next to the patient's head on arm boards—sometimes called the prone "superman" position. Extra padding under the elbow is needed to prevent compression of the ulnar nerve. The arms should not be abducted greater than 90 degrees to prevent excessive stretching of the brachial plexus, especially in patients with the head turned. Finally, elastic stockings and active compression devices are needed for the lower extremities to minimize pooling of the blood, especially with any flexion of the body.

When general anesthesia is planned, the patient is first intubated on the stretcher, and all intravascular access is obtained as needed. The endotracheal tube is well secured to prevent dislodgment and loosening of tape owing to drainage of saliva when prone. With the coordination of the entire operating room staff, the patient is turned prone onto the operating room table, keeping the neck in line with the spine during the move. The anesthesiologist is primarily responsible for coordinating the move and for repositioning of the head. An exception might be cases in which rigid pin fixation is used, and the surgeon holds the pin frame. It is recommended to disconnect blood pressure cuffs and arterial and venous lines that are on the side that rotates furthest to avoid dislodgment, although some clinicians prefer to disconnect all lines and monitors before moving. Pulse oximetry usually can be maintained if applied to the "inside" arm, and full monitoring should be reinstituted as rapidly as possible. Endotracheal tube position and adequate ventilation are reassessed immediately after the move.

Head position is crucial. The patient's head may be turned to the side when prone if neck mobility is adequate. As in the lateral decubitus position, the dependent eye must be checked frequently for external compression. In addition, in patients with cervical arthritis or cerebrovascular disease, lateral rotation of the neck may compromise carotid or vertebral arterial blood flow or jugular venous drainage. In most cases, the head is kept in a neutral position using a surgical pillow, horseshoe headrest, or Mayfield head pins. Numerous commercially available pillows are specially designed for the prone position. Most, including disposable foam versions, support the forehead, malar regions, and the chin, with a cutout for the eyes, nose, and mouth (see Fig. 36-14). The face is not always visible, however, making eye checks more difficult. Mirror systems are available to facilitate intermittent visual confirmation that the eyes are unimpinged, although direct visualization or tactile confirmation of at least the initial appearance is prudent (Fig. 36-15).

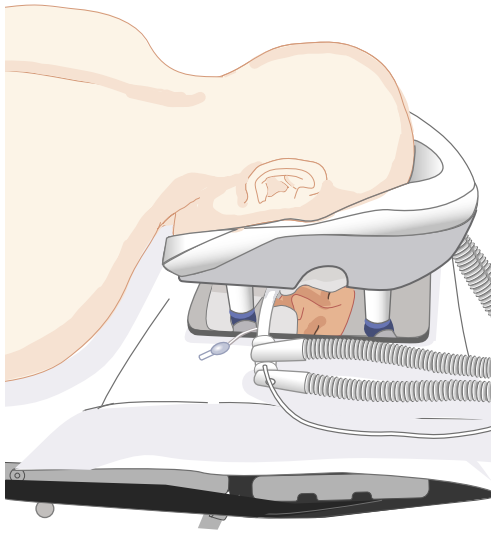

Figure 36-15 Mirror system for prone position. Bony structures of head and face are supported, and monitoring of eyes and airway is facilitated with a plastic mirror.

The horseshoe headrest supports only the forehead and malar regions and allows excellent access to the airway, but it is more rigid and potentially dangerous if the head moves (Figs. 36-16 and 36-17). Mayfield rigid pins support the head without any direct pressure on the face, allow access to the airway, and hold the head firmly in one position that can be finely adjusted for optimal neurosurgical exposure (Fig. 36-18). Rigid pin fixation is rarely used outside cranial or cervical spine surgeries. When properly applied, the pins cause significant periosteal stimulation. A high degree of vigilance also is necessary to prevent patient movement when the head is held in rigid pins; skidding out of pins can result in scalp lacerations or cervical spine injury. Because horseshoe and pin headrests attach to adjustable articu-

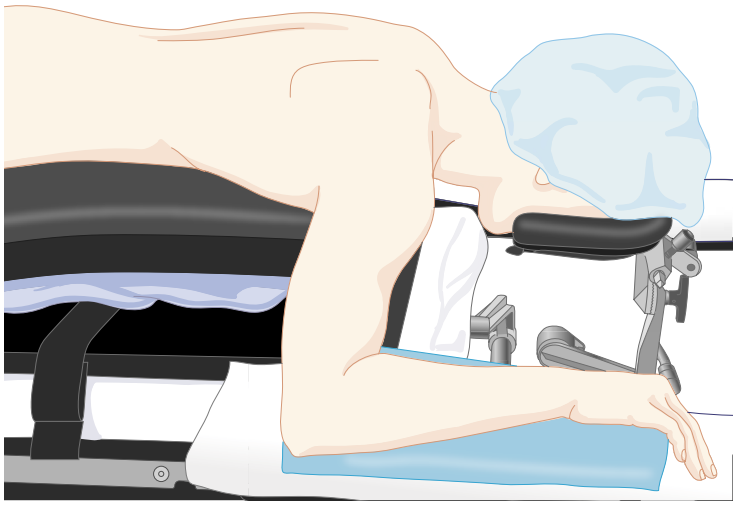

Figure 36-16 Prone position with horseshoe adapter. Head height is adjusted to position neck in a natural position.

lating supports, any slippage or failure of this bracketing device may lead to complications if the head suddenly drops.

Regardless of the technique employed to support the head, the eyes, face, and airway must be checked periodically to ensure that the weight is borne only by the bony structures, and that there is no pressure on the eyes. Proper position is verified frequently and noted in the anesthetic record. The face should be rechecked if any patient motion occurs during surgery, or if the table is significantly repositioned. The prone position is a risk factor for perioperative visual loss, which is discussed in detail subsequently.

Because the abdominal wall is easily displaced, external pressure on the abdomen may elevate intra-abdominal pressure in the prone position. This elevated pressure compromises respiration and transmits elevated venous pressures to the abdominal and spine vessels, including the epidural veins. During spinal surgery, low venous pressure is desirable to minimize bleeding and facilitate surgical exposure. External pressure on the abdomen may push the diaphragm cephalad, decreasing functional residual capacity and pulmonary compliance, and increasing peak airway pressure. Abdominal pressure also may impede venous return through compression of the inferior vena cava. For these reasons, careful attention must be paid to the ability of the abdomen to hang free and to move with respiration.

The thorax is generally supported by firm rolls or bolsters placed along each side from the clavicle to the iliac crest. Multiple commercial rolls and bolsters are available, including the Wilson frame (see Fig. 36-14), Jackson table, Relton frame, and the Mouradian/Simmons modification of the Relton frame. All devices serve to minimize abdominal compression by the operating room table and maintain normal pulmonary compliance. To prevent tissue injury, pendulous structures (e.g., male genitalia and female breasts) should be clear of compression; the breasts should be placed medial to the bolsters. The lower portion of each roll or bolster must be placed under its respective iliac crest to prevent pressure injury to the genitalia and the femoral vasculature.[32] The prone position presents special risks for morbidly obese patients, whose respiration is already compromised, and who may be difficult to reposition quickly. Sometimes it may be necessary to discuss alternative positioning options with the surgeon to ensure patient safety.

Sitting

The sitting position, although infrequently used because of the perception of risk from venous and paradoxical air embolism, offers advantages to the surgeon in approaching the posterior

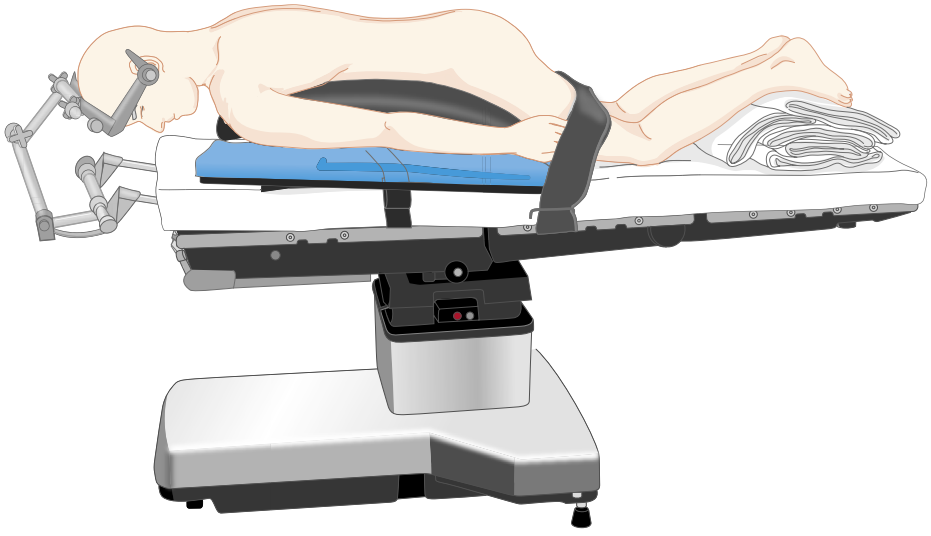

Figure 36-18 Prone position with Mayfield head pins. Rigid fixation is provided for cervical spine and posterior intracranial surgeries. Head position may include neck torsion or flexion that affects endotracheal tube position.

Figure 36-19 "Sitting" position with Mayfield head pins. This is actually a modified recumbent position as the legs are kept as high as possible to promote venous return. Arms must be supported to prevent shoulder traction. In a commonly used variation they are padded and rest on the abdomen, as illustrated in Figure 63-8. Note that the head holder support is preferably attached to the back section of the table so that the patient's back may be adjusted or lowered emergently without first detaching the head holder. If the head holder is connected to the thigh section of the table this cannot be done.

cervical spine and the posterior fossa (Fig. 36-19). The main advantages of the sitting position over the prone position for neurosurgical and cervical spine surgeries are excellent surgical exposure, decreased blood in the operative field, and, possibly, reduced perioperative blood loss.[33] The main advantages to the anesthesiologist are superior access to the airway, reduced facial swelling, and improved ventilation, particularly in obese patients. A variation of the sitting position, the beach chair position is increasingly used for shoulder surgeries, including arthroscopic procedures (Fig. 36-20). Its attraction to the surgeon is superior access to the shoulder from the anterior and posterior aspect, and potential for great mobility of the arm at the shoulder joint.

The head may be fixed in pins for neurosurgery or taped in place with adequate support for other surgeries. Because gravity is pulling the arms caudad, they must be supported to the point of slight elevation of the shoulders to avoid traction on the shoulder muscles and potential stretching of upper extremity neurovascular structures. The knees are usually slightly flexed for balance and to reduce stretching of the sciatic nerve, and the feet are supported and padded.[34]

The hemodynamic effects of placing a supine patient in the sitting position are dramatic. Because of the pooling of blood into the lower body under general anesthesia (see earlier), patients are particularly prone to hypotensive episodes. Incremental positioning and the use of intravenous fluids, vasopressors, and appropriate adjustments of anesthetic depth can reduce the degree and duration of hypotension. Elastic stockings and active leg compression devices can help maintain venous return.

Head and neck position has been associated with complications during surgery to the posterior spine or skull in the sitting position. Excessive cervical flexion has numerous adverse consequences. It can impede arterial and venous blood flow, causing hypoperfusion or venous congestion of the brain. It may impede normal respiratory excursion. Excessive flexion also can obstruct the endotracheal tube and place significant pressure on the tongue, leading to macroglossia. Generally, maintaining at least two fingers' distance between the mandible and the sternum is recommended for a normal-sized adult, and patients should not be positioned at the extreme of their range of motion.[35] Extra caution with neck flexion is advised if transesophageal echocardiography (TEE) is used for air embolism monitoring because the esophageal probe lies between the flexed spine and the airway and endotracheal tube, adding potential for compression of laryngeal structures and the tongue.

Because of the elevation of the surgical field above the heart, and the inability of the dural venous sinuses to collapse because of their bony attachments, the risk of venous air embolism is a constant concern. Arrhythmia, desaturation, pulmonary hypertension, circulatory compromise, or cardiac arrest may occur if sufficient quantities are entrained. If the foramen ovale is patent, even small amounts of venous air may result in a stroke or myocardial infarction owing to paradoxical embolism. TEE has shown some degree of venous air in most patients studied during neurosurgery in the sitting position (≤100%).[36,37] Because of the risk of paradoxical embolus, screening contrast echocardiography to investigate the patency of the interatrial septum is

Figure 36-20 Sitting position adapted for shoulder surgery. This is sometimes called the "beach chair position". Arms must be supported to prevent stretching of the brachial plexus.

often performed before sitting position intracranial or cervical spine surgery. Septal patency may not always be detected, however. Adequate hydration and early detection of entrained air with the use of TEE or precordial Doppler ultrasound may decrease the incidence and severity of venous air embolism.[36]

Peripheral Nerve Injury

Peripheral nerve injury remains a serious perioperative complication and a significant source of professional liability despite the low incidence (approximately 0.11% of 81,000 anesthetic procedures reviewed from 1987 to 1993).[38] Injuries occur when peripheral nerves are subjected to stretch, ischemia, or compression during surgery.[39] Because sensation is blocked by unconsciousness or regional anesthesia, early warning symptoms of pain and the normal spontaneous repositioning are absent. In 1984, the ASA developed a Closed Claims Project to evaluate adverse anesthetic outcomes from the closed claims files of 35 U.S. liability insurance companies. Since the initial report in 1990, the incidence of nerve injury has remained essentially constant, representing 18% of all claims during 1990 through 1994, second only to death (22%).[1-3] Among the total 670 claims filed, ulnar neuropathy remained the most frequent site of injury (28%), followed by the brachial plexus (20%), lumbosacral nerve root (16%), and spinal cord (13%) (Table 36-1).

The distribution of nerve injuries has changed significantly over time. Ulnar neuropathy decreased from 37% in 1980-1984 to 17% in the 1990s, and spinal cord injury increased from 8% in 1980-1984 to 27% in 1990s. Spinal cord injury and lumbosacral nerve root neuropathy were predominantly associated with regional anesthesia. Epidural hematoma and chemical injury represented 29% of the known mechanisms of injury among the claims filed. The injuries probably were related to the use of neuraxial block in anticoagulated patients and the increased usage of blocks for chronic pain management (Table 36-2).[3,40,41]

With the exception of spinal cord injury, the mechanism of nerve injury remains largely unknown. Most injuries, particularly injuries to nerves of the upper extremity, such as the ulnar nerve and brachial plexus, occurred in the presence of adequate positioning and padding. Because of the significant morbidity associated with peripheral nerve injury, in 2000 the ASA published a practice advisory for the prevention of peripheral neuropathies.[16] The advisory was not based on scientific evidence, but the consensus of a consultant expert group. Only 6 of 509 positioning studies reviewed "… exhibited sufficiently acceptable methods and analyses that provided a clear indication of the relationships between interventions and outcomes of interest" (Table 36-3).

Because of the paucity of clear data on the causes and the prevention of peripheral injuries, individual practices vary with regard to specific padding and positional details. Prolonged duration is a risk factor. Good sense would avoid positions that permit stretching of the nerves and pressure to anatomic locations known

Table 36-1 Nerve Injury Claims in the American Society of Anesthesiologists Closed Claims Database

Nerve	No. Claims in Current Database (*N* = 4183)	% of Total (*N* = 670)	No. Claims since 1990 Report	% of Total since 1990 (*N* = 445)
Ulnar	190	28	113	25

to carry nerves prone to injury, such as the ulnar cubital tunnel and the peroneal nerve coursing over the fibular head. Whenever possible, the patient's position should appear as natural as possible. Padding and support should distribute weight over as wide an area as possible; however, no padding material has been shown to be superior. It also is important to anticipate the additional effects of anesthesia and muscle relaxation.

In a retrospective study of 1000 consecutive spine surgeries that used somatosensory evoked potential (SSEP) monitoring, five arm positions were compared with regard to SSEP changes in the upper extremities. A modification of arm position reversed 92% of upper extremity SSEP changes. The incidence of position-related upper extremity SSEP changes was significantly higher in the prone superman (7%) and lateral decubitus (7.5%) positions compared with the supine arms out, supine arms tucked, and prone arms tucked positions (1.8% to 3.2%). Reversible SSEP changes were not associated with postoperative deficits (see Chapter 46).[42]

Ulnar Nerve

The etiology of perioperative ulnar neuropathy is complex and incompletely understood. The ulnar nerve lies in a superficial

Table 36-2 Most Common Nerve Injuries in American Society of Anesthesiologists Closed Claims Database after 1990

Injury	Recommendations for Prevention
Ulnar nerve (25%)	Avoid excessive pressure on postcondylar groove of humerus Keep hand and forearm either supinated or in neutral position
Brachial plexus (19%)	Avoid the use of shoulder braces in patients in Trendelenburg position (use nonsliding mattresses) Avoid excessive lateral rotation of head either in supine or prone position Limit abduction of the arm to <90 degrees in supine position Avoid placement of high axillary roll in decubitus position—keep roll out of axilla Use ultrasound to find internal jugular vein for central line placement
Spinal cord (16%) and lumbosacral nerve root (15%)	Be aware that the fraction of spinal cord injuries is increasing, probably in relation to use of epidural catheters for pain management Follow current guidelines for regional anesthesia in anticoagulated patients*
Sciatic and peroneal (5%)	Minimize time of surgery in lithotomy position Use two assistants to coordinate simultaneous movement of both legs to and from lithotomy position Avoid excessive flexion of hips, extension of knees, or torsion of lumbar spine Avoid excessive pressure on peroneal nerve at the fibular head
Median (4%) and radial (3%)	Be aware that 25% of injuries to the median and radial nerves were associated with axillary block, and 25% of injuries were associated with traumatic insertion or infiltration of an intravenous line

Table 36-3 Summary of American Society of Anesthesiologists Task Force Consensus Findings on Prevention of Perioperative Peripheral Neuropathies

Preoperative Assessment
When judged appropriate, it is helpful to ascertain that patients can comfortably tolerate anticipated operative position
Upper Extremity Positioning
Arm abduction should be limited to 90 degrees in supine patients; patients who are positioned prone may comfortably tolerate arm abduction >90 degrees
Arms should be positioned to decrease pressure on the postcondylar groove of the humerus (ulnar groove). When arms are tucked at the side, a neutral forearm position is recommended. When arms are abducted on armboards, either supination or a neutral forearm position is acceptable
Prolonged pressure on radial nerve in spiral groove of humerus should be avoided
Extension of elbow beyond a comfortable range may stretch median nerve
Lower Extremity Positioning
Lithotomy positions that stretch hamstring muscle group beyond a comfortable range may stretch sciatic nerve
Prolonged pressure on peroneal nerve at fibular head should be avoided
Neither extension nor flexion of hip increases risk of femoral neuropathy
Protective Padding
Padded armboards may decrease risk of upper extremity neuropathy
Use of chest rolls in laterally positioned patients may decrease risk of upper extremity neuropathies
Padding at elbow and at fibular head may decrease risk of upper and lower extremity neuropathies
Equipment
Properly functioning automated blood pressure cuffs on upper arms do not affect risk of upper extremity neuropathies
Shoulder braces in steep head-down positions may increase risk of brachial plexus neuropathies
Postoperative Assessment
Simple postoperative assessment of extremity nerve function may lead to early recognition of peripheral neuropathies
Documentation
Charting specific positioning actions during care of patients may result in improvements of care by (1) helping practitioners focus attention on relevant aspects of patient positioning, and (2) providing information that continuous improvement processes can use to effect refinements in patient care

From ASA Task Force on Prevention of Perioperative Peripheral Neuropathies: Practice advisory for the prevention of perioperative peripheral neuropathies. Anesthesiology 92:1168-1182, 2000.

position at the elbow. Although the incidence is low, the morbidity associated with ulnar neuropathy can be severe. In a prospective study among 1502 patients undergoing noncardiac surgery, 7 patients developed perioperative ulnar neuropathy, of which 3 patients had residual symptoms after 2 years.[43] The neuropathy, if permanent, results in the inability to abduct or oppose the fifth finger, diminished sensation in the fourth and fifth fingers, and eventual atrophy of the intrinsic muscle of the hands creating a claw-like hand.

Previously, injury was thought to be associated with hyperflexion of the elbow and compression by the operating room table of the nerve at the condylar groove and the cubital tunnel against the posterior aspect of the medial epicondyle of the humerus. The current consensus is that the etiology of ulnar nerve palsy is multifactorial and not always preventable. In a large retrospective review of perioperative ulnar neuropathy lasting longer than 3 months, the onset of symptoms occurred more than 24 hours postoperatively in 57% of patients, 70% were male, and 9% experienced bilateral symptoms. Very thin or obese patients were at increased risk, as were patients on prolonged postoperative bed rest. There was no association with intraoperative patient position or anesthetic technique.[44]

The Closed Claims Project also showed that perioperative ulnar neuropathy occurred predominantly in men, in an older population, and with a delayed onset (median of 3 days).[3] Although most ulnar damage claims were associated with general anesthesia, payment also was made for claims where the patient had been awake or sedated during regional anesthesia involving the lower extremity. In a prospective study of medical patients who did not undergo surgical procedures, 2 of 986 patients developed ulnar neuropathy.[45] The large predominance of ulnar injury in men may be explained by anatomic differences. Men have a more developed and thickened flexor retinaculum with less protective adipose tissue and a larger (1.5 ×) tubercle of the coronoid process that can predispose to nerve compression in the cubital tunnel.[46,47] Other risk factors, including diabetes mellitus, vitamin deficiency, alcoholism, cigarette smoking, and cancer, need further studies to be substantiated. In the ASA Closed Claims Project, only 9% of ulnar injury claims had an explicit mechanism of injury, and, in 27% of claims, the padding of the elbows was explicitly stated.[3] It has become accepted that postoperative ulnar nerve palsy can occur without any apparent cause, even when padding and positioning of the patient's arm were done carefully and documented in the anesthetic record.[18]

Brachial Plexus

The brachial plexus is susceptible to injury from stretching or compression because of its long superficial course in the axilla between two points of fixation, the vertebra and the axillary fascia, in association with the mobile clavicle and humerus (Fig. 36-21). The patient often complains of sensory deficit in the distribution of the ulnar nerve. Injury is most commonly associated with arm abduction greater than 90 degrees, lateral rotation of the head, asymmetric retraction of the sternum for internal mammary artery dissection during cardiac surgery, and direct trauma. To avoid brachial plexus injury, patients ideally should be positioned with the head midline, arms kept at the sides, the elbow mildly flexed, and the forearm supinated.

In cardiac surgery patients requiring median sternotomy, brachial plexus injury has been specifically associated with the C8-T1 nerve roots. In a prospective study in which the incidence of injury was 4.9%, the authors found that 73% of the injuries occurred on the same side as the internal jugular vein cannulation.[48] Among noncardiac surgery patients, the incidence is reported to be 0.02%.[49] In the ASA Closed Claims Project, 16% of brachial plexus injuries occurred during a regional block, particularly the axillary block.[3]

Brachial plexus injury also is associated with direct compression, particularly with the use of shoulder braces in patients undergoing surgery in the Trendelenburg position. The nerves are vulnerable to compression as they pass between the clavicle and

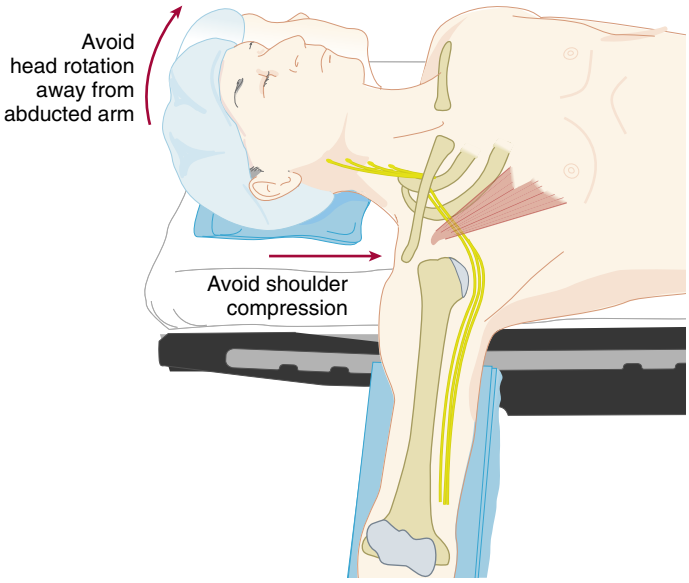

Figure 36-21 The brachial plexus is vulnerable to stretch and compression. Arm abduction is limited to less than 90 degrees whenever possible. Excessive head rotation, especially away from an abducted arm, should be avoided. Shoulder braces should be avoided because they may cause direct compression of the plexus medially between the clavicle and first rib, or laterally below the head of the humerus.

the first rib. Medial placement of the braces can compress the proximal roots, and lateral placement of the braces can stretch the plexus by displacing the shoulders (see Fig. 36-21). The patient with injury often complains of painless motor deficit in the distribution of the radial and median nerves. In the ASA Closed Claims Project, 10% of brachial plexus injuries were directly attributed to patient positioning. Of those, one half involved the use of shoulder braces in patients in the Trendelenburg position.[3] Consequently, nonsliding mattresses should be used in place of shoulder braces.

Other Upper Extremity Nerves

Although quite rare, the radial nerve can be injured from direct pressure as it traverses the spiral groove of the humerus in the lower third of the arm. The injury often manifests as a wrist drop with an inability to abduct the thumb or extend the metacarpophalangeal joints. Isolated median nerve injury most often occurs during the insertion of an intravenous needle into the antecubital fossa in an anesthetized patient where the nerve is adjacent to the medial cubital and basilic veins. Patients with this injury are unable to oppose the first and fifth digits and have decreased sensation over the palmar surface of the lateral three and a half fingers. In an evaluation of the ASA Closed Claims database from 1970 to 2001, Liau[50] found that peripheral intravenous and arterial line insertion accounted for 2.1% of all claims filed, particularly among patients undergoing cardiac surgery where the arms are tucked and the lines are not visible for inspection. Nerve injury accounted for 17% of intravenous line complications second only to skin slough or necrosis (28%) and swelling, inflammation, and infection (17%).

Lower Extremity Nerves

Injuries to the sciatic and common peroneal nerves occur most often in the lithotomy position. Because of its fixation between the sciatic notch and the neck of the fibula, the sciatic nerve can be stretched with external rotation of the leg. Hyperflexion of the hips or extension of the knees also can aggravate nerve stretch in this position. The common peroneal nerve, a branch of the sciatic nerve, can be damaged from the compression of the nerve between the head of the fibula and the frame of the leg support. Most often, patients who sustain injury complain of a foot drop and the inability to extend the toes in a dorsal direction or evert the foot.

In a prospective study of 991 patients undergoing surgery under general anesthesia in the lithotomy position, the incidence of lower extremity neuropathies was 1.5%, with injuries to the sciatic and peroneal nerves representing 40% of the cases. Symptoms were predominantly paresthesia with onset within 4 hours of surgery and resolution generally within 6 months. No motor deficits were noted, but in a previous retrospective study, the same authors found the incidence of severe motor disability in patients undergoing surgery in the lithotomy position to be 1 in 3608.[22,23]

Injury to the femoral or obturator nerves generally occurs during lower abdominal surgical procedures with excessive retraction. The obturator nerve also can be injured during a difficult forceps delivery or by excessive flexion of the thigh to the groin. A femoral neuropathy manifests with decreased flexion of the hip, decreased extension of the knee, or a loss of sensation over the superior aspect of the thigh and medial/anteromedial side of the leg. An obturator neuropathy manifests with inability to adduct the leg with decreased sensation over the medial side of the thigh.

Perioperative Eye Injury and Visual Loss

Although quite rare (incidence of 0.056% in one retrospective review),[51] perioperative eye injuries are a source of significant morbidity and liability (see Chapter 90). In the ASA Closed Claims database, eye complications constituted 3% of all claims and were associated with greater monetary settlements compared with nonocular injuries.[3]

Corneal abrasion is the most common type of perioperative eye injury and is associated with direct trauma to the cornea from facemasks, surgical drapes, or other foreign objects. Corneal abrasion also can be associated with decreased basal tear production or swelling of the dependent eye in patients in the prone position. Patients complain of pain associated with a foreign body sensation in the eye on awakening from surgery. This injury also can occur from a dried section of cornea. Symptoms are generally transient, and treatment comprises supportive care and antibiotic ointment to prevent bacterial infection.

In a prospective study of 671 patients undergoing nonocular surgery, 4.2% of patients reported a new onset of blurred vision lasting at least 3 days after surgery. For most patients, the symptoms resolved within 2 months without complication; 1% required visits to eye care providers.[52] Precautionary measures to reduce the incidence of corneal abrasion include early and careful

taping of the eyelids after induction of anesthesia, care regarding dangling objects when leaning over patients, and close observation as patients awaken. Before they are completely awake, patients often try to rub their eye or nose with pulse oximeter probes, armboards, and intravenous lines attached, inadvertently endangering their eyes.

Postoperative visual loss is a devastating complication that has been associated with specific surgeries and patient risk factors (see Chapter 90). Risk varies with type of surgery. The incidence varies from a range of 1 in 60,965 to 1 in 125,234 for patients undergoing noncardiac, nonocular surgeries[51,53] to 0.06% to 0.113% for patients undergoing cardiac surgery with cardiopulmonary bypass,[54,55] and 0.09% for patients undergoing spine surgery in the prone position.[56] Ischemic optic neuropathy (ION) and, to a lesser extent, central retinal arterial occlusion from direct retinal pressure are the conditions most sited as potential causes. Perioperative factors associated with an increased risk of ION include prolonged hypotension, long duration of surgery especially in the prone position, large blood loss, large crystalloid use, anemia or hemodilution, and increased intraocular or venous pressure from the prone position.[57,58] Intraocular pressure increases in the dependent eye in the lateral decubitus position as well.[59] Patient risk factors associated with ION include hypertension, diabetes, atherosclerosis, morbid obesity, and tobacco use. With the exception of obvious external compression of the eyes, however, the cause of perioperative visual loss seems to be multifactorial in nature with no consistent underlying mechanism.

In 1999, the ASA Committee on Professional Liability established the ASA Postoperative Visual Loss Registry to understand the complication better. By 2005, 131 cases were reported to the registry, of which 73% of reported cases involved patients undergoing spine surgeries, and 9% involved cardiac surgery.[60-62] Of 93 patients with postoperative visual loss after prone spine surgery, Lee and colleagues[62] reported that 89% were diagnosed with ION, predominantly posterior, and 11% were diagnosed with central retinal artery occlusion. In patients who were diagnosed with ION, 66% had documented bilateral involvement, of which 42% had eventual improvement in vision, although often clinically insignificant. Compared with central retinal artery occlusion, patients with ION had significantly higher anesthetic duration (9.8 ± 3.1 hours versus 6.5 ± 2.2 hours), estimated blood loss (median 2 L versus 0.75 L), and crystalloid infusion (9.7 ± 4.7 L versus 4.6 ± 1.7 L). Patients with ION also were relatively healthy (64% ASA class I and II), and 73% were men.[62]

In 2006, the ASA issued a practice advisory for perioperative visual loss associated with spine surgery. No definite recommendations were made concerning the issue of induced hypotension, use of vasopressors, or transfusion threshold owing to the multifactorial nature and the low incidence of the injury. Despite a lack of direct evidence, several suggestions were made for "high risk" patients undergoing complex spine surgery, as follows:[63]

- Discuss the possibility of staging the spine surgery in consultation with the surgeon.
- Avoid excessive increase in intraocular pressure from head position below the body and external compression of the abdomen or chest. Keep the head neutral.
- Use colloids along with crystalloids to maintain intravascular volume. Consider placement of a central venous line for monitoring preload.
- For patients who are anticipated preoperatively to undergo procedures that are prolonged, have substantial blood loss, or both, consider informing the patients of a small, unpredictable risk of perioperative visual loss.

Additional recommendations include frequent eye checks, which may help prevent central retinal artery occlusion, although the required frequency has not been established, and careful attention to factors related to oxygen delivery, including oxygen tension and maintenance of adequate intravascular volume and cardiac output.[64]

Until the causative factors of this devastating type of injury are better defined, it is likely that debate regarding patient management strategies will continue. With regard to patient positioning, the anesthesiologist should be aware that intraocular pressures are elevated in the dependent eye in the lateral position and both eyes in the prone position in the absence of any external pressure. It is sensible to avoid external eye pressure at all times, to document eye checks frequently, and to limit time in the prone position whenever possible.

Evaluation and Treatment of Perioperative Neuropathies

When a nerve injury becomes apparent postoperatively, it is essential to perform and document a directed physical examination to correlate the extent of sensory or motor deficits with the preoperative examination and any intraoperative events. Whether or not an etiology is suspected, it is prudent to seek neurologic consultation to define the neurogenic basis, localize the site of the lesion, and determine the severity of injury for guiding prognostication.[65,66] With proper diagnosis and management, most injuries resolve; however, months to years may be required.[39]

For motor neuropathy, an electromyogram can be performed to determine the exact location of the injury. An electromyogram involves recording the electrical activity of muscle from a needle electrode inserted within it. If present, abnormalities may point to the affected component within the motor unit, which consists of the anterior horn cell, its axon and neuromuscular junctions, and the muscle fibers that it innervates. Certain findings are suggestive of denervation, including the presence of abnormal spontaneous activity in the resting muscle (fibrillation potentials and positive sharp waves, which result from muscle irritability) and increased insertion activity. Insertion activity increases within a few days of muscle denervation, whereas abnormal spontaneous activity takes 1 to 4 weeks to develop, depending on the distance from the nerve lesion to the muscle. From a medicolegal standpoint, the presence of abnormal spontaneous activity in the acute setting may suggest the nerve injury was present preoperatively. In addition, depending on the pattern of abnormalities, an electromyogram may distinguish between radiculopathies, plexopathies, and neuropathies.

For anesthesiologists, nerve conduction studies may be more useful to evaluate potential peripheral nerve injuries, such as ulnar neuropathy. Nerve conduction studies permit the assessment of motor and sensory nerves. To evaluate motor integrity, the nerve is stimulated supramaximally at two points along its course, and a recording is made of the electrical response of one

of the muscles that it innervates. The size of the muscle action potential provides an estimate of the number of motor axons and muscle fibers that are activated by the stimulus. For sensory conduction studies, the nerve fiber is stimulated supramaximally at one point, and the sensory nerve action potential is recorded from another point. The latency of the response can be interpreted as a reflection of the number of functioning sensory axons. Nerve conduction studies are useful for several reasons because they may reveal the presence of a subclinical polyneuropathy that made the individual nerves more susceptible to injury, and help distinguish between axon loss and demyelination, which has significant implications regarding course and overall prognosis.

Most sensory neuropathies are generally transient and require only reassurance to the patient with follow-up, whereas most motor neuropathies include demyelination of peripheral fibers of a nerve trunk (neurapraxia) and generally take 4 to 6 weeks for recovery. Injury to the axon within an intact nerve sheath (axonotmesis) or complete nerve disruption (neurotmesis) can cause severe pain and disability. When reversible, recovery often takes 3 to 12 months. Interim physical therapy is recommended to prevent contractures and muscle atrophy.[65,66]

If a new sensory or motor deficit is found postoperatively, electrophysiologic evaluation by a neurologist within the first week may provide useful information concerning the characteristic and temporal pattern of the injury. Another examination after 4 weeks, when enough time has elapsed for the electrophysiologic changes to evolve, provides more definitive information about the site, nature, and severity of the nerve injury. Regardless, electrophysiologic testing must be interpreted within the clinical content for which it was obtained. No single test can define the etiology of injury.

Anesthesia outside the Operating Room

Anesthesia care providers are increasingly involved with procedures performed for gastrointestinal endoscopy, cardiac catheterization, interventional radiology, neuroradiology, and magnetic resonance imaging/computed tomography, and for office-based procedures (see Chapter 79).[67] Anesthesia care may be requested specifically because a patient is not expected to tolerate the position required for the procedure owing to comorbidities, such as congestive heart failure, pulmonary disease, or morbid obesity. Additionally, positions that are generally safe for patients who are awake may pose serious risks to patients under anesthesia.

Vigilance is particularly important outside the operating room to maintain patient safety because of the less familiar environment, lack of positioning equipment, and variability in staff and nursing training with regard to patient positioning. Many locations do not routinely have safety straps or arm supports available. Diagnostic tables may not lend themselves to established intraoperative solutions to patient positioning challenges. The ability to institute Trendelenburg positioning to augment venous return and cardiac output rapidly is often lacking. In some settings, such as magnetic resonance imaging, the anesthesiologist is not in direct proximity to the patient, and vigilance is more difficult.

Currently, the number of claims in the ASA Closed Claims database for injury during anesthesia care outside the operating room is very small (33 versus 4291 claims for intraoperative surgical anesthesia). Of these claims, 54% were associated with death; 63% were associated with substandard care (predominantly owing to inadequate monitoring); and 58% involved monitored anesthesia care among patients who were ASA class III to V, most of whom were at the extremes of age.[68] In such an environment, where practice patterns have often evolved in the context of nonanesthetized patients, the anesthesiologist is primarily responsible for verifying the safety of each patient's position, and for implementing guidelines for patients under anesthesia.

Summary

The positioning of patients under anesthesia care is a major responsibility requiring great attention to detail and constant vigilance. Rapid positioning and optimal surgical exposure are virtues that may be appreciated instantly, but the potential for lasting harm to patients from improper positioning and physiologic compromise must be kept in mind. Each position has significant physiologic effects on ventilation and circulation. In addition, despite increased awareness, position-related complications, including peripheral nerve injuries, remain a significant source of patient morbidity. Anesthesiologists, surgeons, and nurses must work together when positioning patients to ensure their comfort and safety in addition to the desired surgical exposure. Ideally, the final position should appear natural: a position that the patient would comfortably tolerate if awake and unsedated for the anticipated duration of the procedure.

37 Neuromuscular Disorders and Malignant Hyperthermia

Key Points

1. Dystrophin, along with dystrophin-associated glycoproteins, is involved in sarcolemmal stability. Its defects are responsible for Duchenne's muscular dystrophy (DMD) and Becker's muscular dystrophy (BMD).
2. Whereas the risk for a malignant hyperthermia (MH) mutation in DMD/BMD patients is similar to that in the general population, the incidence of MH-like anesthetic events has been reported to be 0.002 with DMD and 0.00036 with BMD.
3. Succinylcholine is contraindicated in DMD/BMD patients because of the risk of rhabdomyolysis and hyperkalemia as a result of their unstable sarcolemmal membrane.
4. The majority of complications in patients with myotonic dystrophy (MD) were found to be pulmonary related. Pulmonary complications of MD are the result of hypotonia, chronic aspiration, and central and peripheral hypoventilation.
5. Although patients with sodium channel pathology have often been considered to be susceptible to MH, there is no increased risk for MH in these patients.
6. MH is an anesthetic-related disorder of increased skeletal muscle metabolism. It is an inherited condition and it occurs in swine and humans.
7. Skeletal muscle accounts for approximately 40% of body weight; its increased metabolism therefore has a profound effect on whole-body metabolism.
8. Signs of MH, including tachycardia, increased expired CO_2, muscle rigidity, and increased temperature, are related to the increased metabolism.
9. The abnormal function of the ryanodine receptor of skeletal muscle in MH causes barely controlled concentration of calcium within the cell when it is not exposed to triggering agents.
10. The added loss of control of intracellular calcium on exposure to triggering agents or heat stress leads to marked metabolic stimulation within the cell to provide extra adenosine triphosphate to drive the calcium pumps that restore calcium to its reservoirs (e.g., sarcoplasmic reticulum, mitochondria, extracellular fluid).
11. Dantrolene markedly attenuates myoplasmic Ca^{2+} concentrations and thereby restores metabolism to normal, with reversal of the signs of metabolic stimulation.
12. MH is inherited; one mutation accounts for all porcine MH, whereas more than 130 mutations account for human MH.
13. Evaluation of persons susceptible to MH includes contracture of a skeletal muscle biopsy specimen with halothane and caffeine and evaluation of DNA to identify mutations. Only DNA testing is needed to evaluate swine MH.
14. Future MH goals include advancement of genetic evaluations in North American and European medical programs and stronger finances to support genetic studies, identification of the mode of action of dantrolene, determination of the immediate cause of triggering of MH, and the development of effective, nondestructive tests for MH susceptibility.

Neuromuscular disorders, although rarely encountered in routine anesthetic practice, are a group of disorders that challenges both perioperative management and intensive care.

In this chapter, diseases that affect the normal function of peripheral nerves, the neuromuscular junction, and muscles are described. Although such diseases are thought to be rare, the number of patients that a clinician may encounter is increasing annually because of better medical care, increasing longevity, and possibly other yet unidentified factors. As a rule, neuromuscular disorders have significant potential to interact with an improper anesthetic plan, and all affected patients require special perioperative attention for anesthetic management. In this area, the armamentarium of invasive and noninvasive diagnostic tools is being developed, especially in genetics. Also covered in this

chapter is malignant hyperthermia (MH). This fulminant syndrome is elicited by the administration of triggering anesthetic agents, such as a volatile anesthetic or a depolarizing neuromuscular blocking agent. MH has been and continues to be a life-threatening complication of anesthesia if the diagnosis is not made promptly and treatment is not begun in a timely fashion. Unlike other disorders described in this chapter, MH has virtually no characteristic phenotype before exposure to the triggering agent and is truly an example of the interaction of genes and environment.

Multiple Sclerosis

Multiple sclerosis (MS) is an autoimmune disorder characterized by T-cell–mediated autoantibodies against myelin and a subsequent inflammatory response within the central nervous system (CNS: brain and spinal cord). Thus, MS is a disorder of the myelinated part of the axon that leads to secondary nerve conduction failure. The disease affects mainly women, primarily between 20 and 40 or 45 and 60 years of age. Although the etiology is unknown, it has been speculated that MS is caused by environmental factors combined with a genetic predisposition. Naturally, researchers have focused on identifying key events and the genetic origin of the disorder to provide diagnostic and possibly also therapeutic tools for the management of MS patients.

Patients with MS frequently report paresthesias, muscle weakness, and sensory disturbances. Typically, there is a localized or, late in the course of disease, generalized muscle weakness with the legs affected more than the arms. In severe cases, respiration may be involved with the development of hypoxemia. Diplopia and other cranial nerve–dependent impairments are early and frequent signs, along with sensory abnormalities and sometimes disturbed bowel and bladder function. As a rule, symptoms are closely related to the site affected within the CNS, and the amount of symptoms is related to the extent of sclerosing CNS plaque. Notably, MS can be associated with impaired autonomic function, which may lead to adverse reactions to sympathomimetic drugs.[1]

Diagnosis of MS is currently based on a combination of clinical and laboratory tests, including cerebrospinal fluid (CSF) antibody analysis and radiology (detection of CNS plaque by magnetic resonance imaging). Medication consists of various combinations of immunosuppression modalities.

Anesthetic Considerations. It has been speculated that general anesthesia and surgery may increase the risk for aggravation of MS.[2] At present, there is no general consensus on this matter, and patients should therefore be informed of the potential for aggravated symptoms in the postoperative period. In general, preoperative chronic immunosuppressive medication should be continued during the perioperative period. Patients with MS are sensitive to physical (pain, fever, infection) and emotional stress, which makes it more likely that symptoms will be intensified in the perioperative period. Great care must be exercised to minimize changes in body temperature, fluid homeostasis, and central hemodynamics (preload, afterload) and to maintain respiration. Although intravenous induction agents and volatile anesthetics have been used safely, it is wise to avoid administering depolarizing neuromuscular blocking drugs to MS patients. MS-induced denervation or misuse myopathy may lead to a risk for succinylcholine-induced hyperkalemia, which can result in fatal cardiac arrhythmias (see also Chapter 29). Use of nondepolarizing neuromuscular blockers appears to be safe. Regional anesthesia, including epidural application of low concentrations of local anesthetics, has been used in MS patients. Spinal anesthesia exacerbates symptoms in MS and is therefore not recommended for MS patients by most authorities. Notably, postpartum worsening of MS symptoms is noted in 20% of females (also see Chapter 69). The need for postoperative care is dependent on the preoperative symptoms, type of surgery, and status of the patient at the end of the surgical procedure. In this context, MS patients with severe weakness and respiratory distress, including pharyngeal dysfunction, may need extended postoperative care, such as noninvasive respiratory support and intense physiotherapy, to avoid further impairment of their pulmonary function.

Motor Neuron Disorders

Motor neuron disorders involve either the upper or the lower motor neurons of the cerebral cortex, brainstem, and spinal cord. Some forms are mixed, whereas others have predominately upper or lower motor neuron involvement. Amyotrophic lateral sclerosis (ALS) is the most common disease within this group and involves both upper and lower motor neurons. Other examples of motor neuron disease are Kennedy's disease (spinobulbar muscular atrophy), Friedreich's ataxia (mixed upper and lower motor neurons), and spinal muscular atrophy (lower motor neurons).

ALS (Lou Gehrig's disease) is characterized by progressive and variable loss of motor neurons within the cerebral cortex, medullary nuclei of cranial nerves, and nuclei of the ventral horn in the spinal cord. Degenerative loss of these neurons leads to progressive muscle weakness, muscle atrophy, and loss of neuronal mass in these locations. Sensory functions, including intellectual capacity and cognition, as well as bowel and bladder function, are not usually affected in ALS.

ALS has an incidence of about 2 in 100,000, and onset of the disease usually takes place around 40 to 50 years of age, with males more often affected than females. Most cases are sporadic, but rare familial forms (autosomal dominant and recessive forms) do exist. The underlying mechanism or mechanisms for this selective and progressive motor neuronal death are thus far unclear, but it has recently been suggested that superoxide dismutase mutations may have a key role in the increased formation of free radicals seen in subsets of patients. The diagnosis is made by electrophysiology (electromyography [EMG] and electroneurography) and by neurologic examination, which demonstrates early spastic weakness of the upper and lower extremities, typical subcutaneous muscle fasciculations, and bulbar involvement affecting pharyngeal function, speech, and the facial muscles. No curative treatment is currently available, and patients are therefore treated symptomatically.

Anesthetic Considerations. Bulbar involvement in combination with respiratory muscle weakness leads to a risk for aspiration and pulmonary complications. Notably, these patients may have increased sensitivity to the respiratory depressant effects of sedatives and hypnotics. There are reports of sympathetic hyperreactivity and autonomic failure.[3] Succinylcholine should be avoided because of the risk for hyperkalemia as a result of denervation and immobilization. Nondepolarizing neuromuscu-

lar blocking agents may cause prolonged and pronounced neuromuscular blockade and hence should be used with great caution.[4] General anesthesia combined with epidural anesthesia has been used without complications.

Guillain-Barré Syndrome

Guillain-Barré syndrome (GBS) is an acute inflammatory polyneuritis caused by an immunologic reaction. Although the etiology is unknown, in many cases a timely association with a viral (influenza-like) or bacterial infection or even lymphomatous disease can be demonstrated.[5] Symmetric peripheral flaccid muscle weakness and sensory loss develop. The lower extremities are affected first, after which the disease progresses to the upper extremities and cranial nerve–innervated muscles in some cases. Importantly, patients may also have autonomic involvement that could lead to sudden fatal cardiac and circulatory collapse. The diagnosis is made after careful neurologic examination, clinical electrophysiology, and CSF analysis. CSF analysis may show a typical increase in CSF protein in combination with a normal cell count, which is a classic sign of the disease. Treatment focuses on respiratory support, nutritional support, and early initiation of plasmapheresis.

Anesthetic Considerations. Succinylcholine should not be used because of the risk of hyperkalemia. Nondepolarizing muscle relaxants are not contraindicated but should be avoided as a result of the increased sensitivity and risk for prolonged muscle weakness in the postoperative period. The risk for autonomic dysfunction, respiratory failure, and aspiration may require assisted or mechanical ventilation, even in the postoperative period. Great care should be taken to maintain circulatory stability, including adequate cardiac preload and afterload. Careful hemodynamic monitoring is therefore essential in these patients. General anesthesia can be used; however, the combination of general anesthesia and epidural anesthesia is more controversial.[6] Although regional anesthesia is not contraindicated, there are reports of an association between GBS and epidural anesthesia.[7]

Hereditary Motor-Sensory Neuropathies, including Charcot-Marie-Tooth Disease

Hereditary motor-sensory neuropathies include a spectrum of peripheral neurologic disorders, among which Charcot-Marie-Tooth (CMT) disease is often listed. They are caused by a specific mutation in one of several myelin genes that results in defects in myelin structure, maintenance, and formation. Hereditary motor-sensory neuropathies have been classified into seven types and multiple subtypes according to the age at onset, mode of inheritance, predominately involved muscle groups, and genotypes.[8,9] CMT types 1 and 2 are the most common hereditary peripheral neuropathies, with an estimated prevalence of 40 per 100,000.[9] Patients with CMT disease typically experience slow and progressive distal muscle weakness and wasting. Damage to sensory axons may also lead to sensory loss resulting in frequent tripping and falls. Neuropathic pain may develop in some patients. CMT patients usually have normal life expectancy. CMT type 3, also known as Dejerine-Sottas disease, is a very severe condition with an early onset of hypotonia during infancy. Nerve conduction velocity is typically significantly reduced to less than 10 msec.[9] The genetic inheritance pattern for CMT disease is heterogeneous.

Anesthetic Considerations. The anesthesia experience in patients with CMT disease is limited because of the small number of cases. Major considerations include the use of hypnotic agents, muscle relaxants, volatile agents, and neuraxial techniques. CMT type 1 patients have been reported to have significantly increased sensitivity to thiopental at induction that correlates with the severity of both motor and sensory defects. However, total intravenous anesthesia (TIVA) has been performed successfully in a number of cases without any reported problems.[10-12]

Because of the reduced number of acetylcholine receptors, sensitivity to nondepolarizing muscle relaxants is elevated and the response to succinylcholine is also reduced.[13] Although succinylcholine has been used without adverse effect,[14,15] the risk of an exaggerated hyperkalemic response may be sufficient to preclude it from being used in patients with suspected muscular denervation.[15] Prolonged neuromuscular blockade with vecuronium has been reported.[16] As a result of the large variety of disabilities in this patient group, careful baseline assessment of neuromuscular status should be conducted before the use of nondepolarizing neuromuscular relaxants. Normal response to atracurium and mivacurium has been demonstrated.[17,18] Both TIVA and volatile anesthetics have been used safely in CMT patients in a series of cases.[14] Neuraxial techniques for obstetric procedures have been reported to generally be successful in CMT patients.[19-22] However, the use of regional anesthesia can be controversial given that the possible complications may exacerbate the neurologic symptoms.[23] Similar medicolegal concerns may apply to the surgical and anesthesia positioning of CMT patients because of the sensory deficits and limb deformities.

Duchenne's Muscular Dystrophy and Becker's Muscular Dystrophy

Duchenne's muscular dystrophy (DMD) is the most common and severe type of muscular dystrophy, with an incidence of 1 per 3500 live male births[24] and a total male prevalence of about 50 to 60×10^{-6}.[25] Becker's muscular dystrophy (BMD) is relatively rare and has an incidence of about 1 in 18,000 live male births and a prevalence of 23.8×10^{-6}.[25] Both DMD and BMD are X-linked recessive diseases. The defect is located on the short arm of the X chromosome at the Xp21 region, which contains the gene for the large protein Dp427, also known as dystrophin. The dystrophin gene is 2500 kilobases long with more than 70 exons.[25] Dystrophin is distributed not only in skeletal, cardiac, and smooth muscle but also in the brain.[26] Because of the large size of the dystrophin gene, spontaneous new mutations are common and account for a third of new cases.[27]

The most common form of mutation is a deletion within the gene (65% to 70% of cases of DMD and >80% of BMD). Duplication and point mutations are responsible for the rest. It

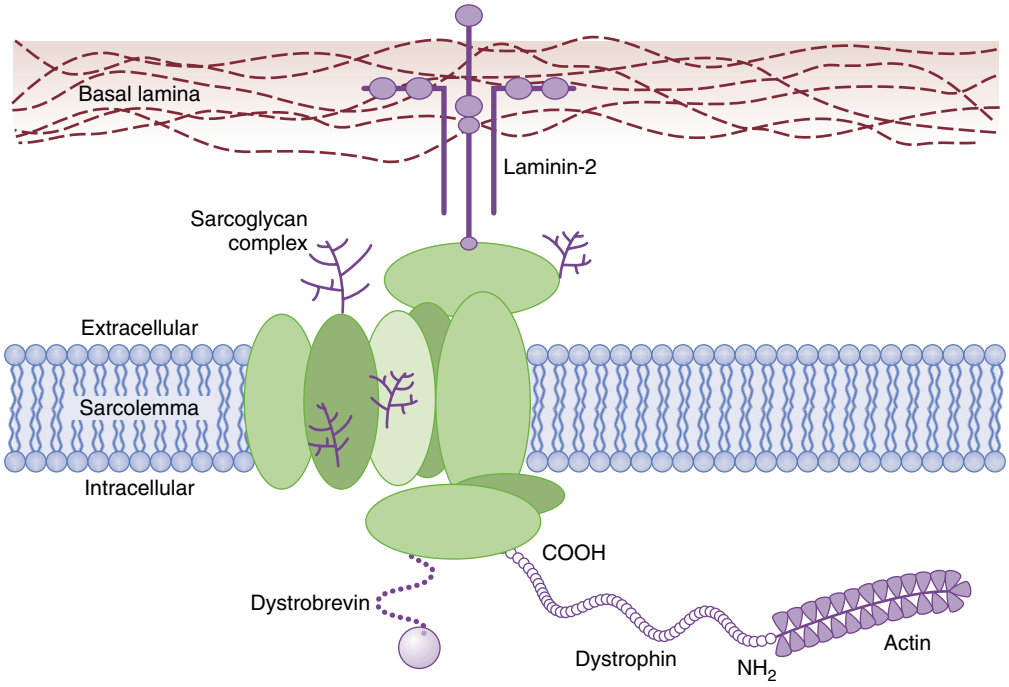

Figure 37-1 Diagram of the cell-surface and cytoskeleton protein complex.

also appears that there are "hot spots" within the first 20 exons and in the central region of the gene (exons 45 to 55) where deletion and duplication are likely to occur.[25] Female cases of DMD have been reported with the 45,X and 46,XX karyotypes. The disease mechanism for the female 46,XX karyotype was thought to be preferential loss of the paternal X chromosome by postzygotic nondisjunction and manifestation of the DMD gene from the maternal X chromosome in muscle cells.[28] BMD is usually milder in severity than DMD because disruption of the translation process occurs in the relatively distal part of the gene, which leads to a reduced amount of truncated dystrophin protein.[25,29]

Dystrophin, along with dystrophin-associated glycoproteins (DAGs), is involved in sarcolemmal stability. Dystrophin is responsible for maintenance of muscle membrane integrity despite the fact that it accounts for only approximately 0.002% of the protein in striated muscle.[30] Dystrophin aggregates and links to actin (at its N terminus) and the DAG complex (at its C terminus) to form a stable structure that interacts with laminin in the extracellular matrix (Fig. 37-1). Lack or dysfunction of dystrophin leads to cellular and membrane instability, with progressive leakage of intracellular components and elevation of creatine phosphokinase (CPK) levels. Eventually, damaged muscle cell units are invaded by macrophages and destroyed. Current study suggests that cytotoxic T cells are probably the culprit. Consequently, clinical pseudohypertrophy of the muscle occurs when the dead muscle shells are replaced by fibrofatty infiltrates. Loss of muscle units accounts for the weakness and contracture.[26]

Both DMD and BMD are characterized by progressive weakness and wasting of predominantly the proximal musculature. Pseudohypertrophy of the calves and other muscle groups is common. As the more severe of the two diseases, DMD tends to be symptomatic early in life. Seventy-four percent of children with DMD were found to manifest the disease by 4 years of age.[24] DMD patients do not usually begin to walk until they are about 18 month of age or later. The initial clinical findings include a waddling gait, frequent falling, and difficulty climbing stairs because of proximal muscle weakness in the pelvic girdle. The classic Gower maneuver describes rising from a sitting to a standing position with the help of both arms. Patients may also show weakness in the shoulder girdle and trunk erectors that leads to thoracolumbar scoliosis. The earlier the onset of disease, the more rapid the disease course. In most cases, children with DMD are unable to walk by the age of 9 to 11. Proximal deep tendon reflexes in the upper extremities and patella may also disappear despite the lack of denervation.[29] Nevertheless, the tendo Achillis reflex remains intact even in later stages of the disease. Sixty percent of patients will have pseudohypertrophy of the calves, and 30% will have macroglossia. Some may also suffer from pain in the calves with activity. The intellectual impairment that can be associated with the disease was thought to be related to limitation of educational opportunities. However, with equalization of educational opportunities, psychometric studies have revealed a significantly lower average intelligence quotient in DMD patients than in healthy groups.[31] This implies a possible effect of dysfunctional dystrophin in the brain on learning. Death in patients with DMD is commonly due to cardiopulmonary compromise in their 30s.[24] BMD is a mild form of DMD. The mutation that causes BMD produces dystrophin that retains partial function. The onset of symptoms occurs in the second or third decade of life. As a result, the life span of BMD patients can reach the early 40s. Pneumonia is the most common cause of death (Fig. 37-2).[29]

The heart is also affected to various degrees, depending on the stage of the disease and the type of mutation. Cardiac degeneration is due to replacement of myocardium by connective tissue or fat, which leads to dilated cardiomyopathy.[32] Cardiac involvement starts early in the course of the disease, although clinical

BMJ 317:991-995, 1998.)*

signs are not usually obvious in the early stage. No correlation has been established between the severity of cardiac disease and the severity of skeletal disease. Studies at necropsy have shown that the cardiomyopathy in DMD involves the posterobasal and contiguous lateral left ventricular walls as initial and primary sites of myocardial dystrophy in the absence of small vessel coronary artery disease in these areas.[33] Typical initial manifestations on the electrocardiogram (ECG) in DMD and BMD are sinus tachycardia, tall R waves in the right precordial leads, prominent left precordial Q waves, increased QT dispersion, and inverted T waves from scarring of the posterobasal portion of the left ventricle. Initially, echocardiography is normal or shows regional wall motion abnormalities in areas of fibrosis. With the spreading of fibrosis, left ventricular dysfunction can be seen and ventricular arrhythmias frequently occur as well. In the final stages of the disease, systolic dysfunction may lead to heart failure and sudden death. Subclinical or clinical cardiac involvement is present in about 90% of DMD/BMD patients, but it is the cause of death in only 20% of DMD and 50% of BMD patients. Angiotensin-converting enzyme inhibitors are recommended in early stages of the disease, and β-blockers may be an additional option if indicated.[32]

Pulmonary insufficiency is a leading cause of morbidity and mortality in DMD.[34] Usually, expiratory muscle function is affected first because of the early onset of abdominal muscle weakness. By contrast, inspiratory muscle function is relatively preserved in the first decade, implying sparing of the diaphragm.[35] Vital capacity (VC) increases in the first decade because of overall body growth, plateaus in early adolescence, and then declines dramatically as the diaphragmatic weakness progresses.[35] Other measured lung volumes such as inspiratory reserve volume and total lung capacity (TLC) follow the same pattern. A disproportionate loss of VC and TLC relative to the respiratory muscle dysfunction results in part from additional factors, such as altered chest wall and lung mechanics, modifications in the distribution of surfactant, micro-atelectasis, and local fibrosis secondary to recurrent pneumonia.[35] Scoliosis further impairs pulmonary function. On average, for each 10 degrees of thoracic scoliosis curvature, forced vital capacity (FVC) decreases by 4%.[30] In 90% of patients, a curvature of greater than 20 degrees develops 3 to 4 years after they are wheelchair bound. Respiratory failure inevitably occurs in the second decade of life and is the most common cause of death.[36]

Diagnosis and Differential Diagnosis. Chronic elevation of the serum CPK level is a general indication of muscle disease. Three serum tests showing elevated CPK levels obtained 1 month apart is diagnostic of muscular dystrophy. CPK represents leakage of enzyme from muscle cells and does not correlate with severity of the disease. CPK could reach 50 to 300 times the normal value in early stages of the disease. The level tends to decrease with the loss of muscle mass. Elevation of the MB fraction of creatine kinase (CK) precludes its use as a marker for cardiac injury.[29] EMG can be supportive of the diagnosis; however, it can be very difficult to perform on children. Muscle biopsy, followed by immunostaining or Western blot analysis for dystrophin, is recommended for diagnostic testing. Multiple polymerase chain reaction is also useful in detecting more than 98% of the existing deletions.[26] The result is usually available within 24 hours, which may render muscle biopsy, the old "gold standard," obsolete.

Anesthetic Considerations. Patients with DMD and BMD may require anesthesia for muscle biopsy, correction of scoliosis, release of contractures, and exploratory laparotomy for ileus,[29] as well as for dental[37] and obstetric[38] procedures. As the natural course of the disease progresses, the risk of surgery increases concomitant with the increased comorbid conditions associated with the later phase of the disease. However, perioperative complications are not proportional to the severity of the disease. They occur even in mildly affected patients. Consequently, patients should undergo careful preoperative consultation and evaluation.

Fifty percent to 70% of patients with muscular dystrophy demonstrate some cardiac abnormality, although it is clinically significant in only 10%.[29] Preoperative cardiology assessment with an ECG and echocardiography is essential. Continuous cardiac Holter monitoring is necessary if an arrhythmia is captured on the ECG or the patient describes symptoms that can be related to cardiac arrhythmias. Echocardiography will demonstrate mitral valve prolapse in 10% to 25% of patients. It may also show posterobasilar hypokinesis in a thin-walled ventricle and a

slow relaxation phase with normal contraction characterizing the cardiomyopathy seen in DMD.[29] However, echocardiography may not always reflect the ability of the diseased myocardium to respond to perioperative stress. Stress echocardiography using angiotensin to detect latent heart failure and identify inducible contraction abnormalities has been advocated.[39]

An estimated 30% of deaths in individuals with DMD are due to respiratory causes.[40] Therefore, careful preoperative pulmonary assessment is important. Webster demonstrated that the manual muscle strength test has a strong statistical correlation with all of the timed functional tests. Peak expiratory flow was not only easy to perform but also correlated statistically with all timed functional tests.[41] The correlation was not significant for VC or forced expiratory volume in 1 second (FEV_1).

Intraoperatively, in terms of airway management, patients with DMD and BMD may have decreased laryngeal reflexes and prolonged gastric emptying time, which increases the risk for aspiration.[42] Decreased ability to cough up the accumulation of oral secretions predisposes muscular dystrophy patients to postoperative respiratory tract infections.[29] Masseter spasm is also a possible complication during induction of anesthesia in these patients.[43] Preparedness for a difficult airway is necessary, especially in patients with potential airway problems.

Postoperatively, DMD patients are at an increased risk for respiratory compromise.[44] Retrospective reviews have indicated that the incidence of prolonged postoperative ventilation (>36 hours) was greatest in DMD patients who had a preoperative FVC of less than 40% of the predicted value.[45,46] Preoperative pulmonary function studies are valuable in determining the postoperative course. Patients with a VC of greater than 30% of the predicted value can usually be extubated immediately after surgery.[29] Sleep apnea may also compound the condition and contribute to the development of pulmonary hypertension. Continuous positive airway pressure and bilevel positive airway pressure have been demonstrated to be effective in the management of postoperative respiratory depression. Delayed pulmonary insufficiency may occur up to 36 hours postoperatively despite the apparent recovery of skeletal muscle strength.[47]

Reports have suggested a relationship between DMD/BMD and MH, but this association is not based on good rational grounds. Whereas the risk for an MH mutation in DMD/BMD patients is similar to that of the general population, the incidence of MH-like anesthetic events has been reported to be 0.002 with DMD and 0.00036 with BMD.[48] Unexplained cardiac arrest[43,49] and acute heart failure[50] have been reported in DMD/BMD patients. Succinylcholine is contraindicated in these patients because of the potential for rhabdomyolysis and hyperkalemia as a result of their unstable sarcolemmal membrane. Succinylcholine-induced hyperkalemia during acute rhabdomyolysis is more likely to result in cardiac arrest and unsuccessful resuscitation than is the potassium efflux resulting from upregulation of acetylcholine receptors in burn patients.[47] The use of nondepolarizing muscle relaxants is usually accompanied by an increase in both maximal effect and duration of action.[51] Narcotics can be used, but small incremental dosing and short-acting medications are recommended given the respiratory depression associated with these medications. Because of reports of inadvertent reactions to volatile anesthetics,[29] TIVA has become more popular.[52] However, consideration needs to be given to the myocardial status of the patient when propofol or barbiturates are used because they may lead to profound hypotension and reduced organ perfusion.[29,53] Regional anesthesia may be a good alternative to general anesthesia in that it avoids the risk of triggering agents and respiratory depression and enables the use of local anesthetics for postoperative analgesia. It may also facilitate chest physiotherapy.[54]

Limb-Girdle Muscular Dystrophy

Limb-girdle muscular dystrophy (LGMD) is a group of disorders with heterogeneous causes. To date, at least 18 genes have been identified as being responsible for this disease, with 7 being autosomal dominant and 11 autosomal recessive.[55] Mutations within the same gene may result in different phenotypes that sometimes are not consistent with LGMD. Proximal muscle (shoulder or pelvic) girdle weakness is the characteristic feature of this group of diseases. Given the marked genetic heterogeneity, clinical manifestations of the disease vary. Autosomal recessive forms are about 10 times more common than autosomal dominant forms. Fukutin-related protein (*FKRP*) and calpain 3 (*CAPN3*) gene mutations have been associated with LGMD. In addition, a number of other disorders not strictly included under LGMD in this classification may have LGMD-like phenotypes.[55] Sporadic cases of LGMD have been reported in the anesthesia literature.[56-58] General approaches to these patients are the same as those for DMD/BMD.

Myotonic Dystrophy

Myotonic dystrophy (MD) is an inherited muscular disorder characterized by progressive muscle weakness and wasting. Two types of MD result from a mutation in either the dystrophia myotonica–protein kinase (*DMPK*) gene, located on chromosome 19q13.3 (MD1, also known as Steinert's disease), or the CysCysHisCys (CCHC)-type zinc finger, nucleic acid binding protein (*CNBP*) gene, located on chromosome 3q21 (MD2).[59] The incidence of MD is 1 in 8000. MD1 is by far the most common of the two types and accounts for about 98% of all cases. MD1 is caused by expansion of a CTG trinucleotide repeat in the *DMPK* gene and is inherited in an autosomal dominant manner.[60] Typical signs and symptoms include muscle weakness and wasting (most prominent in the cranial and distal limb musculature), periodic myotonia, progressive myopathy, insulin resistance, defects in cardiac conduction, neuropsychiatric impairment, cataracts, testicular atrophy, and frontal balding in males. The typical cranial muscle weakness and wasting are manifested not only in the facial, temporalis, masseter, and sternocleidomastoid muscles but also in the vocal cord apparatus. Mitral valve prolapse is found in 20% of patients.[47] The severity of the disease is related to the number of extra trinucleotide repeats.[61] MD1 patients may also have mildly elevated CK levels. Myotonic discharges can be identified on EMG, as well as an inability to relax from a handgrip. During pregnancy, the symptoms may be exacerbated. Uterine atony and retained placenta may also complicate vaginal delivery. First-degree atrioventricular heart block is a common finding on the ECG before the onset of symptoms.[47]

MD2 is also called proximal myotonic myopathy. Intron 1 of the *CNBP* gene contains a complex repeat motif,

(TG)n(TCTG)n(CCTG)n, and expansion of the CCTG repeat was determined as the cause of MD2. Patients with MD2 suffer from myotonia (90% of those affected), muscle dysfunction (82% weakness, pain, and stiffness), and less commonly, cardiac conduction defects, iridescent posterior subcapsular cataracts, insulin-insensitive type 2 diabetes mellitus, and testicular failure.[62]

Anesthetic Considerations. General considerations for MD are similar to those for other muscular dystrophies. Mathieu and coworkers conducted a retrospective study on the anesthetic and surgical complications of MD. The majority of complications were found to be pulmonary related and significantly more frequent in patients undergoing upper abdominal operations and those with severe disability, as assessed by the presence of proximal limb weakness.[63] The pulmonary complications of MD are the result of hypotonia, chronic aspiration, and central and peripheral hypoventilation.[29] Smooth muscle atrophy, which leads to poor gastric motility, when coupled with a diminished cough reflex, promotes aspiration. Succinylcholine will produce contractions lasting for several minutes, thus making intubation and ventilation a challenge. These contractions are not antagonized by nondepolarizing muscle relaxants. Other agents, including methohexital, etomidate, propofol, and even neostigmine, may also induce myotonic reactions. Short-acting nondepolarizing muscle relaxants or avoidance of relaxation is therefore advised.[29] Triggering factors, such as hypothermia, shivering, and mechanical or electrical stimulation, may cause a myotonic reaction.[64] The reaction can be treated with phenytoin (4 to 6 mg/kg/day) or quinine (0.3 to 1.5 g/day).[29] Furthermore, MD patients can be very sensitive to anesthetic agents, with hypersomnolence and CO_2 retention sometimes being observed. Careful titration with relatively short-acting anesthetic agents may be beneficial. Close cardiac monitoring is required for MD patients. Pacing equipments should be readily available because a third of first-degree atrioventricular blocks may not respond to atropine.[29] All patients should be treated as though they have both cardiomyopathy and conduction defects.

Myotonia Congenita

Myotonia congenita (MC) is a congenital form of muscular dystrophy characterized by uncontrolled temporary skeleton muscle excitability as a result of mutations in the muscle chloride channel gene (*CLCN1*). There are two forms of MC, one with autosomal dominant and the other with recessive inheritance. The former is also known as Thomsen's disease and the later as Becker's myotonia. The myotonia in MC patients is usually initiated by a forceful muscle contraction, particularly after rest for at least 10 minutes. The myotonic muscle stiffness then becomes increasingly obvious after a second and third short, but forceful contraction. Further contractions usually dampen the myotonia.[65]

Thomsen's disease was the first myotonic disease to be described. Patients may have a hypertrophic and athletic appearance. The sign of percussion myotonia is described as an indenting-appearing myotonia triggered by tapping the muscle. Lid lag is common and muscle stretch reflexes are normal.[65] Myotonia symptoms in Becker's myotonia usually start at 10 to 14 years of age or even later and are more severe than those of Thomsen's disease. Becker's myotonia may be associated with severe generalized stiffness resulting in falling. It can frequently be misdiagnosed as epilepsy. Antiepileptic medications do improve the symptoms, however.[65]

Anesthetic Considerations. As with many muscle diseases, there have been reports that MC patients are predisposed to MH, but as is the case for almost all of them, there are no data to support this hypothesis.[66-68] However, depolarizing muscle relaxant can lead to severe masseter spasm in MC patients. Generalized spasm involving the respiratory and skeletal muscles has been reported.[66] The findings resemble those of MH, so dantrolene is sometimes administered.[65] Because dantrolene is an inhibitor of calcium release from the sarcoplasmic reticulum (SR), it can usually abolish the myotonia effectively.[66,67] Some believe that local anesthetics and class Ib antiarrhythmic drugs such as lidocaine should be used for myotonic reactions rather than dantrolene.[69] Because shivering in the operating room can trigger the myotonic reaction, MC patients should be kept normothermic during surgery.[65]

Myotubular Myopathy

Myotubular myopathy (MTM) is pathologically defined by the presence of centrally placed nuclei in the majority of extrafusal muscle fibers, an appearance resembling fetal myotubes during normal muscle development. Consequently, MTM is also called centronuclear myopathy (CNM).[70] However, MTM now mostly refers to the X-linked form of the disease, whereas CNM is used for the autosomal form.[70]

MTM and CNM are rare. The estimated incidence of MTM is 1 in 50,000 newborn males.[70] MTM has been linked to the myotubularin (*MTM1*) gene on Xq28. Pregnancy is often complicated by polyhydramnios and reduced fetal movements. Affected males typically have severe floppiness and weakness and respiratory distress at birth. Cardiac muscles are not generally involved. The patient usually has a normal response to pain, but tendon reflexes are absent. The long-term prognosis for MTM is extremely poor.[70] In patients who survive the first year of life, most are either completely or partially ventilator dependent.[71] These patients often have abnormal liver function.[71] Both autosomal recessive and autosomal dominant forms have been observed in CNM patients. Its clinical features include respiratory distress, hypotonia, bulbar weakness, ophthalmoplegia, ptosis, and facial diplegia. Although the exact genetic mechanism is not fully understood, the *MTM1*, myotubularin-related protein (*MTMR2*), and myotubularin-related phosphatase (*MTMR3*) genes have been implicated.[70] Pathologically, MTM and CNM share a similar characteristic histologic feature: predominantly type 1 fiber with centrally placed nuclei seen on hematoxylin-eosin staining of formalin-fixed, paraffin-embedded tissue.[70]

Anesthetic Considerations. Reports of anesthesia for patients with MTM are sparse.[72-77] Nontriggering general anesthesia has been used because of the unfounded concern of possible susceptibility to MH. Agents such as propofol, fentanyl, remifentanil, and nitrous oxide have been used successfully without adverse effects.[72-77] The possibility of a prolonged effect of nondepolarizing muscle relaxants has been suggested with mechanomyography.[72-77] However, in reality, intubation of such patients may not require any muscle relaxant because of their hypotonic state. Costi and van der Walt suspected that the defect in MTM

is distal to the neuromuscular junction,[73] whereas Dorchies and coworkers suggested that muscle in MTM might be intrinsically normal, with myotubularin-deficient motor neurons involved in development of the disease.[78]

Metabolic Myopathies

Two major energy sources for muscle exist: glycogen and fatty acid. Glycogen serves as a dynamic, but limited reservoir of glucose, mainly stored in skeletal muscle and liver. Glycogen storage disorders (GSDs) are a group of metabolism disorders caused by enzyme deficiency or dysfunction. They reduce effective glucose storage by interfering with normal glycogen synthesis and degradation. Synthetic errors cause decreased normal glycogen, whereas degradation errors tend to block the breakdown of glycogen. Subsequently, hypoglycemia and accumulation of glycogen in tissues could occur as a result of substrate use. There are more than 12 types of GSD that are assigned Roman numerals based on the enzyme deficiencies. Types I and II are discussed here.

Glycogen Storage Disease Type I

The incidence of GSD I is approximately 1 in 100,000 live newborns.[79] The incidence in non-Ashkenazi Jews from North Africa may be as high as 1 in 5420 people.[79] The defective enzyme causing the disease is glucose-6-phosphatase, which is the enzyme that converts glucose 6-phosphate (G6P) to glucose in the liver. Type Ia (von Gierke's disease) is due to a deficiency in G6P hydrolase (catalytic subunit) activity and accounts for more than 80% of cases. Types Ib (G6P transporter deficiency), Ic, and Id represent allelic defects in the translocase associated with G6P. Their inheritance is autosomal recessive. The G6P gene (*G6PC*) encoding the hydrolase resides at 17q21, with the gene encoding G6P translocase (*G6PT*) located at 11q23. Mutations responsible for GSD I have been described in both type Ia and Ib patients.[79]

Impaired glycogenolysis results in accumulation of glycogen and G6P in the liver, kidney, intestine, skeletal muscle, and heart and is manifested as hepatomegaly, renomegaly, proximal tubular dysfunction, and diarrhea.[80] Fasting hypoglycemia is the initial manifestation of the disease. As a result, upregulation of the synthesis and transport of counter-regulatory hormones, such as glucagon, cortisol, catecholamines, and growth hormone, becomes obvious and leads to the release of pyruvate, lactate, and free fatty acid. Lipid deposition in lean tissues such as the liver, skeletal muscle, cardiac muscle, and pancreas results in lipotoxicity and organ failure, including pulmonary hypertension, steatohepatitis, end-stage renal disease, insulin resistance, cardiac contractile dysfunction, and pancreatic beta cell failure.[79] For type Ib disease, specific problems such as neutropenia and neutrophil dysfunction are prominent. Patients may have recurrent infections and inflammatory bowel disease.[81]

Anesthesia Considerations. Anesthesia case reports for GSD I patients are rare.[82,83] Patients with GSD I diseases should be given intravenous glucose-containing fluid preoperatively when they have fasted. Lactate-containing solutions should be avoided because these patients are not able to convert the lactic acid to glycogen.[29] Patients need to be monitored frequently to avoid hypoglycemia.

Glycogen Storage Disease Type II (Acid Maltase Deficiency)

The incidence of acid maltase deficiency (AMD) is estimated to be 1 in every 14,000 to 40,000 births. Its inheritance is autosomal recessive with a few exceptions.[84,85] Mutations of the acid maltase gene on chromosome 17q25 cause deficiency of lysosomal acid maltase (acid α-1,4-glucosidase).[85] Cases of AMD have been arbitrarily classified into three groups—infantile, childhood, and adult—according to the age at onset or death, rate of progression, and tissue-organ involvement.[85]

Acid maltase is a lysosomal enzyme that catalyzes the one-way hydrogenation of glycogen to G6P and is found in all tissues, including skeletal and cardiac muscle.[86] Consequently, glycogen accumulates within the muscle tissues of maltase-deficient patients. Infantile AMD, also known as Pompe's disease, is usually manifested within the first few months of life as rapidly progressive weakness and hypotonia and enlargement of the tongue, heart, and liver. Massive amounts of glycogen (8% to 15% of the wet weight of the tissue) accumulate in the heart, liver, and skeletal muscle, with relatively smaller deposits in smooth muscle, eyes, kidneys, endothelial cells, lymphocytes, brain, and spinal cord. Accumulation of glycogen in cardiac muscle leads to cardiac failure in the infantile form.[85] Echocardiography demonstrates marked thickening of the interventricular septum and posterior left ventricular wall, left ventricular outflow obstruction, and trabecular hypertrophy.[85] Ventricular wall thickness may be increased to up to 25 mm.[87] Wolff-Parkinson-White syndrome has been reported.[88] The signs and symptoms of infantile AMD may resemble those of DMD. Death usually results from cardiorespiratory decompensation within several years of disease progression.[89]

Childhood AMD occurs in infancy to early childhood and is manifested by clinical signs of myopathy. Respiratory muscles tend to be selectively affected. Calf enlargement can also occur. The disease progresses relatively slowly in this form, with a few patients surviving beyond the second decade of life.[85] Tongue, heart, and liver enlargement occur infrequently.[90] However, involvement of vascular smooth muscle is more severe than in the infantile form. There has been a report of extensive glycogen deposition in the arterial wall causing basilar aneurysms.[90]

Adult AMD usually occurs after age 20 and is characterized by slow progressive myopathy or symptoms of respiratory failure.[85] The weakness in proximal muscles is more prominent than the weakness in distal muscles. A third of adult AMD patients suffer from respiratory failure with a restrictive pattern. Weakness in the diaphragm causes extensive atelectasis. VC may be significantly reduced.[85]

Anesthetic Considerations. Anesthesia reports in AMD patients are rare.[91-94] Isolated intraoperative cardiac arrest during halothane anesthesia in infantile AMD has been documented.[94] Despite the problem noted with halothane, enflurane[92] and sevoflurane[93] have been used without complications. Theoretically, total intravenous general anesthesia with propofol may cause a reduction in afterload leading to an increased risk for

myocardial ischemia. This may become significant when the patient is tachycardic.[93]

Subendocardial ischemia may occur in patients with a thickened ventricular wall and result in higher left ventricular end-diastolic pressure at lower ventricular volume.[93,95] Close cardiac monitoring is therefore necessary. A central venous or pulmonary artery catheter is not essential in patients who are normovolemic without preexisting heart failure.[93] Adequate filling pressure and normal to high systemic vascular resistance (SVR) are required to ensure effective coronary perfusion.[93] Ketamine has been used successfully in a number of cases because of its ability to maintain SVR and contractility. Respiratory failure and muscle weakness are the other concerns for anesthesiologists. A spectrum of uses of muscle relaxants from none[92] to atracurium[91] to rocuronium[93] have been attempted. Low-dose rocuronium, 0.5 mg/kg, with close monitoring of neuromuscular function and adequate use of reversal agents, has been sufficient to prevent prolonged postoperative weakness.[93] Depolarizing agents should be avoided because of the potential risk of hyperkalemia and rhabdomyolysis.[93,94]

Mitochondrial Myopathies

Mitochondrial diseases refer to defects in the five main steps of mitochondrial metabolism: substrate transport, substrate utilization, the Krebs cycle, the electron transport chain, and oxidation-phosphorylation coupling.[96] However, the term *mitochondrial myopathy* has been reserved for disorders caused by defects in the respiratory chain.[96] The respiratory chain is composed of five multimeric complexes (I to V) embedded in the inner mitochondrial membrane, plus two small mobile electron carriers, coenzyme Q_{10} (CoQ_{10}) and cytochrome *c*, for a total of more than 80 proteins,[96] among which 13 are encoded by mitochondrial DNA (mtDNA) and all others by nuclear DNA (nDNA). mtDNA is different from nDNA in several aspects: (1) mtDNA is circular and contains no intron, (2) it has larger numbers of copies than nDNA does and a much higher spontaneous mutation rate, and (3) its inheritance is maternal. Diagnosis of mitochondrial diseases is difficult because of their clinical heterogeneity.

Primary mtDNA mutations may include point mutations in polypeptide, tRNA, or rRNA encoding regions and large-scale rearrangements, duplications, or deletions.[97] Some of the common conditions caused by point mutations include myoclonic epilepsy with ragged-red fibers (MERRF); mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes (MELAS); neuropathy, ataxia, and retinitis pigmentosa (NARP); maternally inherited Leigh's syndrome; and Leber's hereditary optic neuropathy (LHON).[96] Sporadic large-scale mutations may lead to Kearns-Sayre syndrome, progressive external ophthalmoplegia, and Pearson's syndrome.[96] nDNA mutations can cause deficiencies in complexes I to IV and CoQ_{10} of the electron transport chain.[96]

Mitochondrial myopathy is estimated to have an incidence of 1 in 4000.[98] Among all the mitochondrial functions, abnormalities in electron transport and oxidative phosphorylation are the most common causes of mitochondrial myopathies.[99] Mitochondrial myopathies are characterized by proximal muscle weakness with increased lactic acid and positive muscle biopsy for mitochondrial cytopathy.[100] The hallmark of mitochondrial myopathies is the "ragged red fiber" when muscle biopsy specimens are stained with modified Gomori trichrome stain,[101] and specific defects in the activity of these enzymes have been demonstrated in patients with mitochondrial disease.[102] Fatigue and poor stamina are prominent clinical features. Movement disorders such as ataxia, dystonia, myoclonus, chorea, athetosis, and tremors have also been described as being due to mitochondrial abnormalities.[102]

Anesthetic Considerations

Preoperative Evaluation. Given the heterogeneous types of mitochondrial disease, patients with mitochondrial disease will need a comprehensive preoperative evaluation with a particular focus on neurologic, cardiac, respiratory, musculoskeletal, endocrinopathic, and metabolic compromise (also see Chapters 34 and 35). An ECG and echocardiogram should be considered in patients with signs and symptoms of cardiomyopathy or conduction defects (or both). Although normal lactate and glucose levels cannot rule out mitochondrial diseases, laboratory studies consisting of glucose, electrolytes with anion gap, complete blood count, blood urea nitrogen, lactate, pyruvate, ammonia, CK, biotinidase, acyl carnitines, and blood and urine amino and organic acids could be used as initial investigation for suspected mitochondrial disorders.[103] Further workup should include an erythrocyte sedimentation rate, glycosylated hemoglobin (HbA_{1C}), liver and renal profiles, thyroid function tests, arterial blood gas, and urinanalysis.[98,102] Multidisciplinary consultation with special laboratory and imaging studies may be required.[102]

Induction and Maintenance of Anesthesia. Anesthesia has a significant impact on mitochondrial function. Both barbiturates and propofol inhibit complex I of the electron transport chain.[103] Local anesthetics have been demonstrated to disrupt oxidative phosphorylation and decrease the bioenergetic capacity of mitochondria.[103] Sensitivity to intravenous barbiturates and etomidate has been reported.[104,105] However, midazolam,[106] thiopental,[107] propofol,[108,109] remifentanil,[110] and ketamine[109] have all been used safely. Premedication should avoid respiratory depression caused by impaired respiratory responses to hypoxemia. Volatile agents such as halothane, isoflurane, and sevoflurane have been shown to inhibit complex I.[103] This direct inhibition of mitochondrial electron transport system enzymes and altered mitochondrial bioenergetics in the heart were thought to be the mechanism of cardiac preconditioning by volatile anesthetics.[111,112] Inhaled sevoflurane has been widely used for induction because of its low pungency.[100] In some cases, halothane[106] and isoflurane[106,113] have also been used. Isoflurane has been recommended as the agent of choice in patients with Kearns-Sayre syndrome because rhythm disturbances have been reported with halothane in such patients.[106,113] In addition, artificial pacing capability is recommended when dealing with this specific subset of patients.[100] With use of the bispectral index, higher sensitivity to volatile agents has been suggested in children with mitochondrial diseases, especially with dysfunction of complex I.[114] However, its methodology has been criticized.[115] A decreased minimum alveolar concentration of halothane in patients with mental retardation has also been reported.[116]

Despite no real evidence and the fact that volatile anesthetics are frequently the anesthetic of choice when muscle relaxants are considered, several papers have expressed concern that these myopathies are associated with increased sensitivity to MH. This conclusion is not supported by any data. Increased sensitivity to

nondepolarizing muscle relaxants has been documented for mivacurium,[117] atracurium,[118] and rocuronium.[118,119] In contrast, normal responses to depolarizing and nondepolarizing neuromuscular blockers such as pancuronium,[120] vecuronium,[121] and atracurium[108,122] are also reported. Although muscle relaxants are not absolutely contraindicated based on current literature and research, it is necessary for anesthesia practitioners to administer depolarizing or nondepolarizing neuromuscular blockers with caution to patients with mitochondrial diseases and to use neuromuscular monitoring (see Chapter 47).[98]

Nonsteroidal anti-inflammatory drugs[100] and regional techniques consisting of local,[100,123] spinal,[124] and epidural administration have been reported. However, it is suggested that regional anesthesia be performed when neurologic abnormalities of the spinal cord and peripheral nerves have definitely been ruled out.[124] Importantly, coagulation function should be assessed because of the possibility of hepatic dysfunction.[100]

Opioids should be used with caution because of the increased risk for respiratory depression and their potential to induce respiratory acidosis in addition to the underlying metabolic acidosis.[100] Because patients with mitochondrial diseases have dysfunctional aerobic metabolism, any increase in the basic metabolic rate should be prevented.[102] Shivering, hypoxia, fasting, and hypotension in such patients may exacerbate the lactic acidosis and should therefore be avoided.[125] Finally, the increased postoperative infection rate in patients with mitochondrial diseases may be due to low hepatic mitochondrial activity, phagocytosis by Kupffer cells, and decreased activity of the reticuloendothelial system.[126]

Myasthenia Gravis

Myasthenia gravis (MG) is an autoimmune disorder of the neuromuscular junction. Autoantibodies against the α-subunit of the muscle-type nicotinic acetylcholine receptor destroy acetylcholine receptors of the neuromuscular junction and cause classic transmission failure with muscle weakness and fatigue. Sparing of other α-subunits of neuronal-type nicotinic acetylcholine receptors provides an explanation for the lack of autonomic or CNS involvement of the disease. The incidence of MG varies between geographic regions, being 1.2 per million in Japan and about 14 per 100,000 in some areas of the United States.[127,128] In younger age groups, females are affected more often than males are, whereas in elderly age groups (>60 years), males are more frequently affected.

There is a striking association between MG and hyperplasia of the thymus, with more than 70% of MG patients having thymus hyperplasia and 10% having thymomas.[128] MG may also be seen as a part of a paraneoplastic syndrome.[128]

Typically, patients first report bulbar symptoms consisting of diplopia and ptosis. The bulbar symptoms are often followed by unevenly distributed muscle weakness and fatigue of the extremities and face. Speech and chewing may be affected, as well as pharyngeal function and coordination of swallowing, with a subsequent increased frequency of aspiration of oral contents. The muscle weakness is often exacerbated during exercise and throughout the course of the day. Apart from the patchy distribution of muscle weakness, symptoms may also vary from day to day, and there may be periods of remission of varying duration.

The diagnosis of MG is made by neurologic examination and testing of the tendency to fatigue and exhibit increased weakness during exercise or repeated contractions. The diagnosis can be confirmed by the Tensilon test (administration of an anticholinesterase, e.g., edrophonium). Improvement is usually seen within 5 minutes after administration of the drug and lasts for about 10 minutes. In addition, electrophysiologic evaluation is often performed and shows a classic decrement in the compound muscle action potential after repetitive nerve stimulation.

Anesthetic Considerations. Ideally, careful neurologic consultation in addition to preoperative evaluation should be performed on MG patients with the aim of optimizing drug therapy and preparing for postoperative care. Pulmonary function tests may be indicated to determine the need for mechanical ventilation postoperatively.[117] As a general rule, patients should keep taking their anticholinesterase medication and be informed about the possibility of postoperative ventilator support. Succinylcholine can be used if needed for rapid tracheal intubation. However, patients with MG might need larger than normal doses (1.5 to 2.0 mg/kg body weight) because of the decreased number of functional acetylcholine receptors.[129] On the other hand, as a result of the decrease in cholinesterase activity achieved by anticholinesterase treatment, neuromuscular blocks with succinylcholine or mivacurium are frequently prolonged.[130,131] Nondepolarizing neuromuscular blockers can be used in patients with MG but should be given with caution because their effects are highly unpredictable and the distribution of muscle weakness is often uneven. Consequently, monitoring of neuromuscular function with a peripheral nerve stimulator is not always reliable in MG patients, and dosing of any nondepolarizing muscle relaxant should be increased in small increments corresponding to 0.1 to 0.2 times the 95% effective dose (ED_{95}) until the desired neuromuscular blocking effect is achieved. Perioperative anticholinesterase treatment will modify the response to reversal agents because of the already existing acetylcholinesterase block, and in some cases, recovery of neuromuscular function after the administration of a reversal agent has been reported to be prolonged.[132]

Potent volatile anesthetics have been used successfully in MG patients. Because of the impaired margin of safety at the neuromuscular junction, a volatile anesthetic usually provides adequate muscular paralysis to allow most surgical procedures to be performed without the need for a neuromuscular blocking agent. Epidural and spinal anesthesia can be used in MG patients, provided that muscle function and ventilation are carefully monitored perioperatively, as for general anesthesia. For a more detailed review, see Baraka[133] and Abel and Eisenkraft.[134]

Eaton-Lambert Myasthenic Syndrome

Eaton-Lambert myasthenic syndrome (ELMS) is an immune-mediated channelopathy caused by decreased release of acetylcholine as a result of autoantibodies against presynaptic voltage-gated calcium channels and other presynaptic elements.[135] Patients with ELMS have muscle weakness and fatigability, generally of the proximal limb muscles, with the lower extremities affected more often than the extraocular and bulbar muscle

groups. The syndrome is frequently part of a paraneoplastic phenomenon, usually combined with small cell lung carcinoma. Unlike MG, patients with ELMS are usually worse in the morning with gradual improvement throughout the day. Improvement of muscle function with exercise is due to the accumulation of presynaptic calcium and subsequent improved release of acetylcholine.[136] A minority of patients exhibit autonomic dysfunction. The diagnosis of ELMS is made by careful physical examination combined with clinical electrophysiology showing the typical facilitation of motor action potential with high-frequency nerve stimulation (30 to 50 Hz). Anticholinesterase treatment has little effect on patients with ELMS. Plasmapheresis, immunoglobulin therapy, and 3,4-diaminopyridine (DAP) result in transient improvement.

Anesthetic Considerations. As in patients with MG, those with ELMS should be carefully evaluated for the risk of postoperative respiratory failure and the need for prolonged respiratory monitoring in the postoperative period. Sensitivity to depolarizing and nondepolarizing neuromuscular blocking agents is usually increased. In patients treated with DAP or an anticholinesterase agent, reversal of neuromuscular blockade may be ineffective.

Periodic Paralysis (Hyperkalemic and Hypokalemic)

Hyperkalemic periodic paralysis (HyperPP) is an autosomal dominant disorder first described by Tyler and associates in 1951.[65] It is characterized by attacks of flaccid weakness associated with increased serum potassium.[137] A potassium-rich meal or rest after strenuous exercise may precipitate an attack. Stressful situations may also provoke the onset of paralysis. The paralysis may last for 15 minutes to an hour, with decreased tendon reflexes. In the interictal state, HyperPP is usually associated with mild myotonia that does not impede voluntary movements.[65]

The pathogenesis of HyperPP involves mutations in the voltage-gated sodium channel NaV1.4 of mature muscle fibers; such mutations lead to pathologically increased sodium current and an increased tendency of the muscle fiber to become depolarized.[65,137] Influx of sodium into the muscle is accompanied by simultaneous efflux of potassium and hyperkalemia. Mutant channels exhibit sustained sodium currents that lead to prolonged membrane depolarization, causing myotonia followed by membrane desensitization (or inactivation) and resulting in paralysis. In HyperPP patients, serum CK can be elevated, sometimes 5 to 10 times above the normal limit, whereas serum sodium and potassium levels are normal in the interictal state.[65]

Hypokalemic periodic paralysis (HypoPP) is characterized by a decrease in potassium levels in blood. Attacks of HypoPP can be triggered by rigorous exercise, stress, high-carbohydrate or high-salt meals, pregnancy, menstruation, hypothermia, or drugs such as insulin.[138,139] EMG does not usually show myotonia.[137] The severity of attacks is usually greater than those occurring in patients with HyperPP. HypoPP is an autosomal dominant disease with higher penetration in males. The disease is due to loss of function of one of the two different ion channel types: CaV1.1 and NaV1.4.[137] The most common muscle groups affected are those in the arms and legs; however, the disorder can also affect swallowing and respiratory muscles, which can be fatal in severe cases.[140] The diagnosis of HypoPP is made by laboratory testing demonstrating hypokalemia during attacks and normokalemia between attacks.

Anesthetic Considerations. Potassium, cholinesterase inhibitors, and depolarizing muscle relaxants will aggravate the myotonia in HyperPP patients.[65] Prolonged muscle weakness has been reported when succinylcholine is used.[141] Although one third of patients had no signs of myotonia,[142] masseter spasm and respiratory and skeletal muscles stiffness could still occur during intubation and ventilation.[65] Therefore, neostigmine and succinylcholine should be contraindicated in HyperPP patients. Ideally, all patients with HyperPP need to be admitted preoperatively so that proper preoperative fasting can be accompanied by the administration of dextrose-containing potassium-free maintenance fluid.[143] Postoperatively, HyperPP patients may remain paralyzed for up to several hours. Preventive measures such as maintaining normal body temperature and low serum potassium levels and avoiding hypoglycemia are helpful in limiting such paralysis.[144] Although patients with sodium channel pathology have often been considered to be susceptible to MH, there is no increased risk for MH in these patients.[145] General anesthesia with and without nondepolarizing muscle relaxants has been shown to have satisfactory outcomes.[141,143,144,146] Regional techniques may also be appropriate for this patient group.[142,146] Abortion of the hyperkalemic attack may be accomplished by administering glucose, insulin, epinephrine, and calcium supplements, or alternatively, glucagon may be used. β-Adrenergic treatment with metaproterenol has also been shown to prevent attacks and facilitate recovery.[143]

Management of HypoPP patients should focus on avoiding triggers and medications causing shift of potassium. General anesthesia, postoperative stress, glucose-containing intravenous solutions, and long-acting neuromuscular blockers are associated with postoperative paralytic events.[138] Epidural analgesia has been shown to reduce both pain-related hyperventilation and serum catecholamines, thereby minimizing changes in serum potassium levels.[138] The sympathomimetic effect of epinephrine-containing local anesthetics may also precipitate hypokalemia.[138]

Malignant Hyperthermia

MH is a pharmacogenetic clinical syndrome that in its classic form occurs during anesthesia with a volatile halogenated alkane such as halothane and the depolarizing muscle relaxant succinylcholine. Clinical MH produces rapidly increasing body temperature (by as much as 1°C/5 min) and extreme acidosis as a result of acute loss of control of intracellular calcium levels and compensatory uncontrolled increases in skeletal muscle metabolism that may proceed to severe rhabdomyolysis. Although MH was initially associated with a mortality rate of 70%, earlier diagnosis and the use of dantrolene have reduced the mortality to less than 5%. Current cases of MH are restricted in severity because of diagnostic awareness, early detection through end-expired carbon dioxide, use of less potent anesthetic triggers, and administration of drugs that attenuate its progression. Wilson and colleagues[147] first used the term *malignant hyperthermia* in print in 1966. A Danish survey[148] reported an incidence of fulminant MH of one case per 62,000 anesthetics administered when triggering agents

were not used, but the number of suspected cases was one per 4500 anesthetics administered when triggering agents were administered. Public education and communication in the United States are provided by a layman's organization, Malignant Hyperthermia Association of the United States (MHAUS, 11 E. State Street, P.O. Box 1069, Sherburne, NY 13460-1069; telephone: 1-607-674-7901; fax: 1-607-674-7910; e-mail: info@mhaus.org; website: www.mhaus.org), and by emergency consultation with the MH Hotline (1-800-MHHYPER, or 1-800-644-9737). The North American MH Registry, a professional subsidiary of MHAUS, collates findings from muscle biopsy centers in Canada and the United States and provides access to specific patient data through the hotline or its director Dr. Barbara Brandom (North American MH Registry of MHAUS, Room 7449, Department of Anesthesiology, Children's Hospital, University of Pittsburgh, 3705 Fifth Avenue at DeSoto St., Pittsburgh, PA, 15213-2583; telephone: 1-888-274-7899; fax: 1-412-692-8658; e-mail: bwb@pitt.edu).

Between 50% and 80% of genotyped patients who have had a clinical MH syndrome and a positive muscle biopsy have had their disease linked to 1 of more than 110 mutations in the type 1 ryanodine receptor (RyR1; SR Ca^{2+} release channel) gene and 2 mutations in the L-type Ca^{2+} channel CaV1.1.[149] The genetics of MH and the related abnormal function of RyR1, the dihydropyridine receptor (DHPR), and associated proteins are being investigated at the molecular biologic level, with a porcine model and several new mouse models providing intricate details about the etiology of the disorder. Parallel studies in humans are limited by scarce material for scientific study and are complicated by the fact that phenotypes within a genotype vary as a result of genetic, epigenetic, and environmental modifiers. In vitro muscle biopsy testing remains the only "approved" stand-alone screening test currently available in the United States and elsewhere.

History

Between 1915 and 1925, one family experienced three anesthetic-induced MH deaths with rigidity and hyperthermia and was puzzled for decades regarding the cause of these deaths. MH susceptibility (MHS) was eventually confirmed in three descendants by in vitro muscle biopsy tests.[150] In 1929, Ombrédanne[151] described anesthesia-induced postoperative hyperthermia and pallor in children accompanied by significant mortality but did not detect any familial relationships. Critical worldwide attention to MH began in 1960, when Denborough and Lovell[152] reported a 21-year-old Australian with an open leg fracture who was more anxious about anesthesia than about surgery because 10 of his relatives had died during or after anesthesia. Lovell initially anesthetized him with the then-new agent halothane, halted it when signs of MH appeared, successfully treated the symptoms and aborted the syndrome, and subsequently used spinal anesthesia. Further evaluations by George Locher in Wausau, Wisconsin, and Beverly Britt in Toronto, Canada, led to the discovery that MH risk was indeed familial.[153] It was also found that the cause of the syndrome was the result of skeletal muscle involvement rather than central loss of temperature control by the recognition of increased muscle metabolism or muscle rigidity early in the syndrome, low-threshold contracture responses, and elevated CK values.[154]

Interestingly, a similar syndrome was discovered in swine inbred with breeding patterns designed to produce a rapid growth rate and superior muscle development (e.g., Landrace, Pietrain, Duroc, Poland, China). *Porcine stress syndrome*,[155] which is associated with increased metabolism, acidosis, rigidity, fever, and death from rapid deterioration of muscle and results in pale, soft, exudative pork,[156] can be triggered by any stress, such as separation, shipping conditions, weaning, fighting, coitus, or preparation for slaughter, and had become a significant problem for meat production. In 1966, Hall and coworkers[157] reported that a syndrome that appeared to be identical to MH could be induced in stress-susceptible swine by the administration of halothane and succinylcholine. The cause of this syndrome in pigs was discovered to be a single missense mutation in *RYR1*, and all susceptible swine have the same Arg615Cys mutation in the SR calcium release channel RyR1.[158]

In 1975, Harrison[159] described the efficacy of dantrolene in preventing and treating porcine MH, which was rapidly confirmed in humans by a multihospital evaluation of dantrolene used to treat anesthetic-induced episodes.[160] Today, dantrolene still remains the primary basis for successful MH therapy.

Physiology and Pathophysiology of Excitation-Contraction Coupling and Malignant Hyperthermia

MH is a syndrome caused by dysregulation of excitation-contraction (EC) coupling in skeletal muscle. Normal muscle contraction is initiated by nerve impulses arriving at the neuromuscular junction (i.e., the motor end plate) that trigger the release of acetylcholine from the nerve terminal. Acetylcholine activates cation channels on the muscle membrane essential for initiating action potentials that propagate rapidly along the surface membrane of the muscle. Invaginations of the surface membrane (transverse or T tubules) act as conduits to rapidly and uniformly direct action potentials deep within the myofibrils, where they are transduced by a "voltage sensor," the slow voltage-gated Ca^{2+} channels (DHPRs). In response to membrane depolarization, the voltage sensor then undergoes a conformational change that is mechanically transmitted to the Ca^{2+} release channels (RyR1) concentrated in the junctional face of the SR. The mechanical coupling of DHPRs and RyR1 channels that occurs at specialized junctions (*triadic junctions*) is essential for initiating release of Ca^{2+} stored within the SR. Release of SR Ca^{2+} causes the free, intracellular Ca^{2+} concentration to increase from 10^{-7} to about 10^{-5} M. The Ca^{2+} binds to proteins (troponin C and tropomyosin) in the thin filament to expose the myosin binding sites on actin that activate the thick filament (myosin) and cause muscle contraction. The whole process is called EC coupling. Intracellular Ca^{2+} pumps (i.e., sarcoplasmic/endoplasmic reticulum Ca^{2+}-adenosine triphosphatase [ATPase], or SERCA pumps) rapidly propel Ca^{2+} actively back into the SR, and muscle relaxation begins when the Ca^{2+} concentration falls below 10^{-6} M and ends when the resting myoplasmic Ca^{2+} concentration is restored to 10^{-7} M. Because both contraction and relaxation are energy-related processes that consume adenosine triphosphate (ATP), knowing the molecular events contributing to EC coupling and the associated relaxation is essential to understanding the cause of MH (Fig. 37-3). Clinical and laboratory data from swine and

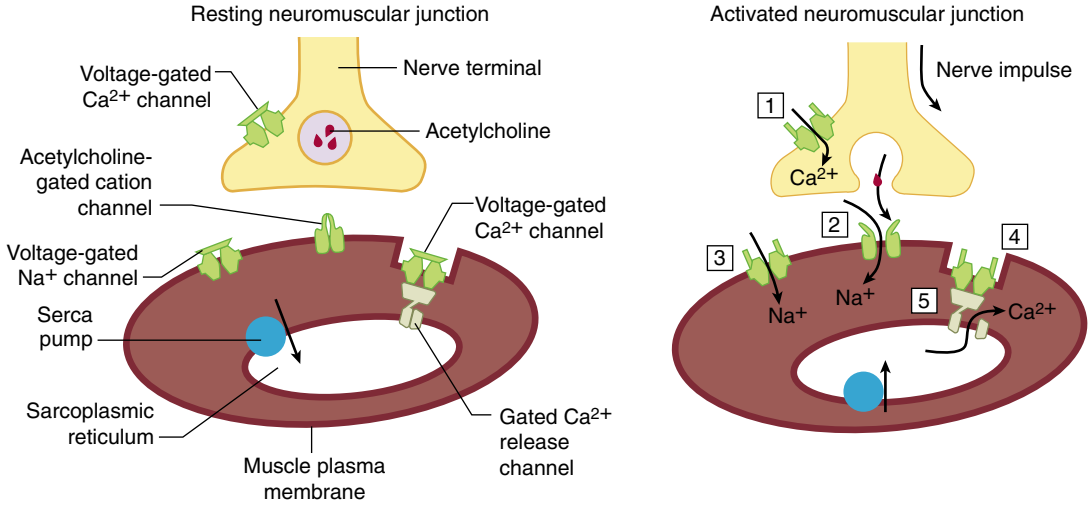

Figure 37-3 Key ion channels involved in neuromuscular transmission and excitation-contraction coupling. Nerve impulses arriving at the nerve terminal activate voltage-gated Ca^{2+} channels (1). The resulting increase in cytoplasmic Ca^{2+} concentration is essential for the exocytosis of acetylcholine. Binding of acetylcholine to postsynaptic nicotinic cholinergic receptors activates an integral nonselective cation channel that depolarizes the sarcolemmal membrane (2). Depolarizing the sarcolemma to threshold activates voltage-gated Na^+ channels (3), which propagate action potential impulses deep into the muscle through the transverse tubule system. Within the transverse tubule system, L-type voltage-gated Ca^{2+} channels sense membrane depolarization and undergo a conformational change (4). A physical link between the α_1-subunit and the ryanodine receptor is thought to be the means by which the signal is transferred to the sarcoplasmic reticulum to induce the release of stored Ca^{2+} (5). *(Adapted from Alberts B, Bray D, Lewis J, et al: Molecular Biology of the Cell, 3rd ed. New York, Garland Press, 1994.)*

humans indicate that the fulminant MH syndrome is associated with a persistent increase in intracellular Ca^{2+}.[161-164] The increased activity of pumps and exchangers trying to correct the increase in Ca^{2+} causes a need for ATP, which in turn produces heat. Thus, the end result is hyperthermia. The rigidity that is frequently seen during a fulminant MH episode is the result of the inability of the Ca^{2+} pumps and transporters to reduce the unbound myoplasmic Ca^{2+} below the contractile threshold. Dantrolene is therapeutic because it reduces the concentration of myoplasmic Ca^{2+}. However, the pathway by which dantrolene lowers myoplasmic Ca^{2+} is complex and still not fully understood.

Malignant Hyperthermia Is the Result of Abnormal Function of Muscle Calcium Release Units

Ryanodine receptors (RyRs), which in muscle are synonymous with the junctional foot protein/SR calcium release channel, are so named because they specifically bind the toxic plant alkaloid ryanodine.[165,166] There are three RyR isoforms encoded by three genes located on human chromosomes 19q13.1, 1q42.1-q43, and 15q14-q15, the "skeletal" (RyR1), "cardiac" (RyR2), and "brain" (RyR3) isoforms, respectively. Each functional RyR consists of four identical subunits (≈5000 amino acids each), and each subunit binds with an accessory protein, calstabin 1 (FK506 12-kd binding protein [FKBP12]). The total mass of the tetramer exceeds 2 megadaltons. Thus, it is one of the largest known proteins and the largest known channel in mammalian species. Evidence of direct coupling of CaV1.1 and RyR1 has been demonstrated by expressing chimeric CaV1.1/CaV1.2 cDNA dysgenic myotubes that lack constitutive expression of either Ca^{2+} channel protein.[167,168] Such studies have provided compelling evidence that the cytoplasmic region between repeats II and III (i.e., cytosolic II-III loop) contains a stretch of 46 amino acids (L720 to Q765) that are essential for engaging bidirectional signaling with RyR1.[169]

In the last 5 years our understanding of EC coupling has increased significantly by identifying protein-protein interactions that regulate both the release and sequestration of Ca^{2+} within skeletal muscle. The elemental unit of function has been named the Ca^{2+} release unit (CRU), and it is localized within junctional regions of T-tubule and SR membranes.[170] The CRU is a macromolecular assembly of interacting proteins that participate in tightly regulating EC coupling. RyR1 is a high-conductance channel that regulates release of SR Ca^{2+} and is the central component of the CRU. The functional RyR1 physically interacts with tetrads composed of four voltage-activated CaV1.1 subunits within the T-tubule membrane to engage bidirectional signaling. Proteins localized within the triad junction that interact with either or both RyR1 and CaV1.1 include Homer 1, which physically binds and functionally couples target proteins, calstabin 1, triadin, junctin, Mg29, junctophilin 1 and 2, calsequestrin, calmodulin, the catalytic and regulatory subunits of protein kinase A, and protein phosphatase 1 (for review see elsewhere[171-174]), and it is likely that this list is not complete. There is experimental support that mutations found in RyR1 ($_{MH}$RyR) alter protein-protein interactions in the CRU.[175-177]

In the presence of certain chemical substances, MH mutations in RyR1 or DHPR cause severe dysregulation of RyR1 channel function. This can be seen in vitro as heightened sensitivity to volatile anesthetics, 4-chloro-*m*-cresol, caffeine, ryanodine, and potassium depolarization.[178-180] Chemically induced dysfunction of the RyR1 complex appears to be the principal cause of triggering uncontrolled skeletal muscle metabolic acidosis (aerobic and glycolytic), rigidity, and hyperkalemia, but the mechanisms governing the syndrome are unclear.

Two essential cations greatly shape the kinetics and magnitude of Ca^{2+} release in response to depolarizing triggers: Ca^{2+} itself and Mg^{2+}. The normal RyR1 complex responds to Ca^{2+} in a biphasic manner. First, Ca^{2+} activates the channel in a graded

manner between 100 nM and 100 μM, whereas higher concentrations inhibit channel activity.[181,182] This biphasic action is thought to occur via binding of Ca^{2+} to two classes of regulatory sites on RyR1, a high-affinity stimulatory site and a low-affinity inhibitory site.[173] Mg^{2+}-induced inhibition is the second important physiologic regulator of RyR1 activity in skeletal muscle.[183,184] Mg^{2+} inhibits RyR1 in a cooperative manner ($n_H \approx 2$; 50% inhibitory concentration [IC_{50}] ≈ 650 μM). It is likely that Mg^{2+} acts by competing with Ca^{2+} at its activator sites and by binding to yet unidentified low-affinity inhibitory sites.[185,186] Possibly, MH mutations introduce allosteric instability into the RyR1 complex that leads to a reduction of inhibition rather than directly altering the binding properties of Ca^{2+} or Mg^{2+}, or both, at the activator or inhibitor sites. Therefore, hypersensitivity to pharmacologic agents is likely to be closely tied to altered responses to physiologic ligands. However, whether MHS channels are primarily hyposensitive to inhibition by Mg^{2+} [187,188] or Ca^{2+} (or both), are hypersensitive to activation by Ca^{2+}, or exhibit altered sensitivities in both directions to both ions remains controversial. Recent studies have also pursued the "leaky channel" hypothesis by examining SR preparations from homozygous R615C MHS pigs and heterozygous R163C and C512S mice; they observed a significantly lower Ca^{2+} loading capacity (38%, 23%, and 22% lower than matched wild type mice, respectively) primarily mediated by the presence of leaky channels that remain active even with 100-nM extravesicular Ca^{2+}.[189,190] These direct measures of MHS RyR1 channel dysfunction are consistent with intracellular calcium measurements made in MHS muscles, myotubes, and myoball preparations and in dyspedic myotubes expressing $_{MH}$RyR1s, all of which have been shown to have chronically elevated resting cytoplasmic $[Ca^{2+}]_i$.[177,179,191] Dirksen and coworkers demonstrated that cells expressing the CaV1.1 R1086H MHS mutation have enhanced RyR1 sensitivity to activation by endogenous (voltage sensor) and exogenous (caffeine) activators.[192-196]

Some experimental evidence suggests that long-range interdomain interactions between regions of RyR1 are involved in channel regulation by stabilizing protein conformations critical for normal channel transitions.[197]

Factors Other Than Ryanodine Receptor Abnormalities

Other cellular processes can affect MH episodes. It has been demonstrated that concurrent administration of nondepolarizing neuromuscular blocking drugs at the same time as triggering agents can delay or prevent the onset of clinical MH syndrome. Pretreatment of MH-susceptible pigs with sufficient nondepolarizing neuromuscular blocking agent to completely abolish muscle twitch elicited by electrical stimulation of the nerve prevented halothane from triggering the clinical syndrome for 90 minutes, the longest time point tested.[198] However, in the continued presence of halothane, when function of the neuromuscular junction was restored by administration of the cholinesterase inhibitor neostigmine, clinical MH was triggered immediately. This suggested a close relationship between functional neuromuscular junctions or depolarization of the sarcolemma (or both) and the clinical syndrome.

Recently, it has been shown that sarcolemmal excitation-coupled Ca^{2+} entry (ECCE) is sensitive to the conformation of the RyR1 and is enhanced by several mutations in RyR1, including MH mutations.[171,176,199] This enhancement is responsible for the observation that MHS muscles are more sensitive to depolarization with KCl. Although the sarcolemmal channel responsible for ECCE has not yet been identified, it is one target for dantrolene's reduction of muscle contraction in response to both electrical and KCl depolarization.[175] In addition to ECCE, classic store-operated capacitive Ca^{2+} entry pathways similar to the store-operated Ca^{2+} entry (SOCE) seen in nonexcitable cells[200] have been shown to be present in skeletal muscle[201-203] and could be more active in MHS muscles as a response to chronic store depletion. Such a SOCE channel has also been suggested to be a target for dantrolene.[204] Together, these data suggest that $_{MH}$RyRs or $_{MH}$CaV1.1 and possibly $_{MH}$Csq1 or another $_{MH}$CRU protein could assume a conformation that enhances Ca^{2+} entry via ECCE or SOCE (or both). This enhanced entry, when combined with decreased sensitivity of $_{MH}$RyRs to Ca^{2+} and Mg^{2+} inhibition, could provide cellular conditions that heighten sensitivity to triggering agents and perpetuate the fulminant clinical MH syndrome.

Dantrolene

Dantrolene is the only drug that has been shown to be effective in reversing the symptoms of MH. Preadministration of dantrolene will also prevent the development of fulminant MH in homozygous pigs or heterozygous MH mice when exposed to a triggering stimulus. Dantrolene sodium is a hydantoin derivative (1-[5-(4-nitrophenyl)-2-furanyl]methylene]imino]-2,4-imidazolidinedione) that does not block neuromuscular transmission but causes muscle weakness by direct muscular action. The properties of dantrolene have been closely correlated with its ability to reduce efflux of Ca^{2+} from the SR in vitro. Dantrolene (20 μM) counteracts the effect of reduced Mg^{2+} inhibition in MH-affected muscle.[61] Dantrolene (20 μM) can inhibit the enhanced sensitivity to caffeine seen in MH muscles, and both dantrolene and its water-soluble analog azumolene (150 μM) have been shown to reduce depolarization-induced release of Ca^{2+}, both in muscle and in triadic vesicles.[205] The idea that dantrolene suppresses SR Ca^{2+} release as a result of direct interactions with RyR1 is somewhat controversial. Paul-Pletzer and associates[206] demonstrated that [^{3}H]azidodantrolene specifically labels the amino terminus of RYR1 defined by the 1400–amino acid residue N-terminal calpain digestion fragment of RYR1. More detailed analysis further localized the [^{3}H]azidodantrolene binding site to a single domain containing the core sequence corresponding to amino acid residues 590 through 609 of RyR1.[206] However, to date we lack evidence of a direct action of dantrolene on single RyR1 channels studied in lipid bilayers, even in the presence of calstabin 1, ATP, and activating concentrations of Ca^{2+}, suggesting that dantrolene's main action is to alter key protein-protein interactions.

Genetics

RYR1 mutations have been found in 50% to 80% of patients and relatives who are labeled MH susceptible by positive contracture tests and in almost all families with central core disease (CCD) and King-Denborough syndrome. More than 143 missense mutations and 8 deletions associated with MH have thus far been detected. Another 29 missense mutations are associated with CCD and multiminicore disease in patients with unknown MH testing status.[149] Interestingly, 40% of missense *RYR1* mutations occur at CpG dinucleotide sequences. Five other loci (17q21-24, 1q32, 3q13, 7q21-24, and 5p) have been linked to families with

positive contracture tests and an unusual response to anesthesia and have been designated MHS loci 2 through 6, respectively. However, of these five, the only gene that has been shown to be associated with MH is *CACNL1A3*,[207] which codes for CaV1.1 (the α_{1S}-subunit of DHPR), in the MHS3 locus. Two causative mutations in this gene are linked to less than 1% of MHS families worldwide. In some of the other loci, all genes within the locus have been ruled out as causing susceptibility to MH. Hence for practical reasons, the *RYR1* gene remains the primary target for current clinical genetic analysis.

Distribution of *RYR1* Mutations

The missense mutations associated with MHS, CCD, or in some cases both, are dispersed throughout the coding region of the *RYR1* gene, and all allow transcription of a protein that is putatively functional.[149,208] Until recently, it was thought that most *RYR1* mutations were clustered in three "hot spots": between amino acid residues 35 and 614 (MH/CCD region 1), between amino acid residues 2163 and 2458 (MH/CCD region 2) in the myoplasmic foot region of the protein, and between amino acids 4643 and 4898 in the carboxyl-terminal transmembrane loop or pore region (MHS/CCD region 3)[209] (Fig. 37-4). It appears that the supposition that there were "hot spots" was simply due to bias in sample analysis inasmuch as the missense mutations associated with MH or CCD (or both) are scattered over 54 of the 107 exons of *RYR1*. Approximately 41% of reported MH mutations are found in multiple families. CCD mutations are predominantly found in the C-terminal region of the gene (exons 85 to 103), and only 10 mutations (17%) have been described in more than one family: R4861H ($n = 14$), V4849I ($n = 9$), I4898T ($n = 7$), L4824P ($n = 4$), A4940T ($n = 4$), G4638D ($n = 3$), R4893W ($n = 3$), R4861C ($n = 2$), R4893Q ($n = 2$), and G4899E ($n = 2$).

MH and CCD have been reported in Western populations predominantly, but more likely than not this is incorrect and the result of the manner and frequency in which cases are reported. The true ethnic distribution of MH and CCD is difficult to ascertain. It does appear that the associated mutations are clustered in a given region of the world, but the distribution and frequency appear to be somewhat population specific. In the United Kingdom, 69 *RYR1* mutations have been discovered, 25 of which are found in only a single family. G2434R is found in approximately 40% of the 434 mutation-positive MH families investigated in the United Kingdom, with the next most common mutations being T2206M (10%) and G341R (8%). In Switzerland, V2168M and I2336H are the predominant mutations,[210] and in Germany, R163C (MH and CCD), R614C (MH), T2206M (MH), G2434R (MH), and R2454H (MH) have each been detected in five or more independent cases.[211,212] G341R and R614C are common in France,[213] and R614C has also been found in several MH families from Italy[213] and Canada.[214] G341R has been found frequently in Belgium.[213] The mutation common to Europe and North America is G2434R, which occurs in 4% to 7% of European and 5.5% of North American families.[215] Single-family mutations are the most common mutations reported in Japanese, Chinese, Taiwanese, Australian, and New Zealand MH families,[216-218] but it is likely that this may reflect the small number of cases investigated there. Because genetic screening in European and North American studies has predominantly targeted only regions 1 and 2 of the original hot spots in the gene, the absence of *RYR1* mutations in some of the screened population could be explained by

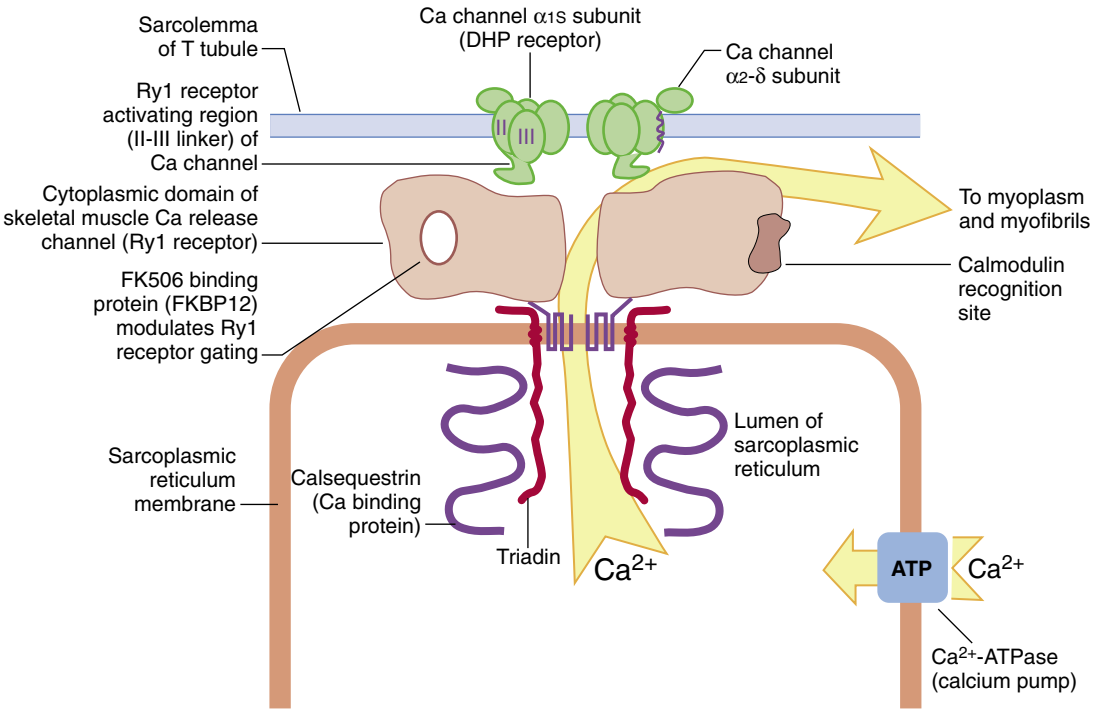

Figure 37-4 Schematic representation of the triad junction of skeletal muscle shows the junctional foot protein (ryanodine [Ry1] receptor) and its associated proteins. In skeletal muscle, the α_{1S}-subunit of the dihydropyridine receptor (DHPR) participates in excitation-contraction coupling. These physical links transmit essential signals across the narrow gap of the triadic junction that activate the Ry1 receptor and release Ca^{2+} from the sarcoplasmic reticulum. *(Adapted from Pessah IN, Lynch C III, Gronert GA: Complex pharmacology of malignant hyperthermia. Anesthesiology 84:1275, 1996.)*

RYR1 mutations located outside these two regions or by involvement of other genes.

Inheritance and Penetrance of Malignant Hyperthermia

Inheritance of human MH can no longer be considered to be solely autosomal dominant with variable penetrance because more than one MH-linked mutation has been identified in some probands and families. Six nonconsanguineous families harbor at least two *RYR1* mutations that have both been linked to MHS, and in two families one is an *RYR1* mutation and the second is a *CaV1.1* mutation.[219] Although MHS homozygotes are common in affected pigs, they are rare in human and transgenic mouse populations. The known MHS homozygous humans appear clinically normal but exhibit stronger responses to IVCT and caffeine/halothane contracture tests (CHCTs) than heterozygous individuals do.[220-223] Homozygosity of two MH mutations in "hot spot" 1 leads to perinatal lethality in mice.[189,190] Double heterozygous individuals do not appear to show any additive effect of the second mutation on IVCT.[219]

Discordance between Genetic and IVCT/CHCT Malignant Hyperthermia Testing

Discordance has confounded linkage analysis worldwide. Examples include MHN patients carrying an *RYR1* mutation associated with MH and MHS patients who do not carry the familial *RYR1* mutation. Several explanations are possible, the most likely being that IVCT/CHCT is not clinically precise and that the thresholds for IVCT or CHCT are inexact. This would lead to errors in determining whether a patient was MHN or MHS. A second possibility is variable penetrance with possible allelic silencing,[224] and a third is that individuals with discordance have mutations in other unknown genes or modifier genes that affect the function of RyR1 and its phenotypic penetrance. The rarity of large kindreds with MH makes linkage analysis and understanding variability in clinical manifestations difficult. Robinson and associates demonstrated by the transmission disequilibrium test (TDT) that loci on chromosomes 5 and 7 and, to a lesser extent, loci on chromosomes 1 and 7 influence susceptibility to MH.[213]

Guidelines for Genetic Screening

In 2000, the European MH group[225] formulated guidelines for *RYR1* mutation screening with linkage data to other loci for some MH families, but all MH investigators emphasized the vital role of IVCT in the diagnosis of MH. These guidelines for screening have reduced the number of relatives requiring contracture testing without increasing the risk of misdiagnosis[226,227] and include the following: (1) confirmation of MHS in a family member (preferably a proband) by IVCT before genetic testing; (2) use of 15 *RYR1* mutations characterized by in vitro functional assays for the genetic protocol; (3) confirmation of MHS and omission of IVCT if a causative mutation is detected in a first-degree relative; and (4) need for performance of IVCT before MHN is diagnosed if a familial mutation is not detected in a first-degree relative.

Only a small number of MH-susceptible families have been investigated extensively in North America by phenotyping, linkage analysis, and screening of specific genes. Collaborative protocols over the past several years between MH biopsy centers and molecular biologists have screened 209 unrelated MHS subjects for mutations in the *RYR1* gene (see "Distribution of *RYR1* Mutations").

A recent consensus meeting agreed to the following: (1) limitations of genetic testing include low sensitivity because of the diversity of mutations and genes; (2) the *RYR1* gene is the primary focus for genetic testing, but further studies are required for more complete understanding of the relationship between mutations and susceptibility; (3) guidelines for referral and education are needed to establish clinical testing in a Clinical Laboratories Improvement Act (CLIA)—certified laboratory; and (4) a North American MH *RYR1* Mutation Panel was not changed from the original panel set out in 2002 (Table 37-1).

Fulminant Malignant Hyperthermia

Fulminant MH is rare. Acute episodes of MH depend on four variables: a genetic (perhaps rarely acquired) predisposition, the absence of inhibiting factors, the presence of an anesthetic or nonanesthetic trigger, and the presence of environmental factors that could potentiate the action of one or more of the other three variables.

Anesthetic Triggering

Anesthetic drugs that trigger MH include ether, halothane, enflurane, isoflurane, desflurane, sevoflurane, and depolarizing muscle relaxants, the only currently used of which is succinylcholine. Desflurane and sevoflurane appear to be less potent triggers than halothane and produce a more gradual onset of MH.[228,229] The onset may be explosive if succinylcholine is used. MH-susceptible swine were traditionally screened by induction with a volatile anesthetic, which led to pronounced hind limb rigidity within 5 minutes, frequently sooner.[230] Prior exercise even an hour before induction of anesthesia increased the severity and hastened the onset of rigidity in swine.[230] Similarly, in the new knock-in mouse models, the onset of limb rigidity after commencing exposure to volatile anesthetics is very rapid. There are also several modifying factors that are more likely to be present in humans than in pigs or mice and can alter (or even prevent) the onset of clinical MH. Mild hypothermia and preadministration of barbiturates, tranquilizers, propofol, or nondepolarizing neuromuscular blockers delay or prevent the onset of MH[163,230-232] in MH-susceptible humans, thus making them respond less predictably than swine or MH knock-in mice. There have been many instances in which fulminant MH has been reported in patients who have previously tolerated potent triggers without difficulty.[233] Why this occurs is unknown, but it is likely to be related to prior or concurrent administration of drugs that prevent or delay onset of the syndrome, as described earlier, or unknown environmental influences that help provoke the positive incident. Thus, onset of the syndrome in humans is extremely variable both in initial symptoms and in the time of onset of the syndrome. Its onset is so variable that making the diagnosis in the setting of a clinical anesthetic can be quite difficult. Although not perfect, the clinical grading scale developed by Larach and colleagues[234] is a useful way for clinicians to retrospectively determine whether a patient who responded abnormally to anesthesia is in any way likely to actually have had a clinical MH episode. However, MH is most easily diagnosed prospectively by vigilance, recognizing its signs and symptoms, and knowing how to treat the syndrome.

Table 37-1 Findings of the North American Malignant Hyperthermia Mutation Panel, 2002

Exon	Mutation*	RyR1 Amino Acid Change	No. of Families in North America†	Estimated Incidence in Europe (%)	Phenotype
6	C487T	R163C	2	2-7	MHS, CCD
9	G742A	G248R	2 (11)	2	MHS
11	G1021A	G341R	1	6-17	MHS
17	C1840T	R614C	6 (42)	4-45	MHS

102	T14693C	I4898T	0	Multiple families	MHS, CCD

*Criteria for the 17 mutations: (1) they occur in more than one family in North America or Europe, and (2) previous testing of a sequence variant shows that it is not a polymorphism.
†Data collaboration of the Uniformed Services University of the Health Sciences, Thomas Jefferson University, Wake Forest University, University of California, Davis, and Barrow Neurological Institute indicates those also found in Canada (e.g., for exon 45, four families with the mutation G2434R were found in Canada).
CCD, central core disease; MHS, malignant hyperthermia susceptibility; RyR1, ryanodine receptor type 1.

The two classic clinical manifestations of fulminant MH syndrome may start in one of the following two scenarios.

1. Rigidity after induction with thiopental and succinylcholine but successful intubation, followed rapidly by the symptoms listed after scenario 2
2. Normal response to induction of anesthesia and uneventful anesthetic course until onset of the following symptoms:
   - Unexplained sinus tachycardia or ventricular arrhythmias, or both
   - Tachypnea if spontaneous ventilation is present
   - Unexplained decrease in O_2 saturation (because of a decrease in venous O_2 saturation)
   - Increased in end-tidal P_{CO_2} with adequate ventilation (and in most cases unchanged ventilation)
   - Unexpected metabolic and respiratory acidosis
   - Central venous desaturation
   - Increase in body temperature above 38.8°C with no obvious cause

The usually muted onset of MH (scenario 2) is in most cases detected quickly by the development of tachycardia, increased levels of expired carbon dioxide, and muscle rigidity. It can be delayed for several reasons and may not be overt until the patient is in the recovery room. Once initiated, the course of MH can be rapid. When clinical signs such as increased expired carbon dioxide, muscle rigidity, tachycardia, and fever suggest MH, more than one abnormal sign must be observed before making the diagnosis because according to a meta-analysis of many reported cases, a single adverse sign does not usually indicate MH.[234] The mechanism by which anesthetics and depolarizing muscle relaxants trigger MH is unsolved, *but* it cannot be ignored that they are etiologic agents and that early diagnosis is critical for successful treatment.

During a fulminant MH episode, triggering agents cause affected subjects to undergo a very large increase in aerobic and anaerobic metabolism that results in intense production of heat, carbon dioxide, and lactate and an associated respiratory and metabolic acidosis.[230,235] These reactions markedly alter whole-body acid-base balance and temperature and are magnified as temperature increases because skeletal muscle makes up 40% of the body mass. Whole-body rigidity occurs in almost all susceptible pigs and mice, as well as in most humans. Temperature may exceed 43°C (109.4°F), P_{aCO_2} may exceed 100 mm Hg, and arterial pH (pH_a) may decrease well below 7.00. The increased permeability of skeletal muscle results in increased serum levels of potassium, ionized calcium, CK (although MH-related changes in serum CK do not differ overall from changes in CK observed during surgery[236]), myoglobin, and serum sodium.[230] Sympathetic hyperactivity is responsible for the cardinal sign of MH—tachycardia—which occurs early as an indication of increased metabolism. With metabolic exhaustion, cellular permeability increases along with whole-body edema, including acute cerebral edema. As MH progresses untreated, disseminated intravascular

coagulation and cardiac or renal failure may develop. It is important to note that MH is a disorder of increased muscle metabolism and, despite its name, need not involve increased temperature! For example, if heat loss is greater than production or if cardiac output plummets early, central temperature will not increase.

Awake Triggering: Exercise and Heat

Whether MH can be triggered in humans in the absence of a triggering agent is controversial. Porcine environmental stress such as exercise, heat, anoxia, apprehension, and excitement triggers fulminant MH (see "History").[230,235] These responses are related to muscle movement or to increased temperature. Increased ambient temperature triggers fulminant MH in two strains of MH mice.[190,191] Epidemiologic studies have shown that exercise-induced symptoms, including rhabdomyolysis, occur more frequently in MHS patients[237]; an Arg401Cys *RYR1* mutation was present in three cases of exercise-induced rhabdomyolysis.[216] Other reports are largely anecdotal and relate heat stroke, sudden and unexpected death, unusual stress and fatigue, or myalgias to possible awake MH episodes. Stresses associated with these episodes include exercise and environmental exposure to volatile nonanesthetic vapors.[238-240]

Malignant Hyperthermia–Associated Syndromes

Masseter Spasm ("Thiopental-Succinylcholine or Halothane-Succinylcholine Rigidity"). Masseter spasm is defined as jaw muscle rigidity in association with limb muscle flaccidity after the administration of succinylcholine. The masseter and lateral pterygoid muscles contain slow tonic fibers that can respond to depolarizing neuromuscular blockers with a contracture.[241,242] This is manifested clinically on exposure to succinylcholine as an increase in jaw muscle tone, well defined by van der Spek and associates.[243] There is a spectrum of responses: a tight jaw that becomes a rigid jaw and then a very rigid jaw (Fig. 37-5). This jaw rigidity may occur even after pretreatment with a "defasciculating" dose of a nondepolarizing relaxant. If there is rigidity of other muscles in addition to trismus, the association with MH is absolute; anesthesia should be halted as soon as possible and treatment of MH begun. However, in more than 80% of patients with trismus but no rigidity of other muscles, it is a variant found in normal patients. If trismus occurs, proper monitoring should include end-expired CO_2, examination for pigmenturia, and arterial or venous blood sampling for CK, acid-base status, and electrolyte levels, particularly potassium. Although scientifically unproven, it is thought that the initial tightness of the jaw and its duration may predict the gravity of the response. For patients with "jaws of steel," the procedure should be halted, especially if the condition persists for more than several minutes. If the jaw is slightly resistant to opening, the anesthesiologist may continue anesthesia with proper monitoring. If the jaw is moderately tight and distinctly a problem, there are two choices: halt the procedure or continue with nontriggering agents. Any suggestion of MH should prompt MH therapy, including administration of dantrolene.

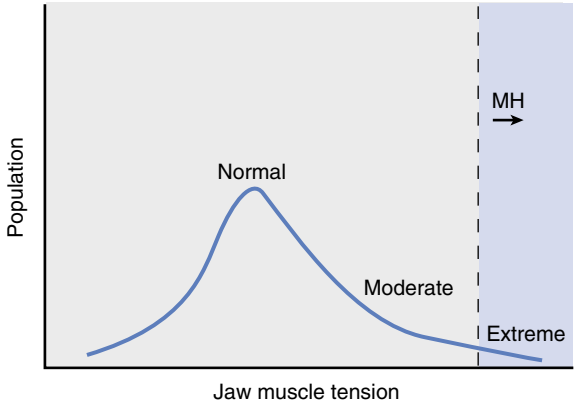

Figure 37-5 Succinylcholine usually increases jaw muscle tone slightly. In some patients this increase is moderate, and in very few, the effect is extreme (i.e., "jaws of steel"). As many as 50% of this latter group may be susceptible to malignant hyperthermia (MH). Somewhere in the area of the declining curve is the boundary for the MH population.

Diagnosis in the Operating Room and Postanesthesia Care Unit

As stated earlier, fulminant MH is rare, and early signs of clinical MH may be subtle. These signs must be distinguished from other disorders with similar signs (Box 37-1). When the diagnosis is obvious (i.e., fulminant MH or succinylcholine-induced rigidity with rapid metabolic changes), marked hypermetabolism and heat production occur, and there may be little time left for specific therapy to prevent death or irreversible morbidity. If the syndrome begins with slowly increasing end-tidal CO_2 (defined earlier), specific therapy can await a complete clinical workup before treatment. In general, MH is not expected to occur when no triggers are administered (see "Anesthesia for Susceptible Patients"). When volatile anesthetics or succinylcholine is used, MH should be suspected whenever there is an unexpected increase in end-expired CO_2, undue tachycardia, tachypnea, arrhythmias, mottling of the skin, cyanosis, increased temperature, muscle rigidity, sweating, or unstable blood pressure. If any of these occur, signs of increased metabolism, acidosis, or hyperkalemia must be sought. Analysis of arterial blood gases demonstrates metabolic acidosis and may show respiratory acidosis if the patient is unable to increase ventilation as metabolism increases. O_2 and CO_2 change more markedly in the central venous compartment than in arterial blood; therefore, end-expired or venous CO_2 levels more accurately reflect whole-body stores. Venous carbon dioxide, unless the blood drains an area of increased metabolic activity, should have P_{CO_2} levels of only about 5 mm Hg greater than that of expected or measured $Paco_2$. In small children, particularly those without oral food or fluid for a prolonged period, the base deficit may be 5 mEq/L because of their smaller energy stores. Any patient suspected of having an MH episode should be reported to the North American Registry via the rare disease protocol (American Medical Record Association [AMRA]), available from the MHAUS website at http://www.mhaus.org/.

Box 37-1 Mimics of Malignant Hyperthermia Disorder

Alcohol therapy for limb arteriovenous malformation
Contrast dye
Cystinosis
Diabetic coma
Drug toxicity or abuse
Environmental heat gain more than loss
Equipment malfunction with increased carbon dioxide
Exercise hyperthermia
Freeman-Sheldon syndrome
Heat stroke
Hyperthyroidism
Hypokalemic periodic paralysis
Intracranial free blood
Muscular dystrophies (Duchenne's, Becker's)
Myotonias
Neuroleptic malignant syndrome
Osteogenesis imperfecta
Pheochromocytoma
Prader-Willi syndrome
Rhabdomyolysis
Sepsis
Ventilation problems
Wolf-Hirschhorn syndrome

Treatment

Acute therapy for MH can be summarized as follows: (1) Discontinue all anesthetic agents and hyperventilate with 100% oxygen. Normal ventilation is that required to remove metabolic carbon dioxide. With increased aerobic metabolism, normal ventilation must increase. However, carbon dioxide production is also increased because of neutralization of fixed acid by bicarbonate; hyperventilation removes this additional CO_2. (2) Administer dantrolene (2.5 mg/kg intravenously [IV] to a total dose of 10 mg/kg IV) every 5 to 10 minutes until symptoms subside. (3) Administer bicarbonate (2 to 4 mEq/kg IV) to correct the metabolic acidosis with frequent monitoring of blood gases and pH. (4) Control fever by administering iced fluids, cooling the body surface, cooling body cavities with sterile iced fluids, and if necessary, using a heat exchanger with a pump oxygenator. Cooling should be halted at 38°C to 39°C to prevent inadvertent hypothermia. (5) Monitor urinary output and establish diuresis to protect the kidney from probable myoglobinuria. (6) Further therapy is guided by blood gases, electrolytes, temperature, arrhythmia, muscle tone, and urinary output. Treatment of hyperkalemia with glucose and insulin should be slow. The most effective way to lower serum potassium is reversal of MH by effective doses of dantrolene. (7) Analyze coagulation studies (e.g., international normalized ratio, platelet count, prothrombin time, fibrinogen, fibrin split or degradation products).

Discontinuation of the trigger may be adequate therapy for acute MH if the onset is slow or if exposure was brief. Dantrolene is packaged in 20-mg bottles with sodium hydroxide for a pH of 9 to 10 (otherwise it will not dissolve) and with mannitol (converts the hypotonic solution to isotonic). The initial dose should be 2.5 mg/kg dantrolene reconstituted in sterile water and administered intravenously. Dantrolene *must* be reconstituted in sterile water rather than salt solutions or it will precipitate. Dantrolene has a half-life of at least 10 hours in children and adults.[244,245] At therapeutic concentrations, dantrolene may prolong the need for intubation and assisted ventilation. Aside from cholestasis during long-term (>3 weeks) therapy, dantrolene has no serious side effects.

The clinical course will determine further therapy and studies. Dantrolene should probably be repeated at least every 10 to 15 hours (its half-life) for at least one and possibly several doses. Recrudescence of MH can approach 50%, usually within 6.5 hours.[246,247] When indicated, calcium and cardiac glycosides may be used safely. They can be lifesaving during persistent hyperkalemia. Permanent neurologic sequelae, such as coma or paralysis, may occur in advanced cases, probably because of inadequate cerebral oxygenation and perfusion for the increased metabolism and because of the fever, acidosis, hypo-osmolality with fluid shifts, and potassium release. Slow voltage-gated calcium channel blockers do not increase porcine survival.[248,249] If uncertain at any time, the physician should contact the MH Hotline to verify treatment and report the case with an AMRA form.

Anesthesia for Susceptible Patients

Safe anesthetics consist of nitrous oxide, barbiturates, etomidate, propofol, opiates, tranquilizers, and nondepolarizing muscle relaxants. Potent volatile anesthetics and succinylcholine must be avoided, even in the presence of dantrolene. There are anecdotal reports that some human patients have experienced a hypermetabolic state despite these precautions, but they have always responded favorably to the administration of intravenous dantrolene. Preoperative dantrolene is never needed because the use of nontriggering agents is almost always associated with uneventful anesthesia. Regional anesthesia is safe and may be preferred. Amide anesthetics such as lidocaine were once considered dangerous in susceptible patients because they were thought to induce or worsen muscle contractures in vitro as a result of their effect of increasing calcium efflux from the SR. Porcine and human studies have consistently demonstrated the lack of danger of amide anesthetics. Before use for MH-susceptible patients, anesthetic machines may be "cleansed" of potent volatile agents by removal or sealing of the vaporizers, changing the soda lime, perhaps replacing the fresh gas outlet hose, and using a disposable circle with a flow of 10 L/min for 5 minutes.[250,251]

The anesthesiologist should confidently discuss anesthetic care with MH-susceptible patients and assure them that all will be done to avoid difficulties with MH and that the appropriate drugs, knowledge, and skills are immediately at hand if any problems occur. Many of these patients have undergone procedures uneventfully, such as dental analgesia and obstetric anesthesia, before the diagnosis of susceptibility was made. The patient can enter the therapeutic environment in a reassured, relaxed, and

comfortable state. Outpatient procedures are feasible in most environments; the time of discharge depends on the usual outpatient criteria.

Any facility using MH triggers on an inpatient or outpatient basis should have dantrolene available immediately.

Evaluation of Susceptibility

Evaluation of susceptibility includes a history and physical examination to detect any subclinical abnormality. A genealogy with specific information about anesthetic exposure and agents can estimate the likelihood of exposure to triggering agents. Blood CK values, when determined in a resting, fasting state without recent trauma, reflect muscle membrane stability. When the CK level is elevated in a close relative of a person with known MHS, the relative may be considered to have MHS without contracture testing. If the CK level is normal on several occasions, there is no predictive value, and contracture studies are necessary. The patient must travel to the test center for surgical biopsy to ensure viability and accurate results. Muscle biopsy contracture studies, performed at about 30 centers around the world, involve exposure to halothane, caffeine, halothane plus caffeine, and ryanodine.[225] 4-Chloro-*m*-cresol may add to precision.[176] It is also important to note that contracture responses are sometimes positive in patients with myopathies that bear no direct relationship to MH and therefore may not indicate susceptibility. Dantrolene must be avoided before biopsy because it masks the response to contracture-producing drugs. After a patient is diagnosed as being MH susceptible, DNA testing for mutations should follow. When a mutation is detected, other relatives with that mutation should be considered to be MH susceptible without the need for an invasive contracture test, and they need not travel to a testing center (see "Genetics").

Advice should be given to susceptible patients. Precautions are necessary in regard to general anesthesia, and triggers include all potent volatile agents and succinylcholine. Awake episodes are uncommon, and if not experienced before diagnosis, they are an unlikely problem. The true predictive value (i.e., percentage of positive results that are true positives) or efficiency (i.e., percentage of all results that are true, whether positive or negative) of contracture testing in determining susceptibility in the general population cannot be estimated because of the selection process that has been used to date for testing (i.e., limited to those with anesthesia reactions who do not have any other muscle disease pathology). False-positive results from cautious interpretation or decreased specificity are masked because the patient will never be exposed to triggering agents. A promising innovative in vivo human application involves physiologically based microdialysis infusion of caffeine or halothane into muscle of MH-susceptible patients to trigger exaggerated localized changes in acid-base balance.[252-256] White blood cells express MH mutations and provide a substrate for genetic analysis.[257-261] Nuclear magnetic resonance has promise,[262,263] but it is difficult to standardize a stress, such as forearm ischemia, that can differentiate susceptible from normal tissue.

Summary

MH is a subclinical myopathy featuring an eerie and erratic metabolic mayhem that is unmasked on exposure to potent volatile anesthetics or succinylcholine. Skeletal muscle acutely and unexpectedly increases its myoplasmic Ca^{2+} concentration, thereby leading to increased oxygen consumption and lactate production and resulting in greater heat production, respiratory and metabolic acidosis, muscle rigidity, sympathetic stimulation, and increased cellular permeability. MH-susceptible skeletal muscle differs from normal muscle in that it is always closer to loss of control of Ca^{2+} concentration within the muscle fiber, and it can involve a generalized alteration in cellular or subcellular membrane permeability. This is an EC coupling defect resulting from an alteration in protein-protein interaction in the CRU. It is a homozygous, single point mutation of *RYR1* in swine and a heterozygous disorder in humans, in whom there may also be a modification of RyR1 protein function by interacting structures, membranes, or enzymes. Diagnosis rests on acute awareness of the signs and symptoms of this syndrome, of which hyperthermia is a late sign. Specific treatment is administration of dantrolene to lower muscle Ca^{2+} levels; symptomatic treatment consists of reversal of the acid-base and temperature changes. Evaluation of affected families is guided by analysis of drug-induced muscle contractures (by European IVCT and North American CHCT protocols) and genetic testing of DNA samples. General or regional anesthesia is safe for patients susceptible to MH, provided that care is taken to specially prepare the anesthesia machine and avoid all potent volatile anesthetics and succinylcholine if a general anesthesia technique is chosen. Research on MH has yielded insight into the physiology of metabolism and into the molecular biology of genetic muscle disorders. Challenges remaining include identification of all genetic mutations responsible for human MH, elucidation of the mechanism that links exposure to subsequent loss of control of Ca^{2+}, development of noninvasive and nondestructive testing for susceptibility, and determination of the mode of action of dantrolene.

38 Fundamental Principles of Monitoring Instrumentation

Key Points

1. Accuracy and precision are different. Accuracy is how close a value is to the true value. Precision is how repeatable the measurements are. An inaccurate, but precise monitor can be recalibrated to be accurate, but an imprecise monitor cannot be improved.
2. Filtering can improve the signal display, but it also can result in smoothing and loss of information.
3. A signal can be extracted from noise by repeated measurements because the noise is random over time, but the signal is not.
4. Electrical signals can be converted from analog to digital. Conversion can introduce some artifacts, but can allow for greater storage and analysis capabilities.
5. Invasive pressure monitors are affected by damping and resonance. Damping leads to distortion, signal loss, and reduction of peak values. Resonance can lead to amplification and overestimation of the peak value.
6. Pulse oximetry combines analysis of optical plethysmography and absorption analysis with empirical data to produce an estimate of Sao_2.
7. Wavelength and frequency are related to the speed of the wave by the following formula: speed = wavelength × frequency. Shorter wavelengths improve the resolution of light and ultrasound measurements.
8. Flow measurements are among the most difficult to obtain and usually involve indirect measures. (For example, a temperature change or pressure decrease is measured, and a flow value is derived. A small error in the initial measurement leads to a much larger error in the derived flow value.)

Why Fundamental Principles Are Important

Patient monitoring has been a key aspect of anesthesiology since its beginnings as a medical specialty. As anesthesiology has grown more sophisticated and complex, so have the monitors and the data that they produce. The anesthesiologist's senses of sight, hearing, and touch, at first expanded with the stethoscope, sphygmomanometer, and electrocardiograph, are now supplemented by the pulse oximeter, expired gas analyzer, evoked potential monitor, and transesophageal echocardiograph, to name a few. The complexity of some of these devices can be intimidating, and the anesthesiologist may be tempted to regard them as incomprehensible "black boxes" that provide clinical data. To do so, however, would be to shirk an important part of the anesthesiologist's clinical responsibility. Anesthesiologists must be able not only to understand and interpret the data from the monitors, but also to anticipate and recognize errors associated with their use. Anesthesiologists cannot accomplish this goal without understanding how these devices work.

This chapter provides an understanding of the scientific principles underlying the design and function of the most commonly used monitors. Some concepts of basic physics are defined first, followed by more detailed descriptions of the principles and their monitoring applications. The text and figures explain these principles predominantly in a qualitative manner. For readers desiring a more quantitative explanation, the relevant physics and equations are provided in the appendices to this chapter.

Basic Principles

Nature of Physics and Measurement

Physics is the science of matter and energy and interactions between the two—that is, it is the study of everything in the physical universe. Physics encompasses everything from the motions and inner workings of the atom to those of galaxies. Physics is quantitative, and mathematics is the language of physics. Newton and Leibnitz invented "the calculus" as a mathematical tool for

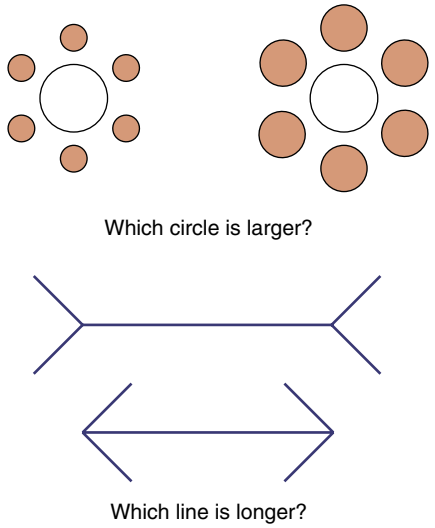

Figure 38-1 Optical illusions. We perceive the circles to be different sizes because we infer the size by relative dimension. The closeness of the smaller circles makes the inner circle appear smaller, and vice versa. The lines appear to be different sizes because we use straight-line perspective to estimate size and distance. This illusion reportedly does not work in cultures where straight lines are not used. Our internal perceptions lead us to err in estimating size and length. In the same way, the internal programming of our monitors can lead us to misinterpret results.

expressing and studying the laws of physics. Our monitors are also quantitative. Before we can discuss and understand the complexity of modern anesthetic monitors, we must quantitatively define what we are attempting to measure and understand the limitations of measurement.

We measure and monitor mass and energy: how much of a substance is present and in what energy state. Much of what we desire to monitor is outside the range of human physical senses. We must make measurements in this insensible realm with devices that enhance or extend our senses. Just as the senses have limitations and can be "fooled" under certain circumstances (Fig. 38-1), our physiologic monitors are limited by their design and can be fooled under some conditions. Intelligent users of these devices must understand their basic design assumptions to predict when they are likely to produce erroneous data.

Accuracy and Precision of Measurements

All measurements have errors. Error is usually determined by the comparison of a measurement with a "gold standard" of that measure. All measurements, even the so-called gold standards, are subject to errors with respect to reproducibility. From a clinician's perspective, a physiologic measurement is dependable only if it is accurate to the degree required for clinical decision making.

Systemic blood pressure can be measured in several ways. We can listen to Korotkoff sounds by the use of a sphygmomanometer cuff and stethoscope; we can rely on an oscillometric automated noninvasive blood pressure device, or if we need continuous measurement, we may place an intra-arterial cannula.[1] Each of these techniques provides slightly different arterial blood pressure values, and each has different sources of error. Our choice of method may be determined by accuracy or by our needs for the frequency of the data and the ease of retrieving these data. An automatic oscillometric device is usually chosen over manual auscultatory measurements for ease of acquisition and reproducibility. Two individuals taking auscultatory blood pressure measurements may hear the Korotkoff sounds at slightly different points and record different blood pressures. The required accuracy of a clinical monitor is determined by the smallest change in the measured variable that could affect a clinical decision. The requirements for "absolute accuracy" (is the measured value correct?) may be different from the requirements for "relative accuracy" (does the measured value follow trends?).

A pulse oximeter estimates arterial hemoglobin oxygen saturation by measuring light absorbance. The pulse oximeter saturation estimate, Spo_2, is compared with the hemoglobin oxygen saturation determined from analysis of an arterial blood sample by a laboratory carbon monoxide oximeter, Sao_2. Some errors are associated with arterial blood sampling and in vitro analysis of the sample by the carbon monoxide oximeter. Nevertheless, the carbon monoxide oximeter is considered to be the gold standard in this comparison of methods.

The pulse oximeter's saturation value can be compared with that of the carbon monoxide oximeter by the determination of bias and precision, as recommended by Bland and Altman (Fig. 38-2).[2] Bias is the average difference between simultaneous values from the two methods, or the systematic error. If a pulse oximeter reads an average of 5% higher than the carbon monoxide oximeter, it has a bias of 5%, and we can adjust for that systematic error by recalibrating the device. Precision is the standard deviation of the difference between the two measurements, and it quantifies the random error, or "scatter." A higher value for precision indicates a larger random error. (This statistic may be more appropriately called "imprecision.") If the random error is too large, the device may not be clinically useful. We can adjust for systematic error (bias) by recalibration, but there is no way to adjust for random error.

Measurement of Mass

Measurement is the determination of a physical quantity. A "dimension" is a specific category or type of physical quantity, such as mass, length, time, energy, or any of their derivatives. Units are specific ways of measuring a given dimension. Examples of units are the meter (length), second (time), kilogram (mass), ampere (current), and degree Kelvin (temperature). Describing a measurement without defining the unit is meaningless. A 30° day in Fahrenheit is literally freezing; a 30° day in Celsius is hot. Units can be base units or derived units. There are seven base units (meter, kilogram, second, ampere, degree-Kelvin, mole, and candela) in the SI (*Système International* [International System of Units]) system used in science, from which multiple other units can be derived.

When we "weigh" a patient, we are determining the force of gravity acting on the patient's mass. We generally mean this to be on the earth's surface, but the concept of weight is applicable to other locations. (On the surface of Jupiter, a 70-kg man would weigh 12 times his Earth weight, but his mass would still be 70 kg.) Because force = mass × acceleration due to gravity (Newton's second law), we *balance* the force on the patient with a known mass to determine the patient's "weight" (the SI units of force or weight are "Newtons") and mass (kg) (Fig. 38-3). The concept of balancing forces applies to multiple other monitoring

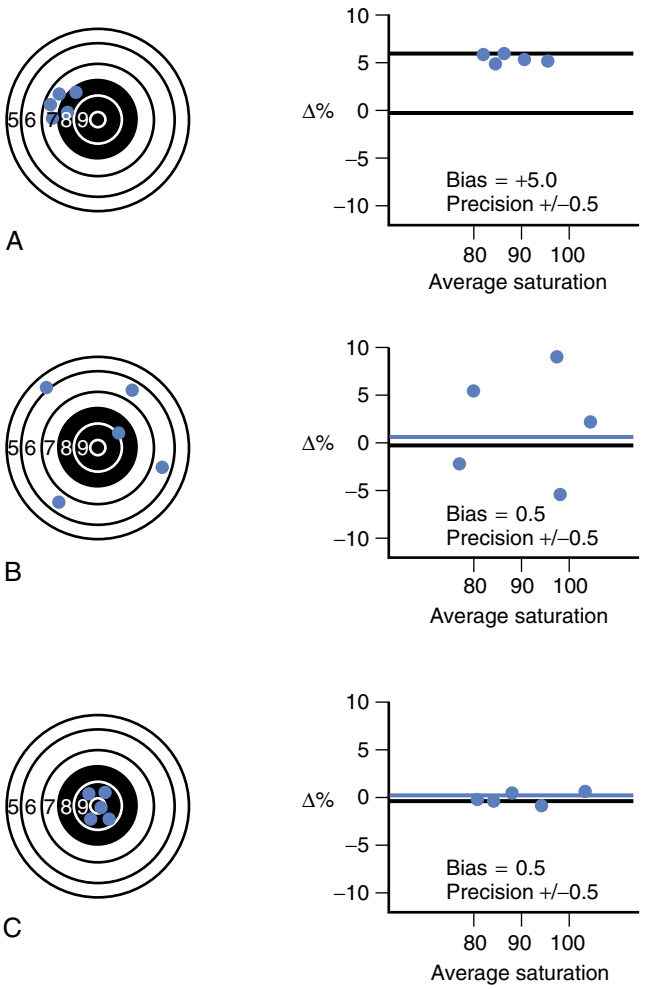

Figure 38-2 Accuracy and precision. The bias plot is a way to compare two different methods of measuring the same variable. **A-C,** Examples are plotted above on the right for saturation values, blood analysis versus pulse oximetry. It is a plot of the difference between the two measurements being compared versus the average of those two measurements. **A,** If one method constantly measures slightly higher than the other by a consistent value, it has a positive bias. If it has only slight variation around that bias, it is said to have very low random error (or precision, which equals the standard deviation of the differences). **B,** The values are randomly scattered, such that the average difference is near zero, but the precision value is very large. This large random error makes the device unusable because calibration would not improve this random error. **C,** The optimal device has a bias near zero and a very small precision (standard deviation of the differences). No amount of calibrating or "sighting in" could cause the device in **B** to become more accurate because the error is randomly scattered.

modalities. When we measure the central venous pressure using a simple manometer, we are observing the balance of forces between the patient's venous pressure and the force of gravity acting on a fluid column (Fig. 38-4). When the same pressure is measured electronically, we are "balancing" a Wheatstone bridge (a system of resistors used to determine an unknown resistance) (Fig. 38-5).

Measurement of Energy

Energy can exist in many different forms. Even matter is related to energy, mathematically defined by Einstein's famous $E = mc^2$

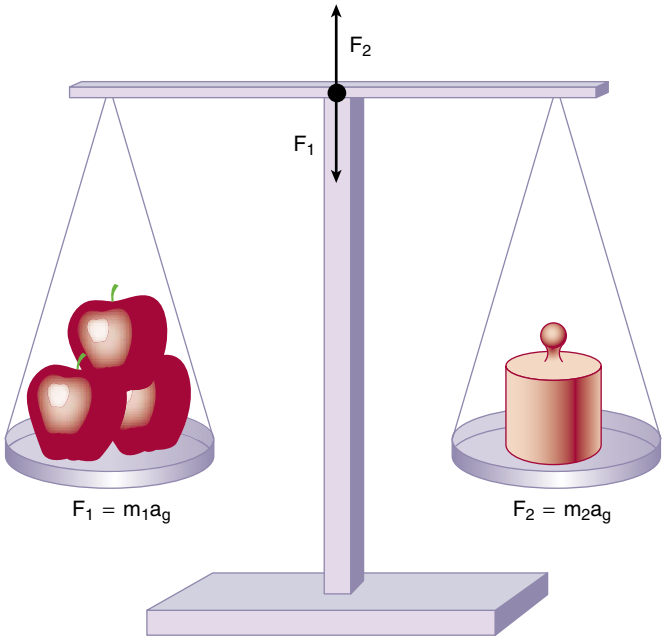

Figure 38-3 Balance. A scale is in balance when the forces are equal and in opposite directions. The force of gravity on the unknown mass of fruit is balanced by the known standard masses on the opposite side of the balance. $F_1 = F_2$, hence $m_1\ a_g = m_2\ a_g$; because $a_g = a_g$, $m_1 = m_2$ (a_g = acceleration due to gravity).

equation; that is to say, matter and energy are different forms of the same "stuff." In the absolute sense, usually reserved for thermonuclear weapons, atomic reactors, and the sun, matter can be converted into energy, and vice versa. If a 1-kg mass were completely converted to energy by means of $E = mc^2$, it would yield 8.987×10^{16} J (Table 38-1).The energy of motion is described as kinetic energy ($KE = \frac{1}{2}\ mv^2$). Temperature is a form of kinetic

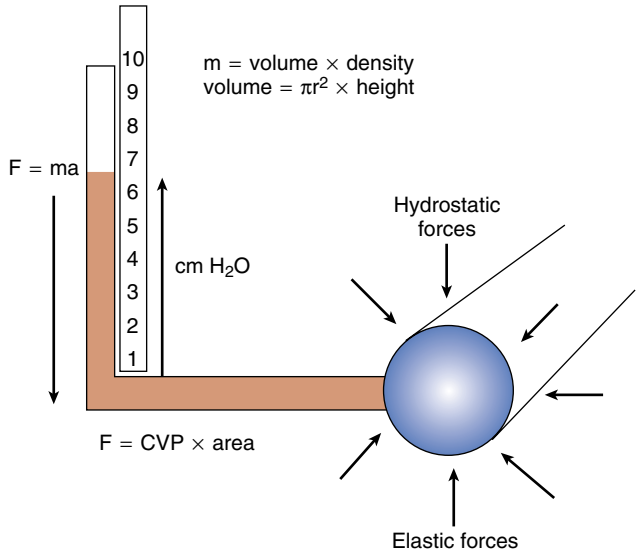

Figure 38-4 Manometer. A water manometer uses a balance of forces. In this case, the downward pressure of the fluid, as determined by its density and height, balances the upward pressure of the central venous system, caused by hydrostatic and elastic recoil forces. CVP, central venous pressure; F, force.

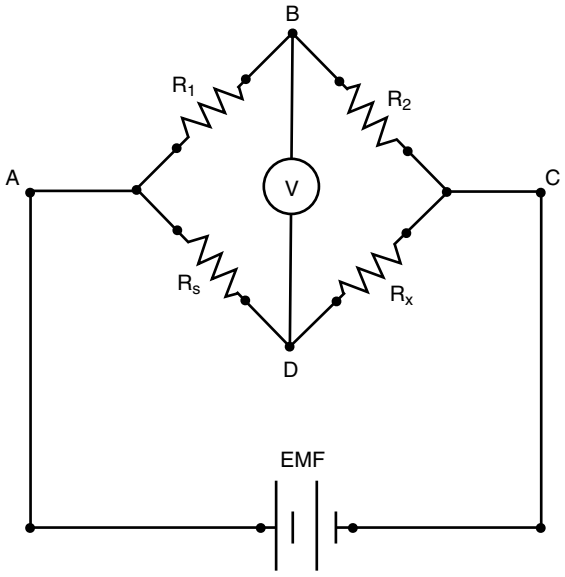

Figure 38-5 Wheatstone bridge. A Wheatstone bridge is an electronic circuit designed so that an unknown resistance can be calculated by knowing two sets of variables: (1) the voltage drop across the bridge and (2) the other resistances in the circuit (see Appendix 3).

energy at the molecular level. Acoustic energy (sound) is a wave of pressure energy transmitted through matter. Light is a form of electromagnetic energy. Potential energy is stored energy and can be of many forms, including gravitational, chemical, pressure, and electromagnetic. The fundamental law of conservation of energy (energy and matter can neither be created nor destroyed, only changed from one form to another) is at the core of understanding many anesthetic monitors.

Table 38-1 Comparison of Energy Levels of Common and Uncommon Events

Event	Energy
1-kg mass falling 1 m on Earth	9.8 J
Heart beat	10 J (at rest, 60 beats/min, 10 W)
Internal defibrillation for ventricular fibrillation	30 J
Maximum output of surface defibrillator	360 J
1 kcal	4186 J
Car battery	1.8 mJ = 1.8×10^6 J
1 kg of fat	3.8×10^7 J
Ton of TNT	4.2×10^9 J
Atomic bomb (Hiroshima)	15 kilotons = $15 \times 10^3 \times 4.2 \times 10^9$ J = 6.3×10^{14} J
Hydrogen bomb	1 megaton = 4.2×10^{15} J
1 kg converted completely to energy	8.987×10^{16} J
The sun (4.2×10^9 kg matter/sec)	3.8×10^{26} J/sec

Signal Processing and Information Theory

When a quantity varies over time, it can be said to contain a "signal." Recording of vital signs and patient data, first begun a century ago by Cushing,[3] is a primitive form of signal analysis. To quote Cushing[4]:

> *In all serious or questionable cases the patient's pulse and blood-pressure, their usual rate and level having been previously taken under normal ward conditions, should be followed throughout the entire procedure, and the observations recorded on a plotted chart. Only in this way can we gain any idea of physiological disturbances—whether given manipulations are leading to shock, whether there is a fall of blood-pressure from loss of blood, whether the slowed pulse is due to compression, and so on.*

Often the signals (the energy or concentration of matter) we are interested in monitoring are too small for our senses to define changes adequately. We must either concentrate or amplify the signal. Often, this information is "transduced" or changed from one form to another for amplification and processing. An old-style gramophone is a good example: The information stored in the shape of the record groove moves a needle attached to a mica diaphragm (the reproducer), which is connected to a sound horn. The mechanical vibrations are reproduced as longitudinal sound waves. These sound waves enter the human ear, contact onto the ear drum, causing it to vibrate, which moves the ossicular chain, resulting in an amplification of the pressure at the oval window, transmitted through the fluid of the inner ear where the appropriate hair cell resonates and generates a neural signal (transduction) (Fig. 38-6). This process is analogous to the process by which our arterial pressure transducers work (Fig. 38-7).

Data Processing

When an analog signal (e.g., voltage versus time) is amplified, the background noise and the desired signal are amplified (Fig. 38-8). Various techniques can be used to enhance the signal-to-noise ratio. Most pulse oximeters assume that a patient's pulse rate is between 30 and 300 beats/min. The instrument filters out any pulsations that occur at frequencies less than 30 or greater than 300 (see the section on alternating current, capacitors, and impedance and Fig. 38-25). Filtering can remove the noise that is outside of this frequency range, improving our ability to discern the signal of interest. Improper filtering can destroy the true signal. In some cases, a desired periodic signal can be repeated and summated, and the accompanying random noise becomes a smaller fraction of the signal. Evoked potentials are an excellent example of this process of "ensemble averaging." The evoked response signal for a single stimulus is actually much smaller than the random noise, but this signal is nearly identical after each stimulus. By summing the potentials after many stimuli, we reinforce the evoked response signal, but not the noise (Fig. 38-9).

Finally, the waveform of any periodic signal can be represented by a summation of sinusoidal waves, called a "Fourier

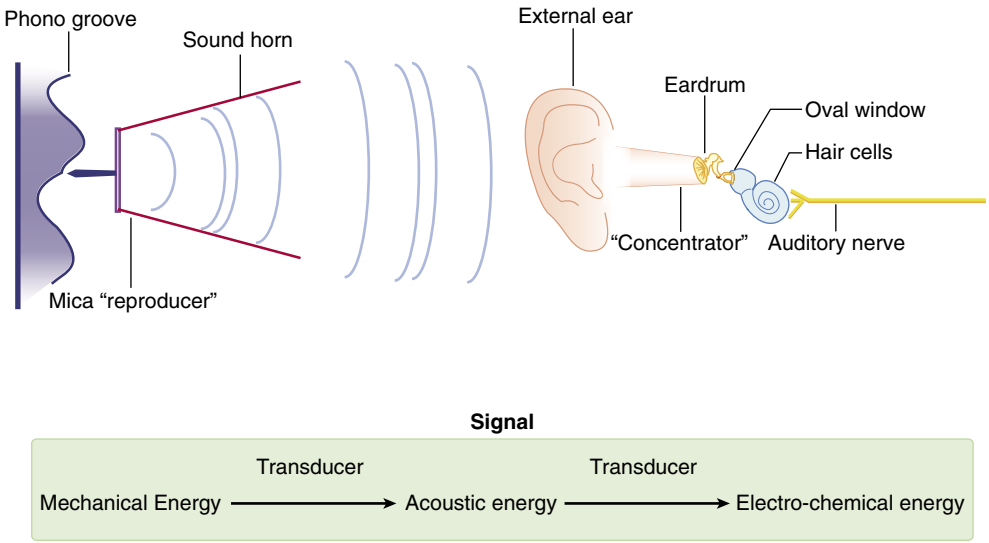

Figure 38-6 Transduction in mechanical and biologic systems. Mechanical energy of the winding mechanism causes the cylinder of the phonograph to rotate. The bumps and curves in the cylinder then move the needle, converting that energy into acoustic energy (a longitudinal wave). The mechanical vibrations are reproduced as longitudinal sound waves. These sound waves enter the human ear, contact the ear drum, causing it to vibrate, which moves the ossicular chain, resulting in an amplification of the pressure at the oval window, transmitted through the fluid of the inner ear where the appropriate hair cell resonates and generates a neural signal (transduction). Loss of hair cells leads to deafness, most commonly in the higher frequency range as one ages. This is analogous to a monitor lacking sensitivity in the desired range.

series" (Fig. 38-10).[5] The component sine waves can be described by their frequency and amplitude (or power, which is proportional to the square of the amplitude). A waveform originally expressed as amplitude versus time is transformed into a plot of power versus frequency (Fig. 38-11). The resulting plot, called the "power spectrum," is a common form for displaying and interpreting some types of waveform data, such as the electroencephalogram (see Chapter 39).

Errors in Signal Analysis

We have all seen movies where car wheels appear to be rotating backward while the car is moving forward. This is the result of a specific type of error, called "aliasing," which occurs when the sampling frequency is too slow to capture the rapid variations of the true signal (Fig. 38-12). Aliasing also can happen with ultrasound, where the display may show echoes from objects that do not actually exist.

In mechanical systems, such as the conventional liquid-filled tubing and pressure transducer for measuring arterial blood pressure, frictional forces can dampen the signal. The signal also can be distorted by resonant amplification, where the energy of the signal is temporarily stored in the compliance of the tubing, and then released (see Appendix 4) (Fig. 38-13). If the display rate is too fast, we also can miss important signals. The systolic pressure variation (alteration in systolic blood pressure with positive-pressure ventilation)[6,7] has been used to determine volume

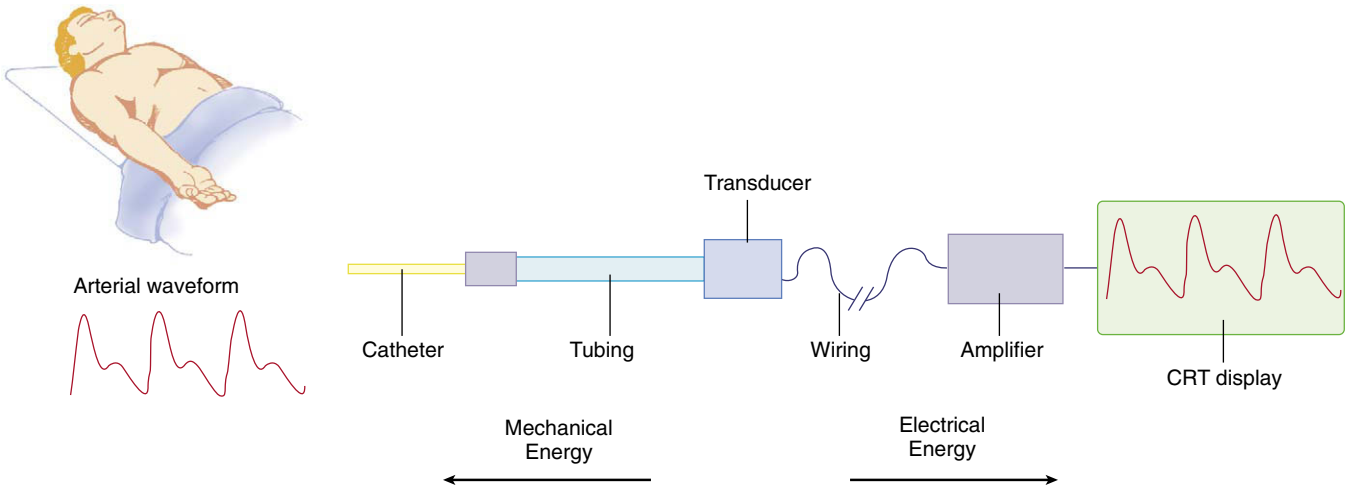

Figure 38-7 Transducer. A transducer changes a signal from one form of energy to another. A common transducer in anesthesia changes mechanical energy (e.g., an arterial pulse) into electrical energy, which is then displayed as time versus amplitude on an LCD or CRT display. Microphones and speakers are also examples of transducers.

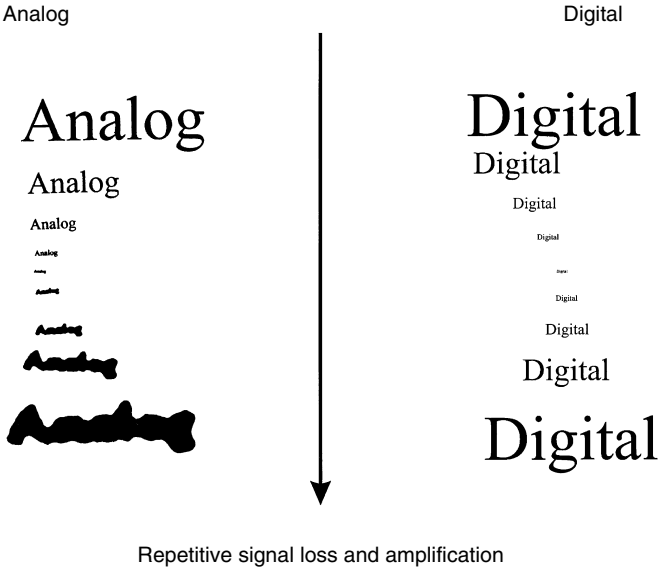

Figure 38-8 Digital and analog signal processing. The analog signal shows distortion and loss of fidelity as it is reduced and then amplified. The digital signal shows no such loss. To create the analog example, a copy machine was used to shrink the text and then enlarge it. For the digital signal, the font size was reduced, the text copied, and the process reversed.

responsiveness in hypotension. Because this change happens much more slowly than the heart rate, and because many displays employ "auto-gain"—that is, they control the size of the display to maintain a constant waveform amplitude (e.g., the plethysmograph display of most pulse oximeters)—the systolic pressure variation has been clinically neglected for many years.

With modern data recording and storage, Cushing's original rationale of correlating changes in patient physiology to intra-

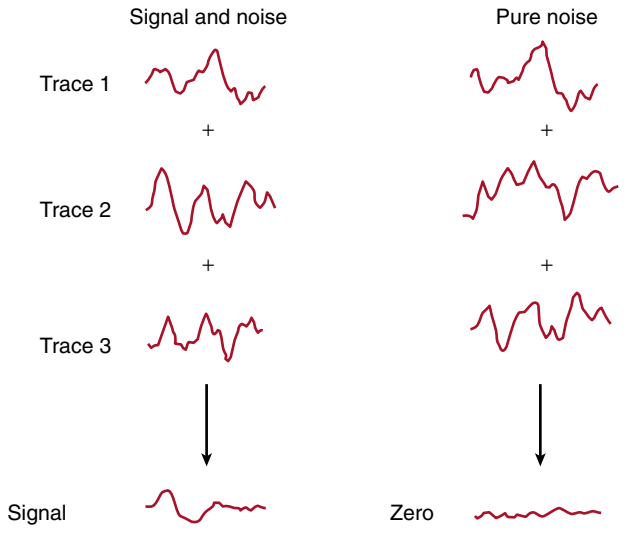

Figure 38-9 Somatosensory evoked potentials. A background signal can be separated from random noise by repeatedly adding the signals. The noise (random) is equally likely to be positive or negative; adding positive and negative yields zero with multiple summations.

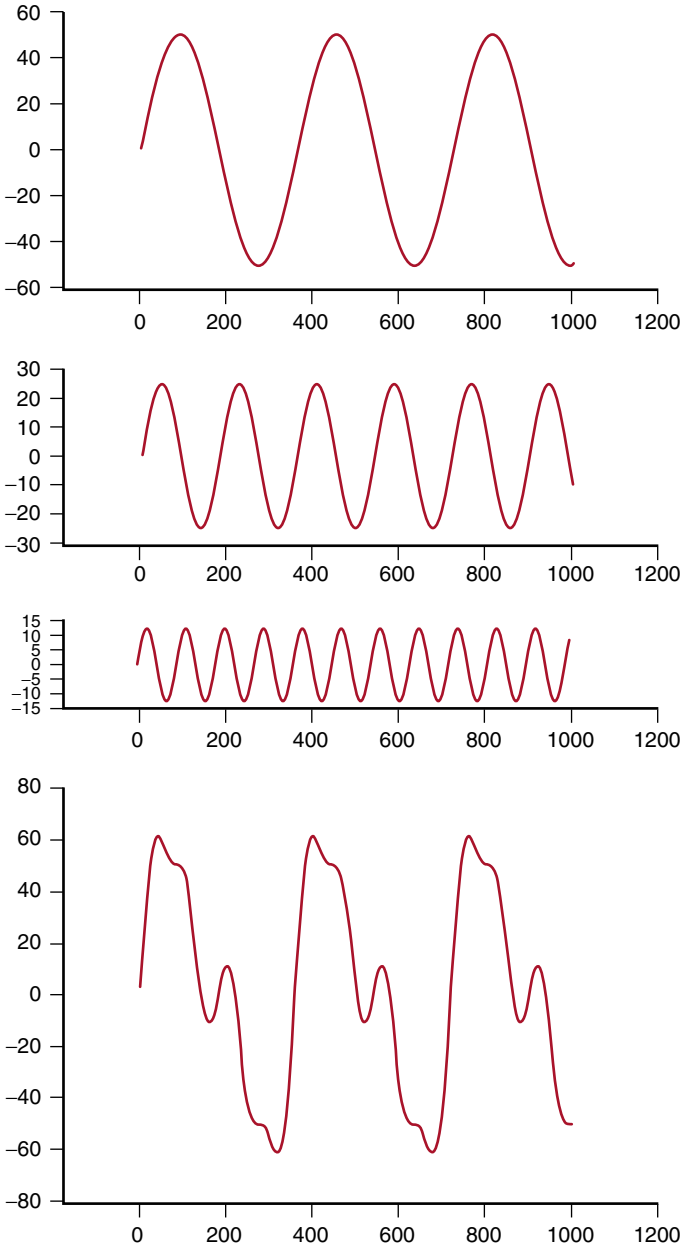

Figure 38-10 Fourier series. This pseudoarterial waveform was generated by adding the three sine waves with the following characteristics, y = 50 sinx, y = 25 sin2x, y = 12 sin4x.

operative events can now be applied to entire populations as well as individuals. The original signal, whether an observed pupillary sign, palpated pulse, transduced pressure, or auscultated breath sound, that was integrated by the anesthesiologist, interpreted (is this real or is it artifact?), and charted (data storage) can now be processed automatically. This point is important because it introduces new possibilities in monitoring (trends, signals, feedback to user) and new pitfalls. Imagine an anesthesia record that would alert you to future potential physiologic issues from currently monitored data and predictive algorithms, that is, an intelligent

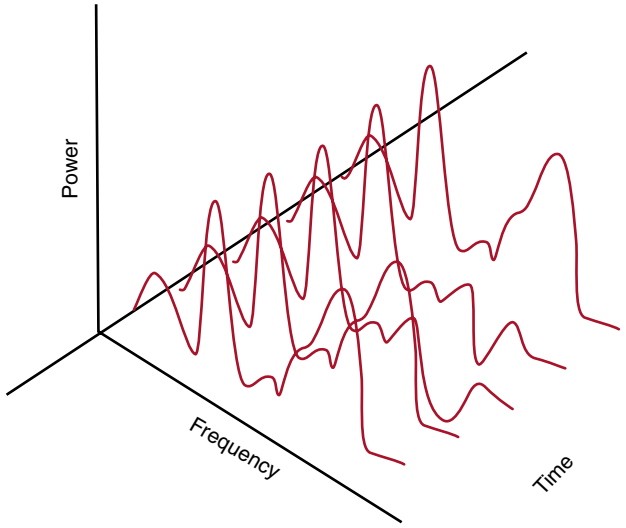

Figure 38-11 Spectral arrays. A compressed spectral array can display the frequency on the *x* axis and power on the *y* axis. A number of these can be aligned with time as a third axis, giving an indication of changes in power over time.

anesthesia record. New problems are introduced by such technology, including security, potential loss of data (loss of not only a single chart or data point, but of all the charts), and erroneous signal processing (imagine a faulty algorithm denying you the very information Cushing sought to use to improve patient care).

Pressure Measurement

Principles of Pressure Measurement

With some of the basics of measurement behind us, we can now work through an example of clinical measurement. As part of a clinical examination, we can note the distention of the jugular vein. What are we really doing? We are visualizing the reflection of light off of the patient's skin changing as the underlying structure (the jugular vein) fills and collapses. But what are the physics of this distention? If we were to insert a clear tube into the vein and hold the tube vertical with respect to gravity, we would observe the mass of blood in the tube raised a certain distance (centimeters) against the force of gravity by the central venous pressure until a balance point is reached. Energy is lost in the work done in raising the fluid column, distending the tubing, and frictional losses. The actual venous pressure is slightly greater than we can reasonably measure. Despite these limitations, a liquid manometer is a simple and effective way to determine central venous pressure.

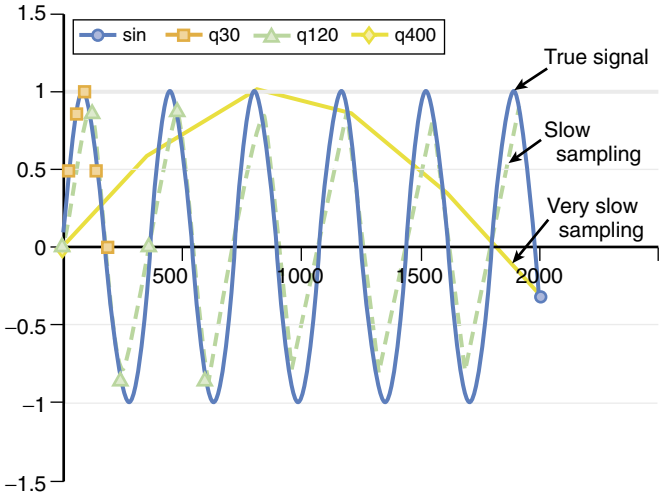

Figure 38-12 Aliasing. Improper sampling leads to an erroneous waveform. A slower sampling rate results in a change in the amplitude and wavelength.

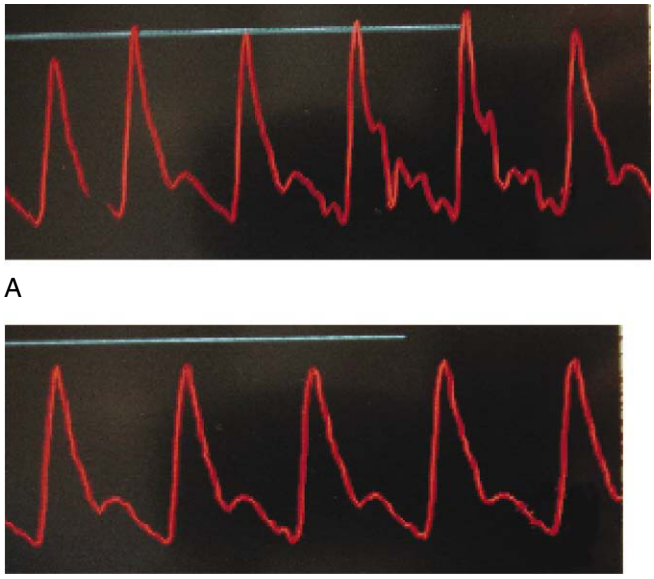

Figure 38-13 Arterial waveform resonance. **A,** A peaked arterial waveform indicating some resonance with overestimation of the systolic blood pressure. **B,** The same patient when damping is added to the system.

The units of pressure measurement can tell us something about how the measurement is made. We commonly define pressure in terms of millimeters of mercury (mm Hg), centimeters of water (cm H_2O), pounds per square inch (psi), or atmospheres (atm). What we have measured in our clear manometer tube is a pressure in centimeters of blood. Given that the content of blood in the tube can vary, we need to have more standard units than centimeters of patient blood. To do so, we must understand the physics of the manometer. The density of a fluid is its mass per unit volume, which has SI units of kilograms per cubic meter (kg/m^3) or, more commonly, grams per milliliter (g/mL). The pressure exerted by a liquid column of height z and density ρ is simply ρgz (see Appendix 2 for derivation). If the manometer liquid is mercury, which has a density of 13,600 kg/m^3 (13.6 g/mL), the manometer pressure in pascals (the SI unit of pressure) is:

$$P\,(\text{Pa}) = 13{,}600 \cdot 9.8 \cdot z\,(\text{m}) = 1.333 \cdot 105 \cdot z\,(\text{m})$$

Because these large numbers are awkward, we often express P in kilopascals (kPa) and z in mm Hg:

$$P\,(kPa) = 0.1333z\,(mm\ Hg)$$

A useful reference for the various pressure units in use today is the pressure of the earth's atmosphere at sea level, called "1 atmosphere" or 1 atm:

$$\begin{aligned} 1\ atm &= 101.3\ kPa \\ &= 760\ mm\ Hg = 29.92\ inches\text{-}Hg \\ &= 14.7\ psi \\ &= 988\ cm\ H_2O \end{aligned}$$

If a fluid-filled catheter is connected to the circulatory system of a patient, the height of the fluid in the manometer determines the mean pressure at the tip of the catheter. If the pressure measured is central venous pressure, we can use these data to infer right ventricular preload. For slowly changing pressures, a water or mercury manometer is simple and dependable (see Fig. 38-4). The manometer cannot respond quickly to rapid changes in pressure because of its inertia; that is, the mass of the liquid column resists rapid changes in height.

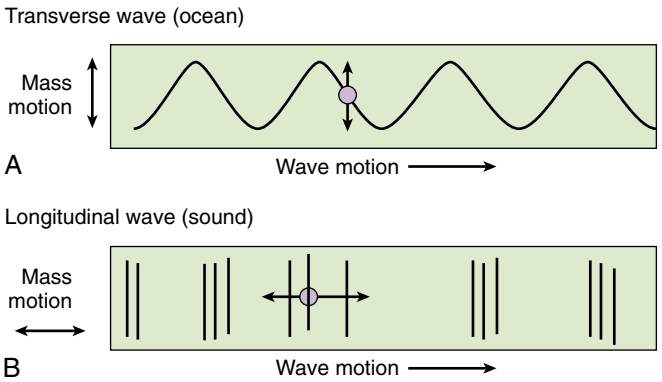

Figure 38-15 Transverse and longitudinal waves. **A,** In transverse waves (e.g., ocean waves), the particles move perpendicular to the motion of the wave. **B,** In longitudinal waves (e.g., sound waves), the particles move back and forth in the direction of the wave. The actual matter in either wave does not move much. The energy transfers without mass transfer. In arterial systems, this can clarify the fact that pressure does not equal flow.

Dynamic Pressure Measurement (Transducer)

Accurate measurement of a rapidly changing pressure signal, such as arterial blood pressure, is more difficult and complex. There are many characteristics of the arterial pressure versus time waveform (Fig. 38-14) that we might wish to determine. Systolic, diastolic, and mean arterial pressures are given by the maximum, minimum, and average pressure values during the cardiac cycle. In addition, we can measure the maximum upward slope of the waveform during systole, which is related to the speed of ventricular ejection. An abnormally rapid downslope after aortic valve closure (indicated by the dicrotic notch) suggests possible aortic insufficiency. The details of the pressure-time waveform and its maxima and minima are important to the clinician. Despite our display of the waveform on a vertical axis, it is important to remember that the arterial pressure is not a transverse wave (similar to a wave on the ocean), but a longitudinal wave (similar to a sound wave or a pulse transmitted through a coiled spring) (Fig. 38-15).

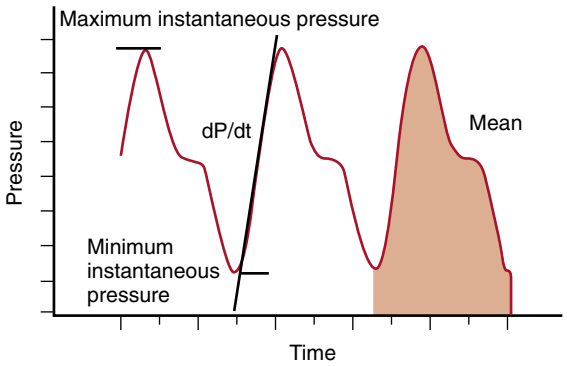

Figure 38-14 Arterial waveform. Systolic pressure is defined as the instantaneous maximal pressure; diastolic, the instantaneous minimum pressure; and mean, the average pressure over a cycle. dP/dT refers to the upstroke of the arterial pressure (i.e., the rate of pressure generation). The mean pressure is estimated as the diastolic plus ⅓ the pulse pressure (systolic-diastolic) when only the systolic and diastolic pressures are known.

A modern pressure transducer is a device that changes either electric resistance or capacitance in response to changes in pressure on a solid-state device. The variable transducer electric resistance is placed in a circuit involving three known resistances (Wheatstone bridge [see Fig. 38-5]; see Appendix 3), and the change in resistance is converted into electric voltage. The moving part of the transducer itself is very small and has little mass. It is not clinically or commercially practical to place the transducer in direct contact with arterial blood (although one manufacturer has done exactly this), so we use a liquid-filled tube to connect the intra-arterial catheter to the external pressure transducer. This system of a fluctuating driving pressure (i.e., the arterial pressure being measured), a liquid-filled tube, and a pressure transducer is mechanically equivalent to the mass-spring harmonic oscillator shown in Figure 38-16. The mass (m) represents the mass of the fluid in the tubing. The spring represents the elasticity of the tubing and transducer. The damper, shown schematically as a piston moving in oil, represents the friction generated by the fluid moving to and fro in the tubing.

A more commonly encountered harmonic oscillator is that of a car driving down a bumpy dirt road (see Fig. 38-16). In this case, the oscillating driving pressure is provided by the bumps in the road, which force the car wheels to oscillate up and down. The car springs are analogous to the compliance of the arterial pressure tubing, and the car's shock absorbers, which oppose motion of the wheel in either direction, are analogous to the friction of the fluid moving back and forth in the fluid-filled tube. Depending on the frequency of the bumps (i.e., driving pressure frequency), the system can either suppress the bumpy road or may initiate dramatically increased oscillations. The frequency of the driving force that causes maximal amplification of the signal is called the natural or resonant frequency (Fig. 38-17). The degree of amplification is directly related to the mass and inversely related to the amount of friction present; for large amounts of

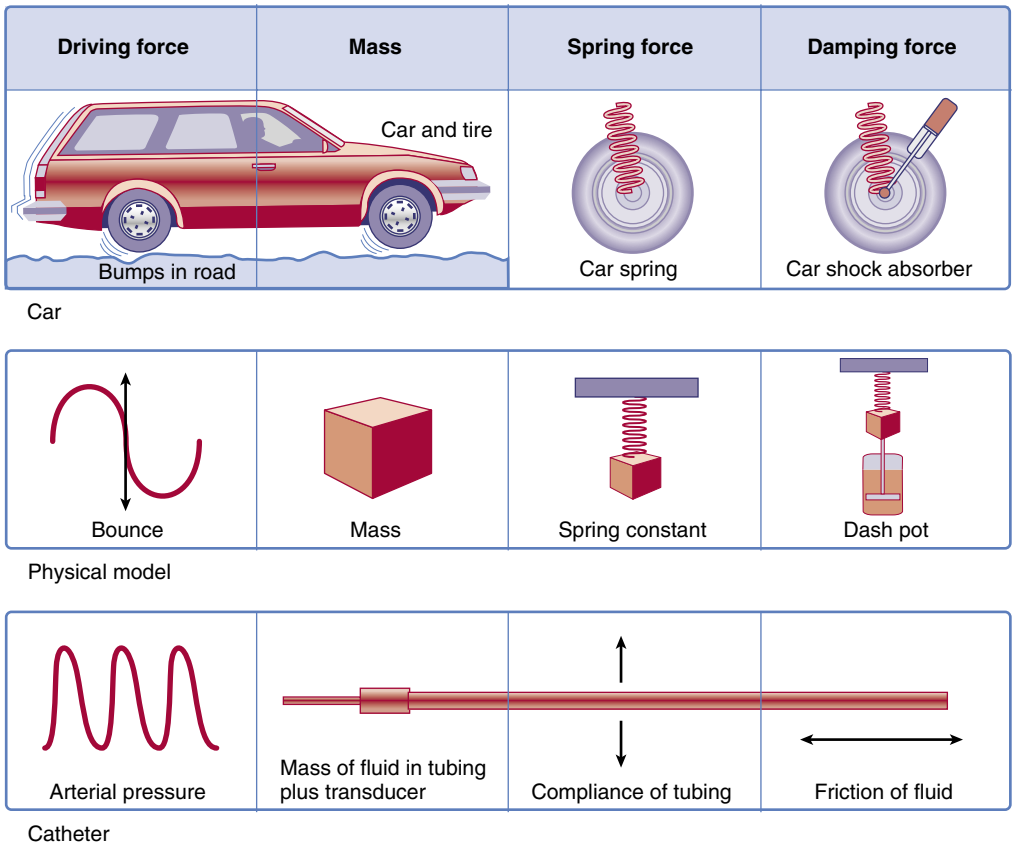

Figure 38-16 Damping and resonance. Pressure measured in an invasive arterial catheter can overshoot or amplify the actual blood pressure. This phenomenon is referred to as the dynamic frequency response of the fluid-filled arterial line and transducer system. This phenomenon has a physical model, which can generate an equation to predict the output pressure response, depending on the frequency of the input pressure and several physical parameters of the system. In the physical model, the driving pressure (the arterial blood pressure) acts on a mass (the fluid within the arterial pressure tubing), pushing it up and down against a spring, which stores energy (the compliant pressure tubing), and a dash pot, which opposes motion in either direction (the resistance of the fluid as it moves to and fro within the pressure tubing). Depending on the input frequency, the output may go through an amplification as it reaches a specific frequency, known as the resonant frequency of the system. There is a common phenomenon noted when a car drives along a bumpy dirt road. In this situation, the driving force is the bumps in the road, which act on the tire. The car spring is equivalent to the compliance to the pressure tubing, and the shock absorber corresponds to the resistance of fluid moving back and forth in the arterial line. The mass of the fluid is analogous to the mass of the front of the car. You may have experienced the phenomenon in which you reach a certain speed as you are driving along a bumpy road when the front of the car starts to oscillate with increasing amplitude. If you speed up or slow down, this phenomenon disappears. The car bounces highest when you have reached the resonant frequency of this harmonic oscillator. (See Appendix 4 for a detailed mathematical description of this process.)

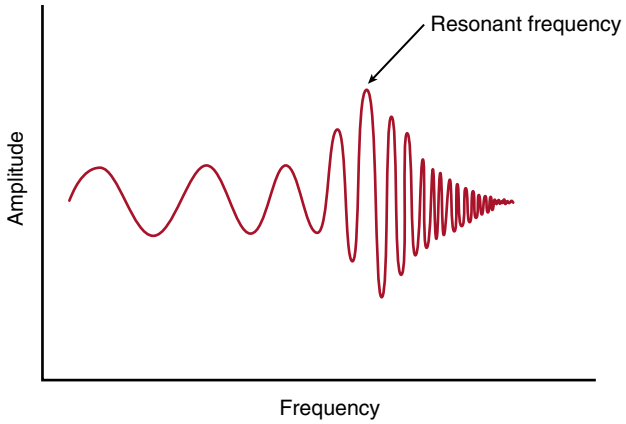

Figure 38-17 Amplitude and frequency. As the frequency increases, the amplification can increase to a maximum, and then the signal becomes attenuated. *(Adapted from Sykes MK, Vickers MD, Hull CJ: Principles of Measurement and Monitoring in Anesthesia and Intensive Care, 3rd ed. Oxford, Blackwell, 1991.)*

friction, attenuation rather than amplification occurs (see Appendix 4).

To visualize this concept intuitively, hang a weight on the end of a rubber band while holding the upper end of the band in your hand. If you move your hand up and down slowly, the weight follows your hand movements almost exactly. As you increase the frequency of your hand oscillations, the weight begins to "lag" behind your hand, and the amplitude of the weight movement begins to increase. As you approach the natural frequency of this simple system, you will observe the phenomenon of "resonance," when the amplitude of the weight motion becomes very large. If you try different rubber bands and weights, you will find that stiffer bands or smaller weights yield higher natural frequencies. The same is true of our fluid-coupled pressure transducer system. Stiffer (i.e., less compliant) tubing or a shorter length of tubing (less mass) produces higher natural frequencies in this system; that is, it requires a much higher pulse rate before amplification.

To minimize the potential of amplification of the real arterial pressure, the system should have noncompliant (i.e., stiff) tubing, and the total mass of liquid in the system should be minimized, which can be accomplished by having small-diameter tubing and as short a length as possible. In most clinical systems, the natural resonant frequency is 10 to 15 Hz, which is much higher than the primary frequency of the arterial waveform (the heart rate is 60 to 120 beats/min or 1 to 2 Hz). The arterial waveform is not a sine wave, however; it is the more complex shape shown in Figure 38-10 and is composed of a summation of sine waves of frequencies that are various multiples of the heart rates—a Fourier series. The higher frequency components of the arterial waveform (higher harmonics) are the ones that are closer to the natural frequency of the system and are amplified. This is why we see a "whip" in the waveform when the peak systolic pressure and the initial upstroke are amplified significantly above the true systolic pressure, even though the heart rate itself is not near the resonant frequency. Theoretically, mean arterial pressure should be the same because this amplification of systolic pressure also produces a reduction in diastolic pressure (see Appendix 4).

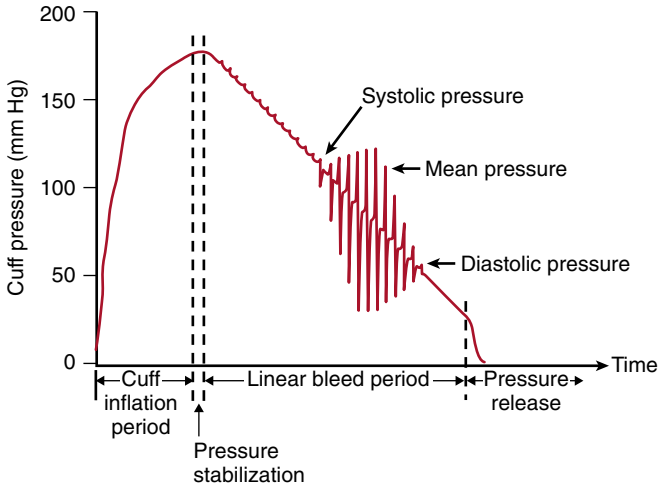

Figure 38-18 Noninvasive blood pressure measurement. Using the signal from the arterial pulse, oscillometric blood pressure measurements are obtained by determining the point at which the signal is first detected, its maximal amplitude, and the signal decay rate. *(Adapted from Ehrenwerth J, Eisenkraft J: Anesthesia Equipment: Principles and Applications. St. Louis, Mosby-Year Book, 1993.)*

Signal-Processed Pressure Measurement (Noninvasive Blood Pressure Monitor)

Systolic pressure can be estimated by noting return of the flow pulse after occlusion of the brachial artery by a cuff. The return of flow can be detected by (1) simple palpation of the radial artery, (2) recording with a Doppler device over the radial artery, or (3) the use of a pulse oximeter. Most anesthesiologists are familiar with the loss of pulse oximeter signal when the noninvasive blood pressure monitor is cycling.

Automated noninvasive blood pressure monitoring devices used in operating rooms employ a more sophisticated application of this principle. These devices monitor the oscillating signal generated in the cuff by the arterial pressure changes. The cuff first inflates to above systolic pressure, at which point the signal and oscillations are abolished. Then the cuff slowly deflates in a stepwise fashion. The pressure at which the oscillating pressure signal first appears is interpreted as the systolic pressure. The signal increases in amplitude as the cuff pressure decreases. The point at which the signal is at maximal amplitude is interpreted as mean arterial pressure. As cuff pressure decreases further, the oscillations drop off rapidly. Diastolic pressure is mathematically inferred from the systolic and mean values (Fig. 38-18).[8]

Errors can be introduced in the same manner as for manual auscultation of Korotkoff sounds: Too small or too large a cuff requires a higher or a lower pressure to occlude arterial flow, and stiff atherosclerotic arteries are resistant to compression. External compression caused by patient motion or the surgeon leaning on the blood pressure cuff can cause pressure oscillations that are not related to arterial pressure and may result in an erroneous reading, most commonly a higher diastolic pressure. Mercury sphygmomanometers are being phased out of use in some countries and hospitals, which leads to questions regarding the accuracy and precision of alternative devices, such as the aforementioned automated noninvasive blood pressure monitors and aneroid sphygmomanometers.[9,10]

Measurements Using Sound Energy (Longitudinal Pressure Wave)

Principles of Sound

Sound waves are small fluctuations in pressure, density, and velocity that can propagate through matter of any form: solid, liquid, or gas (see Fig. 38-15). In contrast to electromagnetic waves such as light (see the section on light), sound cannot propagate in a vacuum. The commonly used unit of sound, the decibel (dB), is not an SI unit, but a logarithmic ratio of the sound energy referenced to 20 μPa (or 0.0002 millibar), the threshold of normal human hearing.

Sound has been used for many years in medical diagnosis and monitoring. It can be used as a diagnostic method in two ways: passive and active. In a passive examination, the sounds generated by the patient are studied. The basic examination of this type uses the stethoscope. In an active examination, acoustic energy is transmitted into the patient, and the resulting interaction of this energy with the patient is analyzed for information. Both types of examination use the same physical principles.

In 1842, Doppler first described the apparent change in pitch of a sound that occurred when either the source of the sound or the listener was moving.[11] This "Doppler effect" now has several applications in patient monitoring, including precordial and esophageal Doppler ultrasound monitoring of local blood velocities or cardiac output.

When a sound source is moving toward the listener, the apparent pitch increases, and vice versa. The exact amount of frequency shift depends on whether the listener or the sound source is moving (Fig. 38-19; see Appendix 7). Because changes in the frequency of sine waves can be measured precisely, the Doppler principle provides a very accurate method of measuring

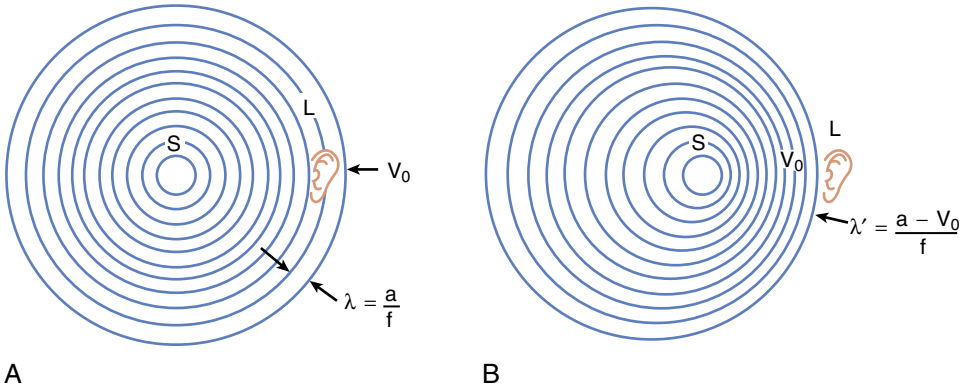

Figure 38-19 Doppler effect. **A,** When a listener is moving toward a stationary sound source, the frequency increases because the listener transverses more waves per unit time than a stationary listener. **B,** When a sound source is moving toward a stationary listener, the wave fronts "stack up," causing an apparent increased frequency.

the velocities of moving sound reflectors. At the high frequencies often used (>5 MHz), objects as small as red corpuscles can scatter enough sound for detection.

Passive Sound Examination (Stethoscope)

Vibrations, such as those caused by the closing and opening of heart valves or air moving through the respiratory passages, travel through the body as sound waves. Sound is conducted better and more rapidly in liquids than in gases. Bronchial breath sounds are heard better when the bronchi are surrounded by lung consolidation. When sound waves reach a sudden change in density (e.g., a liquid-gas interface), some of the energy is reflected.

Some simple facts about sound waves can facilitate an understanding of the reflection and scattering process in the body. First, all sound waves can be represented as a summation of sinusoidal waves of various frequencies and amplitudes. This process of Fourier or power spectral analysis was discussed earlier in this chapter. A note from a musical instrument consists of a sine wave at the "fundamental frequency" plus many "harmonics" at multiples of this frequency. The fundamental frequency describes the pitch of the tone: middle C is standardized at 256 Hz, for example.

All of these many frequencies propagate at the same speed, the speed of sound (called "a"). For ideal gases, the speed of sound is proportional to the square root of temperature. The speed of sound in air at room temperature is 344 msec, or 1129 ft/sec or 770 miles/hr (mph). At an altitude of 13,000 m (40,000 ft), where the standard air temperature is −57°C, the speed of sound is only 295 msec, or 661 mph. The speed of sound is much higher in liquids than in gases. The speed of sound through water at 15°C is 1450 m/sec. This value also approximates the speed of sound through most of the solid parts of the human body. In other solids, the speed of sound varies greatly, with a range of 54 m/sec in rubber to 6000 m/sec in granite. Reflection of sound occurs at interfaces where the product of the density and the speed of sound ($\rho \times a$) changes suddenly. Larger changes in this "acoustic impedance" result in greater reflection and less transmission. In the human body, the largest changes in acoustic impedance occur at gas-tissue boundaries: the lungs and the gastrointestinal tract. Reflection of sound by the lungs makes it difficult to auscultate heart tones through an air-filled, emphysematous chest. For the same reason, a transthoracic echocardiograph provides less detail than the transesophageal technique; in the former case, the lungs are in the way.

The first attempts to gather information about the inside of the patient by using sound involved placing one's ear directly on the patient. Although this procedure had many limitations, it led to the development of the modern stethoscope, which is based on the physical principles of sound transmission. The stethoscope uses a large diaphragm to transmit and concentrate the sound energy. The bell acts as an amplifier and a low-pass filter to transmit low-frequency diastolic rumbles. The physics of stethoscopy were described in depth by Rappaport and Sprague.[12]

In a simple stethoscopic examination, errors are introduced by "signal processing," that is, lack of experience or appropriate knowledge on the part of the listener. Because it is a nonpowered, nontechnologic device (the energy levels come from the phenomena themselves), an esophageal or precordial stethoscope has unique value in being a continuous monitor during power outages. Physical limits to the technique include airspace disease (in itself an informational finding), inability to place the monitor appropriately, and lack of quantifiable data.

Active Sound Examination (Percussion, Echo, Doppler)

The earliest "active" acoustic diagnostic technique was percussion of the chest wall. A skilled clinician can use this method to detect consolidation of the lungs, pleural effusion, and a few other chest pathologies. Although based on transmission and reflection of sound, percussion is purely qualitative and is unable to localize pathologic changes accurately. Modern ultrasound improves on percussion by using shorter wavelength sound waves and quantitative detection of their reflections (echoes). The spatial resolution of an examination is limited by the wavelength of the sound used (Fig. 38-20). Using ultrasound at frequencies in the megahertz (10^6 cycles/sec) range allows resolution of much smaller objects. The wavelength of 1-MHz sound waves in solid tissue is about 1.5 mm, whereas the wavelength of a 256-Hz tone (middle C) in tissue is 5.7 m.

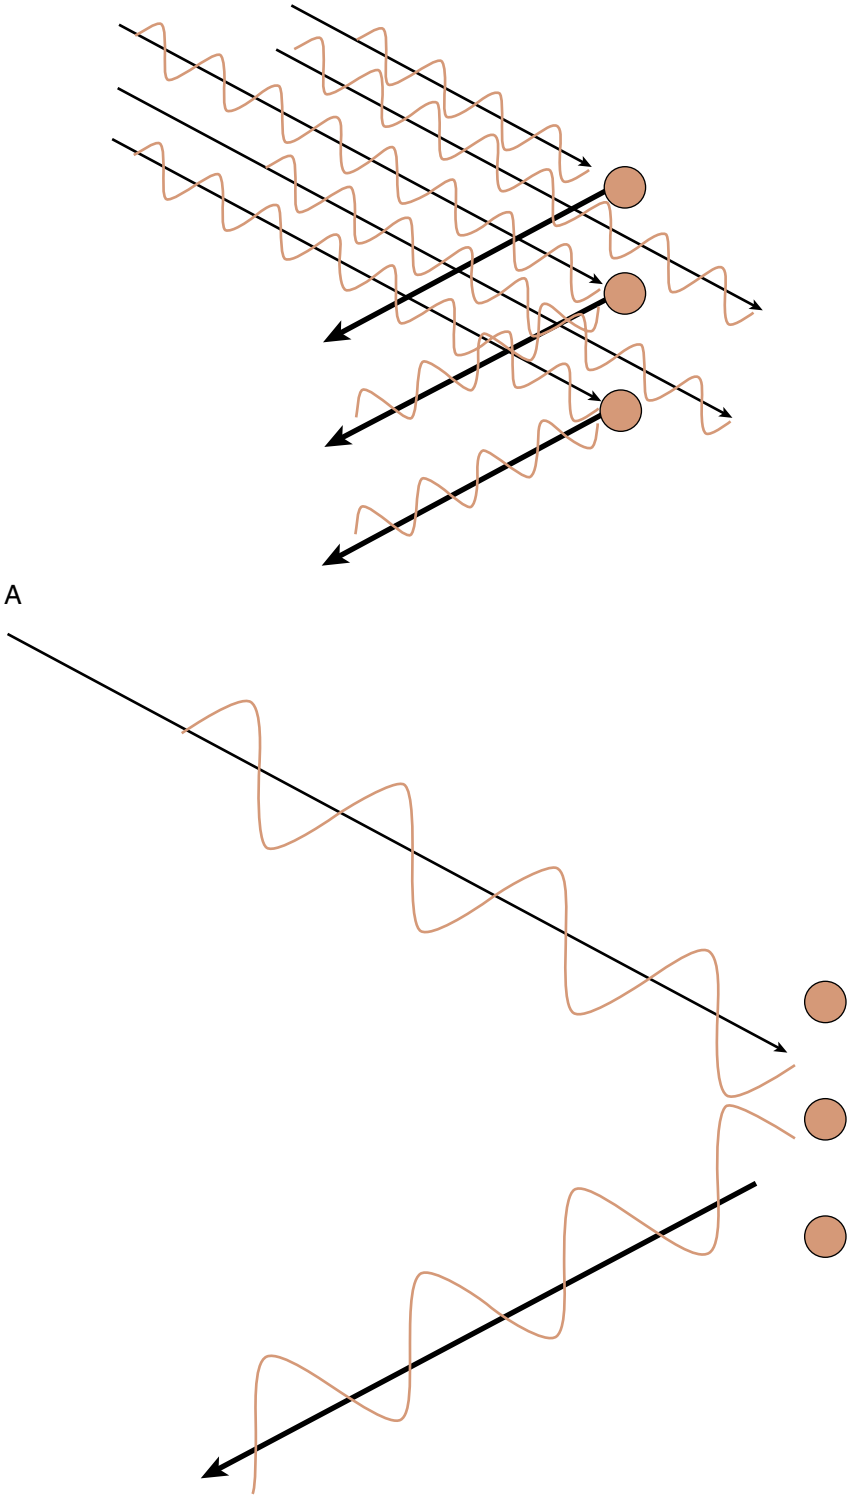

Figure 38-20 Wave size and resolution. Wave reflection depends on the relative size of waves and objects. For small objects, small waves are needed for good reflection and resolution. **A,** The object size is large relative to the wave size, resulting in good spatial resolution. **B,** The object size is small relative to the wavelength, leading to poor resolution of the objects. This principle also applies to light waves. Electron microscopes can resolve smaller objects than light microscopes because the wavelengths used are smaller. Imagine running an unsharpened pencil over a fine (1-mm grid) or coarse (1-cm grid) screen. The pencil sticks in the larger holes, while passing over the smaller ones. Sharpening the pencil to a point improves the resolution.

With the use of esophageal transducers, echocardiography has become a popular intraoperative monitoring technique.[13,14] Sound waves in the 2- to 10-MHz range are transmitted toward the heart in short bursts or pulses. After each pulse, the transducer passively listens to the reflected echoes from various tissues. The ability to place the transducer in the esophagus is advantageous because sound does not have to pass through airspaces or bone on its way to and from the heart. The speed of sound through the heart and surrounding soft tissues is a nearly constant 1540 msec. Exact measurement of the elapsed time between transmission of the pulse and receipt of the echo provides the distance to the reflecting structure. The sound beam from the transducer is projected in a narrow "searchlight" pattern, so the exact direction of reflecting structures also is known.

The Doppler effect is used in echocardiography to determine the presence and degree of valvular regurgitation by converting the Doppler shift of sound waves reflected from erythrocytes into a color display (see Appendix 7; also see Chapter 41). Cardiac output also can be estimated from descending thoracic aortic blood velocity by using a Doppler technique. These devices estimate the blood flow in the descending aorta and ignore flow to the head and arms. They calibrate descending aortic flow to cardiac output by assuming a constant proportional relationship between the two flows.[15]

Measurements Using Electric Energy (Transverse Wave) (see also Chapter 100)

Principles of Electricity

Most monitors and other anesthesiology apparatus use the basic principles of electricity and magnetism. Nearly all transducers use some form of electric energy as their output, and the subsequent data processing and display are entirely electric. We review some basic electromagnetic principles in this section by using examples from medical equipment. Electromagnetic waves, including light, are transverse waves, meaning that the electric and magnetic field vectors are oriented perpendicular to the direction of wave propagation. In contrast to sound, these waves require no media in which to propagate.

Static Electricity

Electricity is a manifestation of a property called "charge" that is inherent in matter. The charge can be negative, positive, or neutral. Static electricity involves charges at rest: Like charges repel one another, whereas opposite charges attract. What we usually mean by the word "electricity" involves the flow of charges, or electric current. Current flows in one direction in direct-current (DC) electronic devices and alternates back and forth in alternating-current (AC) devices.

The SI unit of charge is the coulomb, and the smallest quantum of charge is the charge of an electron (1.6×10^{-19} Coulomb), which is equal but opposite to the charge of a proton. (More recently discovered subatomic particles called "quarks" actually have smaller charges, but this is beyond the scope of this chapter and not relevant to medicine.) An electrostatic force is exerted between two charged objects and is directly proportional to the product of the two charges and inversely proportional to the square of the distance between them:

$$F = k \times q_1 \times q_2 / r^2 \text{—Coulomb's law} \quad (1)$$

This force is attractive when the charges are of opposite sign, and repulsive when they are of the same sign. In a Nobel Prize–winning experiment, Millikan determined the charge of an electron by suspending charged oil drops between two horizontal charged plates such that the electrostatic force balanced the gravitational force, and the drops were held in midair (Fig. 38-21). Approximately 20 years later in 1940, Millikan's son developed one of the earliest infrared ear oximeters, the forerunner of the pulse oximeter (see the section on the pulse oximeter).

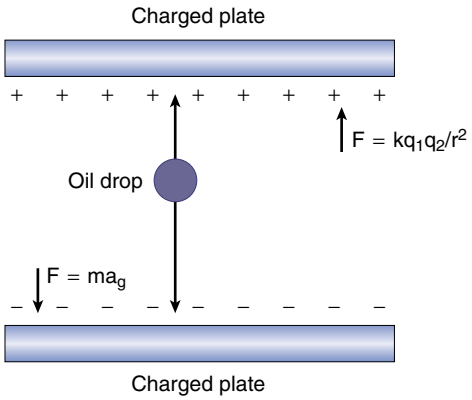

Figure 38-21 Electric force. The quantity of charge on an electron was determined by balancing the electric force on an oil drop against the gravitational force on the same drop. $F_1 = kq_1\, q_2/r^2 = F_2 = m_1\, a_g$.

Direct Current

Just as mechanical energy may be stored as potential energy, electric energy can be stored as a "potential difference." A common analogy is to compare electric potential difference with water pressure (Fig. 38-22 and Table 38-2). The potential difference (V) between points *A* and *B* is defined as the work required to move a unit charge from *A* to *B*. The SI unit of potential difference is the volt; the term *voltage* is often used for potential difference. Charges can move easily through conductors, but they do not move well through insulators, also called "dielectrics." If a potential difference (V) exists between *A* and *B,* and these two points are connected by a conductor, charges will flow between them and produce an electric current (I).

The SI unit of current is the coulomb per second, called the "ampere." If points *A* and *B* are separated by an insulator, no current will flow until the potential difference becomes so great that a breakdown of the insulator occurs. If *A* and *B* are separated by dry air, no current will flow until the potential difference reaches 3000 V/mm. At this very large potential gradient, air ionizes and becomes a conductor, and a current flows in the form of a visible (and audible) spark. To generate a spark between two electrodes 1 cm apart, one must create a potential difference of 30,000 V. The spark plugs in a car have an electrode gap of about 0.8 mm, requiring at least 2400 V from the ignition coil to generate a spark. Lightning is a larger manifestation of the same phenomenon.

A battery is a chemical cell that produces a nearly constant potential difference between two electrodes, which is called "electromotive force (EMF)". The battery can provide a continuous source of electrons, or current, to flow through any conducting circuit connected between its electrodes. Flow of electricity is opposed by resistance, analogous to resistance in water pipes. In most materials, resistance (R) is related to voltage (V) and current flow (I) in the following manner:

$$V = IR \quad (2)$$

This relationship is called Ohm's law, and materials that follow this behavior are called "ohmic" materials. This example is analogous to hemodynamic flow, in which the pressure decrease across the systemic vasculature (mean arterial pressure—central

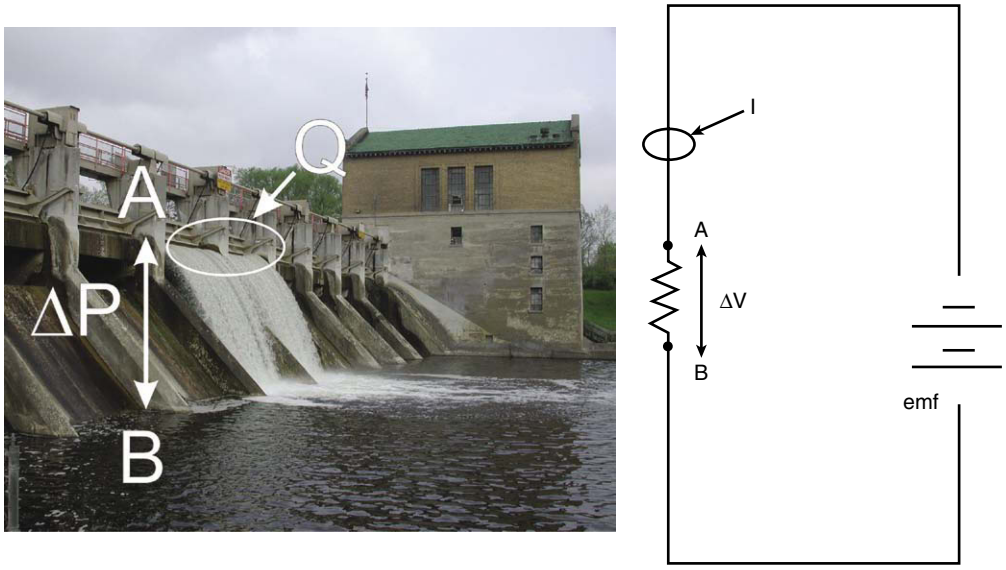

Figure 38-22 Water and electricity. The pressure drop over the dam (*A* to *B*) is analogous to the voltage drop over the resistance (*A* to *B*) (e.g., light bulb). The amount of flow (width of water) (*Q*) is analogous to the current (*I*). Both falling water and electric potential can do work, as evidenced by the use of dams to generate electricity and electricity to pump water.

venous pressure) equals cardiac output times systemic vascular resistance:

$$\Delta P = CO \times SVR \quad (3)$$

The power (i.e., rate of work; see discussion earlier in this chapter) required to produce an electric current is the product of voltage and current: P = VI. By combining this formula with Ohm's law (V = IR), we have $P = I^2R = V^2/R$. If we double the current through a fixed resistance (R), we use four times the original power. This power loss in resistors is dissipated as heat, which is the reason why nearly all electric devices become warm during use. The filament in an incandescent light bulb is merely a resistor that becomes so hot from ohmic heating that it glows, or radiates light.

A capacitor is a device that stores charge (Q) in direct proportion to the potential difference (V) between its two electrodes: Q = CV. The proportionality constant (C) is called "capacitance," which is measured in SI units of farads (1 farad = 1 coulomb/volt). When a capacitor is connected to a battery, current flows until the capacitor is charged to the point that the potential across the capacitor equals the EMF of the battery: V = Q/C = EMF (Fig. 38-23). When we push the "charge" button of a cardiac defibrillator, this kind of circuit is activated to charge a capacitor to the desired level. As shown in Figure 38-23B, time is required to charge a capacitor. For a large capacitor, more time is required. It takes longer to charge a defibrillator to 200 J than to 50 J.

Table 38-2 Comparison of Hydrodynamic and Electrical Energy Commonly Encountered

Water	Electricity	Energy
Squirt gun	Static electric spark	High pressure, low flow, low energy
Garden hose	House current	Moderate pressure, moderate flow, moderate energy
	Car battery	Low pressure, moderate flow, moderate energy
River flood		Low pressure, huge flow, huge energy
Fire hose	High tension wires	High pressure, high flows
	Lightning	High pressure, high flow

Alternating Current

In an AC circuit, the current and the voltage fluctuate rapidly (Fig. 38-24). There are many important differences between AC and DC power. The voltage in common AC "house power" fluctuates sinusoidally at a frequency of 60 Hz (50 Hz in Europe). We characterize the amplitude of such a fluctuating voltage by its root mean square (RMS), that is, the square root of the time average of V^2. For AC house power, V_{RMS} = 115 V (230 V in Europe). Current in an AC system also is constantly changing and is likewise measured as an RMS value.

AC circuits have three forms of impedance: resistance (R), capacitance (C), and inductance (L). An inductor is a circuit element whose impedance, called "inductive reactance," increases with the frequency (f) of the current fluctuations ($R_L = 2\pi fL$). Conversely, the impedance of a capacitor, called "capacitive reactance," decreases with increasing frequency ($R_C = \frac{1}{2}\pi fC$). Inductors tend to block high frequencies, whereas capacitors tend to block low frequencies (Fig. 38-25). This principle is used in stereo systems to direct the signal to either the "woofer" (low-frequency speaker) or the "tweeter" (high-frequency speaker). In medical instruments, inductance and capacitance circuits can be used to "filter" the signal (e.g., decreasing the amount of 60-Hz interference from AC wiring).

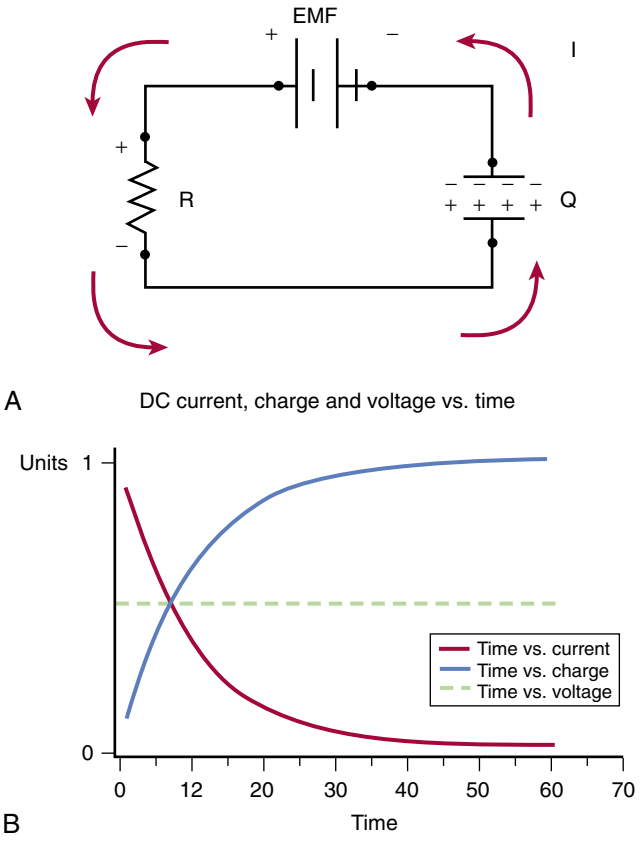

Figure 38-23 Resistance and capacitance in a direct-current circuit. **A,** Under direct current, the resistance impedes flow, resulting in a voltage decrease across the resistance. The capacitor allows current to flow until the charge builds on the capacitor. **B,** Under direct current, the voltage is constant over time, and the current flow decreases as the charge on the capacitor increases. This type of circuit is used to charge a defibrillator.

Passive Electric Examination (Electrocardiograph, Electroencephalograph)

Now that some of the basics of electricity have been described, we can discuss the electrocardiograph (ECG) and the electroencephalograph (EEG), where the sources of EMF are the heart and the brain (see Chapters 40 and 42). Electric potentials on biologic surfaces are too small to observe directly and must be amplified and processed before display. ECG potentials on the skin are in the 1-mV range, and EEG potentials are near 0.1 mV.

Figure 38-26 illustrates why electric potentials on biologic surfaces are so small. The heart generates an electric signal as a result of the synchronous depolarization and repolarization of multiple cells. The electric potentials generated by the heart are measured between two skin electrodes, *A* and *B*. As the figure shows, there are multiple effective resistances and capacitances in the tissues between the EMF source and the measuring electrodes. These impedances reduce the magnitude of the voltage signal at the skin. The "shunt" resistors R_3, R_4, and R_5 combined with the "series" resistors R_1, R_2, and R_3 form what is called a "voltage divider network." Lower values of shunt resistance or higher values of series resistance result in smaller voltages at the skin. The capacitance of the skin (C_s) also acts to attenuate the low-frequency components and distort the waveform. Skin resistance, which may be a megaohm (10^6 ohms) for dry skin, can be reduced to a few hundred ohms by conductive gels.

If a DC voltage is applied between two body surface electrodes, current flows through the tissues between them. Although the electric current in metals consists entirely of electron flow, in tissues, positive and negative ions migrate. Negative ions tend to accumulate at the positive electrode (the anode), and positive ions accumulate at the negative electrode (the cathode). This collection of anions and cations near each electrode creates its own EMF, which opposes the EMF that set up the original current. The current decreases, so the effective impedance between the electrodes increases. This phenomenon, called "polarization of electrodes," has two harmful effects. First, the increased impedance from polarization can attenuate the ECG signal for several seconds after defibrillation or DC cardioversion. Such attenuation could be misinterpreted as a lack of electric activity and result in inappropriate administration of a second shock. The second consequence of prolonged application of DC voltage is accumulation of a local concentration of toxic ions near electrode sites, a condition that can cause burns or tissue necrosis.

A partial solution to the problem is the use of a nonpolarizable electrode, such as a silver and silver chloride combination.

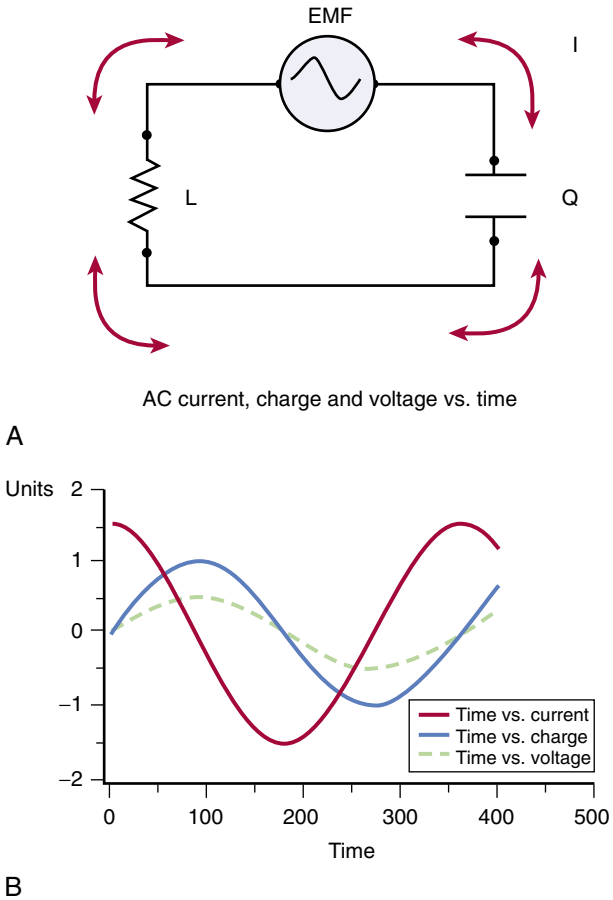

Figure 38-24 Resistance and capacitance in an alternating-current (AC) circuit. **A,** In an AC circuit, in contrast to a direct-current circuit, the capacitor does not block current flow. **B,** The capacitor and resistance act to shift the phase of the AC current. Current changes lag behind voltage changes. EMF, electromotive force.

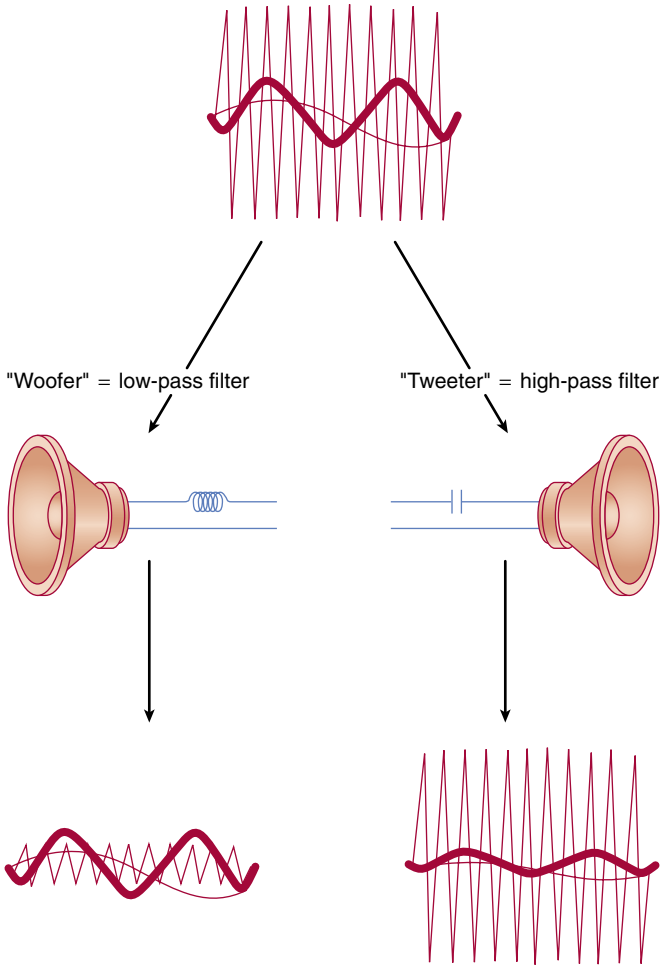

Figure 38-25 Woofer and tweeter. Stereo speakers use resistors to act as an impedance to high-frequency components of sound, allowing only the bass frequencies to pass on to the woofer speaker. Capacitors are used as a high-pass filter to allow only the high frequencies to get to the tweeter. By a similar process, 60-Hz interference from electrical appliances can be decreased. *(From Hecht E: Physics: Algebra/Trig. Pacific Grove, CA, Brooks/Cole, 1994.)*

This electrode can act as a source of, or "sink," for anions and cations, minimizing the accumulation of ions. Most disposable ECG electrodes now use such materials. Even these electrodes are nonpolarizable for only a limited time, however, and the application of prolonged DC voltage between any tissue electrodes must be avoided.

Similar problems complicate measurements of the EEG, but in this case, the raw signal is one tenth the amplitude of the ECG: 100 µV versus 1 mV. The spontaneous EEG provides eight or more channels of surface voltage versus time data, which is of limited use for monitoring in the operating room. For rapid interpretation and diagnosis, the amplitude versus time data are usually transformed into plots of amplitude (or power) versus frequency. This process of power spectral analysis was discussed in the section on signal processing. The EEG power spectrum facilitates rapid diagnosis of hemisphere asymmetries and changes in frequency content that accompany either deep anesthesia or cerebral hypoxia. "Bispectral density" is another method of analyzing the raw EEG that determines levels of correlation (or degree of "phase-locking") between various frequency components in the power spectrum. Another derived parameter is the "burst-suppression ratio," which is the percentage of time during which the EEG amplitude is less than +5 µV. Both of these last two derived quantities have been related to depth of anesthesia in clinical studies (see Chapter 39).

Active Electric Examination (Neuromuscular Block Monitor, Somatosensory Evoked Potentials)

A muscle twitch can be elicited by generating a 0.2- to 0.3-msec pulse of current to depolarize a peripheral motor nerve. This motor nerve conducts the impulse to the muscle, where a twitch is generated. We can understand the "in-use" failings of this device by following the path of the signal. We must start with an adequate power source (no power = no twitch). If the coupling of the electrodes to the patient is poor (i.e., if the electrodes are dry or good skin contact is not made), the circuit will have high resistance, and very little current will flow (see earlier discussion and equation 8), resulting in a diminished twitch. The simplest way to be certain that this monitor is functioning properly is to perform a positive control (see the desired response of thumb twitch before the chosen drug is given) and a negative control (see the twitch disappear in response to administered drug) (see Chapters 46 and 47).

Evoked potential (evoked response) monitors can determine the status of multiple parts of the sensory nervous system by measuring the central nervous system response to a discrete sensory stimulus. The stimulus can be auditory, optical, or peripheral somatosensory. The amplitude of the evoked response measured at the skin can be very small—less than 1 µV in the case of acoustic cortical potentials. This very small signal is in a "sea" of spontaneous EEG (>100-µV amplitude) signals. We resort to a signal enhancement technique called "ensemble averaging." Rather than trying to measure the small response to a single stimulus, we average the responses from hundreds (or thousands) of stimuli. Because the evoked responses that we seek occur consistently at the same time after the known stimulus, this averaging process

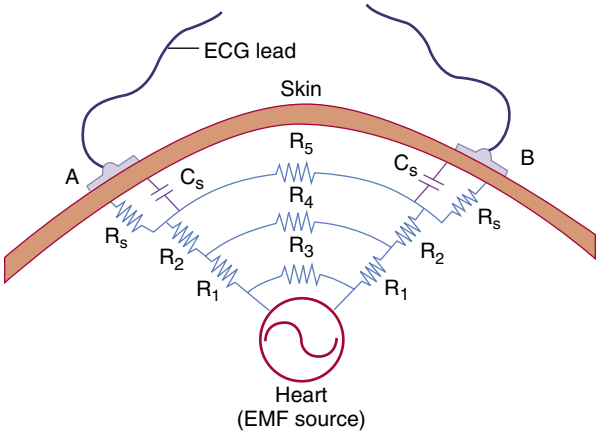

Figure 38-26 Why the electrocardiograph (ECG) is so small. Multiple resistances and capacitances in the body decrease the potential and distort the waveform before the electromotive force (EMF) reaches the surface.

reinforces the signal from the evoked response, and the random "noise" tends to cancel itself. In this way, we commonly measure signals whose amplitude is roughly 1% the amplitude of the background noise (see Fig. 38-9).

Whenever charged particles are moving, a magnetic field is generated in a direction perpendicular to the motion. Paramagnetism is a form of magnetism exhibited only in specific substances in the presence of an external magnetic field. Oxygen is a paramagnetic gas. This property is used to measure inspired and expired oxygen concentrations—chemical methods such as fuel cell amperometric sensors and polarographic electrodes are too slow to respond. In a fast responding paramagnetic oxygen sensor, 100% oxygen can exert a pressure of 3 Pa in a 2.4-T magnetic field.

Measurement Using Light Energy

Principles of Light

What we commonly refer to as light is electromagnetic radiation in the visible range of wavelengths. Every substance with a temperature greater than absolute zero emits electromagnetic radiation, called "black body radiation." This radiation is characterized by a frequency and wavelength that are related by the speed of light: frequency = speed of light ÷ wavelength (c = speed of light = 3×10^8 m/sec or 186,400 miles/sec or 7.5 times around the earth's circumference in 1 second, in a vacuum). High energies or temperatures are associated with high frequencies and short wavelengths, such as those of gamma rays and x-rays. As wavelength increases to the micron range, ultraviolet radiation proceeds to visible light (approximately 0.5 to 0.8 μ), and at larger wavelengths, infrared is followed by microwaves and radio waves with wavelengths in the kilometer range.

Electromagnetic waves and sound waves have some important differences. The particles in motion in sound waves are in the same direction as the propagation (longitudinal waves), whereas in electromagnetic waves, the electric and magnetic fields are perpendicular to the direction of propagation (transverse waves). Sound waves can propagate only through matter, whereas electromagnetic waves propagate through a vacuum without attenuation. The speed of light is about 1 million times faster than the speed of sound in sea-level air. If an observer is moving relative to a sound source, measurement of the speed of sound depends on the observer's own motion, but the speed of light is the same to any observer in any frame of reference. This last statement is the basic premise of Einstein's special theory of relativity. In the high-frequency range of the electromagnetic spectrum are two forms of ionizing radiation: x-rays and gamma rays. These high-frequency waves are capable of knocking electrons out of their orbits and can cause cell injury and death or ontogenesis. Gamma rays are commonly emitted by decaying radioactive nuclei.

Visible light and infrared light have several properties common to all electromagnetic radiation. Light represents a form of energy that, when passing through matter, may be reflected, transmitted, or absorbed. Although light itself cannot be stored, it can be converted into some other form of energy, such as electricity, chemical energy, and heat. In addition, light can be generated from other forms of energy, including heat (incandescent), electric (gas discharge), and chemical (photoluminescent) energy.

Light as a Multifunctional Tool: Beer-Lambert Law

When light passes through matter, it is transmitted, absorbed, or reflected. The relative absorption or reflection of light at different wavelengths is used in several monitoring devices to estimate the concentrations of dissolved substances (e.g., carbon dioxide in respiratory gas and hemoglobin in plasma). This type of measurement is called spectrophotometry and is based on the Beer-Lambert law of absorption, which states that if a known intensity of light illuminates a chamber of known dimensions, the concentration of a dissolved substance can be determined if the incident and transmitted light intensity is measured:

$$I_t = I_i e^{-dC\alpha} \quad (4)$$

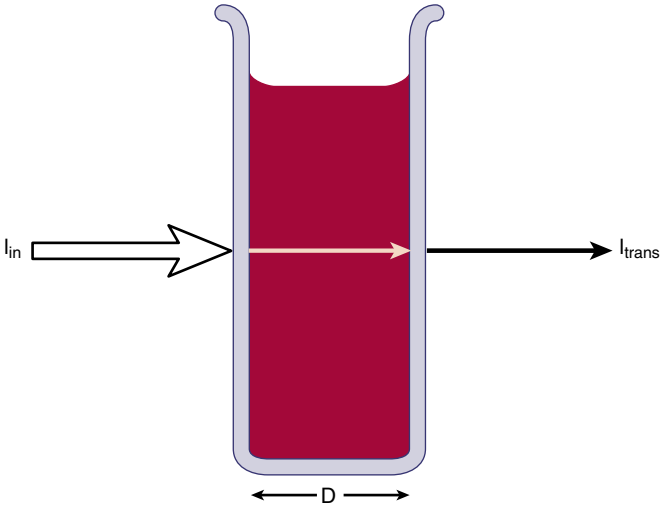
Solved for C:

$$C = \left(1/d\alpha\right)\ln\left[I_i/I_t\right] \quad (5)$$

where C is the concentration of the dissolved substance, d is the path length of the light *a*, and α is an absorption constant for the dissolved substance at the light wavelength used. I_i and I_t are the incident and transmitted light intensity. The unknown C is inversely proportional to d and directly proportional to the log of the ratio of I_i to I_t (Fig. 38-27). Red and infrared light (wavelength 0.6 to 1 μ) are generally used because the constituents of interest to anesthesiologists (anesthetic agents, carbon dioxide, hemoglobin) absorb light within that range. Red and infrared light can penetrate soft tissues and may be used to measure the concentrations of hemoglobin species in vivo (see the section on pulse oximeters). Infrared light is absorbed by small molecules only if they have bonds and are asymmetric; in other words, their molecules have a dipole moment. Nitrogen, oxygen, and helium cannot be measured by infrared light. Another limitation of infrared light is that it is absorbed by ordinary glass; the measurement chambers for these devices must be made of sapphire or other infrared-permeable materials.

Simple Absorbance Monitors (Capnometer, Anesthetic Analyzer)

Capnometers, capnographs, and anesthetic gas analyzers all use the Beer-Lambert law to analyze constituents of the respiratory gas stream (see Chapter 25). A capnometer measures and displays only discrete values of partial pressure of carbon dioxide (P_{CO_2}), such as the end-tidal value. A capnograph provides a continuous plot of P_{CO_2} in the airway versus time. The physical design of capnometers is divided into two categories: mainstream and sidestream. In mainstream capnometers, the light absorption chamber is placed directly in the airway, and the light source shines through the chamber, with carbon dioxide being measured during inspiration and expiration directly. Advantages of this technique are a very fast response time and no problems with clogging of the sampling tubes, which is a disadvantage of sidestream capnometers. Disadvantages of the mainstream geometry include the



$I_{trans} = I_{in}e^{-(D \times C \times a_\lambda)}$

I_{trans} = intensity of light transmitted

I_{in} = intensity of incident light

D = distance light is transmitted through the liquid

C = concentration of solute (oxyhemoglobin)

a_λ = extinction coefficient of the solute (a constant)

Figure 38-27 Cuvette. Light entering the cuvette is reflected and absorbed. The concentration of substances absorbing and reflecting light can be determined by measuring the amount of light entering and exiting the system.

necessity of having a potentially heavy, expensive infrared measurement device placed directly in the airway at the endotracheal tube, and the unavailability of devices that can measure anesthetic agents and carbon dioxide.

The most commonly used devices in the operating room are sidestream capnometers. A thin sampling tube is attached to the airway near the endotracheal tube, and samples are aspirated at 200 to 400 mL/min into the measurement chamber, which is located within the monitor itself. The advantages of this method are the opposite of the disadvantages of the mainstream capnometers; the sampling tube is lightweight, and the device can be used to measure carbon dioxide and anesthetic agents. Disadvantages of sidestream capnometers relate mostly to the delayed response time and potential clogging of the aspiration tubing.[16]

Anesthetic agent analyzers and capnographs function by the same physical principles, but with different wavelengths of light being used (Fig. 38-28). The light absorbances of a mixture of gases can interfere with each other, so compensations are built into current devices.

Processed Absorbance Monitors (Pulse Oximeter)

Oximeters are devices that use light absorbance measurements to determine the concentration of various species of hemoglobin. One of the first in vivo oximeters was a noninvasive monitor used in aviation research during World War II. This device transilluminated tissue (the earlobe) with light of two wavelengths. One wavelength was sensitive to changes in oxyhemoglobin, and the other was not. In effect, the earlobe acted as a test tube containing the suspended hemoglobin. For a review of the development of pulse oximetry, the reader is referred to the excellent article by Severinghaus and Astrup.[17]

Before specific engineering problems are discussed, we need to define what we wish to measure. Adult blood usually contains four species of hemoglobin: oxyhemoglobin (HbO_2), reduced hemoglobin (Hb), methemoglobin (metHb), and carboxyhemoglobin (COHb). The latter two are abnormal hemoglobins (called "dyshemoglobins"), and are normally present in only small amounts. Each of these hemoglobin species has a different light absorption profile. Figure 38-29 illustrates the different absorption constants for each hemoglobin species light from red to infrared light. Fractional hemoglobin saturation ($O_2Hb\%$) is defined as the ratio of HbO_2 to total hemoglobin:

$$O_2Hb\% = HbO_2 / \left(HbO_2 + Hb + metHb + COHb\right)$$

Measuring this quantity in the presence of metHb and COHb requires at least four wavelengths of light, which yield four simultaneous Beer-Lambert equations to solve for the four hemoglobin species. Because metHb and COHb do not contribute to oxygen transport, functional saturation is defined as the ratio of HbO_2 to HbO_2 plus reduced hemoglobin:

$$Sao_2 = HbO_2 / \left(HbO_2 + Hb\right)$$

Although functional saturation depends explicitly on only HbO_2 and Hb, four light wavelengths are still required to measure it in the presence of significant concentrations of COHb and metHb.[18,19] If the concentrations of metHb and COHb are zero, $O_2Hb\%$ and Sao_2 become identical.

The pulse oximeter performs substantial signal processing of optically transduced physiologic data. Although the physical

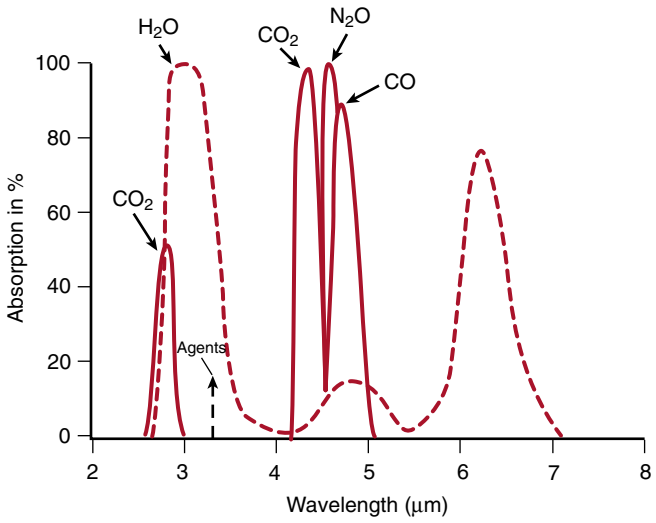


Figure 38-28 Absorption spectra of some gases and materials important to anesthesia. The absorption is not constant over wavelengths. It is important to choose the proper wavelength to measure. Also, when multiple substances are present, it is still possible to measure their concentrations, provided that enough wavelengths are available. (The solution becomes one of multiple equations with multiple unknowns.) *(From Gravenstein JS, Paulus DA, Hayes TJ: Capnography in Clinical Practice. Boston, Butterworths, 1989.)*

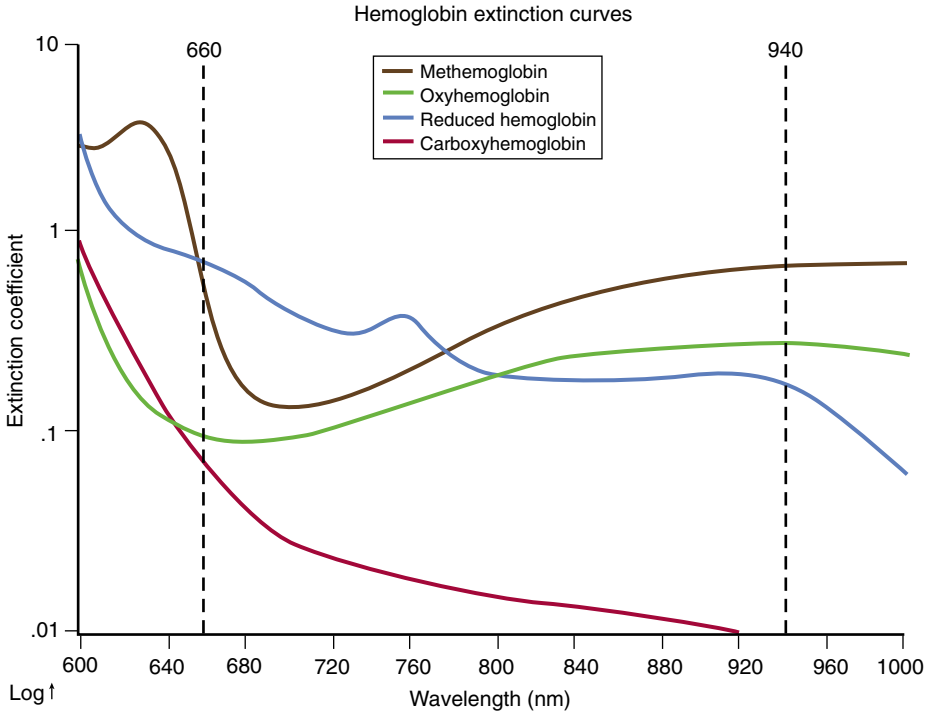

Figure 38-29 Hemoglobin extinction curves. Pulse oximetry uses the wavelengths of 660 nm and 940 nm because these are available in solid state emitters (not all wavelengths are able to be emitted from diodes). Carboxyhemoglobin and oxyhemoglobin absorb equally at 660 nm, and so both read as Sao_2 to a conventional pulse oximeter. In addition, methemoglobin and reduced hemoglobin share absorption at 660 nm and interfere with correct Sao_2 measurement. *(Courtesy of Susan Manson, Biox/Ohmeda, Boulder, CO, 1986.)*

principle governing pulse oximetry is straightforward, application of this principle to produce a clinically useful device involves significant engineering problems.[18,20] The remainder of this section describes the physical and physiologic problems of pulse oximeter design and the engineering solutions to these problems. The discussion is divided into basic design and management of signal artifacts.

Basic Design of Pulse Oximeters

Noninvasive in vivo oximeters measure red and infrared light transmitted through and reflected by a tissue bed. Accurate estimation of Sao_2 by this method entails several technical problems. There are many light absorbers in the transmitted light path other than arterial hemoglobin (e.g., skin, soft tissue, and venous and capillary blood). The pulse oximeter accounts for the effects of absorption of light by tissue and venous blood by assuming that only arterial blood pulsates. Figure 38-30 schematically illustrates the series of absorbers in a typical sample of living tissue. At the top of the figure is the AC component, which represents absorption of light by the pulsating arterial blood. The DC (baseline) component represents absorption of light by the tissue bed, including venous, capillary, and nonpulsatile arterial blood. Pulsatile expansion of the arteriolar bed increases the light path length (see equations 4 and 5), increasing absorbency. Conventional pulse oximeters (including all commercial pulse oximeters until 2005) use only two wavelengths of light, typically 660 nm (red light) and 940 nm (near-infrared light). The pulse oximeter first determines the fluctuating or "AC" component of absorbance at each wavelength and then divides this value by the nonfluctuating or "DC" component to obtain the "pulse-added absorbance," which is independent of the incident light intensity. The oximeter then calculates the ratio (R) of the two pulse-added absorbances (one for each wavelength)[18]:

$$R = \left(AC\ 660/DC\ 660\right)/\left(AC\ 940/DC\ 940\right) \qquad (6)$$

Finally, the value of R (often called the "ratio of ratios") is related to the displayed saturation estimate Spo_2 by a "look-up table" programmed into the oximeter's software. The tables used in all commercial pulse oximeters are based on experimental studies in healthy human volunteers. Although each manufactur-

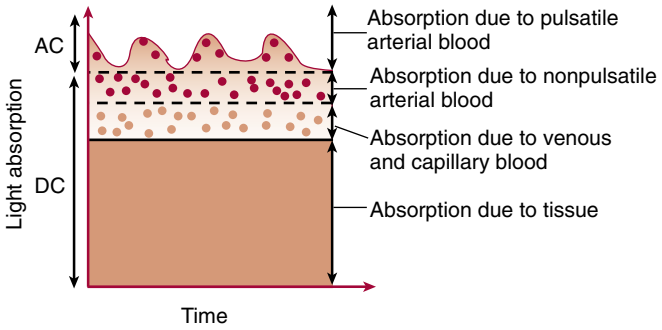

Figure 38-30 Pulse oximetry signals. A primary difficulty with pulse oximetry is that the pulsatile signal is small compared with the total absorbance of the ear or finger being examined. Pulsatile flow is needed to determine the Sao_2. AC, alternating current; DC, direct current. *(Adapted from Ohmeda Pulse Oximeter model 3700 Service Manual.)*

er's exact calibration curve is proprietary, these curves are very similar. When the ratio of red-to-infrared pulse-added absorbance is 1.0, the displayed Spo_2 is approximately 85%. This fact has clinical implications that are discussed in the next section.

Signal Artifact Management

One of the most difficult engineering problems in pulse oximetry is identification of the fluctuating absorbance pattern of arterial blood in a sea of electromagnetic and other artifacts. Artifacts have four major sources: ambient light, low perfusion (weak pulse, low AC-to-DC signal ratio), venous blood pulsations (caused by patient motion, among other things) and additional light absorbers in the blood (e.g., dyshemoglobins, intravenous dyes). All these sources of artifacts produce a low signal-to-noise ratio, resulting in either erroneous Spo_2 values or no value at all.

The photodiodes used in the sensor to detect light cannot differentiate one wavelength of light from another. The detector does not know whether the light received originates from the red (660 nm) light-emitting diode (LED), the infrared (940 nm) LED, or the room lights. This problem is solved in most pulse oximeters by alternating the red and infrared LED sources. The red LED is turned on first, and the photodiode detector produces a current resulting from the red LED plus the room lights. Next, the red LED is turned off, and the infrared LED is turned on. The photodiode signal then represents the infrared LED plus the room lights. Finally, both LEDs are turned off, and the photodiode generates a signal from the room lights alone. This sequence is repeated hundreds of times per second. In this way, the oximeter attempts to eliminate light interference even in a quickly changing background of room light.[18] Some sources of fluctuating light can cause problems despite this clever design. Artifact from ambient light can be minimized simply by covering the sensor with an opaque shield.

Another engineering problem is that of a low AC-to-DC signal ratio, or low perfusion. When a small pulsatile absorbance signal is detected, the conventional pulse oximeter amplifies the signal and estimates saturation from the ratio of the amplified absorbances. In this way, the pulse oximeter can estimate saturation values of Spo_2 for a wide range of patients who generate different amplitudes for pulsatile absorbance. As with a radio receiver, when a weak signal is amplified, the background noise, or "static," also is amplified. At the highest amplifications (which can be up to 1 million times), some pulse oximeters may "analyze" this noise signal and generate an Spo_2 value from it. Because the noise is usually equal in the red and the infrared signals, the ratio of the two is often near unity (1.0), which yields a displayed saturation of approximately 85%.

This problem could be shown in early pulse oximeters by placing a piece of paper in the sensor between the photodiode and the LED. Some early models amplified the background noise while searching for a pulse until they eventually displayed a pulse and saturation value for the piece of paper. To prevent this type of artifact, many manufacturers have now incorporated minimum values for the signal-to-noise ratio, below which the device displays no value for Spo_2. Some oximeters also display a low signal strength error message; in addition, many display a plethysmographic wave for visual identification of noise.

Patient motion, causing venous pulsations with a high AC-to-DC signal ratio, may be the most difficult artifact to eliminate. Engineers have tried several approaches to this problem, beginning with simply increasing the signal averaging time. If the device averages its measurements over a longer period, the effect of an intermittent artifact is usually less. This longer averaging period also slows the response time to an acute change in Sao_2, however, and it may result in "frozen" Spo_2 values being displayed when the true saturation is rapidly changing. Most pulse oximeters now allow the user to select one of several time-averaging modes. In addition, some manufacturers use more sophisticated algorithms to identify and reject spurious signals.

One innovation aimed at reducing motion artifact is based on the premise that motion causes pulsations of venous blood within the tissue bed. Conventional pulse oximetry cannot distinguish venous pulsations from those of arterial blood; large low-reading errors or loss of signal can result. In the newer signal-processing algorithm developed by Masimo, Inc. (Irvine, CA), the oximeter computes a venous "noise reference signal," which is common to both light wavelengths. The noise reference is subtracted from the total signal, and a "true" arterial signal is left. This is one of five "parallel engine" algorithms that Masimo SET (Signal Extraction Technology) uses simultaneously to find the most reliable Spo_2 value for the current signal conditions. Tests in human volunteers and preliminary clinical studies indicate that this new technology represents an improvement in pulse oximeter performance in low signal-to-noise ratio situations.[21,22]

More recently, Masimo has brought to market the first multiwavelength pulse oximeter: the Rainbow Rad-57 Pulse CO-oximeter. This device employs eight light wavelengths rather than the usual two, making it capable of measuring COHb and MetHb, in addition to the conventional Spo_2 value and pulse rate. The first human volunteer study of this instrument shows that it can measure COHb with an uncertainty of ±2%, and MetHb with an uncertainty of ±0.5%.[23]

Other in vivo oximeters have been developed to measure light reflected by living tissue in an attempt to determine hemoglobin saturation in specific organs. Using reflected rather than transmitted light adds complexity because the path lengths of the light through the tissue may be varied and tortuous, making calibration difficult. Nevertheless, a signal reflected from living tissue may produce useful information regarding the average saturation of the hemoglobin within that tissue.[24] A cerebral oximeter may be able to measure mean brain hemoglobin saturation, which reflects the intracerebral balance among venous, arterial, and capillary blood, and the oxygenation of all three.

Measurement of Temperature

Principles of Temperature

Moving matter contains energy. Even stationary objects are moving at the atomic level. This kinetic energy of molecules and atoms is described as temperature. When all molecular motion (translational, vibrational, and rotational) ceases, the substance is said to be at a temperature of absolute zero—the lowest possible temperature. This temperature is equivalent to −273°C, and is defined as 0°K. This state provides a reference point for all temperature measurements, which in all thermodynamic calculations must be expressed in degrees Kelvin.

Heat is a form of internal kinetic energy that can flow between two contacting bodies that are at different temperatures.

The amount of heat required to increase the temperature of 1 g of a given substance by 1°C is called the specific heat of that substance. The calorie, a common heat unit, is the amount of heat required to increase the temperature of 1 g of water from 14.5°C to 15.5°C. One calorie is equivalent to 4.184 J of energy. When we refer to calories in terms of the calories in the food that we eat or the calories that we expend while exercising, we are actually referring to kilocalories, or thousands of calories (also called "kitchen calories"). The total amount of heat energy in an object depends on its specific heat, its temperature, and its mass. Although a cup of 60°C coffee is much "hotter" than a 30°C swimming pool, the coffee contains much less total thermal energy than the pool does. The same is true for potential energy stored as pressure potential or electric potential. A small container at high pressure may have less potential energy than a larger container at lower pressure (see Chapter 48).

Temperature Monitors (Thermometer, Thermistor, Thermopile, Liquid Crystal)

Three techniques are commonly used for measuring temperature: based on expansion of a material as its temperature increases, based on changes in electric properties with temperature, and based on optical properties of a material. As heat is added to most substances (gases, liquids, or solids), motion of the molecules increases, and the volume of the material increases at constant pressure. Depending on the material, this expansion can be calibrated directly to changes in temperature. Liquids are most commonly used, such as mercury because its effective range extends from its freezing point of −39°C to approximately 250°C.[25] Mercury thermometers have two disadvantages. First, they require 2 to 3 minutes for complete thermal equilibration (mercury is a liquid metal with a high specific heat). Second, they are enclosed in a glass tube, which may break and cause injuries.[26] Thermometers based on the expansion of gas (Bourdon tube) or metal (bimetallic strip) are frequently used in thermostats because they also respond slowly to transient changes in temperature.

Electric techniques for measuring temperature can be subdivided into three categories: resistance thermometers, thermistors, and thermocouples. Resistance thermometers operate on the principle that the electric resistance of metals increases with temperature. These devices most frequently use a platinum wire as the temperature-sensitive resistor, a battery, and a galvanometer to measure current, which can be calibrated to temperature. The platinum wire is incorporated into a Wheatstone bridge circuit, which accurately measures very small changes in resistance (see Fig. 38-5).

Compared with a platinum thermometer, a thermistor is a semiconductor that displays the opposite behavior with regard to electric resistance. As the thermistor is heated, its resistance decreases. Thermistors, being solid-state devices, can be manufactured in extremely small sizes and have a fast response to change in temperature (i.e., little heat is needed to increase their temperature). Most of the temperature probes used in anesthesia, from the ones at the end of pulmonary artery catheters to esophageal probes, are thermistors. Physical problems with thermistors are few: Cracked or broken wires lead to high resistance and incorrect temperature readings. More common problems are poor probe placement and misinterpretation of the resulting value (e.g., placing an esophageal probe in the oropharynx and measuring airway temperature rather than core temperature). Thermocouples are conductors that generate a voltage in response to a temperature gradient.

The optical properties of materials can be used to measure temperature in two ways: (1) the infrared "black body" emissions of an object can be measured by using a device known as a thermopile, and the emission can be converted to temperature, and (2) a liquid crystal "matrix" can be placed in direct contact with the desired zone, and an optical change can be observed (a change in color). The most commonly encountered example of infrared temperature measurement involves the tympanic membrane temperature monitor used in recovery rooms, pediatrics, and hospital wards.[27] The infrared detector produces an electric signal that is proportional to the fourth power of the difference in absolute temperatures of the objects. The following formula describes this phenomenon: $Q_{1,2} = K (T_1^4 - T_2^4)$, where $Q_{1,2}$ is net heat transfer (W/cm^2), K is the Stefan-Boltzmann constant, and T_1 and T_2 are the absolute temperatures of the two objects (°K).

In theory, this method of measuring the core temperature should be accurate. In practice, improper placement and lack of calibration, but not ear canal cerumen, contribute to real-world errors.[28-30] Additionally, the probe is large for intraoperative use.

Liquid crystal measures of temperature (found in "mood rings") are often used for skin temperature monitoring. Just as the molecules in a liquid crystal watch display change their optical properties with a small electric current, becoming polarized and dark, the molecules in a liquid crystal temperature device change their optical properties with temperature, resulting in a rainbow of colors. The crystal matrix is sensitive to pressure and temperature. (By touching an LCD display panel, one can note the visual rainbow of changing colors.) The reported clinical accuracy of liquid crystal devices varies.[31,32]

Measurement of Flow

Principles of Flow

Although conceptually one of the easier measurements to understand as volume or mass movement over time, flow is actually not easy to measure. We must clearly distinguish between fluid flow and fluid velocity, which are often confused. Flow (Q) refers to the volume of fluid passing a particular surface area per unit of time; its SI units are cubic meters per second (m^3/sec), but in medicine, it is more commonly measured in mL/sec or L/min. Fluid velocity (U) is simply the speed of the fluid at a particular point in space, measured in msec. By analogy, imagine a multilane freeway: the speed (velocity) of individual cars may vary depending on the lane; the flow is the number of cars passing a point per minute.

Mass and Volume Flow Meters (Urometer, Volumeter)

Flow can be measured directly, by diverting the flow into a measuring chamber. We can measure the mass or volume of fluid flowing per unit time by catching the fluid in a container and either weighing it or measuring its volume. The common urom-

eter for measuring urine volume is an example. The volumeter used in North American Drager anesthesia machines also measures aliquots of volume integrated over time to measure tidal and minute volume (Fig. 38-31).[33]

Dilutional Flow Meters (Thermodilution, Fick Principle)

Volume and mass flow also can be measured by dilutional techniques. If some measurable indicator (a bolus of dye, a thermal pulse, oxygen consumption, carbon dioxide production) is injected into a flow, and its concentration is measured as a function of time at a point downstream, the volume flow (Q) can be calculated by integration. The most common medical application is determination of cardiac output by the pulmonary artery thermodilution method (see Appendix 6). Errors associated with these methods involve using the wrong injectate volume (too small a volume resulting in an overestimate of flow) or an error in temperature measurement (see the section on temperature).

"Continuous" thermodilution cardiac output using an electric heating coil to warm the pulmonary artery blood removes errors associated with fluid injectate techniques but introduces the need to average the smaller signal over a longer time interval. Additionally, there is an upper limit to warming the blood without cellular damage, so signal quality is reduced in febrile patients.[34] A slightly different approach is to measure the electric current required to maintain a constant temperature at the catheter tip. This is the principle of a constant temperature hot wire anemometer (used to measure gas flows in wind tunnels and in some anesthesia machines) applied to cardiac output.

The rate of carbon dioxide production or oxygen consumption can be used to measure cardiac output by modifications of the Fick equation (see Appendix 6). When using these variables, a change in metabolic rate can lead to errors in cardiac output measurement.

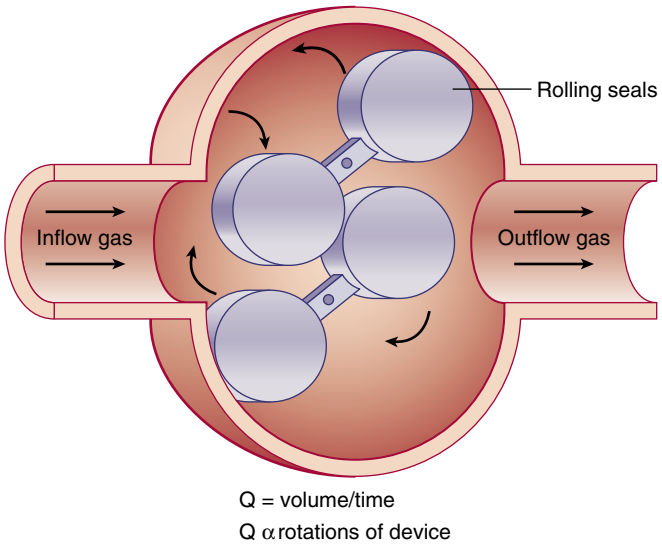

Figure 38-31 Volumeter. Flow can be described as volume over time. This design of flow meter allows gas to pass in only small aliquots, each of which turns a counter to measure the amount flowing past. When divided by time, this results in a flow measurement. *(Adapted from Ehrenwerth J, Eisenkraft J: Anesthesia Equipment: Principles and Application. St. Louis, Mosby-Year Book, 1993.)*

Velocity and Pressure Flow Meters (Venturi, Pitot)

Flowing fluids in tubes generate velocity and pressure, which can be used to measure the flow indirectly. Pressure in fluids can be thought of as a form of potential energy, as described earlier. Kinetic energy in fluids is expressed in terms of flow, the bulk movement of fluid with a given direction and magnitude. The potential energy of pressure can be converted into the kinetic energy of flow; for example, the hydrostatic pressure generated by gravity acting on a vertical column of liquid can be transformed into flow by opening a valve at the bottom of the column. Pressure and flow also can change independently. With the human circulatory system used as an example, a healthy young trauma patient in hypovolemic shock can have normal blood pressure, but low blood flow with high systemic vascular resistance. A septic patient can have very low blood pressure accompanied by high blood flow and low systemic vascular resistance (high-output septic shock). The total mechanical energy of a moving fluid is the sum of the kinetic (flow) energy and the potential (pressure) energy (see Table 38-2).

A pressure gradient (changing pressure in a particular spatial direction) exerts a force on the fluid, and the fluid tends to accelerate in the direction of decreasing pressure. Pressure gradient is only one of the forces that commonly act on fluids; other forces include gravity (discussed earlier) and viscous force or friction. If these other forces are negligible, and the fluid is incompressible (i.e., a liquid with constant density), the equation of motion (F = ma) can be integrated to yield:

$$P + \tfrac{1}{2}\rho U^2 = P_0 \qquad (7)$$

where P is pressure, ρ is fluid density, U is the magnitude of the fluid velocity, and P_0 is a constant called the "stagnation pressure" (see Appendix 5). This form of the Bernoulli equation tells us that pressure decreases as velocity increases in a frictionless flow, and vice versa. This equation dispells the common misconception that pressure always decreases in the direction of flow. In the flow inside a tube (a pipe or a large vein) of gradually increasing diameter, fluid velocity (U) decreases in the downstream direction as the diameter and cross-sectional area of the tube increase. As U decreases, equation 5 tells us that P increases in the direction of flow. This example shows the relationship of potential and kinetic energy in fluids: As the kinetic energy of this tube flow decreases (U^2 falls) in the flow direction, the potential energy increases (P rises) by an equal amount. The total energy remains constant because we have assumed no friction.

Flow can be determined by measuring the average velocity of the fluid across the tube. In laminar tube flow (Fig. 38-32A), the velocity profile has a parabolic shape, with the highest velocity at the center line and the fluid at the walls being stationary. In turbulent tube flow, the velocity profile is "flattened" as shown in Figure 38-32B.

The Bernoulli equation applies to a specific subset of frictionless flows, as described earlier. Many flows important to anesthesiologists do not follow the Bernoulli equation. Most com-

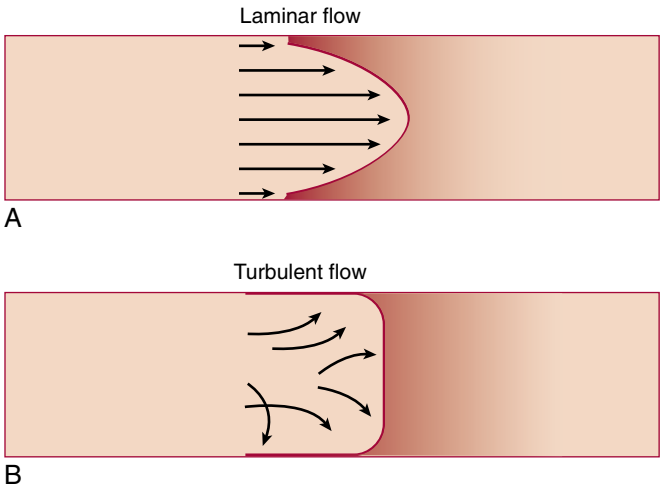

Figure 38-32 Laminar and turbulent flow. **A,** In a smooth-walled tube at low flow rates (i.e., small pressure gradients), the flow rate is laminar; that is, flow moves smoothly in concentric circles, with the centermost area having the greatest flow velocity and the area nearest the wall of the tube being virtually stationary. **B,** As flow rate (and pressure gradient) increases, the flow transitions from laminar to turbulent. Instead of a neatly ordered flow, the velocities are more randomly distributed, energy is dissipated as heat, and the energy needed for a given flow rate increases. Many factors govern this transition, including size of the tube, viscosity of the fluid, flow rate, and pressure gradient. These factors are combined in the determination of the Reynolds number (see Appendix 5).

monly, the flow that we desire to measure is not laminar, but turbulent. The transition from laminar to turbulent flow depends on the type of fluid, the speed of the flow, and the shape of the flow. The fluid factors are combined in a dimensionless ratio called the "Reynolds number (Re)":

$$Re = \rho UL/\mu \quad (8)$$

where ρ is the density of the fluid, U is the mean flow velocity, L is a characteristic dimension (length) of the flow, and μ is the viscosity of the fluid. For a given flow geometry (e.g., flow through a tube of circular cross-section), transition from laminar to turbulent flow occurs at a critical value of Re. In straight, smooth, circular tubes, transition from laminar to turbulent flow occurs at Re of approximately 2100 (see Appendix 5).

A Venturi tube is a circular tube with a gradual contraction and expansion in diameter, in contrast to the sudden contraction-expansion of an orifice flow meter (Fig. 38-33). Because the contraction is smooth and gradual, the Bernoulli equation (equation 7) applies to this geometry. For conservation of mass and energy to apply, as we restrict the flow by narrowing the tube, the speed *increases*; the pressure on the walls *decreases* to keep the total energy (the "stagnation pressure" of the Bernoulli equation) constant. The total mass flow on both sides of the contraction must be equal (we have not created or lost any matter). If we measure the pressure difference between the widest and the narrowest parts of the Venturi tube, we can solve the Bernoulli equation for velocity (see Appendix 5). The Venturi tube derives fluid velocity (U) from the pressure difference, not volume flow (Q). The Venturi tube is used in many industrial applications and is used on some aircraft to measure speed.

To have a measurable pressure gradient, there must be some resistance in the fluid path. The lower the rate of flow, the

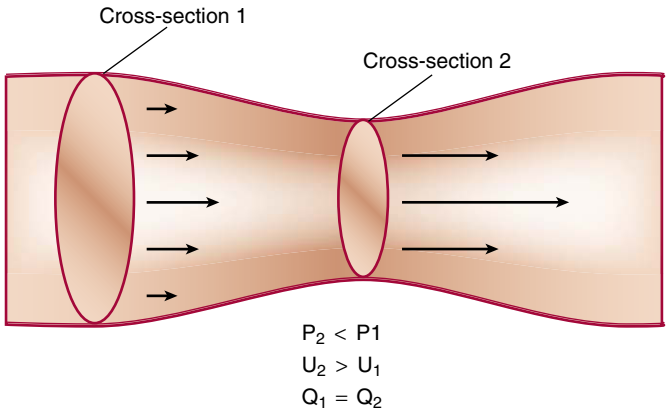

Figure 38-33 Venturi tube. By measuring the pressure difference between two points in a laminar flow, the average flow velocity can be determined because the mass flow and total energy (minus frictional losses) must be the same (see Appendix 5).

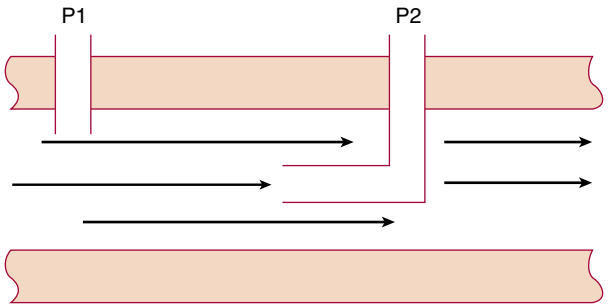
greater the resistance must be to generate the same pressure gradient. In respiratory applications, pediatric flow meters have too much resistance (owing to lower flows) to use in adults, and adult flow meters do not generate enough resistance to give an adequate signal (pressure change) in pediatric patients. A variable resistance flow meter has been devised (Ohmeda 7900/Aisys (GE Healthcare, Madison, WI) wherein the orifice is a flap that moves as the flow increases. No simple equation or relationship exists between the pressure above and below the restriction; this flow meter must be empirically calibrated, and the calibration curve for each sensor must be stored electronically.

A Pitot tube is a cylindric tube whose open end is pointed directly into the flow, that is, "upstream" (Fig. 38-34). The pressure measured in the Pitot tube approximates the stagnation pressure, given earlier by equation 7. If we independently measure the static pressure p (the p_1 side port in the Fig. 38-34) at the same location, and we know the fluid density ρ, we can easily solve equation 7 for the fluid velocity U. The Pitot tube derives velocity U, not volume flow Q. The Pitot tube is simple and reliable, and is used



$$Q^2 \alpha (P_2 - P_1)$$

$$Q \alpha \sqrt{(P_2 - P_1)}$$

Figure 38-34 Pitot tube. As flows increase, wall pressure decreases as a result of the Bernoulli principle. The Pitot tube measures the difference in pressure from the middle of the flow to the wall and converts this to a flow measurement (see Appendix 5). *(Adapted from Ehrenwerth J, Eisenkraft J: Anesthesia Equipment: Principles and Applications. St. Louis, Mosby-Year Book, 1993.)*

on most aircraft to measure their speed. In anesthesia, the Pitot tube is used in Datex Ultima monitors (GE Healthcare, Helsinki, Finland). To measure gas flow in two directions, the Datex monitor incorporates two Pitot tubes, one facing in each direction. Additionally, the monitor samples gas composition to correct for the density and viscosity of the gas mixture.

Balance-of-Pressure Flow Meters (Thorpe Tube, Bourdon Tube)

If flow in a tube passes through a sudden restriction such as an orifice, the volume flow Q is proportional to the area of the orifice and the square root of the pressure drop through the orifice. (The Bernoulli equation does not apply to this flow geometry.) This is the principle of all orifice flow meters, including the rotameter of an anesthesia machine (see Appendix 5).

The most common flow meter seen by anesthesiologists is the floating bobbin rotameter on the anesthesia machine, the Thorpe tube (Fig. 38-35). This variable-orifice flow meter uses a balance of forces to determine pressure change and measure flow. When the flow meter valve is opened, the flow of gases through the annular orifice between the bobbin and the tapered glass tube provides a force to raise the bobbin. As the bobbin rises, the area of the annular gap between the bobbin and the tube increases as a result of the taper of the tube. As the area of this gap (orifice) increases, the pressure change across the bobbin decreases because the pressure change across an orifice is inversely proportional to the square of the orifice area. The bobbin ceases its upward motion at an equilibrium point when the downward force of gravity (weight of the bobbin) is balanced by the upward pressure force. The height of the bobbin in the tube is directly related to the gas flow. Although this flow meter is simple in principle, its application becomes more complex when the flow in the tube changes from laminar to turbulent as velocity and diameter increase. For mathematical derivations, see Appendix 5.

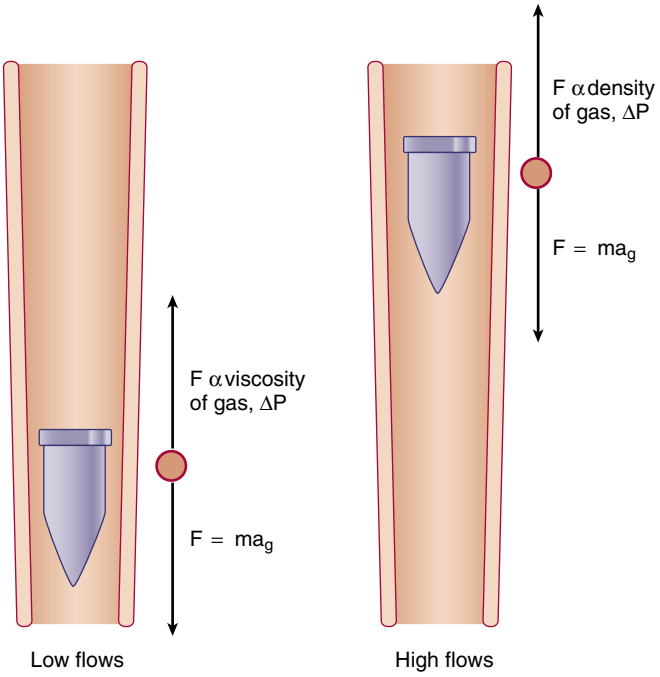


Figure 38-35 Thorpe tube flow meter. At low flows, viscosity of gas predominates, and the flows balance when the gravitational attraction equals the pressure gradient across the equivalent orifice. At higher flows, density takes over, and the balance is the same except for the formula determining pressure (acts like an orifice) (see Appendix 5).

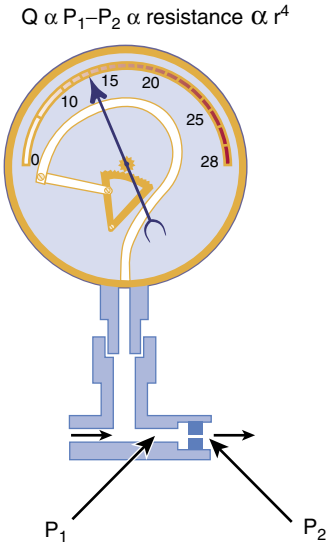

Figure 38-36 Bourdon tube flow meter. In contrast to the Thorpe tube, which has a constant pressure, but a variable orifice, the Bourdon tube has a constant orifice, but a variable pressure. The tube uncoils under the high back pressure. This drawback makes it unsuitable for use in low-pressure respiratory systems. It receives much use in portable oxygen tanks, however. If the orifice is increased in radius, the flow meter will under-read actual flow. If the orifice is dirty (i.e., decreased radius), the flow will be overestimated. *(From Mushin WW, Jones PL: Physics for the Anaesthetist, 4th ed. Oxford, Blackwell, 1987.)*

Another flow meter, the Bourdon tube (Fig. 38-36), keeps the orifice constant and allows the pressure to vary. As flow Q increases, the gradient of P_1 to P_2 increases and causes the flattened metal tube to uncoil and move the pointer.

Kinetic Energy Flow Meters (Wright Spirometer)

Vanes or propellers placed in a confined flow turn at a rate proportional to the volume flow if there is no friction in the propeller bearings. Various vane spirometers (Fig. 38-37) (e.g., Wright spirometer) work by this principle. These devices tend to be less accurate at very high and low flow rates because of frictional forces.

Summary of Flow Measurement

Every method of measuring flow has its particular limitations and uncertainties. Because gases are not always pure with a known, constant density, flow meters based on the Bernoulli equation (equation 7) are subject to errors. Any device inserted into a fluid flow can disturb the flow by its presence. A rotating vane spirom-

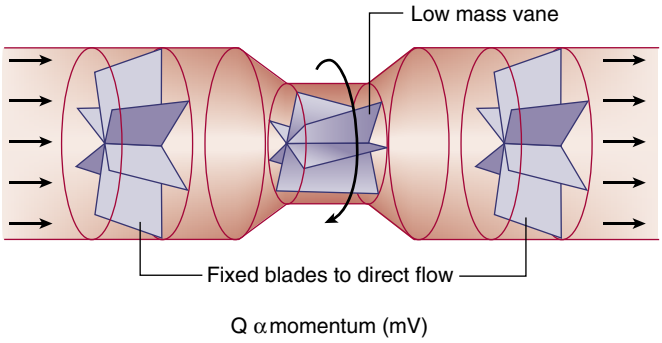

Figure 38-37 Vane spirometer. Moving gases contain kinetic energy. This can be sampled by a rotating "windmill" in the gas stream. *(Adapted from Ehrenwerth J, Eisenkraft J: Anesthesia Equipment: Principles and Applications. St. Louis, Mosby-Year Book, 1993.)*

eter may reduce the gas flow at high flow rates because of internal friction. Several methods of flow or fluid velocity measurement depend on a pressure measurement (Pitot tube, Venturi tube, orifice flow meter); the flow measurement is no more accurate than the pressure measurement.

Conclusion

New monitors are being developed almost continuously, but new physical principles are revealed only rarely. The science of physics is a constant effort to understand, simplify, and predict the behavior of the universe in quantitative terms. The terms and principles outlined here will be referred to multiple times in subsequent chapters.

Appendix 1

Distance versus Time under Constant Acceleration: Equivalence of Potential and Kinetic Energy

Velocity (v) is the rate at which distance is changing; that is, it is the time derivative of distance:

$$\mathbf{v} = d\mathbf{x}/dt \quad (1)$$

The variable v is in boldface type to indicate that it is a vector: it has magnitude and direction. Distance **x** is a vector pointing from the origin to the present location of the particle or object; it is called the "position vector." Time (t) is a scalar; it has magnitude, but no direction and is in plain type.

Acceleration (**a**) is the time rate of change of velocity. It is the time derivative of the velocity vector, or the second derivative of distance with respect to time:

$$\mathbf{a} = d\mathbf{v}/dt = (d/dt)(d\mathbf{x}/dt) = d^2\mathbf{x}/dt^2 \quad (2)$$

If an object starts with zero velocity ($\mathbf{v} = 0$) at time zero ($t = 0$) and then accelerates with constant acceleration (a), its velocity at time t will be simply $\mathbf{v} = \mathbf{a}t$. To calculate the distance traveled by the object between time $t = 0$ and time t, we must divide the time interval 0 to t into a series of very small intervals, each of time length dt. The distance traveled during the interval dt is simply the velocity at that time multiplied by the time interval:

$$d\mathbf{x} = \mathbf{v}dt = (\mathbf{a}t)dt \quad (3)$$

In the second step, we have substituted the constant acceleration relationship $\mathbf{v} = \mathbf{a}t$ from above. Now to compute the total distance traveled, we must sum the distance from all of the small dt time intervals that occur between 0 and t:

$$\mathbf{x} = \Sigma(\mathbf{a}t)dt \quad (4)$$

If we allow the length of the time interval dt to approach zero, the summation process becomes the integral with respect to time from time zero to time t:

$$\mathbf{x} = \int \mathbf{v}dt = \int (\mathbf{a}t)dt = \frac{1}{2}\mathbf{a}t^2 \quad (5)$$

An object starting from rest at $t = 0$ and moving with constant acceleration (**a**) will move a distance $\frac{1}{2}\ \mathbf{a}t^2$ in time t. If this is a falling object (in a vacuum, where there is no air resistance), $a = g = 9.8$ msec^2, and the distance formula becomes:

$$\mathbf{x} = \frac{1}{2}gt^2 = (4.9)t^2 \quad (6)$$

In the first second, the object falls 4.9 m; at the end of 2 seconds, it has fallen 19.6 m; after 3 seconds, 44.1 m; and so on.

The kinetic energy (KE) of a moving object is

$$KE = \frac{1}{2}mv^2 \quad (7)$$

where m is the mass of the object, and v is the magnitude of its velocity (also called speed). Note that v used in this sense is in plain type, not boldface. Consider again the falling object that started at position $x = 0$ at time $t = 0$ and falls a distance h:

$$h = \frac{1}{2}gt^2, \text{ or}$$

$$t = \sqrt{(2h/g)} \quad (8)$$

Because velocity $v = at = gt$, we have by substitution from equation 8:

$$V = gt = g\sqrt{(2h/g)} = \sqrt{(2gh)} \quad (9)$$

The kinetic energy is given by:

$$KE = \frac{1}{2}mv^2 = \frac{1}{2}m(2gh) = mgh \quad (10)$$

Now let us consider the work required to lift the fallen object back to its original height of h. Work is defined as the force exerted times the distance over which the force acts: $W = Fd$. The force of gravity acting on our object is $F_g = mg$, so the work required to lift it the distance (h) back to $x = 0$ is:

$$W = Fd = (mg)d = mgh \quad (11)$$

The work required to restore the object equals the kinetic energy possessed by the object at the bottom of its fall, $KE = W = mgh$. When we lift the object from $x = h$ back to $x = 0$, we have increased its potential energy (PE) by the amount mgh. This potential energy can be converted to kinetic energy by allowing the object to fall the distance h. This type of potential energy, called gravitational potential, has a value that clearly depends on where we locate the origin of our coordinates, $x = 0$. It is the change in potential energy, however, and not its absolute value, that the potential energy/kinetic energy balances:

$$\Delta KE = -\Delta PE \quad (12)$$

The change in kinetic energy is equal to and of opposite sign to the change in potential energy.

Appendix 2

Physics of Hydrostatic Pressure

A liquid manometer is a simple and reliable means of monitoring pressures that do not change rapidly. It simply uses the weight of a measured vertical column of liquid to balance the pressure exerted against the bottom of the column. We have defined weight as the force exerted by gravity on a mass (m): $F_g = mg$. To determine the weight of a column of liquid of known dimensions (the manometer in Fig. 38-4), we must first know the density (mass per unit volume) of the liquid. Density has dimensions of m/L^3, and the SI units are kilograms per cubic meter (kg/m^3). Because liquids are almost incompressible, their density is influenced little by pressure (but affected by temperature). The density of water at room temperature is 997.8 kg/m^3, or 1 g/cm^3.

The pressure (p) exerted by the bottom of the vertical column of liquid in a manometer (see Fig. 38-4) is determined as

follows. If the cross-sectional area of the liquid cylinder is A, and the height of the cylinder is z, its volume is V = Az. If the liquid has a density of ρ, the mass of the column is:

$$m = \rho V = \rho Az \quad (1)$$

Its weight is:

$$W = mg = \rho Azg \quad (2)$$

The liquid column exerts a force equal to its weight on its base, whose surface area is A, creating the following pressure on the surface:

$$p = \text{force}/\text{area} = \rho Azg/A = \rho gz \quad (3)$$

The pressure exerted by the manometer is independent of its cross-sectional area (A); it depends on only the density of the working fluid and the vertical height of the column. If we know the liquid density, measurement of the column height (z) allows us to calculate the pressure (p). If the working fluid is mercury (e.g., sphygmomanometers), the density is 13,680 kg/m^3 (13.68 g/cm^3, or 13.68 times the density of water). The relationship of pressure to height of the column is:

$$p = \rho gz = (13{,}600\ \text{kg}/\text{m}^3)(9.8\ \text{N}/\text{kg})(z)$$
$$p[\text{N}/\text{m}^2] = 133{,}300(z) \quad (4)$$

The unit of pressure newton/meter^2 (N/m^2) is called the pascal (Pa). Because a pascal is a small unit of pressure, we usually use kilopascals (10^3 Pa or kPa). If we express p in kPa and z in mm Hg (rather than meters), equation 4 becomes:

$$p[\text{kPa}] = 0.1333(z)[\text{mm}] \quad (5)$$

Appendix 3

Wheatstone Bridge

The Wheatstone bridge is a network of four resistors connected as shown in Figure 38-5, with a battery or direct-current voltage source (electromotive force) connected between *A* and *C* and a voltmeter (V) connected between *B* and *D*. The bridge is said to be "balanced" when the voltmeter reads zero potential difference between points *B* and *D*. From Ohm's law (V = IR), it is easy to show that balance occurs when $R_x = R_s \times (R_2/R_1)$. If R_s is an adjustable standard resistor, and R_1 and R_2 are fixed known resistors, the balanced bridge provides a very precise means of determining R_x, the unknown resistance. This principle has many applications in biomedical engineering, including strain gauge pressure transducer measurements. In this case, the transducer itself is the unknown resistance R_x.

Appendix 4

Amplification Artifact of a Fluid Tube/Transducer Pressure Wave

The amplification artifact of a fluid tube/transducer pressure waveform can be calculated if a few properties of the system are known. The most relevant part of this solution is the response amplitude, which is plotted against the driving frequency (f) in Figure 38-17. This figure shows some important properties of fluid-coupled transducers and other harmonic oscillators. One of these properties is the existence of a resonant frequency, f_0, which is defined as follows:

$$f_0 = \frac{1}{2}\pi\sqrt{k/m} \quad (1)$$

m is the mass of the system, and k is the elasticity, or spring constant.

As we increase the amount of damping (i.e., friction; c is the friction constant), we observe a decrease in the peak amplitude at resonance, and the frequency at which the peak occurs decreases slightly. The damping coefficient (z) is defined as follows:

$$z = c/\sqrt{2km} \quad (2)$$

Although the arterial pressure waveform is not actually sinusoidal, Figure 38-16 shows the most important characteristics of the pressure transducer response. Any combination of catheter, tubing, and transducer can be characterized by two quantities: a resonant frequency (f_0) and a damping coefficient (z). Gardner measured these quantities for many transducer and tubing systems and found that most systems have resonant frequencies of 10 to 20 cycles/sec or Hz and damping coefficients of 0.2 to 0.3. For clinical systems, the maximum amplification factor (ratio of transducer output to input waveform amplitude) at resonance is near 2.5.

If the resonant frequency is 10 Hz (600 cycles/min), one might conclude that amplification plays little role in the clinical range of pulse rates, which are 5 to 10 times smaller. The arterial pressure waveform is not a sine wave, however. It can be represented as a summation of sine waves (a Fourier series) with frequencies up to many times the pulse rate. These higher harmonic frequencies are amplified most and yield the spiked appearance of a poorly processed arterial waveform. Depending on the shape of the actual arterial pressure wave, this distortion can introduce a 20% to 40% "overshoot" error in systolic blood pressure readings. Even worse, this error depends on the pulse rate, so an error determined for a particular patient at the beginning of administration of an anesthetic may not remain constant.

From this discussion, we can easily predict how to optimize the performance of a pressure transducer system. First, the resonant frequency (f_0) should be as high as possible. The value for k

in equation 1 should be large (i.e., the spring should be "stiff"), and the value for m should be small (i.e., the cannula and pressure tubing should be as stiff and inelastic as possible). To minimize the mass of the moving fluid, the tubing should be short in length and small in diameter. Judging from plots of amplitude versus frequency/resonant frequency at different damping coefficients, the optimal damping coefficient would be 0.4 to 0.5. One also should carefully eliminate air bubbles from the system because they add elasticity and friction, lowering the resonant frequency. In a clinical system, one can determine the approximate f_0 and z of a transducer system if graphic output is available. If the high-pressure flush is turned on and then quickly turned off at a high chart speed (50 mm/sec), the tracing oscillates through several cycles at a frequency near f_0. The damping coefficient can be found by determining the ratio of amplitudes of successive peaks on the tracing. This is a practical example of how fundamental principles of mechanics can be used to predict and optimize the performance of monitoring systems. These concepts of mechanics recur in other sections of this chapter.

Appendix 5

Flow Meters, Bernoulli's Principle, Laminar and Turbulent Flow

The equations governing the motion of fluids are expressions of Newton's second law, F = ma. Forces associated with fluids fall into three major categories: (1) gravity, (2) pressure, and (3) friction. In the example using manometers, the gravitational force per unit volume of fluid is simply ρg, acting in the vertical direction. Pressure forces are the result of differences in pressure from one point to another and are expressed mathematically as the negative of the pressure gradient. (A pressure gradient is a vector in the direction of the maximal rate of pressure increase, with magnitude equal to the pressure derivative in that direction.) Friction is proportional to viscosity, the physical property of a fluid that relates shear stress to rate of strain:

$$P_0 = p + \frac{1}{2}\rho U^2 + \rho g z \quad (1)$$

Equation 1 shows the relationship between velocity and pressure of a fluid in a flow that meets the conditions described. For flows in tubes, the manometer technique provides an easy method of measuring mean pressure. The simplest flow meters apply a combination of these two principles to a tube of changing cross-sectional diameter. The Venturi flow meter shown in Figure 38-33 consists of a tube of varying cross-sectional area that has two ports for measurement of pressure. The Bernoulli equation for points 1 and 2 in the figure becomes:

$$P_1 + \frac{1}{2}\rho {U_1}^2 = P_2 + \frac{1}{2}\rho {U_2}^2 \quad (2)$$

Here, the gravity terms have canceled out because the tube is horizontal, but these terms are usually negligible for gas flows in any direction.

The volume of the fluid flow (Q) (also called flux) at both locations must be the same because no fluid is entering or leaving through the tube walls. The dimensions and SI units for the volume of fluid flow are L^3/t and m^3/sec. This volume is determined at each cross-section of the tube by multiplying the average velocity (U) by the cross-sectional area (A):

$$Q = U_1 A_1 = U_2 A_2 \quad (3)$$

Assuming that A_1, A_2, P_1, and P_2 are known, we now have two equations for the two unknowns U_1 and U_2. Solving these for the velocity U_1 produces:

$$U_1 = \sqrt{\left[2\left(P_1 - P_2\right)/\rho\left(1 - {A_1}^2/{A_2}^2\right)\right]} \quad (4)$$

To find the volume of the flow (Q), we multiply this result by A_1. Velocity is proportional to the square root of the pressure drop, or the pressure change varies as velocity is squared. For a given U_1, or the magnitude of flow velocity, the pressure drop varies as the square of the ratio of the areas, or the fourth power of the ratio of the diameters. If we choose an A_2 greater than A_1, equation 4 implies that P_2 is greater than P_1. In this case, the pressure increases in the direction of flow, a change that initially seems contrary to intuition.

The bobbin flow meters (also called variable-orifice flow meters) in anesthesia machines use a similar principle. These devices consist of a slightly tapered vertical tube and a bobbin or ball that fits inside the tube (see Fig. 38-35). The cross-sectional area of the ring-shaped gap between the bobbin and the tube wall is proportional to the height of the bobbin. Because changes in the cross-sectional area of flow are abrupt rather than gradual (as in Fig. 38-33), the Bernoulli equation does not accurately describe this type of flow. The flow above the bobbin (i.e., downstream) is highly turbulent, and turbulence is a condition that dissipates kinetic energy into heat. Introduction of the empirical constant C_d enables one to use the same formulation as in equation 4:

$$Q = C_d A \sqrt{\left[2\left(P_1 - P_2\right)\right]/\rho} \quad (5)$$

and

$$P_1 - P_2 = \left(\frac{1}{2}\rho Q^2\right)\Big/\left(C_d{}^2 A^2\right) \quad (6)$$

where C_d is a dimensionless constant called the "discharge coefficient." This constant varies with the shape of the orifice and with the value for another dimensionless parameter, the Reynolds number (Re). Re, the overall ratio of inertial forces to viscous forces in a particular flow, is determined as follows:

$$Re = \rho U L/\mu \quad (7)$$

where U is mean flow velocity, L is a characteristic length for the flow (in our flow meter, L is the diameter of the tube), and μ is the viscosity of the fluid. The dimension for viscosity is M/LT. The value for Re is important to any fluid flow because it determines some of the most important characteristics of the flow. The transition from laminar, or "smooth," flow to turbulent flow is determined by the shape of the flow and Re. Flow in a long, straight, smooth-walled tube becomes turbulent at an Re value of approxi-

mately 2100. Flow through an abrupt orifice, such as that of the flow meter in Figure 38-36, becomes turbulent at an Re value of less than 100.

Returning now to the function of the flow meter, one can see that as gas flows upward through the tapered tube, the bobbin begins to rise. As the bobbin rises, the cross-sectional area of the orifice (A) increases because of the taper of the tube; the drop in pressure ($P_1 - P_2$) decreases. The bobbin reaches an equilibrium position for a given volume of flow (Q) when the pressure lifting the bobbin is exactly equal to the weight of the bobbin. In this type of flow meter, the pressure difference is fixed by the bobbin weight, and the area of the orifice varies with the volume of the flow—hence the name "variable-orifice flow meter." Equations 5 and 6 show that calibration of these flow meters depends on the density and the viscosity of the gas: density (ρ) appears explicitly, and viscosity (μ) appears in the dependence of Cd on Re. If we use the wrong gas in a particular flow meter, equations 5 and 6 and the viscosity and density of the new gas enable us to predict the change in calibration.

Appendix 6

Measurement of Cardiac Output by Thermal Dilution and Mass Flow Technique

A commonly used method of measuring blood flow is dilutional calculation—dye or thermal dilution. These methods are simply mass or energy balances that determine the volume of fluid that has been diluted by adding a volume of dye or a given thermal energy. If you have a bucket of water at room temperature (25°C), and you want to determine the volume of water in the bucket, you could add a known volume of water at a known temperature. If 100 mL of water at 35°C is added to the bucket, and the final temperature is 27°C, the unknown volume can be calculated by balancing the heat energy associated with the dilutional process, assuming that no heat is lost to the environment. This dilutional process can be used to measure blood flow by completing this same heat balance measured over time. Thermodilution cardiac output measurements can have significant error as a result of the many assumptions associated with the technique, such as rapid injection of the thermodilution injectate; accurate temperature and volume of the injected fluid; constant known heat capacity of blood, which in reality is a function of the hematocrit value; and little heat loss to the lung.

Thermistor probes are most commonly used for clinical monitoring of patient temperature because they are inexpensive, small, and flexible. For these reasons, the thermistor probe also is used to measure cardiac output determined by the thermodilution technique. Computation of cardiac output performed in this manner is, in effect, a heat balance for the right side of the heart. (Heat balance is a method of accounting for all heat in a process or change involving transfer of heat.) The technique consists of quick injection of a known volume of a sterile solution (usually 10 mL of 5% dextrose in water) into the right side of the heart, while a sensor notes the temperature of the blood in the pulmonary artery. It is assumed that the cold injected solution equilibrates thermally with the blood as it perfuses the pulmonary artery, but that the solution does not acquire heat from other tissues. The following equation is the solution of this heat balance:

$$CO = \left[\rho i Ci Vi\left(T_b - T_i\right)(60Cr)\right] \Big/ \left[\left(\rho_b C_b \int_0^\infty T_b(t)dt\right)\right] \qquad (1)$$

where CO is cardiac output (L/min), ρ_i and ρ_b are the densities of the injectate and blood, C_i and C_b are the heat capacities of the injectate and blood, V_i is the volume of the injectate, T_b and T_i are the temperature of the blood and the injectate, *Cr* is a computational constant that corrects for the increasing temperature of the injectate, and the integration is the area under the thermodilution curve. Because the injectate warms as it is injected through the catheter before mixing with the blood, the correction factor Cr is applied to the equation.

The same principle of balance used for temperature determination of cardiac output can be applied to oxygen or carbon dioxide (CO_2) balance as well. Classically, oxygen balance is used as described by Fick. Measurement of oxygen consumption and content is cumbersome, and a modification of the Fick equation using CO_2 production is used. NICO is a new partial rebreathing method using the following equation:

$$Q = \dot{V}_{CO_2} \Big/ \left(C\bar{V}_{CO_2} - Ca_{CO_2}\right) \qquad (2)$$

Cardiac output (Q) is simply the expired CO_2 divided by the arterial-venous difference in CO_2. Assuming that Q does not change, the equations for CO_2 elimination must be the same with or without rebreathing, where *N* indicates normal breathing, and *R* indicates rebreathing. By rearranging the equations, cardiac output is the ratio of the change in elimination of CO_2 divided by the change in arterial CO_2 content. Arterial CO_2 content is derived from the slope of end-tidal pressure of CO_2 (P_{ETCO_2}):

$$Q = \dot{V}_{CO_{2N}} \Big/ \left(C\bar{V}_{CO_{2N}} - Ca_{CO_{2N}}\right) = \dot{V}_{CO_{2R}} \Big/ \left(C\bar{V}_{CO_{2R}} - Ca_{CO_{2R}}\right) = \frac{\Delta \dot{V}CO_2}{\Delta CaCO_2} \qquad (3)$$

We can see that potential errors are induced by violations of the following assumptions: (1) change in Q during the measurement period, (2) change in metabolic rate and production of CO_2, and (3) change in ventilation. As a trend analysis, patients with chronic obstructive lung disease, in which the absolute value of $PaCO_2$ is widely different from P_{ETCO_2}, may have an absolute error in Q determination by this method, but the relative changes should track.

Appendix 7

Ultrasound

The simplest sound wave to represent mathematically is a sinusoidal wave propagating in one dimension:

$$p' = p_0 \sin\left[(2\pi/\lambda)(x - at)\right] \quad (1)$$

where p' is the pressure fluctuation, λ is the wavelength (distance between waves), x is the coordinate in the direction of propagation, and *a* is the speed of propagation, or the speed of sound.

The amplitude of a sound wave is measured by the root mean square value of the pressure fluctuations. This value is called the sound pressure level (SPL). Because the range of SPL values is often very wide, a logarithmic scale is used:

$$SPL = 20\log\left(p^*/P_0\right) \quad (2)$$

where p^* is the root mean square pressure fluctuation, and P_0 is a reference pressure chosen as the lowest sound pressure detectable by the human ear. This pressure representing the threshold of hearing is 2×10^{-8} kPa at a sound frequency of 2 kHz (2000 cycles/sec). The units in this SPL scale are called decibels. A sound pressure of 2×10^{-8} kPa corresponds to an SPL of 0 dB, the lowest audible sound level [$(p^*/P_0 = 1$; log (1) = 0)]. Quiet conversation has an SPL of approximately 40 to 50 dB, or a pressure 10 to 300 times that of the threshold of hearing.

When sound waves encounter a sudden change in the properties of the conducting medium, some of the sound is transmitted through the new medium, and some of it is reflected, or "scattered," in many directions. Although the mathematics of this process are complex, one conclusion is readily apparent: The greater the mismatch in density and compressibility between the two media, the more sound that is reflected. The quantity that best determines the degree of reflection at an interface between two media is the ratio (R) of the products of density (ρ) and the speed of sound (a) through the two media:

$$R = (\rho_1 a_1)/(\rho_2 a_2) \quad (3)$$

We can easily see that the greatest acoustic mismatch in the body occurs between solid tissues and the lungs. The density and the speed of sound are much lower in the air-filled lungs than in solid tissues. Ultrasonography cannot "look" through the lungs at tissues or organs on the other side. The second greatest mismatch occurs between soft tissues and bone, the latter having a much higher ρa than the former. In 1842, Doppler first described the apparent change in pitch of a sound that occurred when either the source of the sound or the listener was moving. This Doppler effect now has several applications in patient monitoring, including precordial and esophageal Doppler ultrasound devices that measure local blood velocities or cardiac output. If a sound source radiating a frequency (f) is stationary, and the listener is moving (see Fig. 38-19A), the wavelength of the waves can be determined by the equation:

$$\lambda = a/f \quad (4)$$

because the time between wave fronts is 1/f, and the waves are moving at the speed of sound (a). If the listener moves toward the source at speed V_0, the velocity of the listener relative to the moving wave fronts is $(a + V_0)$. The number of wave fronts that the listener encounters per unit time is:

$$f' = \text{velocity}/\text{distance between waves} = (a + V_0)/\lambda \quad (5)$$

Because the sound frequency for a stationary listener is $f = a/\lambda$ (equation 4), the frequency f' heard by the moving listener becomes:

$$f' = (a + V_0)/\lambda = f + \left(V_0/\lambda\right) = f + \left(V_0 f/a\right) = f\left[1 + \left(V_0/a\right)\right] \quad (6)$$

The apparent frequency of the listener is increased by the factor $[1 + (V_0/a)]$. A listener moving toward the source at half the speed of sound hears a frequency 1.5 times that of a stationary listener.

Now consider a stationary listener and a source moving at speed V_0, as shown in Figure 38-19B. The wave fronts are no longer concentric circles; they are more closely spaced in the direction that the source is moving. If the frequency of the sound emitted at the source is f, the source moves a distance V_0/f during each vibration. The wavelength in the direction of motion is shortened by V_0/f and becomes $l = (a - V_0)/f$. The waves themselves are traveling at speed a, so the frequency heard by the stationary listener is:

$$f' = a/\lambda' = af/(a - V_0) = f\left[1/\left(1 - V_0/a\right)\right] \quad (7)$$

If the source is moving at half the speed of sound toward the listener, the apparent frequency doubles. Compare this situation with the preceding one in which the listener is moving, and the apparent frequency increases by only 50%. Doppler ultrasound systems combine the two situations shown in Figure 38-19. The initial acoustic source is a stationary transducer, and the sound from this device is scattered from a moving target (e.g., red blood cells). The scattered sound returns to a stationary listener—the receiving transducer. In effect, the target is a moving listener hearing a stationary source; the target re-radiates the sound as a moving source toward a stationary listener. The frequency heard by the receiving transducer is obtained by combining equations 6 and 7:

$$f' = f\left[\frac{1 + V/a}{1 - V/a}\right] \quad (8)$$

In this example, we have assumed that the target is moving toward the ultrasound transducers at speed V. If the target is moving at half the speed of sound, the observed frequency is increased by a factor of 3. Because changes in the frequency of sine waves can be measured precisely, the Doppler principle provides an accurate method of measuring the velocity of moving sound reflectors. At the high frequencies often used (ε5 MHz), objects as small as red corpuscles can scatter enough sound for detection.

Ultrasound imaging is exceptionally complex. For simplicity's sake, recall the submarine movies wherein the sonar operator calls out "range 2000 yards, bearing 36 degrees." These two parameters are crucial in describing some of the math of ultrasound.

The first factor to consider is the maximal range of the ultrasound, which is described by the following relationship:

$$r_{max} = cT/2 \quad (9)$$

That is, the maximal range equals the speed of sound in tissue (≈1540 msec) multiplied by time T between pulses divided by 2. A further limitation is the fact that the energy dissipates in the tissue. (You need to tap harder when percussing to detect deeper structures). For deeper penetration into tissues, one requires

higher energies and slower pulse rates. Wavelength and frequency are related in the following manner:

$$\lambda = c/f \quad (10)$$

where f is the frequency, λ is the wavelength, and c is the speed of sound.

Next, we need to consider the axial resolution (is the enemy destroyer 2000 yards distant, or 2005?) and the annular resolution (is the bearing 36 or 38 degrees?). Sound in tissue spreads out in a bandwidth around a fundamental frequency. To determine the necessary bandwidth for an axial resolution of 2 mm, the following rough approximation holds:

$$B = 2c/\Delta r \quad (11)$$

where Δr is the axial resolution. We need a bandwidth of 1.54 MHz to get an axial resolution of 2 mm.

For annular resolution (Δθ), the beam spreads out the farther it goes from the source. Without deriving the mathematics, two factors determine annular resolution—the frequency and the aperture. Aperture size is limited to a size that fits into or onto a human. A 1-degree error at a 1-cm range increases at a 10-cm range: circumference = 2πr: $\frac{1}{360} \times 2 \times \pi \times 1 = 0.17$ mm; at 10 cm, circumference = 1.7 mm.

39 Monitoring the Depth of Anesthesia

Key Points

1. The definition of "depth of anesthesia" has constantly evolved since the first demonstration of clinical anesthesia in the 1840s. The changing definitions have revolved around the available drugs used to provide anesthesia and the body of knowledge on their effects in humans.
2. Anesthesia is not a single pharmacologic process. It is a complex interaction of multiple stimuli, diverse responses, and the drug-induced probability of nonresponsiveness to the stimuli.
3. Anesthesia can be defined by hypnotic (unconsciousness) and analgesic (pain relief) components. The hypnotic component can be created by intravenous and inhaled anesthetics, whereas the analgesic component can be created by opioids and local anesthetics. Some drugs, such as ether, nitrous oxide, and ketamine, provide both hypnotic and analgesic components to some degree.
4. Hypnotics, when given alone, allow significant hemodynamic response to intense noxious stimuli. Opioids, when given alone, do not guarantee consistent unconsciousness or lack of movement response to intense noxious stimuli. The combination of the two can result in predictable unconsciousness and lack of hemodynamic response to intense noxious stimuli.
5. The interaction of the hypnotic and analgesic components can be characterized by a three-dimensional surface with hypnotic concentration on the *y* axis, analgesic concentration on the *x* axis, and the probability of nonresponse on the *z* axis.
6. Characterization of the three-dimensional surface requires precise stimuli to be applied and specific responses to be measured at defined effect-site concentrations of the hypnotic and analgesic.
7. The specific stimuli-response pairs used to define anesthetic depth range from easily suppressed responses to mild stimulation, such as the verbal response to a verbal command, to difficult-to-suppress responses to intense stimuli, such as the hemodynamic response to intubation.
8. The interaction of hypnotics and analgesics is generally synergistic.
9. Current clinical anesthesia involves the physician carefully observing the clinical response to defined stimuli and then adjusting the hypnotic or analgesic dosage (or both) by using the synergistic interaction to achieve the clinical goals of hemodynamic control, lack of awareness, and rapid, safe induction and emergence.
10. The hypnotic effects of the intravenous and inhaled anesthetics can be measured with empirically derived indices calculated from the electroencephalogram (EEG).
11. EEG-based indices of hypnotic drug effect correlate with hypnotic-induced sedation, amnesia, loss of consciousness, and reduced cerebral metabolic rate.
12. A consequence of inadequate anesthetic depth is intraoperative awareness. The incidence of awareness in healthy patients is approximately 0.1% and can increase to 1.0% to 1.5% in higher-risk patient populations.
13. There is emerging evidence that intraoperative monitoring of the hypnotic component of an anesthetic regimen may significantly decrease the risk of awareness associated with anesthesia. However, it does not totally eliminate the risk.
14. Maintenance of a high steady-state concentration of a volatile anesthetic may reduce the risk of awareness if the consequences of a high concentration can be tolerated by the patient.

A corollary to the aphorism "if you don't know where you are going, then any road will do" is that if you don't know what anesthesia is, any monitor of anesthetic depth will do. What is anesthesia? Anesthesiologists have multiple inconsistent definitions of the anesthetic state and hold strong opinions on how to measure it. Fortunately, an integrated, quantitative concept of the anesthetic state can now be built on the incremental knowledge developed since the introduction of anesthesia more than a century ago. As our understanding of the anesthetic state has advanced, so has our ability to control it pharmacologically and monitor it in real time.

The chapter is divided into four sections. The first reviews evolving definitions of depth of anesthesia. Anesthesia will be defined in terms of two fundamental pharmacologic components, the hypnotic effect and the analgesic effect, with clinical anesthesia requiring both components. The second section reviews memory and awareness, critical components of anesthetic depth. The third reviews basic pharmacologic concepts that are linked to depth of anesthesia. The last section discusses electrophysiologic approaches to assessing depth of anesthesia, including the influence of specific drugs on electrophysiologic approaches. The perspective of the authors is that anesthesia is a pharmacologically induced state that renders patients insensitive to surgery. Because pharmacology is inextricably linked to defining and measuring anesthetic depth, the pharmacology of hypnotics and opioids is discussed from different perspectives in each section. There is unavoidable overlap because monitoring the depth of anesthesia, the focus of this chapter, means monitoring the pharmacologic effects of the drugs used to render patients insensate.

Definitions of Anesthetic Depth

In a 1987 editorial, Prys-Roberts[1] examined clinical components truly relevant to the depth of anesthesia. He began by observing that depth of anesthesia is difficult to define because anesthetists have approached the issue in terms of the drugs available to them rather than the patient's needs during surgery. Prys-Roberts believed that the noxious stimulation of surgery induces a variety of reflex responses that may be independently modulated. One important observation was that pain is the conscious perception of noxious stimulation. Thus, he defined anesthesia as a state of drug-induced unconsciousness in which the patient neither perceives nor recalls noxious stimulation. The loss of consciousness is an all-or-none phenomenon. By this definition, there can be no variable depth of anesthesia. The patient is either conscious or unconscious.

Prys-Roberts defined noxious stimulation as a mechanical, chemical, thermal, or radiation-induced trespass causing potential or actual cell damage. Figure 39-1 shows the somatic and autonomic responses to noxious stimulation. Noxious stimulation arises from somatic or visceral tissue, and responses can be somatic or autonomic. Somatic responses include both sensory and motor activity. A sensory response is perception of pain. Low concentrations of inhaled or intravenously administered anesthetics can eliminate pain, particularly in combination with opioids, but they allow a motor response. The motor response to noxious stimuli is typically an all-or-none withdrawal of the stimulated part. This is the same concept that Eger and colleagues[2] used more than 4 decades earlier when they defined the minimum

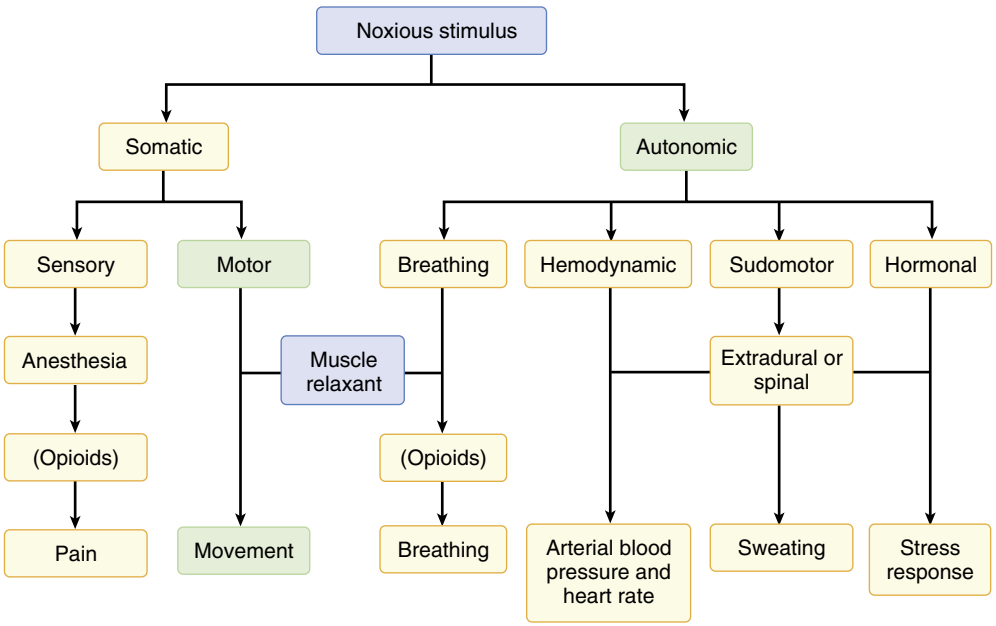

Figure 39-1 Depth of anesthesia can be defined by suppression of the clinically relevant responses to noxious stimuli, as proposed by Prys-Roberts. The figure is read from left to right and from top to bottom to see the order in which reflex responses are suppressed by anesthetic drugs. *(Modified from Prys-Roberts C: Anaesthesia: A practical or impossible construct? [editorial] Br J Anaesth 59:1341, 1987.)*

alveolar concentration (MAC) as the drug concentration that blocked movement in response to noxious stimulation.

Prys-Roberts divided autonomic responses into four categories: breathing, hemodynamic, sudomotor, and hormonal. The ventilatory response may occur even if there is no somatic motor response to surgical stimulation. A higher concentration is required to suppress the breathing response than is required to suppress the somatic response to noxious stimuli.

The hemodynamic response consists of autonomic responses to noxious stimuli, namely, increased sympathetic tone, which elevates arterial blood pressure and the heart rate. The sudomotor response consists of sweating, whereas the hormonal response consists of catecholamines and corticosteroids.

Prys-Roberts considered pain relief, muscle relaxation, and suppression of autonomic activity to be discrete pharmacologic effects. Some drugs can produce all these end points. Others produce only one or two. The only feature common to most anesthetics is suppression of sensory perception and production of unconsciousness. He considered the inclusion of muscle relaxation in the definition of the anesthetic state to be illogical and confusing. Although muscle relaxation is necessary for laryngoscopy and surgical access, it is neither a component of anesthesia nor an alternative to adequate anesthesia.

In a 1993 editorial, Kissin[3] expanded, refined, and further contributed to the definition of anesthesia. Similar to Prys-Roberts, Kissin began by indicating that a wide spectrum of pharmacologic actions via different drugs can be used to create the anesthetic state. Such pharmacologic actions include analgesia, anxiolysis, amnesia, unconsciousness, and suppression of somatic motor, cardiovascular, and hormonal responses to the stimulation of surgery. Kissin stated that the spectrum of effects that constitutes the state of general anesthesia should not be regarded as several components of anesthesia resulting from one anesthetic action but, rather, regarded as representing separate pharmacologic actions, even if the anesthesia is produced by one drug. Kissin then reviewed a series of investigative studies and concepts that supported his hypothesis:

1. Several groups of drugs (benzodiazepines, opioids, α_2-agonists) that induce anesthesia by acting on specific receptors can have their anesthetic effects reversed by the administration of a specific receptor antagonist.
2. There is growing understanding that the molecular mechanisms of general anesthesia are more specific than was suggested by the previous unitary hypothesis of anesthesia.
3. The rank order of effects for two important goals of anesthesia (hypnotic effect and blockade of somatic motor response to noxious stimuli) can be different for different classes of anesthetics. Opioids induce blockade of movement response to noxious stimulation before hypnosis occurs. For intravenous anesthetics, the opposite occurs.
4. When studies of anesthetic interactions are undertaken, the type of interaction (synergism, antagonism, summation) for one component of anesthesia may differ from that of another component.
5. Classic theories of anesthesia, based on the unitary nonspecific mechanisms of anesthetic action, suggest that one anesthetic may be freely replaceable by another and that the effects of anesthetic combinations should be additive. This appears to be true for inhaled anesthetics,[4] but most combinations of intravenous anesthetic drugs are synergistic for hypnotic effects, a finding that suggests diverse drug targets for drug-induced hypnosis.

If one understands general anesthesia as a spectrum of separate pharmacologic actions that vary according to the goals of anesthesia, certain conclusions can be made regarding the measurement of anesthetic potency and depth of anesthesia. Kissin stated that the "diversity of pharmacological actions that in combination provide anesthesia make[s] it almost impossible to determine the potency of different actions with one measure."[3]

A Modern Definition of the Anesthetic State

What is Anesthesia?

The sine qua non of the anesthetized state is unconsciousness or the lack of thought processing. The crux of the difficulty in defining "anesthetic depth" is that unconsciousness cannot be measured directly. What can be measured is response to stimulation. Does the patient respond to command? Does the response to incision suggest conscious perception? Does the heart rate or blood pressure go up in response to surgical manipulation? Does the patient remember events, conversations, or pain? As observed by Prys-Roberts, anesthesia is nonresponsiveness. The "depth" of anesthesia is determined by the stimulus applied, the response measured, and the drug concentration at the site of action that blunts responsiveness.

The state of consciousness can be assessed clinically with tools such as the Modified Observer Assessment of Alertness/Sedation (MOAA/S) scale (Table 39-1).[5] As defined later in this chapter, the state of consciousness can be inferred, although not directly measured, by analysis of information on the electroencephalogram (EEG). This can be done with either spectral techniques, such as the bispectral index (BIS) or with evoked potentials, such as auditory evoked potentials (AEPs). These indices do not directly measure unconsciousness or unresponsiveness. However, we know through extensive validation that these measures are predictive of the likelihood of response, provided that the anesthetic state has been induced with the drugs used to calibrate the electrophysiologic measure.

Nonresponsiveness can be induced by deep sleep or by 2% isoflurane. What distinguishes the nonresponsiveness of the anesthetic state from the nonresponsiveness of normal sleep is the stimulus intensity required to penetrate the state of nonrespon-

Table 39-1 Modified Observer's Assessment of Alertness/Sedation Scale

Score	Responsiveness
5	Responds readily to name spoken in a normal tone
4	Lethargic response to name spoken in a normal tone
3	Responds only after name is called loudly and/or repeatedly
2	Responds only after mild prodding or shaking
1	Responds only after painful trapezius squeeze
0	No response after painful trapezius squeeze

Box 39-1 Components Needed to Define Depth of Anesthesia

siveness and rouse the brain to conscious perception. The hypnotic drugs used in anesthesia (propofol, thiopental, inhaled anesthetics, ketamine) are each capable of producing such profound central nervous system (CNS) depression that even the most painful surgical stimulus cannot rouse the patient from a state of near-total nonresponsiveness. However, if the painful surgical stimulus can be attenuated before reaching the cortical level, the dose required to maintain the state of nonresponsiveness can be reduced.

Attenuation of surgical stimulation is the function of systemic analgesics (e.g., opioids) and local anesthetics. The interaction between analgesics and hypnotics is thus fundamental to understanding and defining anesthetic depth. Box 39-1 indicates the components of defining the depth of anesthesia used in the remainder of this chapter.

Extending ideas proposed by Glass in 1998,[6] consciousness can be perceived as the balance between depression and excitation within the cortex (Fig. 39-2, upper right). The cortex is primarily depressed by hypnotics, although opioids and nitrous oxide also have sedating properties that depress the cortex. Cortical depression promotes unconsciousness. These effects are opposed by ambient stimulation (e.g., loud music, a hard cold operating table) and the excitatory effects of pain projected on the cortex.

Figure 39-2 also shows the influence of opioids, nitrous oxide, and local anesthetics in preventing noxious stimulation from reaching the cortex. Systemic opioids act on the midbrain and thalamus,[7] although spinal actions are also critical for their analgesic effects.[8] Neuraxial opioids clearly act primarily on the spinal cord. Local anesthetics act either at the spinal cord (for neuraxial blocks) or on peripheral nerves (e.g., nerve blocks and local infiltration). Nitrous oxide exerts some of its analgesic effects through spinal mechanisms,[9,10] as well as the midbrain,[11] but for simplicity we will lump nitrous oxide with opioids at the midbrain. The net effect of analgesic and local anesthetics is to attenuate the transmission of painful sensation to the cortex, thereby reducing the amount of hypnotic required to obtain a state of nonresponsiveness.

Pharmacologic View of the Anesthetic State

Figure 39-3 reduces the model in Figure 39-2 to a highly simplified pharmacologic view.[12] The subcortical actions in Figure 39-2 have been compressed to a single site of action in the lower left of Figure 39-3, and all analgesics, including nitrous oxide, local anesthetics, and opioids, have been compressed to just "opioids." The simplification produces a mathematically tractable pharmacologic structure and may provide insight into the interaction between analgesics and hypnotics on consciousness and responsiveness.

In Figure 39-3, painful stimuli arrive in the lower left. Opioids (and all other analgesics) attenuate the painful stimulus.

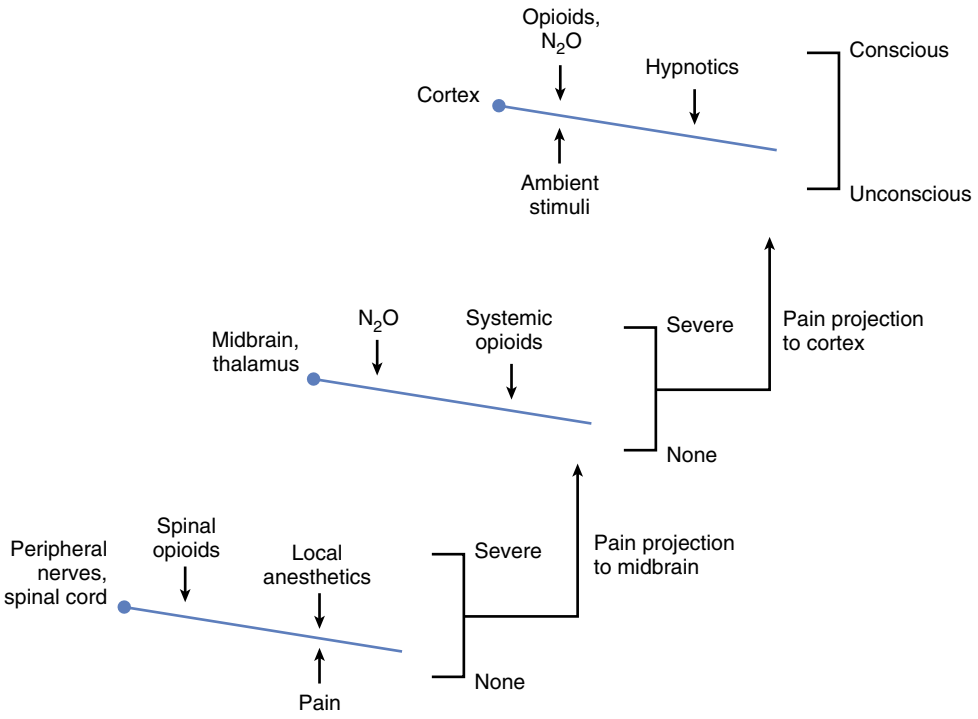

Figure 39-2 Stylized view of the interaction between hypnotics, which depress consciousness, and analgesics, which suppress noxious stimuli.

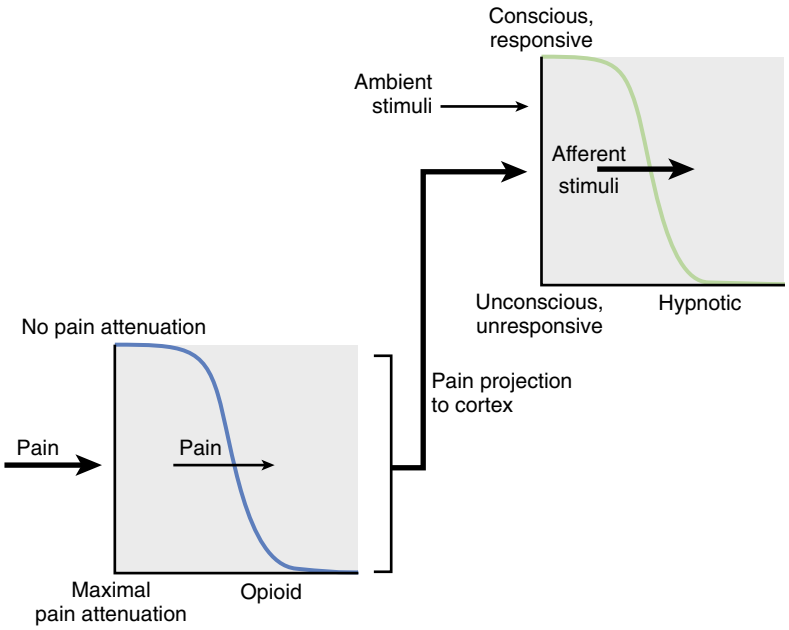

Figure 39-3 Pharmacologic interpretation of the interaction between hypnotics and analgesics. All measures of responsiveness appear in the upper right as "unconsciousness, unresponsive" which lumps the cortical and subcortical responses.

The magnitude of the stimulus affects both the magnitude of the output and the apparent potency of the opioids. Another way of saying this is that it takes more opioid to attenuate a powerfully painful stimulus than a moderately painful stimulus. This has repeatedly been demonstrated, as shown in Figure 39-4.[13] Pharmacologically, the effect of "opioids" on attenuating the pain signal can be expressed by using a standard sigmoid Emax pharmacodynamic equation:

$$\text{Pain out} = \text{Pain in} \cdot \left(1 - \frac{\text{Opioid}^{\gamma}}{\text{Opioid}^{\gamma} + \left[\text{Opioid}_{50} \cdot \text{Pain in}\right]^{\gamma}}\right)$$

in which "pain in" is the afferent painful stimulus, "pain out" is the efferent painful stimulus transmitted to the cortex, "opioid" is the steady-state opioid concentration, "opioid$_{50}$" is the equilibrated opioid concentration associated with 50% attenuation of the "pain in" for an afferent pain intensity of 1, and γ is the steepness of the opioid concentration-versus-response relationship. Opioid$_{50}$ is multiplied by "pain in" to reflect the decreased potency of opioids in attenuating severe pain, as shown in Figure 39-4.

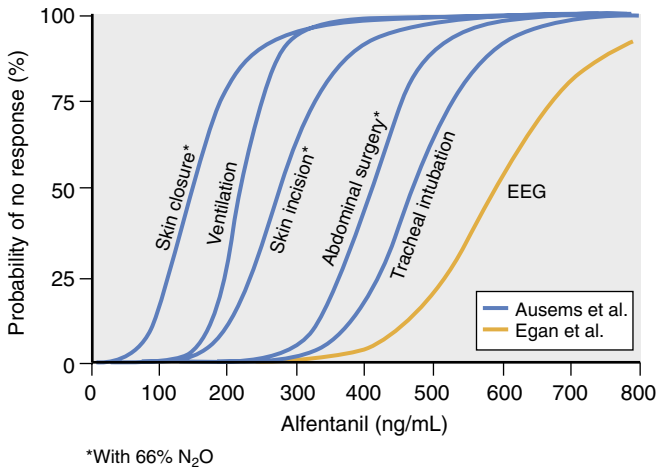

Figure 39-4 The effect of increasingly painful stimulation on the opioid concentration-versus-response relationship.[13] As pain intensity increases, the apparent potency of the opioids decreases. EEG, electroencephalogram.

In Figure 39-3 the output of the attenuated noxious stimulation is projected to the cortex, where the CNS-arousing characteristics of pain are balanced by the CNS-depressant effects of hypnotics. The pharmacologic expression of this would be

$$\text{Probability of responsiveness} = 1 - \frac{\text{Hypnotic}^{\eta}}{\text{Hypnotic}^{\eta} + \left[\text{Hypnotic}_{50} \cdot \text{Stimulus in}\right]^{\eta}}$$

where "stimulus in" is the "pain out" projecting from lower structures plus the ambient stimulation, "hypnotic" is the steady-state concentration of the sedative-hypnotic, "hypnotic$_{50}$" is the concentration associated with a 50% probability of nonresponsiveness when the "stimulus in" equals 1, and η is the steepness of the hypnotic concentration–versus–probability of nonresponsiveness relationship.

This cascading model of drug effect produces the response surface shown in Figure 39-5. The *x* and *y* axes in Figure 39-5 are the equilibrated concentrations of opioid and hypnotic, respectively, The *z* axis in Figure 39-5 is the probability of nonresponsiveness. This surface has the fundamental properties of the opioid-hypnotic relationship. Near the origin for drug concentrations, labeled "1" on the surface, there is no chance of nonresponsiveness, and the patient is probably wide awake. In fact, the floor of the figure indicates that there is a minimum amount of drug that must be given before the patient has any chance of nonresponsiveness. On the other side of the surface, labeled "2", there is enough opioid and hypnotic to ensure virtually no chance of response. The red line in the middle of the surface, labeled "5", is the 50% isobole. This line shows the opioid and hypnotic concentrations associated with a 50% probability of responsiveness. It extends from the curve for the hypnotic-versus-response relationship in the absence of opioids on the far left, labeled "3," to

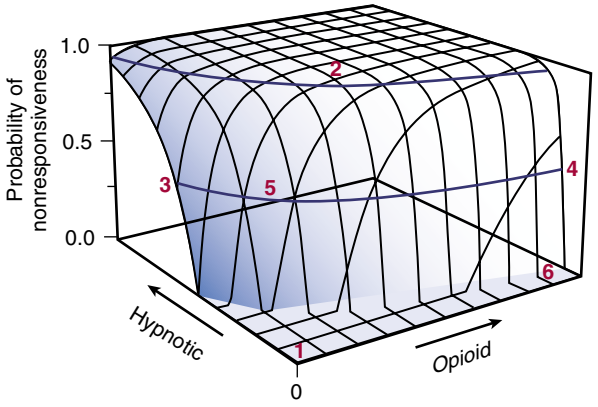

Figure 39-5 Relationship between opioid and hypnotic drug concentrations and the probability of nonresponsiveness. 1, No chance of nonresponsiveness; 2, no chance of response; 3, hypnotic-versus-response relationship in the absence of opioids; 4, hypnotic-versus-response relationship in the presence of large doses of opioids; 5, area of maximum synergy between opioids and hypnotics; 6, in the absence of opioids even profound levels of opioids cannot suppress response; *blue line* in the middle of the surface, the 50% isobole; *blue curve* at the top of the surface, 95% isobole.

the hypnotic-versus-response relationship in the presence of large quantities of opioids on the right, labeled "4." The relationship between hypnotics and opioids is highly synergistic in that when the drugs are used in combination (for example, at the point labeled "5"), it takes far less of either drug than would be the case were the opioids or hypnotics used alone. The model predicts that some hypnotic is required to achieve the anesthetized state. In the absence of a hypnotic, even profound levels of opioids are unable to produce a state of nonresponsiveness, as can be seen at point "6" on the surface.[14-17] However, a modest amount of opioid profoundly reduces the concentration of hypnotic necessary for nonresponsiveness, as seen at point "5." Beyond this, additional opioid has only modest effect in further reducing the hypnotic dose required for a drug effect. The corollary is that large doses of hypnotic are required in the absence of an opioid.[18-20] The blue curve at the top of the surface is the 95% isobole. This curve defines the opioid and hypnotic combinations associated with a 95% probability of nonresponsiveness. Because the surface is very steep, as soon as there is a modest probability of nonresponsiveness, a modest increase in drug concentration is all that is required to move from a 50% chance of nonresponsiveness to a 95% chance of nonresponsiveness.

Figure 39-5 shows that the model of the anesthetic state presented in Figure 39-2 generates a pharmacologic response surface that is very much like those seen in virtually all drug interaction trials.[21]

The ability of inhaled anesthetics to induce immobility in response to noxious stimulation is mediated by the spinal cord, not the cortex.[22,23] Experimentally, the interaction between inhaled anesthetics and opioids in preventing movement response to noxious stimulation[24] resembles Figure 39-5. As such, a pharmacologic model of the effect of opioids on MAC would resemble Figure 39-3 except that the response end point (movement) is mediated by the spinal cord rather than the cortex.

Experimental Characterization of the Anesthetic State

To quantify anesthetic depth, we must be rigorous about the definition of the *z* axis in Figure 39-5, the probability of nonresponsiveness. Consider the matrix of stimuli and responses shown in Figure 39-6. Stimuli can be roughly divided into benign and noxious. Benign stimuli are not physically painful. Thus, responses to benign stimuli are readily suppressed by hypnotics alone, with minimal need for analgesic drugs. Noxious stimuli are physically painful, and thus responses to noxious stimuli are more readily suppressed in the presence of analgesics. Skin incision appears somewhat in the middle of noxious stimuli, being more stimulating than electrical pain but much less stimulating than laryngoscopy and intubation. Figure 39-6 represents the noxious stimuli in approximately increasing order of intensity.

Figure 39-6 shows 10 responses in approximate rank order of difficulty to suppress and 14 stimuli of approximately increas-

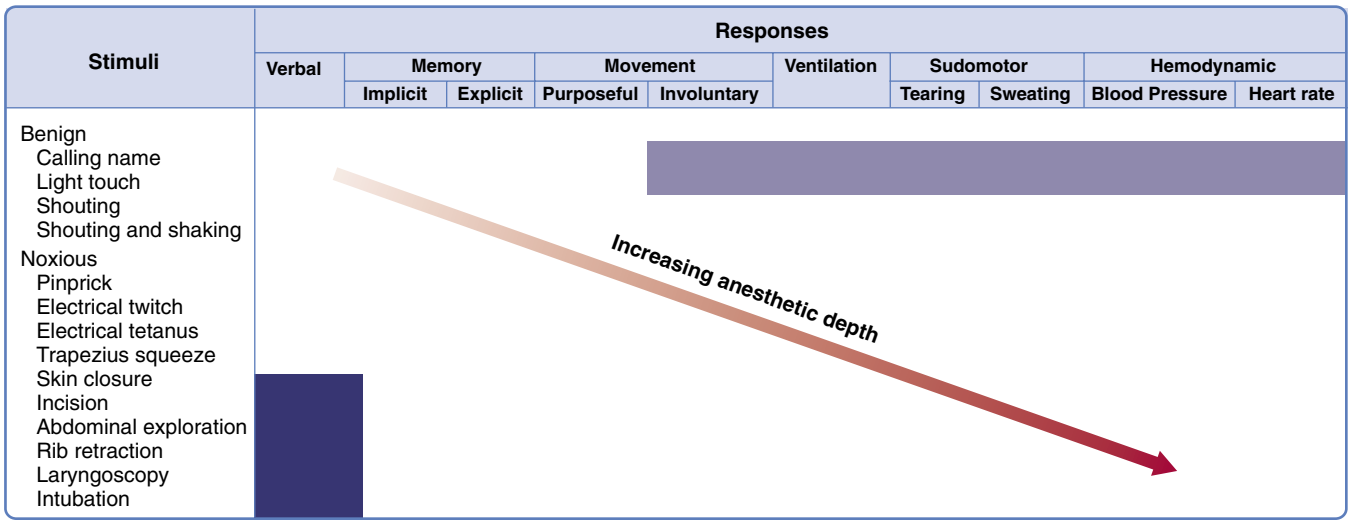

Figure 39-6 Matrix of relevant stimuli and responses. Stimuli are in approximately increasing order of noxiousness. Responses are in approximately increasing order of difficulty of suppression. As the cells progress from left to right and from top to bottom, increasingly larger doses of anesthetic drug are required to suppress the given response to the given stimulus.

ing intensity. The grayed-out cells have been removed as being clinically uninteresting, which leaves 122 cells to define anesthetic depth. If we wanted to fully characterize the ability of isoflurane and fentanyl to create a state of nonresponsiveness for each of the listed responses to any of the listed stimuli, we would need to characterize the response surface (i.e., Fig. 39-5) for each clinically relevant cell! With so many choices of stimuli and interactions, it is not surprising that anesthesiologists cannot agree on a simple definition of anesthetic depth.

Fortunately, it is not necessary to characterize the response to every stimulus. If we characterize the response to a benign stimulus, such as shaking and shouting, and several noxious stimuli, such as electrical tetanus, incision, laryngoscopy, and intubation, we will have captured the clinically relevant range of benign and noxious stimulation.

To our matrix of stimuli and responses we must add the matrix of hypnotics and opioids. Commonly used hypnotics include the anesthetic vapors halothane, isoflurane, sevoflurane, and desflurane and the intravenous hypnotics propofol, thiopental, etomidate, and midazolam. Commonly used opioids include fentanyl, alfentanil, sufentanil, remifentanil, morphine, meperidine, hydromorphone, methadone, tramadol, and piritramide. With 8 hypnotics and 10 opioids, there are 80 combinations. Eighty combinations times 122 interactions yields 9760 combinations of opioids, hypnotics, stimuli, and responses. To this we must then add the influence of age, disease, genetics, and other factors. Clearly, it is impossible to create response surfaces to characterize how opioids and hypnotics produce a state of nonresponsiveness for all possible combinations of drugs, patients, stimuli, and responses.

Fortunately, there are powerful generalizations that provide clinical insight and tractable experimental design. The most important is that for any stimulus-response pair, the depth of anesthesia is the probability of nonresponse. Specifically, *the depth of anesthesia is the drug-induced probability of nonresponse to stimulation, calibrated against the strength of the stimulus and the difficulty of suppressing the response*. Anesthetic depth ranges from fully awake (i.e., verbally responsive to a simple command) to a 100% probability of nonresponse for a difficult-to-suppress (e.g., tachycardia) to a profoundly noxious stimulation (e.g., intubation). Thus, a fully integrated view of anesthetic depth requires consideration of the components shown in Box 39-1.

Figure 39-7 shows an experimentally tractable and clinical useful distillation of the matrix of stimuli and responses from Figure 39-6. The matrix has been reduced to three stimuli, calling name, incision, and intubation, and three responses, verbal response, purposeful movement, and hemodynamic response. Within three of the cells are representative opioid-hypnotic interaction surfaces. As seen in the cells, verbal response to name calling is readily suppressed by hypnotics, with only modest effect from opioids. The middle surface shows that suppression of movement in response to incision requires more hypnotic and opioid to suppress than does a verbal response to a patient's name being called. Additionally, the vertical probability axis stretches for the more profound stimuli to indicate that a 100% chance of nonresponse to incision is a more profound level of drug effect than is a 100% chance of nonresponse to calling the patient's name. Suppressing the most refractory response, hypertension and tachycardia, to the most profound stimulus, intubation, requires yet more opioid and hypnotic. As demonstrated by Figure 39-7, anesthetic depth ranges from a 100% chance of a verbal response to a verbal command (wide awake, no drug) to enough opioid and hypnotic to provide a 100% chance of no hemodynamic response to intubation.

MAC creates a unifying principle of anesthetic depth for the inhaled anesthetics. Although each inhaled anesthetic has some pharmacologic peculiarities, in general they have parallel dose-response curves across drugs (e.g., isoflurane versus sevoflurane versus desflurane) and across stimuli-response pairs. Examples are the inhaled concentration associated with response to

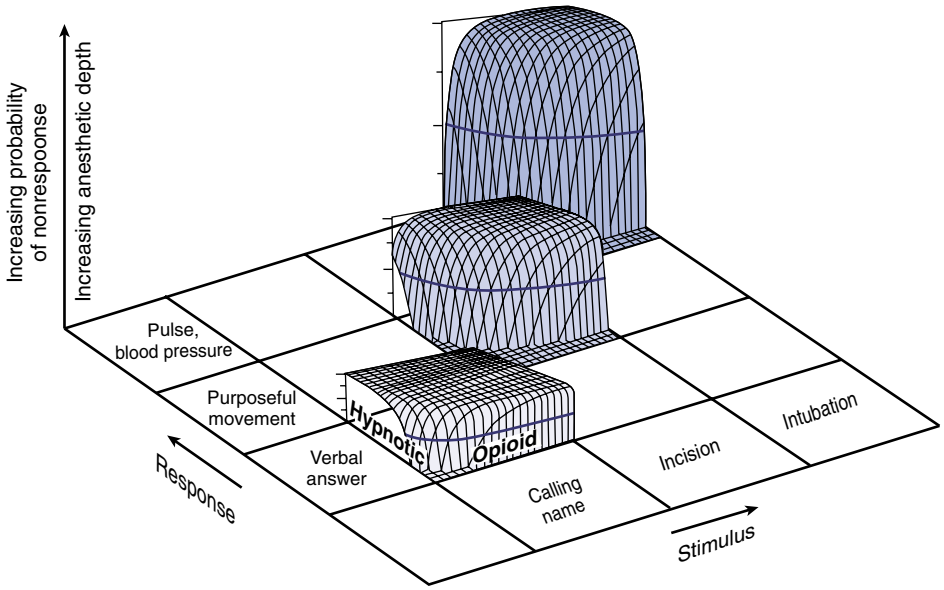

Figure 39-7 The role of opioid and hypnotics in the stimulus-response relationship for three stimuli of increasing intensity and three increasingly difficult responses to suppress. Each cell would have its own opioid-hypnotic interaction surface, and three are displayed. The vertical axis is the probability of nonresponse. Verbal nonresponsiveness to name calling is readily suppressed, even at light levels of anesthesia. In contrast, profound levels of anesthesia are required to suppress the hemodynamic response to intubation.

verbal stimulation (MAC-awake),[25] movement to incision (MAC), and hemodynamic response to incision (MAC-BAR).[26] Thus, by knowing the relative values of MAC, one can infer the relative values of the other stimulus-response relationships. There is less similarity among the intravenous hypnotics. Fortunately, the only intravenous drugs regularly used to maintain the anesthetic state are propofol and midazolam, which limits the number of clinically interesting intravenous anesthetic combinations.

Fentanyl, alfentanil, sufentanil, and remifentanil appear to differ mainly in potency and time course of drug effect, despite conflicting reports of pharmacologic idiosyncrasies for each member of the fentanyl series. Morphine, meperidine, hydromorphone, and methadone appear to differ in potency and intrinsic efficacy and have a slightly reduced maximum analgesic effect than the fentanyl series of opioids does. These latter four drugs also have their own pharmacologic quirks, particularly meperidine, which has only a limited role as an analgesic in contemporary practice.

Nitrous oxide is not only the oldest of the anesthetic drugs still in common use but also remains one of the least well understood. It has properties of hypnotics, with a MAC that slightly exceeds 1 atm,[27] as well as potent analgesic properties. Although the interaction of nitrous oxide with opioids,[28] inhaled anesthetics,[29] and propofol,[30] has been characterized, no studies have gathered enough data to generate the response surfaces needed to fully understand the interactions of this nearly ubiquitous anesthetic drug.

Fundamental Relationships That Characterize the Anesthetic State

Based on the simplifying assumptions just stated, we can comprehend anesthetic depth by understanding a limited number of prototypical drug combinations: isoflurane-fentanyl, isoflurane-nitrous oxide, nitrous oxide-fentanyl, propofol-fentanyl, propofol-nitrous oxide, midazolam-nitrous oxide, and midazolam-fentanyl. For each of these combinations, characterization of the response surface for a handful of stimuli and responses, as suggested in Figure 39-7, would allow understanding of current clinical practice and provide for definition of the full range of anesthetic depth:

1. Loss of response to shouting and shaking:
   a. Any response is considered, (i.e., "MAC-awake")
2. Loss of response to electrical tetanus:
   a. Verbal response or purposeful movement
   b. Any autonomic (hemodynamic or sudomotor) response
   c. Any memory response
3. Loss of response to an intermediate stimulus (incision, trapezius muscle squeeze):
   a. Purposeful movement (i.e., "MAC")
   b. Any autonomic (hemodynamic or sudomotor) response (i.e., "MAC-BAR")
   c. Any memory response
4. Loss of response to laryngoscopy/intubation:
   a. Purposeful movement
   b. Any autonomic (hemodynamic or sudomotor) response
   c. Any memory response
5. The concentration-versus-EEG response relationship in the absence of stimulation

We now have a matrix of just 11 stimuli-versus-response relationships. Multiplied by our seven prototypical drug combinations yields 77 response surfaces, from which we can infer the rest of the surfaces through scaling based on the MAC for inhaled drugs and C_{50} (concentration associated with a 50% probability of drug effect) for intravenous drugs and the relative rankings of stimuli and responses. Moreover, the combinations range from light anesthesia with modest stimulation and easily attenuated responses, found in the upper left corner of Figure 39-6, to deep anesthesia with profound stimuli and very difficult-to-ablate responses, found in the lower right corner of Figure 39-6.

Figure 39-8 shows examples of response surfaces for a modest and a profound stimulus. These interaction surfaces are based on the same model as the interaction surface shown in Figure 39-5, differing only in the intensity of the afferent painful signal. We find the same pattern when we examine real data. Figure 39-9 shows response surfaces for the potentiation of isoflurane by fentanyl (left)[16] and for the potentiation of propofol by alfentanil (right).[17] The shapes of these curves are not exactly like

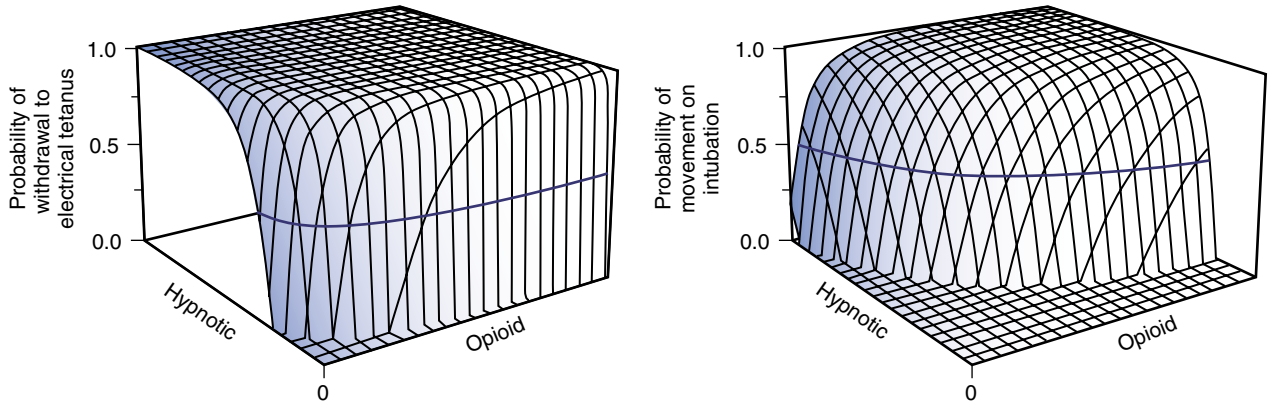

Figure 39-8 Examples of response surfaces for a modest stimulus on the *left* (withdrawal to electrical tetanus) and a profound stimulus on the *right* (movement response to intubation) based on the model shown in Figure 39-5 with differing intensity of the afferent painful signal. The figure on the *left* shows a relatively mild stimulus-response combination, whereas the figure on the *right* shows a profoundly noxious stimulus-response combination.

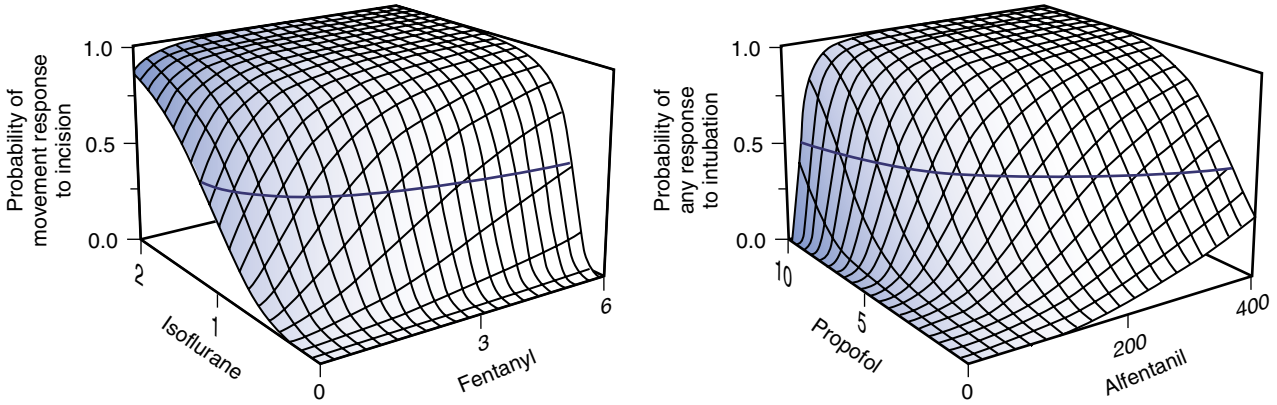

Figure 39-9 The *left* image shows the response surface for reduction in the minimum alveolar concentration of isoflurane by fentanyl.[16] The *right* image shows the interaction of propofol with alfentanil on blunting all responses to intubation.[17] Both figures demonstrate the intrinsic synergy between opioids and hypnotics in producing unresponsiveness.

the shapes derived from our hypnotic-opioid interaction model because (1) the investigators were interested only in characterizing the interaction at the 50% response level and thus did not gather enough data to characterize the upper and lower edges of either curve and (2) the mathematical function was logistic regression, which has several shortcomings as a model of drug interaction. Nevertheless, the figures demonstrate the intrinsic synergy between opioids and hypnotics in producing unresponsiveness, as well as the tendency for more profoundly noxious stimulation (e.g., intubation) to generate more synergy between the analgesic and hypnotic components of anesthesia.

Given our broad definition of anesthetic depth as providing nonresponsiveness to a wide range of stimuli-response pairs (see Fig. 39-6), one might wonder what drugs constitute "anesthetics"? Drugs are defined by their actions, and "anesthesia" is too nonspecific to characterize a drug effect. Because creation of a state of nonresponsiveness ("anesthesia") involves so many drug actions, the term "anesthetic" should not be used to suggest a particular drug class. In particular, "anesthetics" should not be used to describe drugs that suppress consciousness inasmuch as these drugs are more accurately termed "hypnotics." The one exception might be "inhaled anesthetics" because the drugs in this class (halothane, isoflurane, desflurane, and sevoflurane) suppress most of the responses to noxious stimuli.

Awareness and Memory

A spectrum of cognitive activity, including awareness, unconscious memory formation, and dreaming, has been reported during the administration of drugs that are intended to induce and maintain general anesthesia (Fig. 39-10). In addition, a range of physical and physiologic responses have been reported that may indicate perception of painful stimulation, whether conscious or unconscious. The nomenclature used to describe these phenomena has been varied and confusing. In this chapter we use the following widely accepted definitions (Box 39-2).

Awareness

Awareness during anesthesia is an important clinical problem that sometimes results in disabling psychological sequelae for the patient.[34] Although substantial improvements in prevention and treatment of awareness have been made in recent decades, further reductions are hopefully possible through improved training, continuing education, and perioperative care.

Incidence of Awareness

Measuring the Incidence of Awareness

No "cast-iron" method of measuring the incidence of awareness is available because awareness is a subjective cognitive experience that may not be completely understood by the patient or revealed by the patient to the interviewer.[35] Nevertheless, a consensus has developed about an acceptable form of questioning that is based on the questions first used by Brice, Hetherington, and Utting[36] published in 1970:

1. What was the last thing you remembered happening before you went to sleep?

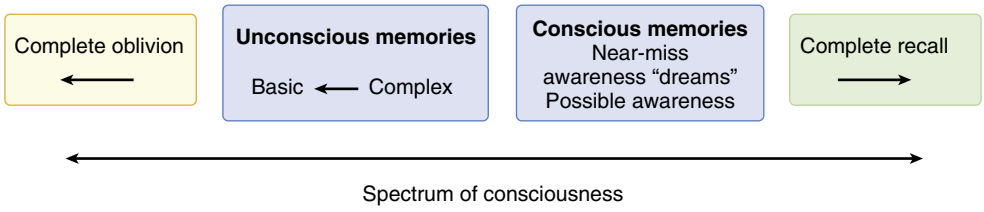

Figure 39-10 Spectrum of cognitive activity reflecting the pharmacologic activity of drugs that induce and maintain the anesthetized state, including awareness, unconscious memory formation, and dreaming.

Box 39-2 Definitions of Awareness and Memory

Awareness—Postoperative recall of events occurring during general anesthesia[31]

Amnesic wakefulness—Responsiveness during general anesthesia without postoperative recall[31]

Dreaming—Any experience (excluding awareness) that patients are able to recall postoperatively that they think occurred during general anesthesia and that they believe is dreaming[32]

Explicit memory—Conscious recollection of previous experiences ("awareness" is evidence of explicit memory)[33]

Implicit memory—Changes in performance or behavior that are produced by previous experiences but without any conscious recollection of those experiences ("unconscious memory formation" during general anesthesia)[33]

2. What is the first thing you remembered happening on waking?
3. Did you dream or have any other experiences while you were asleep?

Abouleish and Taylor[37] modified the Brice questionnaire to the form most commonly used in subsequent studies:

1. What was the last thing you remembered before going to sleep?
2. What was the first thing you remembered on waking?
3. Do you remember anything between going to sleep and waking?
4. While you were sleeping during the operation, did you dream?

An important feature of the modified questionnaire is that it includes a direct question about memory of intraoperative events without making any suggestion about what form these memories might take. A direct question is desirable inasmuch as previous research has suggested that patients may not volunteer information about their awareness episode.[38] In addition, patients should be questioned on more than one occasion postoperatively to maximize the likelihood of detecting all cases of awareness. Residual anesthetic effects, preoccupation with immediate postoperative problems such as pain, and memory suppression as a result of post-traumatic stress disorder[39] (PTSD) may inhibit patients from reporting their awareness experience at an early postoperative interview.

Clinicians should note that the modified Brice questionnaire has been administered to tens of thousands of patients in quality assurance audits and research projects without reports of undue distress to patients, thereby making it a useful tool for their routine postoperative rounds.

Studies of the Incidence of Awareness

Case reports of awareness date from the first demonstration of ether anesthesia by William Morton in 1846. Although the demonstration was deemed a success—because the patient was unresponsive during surgery—it was later revealed that the patient recalled part of the procedure. Patients continued to experience awareness in subsequent decades, but it was not until the introduction of curare into anesthetic practice in 1942 that the modern era of awareness began. The use of muscle relaxants allowed anesthesiologists to administer lower doses of volatile anesthetic agents because they were no longer relying on them to prevent movement during surgery. Case reports of recall of intraoperative paralysis began to appear. In the first prospective study, published by Hutchinson in 1960, a 1.2% incidence of awareness was reported.[40]

Many cohort studies and randomized trials have been published subsequently, the largest of which are presented in Table 39-2. This table reveals a 10-fold decrease in the incidence of awareness in the last 50 years, from about 1% to about 0.1%. In these recent studies, patients undergoing high-risk surgery were included in the mix and a substantial proportion received muscle relaxants. Most patients were attending tertiary referral centers where anesthesia was provided by qualified anesthesiologists and nurse anesthetists, as well as practitioners in training. Patients were asked a direct question about awareness and in two studies were interviewed more than once.

Several other recent studies have reported a substantially different incidence of awareness. Enlund and Hassan[52] did not identify any episode of awareness in 5216 patients undergoing minor surgery at a surgery center. A "high-dose" propofol-opioid protocol without muscle relaxants was administered to 93% of the patients. These patients were interviewed once at discharge from the postanesthesia care unit with the modified Brice questionnaire. The authors and others[62] questioned whether the patient mix, anesthesia protocol, and timing or number of interviews were responsible for the absence of awareness. Pollard and coauthors[33] also reported a low incidence of awareness in 87,361 patients undergoing all types of surgery (six cases [0.0068%]). Four of the aware patients were having cardiac surgery (incidence of 0.12% in cardiac surgery patients). This study was conducted in a tertiary referral hospital (56% of patients) and seven community hospitals and surgery centers (44% of patients). Anesthesia was administered by qualified nurse anesthetists and anesthesiologists using volatile anesthetic–based protocols. The authors and others[63,64] questioned whether the data collection method, which did not include a direct question about recall of events during surgery, the patient population, the absence of anesthesia providers in training, and the anesthetic protocols were responsible for the low incidence of awareness.

In contrast, several recent studies have reported higher rates of awareness. Chaiwat and colleagues[54] reported five cases of awareness in 802 American Society of Anesthesiologists (ASA) class 1 and 2 patients (0.62%) undergoing elective noncardiac, nonobstetric surgery in a Thai tertiary referral center. Volatile-based anaesthesia with muscle relaxants was administered. A cogent reason for each of the cases was present (i.e., inadequate anesthetic delivery, cardiovascular instability, increased anesthetic requirement). Errando and colleagues[61] recently reported 39 cases of awareness in 3921 patients (1%) undergoing noncardiac surgery at a tertiary referral center in Spain. The patients were enrolled between 1995 and 2001, and critically ill and traumatized patients were excluded. A higher incidence of awareness was reported in patients whose anesthesia was maintained with propofol (1.1%) or nitrous oxide (5%) than in patients maintained with a volatile anesthetic (0.59%).

Many studies have sought to determine the incidence of awareness in specific patient groups. These studies report an

Table 39-2 Prospective Cohort Studies of Awareness in Adult Patients

Year	Patients	*N*	Interviews	Incidence (%)	Type of anesthesia	Reference
1960	General surgery*	656	1	1.2	N_2O based and volatile based combined	Hutchinson[40]
1971	Obstetric surgery	880	1	3.3; 0.2	N_2O based versus volatile based	Crawford[41]
1975	General surgery	490	1	1	N_2O based and volatile based combined	Wilson[42]
1985	Cesarean section	777	1	6; 1	Low versus higher dose volatile based	Crawford[42a]
1991	General surgery	1000	1	0.2	Not stated	Liu[43]
1991	Cesarean section	3076	1	1.3; 0.4	Low- versus higher-dose thiopental/volatile	Lyons[44]
1993	Cardiac surgery	700	1	1.1	Volatile based	Phillips[45]
1993	Noncardiac surgery	1727	1	0.3	Propofol based	Sandin[46]

increased risk in patients undergoing cardiac surgery,[65] trauma surgery,[66,67] cesarean section,[44,59] airway endoscopic surgery,[68,69] and pediatric surgery[70,71] (although these incidences have also decreased over time). The reasons that these patients may be more at risk for awareness are discussed in the following paragraphs.

Risk Factors for Awareness

Awareness results from an imbalance between anesthetic requirement and anesthetic delivery. This imbalance may be summarized under three main headings:

Normal Requirement—Low Delivery

Inadequate delivery of anesthesia to patients with a normal anesthetic requirement is a common cause of awareness and one that exposes anesthesiologists to peer review, media attention, and litigation.[72,73]

Historically, anesthesia was commonly maintained with nitrous oxide supplemented by residual premedication and induction drugs—a technique associated with a greater than 1% incidence of awareness.[40] Appreciation of this fact resulted in increased use of volatile anesthetics and opioids and a decline in the incidence of awareness, particularly during cesarean section. Similarly, for cardiac surgery, high doses of opioids with or without an adjuvant hypnotic were favored because of stable patient hemodynamics. Unfortunately, however, responsiveness to noxious stimulation was ablated and a high risk of awareness was reported.[65,74] Influential commentary that questioned whether opioids were really capable of producing general anesthesia,[75] as well as a desire for rapid tracheal extubation ("fast tracking"), led to a change in practice and a reduced risk of awareness.[68]

Errors in knowledge, judgment, vigilance, or technical expertise can lead to inadequate anesthetic delivery during any type of general anesthesia.[76-78] However, inhaled and intravenous anesthetics each have their unique problems. During anesthesia with inhaled agents, awareness can result from vaporizer, anesthetic circuit, or end-tidal anesthetic gas monitor malfunctions

that lead to inadequate delivery of nitrous oxide or volatile anesthetic agents (or both).[78] Interruptions in delivery of volatile anesthetics when moving patients from anesthetic induction rooms to operating rooms may also have contributed to the historical incidence of awareness, especially in children.[31,70,71] During intravenous anesthesia, problems in every part of the system from the syringe driver to the site of intravenous access have been reported.[76,79] However, despite early concern about an increased incidence of awareness during propofol-maintained anesthesia,[80] only the Errando study identified a risk,[61] with other studies failing to confirm this risk.[52]

Low Requirement—Very Low Delivery

Delivering adequate anesthesia to patients with a low anesthetic requirement or low cardiovascular reserve presents a particular challenge. For example, pregnant women have a lower anesthetic requirement than nonpregnant women do.[81,82] However, concern about uterine contractility, placental blood flow, and neonatal respiratory depression makes anesthesiologists cautious about anesthetic delivery during cesarean section. The incidence of awareness during cesarean section was particularly high when nitrous oxide–based anesthesia was the norm. Recently, however, the risk of awareness appears to have diminished because of supplementation with volatile anesthetics and possibly the advent of EEG-based monitors.

Patients with low perfusion states as a result of hypovolemia or cardiac failure have a lowered anesthetic requirement, but the anesthetic doses required for adequate anesthesia may still be greater than those that can be tolerated by the cardiovascular system. The result is a higher incidence of awareness in cardiac[65,77] and trauma surgery patients.[66,67] This issue applies particularly to young cardiac and trauma patients, in whom the discrepancy between the vigor of the brain and the cardiovascular system is greatest.

High Requirement—Normal Delivery

Anesthetic requirements may be higher than usual in patients who are tolerant of sedative or analgesic drugs, such as alcohol, benzodiazepines, and opioids (unless the patient is acutely intoxicated, in which case anesthetic requirements may be lower).[54] In addition, there is normal variability in the population with respect to anesthetic requirements. Some patients have multiple episodes of awareness or have family members who have suffered awareness, thus suggesting a genetic etiology.[38,54] Recent evidence also links increased anesthetic requirements to the phenotype of red hair[83] and to childhood.[71] Finally, women recover more rapidly from anesthesia than men do, which potentially increases their risk of awareness if anesthetic delivery becomes inadequate.[84,85]

Preventing Awareness

The incidence of awareness has decreased substantially over recent decades, possibly because of the recognition that awareness has significant consequences for patients and their anesthesiologists and that some anesthetic techniques are associated with increased risk. Nevertheless, further reductions are hopefully possible through further training, continuing education, and perioperative care (Fig. 39-11).

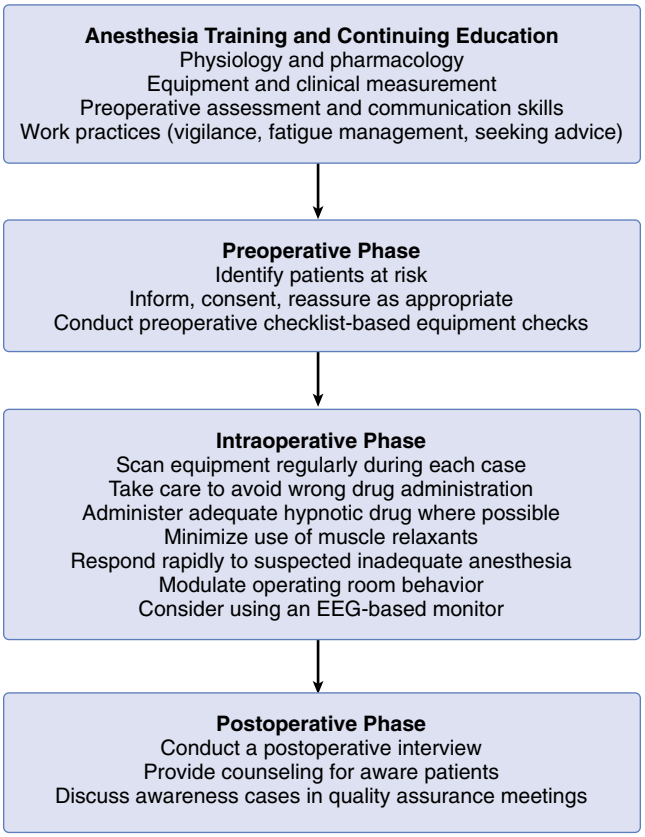

Figure 39-11 Steps to reduce intraoperative awareness by integrating training with perioperative vigilance. EEG, electroencephalogram.

Identifying Patients at Risk

An ASA task force recently promulgated a Practice Advisory that combined an evidence-based approach with expert opinion and open forum commentary.[34] The consensus was that a preoperative interview may be useful in identifying patients at increased risk for awareness and that patients at increased risk should be informed of the possibility of awareness preoperatively.[61] To elicit a past history of awareness, direct questioning may be required.[86]

Reducing Intraoperative Risk

A thorough checklist-based evaluation of equipment should be adhered to preoperatively.[61] During anesthesia, anesthesiologists should develop the habit of scanning drug delivery systems regularly to specifically detect inadequate delivery (e.g., leakage of propofol or air entrainment). Special care should be taken to avoid incorrect drug administration (e.g., giving a muscle relaxant instead of midazolam before induction).[73] Sufficient hypnotic should be administered when possible, and muscle relaxants should be avoided unless required. There should be a rapid response to suspected inadequate anesthesia because memories can take some seconds or minutes to be encoded. This response may include increasing delivery of hypnotic drug, reducing nociception by halting surgery and administering analgesics, and speaking reassuringly to the patient.[86]

Awareness cannot be directly measured as it occurs because by definition, it relies on postoperative recall of intraoperative events.[33] Traditional clinical signs such as movement, tachycardia, hypertension, pupillary responses, and lacrimation are thought to be unreliable predictors of awareness, but they

should still be monitored in every patient and treated on their merits.[35,37,54,55,61,86,87]

The utility of the BIS (Aspect Medical Systems, Inc.) in preventing awareness has been investigated in three large studies. Ekman and colleagues[88] conducted a prospective cohort study in Swedish patients undergoing noncardiac surgery under relaxant general anesthesia with routine BIS monitoring. Patients were interviewed three times with a modified Brice questionnaire. The incidence of awareness was significantly reduced in the BIS-monitored group in comparison to a historical control group without BIS monitoring (0.04% versus 0.18%; $P = .038$).

Myles and coworkers[55] conducted an international randomized controlled trial in 2463 patients at high risk of awareness who were undergoing all types of surgery under relaxant general anesthesia (the B-Aware Trial). Patients were randomized to receive BIS-guided anesthesia (BIS titrated to 40 to 60) or routine care and were interviewed three times with a modified Brice questionnaire. The overall incidence of awareness was 0.5%. There were two confirmed cases of awareness in the BIS-guided group and 11 confirmed cases in the control group (odds ratio, 0.18; 95% confidence interval, 0.02 to 0.84; $P = .022$). Awareness was not predicted from clinical signs in any case. The authors concluded that BIS monitoring is warranted in patients at high risk for awareness undergoing relaxant general anesthesia.

Recently, Avidan and coauthors[60] reported the results of a single-center randomized controlled trial in 1941 patients at higher risk for awareness who were undergoing all types of surgery under relaxant general anesthesia. Patients were randomized to receive BIS-guided anesthesia (BIS titrated to 40 to 60) or end-tidal anesthetic gas (ETAG) concentrations of 0.7 to 1.3 MAC and were interviewed three times with a modified Brice questionnaire. The overall incidence of awareness was 0.2%. There were two cases of awareness in each group (absolute difference, 0%; 95% confidence interval, −0.56% to 0.57%). The authors concluded that their results did not support routine BIS monitoring. Subsequently, it has been shown that the study was underpowered to confirm a difference inasmuch as the incidence of awareness was much lower than anticipated by the sample size calculation, the patients were at relatively low risk, and ETAG concentrations in the 0.7 to 1.3 MAC range are likely to prevent awareness (if the hemodynamic consequences can be tolerated by the patient).[89] In fact, adequate power to detect a difference between BIS and ETAG would have required a group size of more than 9000 patients.[90] Although it is not possible to draw a conclusion about the relative effectiveness of BIS and ETAG from this study, Avidan and coworkers have provoked a discussion about whether ETAG-guided anesthesia is a viable means of preventing awareness.[60] This hypothesis awaits confirmation by a suitably designed trial.

Overall, the current evidence indicates that BIS monitoring may reduce but not eliminate the risk of awareness.[91,92] Failure to respond adequately to changes in the index (i.e., allowing sustained BIS values above the recommended range),[55,60] failure to recognize the possibility of misleading values or artifact,[93,94] and the possibility that awareness may occur at BIS values within the recommended range[55,60] are all reasons why awareness may still occur in BIS-monitored patients. Furthermore, no specific data exist for the other available EEG-based monitors. On this basis, the ASA taskforce concluded that "the decision to use a brain function monitor should be made on a case-by-case basis by the individual practitioner for selected patients (e.g., light anesthesia)."[34] This analysis should also take into account the potential cost of using this technology to prevent a relatively rare complication of anesthesia.[55,60,95]

Consequences of Awareness

Earlier reports on the psychological consequences of awareness were based on retrospective study designs in which patients were identified by advertisement, referral, or analysis of closed claims.[35,72,96] These studies illustrated the distress that may result from an awareness episode but did not confirm the spectrum of symptoms or the incidence of PTSD. More recently, Lennmarken and colleagues[97] audited the incidence of psychological sequelae in 18 prospectively identified awareness cases. Three weeks after the episode, all patients appeared to be coping well and follow-up was discontinued. Two years later, two patients could not be contacted, one had died, and six refused to be interviewed. Of the nine interviewed patients, four were severely disabled by PTSD and another three reported more minor symptoms. These authors suggested that the incidence of PTSD could be greater than 50% inasmuch as avoidance of medical situations is one of the signs of PTSD. Subsequently, this group of researchers reported a contrasting result.[38] They asked 2681 consecutive patients whether they had been aware in the past and identified greater emotional stress in the few days after the episode than later (incidence of late psychological symptoms, 33%). They concluded that the study methodology may influence the result.

Risk factors for PTSD in the awareness setting have not been identified. Commentators have suggested that memory of the pain of surgery and an unsympathetic response from caregivers may contribute.[35,97] The psychological literature suggests that peritraumatic dissociation is a predictor of the severity of posttraumatic symptoms.[39] Further research is required in this area.

An episode of awareness may have consequences for the anesthesiologist as well. Most patients who suffer an awareness episode do not proceed to litigation or generate unwanted attention from the media or regulatory authorities. One could hope that good communication and patient support may prevent not only adverse patient sequelae but also lawsuits.[98] The ASA Closed Claims Project provides a valuable analysis of cases that have proceeded to litigation in the United States. In the period 1990 to 2001, 55 claims were made, substandard care was identified in 47% of cases, and 46% were settled with a patient payment (median payment, $41,210 [substantially lower than the median payment for other general anesthesia claims]).[98] It is difficult to say whether the recent attention paid to awareness[34] and the advent of EEG-based monitoring[55] will increase or decrease the liability for awareness in the future.

Unconscious Memory Formation During Anesthesia

Whether patients can form unconscious memories during anesthesia and whether these memories matter are interesting questions and ones that have occupied researchers for the last 40 years.[99] In the first systematic study of this subject, Levinson[100] staged a mock crisis during anesthesia and then hypnotized the patients to determine whether unconscious memories of the crisis had been retained. No patient had active recall of events occurring during anesthesia, but under hypnosis, 4 of the 10 patients could recount the crisis accurately. However, this study

and subsequent ones[99] were confounded by the inability to discount inadequate anesthesia or reduce the influence of active recall when testing for unconscious memory.

Since the mid-1990s, investigators have more carefully controlled anesthetic depth by using EEG-based monitoring and have used perceptual priming tests that measure explicit and implicit memory in a single test involving the process dissociation paradigm.[101] These studies revealed that unconscious memories are retained if anesthesia is relatively light or variable in depth and word presentation occurs during surgery.[102-104] For example, Lubke and coworkers[102] investigated patients in whom general anesthesia was induced for trauma surgery by using the word stem completion test and process dissociation paradigm. The number of stem completions with words presented during surgery ("hits") increased with increasing BIS values, and implicit memory was demonstrated at BIS values of less than 60. Stonell and coauthors[103] reported successful priming at BIS values greater than 50, whereas Deeprose and colleagues[104] reported priming at mean BIS values of 42. In contrast, Kerssens and colleagues[105] targeted a similar BIS range but achieved a lot less fluctuation in BIS values (1% versus 8% to 11% in the previously mentioned studies[103,104]). They could not demonstrate any unconscious memory formation. This study emphasizes that excursions into light planes of anesthesia appear to be necessary for memory formation.

Finally, does unconscious memory formation during anesthesia have any consequences for the patient? In the psychological literature, priming has been reported to enhance existing tendencies—this is the foundation of subliminal advertising techniques. However, there is no evidence yet that unconscious memory formation has adverse or even therapeutic effects after general anesthesia. Nevertheless, we should avoid making comments during anesthesia that we do not want our patients to hear.[106]

Dreaming During Anesthesia

Dreaming during anesthesia is a commonly reported and fascinating phenomenon that nevertheless remains poorly understood. The incidence of dreaming during anesthesia varies according to the age and sex of the patients, the type of anesthesia, and the timing of the postoperative interview. Dreaming is more commonly reported by younger patients[107,108] and after propofol-based,[108] opioid-based,[36] or ketamine-based[109] anesthesia. If an interview is conducted at emergence from anesthesia, about 25% of patients will report that they have been dreaming.[108] However, if the interview is delayed until discharge from the postanesthesia care unit, the incidence falls to around 6%.[55]

Early reports of dreaming were often suggestive of near-miss awareness: (1) "A patient dreamed that he was at a fairground and someone was throwing darts at his stomach,"[110] (2) "A patient dreamt that the pages of a heavy book were being slowly turned over at regular intervals,"[40] and (3) "A patient dreamed of a party at a public house in which there was a generous supply of gin and the anaesthetist was the landlord!"[36] It was also reported that dreaming patients exhibited more signs of light anesthesia, were more likely to report awareness, and were less likely than nondreaming patients to have been BIS monitored.[36,107,111]

Subsequent studies suggested, however, that most dreaming is not related to inadequate anesthesia and may occur during recovery. Leslie and coworkers[108] conducted a prospective cohort study of 300 young healthy patients undergoing relaxant general anesthesia for noncardiac surgery. No difference in median BIS values during surgery between dreamers and nondreamers was reported. The form and content of the dreams were suggestive of the dreams of sleep onset, and the authors postulated that dreaming was occurring during physiologic sleep (a hypothesis that awaits confirmation).

Almost all dreaming during anesthesia is harmless, unimportant, and quickly forgotten. Only dreams that worry the patient or that are suggestive of awareness should receive further attention. These patients should receive similar follow-up to patients with frank recall of intraoperative events.[108]

Hypnotics, Analgesics, and Anesthetic Depth

Inhaled Anesthetics

Movement Response and the MAC Concept

Purposeful movement of a body part in response to noxious stimuli has been extensively used as a clinical sign of anesthesia. Using this movement to quantitate anesthetic response induced by potent inhaled anesthetics, Eger, Merkel, and their colleagues[2,112] defined MAC as the minimum alveolar concentration of inhaled anesthetic required to prevent 50% of subjects from "gross purposeful movement" in response to a skin incision. As suggested by the definition, "minimum" is a slight misnomer, and "median" would probably have been a better descriptor. Readers are referred to the excellent review articles that document development of the MAC concept and its many applications in anesthesia.[113,114]

The MAC concept has three basic components: (1) an all-or-none (quantal) movement response must occur after applications of a "supramaximal" noxious stimulus; (2) end-tidal concentrations of anesthetic in the alveoli, considered an equilibrated sample site, are used as an indication of the concentration of anesthetic in the brain; and (3) MAC is a unifying concept of inhaled anesthetic potency.

For determination of MAC in humans, the standard noxious stimulus has been the initial surgical skin incision.[2] Skin incision represents a reproducible noxious stimulation. There has been no systematic examination of other perioperative surgical stimuli (e.g., peritoneal traction) representing more profound surgical manipulation than skin incision or endotracheal intubation. For determination of MAC in animals, the standard stimulus has been application of a surgical clamp to the base of the tail. After examining other noxious stimuli in dogs, Eger and colleagues[2] concluded that tail clamping represented the most noxious stimulation that was experimentally reproducible and not excessively traumatic.

A second component of the MAC concept involves use of the alveolar concentration of an anesthetic as an indication of drug concentration. The steady-state (i.e., equilibrated) partial pressures of inhaled anesthetics must be identical in all body tissues, such as alveoli, blood, and brain. Thus, the measured end-tidal partial pressure of an inhaled anesthetic (representative of the alveolar concentration) is in direct proportion to the underlying concentration in the brain at steady state. Because the brain

is so well perfused relative to its mass, it is possible to achieve an equilibration among end-tidal, alveolar, arterial, and brain anesthetic partial pressures within 15 minutes of exposure to a constant end-tidal anesthetic concentration.[115]

A third component of MAC is that it has served as a unifying measure of inhaled anesthetic potency. This has resulted in the concept of MAC fractions or MAC multiples for end points other than movement response to skin incision. Stoelting and colleagues determined the MAC of an anesthetic that would allow opening of the eyes on verbal command during emergence from anesthesia ("MAC-awake").[116] This stimulation is less intense than surgical skin incision, and response occurs at lower concentrations of anesthetic than movement to skin incision does. Generally, the MAC-awake values are a third to a fourth of the MAC values for surgical incision. Yakaitis and coworkers[117] determined the MAC of an inhaled anesthetic that would inhibit movement and coughing during endotracheal intubation ("MAC-intubation"). Intubation is significantly more stimulating than skin incision, with higher concentrations of inhaled anesthetic required to eliminate movement response. Finally, Roizen and associates[118] investigated the MAC of anesthetics necessary to prevent an adrenergic response to skin incision ("MAC-BAR"), as measured by the concentration of catecholamine in venous blood. When one examines the values for (1) MAC-awake, (2) MAC–skin incision, (3) MAC-intubation, and (4) MAC-BAR, one sees a family of concentration-versus-response curves that characterize the hypnotic effects of inhaled anesthetics relative to defined clinical stimuli.

Zbinden and colleagues undertook a comprehensive examination of the effects of different noxious stimuli on the purposeful movement response with isoflurane.[119] Twenty-six healthy surgical patients were administered only isoflurane with adequate inspired/end-tidal equilibration. Multiple noxious stimuli were applied at varying end-tidal isoflurane concentrations. From the resulting data, the authors were able to define a family of concentration-versus-response curves for different noxious stimuli, as displayed in Figure 39-12. The percent end-tidal isoflurane concentrations that resulted in a 50% probability of no movement response for different stimuli were as follows: verbal responsiveness, 0.37%; trapezius muscle squeeze, 0.84%; laryngoscopy, 1.0%; 50-Hz electrical tetanus, 1.03%; skin incision, 1.16% (MAC, by definition); and laryngoscopy with intubation, 1.76%. This study demonstrates how varying clinical stimuli require different isoflurane concentrations to prevent a clinical response and can be used to define a concentration-versus-response relationship for the hypnotic effects of isoflurane. When different inhaled anesthetics are compared, the ratio of MAC–skin incision to MAC-intubation or MAC-awake is relatively constant.

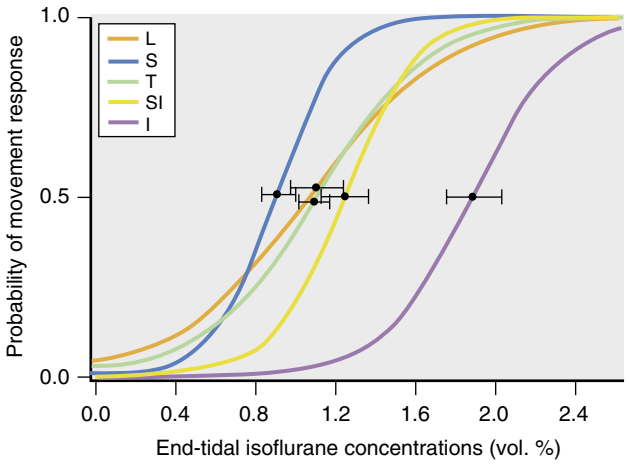

Figure 39-12 Logistic regression analysis of the end-tidal isoflurane concentration relative to the predicted probability of no movement response for different noxious stimuli. *Bars* indicate the 95% confidence intervals the end-tidal concentration with a 50% probability of response. I, laryngoscopy/intubation; L, laryngoscopy; S, trapezius muscle squeeze; SI, skin incision; T, tetanic nerve stimulation. *(Modified from Zbinden AM, Maggiorini M, Petersen-Felix S, et al: Anesthetic depth defined using multiple noxious stimuli during isoflurane/oxygen anesthesia. I. Motor reactions. Anesthesiology 80:253-260, 1994.)*

Table 39-3 Factors that Affect Minimum Alveolar Concentration

Effect on MAC	Factors (Study Subjects)
Decrease	Hypothermia (animals) Severe hypotension (animals) Advanced age (humans) Opioids, ketamine (humans, animals) Chronic administration of amphetamine (animals) Reserpine, α-methyldopa (animals) Cholinesterase inhibitors (animals) Intravenous local anesthetics (humans, animals) Pregnancy (animals) Hypoxemia (Pa_{O_2} < 40 mm Hg) (animals) Anemia (animals) α_2-Agonists (animals, humans)
Increase	Hyperthermia (animals) Hyperthyroidism (animals) Alcoholism (humans) Acute administration of dextroamphetamine (animals) Young age (humans, animals)
No effect	Duration of anesthesia (humans, animals) Sex (human, animals) Metabolic acid-base status (animals) Hypercapnia and hypocapnia (humans, animals) Isovolemic anemia (animals) Hypertension (animals)

Other drugs used in anesthesia increase the apparent potency of inhaled anesthetics by decreasing the anesthetic requirement, as measured by a reduction in MAC. Numerous altered physiologic states (e.g., aging) also change the apparent potency of inhaled anesthetics. Several review articles have described the many studies applying the MAC concept to the clinical practice and science of anesthesia.[38] Table 39-3 summarizes the results of these studies regarding the factors that affect MAC.

Much of the previous research on MAC assumed that the lack of movement response from inhaled anesthetics was due to anesthetic effects on the central, cortical brain tissues. This assumption has been challenged. In 1993, Rampil and coworkers demonstrated in decorticate rats that the spinal cord was the primary site mediating immobility for inhaled anesthetics.[22] Antognini and Schwartz also drew the same conclusions from experiments in goats with isolated brain/body perfusion.[23] These investigators demonstrated that the MAC value for the goat was

Table 39-4 Hemodynamic Response to Defined Noxious Stimuli Under Isoflurane Anesthesia

Stimulus	End-Tidal Concentration That Suppresses Movement In 50% of Patients (ET_{50}) (Percent atm)	Change in Systolic Blood Pressure for Patients at ET_{50} (mm Hg)	Change in Heart Rate for Patients at ET_{50} (Beats/min)
Trapezius muscle squeeze	0.90	9	5
Electrical tetanus	1.10	15	15
Laryngoscopy	1.07	23	17
Skin incision	1.24	34	35
Laryngoscopy and intubation	1.87	53	36

ET, end-tidal concentration.

approximately twice as large when only the brain was exposed to isoflurane than when both the brain and spinal cord were exposed to the anesthetic.

Other Clinical Responses

Responses other than purposeful movement have been investigated as possible clinical measures of the depth of anesthesia: the rate and volume of ventilation in spontaneously breathing subjects, eye movement, the diameter and reactivity of pupils to light, heart rate, arterial blood pressure, and autonomic signs such as sweating. It has not been possible to use these clinical signs to generate uniform measures of the depth of anesthesia for inhaled anesthetics. Although some clinical signs do correlate with depth of anesthesia for certain inhaled anesthetics, the same cannot be said for other inhaled anesthetics.[120]

We have previously noted that the hemodynamic response is harder to suppress than movement. This was particularly well demonstrated by Zbinden and colleagues[121] in a systematic study of the hemodynamic response to different noxious stimuli at increasing isoflurane concentrations. In 26 healthy surgical patients receiving different equilibrated end-tidal concentrations of isoflurane, the following noxious stimuli were applied, several of them on multiple occasions: trapezius muscle squeeze, 50-Hz electrical tetanus, laryngoscopy, laryngoscopy with intubation, and skin incision. With continuous recording of intra-arterial hemodynamics, acute increases in heart rate and systolic blood pressure were recorded and related to the isoflurane concentration and presence or absence of purposeful movement. Table 39-4 presents the absolute increase in systolic blood pressure and heart rate at the isoflurane end-tidal concentration that had a 50% probability of no purposeful movement for that specific stimulus. As stated earlier, different noxious stimuli result in different degrees of hemodynamic response. There is a relative rank order of the degree of hemodynamic response, with laryngoscopy and intubation being the most intense stimuli. Multiple regression analysis demonstrated that the type of stimulation had the most influence on the increase in blood pressure, with the isoflurane concentration being the least important. Figure 39-13 presents the baseline systolic blood pressure and subsequent increase in systolic pressure at a measured isoflurane concentration for subjects receiving a skin incision. Increasing isoflurane concentration did not prevent the increase in systolic blood pressure, even at very high end-tidal concentrations. Rather, increasing isoflurane concentration only decreased the prestimulation systolic

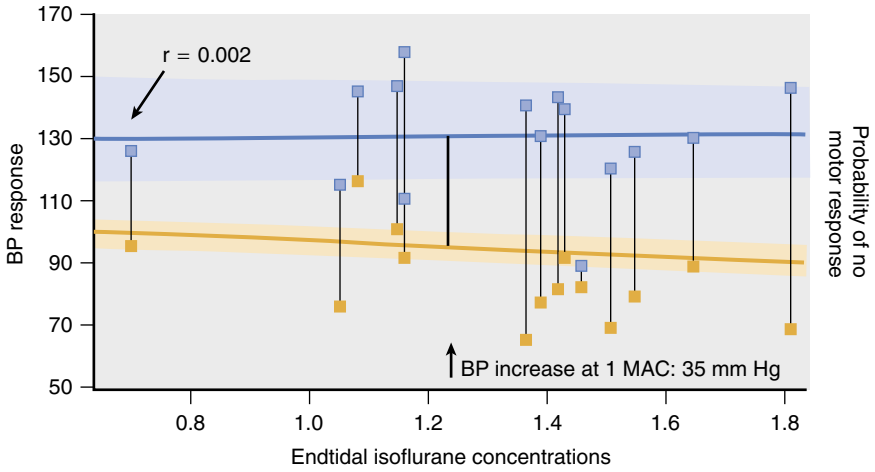

Figure 39-13 Response of systolic blood pressure (BP, in mm Hg) to skin incision as a function of end-tidal isoflurane concentration. Yellow squares, systolic blood pressure before stimulation; Blue squares, systolic blood pressure after stimulation; *lower oblique line*, regression line to systolic BP before stimulation (r = –0.46); *upper line*, regression line to systolic BP after skin incision (r = 0.0002); *shaded area*, 95% confidence interval for regression lines; *vertical arrow*, median effective isoflurane concentration for the motor response of the stimulation pattern. The *shaded areas* represent the linear regression relationship of isoflurane concentration versus prestimulus and poststimulus systolic BP. MAC, minimul alveolar concentration. *(From Zbinden AM, Maggiorini M, Petersen-Felix S, et al: Anesthetic depth defined using multiple noxious stimuli during isoflurane/oxygen anesthesia. I. Motor reactions. Anesthesiology 80:253-260, 1994.)*

pressure such that the noxious stimuli returned systolic pressure closer to the normal, awake values.

The clinical implications of these data relative to judging anesthetic depth from the hemodynamic response for inhaled anesthetics are significant. When used as a sole agent, even in high concentrations, isoflurane is unable to suppress hemodynamic responses to noxious stimuli. Rather, the hemodynamic control seen with high isoflurane concentrations occurs as a result of a decrease in the prestimulation hemodynamic baseline. Thus, although hemodynamic responses are the most commonly used clinical measures to judge inhaled anesthetic depth of anesthesia, the scientific basis for such application is tenuous.

Zbinden's work is important evidence that isoflurane provides hypnotic effects with minimal analgesic effect, as judged by the profound hemodynamic response to noxious stimuli in the presence of 1.8 MAC isoflurane. In clinical practice, additional drugs are commonly used with inhaled anesthetics. Daniel and colleagues[26] examined how fentanyl (0 to 3 µg/kg) and 60% nitrous oxide alter the heart rate, mean arterial blood pressure, and catecholamine response (components of MAC-BAR) during desflurane and isoflurane anesthesia. Fentanyl, 1.5 µg/kg, reduced MAC-BAR for desflurane from 1.3 to 0.4 MAC and for isoflurane from 1.3 to 0.55 MAC. Increasing the fentanyl dose to 3 µg/kg did not cause further change in MAC-BAR values for both inhaled anesthetics. Figure 39-14 shows an interaction surface for fentanyl and isoflurane based on modifying the model reported by McEwan to increase C_{50} in the absence of fentanyl by 1.3 and adjusting the isoflurane C_{50} in the presence of an effect-site fentanyl concentration of 1.36 ng/mL (corresponding to a 1.5-µg/kg bolus) to 0.4 MAC. The red arrow shows the reduction in MAC-BAR demonstrated by Daniel and coworkers.[26] It is clear from the figure that additional opioid would not be expected to yield further significant reductions in MAC-BAR. This study suggests that the addition of analgesic components, such as nitrous oxide and fentanyl, can prevent the sympathetic stimulation and hemodynamic responses seen with noxious surgical stimuli when inhaled anesthetics are used.

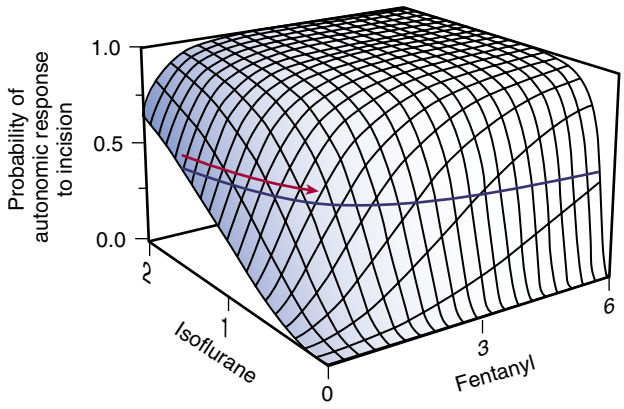

Figure 39-14 Interaction surface for fentanyl and isoflurane reflecting suppression of the autonomic response. The surface is based on the isoflurane interaction reported by McEwan and colleagues,[16] but modified to increase the C_{50} of isoflurane in the absence of fentanyl by 1.3 minimum alveolar concentration (MAC) and adjusting the isoflurane C_{50} in the presence of an effect-site fentanyl concentration of 1.36 (corresponding to a 1.5-µg/kg bolus) to 0.4 MAC, as reported by Daniel and coauthors.[26] The *red arrow* shows the reduction in MAC-BAR demonstrated by Daniel and coworkers.[26]

Intravenously Administered Hypnotics

Traditionally, intravenous hypnotics were used for induction of anesthesia as a single intravenous bolus. The introduction of propofol allowed these drugs to be infused for maintenance of anesthesia, where assessment of depth of anesthesia becomes more relevant.

Assessing Depth During Induction of Anesthesia

Induction of anesthesia often consists of a rapid intravenous bolus injection of an intravenous hypnotic (e.g., propofol, thiopental, etomidate). Plasma concentrations peak within a half to 1 minute and decline rapidly on redistribution of the drug. The rapidly changing plasma concentrations cause a corresponding fluctuation in the degree of CNS depression. Depth of anesthesia increases rapidly (causing loss of consciousness), peaks, and then decreases as plasma concentrations decline. CNS depression lags behind plasma concentrations and is manifested as hysteresis on curves plotting effect against plasma concentration. All the concepts discussed earlier regarding non–steady-state conditions produced by rapid administration of a drug make assessment of the relationship of plasma concentration and depth of anesthesia difficult, if not impossible, during bolus intravenous administration.

Clinical end points useful in assessing depth of anesthesia during induction include loss of verbal responsiveness, loss of eyelid reflex, and loss of corneal reflex. Typical stimulation occurring during induction of anesthesia includes laryngoscopy and intubation, which are profoundly noxious stimuli. Frequently, response to these two procedures cannot be eliminated completely with just the intravenously administered hypnotic. In one study, administration of thiopental (6 mg/kg) was followed by an average increase in systolic blood pressure of 53 mm Hg on laryngoscopy and intubation.[122] In another study, administration of thiamylal (4 mg/kg) was followed by an increase in mean arterial blood pressure from 92 mm Hg (control) to 136 mm Hg on laryngoscopy.[123] Because most intravenous hypnotics do not provide significant analgesia, the hemodynamic response to major noxious stimuli is great, even when large doses are given. Thus, assessment of depth of anesthesia with clinically relevant noxious stimuli such as laryngoscopy and intubation requires the concurrent administration of other analgesic drugs (opioids or nitrous oxide) to provide reasonable and clinically acceptable hemodynamic control.

Assessing Depth During Maintenance of Anesthesia

Becker[124] presented one of the first studies that quantified the relationship between plasma concentrations of an intravenous anesthetic (in this case, thiopental) and clinical measures of depth of anesthesia.

Hung and coauthors[125] proposed a conceptual approach that used clinical measures to examine intravenous anesthetic pharmacodynamics. A target controlled infusion of thiopental rapidly achieved and then maintained a low (10 to 40 µg/mL) and then high (40 to 90 µg/mL) thiopental concentration in 26 surgical patients. After allowing 5 minutes for blood-brain equilibration, increasingly noxious stimuli (verbal command, 50-Hz electrical tetanus, trapezius muscle squeeze, laryngoscopy, and intubation) were applied at 1-minute intervals until the patient responded verbally or moved purposefully. The approach sepa-

rated the increasing levels of thiopental required to block increasingly noxious stimulation.

Kazama and colleagues[19] examined the pharmacodynamics of propofol alone and then of propofol with fentanyl by using the defined noxious stimuli/movement responses that Hung and coworkers[125] used for thiopental and the hemodynamic methodology developed by Zbinden and associates[121] for isoflurane. These results are shown in Figure 39-15. Verbal response was easily suppressed by propofol, whereas the response to intubation was the most difficult to suppress. Tetanus, incision, and laryngoscopy were similarly noxious in this paradigm. Kazama and colleagues also found that addition of a steady-state fentanyl concentration of 1 or 3 ng/mL minimally decreased the amount of propofol required to suppress verbal response but profoundly decreased the amount of propofol required to suppress the response to tetanus, laryngoscopy, skin incision, and intubation.[19] Similar to what Zbinden and associates[121] described for isoflurane, the addition of fentanyl to propofol attenuated the increases in systolic blood pressure in a dose-dependent manner. The conceptual methodology used by Kazama and coworkers allows characterization of anesthetic depth by using multiple, defined noxious stimuli, as discussed previously in this chapter, and supports the intellectual framework for anesthetic depth shown in Figure 39-7.

Quantitation of clinical depth of anesthesia for the combination of an opioid and intravenous anesthetic was reported by Vuyk and coauthors.[126] Using the pharmacodynamic methodology developed by Ausems and colleagues,[28] the interaction of a constant plasma concentration of propofol (in place of nitrous oxide) was examined as the alfentanil was titrated to clinical responses. Propofol exhibited a significant interaction with alfentanil, thus decreasing the total dose of alfentanil and the alfentanil plasma concentrations needed for adequate anesthesia. Table 39-5 indicates how the total dose of alfentanil needed decreased from 22.8 mg with 66% nitrous oxide to 10.3 mg with a steady-state propofol plasma concentration of 4 µg/mL. The mechanism of this decreased dose requirement was marked potentiation of alfentanil such that the alfentanil plasma concentrations needed to achieve the same degree of pharmacologic effect were two to four times lower with propofol.

Modified from Vuyk J, Lim T, Engbers FH, et al: Pharmacodynamics of alfentanil as a supplement to propofol or nitrous oxide for lower abdominal surgery in female patients. Anesthesiology 78:1036-1045, 1993.

In a subsequent study, Vuyk and colleagues used this same methodology, but they randomized the surgical subjects to a range of constant propofol blood concentrations.[17] With blood propofol concentrations increasing from 2 to 10 µg/mL, the alfentanil Cp_{50} decreased from 170 to 25 ng/mL for laryngoscopy, from 280 to 23 ng/mL for intubation, from 259 to 9 ng/mL for opening of the peritoneum, and from 209 to 16 ng/mL for the intra-abdominal surgical stimulus. With plasma alfentanil concentrations increasing from 10 to 150 ng/mL, the propofol Cp_{50} for regaining of consciousness decreased from 3.8 to 0.8 µg/mL. This study confirms the profound, synergistic interaction of propofol with alfentanil. Vuyk and colleagues used computer simulations of their gathered data to suggest that the optimal blood propofol and plasma alfentanil concentrations that allow the most rapid recovery from intraoperative anesthesia occur at 3.5 and 85 ng/mL, respectively. An editorial[127] comment on this study provided more general guidelines for using the quantitative interaction of propofol and alfentanil to design dosing regimens for total intravenous anesthesia.

Opioids

As indicated earlier, large intravenously administered doses of thiopental or propofol are ineffective at eliminating the hemodynamic response to highly noxious stimuli such as laryngoscopy and intubation (also see Chapter 27).[19,122,123] Fentanyl decreases the anesthetic requirement for thiopental or propofol by providing antinociceptive effects that the intravenous hypnotics do not provide.[19,128] Although not absolutely necessary to achieve the end points shown in Figure 39-6, as Figure 39-7 suggests, opioids are typically combined with hypnotic drugs to create the state of nonresponsiveness we recognize as anesthesia.

Opioids as Complete Anesthetics

In 1947, Neff and associates[129] used meperidine as an intravenous supplement to nitrous oxide/oxygen anesthesia. The later use of opioids without the concurrent use of hypnotics coincided with

the development of cardiac surgery and intensive care during the 1970s. Providing anesthesia for patients with severe valvular or congenital heart disease without causing cardiovascular collapse was difficult before the introduction of high-dose opioid anesthesia. These early cardiac surgery patients were extremely ill and had little or no circulatory reserve. During the late 1960s, Lowenstein and coauthors[130] noted the hemodynamic stability of patients undergoing mechanical ventilation who were given frequent large doses of intravenous morphine to suppress respiration in the intensive care units. This observation encouraged Lowenstein and coworkers to become the first to administer morphine (0.5 to 3.0 mg/kg) as the only "anesthetic" drug. The resulting cardiovascular stability in acutely ill patients with acquired valvular heart disease was impressive. As cardiac surgery advanced in methodology, patients with ischemic heart disease began to undergo surgical anesthesia. Unfortunately, morphine anesthesia was less satisfactory for these patients, in whom hypertension, tachycardia, and awareness developed during surgery.[130]

In 1978, Stanley and Webster[131] introduced the use of high-dose fentanyl for cardiac anesthesia. This technique minimized the undesirable effects of morphine on induction (hypotension) and provided better hemodynamic stability in patients with good ventricular function and ischemic heart disease. As clinical experience with fentanyl increased, however, investigators found that even enormous doses of fentanyl could not reliably produce the anesthetic state, as defined in Figure 39-7, for the most potent stimuli and difficult-to-suppress responses.[132] This discovery demonstrated that opioids are not "anesthetics," but only potent analgesics and weak hypnotics, as suggested by Figure 39-2.

Many studies confirm this finding. Wynands and colleagues[14] used moderate to large doses of fentanyl (50 to 150 µg/mL) only, with no other anesthetic drugs (no hypnotic component), and measured plasma concentrations at defined surgical stimuli (intubation, skin incision, sternotomy, aortic root dissection) in patients undergoing coronary surgery with good ventricular function. In approximately 20% of patients, extremely high plasma concentrations of fentanyl (15 ng/mL) did not eliminate hemodynamic responses, defined as a 20% increase in systolic blood pressure. These results have been confirmed by Hynynen and colleagues[133] and Philbin and associates.[134]

Murphy and Hug[135] measured the ability of fentanyl to decrease enflurane MAC in dogs. They first anesthetized the dogs with enflurane and determined MAC. Fentanyl was then infused at progressively higher rates to obtain a constant steady-state plasma concentration of fentanyl in each animal. After each increase in infusion rate, enflurane MAC was determined again. Murphy and Hug found that even very high plasma concentrations of fentanyl (20 ng/mL) did not decrease enflurane MAC beyond 60% to 70% of its initial value (Fig. 39-16). That is, there was a ceiling to the enflurane-sparing effect. Morphine, sufentanil, and alfentanil also decrease enflurane MAC and have a similar ceiling effect in dogs.[136-138]

McEwan and colleagues undertook similar studies in humans and characterized the decrease in isoflurane MAC with varying constant fentanyl plasma concentrations achieved with a computer-driven infusion pump.[16] Movement response to initial skin incision was examined relative to end-tidal isoflurane concentrations. McEwan and coworkers[16] found the results in humans to be very similar to those observed by Hug and colleagues in dogs. Isoflurane MAC decreased 39% at a steady-state fentanyl plasma concentration of 1 ng/mL and 63% at a fentanyl plasma concentration of 3 ng/mL. Increasing fentanyl plasma concentrations to more than 3 ng/mL produced a minimal further reduction in isoflurane MAC. The maximal reduction in MAC was 82% at a steady-state fentanyl plasma concentration of 10.6 ng/mL. Similar MAC reduction results have been obtained with other inhaled anesthetics (desflurane, sevoflurane) and other opioids (alfentanil, sufentanil, remifentanil).[6,139]

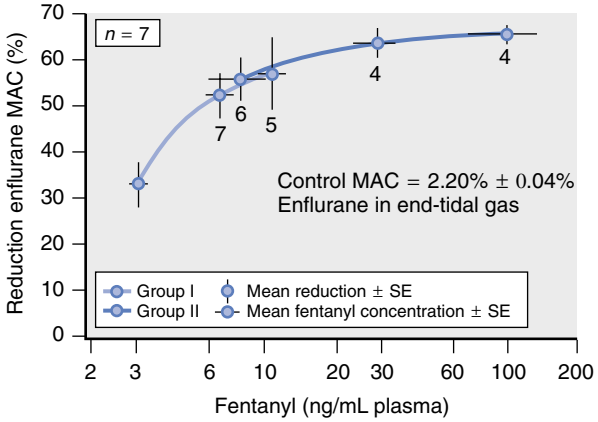

Figure 39-16 Percent reduction in enflurane minimum alveolar concentration (MAC) as a function of the plasma concentrations of fentanyl. Each point represents the mean concentration (± SEM) for fentanyl in plasma and the average percent (± SEM) reduction in enflurane MAC. Numbers of dogs below the vertical standard error bars indicate the numbers per data point. SE, standard error. *(From Murphy MR, Hug CC Jr: The anesthetic potency of fentanyl in terms of its reduction of enflurane MAC. Anesthesiology 57:485-488, 1982.)*

Similar results are found when other end points of inhaled anesthetics and opioid interactions are examined, including MAC-awake and MAC-BAR[118,140,141]: a ceiling effect of the opioid occurs at defined steady-state plasma concentrations.

Clinical Signs of Inadequate Anesthesia and Plasma Concentration of Opioids

Ausems and colleagues[142] used pharmacodynamic modeling concepts to relate clinical signs of inadequate opioid anesthesia to plasma concentrations of the drug. In their study paradigm, patients were premedicated with a benzodiazepine, anesthesia was induced with alfentanil (150 µg/kg), and the trachea was intubated with the aid of succinylcholine. Anesthesia was maintained with 70% nitrous oxide and a variable-rate infusion of alfentanil. The infusion was titrated to the following clinical end points: (1) systemic arterial blood pressure increased to greater than 15 mm Hg higher than the patient's normal value; (2) heart rate exceeding 90 beats/min in the absence of hypovolemia; (3) somatic responses, such as body movements (minimal muscle paralysis allowed physical movement), swallowing, coughing, grimacing, or opening of the eyes; and (4) autonomic signs of inadequate anesthesia (e.g., lacrimation, flushing, or sweating). If any clinical signs occurred, the infusion rate was increased 25 to 50 µg/kg/hr, and a small bolus dose (7 µg/kg) was given. Good hemodynamic control was possible in all subjects. If no clinical signs occurred, however, the infusion rate was decreased at regular 15-minute intervals.

Figure 39-17A shows the relationship between the plasma concentration of alfentanil and response/no response for three clinical end points: intubation, skin incision, and skin closure. Figure 39-17B shows the individual subject curves for the proba-

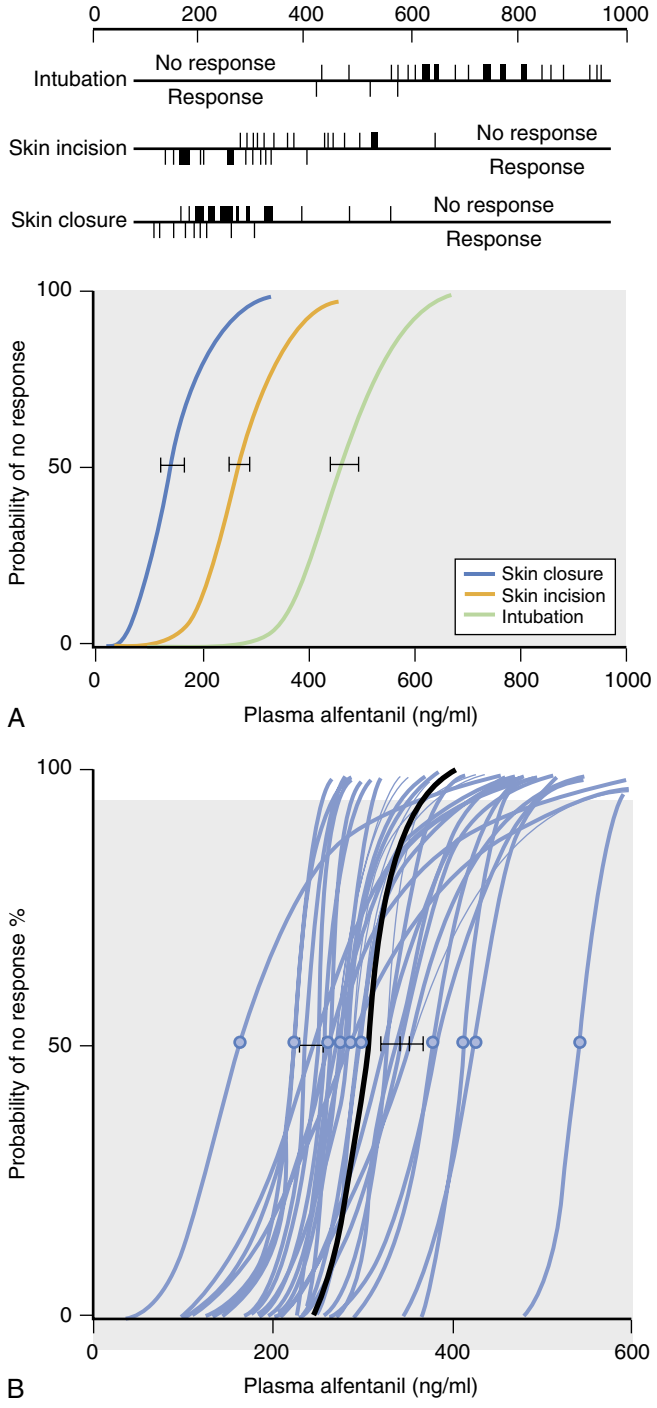

Figure 39-17 **A,** Relationship between the plasma concentration of alfentanil and response/no response at three specific events of short duration. The quantal data are characterized by logistic regression in the lower panel, ± standard error for Cp_{50}, which is the alfentanil plasma concentration associated with a 50% probability of no response. **B,** Plasma concentration of alfentanil versus the probability of no response for each of 34 patients during the intra-abdominal phase of lower abdominal surgery. *Circles* represent the Cp_{50} values, and the *black line* represents the average response of the 34 patients. (***A,*** *From Ausems ME, Hug CC Jr, Stanski DR, Burm AG: Plasma concentrations of alfentanil required to supplement nitrous oxide anesthesia for general surgery. bility of no response during surgery. Attenuating the response to intubation required significantly higher plasma concentrations of alfentanil than attenuating the response to skin incision did. Cp_{50} values for these clinical responses are shown in Table 39-6.

Remifentanil is the newest opioid in the fentanyl family and has a unique ester bond that is susceptible to hydrolysis by nonspecific blood and tissue esterases, which results in very rapid metabolism. Minto and colleagues[143,144] quantitated the population pharmacokinetics and dynamics of this opioid by using simulation techniques to develop dosing guidelines. Drover and Lemmens[145] applied the opioid anesthetic depth concepts developed by Ausems and coworkers[28] to define therapeutic plasma concentrations of remifentanil in surgical patients.

The approach to opioid administration presented by Ausems and colleagues[28] provides useful insight into the clinical assessment of depth of anesthesia. Overdosage with opioids cannot be judged intraoperatively in a paralyzed patient. Only at the end of anesthesia, when spontaneous ventilation should occur, does one know whether administration of opioids has been excessive. To prevent overdosage, Ausems and coworkers[28] proposed titrating the alfentanil infusion rate to clinical effect to find the lowest possible effective rate of opioid administration. Once the infusion rate associated with hemodynamic responsiveness (i.e., "light anesthesia") has been determined, one increases the rate slightly to provide an adequate analgesic component to achieve a nonresponsive state. Intermittent intravenous bolus administration of opioids is not as efficient as variable-rate infusion when titrating plasma concentrations of opioids to clinical effect.[142] The steep slope of the concentration-versus-response curve for alfentanil (Fig. 39-17B) demonstrates that a small increase in the plasma concentration of the drug rapidly converts an inadequate anesthetic state (100% probability of response to stimuli) to an adequate anesthetic state. Because of moderate variability in the pharmacokinetics of alfentanil, this process of titrating the infusion rate against clinical effect and pharmacodynamics is necessary for each patient. Egan and Shafer have referred to this concept as "surfing" the concentration-versus-response curve.[146] This concept is nearly ideal for remifentanil because of the rapid and

Table 39-6 Cp_{50} Values for Perioperative Events and Intraoperative Manipulation Associated with Three Types of Surgical Procedures During Alfentanil Anesthesia

Event	Cp_{50} (ng/mL)
Single events	
Intubation	475 ± 28*
Skin incision	279 ± 20
Skin closure	150 ± 23

predictable pharmacokinetic profile along with rapid blood-brain equilibration.[143]

Electrophysiologic Monitoring

(see also Chapter 46)

Spontaneous Electroencephalogram

The realization that anesthetic drugs alter the EEG dates back to the discovery that the brain produces electrical activity. In 1875, Caton used chloroform to convince himself that the electrical oscillations from the brain were indeed biologic in origin.[147] During the 1920s and 1930s, when electronic amplifiers allowed recording of these small voltages through the skull, Berger measured the influence of chloroform on the EEG.[148] In 1937, Gibbs and coauthors reported that anesthetics changed EEG activity from low-voltage fast waves to high-voltage slow waves and postulated that the EEG could be used to measure the effects of anesthesia.[149] In 1952, Faulconer demonstrated with ether that the depth of anesthesia, based on recognition of EEG patterns, correlated with the arterial concentration of ether.[150] He also demonstrated that the presence of nitrous oxide lowered the arterial concentration of ether necessary to produce a given effect on the EEG.

Hypnotic general anesthetics produce a biphasic EEG effect that was first described by Martin and colleagues.[151] With light anesthesia, there is EEG desynchronization and increased frequency associated with the excitement phase. This is followed by progressive synchronization, slowing, and an initial increased amplitude eventually leading to burst suppression with lengthening periods of EEG silence. With induction of anesthesia the topographic distribution also changes from occipital dominance to frontal dominance. Loss of spatial localization may occur with arousal.

The EEG can be considered a measure of the depth of anesthesia for several reasons:

1. It represents cortical electrical activity derived from summated excitatory and inhibitory postsynaptic activity, which in turn is the result of subcortical events, including those that pass through subcortical thalamic nuclei.
2. Cerebral blood flow and cerebral metabolism are related to the degree of EEG activity.[152]
3. Anesthetic drugs affect cerebral blood flow, metabolism, and EEG patterns.
4. Surgical stimulation affects cerebral blood flow, metabolism, and the EEG.

The EEG is thus a continuous, responsive, noninvasive indicator of cerebral function even when the patient is unconscious and unresponsive.

Noxious stimulation during inadequate anesthesia generally causes EEG activation. Peripheral noxious stimuli reach the brain through afferent systems that pass through the ascending reticular activating systems of the brainstem. These systems regulate cerebral function and thus affect the underlying EEG pattern. Noxious stimuli can cause three types of changes in the EEG:

1. Desynchronization with the appearance of 20- to 60-Hz fast rhythms (EEG activation)
2. The appearance of 6- to 10-Hz spindles
3. Bursts of 1- to 3-Hz slow waves[153]

These EEG patterns vary with individual anesthetics and with the nature of the stimulation, and there is a distinct drug plasma concentration that blocks responses to noxious stimulation.[154,155]

Early studies concluded that the EEG was not a meaningful measure of the depth of anesthesia. Galla and colleagues examined raw EEG signals for 43 patients and correlated EEG patterns with clinical signs of anesthesia.[156] A discrepancy seemed to exist between the clinical signs and EEG patterns, especially during induction and emergence. During induction, clinical signs indicated that the patients were more lightly anesthetized than the EEG patterns suggested, whereas on emergence, clinical signs indicated greater anesthetic depth.

Although recording of raw EEG signals involves accumulating a large amount of information and EEG tracings, current computer analysis techniques can summarize and distill the EEG into a condensed, descriptive format (the "processed" EEG).[157,158] Levy investigated processed EEG signals during induction and before cardiopulmonary bypass.[159] He examined a series of univariate descriptors, including median frequency (the frequency below which 50% of the EEG power is located) and spectral edge (the frequency below which 95% of the EEG power is located). He concluded that the multimodal EEG activity observed in 64% of cases precluded the use of single univariate parameters to describe the anesthetic state.

Clinical assessment of the depth of anesthesia did not correlate well with EEG patterns but suggested that some patterns may be useful trend monitors. Drummond and colleagues examined five numeric descriptors derived from the processed EEG during imminent arousal (spontaneous movement, coughing, or eye opening) from isoflurane/nitrous oxide anesthesia.[160] These authors determined the threshold value for each parameter that best predicted imminent arousal. Although several parameters (median frequency, spectral edge 90% frequency, total power, and frequency band ratio) predicted imminent arousal with a sensitivity of 90% and specificities of 82% to 90%, none of the EEG descriptors could serve as a completely reliable, sole predictor of imminent arousal. Long and coworkers undertook a similar analysis using either isoflurane or fentanyl anesthesia.[161] For isoflurane anesthesia, these investigators found that awakening was always presaged by an abrupt overall decrease in power in the 1- to 4-Hz frequency range (decrease in delta power). During emergence from fentanyl/nitrous oxide anesthesia, obvious change in the overall EEG power spectrum was not noted; however, the same numeric EEG descriptors that were predictive of awakening from isoflurane also occurred during emergence from fentanyl. These two studies concluded that consistent trends in the EEG can be expected to occur with changing depth of anesthesia, with the available EEG descriptors providing potentially useful trend information regarding the changing depth of anesthesia. However, the sensitivity and specificity of the available parameters are such that no one parameter can serve as the sole indicator of anesthetic depth.

Dwyer and colleagues examined the power spectrum of the EEG in surgical patients receiving 0.6 to 1.4 MAC isoflurane-only anesthesia with skin incision.[162] A second group of volunteers

received 0.15 to 0.45 MAC isoflurane with memory testing. Different time-dependent EEG frequency parameters (e.g., spectral edge, median frequency) were examined relative to the clinical measures. The authors found that isoflurane caused some decrease in EEG activity. However, no difference in EEG parameters was found between subjects who moved and those who did not move with skin incision. In volunteers receiving low-dose isoflurane, memory of the information presented did not correlate with values of any EEG parameter. The authors concluded that the EEG parameters examined did not predict depth of anesthesia as defined by response to surgical skin incision, response to verbal command, or development of memory.

The previously described clinical research attempting to relate EEG effects to clinical anesthetic depth resulted in inconclusive findings. When single anesthetic drugs are examined under defined conditions, it has been possible to demonstrate unambiguous relationships between EEG parameters and anesthetic drug concentrations and to use pharmacokinetic and pharmacodynamic modeling concepts to link drug concentrations to EEG drug effects.[163] Application of the EEG to measure clinical depth of anesthesia failed previously for several reasons:

1. A lack of understanding of the effects of interactions of several concurrently administered anesthetic drugs on the EEG
2. No standard approach to choosing an optimal EEG parameter
3. No clear definition of a "gold standard" for measurement and assessment of the clinical depth of anesthesia

Multiparameter Electroencephalographic Monitoring

In the 1990s, Aspect Medical Systems undertook an integrated research effort to develop the EEG as a measure of anesthetic depth. The Aspect EEG monitor, or the BIS, quantitates anesthetic effects on the brain, specifically, the hypnotic component of anesthesia. Other devices have followed this example but have used somewhat different approaches to EEG analysis (see later). Manufacturers differ in their willingness to disclose all the details of the algorithms, but they typically follow principles similar to those used by Aspect. In terms of clinical evaluation, the volume of literature on the BIS far exceeds that of any other device.

The common principles are shown in Figure 39-18:

1. The devices present a continuous EEG parameter, the specific index, that ranges from an awake, no-drug-effect value of 95 to 100 to 0 with no detectable EEG activity.
2. Multiple EEG signal–processing approaches that capture incremental information not captured with traditional approaches based on a single signal-processing approach, such as fast Fourier transformation, are used simultaneously.
3. Multiple clinically relevant measures (movement, hemodynamics, lash reflex, response to verbal command, recall, and drug concentration) were gathered in volunteers and patients with concurrent EEG data as part of the validation process.
4. Advanced multivariate statistical data analysis was used to correlate the components of the multiple EEG signal–processing approaches with the clinical data to create the univariate parameter.
5. Prospective clinical evaluation of the index is performed at multiple institutions under varying anesthetic and surgical conditions.
6. The indices measure the hypnotic components of the anesthetic and are relatively insensitive to the analgesic (e.g., opioid) components of an anesthetic.
7. Prospective clinical trials demonstrate that the monitors can improve the outcome of an anesthetic regimen.
8. Simple hardware and sensors were developed and are commercially available to facilitate capture of high-quality signals despite the noisy electrical environment of the operating room.

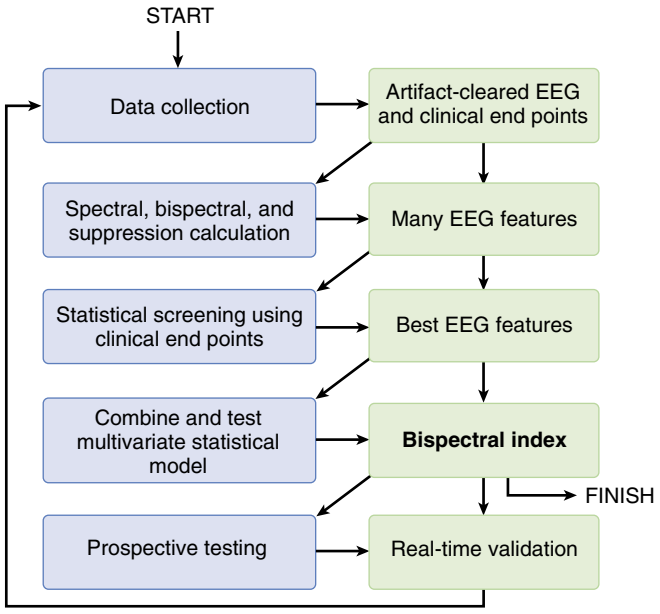

Figure 39-18 Key steps used during development of the bispectral index algorithm. Statistical modeling was used to identify the best features of the electroencephalogram (EEG) for recognition of clinical end points. The circular path notes that the process was iterative. *(From Kelley SD: Monitoring Level of Consciousness during Anesthesia and Sedation. Aspect Medical Systems, 2003.)*

Electroencephalographic Signal Processing

Most EEG signal processing has previously involved a form of spectral analysis that examines the EEG signal during a small slice of time (epoch) as a function of frequency. The frequency analysis decomposes the EEG signal into a series of sine waves by Fourier analysis. Because the signal is digitally sampled, Fourier analysis is performed by a mathematical transformation called the discrete Fourier transformation. The discrete Fourier transformation calculates the phase and amplitude of discrete sine waves at frequencies ranging from 0 to half the sampling frequency in increments of 1/x (x is the number of seconds in each "epoch" or segment of the EEG signal). The frequency of each sine wave is the number of cycles per second, although the mathematics of the discrete Fourier transformation necessarily calculate only uniformly spaced frequencies. The amplitude is half the peak-to-

peak voltage. The phase angle describes the time offset of the sine wave relative to the start of the epoch.

The conventional output of the discrete Fourier analysis is a spectral histogram showing the frequency and amplitudes of the sine waves in the underlying EEG signal. The phase information is typically ignored. Fourier analysis assumes that the signal pattern is constant during the epoch. Thus, it poorly handles signals that abruptly change during an epoch, such as burst suppression.

In "bispectral" analysis, the phase information is not ignored, and a more complex algorithm incorporates the phase information to look for evidence of phase coupling among frequency bands, such as bicoherence. Bispectral analysis was originally developed by the statistician John Tukey[164] and found one of its first applications in submarine warfare.[165] The anatomic, electrophysiologic, and clinical meaning of EEG phase relationships is unknown. However, the general notion is that an awake brain has multiple signal generators working independently and hence displays little synchronization. With progressive drug-induced loss of consciousness, fewer independent signal generators are active, and thus the resulting EEG is more likely to reflect coupling between signal generators. In addition, several useful techniques that promote noise suppression beyond what is possible with conventional spectral analysis are used.[166] Thus, the analyses provide additional information about the EEG signal than is captured by traditional spectral analysis approaches in which only frequency and amplitude are considered.

The Bispectral Index

Bispectral EEG signal processing has been reviewed by Rampil[166] and by Sigl and Chamoun.[167] Johansen and Sebel reviewed the clinical development of BIS monitoring.[168] Its development and validation are described here in some detail because it has the largest literature describing its development and it serves to illustrate the path that other devices would have to follow.

The BIS is a complex, proprietary EEG parameter developed by Aspect Medical Systems. In 1996, the U.S. Food and Drug Administration approved the commercially available version as a monitor of anesthetic effect on the brain. Figure 39-18 displays the conceptual process whereby Aspect took EEG and clinical data from approximately 1500 subjects and 5000 hours of EEG signal gathered under a broad range of anesthetic regimens. The EEG was processed by first removing high- and low-frequency artifacts, electrocardiographic signals, pacemaker spikes, eye blinks, wandering baseline, and interference by alternating current. The EEG data were then analyzed by three different approaches: Fourier spectral analysis, bispectral analysis, and time domain analysis (Fig. 39-19). Time domain analysis was used to characterize burst suppression (seen at a BIS value of less than 40) and isoelectricity. The EEG was smoothed across the power spectrum and bispectrum by using a moving average. The analysis then examined the degree of beta or high frequency (14 to 30 Hz), the amount of low-frequency synchronization, and the

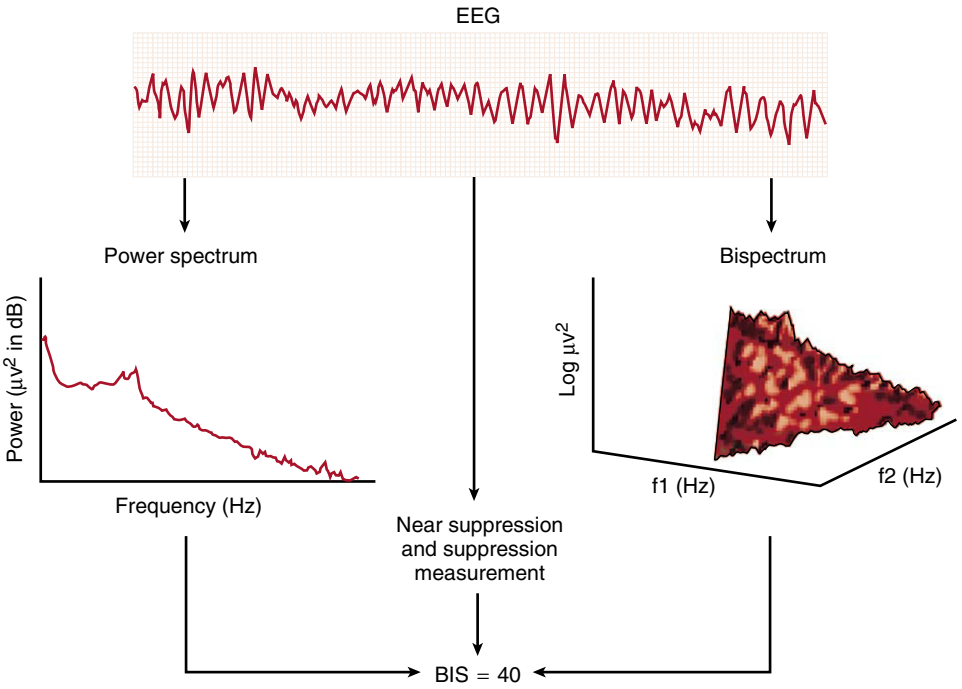

Figure 39-19 Schematic diagram of signal processing paths integral to generating a single bispectral index (BIS) value. After digitization and artifact rejection, original electroencephalographic (EEG) epochs undergo three primary paths of analysis: power spectral analysis, bispectral analysis, and time-based analysis for suppression/near suppression to look for key EEG features. The BIS algorithm, based on statistical modeling, combines the contributions of each of the identified features to generate the scaled BIS. *(From Kelley SD: Monitoring Level of Consciousness during Anesthesia and Sedation. Aspect Medical Systems, 2003.)*

presence of fully or nearly suppressed periods (i.e., isoelectric signal). The algorithm to determine the relative weighting in the final calculation of the BIS value (0 to 100) involved performing a multivariate statistical analysis, similar to semilinear canonic correlation, on the aforementioned EEG data relative to a clinical database that was gathered from multiple different clinical studies over the past 15 years.[169] As prototype versions of the BIS were developed over a period of several years, subsequent clinical testing was used to improve and refine the algorithms and components of the EEG parameter. The BIS algorithm was adapted to handle burst suppression EEG, to minimize the initial activation of the EEG seen with some anesthetic drugs, and to optimally use the components of Fourier analysis and bispectrum analysis. Thus, the BIS is a complex parameter composed of a combination of time domain, frequency domain, and higher-order spectral components derived from clinical data that measure the hypnotic component of an anesthetic.[166] Over the past decade, the BIS parameter has been modified on the basis of new data about the EEG response to novel anesthetic drugs and drug combinations, as well as to incorporate new signal collection and noise rejection technology. This is important to bear in mind as one reviews studies performed years apart.

The initial studies with early versions of the BIS algorithm in the early 1990s attempted to correlate the BIS to predict movement in response to skin incision with the use of isoflurane/oxygen,[167] propofol/nitrous oxide,[170] or propofol/alfentanil anesthesia.[171] In the first major clinical evaluation of the BIS technology, a large, multicenter study by Sebel and colleagues randomized 300 patients into two groups.[172] Both groups received an anesthetic regimen designed so that approximately half of all patients would move at skin incision. In the control group, the BIS was passively recorded and not used for titration. In the BIS-titrated group, drug concentrations were increased to produce a BIS value of less than 60. In the control group, the BIS was a mean of 66 ± 19 (standard deviation [SD]) with a 43% movement rate. In the BIS-adjusted group, the BIS was lower, a mean of 51 ± 9 (SD) with a significantly lower movement rate of 13%. In this multicenter trial, some centers used primarily opioids with nitrous oxide, whereas others used propofol or isoflurane as the primary anesthetic. The study also found that reliability of the BIS was strongly influenced by anesthetic technique. When hypnotic drugs such as propofol or isoflurane are used as the primary anesthetic, changes in the BIS correlate with the probability of a movement response to skin incision. When opioid analgesics are used at higher doses, the correlation to patient movement became much less significant. This information, when linked to the understanding that purposeful movement upon skin incision reflects the spinal action of anesthetics instead of their cortical effects,[22,23] provided fundamental understanding of how development of the BIS algorithm had to be focused on the hypnotic components of anesthesia, specifically, the clinical measures of consciousness and memory. A subsequent series of studies described in the following paragraphs provided the data and clinical understanding to create the current algorithm to calculate the BIS.

Glass and coworkers designed a study to examine the relationship among BIS, measured drug concentrations, and increasing levels of sedation when the anesthetic drugs propofol, midazolam, isoflurane, and alfentanil were given to volunteers in a controlled manner.[173] Data from this study were used to further optimize the BIS algorithm. Seventy-two volunteers received a single drug at four or five defined, increasing target plasma concentrations that ultimately created an unconscious subject. The BIS, arterial drug or end-tidal concentrations, and subjective sedation and memory scores were measured. The BIS was significantly correlated to measured drug concentrations, as well as clinical measures of sedation. None of the alfentanil patients lost consciousness and had minimal change in the BIS, a finding confirming that the BIS is not sensitive to low concentrations of opioid analgesics. Fifty percent and 95% of the volunteers were unconscious at BIS values of 67 and 50, respectively.

Liu and colleagues demonstrated in 26 surgical subjects that the BIS accurately tracked the degree of clinical sedation with intermediate (4 mg) to large (20 mg) doses of midazolam given during regional anesthesia.[174] Response to a loud voice corresponded to a BIS of 87 ± 6 (SD) and a 40% probability of recall. A deeper end point, lack of response to mild prodding, corresponded to a BIS value of 81 ± 8 (SD) and resulted in complete lack of recall. When midazolam created an unresponsive subject, the mean BIS value was 69.2 ± 13.9 (SD). Similar results were found by these investigators for propofol when given under regional anesthesia[175] and were reported by Katoh and coworkers with low, sedating doses of sevoflurane and also with higher, anesthetic concentrations in 69 surgical patients.[176] Both the BIS and end-tidal sevoflurane concentrations were correlated to clinical sedation scores of the patients. The BIS decreased almost linearly from a median value of 95 to 45 with an end-tidal sevoflurane concentration increasing from 0.2% to 1.4%. Sevoflurane concentrations greater than 1.4% produced a limited further reduction in the BIS.

Flaishon and colleagues examined the behavior of the BIS when surgical patients were given a single intravenous bolus of propofol, 2 mg/kg, or thiopental, 4 mg/kg, with concurrent muscle relaxants.[177] The isolated arm technique was used to identify loss and then return of consciousness. No patient with a BIS value of less than 58 was conscious; a BIS value of less than 65 signified a less than 5% probability of return of consciousness within 50 seconds.

A more detailed examination of memory and response to command was undertaken by Kearse and associates during propofol/nitrous oxide sedation with BIS monitoring.[178] These investigators found a strong association between the BIS and response to command, whether the command consisted simply of a uniform voice asking a volunteer to move a hand or foot or incorporated graded and then varied stimuli. The relationship between the BIS and responsiveness scores remained consistent over time and with increases or decreases in propofol concentrations. No subject was responsive when the BIS was less than 57.

Clinically, a unilateral self-adhesive frontotemporal montage provided by the proprietary BIS sensor is used. The monitor displays the BIS number, a single channel of raw EEG signals, and an index of activity on the electromyogram (EMG). Current devices can be seen at http://www.aspectmedical.com/. A BIS value of less than 55 is recommended during general anesthesia.

Entropy

Because the EEG displays chaotic or nonlinear behavior, it seems reasonable to apply methods from the theories of nonlinear dynamics. Entropy is used in chemistry to describe the microstates of gases and liquids and the ability of atoms to move in

multiple directions (i.e., the amount of disorder). As a substance changes from a solid to a liquid to a gas, the mobility and potential for interaction among atoms increases and entropy also increases. The converse applies in going from a gas to a solid.

In 1948, Claude Shannon applied these concepts to information theory such that entropy described the complexity, irregularity, or unpredictability of a signal.[179] A pure sinusoidal wave would have an entropy of zero because it is regular and predictable, whereas a wave containing hugely variable frequencies (e.g., noise) would have very high entropy. Unfortunately, as originally described by Shannon, entropy is not normalized to the total power, so there is great interindividual variation. This limits clinical use because one wants the same index value to indicate a similar depth of anesthesia among patients.

There are multiple entropy algorithms, but only spectral entropy has been used in a commercially available device, the GE Healthcare Entropy Module (formerly Datex-Ohmeda M-Entropy), which was commercially released in 2003. The exact algorithm was published in 2004 and is in the public domain.[180,181] The algorithm uses the time domain (i.e., burst suppression) and frequency domain from Fourier analysis and then also applies the Shannon function to the frequency data. This approach has been termed "time-frequency balanced spectral entropy."

The facial EMG has a frequency range (approximately >20 Hz) that overlaps with the "traditional" EEG (0.8 to 32 Hz), thereby confounding analysis of cortical activity. The facial EMG changes with level of consciousness and the use of neuromuscular blocking drugs. EMG analysis was briefly and unsuccessfully tried as a depth-of-anesthesia monitor.[182,183] Some authorities have the impression that the EMG may be more related to analgesia requirements. Datex-Ohmeda tried to exploit this by creating two indices, State Entropy (SE) and Response Entropy (RE). SE is computed from the EEG in the 0.8- to 32-Hz range and should encompass mainly the hypnotic elements of the EEG, whereas RE is computed from 0.8 to 47 Hz, which includes a significant amount of the facial EMG.[180] Thus when EMG activity is low, SE and RE should be the same, but with arousal and an increase in facial EMG, RE should increase. The initial clinical studies with this device showed that it produced results comparable to those of the BIS when tested with intravenous and inhaled hypnotic anesthetics.[184-186]

The GE Entropy Module uses the same unilateral self-adhesive frontotemporal sensor as the BIS but specifically made for the GE product (i.e., they are not interchangeable). The module works only with GE monitoring systems with the appropriate software loaded. The SE, RE, and a single channel of the raw EEG are displayed on the same screen as the other monitored variables. The displayed SE range is 0 (isoelectric EEG) to 91 (fully awake), and the RE range is 0 to 100. The anesthetic range is 40 to 60, and the manufacturer recommends that SE outside this range may require a change in hypnotic dosing, whereas if the SE is in this range but the RE is more than 10 above the SE, more analgesic may be required. Good substantiation of this recommendation is lacking.

Patient State Index

The Patient State Index (PSI) from Physiometrix, Inc., also incorporates a proprietary algorithm. In addition to using time, frequency, and phase information, the PSI also uses spatial information as EEG dominance changes with induction of anesthesia from occipital to frontal and with arousal.[187,188] A self-adhesive five-lead bilateral frontotemporal montage is used that provides greater spatial analysis than can be achieved with a unilateral montage. Development of the algorithm involved extensive use of EEG databases[189] and is illustrated in Figure 39-20. Development of the PSI has recently been reviewed.[190] Figure 39-21 shows the complexity of analyses continuously performed in the process of updating the PSI. Similar complexity occurs with most such monitors. Initial studies show it to be comparable to the BIS in tracking sedation levels.[191,192]

The portable monitor displays the PSI, with 25 to 50 being the anesthetic range. The index is shown as the current number, as well as the trend, which is color-coded to indicate whether it is in the anesthetic range, too light, or too deep. In addition, there are qualitative indicators of the EMG, artifacts, and burst suppres-

sion. Other optional displays include four channels of EEG and the digital spectral array, an alternative way of showing frequency data.

Narcotrend

The Narcotrend monitor takes a somewhat different approach to EEG analysis by using a categorization system initially developed for analyzing the sleep EEG. In 1937, Loomis and coworkers categorized the sleep EEG into characteristic patterns labeled A to E.[193] This pattern was extended to include substages and made more appropriate for anesthesia with stages labeled A to F.[194] After artifact rejection, multiple time and frequency domain analyses are used to derive the most appropriate anesthetic stage. Initial validation also involved testing a large data set of EEGs during anesthesia. Early clinical studies found the Narcotrend to be similar to the BIS.[195-197]

This monitor uses standard electrocardiography electrodes rather than a proprietary electrode strip. The monitor displays a single channel of raw EEG, the Narcotrend stage indicated by a capital letter and a numerical subscript (e.g., D_2), the power spectrum, and the trend of the stages.

Other EEG-Based Devices

There is a steady increase in the number of devices emerging on the market. Although they differ in display format, size, electrodes, and other features, they are to a greater or lesser extent similar in principle to the devices described earlier. Examples include the SNAP Index (Viasys Healthcare, Madison, WI) and Cerebral State Monitor (Danmeter, Odense, Denmark).

Evoked Responses as Monitors of the Depth of Anesthesia

Sensory, including auditory, stimulation produces a low-amplitude signal, or evoked response, within the CNS. This evoked response can be separated by means of computer signal-averaging techniques from the underlying, spontaneous EEG. The ability to evoke a response is a measure of the functional integrity of the pathways between the sensory receptor and the neural generator of peaks in the evoked response waveform. Because evoked responses are sensitive to anesthetic drugs, they have been investigated as possible measures of anesthetic drug effect and depth of anesthesia.[198]

Recording of evoked responses involves recording EEG epochs synchronized to the repetitive sensory stimuli. Computer techniques extract the evoked potential from the underlying EEG. Typically, the algorithm requires 100 to 1000 stimuli to confidently extract the evoked potential from the underlying EEG signal. Therefore, the evoked response represents a time-versus-voltage relationship that can be quantitated by measuring the poststimulus latency and interpeak amplitudes in the waveform. Evoked response methodology has been reviewed in detail.[199]

Many investigations have been performed with evoked potentials, with special emphasis on midlatency auditory evoked potentials (MLAEPs).[198,200-203] MLAEPs have been shown to be significantly affected by anesthetic hypnotic drugs in a graded, reversible, and nonspecific manner. Specifically, the amplitudes (microvolts) and the latency (milliseconds) of the waves Pa and Nb have been examined. Hypnotic anesthetic drugs decrease the amplitudes and increase the latencies of these two waves. Opioids in clinically relevant concentrations produce minimal changes in MLAEPs.[204]

Measuring MLAEPs can be inconvenient, and this may have limited their clinical use to date. Limitations include the following:

1. Considerable time needed to produce a response, 0.5 to 5 minutes
2. Complex setup, with MLAEPs typically requiring more than 5 minutes of patient preparation
3. Need for intact hearing
4. Lack of a univariate parameter calibrated to the anesthetic state

Kenny and colleagues addressed some of these limitations by introducing a new MLAEP parameter, the AEP index, based on a proprietary algorithm.[205,206] The AEP index simplifies interpretation of the MLAEP waveforms, but it still requires significant time for the signal-averaging process. Jensen and coworkers developed a new adaptive method for extracting the MLAEP from the EEG signal that involves an autoregressive model with an exogenous input (ARX) to allow extraction of the AEP signal within 15 to 25 sweeps of 110-msec duration; the process results in only a 6-second delay.[207] This concept has been incorporated into a commercial device that calculates the A-Line ARX Index (AAI) from the fast-extracted MLAEP waveform analysis (A-Line Monitor, Danmeter A/S, Odense, Denmark). The AAI, like the BIS, ranges from 100 (awake) to 0 (deep hypnotic effect), and the recommended surgical anesthesia range is 15 to 25. The software has recently been updated and the current iteration, the AEP monitor/2, also uses EEG-derived data to supplement the AEP data.[208]

In clinical studies the A-Line performed comparably to the BIS and other EEG-based monitors but did not demonstrate advantages that would outweigh the nuisance of ear plugs and continuous high-frequency clicking sounds in patients' ears.[209-211]

Clinical Interpretation and Effects of Drugs on Electrophysiologic Monitors

All of the currently available devices have adopted a scale of 0 to 100, where 0 represents an isoelectric EEG and 100 represents an awake patient. The documentation for these monitors recommends specific ranges for wakefulness, sedation, light anesthesia, deep anesthesia, and excessive anesthesia. The clinical ranges are not identical across devices, so care is required when using or comparing different devices. For example, the BIS "anesthesia" range is 40 to 60, whereas the PSI "anesthesia" range is 25 to 50. Figure 39-22 displays the numerical value of the BIS from 0 to 100 relative to clinical end points and the underlying EEG signal.

After administration of a hypnotic drug, the index decreases from awake values of 80 to 100 as the patient's level of consciousness undergoes a series of transitions. At a device's threshold index of anesthesia, the probability of consciousness is low. The "anesthesia" range reflects adequate hypnotic effect for loss of consciousness with reasonably rapid recovery to consciousness. Like all electrophysiologic measures, in each patient one must correlate the clinical state to the reported value to adjust for variability between patients. Figure 39-23 displays the relationship between the BIS value and the probability of response to voice or the probability of explicit memory recall during propofol anesthesia.[212] Response to verbal command is preserved at lower BIS values than explicit recall is.

A limited number of studies examined the relationship of the BIS to direct measures of brain function. Alkire[213] studied the correlation between the cerebral metabolic rate, as measured by positron emission tomography, and the BIS during propofol and isoflurane anesthesia. Volunteers served as their own controls. After baseline measurements, volunteers received increasing amounts of propofol or isoflurane until they were unconscious (BIS values of 30 to 50). This study demonstrated a linear relation-

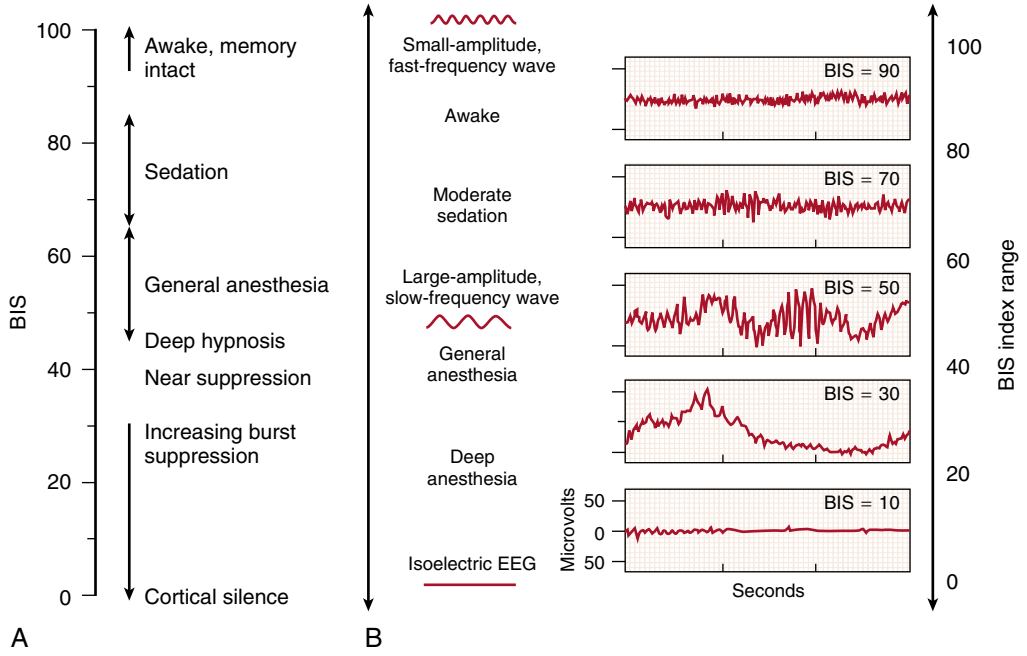

Figure 39-22 **A,** Clinical correlations of the bispectral index (BIS). Maintaining the BIS value of 45 to 60 during general anesthesia appears to ensure unconsciousness with a hypnotic/opioid anesthetic technique while providing for rapid emergence. **B,** Changes on the electroencephalogram (EEG) observed with increasing depth of anesthesia. (***A,*** *Adapted from Johansen JW, Sebel PS: Development and clinical application of electroencephalographic bispectrum monitoring. ship between decreasing BIS and a reduction in cerebral metabolic rate (r = −0.81), indicating a physiologic link between the EEG and the cerebral metabolic response to hypnotic drugs.

Ludbrook and colleagues examined the relationship between propofol brain concentrations, as estimated by simultaneous arterial/jugular bulb venous blood sampling during propofol induction of anesthesia, cerebral blood flow, and BIS measurements.[214] Although significant intersubject variability was seen, calculated propofol brain concentrations and BIS values correlated closely. Similar results have been found by using the estimated propofol or sevoflurane effect-site concentration. There is high correlation in the prediction probability of BIS, entropy, and effect-site propofol concentration, but differences between the devices are not of clinical significance.[185,186]

BIS values less than 60 are associated with 0 probability of awareness. *(Iselin-Chaves IA, Flaishon R, Sebel PS, et al: The effect of the interaction of propofol and alfentanil on recall, loss of consciousness, and the bispectral index. Anesth Analg 87:949-955, 1998.)*

Hypnotics

The relationship between depth-of-anesthesia indices and commonly used hypnotics such as midazolam, propofol, isoflurane, sevoflurane, and desflurane has been assessed in both patients and volunteers. The approach is to use stepwise increases in drug concentration and correlate this with a clinical sedation grading scale such as MOAA/S (see Table 39-1).[5] The MOAA/S scale requires stimulating the subject, which may change the depth-of-anesthesia index. Whether the index is recorded before or after stimulation is not always reported.

Studies of all currently available devices show a good relationship with the MOAA/S scale for commonly used hypnotics.[173-176,190,209,210,215-220] Indeed, such a relationship is a requirement for regulatory approval and integral for development of the software (see earlier). The relationship between sedation and the derived electrophysiologic index does not seem to be influenced by age in adults.[221] Although the average index tracks the sedation scale well at steady state, there is huge interindividual variation, particularly during non–steady-state conditions such as induction and emergence.[222] While awake, the index may range from 70 to 100, but once anesthetized, the index might be in the range of 25 to 65. Schnider and colleagues reported an extreme example in a patient with genetically determined low-voltage EEG.[223] This otherwise unremarkable volunteer had a baseline BIS of 40, which paradoxically increased with the administration of xenon. Thus,

intersubject variability in the EEG requires assessment of awake values before titration of hypnotic to a given target EEG index.

Opioids

Early studies demonstrated that low concentrations of opioids did not change the BIS response during propofol or inhaled anesthesia.[172,173] Iselin-Chaves and coworkers performed a volunteer study that examined sedation score and the presence/absence of recall during stepped increases in propofol and propofol with alfentanil (50 or 100 ng/mL).[212] The BIS, sedation, and memory function were highly correlated, and the BIS value was not affected by the low alfentanil concentration.

A similar limited interaction has also been found with remifentanil[224] and sufentanil.[225] In contrast, Koitabashi and associates found that the addition of increasing doses of remifentanil reduced BIS for the same propofol dose.[226] Struys and colleagues examined the propofol estimated effect-compartment concentration needed to prevent response to verbal stimulation, eye lash reflex, and tetanic stimulation in patient volunteers given one of three remifentanil target concentrations: 0, 2, or 4 ng/mL.[215] BIS and the AAI were monitored as well. The indices decreased monotonically as propofol was increased. For both indices, the value at loss of response was higher with each successive dose of remifentanil; specifically, with remifentanil the volunteers were "asleep" with less propofol and at higher BIS or AAI. This relates to the definition of anesthetic depth at the beginning of the chapter. Struys and colleagues required a stimulus to assess anesthetic depth, and interpretation of the index from the processed EEG requires consideration of the opioid and hypnotic component together.

Ferenets and coworkers used a similar paradigm to study entropy and complexity measures, including spectral entropy, approximate entropy, Higuchi fractal dimension, Lempel-Ziv complexity, relative [beta] ratio, and the SyncFastSlow measure.[227] They found that the effect of remifentanil was critically dependent on the frequency range used for the calculations, which may further explain the conflicting literature on opioids and depth-of-anesthesia devices.

Bouillon and colleagues used response surface modeling to assess the likelihood of response, BIS, and approximate entropy.[12] Figure 39-24 shows the synergy between propofol and remifentanil on the probability of response to laryngoscopy (A) and the additive effects of propofol and remifentanil effect on the BIS (B). Most critically, the trajectory lines on figure B show the trajectory of equipotent combinations of propofol and remifentanil for probabilities of no response to laryngoscopy ranging from 5% to 95%. Because the interaction on the BIS has a different shape from the interaction on the probability of nonresponse to noxious stimulation, the "right" BIS value for any desired probability of nonresponse is a function of the relative amounts of propofol and remifentanil. If the drugs are used at the point of maximum interaction, the "right" BIS value associated with nonresponse will be higher than if the drugs are not well balanced and synergy is reduced.

Most commercially available monitors have been calibrated for the combination of opioids and hypnotics, as suggested by Figure 39-24. The commercially available indices are therefore most accurate when used with anesthesia consisting of a low or moderate dose of opioid and a hypnotic drug (volatile inhaled anesthetic, intravenous anesthetic) titrated to the average anesthetic range of the monitored index. When using high doses of opioids it is important to provide an adequate dose of hypnotic to guarantee lack of awareness.[228]

Nitrous Oxide

Most studies suggest that nitrous oxide given in concentrations of up to 70% has minimal effect on the BIS. Rampil and coworkers demonstrated in volunteers that nitrous oxide concentrations of up to 50% alter the spectral content of the EEG with surprisingly little change in the BIS.[229] However the subjects did not exhibit CNS depression at these concentrations. In a different study, 70% nitrous oxide produced unconsciousness but still did not alter the BIS.[230] The addition of nitrous oxide to a hypnotic, even up to 70%, may reduce the BIS, have no effect, or increase it.[231-233] The effect of nitrous oxide appears to be dependent on the monitor used. Soto and colleagues found that neither BIS nor PSI demon-

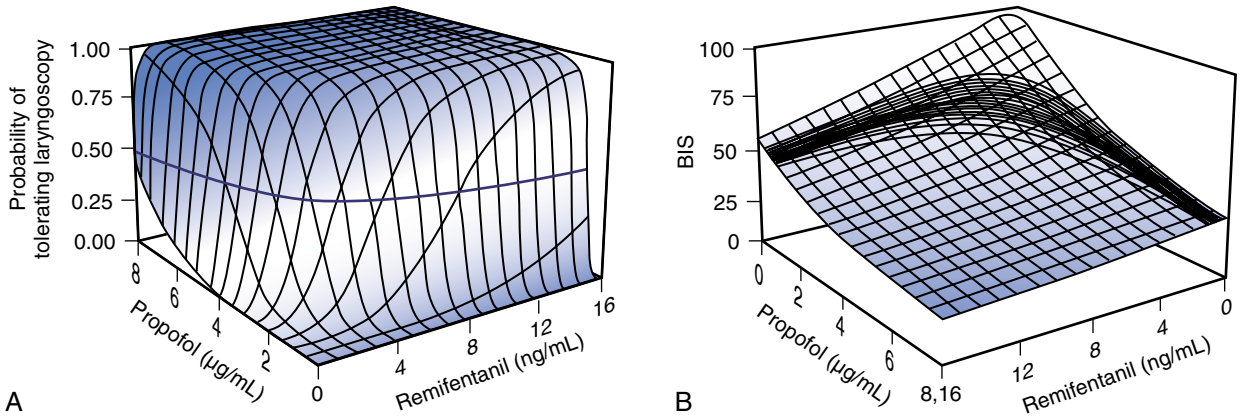

Figure 39-24 **A,** Interaction between propofol and remifentanil for a decreased probability of response to laryngoscopy based on the model shown in Figure 39-3. **B,** Interaction between propofol and remifentanil for their effects on the bispectral index (BIS); additivity is demonstrated. The trajectory lines show the BIS values at equipotent combinations of propofol and remifentanil for 5% to 95% probabilities of no response to laryngoscopy based on **A.** *(From Bouillon TW, Bruhn J, Radulescu L, et al: Pharmacodynamic interaction between propofol and remifentanil regarding hypnosis, tolerance of laryngoscopy, bispectral index, and electroencephalographic approximate entropy. Anesthesiology 100:1353-1372, 2004.)*

strated a change in index but SE did when nitrous oxide was added or removed.[234]

Ketamine

The dissociative anesthetic ketamine produces excitatory effects on the EEG. Ketamine doses that create unresponsiveness (0.25 to 0.5 mg/kg) did not change the BIS.[235]

When ketamine is used with propofol, an additive anesthetic interaction occurs[24] that is not reflected in the BIS,[236] and the response to ketamine may differ by device used.[237] Thus, the addition of ketamine to an anesthetic complicates interpretation of the processed EEG, again emphasizing the need to consider the clinical circumstance and drugs used when interpreting a "depth-of-anesthesia" index.

Interaction with Muscle Relaxants

The algorithms used in the currently available devices all, to a greater or lesser extent, include some EMG activity inasmuch as EMG and EEG frequencies overlap at values greater than 30 Hz. Indeed, the GE Entropy device deliberately includes EMG in the belief that it may be an index of need for analgesia (see earlier). Muscle relaxants may confound the accuracy of devices in relation to the depth of anesthesia (also see Chapter 29). Ekman and coworkers[238] recently found that BIS and AAI responses to noxious stimulation were affected by the degree of neuromuscular block and that the block did not affect the indices in the absence of noxious stimulation.

Fluctuating muscle tension and tonic input from muscle spindles contribute to CNS arousal. As a result, muscle relaxants may deepen anesthesia by reducing neural traffic.[239] Multiple studies have demonstrated an effect of muscle relaxants in appearing to deepen anesthesia.[240-242] The most bizarre was the study by Messner and associates, in which awake volunteers (the investigators themselves) received succinylcholine with no hypnotic (!) and the BIS decreased to as low as 33.[243] Reversal of muscle relaxation can also change the amount of EMG activity and influence the monitor.[244]

Not all studies have demonstrated an effect of muscle relaxants.[245] The differences among studies probably reflect the algorithm being used,[246] which may change among iterations of the same device. Additionally, deep anesthesia at baseline may already have eliminated much of the EMG activity.[247]

Other Drugs

Drugs that affect the sympathetic nervous system may influence depth-of-anesthesia devices. Infusion of a β-blocker such as esmolol can also alter the BIS in some studies. Johansen found that during stable propofol/alfentanil anesthesia, a 30-minute infusion of esmolol (1-mg/kg bolus, 250 μg/kg/min) decreased the BIS from 37 ± 6 (SD) to 22 ± 6.[248] Discontinuation of esmolol reversed these changes. In other studies there was no effect of the β-blocker when there was no stimulation, but the increase in BIS with intubation was attenuated.[249,250] Epinephrine also has an effect on arousal and BIS. Andrzejowski and colleagues established a stable level of propofol sedation (OAA/S = 2) and then gave a bolus of 15 μg of epinephrine.[251] The sedation level increased (OAA/S = 4) and the BIS rose on average by 13. These studies indicate that there is a complex interaction among β-receptors, level of arousal, and BIS during anesthesia. β-Adrenoreceptor blockade can alter the EEG arousal response to noxious stimuli even when inadequate analgesia is present and can decrease the BIS during adequate clinical anesthesia. The effect of dexmedetomidine on depth-of-anesthesia monitors has not yet been well studied. Initial studies indicate that the BIS performs appropriately, whereas auditory responses do not change substantially.[252,253]

Response to Noxious Stimulation

Guignard and associates examined the response of the BIS to laryngoscopy and tracheal intubation during propofol administration with and without remifentanil.[254] Hemodynamics, movement response, and BIS were measured. With propofol at a target effect-site concentration of 4 μg/mL, the BIS decreased to a mean of approximately 45. Intubation increased the BIS to a mean of 70. When computer-controlled infusion of remifentanil was added to achieve target effect-site concentrations of 2 to 16 ng/mL, the interaction of remifentanil on BIS values was obvious. Before intubation, these remifentanil concentrations did not change the BIS values during propofol hypnosis. Progressively increasing concentrations of remifentanil blunted the increase in BIS after intubation. Remifentanil target effect-site concentrations of 8 and 16 ng/mL resulted in a minimal increase in the BIS, hemodynamic stability, and no purposeful movement. This study demonstrated that significant noxious stimuli given with only a hypnotic present (e.g., propofol, inhaled anesthetics) will result in a significant hemodynamic response with an increase in BIS values. The addition of adequate opioid analgesia results in hemodynamic control and less or no change in the BIS value. Ropcke and colleagues demonstrated similar EEG activation and an increase in BIS values when desflurane only (no opioids) was given to surgical patients during intra-abdominal surgery.[255] They demonstrated that in unstimulated patients before the initiation of surgery, a desflurane end-tidal concentration of 2.2% was needed to achieve a mean BIS value of 50. The desflurane end-tidal concentration needed to achieve a BIS value of 50 increased to 6.8% during intra-abdominal noxious surgical stimulation. The authors did not examine whether opioid analgesia would change the response observed with desflurane. A study in volunteers subjected to different combinations of propofol and remifentanil and progressively increasing stimulation (shouting, shaking, laryngoscopy) found that BIS, entropy, spectral edge 95, measured drug concentrations, and predicted drug concentrations all had a very good prediction probability for hypnosis but barely acceptable prediction probability for airway manipulation.[216]

Epidural anesthesia can also decrease the amount of hypnotic anesthetic needed for sedation. Hodgson and Liu have shown that the end-tidal concentration of sevoflurane needed to achieve a BIS value of 50 was 0.59% in patients receiving a lidocaine epidural for surgical procedures, whereas a sevoflurane end-tidal concentration of 0.92% was needed to achieve a BIS value of 50 in patients receiving general anesthesia or general anesthesia with an intravenous infusion of lidocaine to match the plasma concentrations achieved during the epidural anesthetic.[256] This study demonstrates that the deafferentation induced by regional anesthesia results in supraspinal effects that change hypnotic anesthetic requirements.

Studies such as these show that EEG activation is dependent on the amount of neural traffic. Processed EEG indices are good indicators of hypnosis at a given amount of stimulation but may not accurately predict the changes that will occur when

stimulation changes. The behavioral, hemodynamic, and EEG response to painful stimuli can be prevented by adequate analgesia.

Clinical Utility of Depth-of-Anesthesia Devices

Drug Titration

Depth-of-anesthesia devices primarily measure the effects of hypnotics on the EEG. The synergistic interaction of opioids on clinical end points (hemodynamics, movement responses) is more profound than reflected by the EEG. As a result, these devices are most accurate when used with anesthesia consisting of a low or moderate dose of opioid analgesic and a hypnotic drug (volatile inhaled anesthetic, intravenous anesthetic).

Clinical use involves separating the hypnotic and analgesic components of an anesthetic regimen. The concept entails titration of the hypnotic component to the anesthetic range that is associated with a high probability of unconsciousness. A small to moderate amount of analgesic (opioid) decreases the noxious input to the CNS, thus providing hemodynamic stability and decreasing the probability of response.

The anesthesiologist must continuously evaluate the clinical and monitored responses to the surgical stimulation. During intense surgical stimulation, if the index increases or the patient exhibits movement and hemodynamic responses (or both), the anesthesiologist should respond by increasing the hypnotic component to lower the index if it is elevated. Incremental opioid should be given to increase the analgesic component until movement and hemodynamics are controlled. As the end of the anesthetic regimen approaches, the hypnotic component should be decreased to allow the index to increase. These devices therefore add another monitored parameter but in no way relieve the anesthesiologist of the need to use clinical judgment and to be vigilant at all times to ensure that patients are adequately anesthetized.

Drug Consumption, Costs, and Recovery

Several studies have examined the clinical and economic outcome benefits of BIS monitoring in routine surgery. Gan and colleagues[257] studied 302 subjects receiving a propofol/alfentanil/nitrous oxide anesthetic regimen in four different institutions. Half the subjects were randomized to "standard practice" whereby the propofol and alfentanil were titrated to provide stable anesthesia with the fastest possible recovery. The BIS was recorded in this group but not displayed to the practitioner. The remaining subjects received "standard practice plus BIS monitoring." In this group, propofol infusions were titrated to achieve a target BIS value between 45 and 60 during surgery and 60 to 75 during the final 15 minutes of anesthesia. Patients in the BIS group required significantly lower normalized propofol infusion rates (134 versus 116 μg/kg/min), were extubated significantly sooner (11.2 versus 7.3 minutes), had a higher percentage of patients oriented on arrival in the recovery room (43% versus 23%), and had more rapid discharge from the recovery room. This study demonstrated that titrating propofol with BIS monitoring during balanced anesthesia decreased propofol use and significantly improved recovery with no difference in intraoperative conditions.

Song and colleagues[258] presented similar findings with inhaled anesthetics. Sixty surgical patients were randomized to receive desflurane or sevoflurane with 65% nitrous oxide and low doses of fentanyl. Half the patients were randomized to standard practice in which the inhaled anesthetic was titrated according to clinical end points and judgment. The second group had the volatile anesthetic titrated to a BIS value of 60. During the maintenance period, BIS values were significantly lower in the standard-treatment group (mean of 42), a finding suggesting deeper anesthesia than in the BIS-titrated group with a mean of 60. Volatile anesthetic use in the BIS-titrated group was 30% to 38% lower than in the control group. Similarly, times to verbal responsiveness were 30% to 55% shorter in the BIS-titrated group. This study demonstrated that titrating desflurane and sevoflurane with the use of BIS monitoring decreased utilization of the drugs and contributed to faster emergence from anesthesia.

A meta-analysis of 11 trials involving 1380 patients found that BIS monitoring reduced drug consumption by 19%, nausea and vomiting by 6%, and recovery room time by 4 minutes.[259] The cost saving from drugs was offset by the cost of the monitoring electrodes, so the actual cost was 5.55 U.S. dollars higher in the monitored group. A recent review for the Cochrane Database of 20 studies with 4056 patients found that BIS monitoring reduced drug consumption and shortened recovery times by 2 to 8 minutes.[260] Similar results have been found with other devices.[261,262] Although it seems the devices can save on drug costs and time in the early recovery period, the overall benefit from a cost and time perspective is probably modest.

Outcome

The relationship of anesthetic management to patient morbidity and mortality has generally focused on the immediate perioperative period. Information on the effects of anesthetic management on long-term postoperative mortality rates is limited. Monk and coworkers monitored the BIS in 1064 patients undergoing general anesthesia for major elective surgery (excluding cardiac and intracranial procedures) lasting at least 2 hours.[263] The anesthetic technique was not controlled, and the anesthesiologist was blind to the BIS values. The authors examined the incidence of death at 1 year. Independent predictors of mortality were comorbid conditions (relative risk [RR] of 16), cumulative deep hypnotic time with a BIS value less than 45 (RR of 1.24), and systolic hypotension (RR of 1.03). There are many concerns with this study, including the fact that it has not been replicated nor has the outcome parameter "cumulative deep hypnotic time" been validated.

Lindholm and colleagues looked at mortality within 2 years of surgery in 4087 surgical patients monitored with the BIS.[264] They found that the duration of a BIS value less than 45 was statistically associated with increased 1- and 2-year postoperative mortality (hazard ratio, 1.13 and 1.18, respectively) if preexisting malignancy was not included among the covariates. Importantly, when preexisting malignancy was included among the covariates, the hazard ratio was reduced to 1.08 and did not reach statistical significance. They concluded that the linkage of a BIS value lower than 45 to postoperative mortality is "very weak in comparison with co-morbidity as assessed by ASA physical score, the preexisting malignancy status at surgery, and age," and a causal relationship, if any, can only be assessed in a prospective randomized trial.

Conclusions

Anesthetic depth can be defined as the drug-induced probability of nonresponse to stimulation, calibrated against the strength of the stimulus and the difficulty of suppressing the response. This definition requires that multiple different stimuli and responses are measured at precisely defined drug concentrations to permit estimation of the full drug-versus–probability of nonresponse surface for clinically important stimuli. There is no one stimulus and response measurement that will capture depth of anesthesia in a clinically or scientifically meaningful manner. The anesthesiologist must understand a complex matrix of stimuli, responses, and "anesthetic" drugs, including their pharmacodynamic (and generally synergistic) interactions. This definition captures the nature of routine clinical care whereby anesthesiologists observe a series of stimuli ranging from talking to the patient preoperatively to intubation to skin incision. They also observe a range of responses ranging from verbal response to movement to tachycardia and hypertension, and they calibrate these observations of stimuli and responses against the drugs used to reduce the probability of response by constantly adjusting the administered dose to achieve the desired anesthetic depth.

Our definition of "depth of anesthesia" identifies two critical components to maintain the anesthetic state: hypnosis from drugs such as propofol or the inhaled anesthetics and analgesia from opioids or nitrous oxide. We demonstrate the scientific evidence that profound degrees of hypnosis in the absence of analgesia will not prevent the hemodynamic responses to profoundly noxious stimuli and that profound degrees of analgesia do not guarantee unconsciousness. However, the combination of hypnosis and analgesia suppresses the hemodynamic response to noxious stimuli and guarantees unconsciousness. The synergy between hypnotics and analgesics is used every day by every anesthesiologist in clinical practice. We also demonstrate that this concept can be captured with a three-dimensional interaction surface (hypnotic concentration on the *y* axis, analgesic concentration on the *x* axis, probability of nonresponsiveness for defined stimuli on the *z* axis) that can be accurately estimated with available clinical data for currently used anesthetic drugs.

Awareness during anesthesia is an important clinical problem that sometimes results in prolonged disabling psychological sequelae for the patient. Comprehensive understanding of the sciences underpinning anesthesia, thorough preoperative evaluation and preparation, careful intraoperative observation, and postoperative debriefing may help reduce the incidence of awareness and the severity of its consequences. Unconscious memory formation and dreaming remain fascinating but probably harmless phenomena.

There are now many electrophysiologic monitors that can be used to assess the magnitude of the drug-induced changes in the EEG and evoked responses and help guide titration of anesthetics. Of these, the BIS is the most extensively validated. These monitors correlate well with the effects of hypnotics (particularly propofol, thiopental, and inhaled anesthetics) on memory, sedation, and consciousness but should always be used in conjunction with clinical assessment of the patient, the stimulus, and the drugs used. Titration guided by the BIS decreases the incidence of intraoperative awareness. An electrophysiologic measure of analgesia is not currently available.

There is considerable room for the development of additional technology and pharmacologic insight into measures of the depth of anesthesia. The opioid/hypnotic concentration-versus-response surface has not been characterized for many stimulus-response pairs. There are many additional drug interactions that might be profitably characterized (e.g., opioids versus α_2-adrenergic agonists), as well as higher-dimensional drug interactions (e.g., three-drug interaction surfaces). There are cells in the stimulus-response matrix for which only poor EEG predictors exist (e.g., movement with opioid/nitrous oxide anesthesia, ketamine). There are important responses that are poorly understood (e.g., inflammatory, humeral, neurophysiologic, and psychological responses). Our definition of anesthetic depth, as well as measurement of anesthetic depth, will expand as the matrix of stimuli, responses, and drugs that influence the probability of nonresponse expands with new research and new knowledge.

40 Cardiovascular Monitoring

Key Points

1. Although a stethoscope should be present in every anesthetizing location, continuous stethoscopy is an insensitive method for early detection of untoward hemodynamic events.
2. Most automated noninvasive blood pressure measuring devices use an oscillometric measurement technique and rarely cause complications. Caution should be exercised in patients who cannot complain of arm pain, those with irregular rhythms that force repeated cuff inflation, and individuals receiving anticoagulant therapy.
3. Direct arterial pressure monitoring should be widely used in operative patients with severe cardiovascular diseases or those undergoing major surgical procedures that involve significant blood loss or fluid shifts.
4. The Allen test for palmar arch collateral arterial flow is not a reliable method to predict complications from radial artery cannulation. Despite the absence of anatomic collateral flow at the elbow, brachial artery catheterization for perioperative blood pressure monitoring is a safe alternative to radial or femoral arterial catheterization.
5. The accuracy of a directly recorded arterial pressure waveform is determined by the natural frequency and damping coefficient of the pressure monitoring system. Optimal dynamic response of the system will be achieved when the natural frequency is high, thereby allowing accurate pressure recording across a wide range of damping coefficients.
6. Rather than the common placement at the midaxillary line, the preferred position for alignment (or "leveling") of external pressure transducers is approximately 5 cm posterior to the sternomanubrial junction. When using external transducers and fluid-filled monitoring systems, this transducer location will eliminate confounding hydrostatic pressure measurement artifacts.
7. Because of wave reflection and other physical phenomena, arterial blood pressure recorded from peripheral sites has a wider pulse pressure than central aortic pressure does.
8. Dynamic measures of cardiac preload, such as systolic pressure variation and pulse pressure variation, are better predictors of volume responsiveness than static indicators such as central venous pressure (CVP) or pulmonary capillary wedge pressure.
9. Selecting the best site, catheter, and method for safe and effective central venous cannulation requires that the physician consider the purpose of the catheterization, the patient's underlying medical condition, the intended operation, and the skill and experience of the physician performing the procedure. Right internal jugular vein cannulation is favored by most anesthesiologists because of its consistent, predictable anatomic location and its relative ease of access intraoperatively.
10. Methods to reduce mechanical complications from central venous catheters include the use of ultrasound vessel localization, venous pressure measurement before insertion of large catheters, and radiographic confirmation that the catheter tip rests outside the pericardium and parallel to the walls of the superior vena cava.
11. When using CVP as a measure of intravascular volume, the influences of ventricular compliance and intrathoracic pressure must be taken into consideration. In general, a trend in CVP values or its change with therapeutic maneuvers is more reliable than a single measurement. Important pathophysiologic information can be obtained by careful assessment of the CVP waveform morphology.
12. Of the many complications of central venous and pulmonary artery catheters, catheter misuse and data misinterpretation are among the most common.
13. Pulmonary artery wedge pressure is a delayed and damped reflection of left atrial pressure. The wedge pressure provides a close estimate of pulmonary capillary pressure in many cases but may underestimate capillary pressure when postcapillary pulmonary vascular resistance is increased, as in patients with sepsis.

14. Use of central venous, pulmonary artery diastolic, or pulmonary artery wedge pressure as an estimate of left ventricular preload is subject to many confounding factors, including changes in diastolic ventricular compliance and juxtacardiac pressure.
15. Most randomized prospective clinical trials have failed to show that pulmonary artery catheter monitoring results in improved patient outcome. Reasons cited for these results include misinterpretation of catheter-derived data and failure of hemodynamic therapies that are guided by specific hemodynamic indices.
16. Thermodilution cardiac output monitoring, the most widely used clinical technique, is subject to measurement errors introduced by rapid intravenous fluid administration, intracardiac shunts, and tricuspid valve regurgitation.
17. Mixed venous hemoglobin oxygen saturation is a measure of the adequacy of cardiac output relative to body oxygen requirements. It is also dependent on arterial hemoglobin oxygen saturation and hemoglobin concentration.
18. Newer methods of cardiac output monitoring, including esophageal Doppler and pulse contour analysis, allow beat-to-beat estimation of left ventricular stroke volume and measurement of other cardiovascular variables.

Introduction to Cardiovascular Monitoring: Focused Physical Examination

Although cardiovascular monitors receive prime emphasis, the fundamental basis for circulatory monitoring remains in the eyes, hands, and ears of the anesthesiologist. In many ways, the clinician's senses capture more information than even the most sophisticated electronic monitors do. Combined with knowledge, experience, and sound clinical judgment, the clinician's senses offer an integrated, panoramic view of the patient's condition, made even more valuable by an understanding of the clinical context present. Whereas electronic instruments accurately and monotonously collect huge volumes of quantitative data, the clinician plays a vital role in patient monitoring by integrating, evaluating, and interpreting these data.[1] Just as inspection, palpation, and auscultation are the cornerstones of physical examination of the cardiovascular system, these same clinical procedures are fundamental elements of perioperative cardiovascular monitoring. However, they must be adapted and focused on the unique requirements of surgical and critically ill patients, and their limitations must be recognized.

Many standard physical means of assessing the circulation are used throughout an operation. For many healthy patients undergoing minor procedures, these physical signs provide a considerable fraction of the total cardiovascular monitoring. For higher-risk patients and longer, more complicated operations, the extent of supplemental electronic monitoring grows accordingly. However, careful physical assessment still provides the clinician with an all-important backup system to confirm or refute information derived from other monitoring devices. The most obvious, perhaps trivial, example is a patient whose electrocardiogram (ECG) shows asystole. Detection of a normal pulse by direct palpation focuses the anesthesiologist on correcting the monitoring artifact rather than initiating cardiopulmonary resuscitation.

Early advances in cardiovascular assessment beyond basic physical examination were not readily accepted into medical practice. Around 1900, the introduction of sphygmomanometry to measure blood pressure was criticized because it would weaken clinical acuity by blunting the senses and acute perceptions of the clinician. Even stethoscopy had its critics, simply on the basis that it placed the physician at greater distance from the patient.

Palpation of the pulse and its rate and character should not be forgotten in the perioperative setting. Environmental constraints in the operating room may dictate which pulses are accessible for monitoring, but they also provide unique opportunities for pulse monitoring during surgery. For example, during cardiac surgery the beating heart may be observed directly, and palpation of the ascending aorta by the surgeon provides a useful estimate of aortic blood pressure. In fact, the surgeon's evaluation of any arterial pulse within the surgical field should be considered whenever severe hemodynamic instability develops.

Clinical evaluation of venous pressure during anesthesia is technically difficult because of unusual patient positions, positive-pressure mechanical ventilation, and lack of access to observe the neck veins. However, early recognition of venous obstruction in an extremity or in the head and neck may have important clinical consequences. Not only might this observation herald hemodynamic problems for the patient, but communicating these observations to the operating surgeon should also allow timely correction of contributing surgical factors.

Given that the cardiovascular system is responsible for the transport of substrates and by-products to and from all organ systems, monitoring end-organ function can be used to assess the adequacy of cardiovascular performance. Inspection of mucous membranes, skin color, and skin turgor can reveal pertinent clues about hydration, oxygenation, and perfusion. Additional simple clinical techniques include empirical estimation of fluid deficits and blood loss, measurement of urine output, and detection of altered mental status. Unfortunately, interpretation of these clinical signs and symptoms is often confounded by preexisting organ dysfunction and the direct effects of anesthetic drugs on organs. As a result, use of these clinical assessment tools is of limited value in many anesthetized or critically ill patients. Frequently, additional cardiovascular monitoring techniques are required.

Stethoscopy

Although Laennec is credited with introducing the stethoscope into general medical practice in 1818, nearly a century elapsed before Harvey Cushing proposed in 1908 that the stethoscope be used as a routine cardiopulmonary monitoring device during surgery.[2] For many years thereafter, intraoperative monitoring with either a precordial or an esophageal stethoscope became the

most common simple method for monitoring ventilation and circulation in anesthetized patients.

Stethoscopy provides a simple and reliable means of listening to heart and breath sounds continuously throughout an operation. The most common equipment used for precordial stethoscopy consists of a heavy metal bell or accumulator attached to a length of rubber or plastic extension tubing and a custom-molded monaural plastic earpiece. Electronically amplified stethoscopes have been designed to improve the quality and clarity of heart and breath sounds but have not supplanted standard inexpensive mechanical devices in everyday practice.[3] Though minimally invasive and practical only for patients receiving general endotracheal anesthesia, the esophageal stethoscope provides monitoring benefits not available with its precordial cousin. Clear breath sounds and distinct heart sounds are audible in most patients when the tip of the stethoscope is positioned 28 to 30 cm from the incisors, and esophageal temperature can be measured with an incorporated thermistor.[4] Although use of the esophageal stethoscope is generally without significant risk, rare complications include hypoxemia from unintended tracheobronchial placement or compression of the membranous posterior portion of the trachea in small infants, loss down the esophagus, detachment of the acoustic cuff, and distortion of surgical anatomy in the neck. Placement of the esophageal stethoscope may also cause pharyngeal or esophageal trauma and interfere with nasogastric tube positioning or transesophageal echocardiography.

Despite the purported value of the precordial or esophageal stethoscope for basic monitoring of patient safety, its widespread application in clinical practice has diminished in recent years.[5,6] This decline may be driven by the routine use of pulse oximetry, capnography, and other electronic monitors that have become ubiquitous.[7] As a practical matter, clinicians may not recognize changing heart or breath sounds as readily as might be expected because of reliance on more modern electronic devices, distraction, or operating room noise. These practice patterns appear to be borne out by the 1993 Australian Incident Monitoring Study, which noted that a stethoscope was used in only 5% of the 1256 critical incidents reported and was the first monitor to detect the morbid incident—cardiac arrest—in only one instance.[5] As a result, the current role of intraoperative stethoscopy as a continuous monitor has become limited to special applications (e.g., pediatric anesthesia) and to institutions with insufficient resources to purchase electronic monitors.

Heart Rate Monitoring

The simplest and least invasive form of cardiac monitoring remains measurement of the heart rate. Under most circumstances in modern anesthesia practice, electronic devices are used to continuously monitor this vital sign and provide an important guide to the influence of anesthetics and surgical stimuli on the patient's condition. The ability to estimate the heart rate quickly with a "finger on the pulse" is a skill as important as this expression is common.

Although any monitor that measures the period of the cardiac cycle can be used to determine the heart rate, the ECG is the most common method used in the operating room (see Chapter 42). Measurement of the heart rate by ECG begins with accurate detection of the R wave and measurement of the R-R interval. The digital value displayed for the heart rate is generated from an algorithm designed to count and average a certain number of beats and then display a number that is updated every 5 to 15 seconds.[8] As a result, transient dysrhythmias may have little impact on the displayed digital heart rate value (Fig. 40-1).

Occasionally, the clinician must check electrode attachment, increase signal gain on the ECG, or select alternative ECG leads to improve the accuracy of heart rate monitoring. Most monitors allow manual adjustment of the threshold or sensitivity for R-wave detection and recognition of electronic pacing spikes. In the operating room, ECG artifacts are common, particularly those caused by the electrosurgical unit. The ECG trace should always be inspected visually to confirm the numeric value for the heart rate displayed on the monitor. In addition, the arterial pressure waveform or the pulse oximeter plethysmograph should be used to confirm the pulse rate in these instances.

Electrical interference in the ECG trace may arise from sources other than the electrosurgical unit. Power line noise appears as a 60-Hz artifact and may be eliminated by selecting narrower-bandpass ECG filters, including a 60-Hz notch filter. Other artifacts result from muscle twitching and fasciculations, as well as from various medical devices, including lithotripsy machines, cardiopulmonary bypass equipment, and fluid warmers.[9] Paced rhythms can produce problems with measurement of the heart rate on the ECG. When tall pacing spikes are present, the monitor may misinterpret these high-amplitude signals as R waves and miscalculate the heart rate. Tall T waves may produce the same artifact when the monitor mistakenly

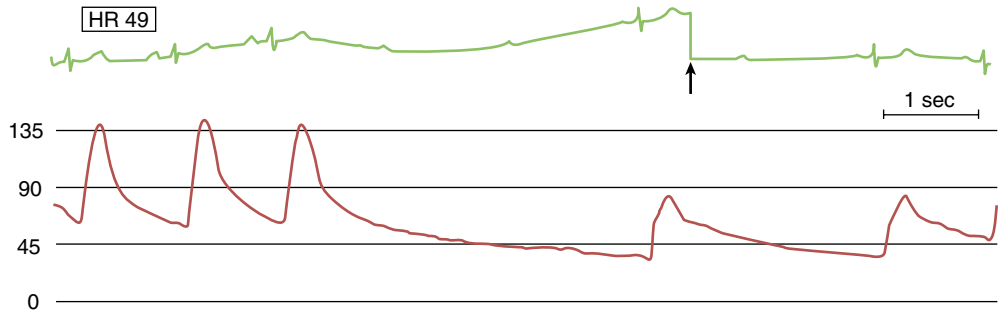

Figure 40-1 Digital heart rate (HR) displays may fail to warn of dangerous bradyarrhythmias. Direct observation of the electrocardiogram (ECG) and the arterial blood pressure traces reveals a complete heart block and a 4-second period of asystole, whereas the digital display reports an HR of 49 beats/min. Note that the ECG filter (*arrow*) corrects the baseline drift so that the trace remains on the recording screen. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998, Fig. 13-2.)*

counts these T waves as R waves. These problems may be ameliorated by decreasing ECG gain, adjusting the sensitivity for detection of R waves, changing the ECG lead to one with a smaller pacing spike or T-wave amplitude, or selecting pacing detection modes that distinguish pacing spikes from other ECG features.

Pulse Rate Monitoring

The distinction between heart rate and pulse rate centers on whether a given electrical depolarization and systolic contraction of the heart (heart rate) generate a palpable, peripheral arterial pulsation (pulse rate). Pulse deficit describes the extent to which the pulse rate is less than the heart rate. Such deficit is typically seen in patients with atrial fibrillation, in which short R-R intervals compromise cardiac filling during diastole and result in reduced stroke volume and an imperceptible arterial pulse. The most extreme example of a pulse deficit is electrical-mechanical dissociation, or pulseless electrical activity, seen in patients with cardiac tamponade, extreme hypovolemia, and other conditions in which cardiac contraction does not generate a palpable peripheral pulse.

Most monitors report heart rate and pulse rate separately. The former is measured from the ECG trace and the latter is determined from a selectable pulse source. The pulse oximeter plethysmograph trace is the most common source for measurement of the pulse rate, but it may be of poor quality in patients with severe arterial occlusive disease or marked peripheral vasoconstriction. In addition to indicating the pulse rate, this waveform may also provide supplementary diagnostic clues to cardiovascular function[10,11] (see systolic pressure variation in the later section "Arterial Pressure Monitoring for Prediction of Volume Responsiveness"). Other pulse rate sources include the directly measured arterial pressure waveform and automatic noninvasive blood pressure (NIBP) monitors, which determine the pulse rate from the pressure oscillations detected by the surrounding cuff. Pulse rate monitoring and heart rate monitoring complement one another. Although monitoring both may seem redundant, such redundancy is intentional and being applied to modern computerized monitoring algorithms to reduce measurement errors and false alarms.[12]

Arterial Blood Pressure Monitoring

Like the heart rate, blood pressure is a fundamental cardiovascular vital sign and a critical part of monitoring anesthetized or seriously ill patients. The importance of monitoring this vital sign is underscored by the fact that standards for basic anesthetic monitoring mandate measurement of arterial blood pressure at least every 5 minutes in all anesthetized patients.[13]

Techniques for measuring blood pressure fall into two major categories: indirect cuff devices and direct arterial cannulation and pressure transduction. These methods differ most notably in terms of the physical signal being monitored and their level of invasiveness. Although direct arterial blood pressure measurement is the reference standard against which other methods are compared, even this technique can yield spurious results. Consequently, blood pressure measured in clinical practice with different techniques often yields significantly different values.[14]

Indirect Measurement of Arterial Blood Pressure

Manual Intermittent Techniques

Most indirect methods of measuring blood pressure rely on a sphygmomanometer similar to the one first described by Riva-Rocci in 1896.[15] This apparatus included an arm-encircling inflatable elastic cuff, a rubber bulb to inflate the cuff, and a mercury manometer to measure cuff pressure. Riva-Rocci described the measurement of systolic arterial blood pressure by determining the pressure at which the palpated radial arterial pulse disappeared as the cuff was inflated.

A commonly used variation of the Riva-Rocci method, termed the "return-to-flow technique," records the pressure during cuff deflation at which the pulse reappears and is detected by palpation. When the patient has a finger pulse oximeter or an indwelling arterial catheter in the ipsilateral arm, return to flow can be detected by reappearance of the plethysmographic or arterial pressure waveforms. Return-to-flow methods provide a simple, rapid estimation of systolic blood pressure during urgent situations but do not allow measurement of diastolic blood pressure.

To measure both systolic and diastolic arterial pressure, the most widely used intermittent manual method is the auscultatory technique, originally described by Korotkoff in 1905.[16] Using a sphygmomanometer, cuff, and stethoscope, Korotkoff measured blood pressure by auscultating sounds generated by arterial blood flow. These sounds are a complex series of audible frequencies produced by turbulent flow beyond the partially occluding cuff. The pressure at which the first Korotkoff sound is heard is generally accepted as systolic pressure (phase I). The character of the sound progressively changes (phases II and III), becomes muffled (phase IV), and is finally absent (phase V). Diastolic pressure is recorded at phase IV or V. However, phase V may never occur in certain pathophysiologic states such as aortic regurgitation.[17]

A fundamental shortcoming of the auscultatory method of blood pressure measurement is its reliance on blood flow to generate Korotkoff sounds. Pathologic or iatrogenic causes of decreased peripheral blood flow, such as cardiogenic shock or high-dose vasopressor infusion, can attenuate or obliterate the generation of sound and result in significant underestimation of blood pressure.[18] In contrast, low compliance of the tissues underlying the cuff, as encountered in a shivering patient, will require an excessively high cuff-occluding pressure and produce "pseudohypertension." A similar situation exists in patients with severe calcific arteriosclerosis, whose noncompressible arteries may be palpated distal to a fully inflated cuff (positive Osler sign).[17]

Other common sources of error during intermittent manual blood pressure measurement include selection of an inappropriate cuff size and excessively rapid cuff deflation. The optimal cuff should have a bladder length that is 80% and a width at least 40% of arm circumference.[17] The cuff should be applied snugly, with the bladder centered over the artery and any residual air squeezed out. Although too large a cuff will generally work well and produce little error, use of cuffs that are too small will result in overestimation of blood pressure.[17] The cuff deflation rate is another impor-

tant variable that influences manual blood pressure measurement. The decrease in cuff pressure should proceed slowly enough for the Korotkoff sounds to be detected and properly assigned to the current pressure in the cuff. Failure to identify the initial Korotkoff sounds will result in a falsely low measurement of blood pressure.

Automated Intermittent Techniques

Many limitations of manual intermittent blood pressure measurement have been overcome by automated NIBP devices, which are now used widely. In addition, automated NIBP devices provide audible alarms and can transfer data to a computerized information system. However, the greatest advantage of automated NIBP devices over manual methods of blood pressure measurement is that they provide frequent, regular blood pressure measurements and free the operator to perform other vital clinical duties.

Most automated NIBP devices are based on oscillometry, a technique first described by Marey in 1876.[17] In this method, variations in cuff pressure resulting from arterial pulsations during cuff deflation are sensed by the monitor and used to determine arterial blood pressure values. The pressure at which the peak amplitude of arterial pulsations occurs corresponds closely to directly measured mean arterial pressure (MAP), and values of systolic and diastolic pressure are derived from proprietary formulas that examine the rate of change of the pressure pulsations.[19,20] Consequently, systolic and diastolic values are less reliable than MAP values.[17] Systolic pressure is typically identified as the pressure at which pulsations are increasing and are at 25% to 50% of maximum. Diastolic pressure is the most unreliable oscillometric measurement and is commonly recorded when the pulse amplitude has declined to a small fraction of its peak value (Fig. 40-2).

Although oscillometry is used primarily in automated NIBP measurement, the same principles may be applied to determine blood pressure manually with a standard cuff and aneroid manometer. If the cuff is deflated slowly until the needle on the aneroid gauge begins to flicker or oscillate, the corresponding pressure value provides a close estimate of systolic blood pressure. Like the return-to-flow technique, "manual oscillometry" can be performed quickly, with only one hand on the inflation bulb and pressure relief valve and observing the aneroid gauge needle for the onset of oscillation.

In clinical practice, oscillometric automated NIBP measurement has focused largely on pressure measured from the upper part of the arm. If a patient's surgical procedure or medical condition requires that the cuff be applied to the calf, ankle, or thigh, an appropriately sized cuff must be used.

Other methods using a variety of sensing techniques, including Doppler, photo-oscillometry, and motion of the arterial wall, have also been described for automated intermittent NIBP measurement.[21] Although these methods have been found to measure blood pressure with reasonable accuracy under limited clinical circumstances, they all require additional sensing transducers, their accuracy in critically ill patients is uncertain, and consequently, none has supplanted the standard oscillometric technique.

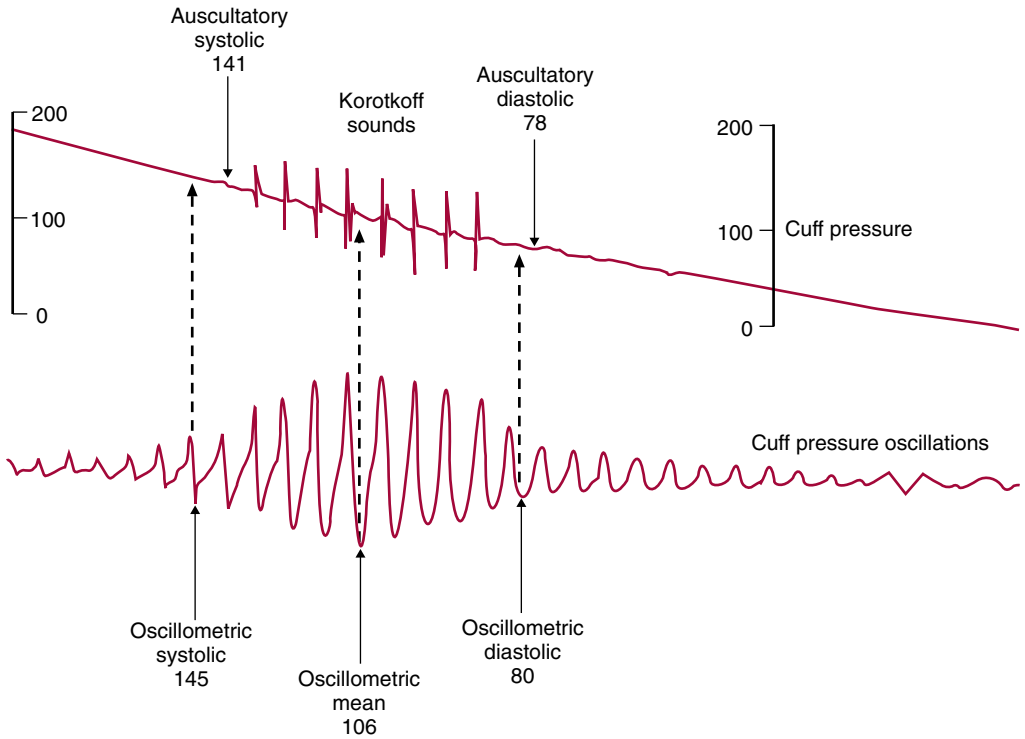

Figure 40-2 Comparison of blood pressure measurements via Korotkoff sounds and oscillometry. Oscillometric systolic blood pressure is recorded at the point where cuff pressure oscillations begin to increase, mean pressure corresponds to the point of maximal oscillations, and diastolic pressure is measured at the point where the oscillations become attenuated. Note the correspondence between these measurements and the Korotkoff sounds that determine auscultatory systolic and diastolic pressure. *(From Geddes LA: Cardiovascular Devices and Their Applications. New York, John Wiley, 1984, Fig. 34-2. Reprinted by permission of John Wiley & Sons, Inc.)*

Even though automated NIBP measurements have been shown to closely approximate directly measured arterial pressure in controlled clinical settings, numerous investigations underscore the disagreement that often exists when direct and indirect pressure measurements are compared, particularly when techniques are compared under changing hemodynamic conditions.[14,17] Standards for performance of automated NIBP devices have been advanced by the Association for the Advancement of Medical Instrumentation, the British Hypertension Society, and other organizations. These standards generally require accuracy within 5 mm Hg with respect to reference methods.[17,21] However, the clinical performance of an NIBP monitor should be evaluated by other criteria, including the number of outlier values, duration of discrepancies, magnitude of individual errors, and performance under variable clinical conditions.[21]

Complications of Noninvasive Blood Pressure Measurement

Although automated blood pressure measurement techniques are considered noninvasive and relatively safe, complications have been reported, including rare severe events such as compartment syndrome (Box 40-1).[22] These morbid events occur more often after prolonged periods of excessively frequent cycles of cuff inflation/deflation and are due to trauma or impaired distal limb perfusion. Other factors that may contribute include cuff misplacement across a joint or repeated attempts to determine blood pressure in the presence of an artifact-producing condition such as involuntary muscle tremors. Caution should be exercised when using these monitors in patients with depressed consciousness, preexisting peripheral neuropathies, arterial or venous insufficiency, or irregular cardiac rhythms, as well as in those receiving anticoagulant or thrombolytic therapy.

Automated Continuous Techniques

Advances in microprocessor and servomechanical control technology have enabled noninvasive techniques to provide a reasonable representation of the arterial pressure waveform and nearly continuous assessment of blood pressure without resorting to direct arterial cannulation. One such device measures finger blood pressure with an arterial volume-clamp method designed and first reported by Penaz in 1973.[23] Although several clinical investigators have demonstrated reasonable accuracy of finger blood pressure as a surrogate for intra-arterial pressure measurements, a number of factors have precluded more widespread application of this technology.[24] In many circumstances, finger blood pressure monitoring will not reflect brachial arterial pressure. In addition, finger arteries are prone to spasm with the potential for distal ischemia, hand position will influence pressure values, and blood sampling cannot be performed without indwelling catheters.

Box 40-1 Complications of Noninvasive Blood Pressure Measurement

- Pain
- Petechiae and ecchymoses
- Limb edema
- Venous stasis and thrombophlebitis
- Peripheral neuropathy
- Compartment syndrome

Other automatic continuous noninvasive techniques have been used to measure blood pressure by applying technologies based on arterial wall displacement, pulse transit time, arterial tonometry, and other methods. All techniques have limitations, including the need for calibration, sensitivity to motion artifact, and limited applicability in critically ill patients.[17,21,25] It remains unclear whether any noninvasive technique will reduce the need for direct arterial pressure monitoring or whether these methods will replace automated intermittent oscillometry as the standard NIBP monitoring method in anesthesia and critical care.

Direct Measurement of Arterial Blood Pressure

Arterial cannulation with continuous pressure transduction and waveform display remains the accepted reference standard for blood pressure monitoring despite the fact that it is more costly, has the potential for more complications, and requires more technical expertise to initiate and maintain than noninvasive monitoring does. There are a number of reasons why clinicians should use this form of invasive pressure monitoring (Box 40-2). First and foremost, direct arterial pressure monitoring should be used when moment-to-moment blood pressure changes are anticipated and rapid detection is vital. These conditions typically apply to patients with preexisting severe cardiovascular disease or hemodynamic instability or when the planned operative procedure is likely to cause large, sudden cardiovascular changes, rapid blood loss, or large fluid shifts. The Australian Incident Monitoring Study of 1993 confirmed the superiority of direct arterial pressure monitoring over indirect monitoring techniques for the early detection of intraoperative hypotension.[26]

In addition to continuous blood pressure monitoring, arterial catheterization provides reliable vascular access for frequent blood sampling and allows monitoring of blood pressure when NIBP measurement is impossible (as during nonpulsatile cardiopulmonary bypass). Perhaps the most underemphasized value of direct arterial pressure monitoring is that analysis of the arterial pressure waveform may provide many important diagnostic clues to the patient's condition. More than a half-century ago, Eather and colleagues emphasized these diagnostic insights in a paper that first introduced and advocated direct monitoring of "arterial pressure and pressure pulse contours" in anesthetized

Box 40-2 Indications for Arterial Cannulation

- Continuous, real-time blood pressure monitoring
- Planned pharmacologic or mechanical cardiovascular manipulation
- Repeated blood sampling
- Failure of indirect arterial blood pressure measurement
- Supplementary diagnostic information from the arterial waveform
- Determination of volume responsiveness from systolic pressure or pulse pressure variation

patients.[27] Some of these diagnostic insights are readily apparent and commonly sought, such as identification of the arterial dicrotic notch to guide proper timing for intra-aortic balloon counterpulsation, whereas others are more subtle, such as recognition of excessive variation in systolic blood pressure as a sign of hypovolemia.[28]

Percutaneous Radial Artery Cannulation

The radial artery is the most common site for invasive blood pressure monitoring in anesthesia and critical care because it is technically easy to cannulate and complications are uncommon, in part because of the good collateral circulation of the hand.[29] Slogoff and coauthors described the results of radial artery cannulation in 1700 cardiovascular surgical patients who underwent the procedure without ischemic complications despite evidence of radial artery occlusion after decannulation in more than 25% of the patients.[30]

Before attempting radial artery cannulation, many clinicians assess the adequacy of collateral flow to the hand by performing a modified Allen test. This bedside examination, originally described by E. V. Allen in 1929, provided a technique to assess arterial stenosis in the hands of patients with thromboangiitis obliterans.[31] To perform the Allen test, the examiner compresses the radial and ulnar arteries and asks the patient to make a tight fist to exsanguinate the palm. The patient then opens the fist while avoiding hyperextension of the wrist or fingers, and as occlusion of the ulnar artery is released, the color of the open palm is observed. Normally, the palm will show a striking flush in several seconds; severely reduced ulnar collateral flow is present when the palm remains pale for more than 10 seconds.

Although the Allen test is often used to identify patients at high risk for ischemic complications from radial artery catheterization, the predictive value of this test is uncertain. Numerous reports of permanent ischemic sequelae note that a normal Allen test result was present before catheterization.[32] In contrast, there are many descriptions of uncomplicated radial artery catheterization despite the presence of an abnormal Allen test result before the procedure.[30] In recent years, the radial artery has been used safely as an access site for coronary stenting or excised and used as a graft for coronary bypass surgery, even in individuals with abnormal Allen test results.[33,34] Although most patients show radial artery dominance with respect to overall hand perfusion, total radial artery occlusion does not appear to compromise distal perfusion, perhaps because of collateral recruitment.[34] Furthermore, Allen test results bear little relation to distal blood flow, as measured by fluorescein dye injection or photoplethysmography. Although it is obviously of great importance that the clinician minimize the chance of significant distal ischemia from arterial pressure monitoring, the Allen test cannot be relied on to avoid this adverse outcome.

Consistent, successful radial artery cannulation should be easily achievable with attention to a number of procedural details. The wrist and hand are immobilized in mild dorsiflexion and secured with the wrist resting across a soft pad. Excessive dorsiflexion of the wrist should be avoided because of the possibility of attenuating the pulse. The course of the radial artery proximal to the wrist is identified by gentle palpation, the skin is prepared with an antiseptic, and a local anesthetic is injected intradermally and subcutaneously alongside the artery. Arterial catheterization can then be performed with a standard intravenous catheter or an integrated guidewire-catheter assembly designed for this purpose. A recent educational video provides greater detail about this standard procedure.[35]

Once the catheter is fully advanced into the vessel lumen, the radial artery is occluded by applying proximal pressure, the needle is removed, the monitoring system pressure tubing is fastened to the catheter, an appropriate sterile dressing is applied, and the apparatus is taped and secured to the wrist. Although a soft armboard can be used to maintain the wrist in an anatomically neutral position during arterial pressure monitoring, extreme wrist dorsiflexion should always be avoided because it may lead to median nerve injury.[36,37]

Some clinicians choose the "transfixion" technique for arterial cannulation, in which the front and back walls of the artery are punctured intentionally, the needle is removed from the catheter, and the catheter is withdrawn into the vessel lumen. Although it is unnecessary to place an additional hole in the back wall of the radial artery for successful cannulation, the technique per se does not appear to influence the success rate or incidence of postcannulation complications.

Other aids to arterial cannulation include the use of ultrasound imaging to guide catheter insertion.[38] This may be particularly helpful when standard placement attempts by palpation have failed. Although some authors have suggested that ultrasound or guidewire-based techniques will improve success rates of arterial cannulation, it appears that this is more a function of operator experience and personal preference.[39]

Alternative Arterial Pressure Monitoring Sites

If the radial arteries are unsuitable for monitoring pressure, several alternative cannulation sites are available. The *ulnar artery* is cannulated with a technique much like that described for the radial artery.[40] Even in circumstances in which previous attempts to cannulate the ipsilateral radial artery have failed, the ulnar artery may be cannulated safely.[30]

Although in theory the *brachial artery* does not have the anatomic benefit of the collateral circulation present in the hand, clinical trials have confirmed the safety of this cannulation site. Bazaral and coauthors reported the use of more than 3000 brachial artery catheters in patients undergoing cardiac surgery over a 3-year period, with only one patient requiring postoperative thrombectomy and no untoward sequelae.[41] A slightly longer catheter is preferred for the brachial site because of the need for the catheter to traverse the elbow joint. Other peripheral arteries occasionally chosen for monitoring pressure include the *dorsalis pedis*, *posterior tibial*, and *superficial temporal arteries*. The dorsalis pedis and posterior tibial arteries are generally reserved for pediatric applications.

The *axillary artery* provides another site for long-term pressure monitoring. Advantages include patient comfort, mobility, and access to a central arterial pressure waveform. Complications appear to be infrequent and similar in incidence to radial and femoral artery catheterization.[42] If the axillary approach is chosen, the left side is preferred over the right because the axillary catheter tip will lie distal to the aortic arch and great vessels. Clinicians should be aware, however, that the risk of cerebral embolization is increased whenever more centrally located arterial catheters are used.

The *femoral artery* is the largest artery commonly selected for monitoring blood pressure, and it appears to have a safety record comparable to that of other sites.[42] As with axillary artery pressure monitoring, the femoral artery waveform more closely

resembles aortic pressure than do waveforms recorded from peripheral sites. When compared with radial artery catheterization, the risk of distal ischemia after femoral artery cannulation may be reduced because of the large diameter of the artery, but atherosclerotic plaque embolization is more likely during initial guidewire and catheter placement. Catheterization of the femoral artery is best achieved with a guidewire technique. The operator must be careful to puncture the femoral artery below the inguinal ligament, thereby limiting the risk of arterial injury causing uncontained hemorrhage into the pelvis or peritoneum, a potentially catastrophic complication.[43]

Complications of Direct Arterial Pressure Monitoring

Widespread application of invasive arterial pressure monitoring in anesthesia and intensive care is related, no doubt, to the extremely good safety record of this technique. Large clinical investigations confirm the low incidence of long-term complications after radial artery cannulation, in particular, the small risk of distal ischemia, which is probably less than 0.1%.[29,30,42] Although vascular complications from radial artery cannulation are uncommon, factors that may increase risk include vasospastic arterial disease, previous arterial injury, thrombocytosis, protracted shock, high-dose vasopressor administration, prolonged cannulation, and infection.[44,45]

Additional rare, but serious complications have been reported after arterial cannulation (Box 40-3). In most cases there were technical problems during catheter placement or confounding medical problems such as shock or coagulopathy. The Australian Incident Monitoring Study provides some noteworthy observational data on the incidence and types of complications of blood pressure monitoring.[26,46] Of 2000 untoward clinical events reported in this investigation, only 13 were related to peripheral arterial cannulation, less than the number associated with central venous or peripheral venous cannulation (18 and 33 incidents, respectively). Five of these 13 cases involved equipment faults or misassembly, in 3 cases the arterial line was mistaken for an intravenous line and used for injection of drugs, in 3 cases the arterial line was either disrupted or kinked, in 1 case a fragment of guidewire broke off inside the patient, and in only 1 instance did transient vasospasm follow radial artery cannulation. A second report from this study noted that direct pressure monitoring failed or gave misleading results in 10 instances, including 5 in which there was either incorrect calibration, incorrect interpretation of the pressure display, or unrecognized subclavian artery stenosis. These data suggest that most complications of direct arterial pressure monitoring can be attributed to equipment misuse. This serves to highlight the importance of having a backup system readily available for manual measurement of blood pressure.

Box 40-3 Complications of Direct Arterial Pressure Monitoring

- Distal ischemia, pseudoaneurysm, arteriovenous fistula
- Hemorrhage, hematoma
- Arterial embolization
- Local infection, sepsis
- Peripheral neuropathy
- Misinterpretation of data
- Misuse of equipment

Technical Aspects of Direct Blood Pressure Measurement

Direct measurement of arterial blood pressure requires that the pressure waveform from the cannulated artery be reproduced accurately on the bedside monitor. Not surprisingly, the displayed pressure signal is influenced significantly by the measuring system, including the arterial catheter, extension tubing, stopcocks, flush devices, transducer, amplifier, and recorder.[47]

Blood pressure monitoring systems used in the operating room and intensive care units are described as underdamped, second-order dynamic systems.[47-49] These fluid-filled systems may be modeled after mass-spring systems that demonstrate simple harmonic motion and exhibit similar behavior that depends on the physical properties of elasticity, mass, and friction. These three properties determine the system's operating characteristics, termed the *frequency response* or *dynamic response*, which in turn are characterized by two important system parameters, *natural frequency* (f_n, ω) and *damping coefficient* (ζ, Z, α, D). The natural frequency of the monitoring system quantifies how rapidly the system oscillates, and the damping coefficient quantifies the frictional forces that act on the system and determine how rapidly it comes to rest. Both parameters may be estimated or measured at the bedside, and they dramatically influence the appearance of the recorded pressure waveform.

Natural Frequency, Damping Coefficient, and Dynamic Response of Pressure Monitoring Systems

The arterial blood pressure waveform is a periodic complex wave that can be reproduced by Fourier analysis, which recreates the original complex pressure wave by summing a series of simpler sine waves of different amplitudes and frequencies.[50,51] The original pressure wave has a characteristic periodicity termed the *fundamental frequency*, which is equal to the pulse rate. Although the pulse rate is reported in beats per minute, fundamental frequency is reported in cycles per second or hertz (Hz).

The sine waves that sum to produce the complex wave have frequencies that are multiples or harmonics of the fundamental frequency. A crude arterial waveform that displays a systolic upstroke, systolic peak, dicrotic notch, and so forth can be reconstructed with reasonable accuracy from two sine waves, the fundamental frequency, and the second harmonic (Fig. 40-3). If the original arterial pressure waveform contains high-frequency components such as a steep systolic upstroke, higher-frequency sine waves (and more harmonics) are needed to provide faithful reconstruction of the original pressure waveform. As a general rule, 6 to 10 harmonics are required to provide distortion-free reproduction of most arterial pressure waveforms.[50,52] Hence, accurate blood pressure measurement in a patient with a pulse rate of 120 beats/min (2 cycles/sec or 2 Hz) requires a monitoring system dynamic response of 12 to 20 Hz. The faster the heart rate and the steeper the systolic pressure upstroke, the greater the dynamic response demands on the monitoring system.

If the monitoring system has a natural frequency that is too low, frequencies in the monitored pressure waveform will overlap the natural frequency of the measurement system. As a result, the system will resonate and pressure waveforms recorded on the monitor will be exaggerated or amplified versions of true intra-arterial pressure (Fig. 40-4). This phenomenon is the familiar

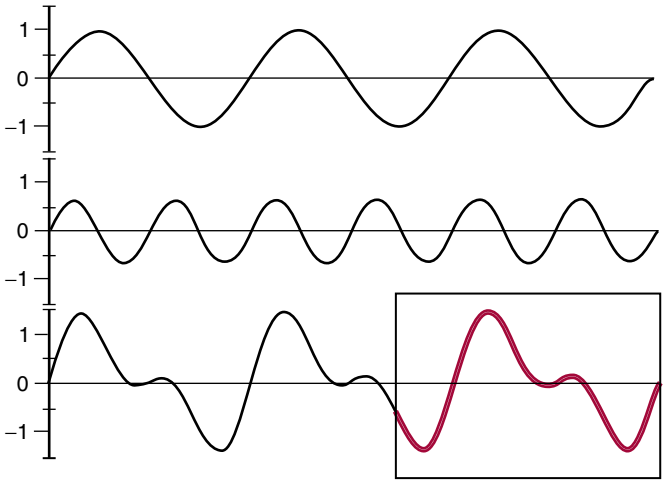

Figure 40-3 Arterial blood pressure waveform produced by summation of sine waves. The fundamental wave (*top*) added to 63% of the second harmonic wave (*middle*) results in a pressure wave (*bottom*) that resembles an arterial blood pressure waveform (*box*). *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998, Fig. 9-1.)*

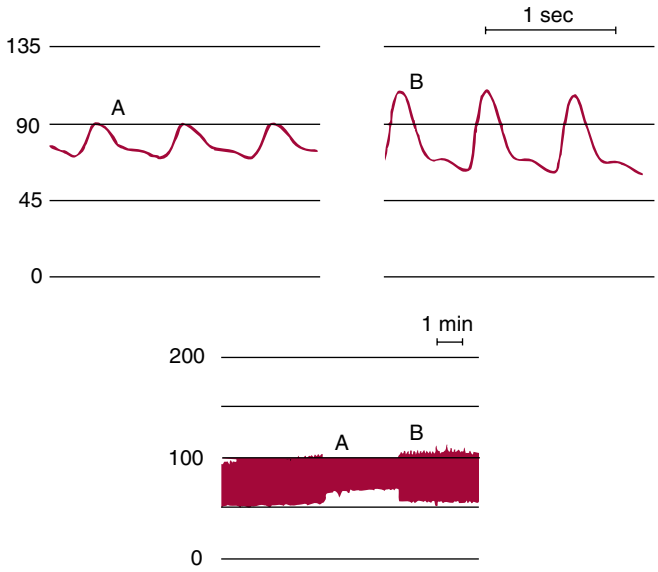

Figure 40-5 Overdamped arterial pressure waveform. The overdamped pressure waveform (A) shows a diminished pulse pressure when compared with the normal waveform (B). The slow-speed recording below demonstrates a 3-minute period of damped arterial pressure. Despite the damped pressure waveform, mean arterial pressure remains unchanged during this period. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998, Fig. 9-3.)*

arterial pressure waveform that displays overshoot, ringing, or resonance. In these instances, the recorded systolic blood pressure overestimates true intra-arterial pressure.

In addition to a sufficiently high natural frequency, the bedside monitoring system must also have an appropriate damping coefficient. An overdamped arterial pressure waveform is recognized by its slurred upstroke, absent dicrotic notch, and loss of fine detail. Severely overdamped pressure waves display a falsely narrowed pulse pressure, although MAP may remain reasonably accurate (Fig. 40-5). In contrast, underdamped pressure waveforms display systolic pressure overshoot and contain additional artifacts produced by the measurement system that are not part of the original intravascular pressure wave (see Fig. 40-4). It is a mistake to attach physiologic significance to these small artifactual waves produced by an underdamped monitoring system that continues to ring or oscillate abnormally in response to the input pressure signal.

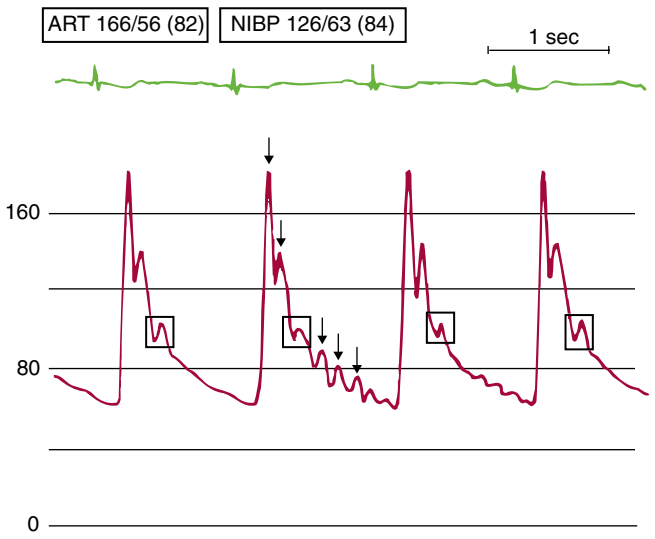

Figure 40-4 Underdamped arterial pressure waveform. Systolic pressure overshoot and additional small, nonphysiologic pressure waves (*arrows*) distort the waveform and make it hard to discern the dicrotic notch (*boxes*). Digital values displayed for direct arterial blood pressure (ART, 166/56; mean, 82 mm Hg) and noninvasive blood pressure (NIBP, 126/63; mean, 84 mm Hg) show the differences in pressure measurement that arise because of an underdamped arterial pressure waveform. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998, Fig 9-4.)*

Most catheter-transducer systems are underdamped but have an acceptable natural frequency that exceeds 12 Hz. If the system's natural frequency is lower than 7.5 Hz, the pressure waveform is often distorted, and no amount of damping adjustment can restore the monitored waveform to adequately resemble the original waveform.[47] If, on the other hand, the natural frequency can be increased sufficiently (e.g., 24 Hz), damping will have minimal effect on the monitored waveform, and faithful reproduction of intravascular pressure is achieved more easily (Figs. 40-6 and 40-7). In other words, the lower the natural frequency of the monitoring system, the more narrow the range of damping coefficients that can be tolerated to ensure faithful reproduction of the pressure wave. For example, if the monitoring system's natural frequency is 10 Hz, the damping coefficient must be between 0.45 and 0.6 for accurate monitoring of the pressure waveform. If the damping coefficient is too low, the monitoring system will be underdamped, resonate, and display factitiously elevated systolic blood pressure; if the damping coefficient is too high, the system will be overdamped, systolic pressure will be falsely decreased, and fine detail in the pressure trace will be lost.

From these considerations it follows that a pressure monitoring system will have optimal dynamic response if its natural frequency is as high as possible.[51] In theory, this is best achieved by using short lengths of stiff pressure tubing and limiting the

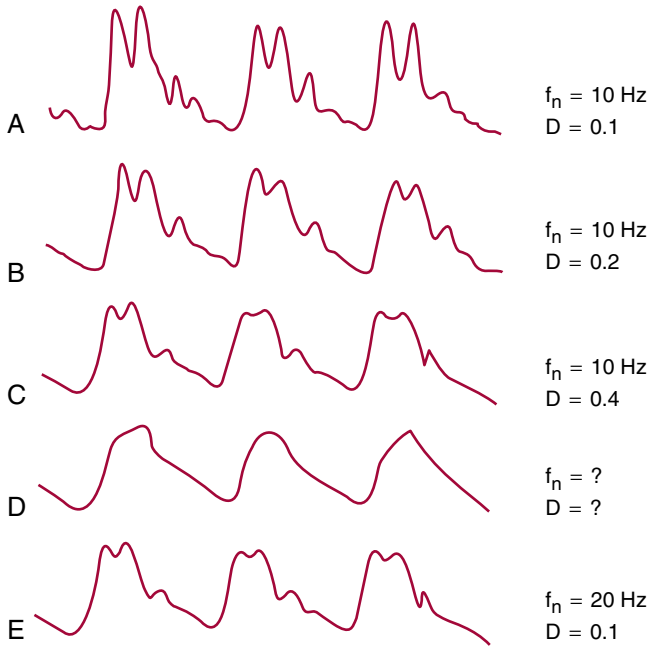

Figure 40-6 Interaction between damping coefficient (D) and natural frequency (f_n) in pressure waveform recordings. **A,** An underdamped pressure waveform (f_n = 10 Hz; D = 0.1) displays small artifactual waves and systolic pressure overshoot. **B,** A small increase in D (0.2) diminishes these artifacts. **C,** Critical damping (D = 0.4) provides an accurate pressure waveform even though f_n remains low. **D,** Overdamping results in loss of fine detail and precludes determination of f_n or D. **E,** Increased f_n (20 Hz) allows a low D (0.1) to have minimal impact on waveform morphology. Notice the similarities between waveforms **C** and **E**. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998, Fig. 9-7.)*

number of stopcocks and other monitoring system appliances. Blood clots and air bubbles trapped and concealed in stopcocks and other connection points will have similar adverse influences on the system's dynamic response. As a general rule, adding air bubbles to monitoring systems will not improve their dynamic response because any increase in system damping is always accompanied by a decrease in natural frequency. Somewhat paradoxically, monitoring system resonance may increase and cause even greater systolic pressure overshoot (Fig. 40-8).

To assess the amount of distortion existing in a pressure monitoring system, the fast-flush test provides a convenient bedside method for determining the system's dynamic response.[47,49,51] To perform this test, the fast-flush valve is opened briefly, and the resulting flush artifact is examined. Natural frequency is inversely proportional to the time between adjacent oscillation peaks. It can be calculated as 1 cycle/1.7 mm × 25 mm/sec = 14.7 cycles/sec (14.7 Hz) (Fig. 40-9). Monitoring systems with shorter oscillation cycles will have higher natural frequencies.[51]

The damping coefficient is related to the amplitudes of successive oscillation peaks. The amplitude ratio thus derived indicates how quickly the measuring system comes to rest. The damping coefficient can be calculated mathematically, but it is usually determined graphically from the amplitude ratio.[47,51] For example, if the amplitudes of two successive oscillation cycles are 24 and 17 mm, the amplitude ratio is 17/24, or 0.71. This corresponds to a damping coefficient of 0.11 based on the graphic solution (Fig. 40-9). Note that the monitoring system illustrated has an adequate natural frequency (approximately 15 Hz) but is underdamped (damping coefficient of 0.11), and one would expect to find systolic pressure overshoot in such a system.

Although the technical requirements for accurate blood pressure measurement are well known, these conditions are often unmet in routine clinical practice. Schwid examined the frequency response of 30 radial artery catheter-transducer systems used in routine intensive care monitoring.[53] Mean values (± SD) for natural frequency (14.7 ± 3.7 Hz) and damping coefficient (0.24 ± 0.07) were worse than values typically reported for measurements made under laboratory conditions, instead falling in the underdamped response region reported by Gardner.[47] Furthermore, the range of frequency responses (10.2 to 25.3 Hz) and damping coefficients (0.15 to 0.44) measured in this setting suggests that distortion of the arterial waveform is common in clinical practice, particularly systolic arterial pressure overshoot resulting from an underdamped system (see Fig. 40-7).

Components of Pressure Monitoring Systems

Arterial pressure monitoring systems have a number of components, beginning with the intra-arterial catheter and including extension tubing, stopcocks, in-line blood sampling set, pressure transducer, continuous-flush device, and electronic cable connecting the bedside monitor and waveform display screen. The stopcocks in the system provide sites for blood sampling and allow the transducer to be exposed to atmospheric pressure to establish a zero reference value. Needleless blood sampling ports and in-line aspiration systems permit drawing of blood without the use of sharp needles and allow aspirated waste blood to be

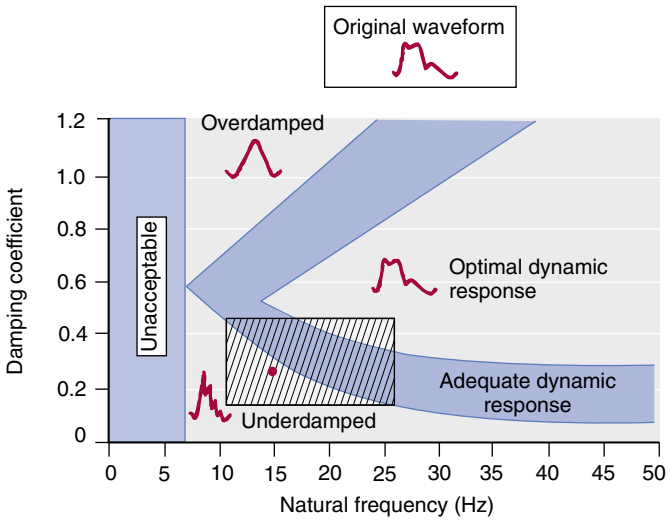

Figure 40-7 Interaction between damping coefficient and natural frequency. Depending on these two system parameters, catheter tubing-transducer systems fall into one of five different dynamic response ranges. Systems with an optimal dynamic response will faithfully record the most demanding pressure waveforms, whereas those with an adequate dynamic response will accurately record most pressure waveforms seen in clinical practice. Overdamped and underdamped systems introduce artifacts characteristic of these technical limitations. Systems with a natural frequency of less than 7 Hz are considered unacceptable. The *rectangular crosshatched box* indicates the ranges of damping coefficients and natural frequencies commonly encountered in clinical pressure measurement systems. The point within the box shows the mean values of 30 such systems recorded by Schwid.[53] *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998, Figs.9-6, 9-8, and 9-11.)*

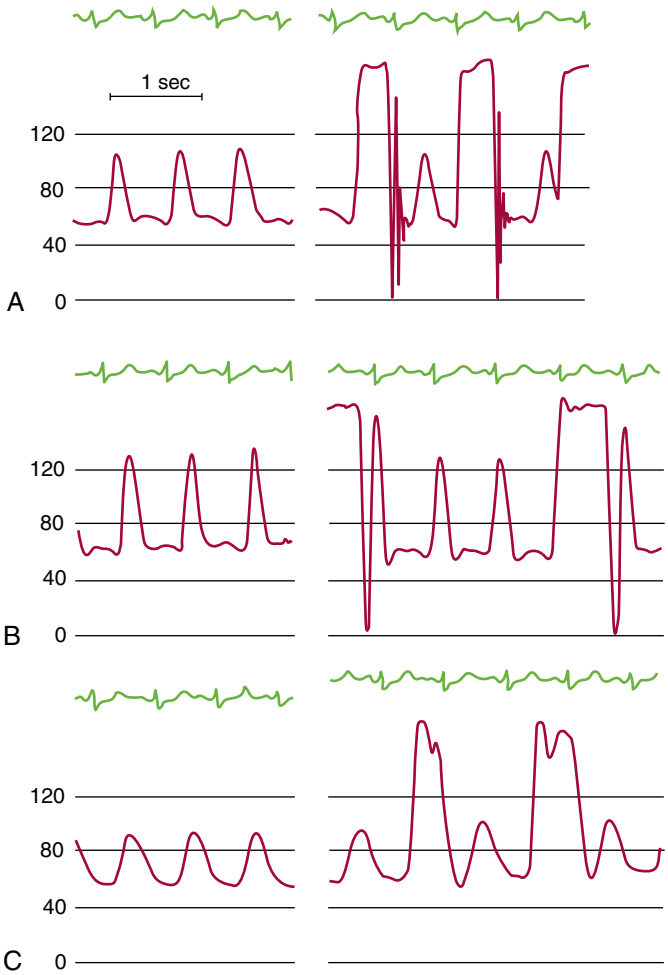

Figure 40-8 Effect of small air bubbles within arterial pressure monitoring systems. Arterial pressure waveforms are displayed, along with superimposed fast-flush square-wave artifacts. **A,** The original monitoring system has an adequate dynamic response (natural frequency, 17 Hz; damping coefficient, 0.2). **B,** A small 0.1-mL air bubble added to the monitoring system produces a paradoxical increase in arterial blood pressure. Note the decreased natural frequency of the system. **C,** A larger 0.5-mL air bubble further degrades the dynamic response and produces spurious arterial hypotension. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998, Fig. 9-14.)*

returned to the patient within a convenient closed system. Modifications such as these are intended to reduce the incidence of needle injury and decrease waste of the patient's blood during sampling. However, these additional features may degrade the dynamic response of the monitoring system and further exacerbate systolic arterial pressure overshoot.

The flush device provides a continuous, slow (1 to 3 mL/hr) infusion of saline to purge the monitoring system and prevent thrombus formation within the arterial catheter. Dextrose solutions should not be used because flush contamination of sampled blood may cause serious errors in blood glucose measurement.[54] A dilute concentration of heparin (1 to 2 units heparin/mL saline) has been added to the flush solution to further reduce the incidence of catheter thrombosis, but this practice increases the risk for heparin-induced thrombocytopenia and should be avoided. The flush device not only ensures continuous slow flushing of the line and catheter but also includes a spring-loaded valve for periodic, high-pressure flushing. This rapid flushing is used to purge the extension line of blood after an arterial sample has been taken or to restore the dynamic response characteristics of the pressure monitoring system, which will otherwise slowly deteriorate over time.[55]

Transducer Setup: Zeroing and Leveling

Before initiating patient monitoring, the pressure transducer must be zeroed, calibrated, and leveled to the appropriate position on the patient. The initial step in this process is to expose the transducer to atmospheric pressure by opening the adjacent stopcock to air, pressing the zero pressure button on the monitor, and

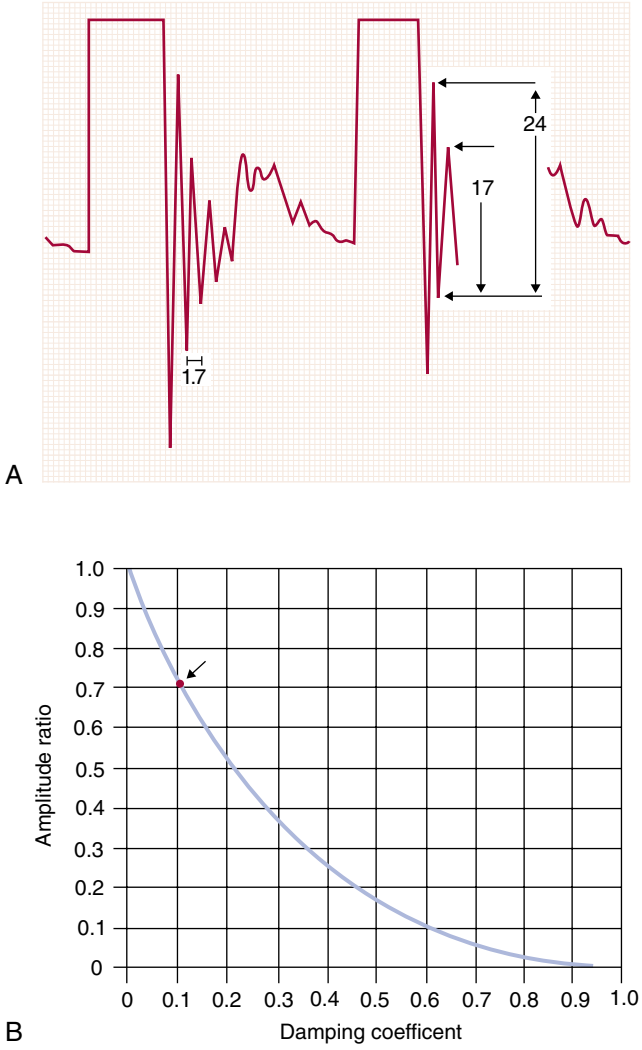

Figure 40-9 Clinical measurement of natural frequency and damping coefficient. **A,** Two square-wave fast-flush artifacts interrupt an arterial pressure waveform recorded on standard 1-mm grid paper at a speed of 25 mm/sec. Natural frequency is determined by measuring the period of one cycle of adjacent oscillation peaks (1.7 mm). The damping coefficient is determined by measuring the heights of adjacent oscillation peaks (17 and 24 mm). From these measurements a natural frequency of 14.7 Hz and an amplitude ratio of 0.71 may be calculated. See text for greater detail. **B,** Relationship between amplitude ratio and damping coefficient. The amplitude ratio determined in the fast-flush test in **A** corresponds to a damping coefficient of 0.11. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998, Figs.9-9 and 9-10.)*

thereby establishing the zero pressure reference value. The transducer now has a reference—ambient atmospheric pressure—against which all intravascular pressures are measured. This process underscores the fact that all pressures displayed on the monitor are referenced to atmospheric pressure outside the body. Although clinicians generally refer to "zeroing the transducer," the transducer is actually exposed to atmospheric pressure through an open stopcock affixed to the transducer. To be precise, it is this air-fluid interface at the level of the stopcock that is the zero pressure locus. This point must be aligned with a specific position on the patient to ensure the correct transducer level.

When a significant change in pressure occurs, the zero reference value can be rechecked quickly by opening the stopcock and noting that the pressure value on the bedside monitor is still zero.[52] Occasionally, a faulty transducer, cable, or monitor will cause the zero baseline to drift. Though uncommon with modern monitoring components, this zero drift artifact must be identified to avoid important diagnostic errors.[56,57]

Historically, calibration of the transducer was the next step after zeroing. Calibration is an adjustment in system gain to ensure accurate transducer measurement relative to a known reference pressure value. Though traditionally calibrated against a mercury manometer, current disposable pressure transducers meet accuracy standards established by the Association for the Advancement of Medical Instrumentation and the American National Standards Institute.[56] As a result, bedside calibration of the transducer is no longer performed. Nonetheless, on rare occasion, despite successful transducer zeroing, the measured blood pressure values seem erroneous, and a malfunctioning pressure transducer, cable, or monitor must be suspected and replaced.[57]

The final step in transducer setup is to adjust the pressure monitoring zero point to the appropriate level relative to the patient. Note that transducer zeroing and leveling are two distinct procedures. Zeroing exposes the transducer to ambient atmospheric pressure through an open stopcock. Leveling assigns this zero reference point to a specific position on the patient's body. Although precise location of the zero reference level is essential for accurate monitoring of blood pressure, it is also critically important for measurement of cardiac filling pressures, where a small absolute error in pressure measurement will cause a large relative error.

Arterial pressure transducers should be placed at a level that will best estimate aortic root pressure. In a supine patient, pressure transducer levels are often adjusted to the midchest position in the midaxillary line. However, based on physical principles and measurement of the uppermost fluid levels in the cardiac chambers, Courtois and associates have shown that cardiac filling pressures will be overestimated by as much as 7 mm Hg when transducers are leveled to the midchest rather than a position approximately 5 cm posterior to the sternal border.[58] This preferred (more anterior) transducer location obviates the confounding effect of hydrostatic pressure on cardiac filling pressure measurements. Inasmuch as this transducer location will provide the most accurate measurement of left ventricular pressure, the same transducer level is optimal for arterial blood pressure measurement. Other investigators have confirmed that leveling of pressure transducers to the midchest position will cause overestimation of cardiac filling pressure and presumably aortic root pressure.[59]

In some circumstances, the clinician may choose to adjust the arterial transducer level to a different position on the body. It is critically important to recognize that when this is done, the pressure is being measured at the level of the transducer and not at the level of the aortic root. For example, during sitting neurosurgical operations, if the arterial pressure transducer is raised to a level even with the patient's ear to approximate the location of the circle of Willis, the clinician is measuring blood pressure at the level of the brain and must recognize that the aortic root pressure is higher (by an amount equal to the vertical difference in height between the pressure transducer and the aortic root). Whenever the level of the pressure transducer is adjusted, there is no need to rezero the transducer because atmospheric pressure changes little over the few inches of height adjustment.

Common errors in blood pressure measurement occur when pressure transducers are fixed to an intravenous pole and the height of the patient's bed is adjusted. Raising the height of the bed relative to the transducer will cause overestimation of blood pressure, whereas lowering the patient below the transducer will cause underestimation of blood pressure.

Proper interpretation of blood pressure measurements from a patient in the lateral decubitus position requires an understanding of the distinction between zeroing and leveling pressure transducers and the differences between noninvasive and invasive blood pressure measurement (Fig. 40-10). When a patient is in the lateral decubitus position, one arm is higher than the heart (and aortic root) and the other arm is lower. Regardless of whether direct arterial pressure is measured from the right or the left arm, as long as the pressure transducer remains fixed at the level of the heart, the location of the arms has no influence on the measured arterial pressure. However, noninvasive cuff blood pressure measurements will be different in the two arms, higher in the dependent (down) arm and lower in the nondependent (up) arm (see Fig. 40-10). Note that if the arterial pressure transducers were attached to the arms rather than fixed at the level of the heart, pressures recorded from the right and left radial artery catheters would equal those recorded by the ipsilateral noninvasive cuffs and would be higher in the dependent arm than in the nondependent arm.

Normal Arterial Pressure Waveforms

Direct arterial pressure monitoring in anesthetized patients began nearly 60 years ago.[27] In that early era, arterial pulse waveform analysis was noted to provide useful diagnostic information, but somewhat surprisingly, modern physicians pay little attention to the morphology and detail of the arterial pressure waveform. O'Rourke and Gallagher attribute this change in practice to the reliance on cuff sphygmomanometry, which provides "numbers which came to be linked in a simplistic way to cardiac strength (systolic pressure) and arteriolar tone (diastolic pressure). Pseudoscience had arrived with (these) numbers. … Even when monitored directly in operating theatres and critical care areas, anesthetists and intensivists show little interest in the waveform and base their judgments on values of systolic, diastolic and mean pressure."[60]

Because clinicians today benefit from the widespread availability of high-resolution, multicolored monitor displays, renewed interest in waveform analysis should expand clinical monitoring capabilities.[28] Appreciation of the diagnostic clues provided by the direct arterial pressure waveform requires full understanding of normal waveform components, their relationship to the cardiac cycle, and differences in waveforms recorded from different sites in the body.

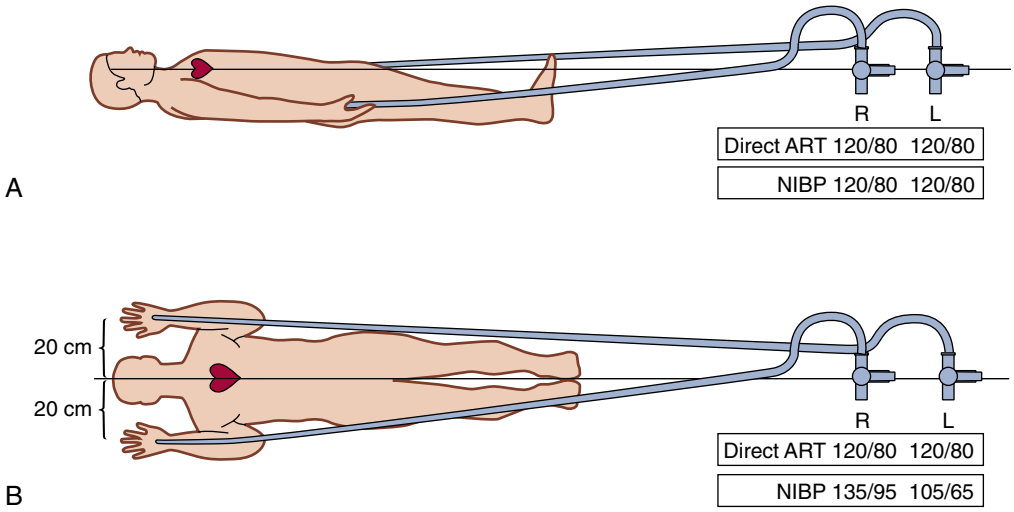

Figure 40-10 Effect of patient position on the relationship between direct arterial blood pressure (ART) and indirect noninvasive blood pressure (NIBP) measurements. **A,** In a supine patient, pressures measured from the right (R) or left (L) arms by either technique will be the same. **B,** In the right lateral decubitus position, ART recorded directly from the right and left radial arteries will remain unchanged as long as the respective pressure transducers remain at heart level. However, NIBP will be higher in the dependent right arm and lower in the nondependent left arm. Differences in NIBP are determined by the positions of the arms above and below the level of the heart and are equal to the hydrostatic pressure differences between the level of the heart and the respective arm. A 20-cm difference in height produces a 15–mm Hg difference in pressure. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998, Fig. 9-22.)*

The systemic arterial pressure waveform results from ejection of blood from the left ventricle into the aorta during systole, followed by peripheral arterial runoff of this stroke volume during diastole (Fig. 40-11). The systolic components follow the ECG R wave and consist of a steep pressure upstroke, peak, and decline and correspond to the period of left ventricular systolic ejection. The downslope of the arterial pressure waveform is interrupted by the dicrotic notch, then continues its decline during diastole after the ECG T wave, and reaches its nadir at end-diastole. The dicrotic notch recorded directly from the central aorta is termed the *incisura* (from the Latin, "a cutting into"). The incisura is sharply defined and is undoubtedly related to closure of the aortic valve.[61] In contrast, the peripheral arterial waveform generally displays a later, smoother dicrotic notch that only approximates the timing of aortic valve closure and depends more on properties of the arterial wall. Note that the systolic upstroke of the radial artery pressure trace does not appear for 120 to 180 msec after inscription of the ECG R wave (see Fig. 40-11). This interval reflects the sum of times required for spread of electrical depolarization through the ventricular myocardium, isovolumic left ventricular contraction, opening of the aortic valve, left ventricular ejection, transmission of the aortic pressure wave to the radial artery, and finally, transmission of the pressure signal from the arterial catheter to the pressure transducer.

The bedside monitor displays numeric values for the systolic peak and end-diastolic nadir pressures. Measurement of mean pressure is more complicated and depends on the algorithm used by the monitor. In simplest terms, MAP is equal to the area beneath the arterial pressure curve divided by the beat period and averaged over a series of consecutive heartbeats. Although MAP is often estimated as diastolic pressure plus one third times pulse pressure, this estimate is valid only at slower heart rates because the proportion of the cardiac cycle spent in diastole decreases during tachycardia.[62]

One of the most important features of the arterial pressure waveform is the phenomenon of distal pulse amplification. Pressure waveforms recorded simultaneously from different arterial sites will have different morphologies because of the physical characteristics of the vascular tree, namely, impedance and harmonic resonance[21,60] (Fig. 40-12). As the arterial pressure wave travels from the central aorta to the periphery, the arterial upstroke

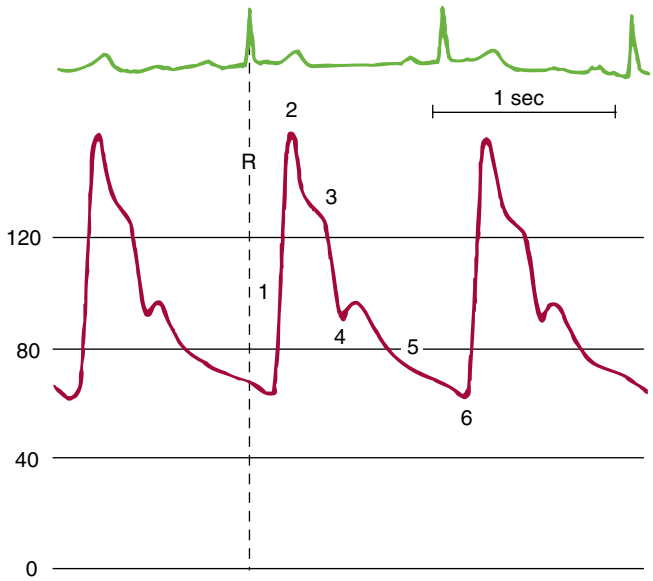

Figure 40-11 Normal arterial blood pressure waveform and its relationship to the electrocardiographic R wave. 1, Systolic upstroke; 2, systolic peak pressure; 3, systolic decline; 4, dicrotic notch; 5, diastolic runoff; 6, end-diastolic pressure. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998, Fig. 8-1.)*

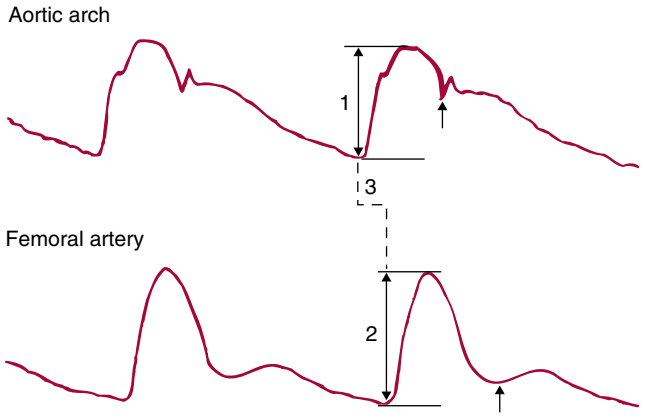

Figure 40-12 Distal pulse wave amplification of the arterial pressure waveform. When compared with pressure in the aortic arch, the more peripherally recorded femoral artery pressure waveform demonstrates a wider pulse pressure (compare 1 and 2); a delayed upstroke (3); a delayed, slurred dicrotic notch (compare *arrows*); and a more prominent diastolic wave. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998, Fig. 8-4.)*

becomes steeper, the systolic peak becomes higher, the dicrotic notch appears later, the diastolic wave becomes more prominent, and end-diastolic pressure becomes lower. Thus, when compared with central aortic pressure, peripheral arterial waveforms have higher systolic pressure, lower diastolic pressure, and wider pulse pressure. Furthermore, there is a delay in arrival of the pressure pulse at peripheral sites, so the systolic pressure upstroke begins approximately 60 msec later in the radial artery than in the aorta. Despite morphologic and temporal differences between peripheral and central arterial waveforms, MAP in the aorta is just slightly greater than MAP in the radial artery.

Pressure wave reflection is the predominant factor that influences the shape of the arterial pressure waveform as it travels peripherally.[60] As blood flows from the aorta to the radial artery, mean pressure decreases only slightly because of little resistance to flow in the major conducting arteries. At the arteriolar level, mean blood pressure falls markedly as a result of the dramatic increase in vascular resistance at this site. This high resistance to flow diminishes pressure pulsations in small downstream vessels but acts to augment upstream arterial pressure pulses because of pressure wave reflection.[63] These intrinsic vascular phenomena determine the shape of the arterial pulse wave recorded from different sites in the body, in both health and disease. For example, elderly patients have reduced arterial distensibility, which results in early return of reflected pressure waves, increased pulse pressure, a late systolic pressure peak, and disappearance of the diastolic pressure wave (Fig. 40-13).

From these considerations it becomes evident that the morphology of the arterial waveform and the precise values of systolic and diastolic blood pressure vary throughout the body under normal conditions in otherwise healthy individuals. Perhaps of even greater importance, the relationship between central and peripheral arterial pressure varies with age and is altered by various physiologic changes, pathologic conditions, and pharmacologic interventions.

Arterial Blood Pressure Gradients

In addition to the normal physiologic phenomena that exert subtle influences on the arterial pressure waveform, a number of pathophysiologic conditions cause exaggerated arterial pressure gradients in the body. Frank and coworkers demonstrated that 21% of patients undergoing peripheral vascular surgery had a blood pressure difference between the two arms that exceeded 20 mm Hg.[64] In view of the prevalence of this problem, when blood pressure is lower in one arm than in the other or when the pulses are weaker on one side, one should never insert an arterial catheter on the side with the weaker pulse because determination of blood pressure from this site will probably underestimate true aortic pressure. In addition to atherosclerosis, other pathologic conditions such as arterial dissection or embolism preclude accurate monitoring of pressure from the affected sites.

Unusual patient positions during surgery may produce regional arterial compression, and surgical retraction, particularly during cardiothoracic operations, can produce local vascular compression.[65,66] The nature of the operative procedure is always an important determinant of the appropriate site for monitoring arterial pressure. Operations requiring placement of a descending thoracic aortic cross-clamp may interrupt arterial flow to the left subclavian artery and its tributaries in the left arm, as well as branches of the aorta beyond the clamp. In these cases, blood pressure monitored from the right arm best estimates aortic root pressure and carotid arterial pressure and is used to guide anesthetic management. In addition, pressure may be monitored simultaneously from a femoral artery in an attempt to estimate perfusion pressure to vital organs distal to the aortic cross-clamp.

Various pathophysiologic disturbances may produce generalized arterial pressure gradients in the body and should be considered when choosing a site for monitoring arterial pressure. Large differences in peripheral and central arterial pressure may be seen in patients in shock. Femoral artery systolic pressure may exceed radial artery systolic pressure by more than 50 mm Hg in septic patients who require vasopressor infusions, an observation that has significant therapeutic implications for the management of critically ill patients.[67] Other vasoactive drugs, anesthetics (particularly neuraxial blockade), and changes in patient temperature produce pressure gradients that alter the relationship between central and peripheral arterial pressure measurements.[21] During hypothermia, thermoregulatory vasoconstriction causes radial

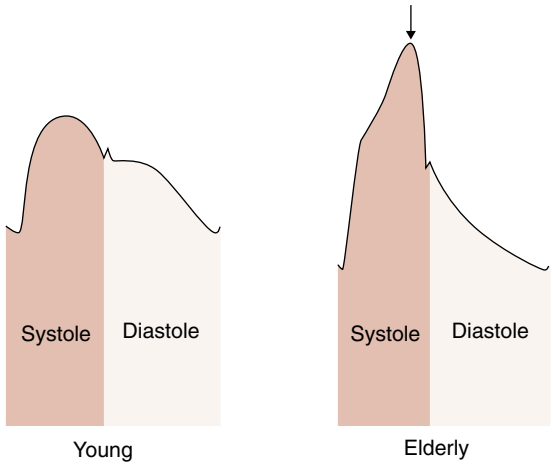

Figure 40-13 Impact of pressure wave reflection on arterial pressure waveforms. In elderly individuals with reduced arterial distensibility, early return of reflected waves increases pulse pressure, produces a late systolic pressure peak (*arrow*), and attenuates the diastolic pressure wave.

artery systolic pressure to exceed femoral artery systolic pressure, whereas during rewarming, vasodilation reverses this gradient and causes radial artery pressure to underestimate femoral artery pressure.[68]

Large differences between central and peripheral arterial blood pressure have also been described in cardiac surgical patients undergoing cardiopulmonary bypass (Fig. 40-14). Shortly after initiation of cardiopulmonary bypass, mean radial artery pressure is lower than mean femoral artery pressure, and this difference seems to persist during the bypass procedure.[69] Furthermore, in the initial minutes after bypass, radial arterial pressure continues to be lower than central aortic pressure, often by more than 20 mm Hg.[70] In most patients, these pressure differences persist after bypass for only several minutes and resolve within an hour, but occasionally these pressure gradients are still present during the postoperative period.

Abnormal Arterial Pressure Waveforms

Detailed examination of the morphologic features of individual arterial pressure waveforms can provide important diagnostic clues to a variety of pathologic conditions (Table 40-1). *Aortic stenosis* produces a fixed obstruction to left ventricular ejection that results in reduced stroke volume and an arterial pressure waveform that rises slowly (*pulsus tardus*), peaks late in systole, and is small in amplitude (*pulsus parvus*) (Fig. 40-15A and B). A distinct shoulder, termed the *anacrotic notch*, often distorts the pressure upstroke, and the dicrotic notch may not be discernible. These features make the arterial pressure waveform appear overdamped.

In *aortic regurgitation*, the arterial pressure wave displays a sharp rise, wide pulse pressure, and low diastolic pressure as a result of runoff of blood into the left ventricle and the periphery during diastole. Because of the large stroke volume ejected from the left ventricle in this condition, the arterial pressure pulse may have two systolic peaks (*bisferiens pulse*) (see Fig. 40-15C). These peaks represent separate percussion and tidal waves, the former resulting from left ventricular ejection and the latter arising from the periphery as a reflected wave. In *hypertrophic cardiomyopathy*, the arterial pressure waveform assumes a peculiar bifid shape termed a "spike-and-dome" configuration. After an initial sharp pressure upstroke that results from rapid left ventricular ejection in early systole, arterial pressure falls rapidly as dynamic left ventricular outflow obstruction develops during midsystole and is followed by a late systolic reflected wave, thereby creating the characteristic double-peaked waveform (see Fig. 40-15D).

Observation of arterial waveform patterns over consecutive heartbeats provides an additional set of diagnostic clues. *Pulsus alternans* is recognized by the alternating beats of larger

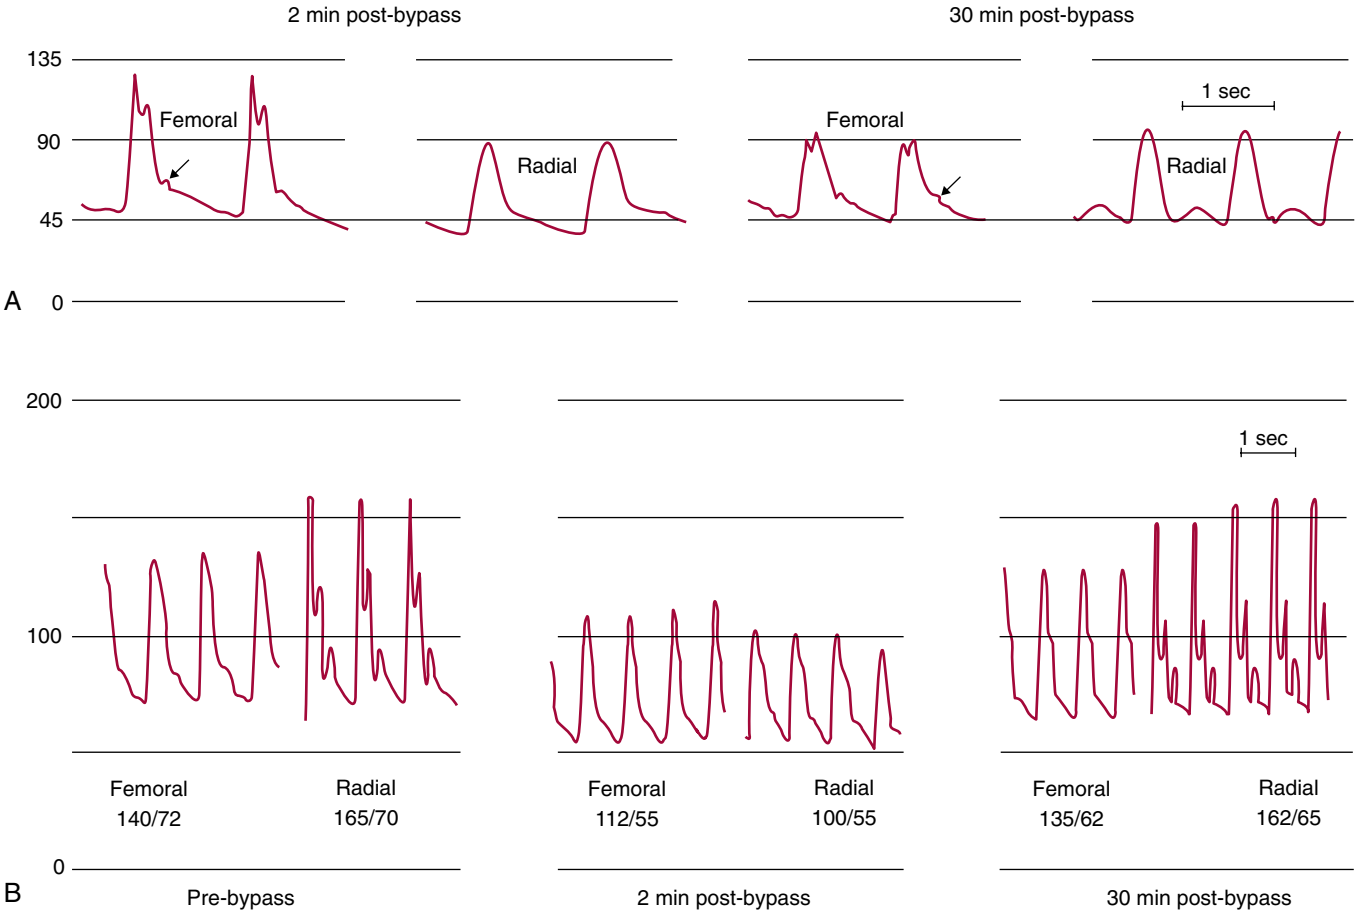

Figure 40-14 Arterial pressure gradients after cardiopulmonary bypass. **A,** Femoral and radial artery pressure traces recorded 2 minutes after bypass, when radial artery pressure underestimates the more centrally measured femoral artery pressure, and 30 minutes later, when radial and femoral arterial pressure has been equalized and radial pressure has assumed a more typical morphology. Note that the dicrotic notch (*arrows*) is visible in the femoral pressure trace after bypass but not initially in the radial pressure trace. **B,** Femoral and radial artery pressure traces recorded before cardiopulmonary bypass, 2 minutes after bypass, and 30 minutes after bypass. Note the changing relationship between femoral and radial artery pressure measurements (in mm Hg) at these different times.

Table 40-1 Arterial Blood Pressure Waveform Abnormalities

Condition	Characteristics
Aortic stenosis	Pulsus parvus (narrow pulse pressure) Pulsus tardus (delayed upstroke)
Aortic regurgitation	Bisferiens pulse (double peak) Wide pulse pressure
Hypertrophic cardiomyopathy	Spike-and-dome pattern (midsystolic obstruction)
Systolic left ventricular failure	Pulsus alternans (alternating pulse pressure amplitude)
Cardiac tamponade	Pulsus paradoxus (exaggerated decrease in systolic blood pressure during spontaneous inspiration)

and smaller pulse pressures (Fig. 40-16A). In general, it is considered to be a sign of severe left ventricular systolic dysfunction, often noted in patients with advanced aortic stenosis. Pulsus alternans should be distinguished from the bigeminal pulse that arises from a bigeminal rhythm, usually ventricular bigeminy. Both abnormalities create an alternating pulse pressure in the arterial pressure waveform, but the rhythm is regular in pulsus alternans.

Pulsus paradoxus is an exaggerated inspiratory fall in systolic arterial pressure that exceeds 10 to 12 mm Hg during quiet breathing (see Fig. 40-16B).[71,72] The term is confusing because a small inspiratory reduction in blood pressure is a normal phenomenon and pulsus paradoxus is not truly paradoxical, but rather an exaggeration of the normal inspiratory decline in blood pressure. Pulsus paradoxus is a characteristic, almost universal finding in cardiac tamponade that occurs in many patients with pericardial constriction. It is said to occur in patients with airway obstruction, bronchospasm, dyspnea, or any condition characterized by large swings in intrathoracic pressure. However, in cardiac tamponade, pulse pressure and left ventricular stroke volume decrease during inspiration, in contrast to the blood pressure changes observed in patients with forced breathing patterns and exaggerated changes in intrathoracic pressure, in whom pulse pressure is relatively unchanged.[73]

The arterial pressure waveform provides diagnostic clues in other unusual physiologic states, such as for proper timing of intra-aortic balloon counterpulsation (Fig. 40-17A). During nonpulsatile cardiopulmonary bypass, minor variations in blood pressure created by the arterial roller head allow calculation and confirmation of the adequacy of systemic blood flow[28] (see Fig. 40-17B).

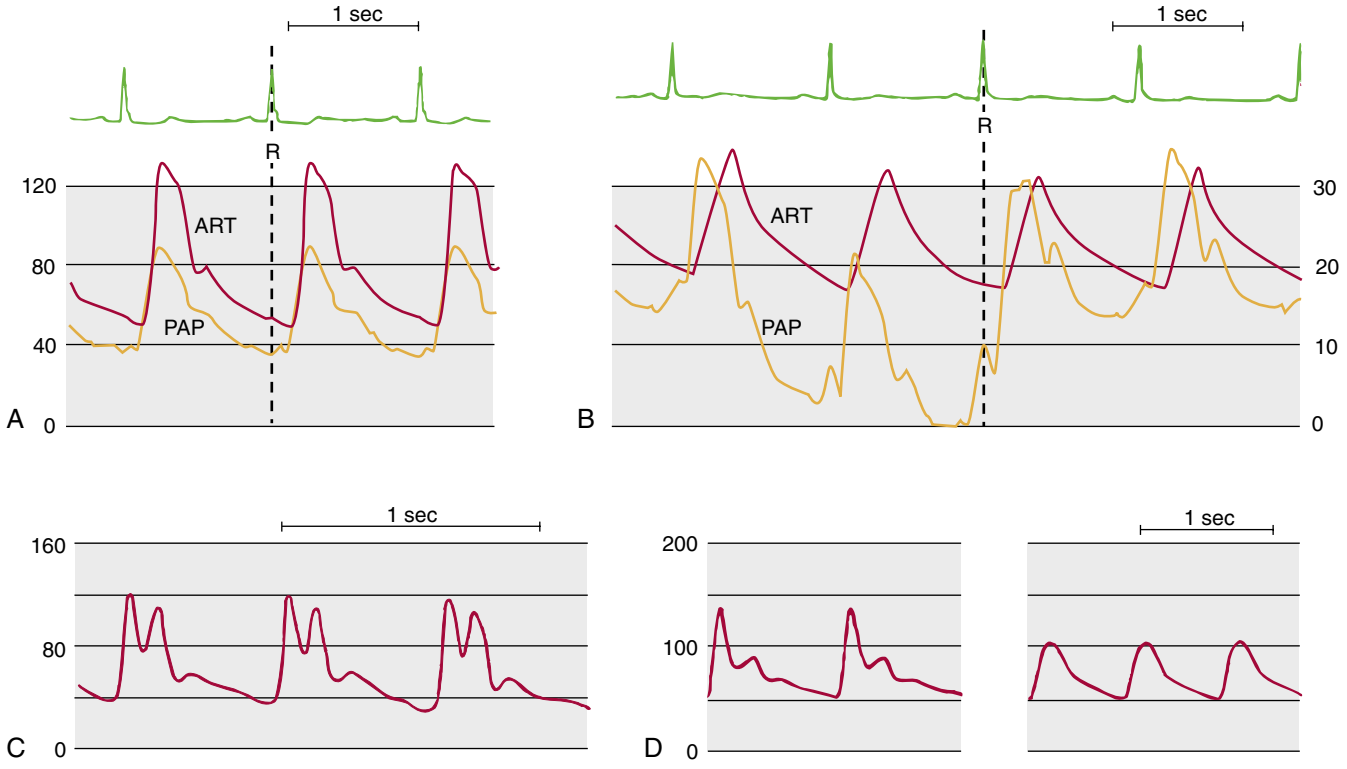

Figure 40-15 Influence of pathologic conditions on arterial pressure (ART) waveform morphology. **A,** *Normal* ART and pulmonary artery pressure (PAP) waveform morphologies demonstrating the similar timing of these waveforms relative to the electrocardiographic R wave. **B,** In *aortic stenosis*, the ART waveform is distorted and demonstrates a slurred upstroke and delayed systolic peak. These changes are particularly striking in comparison to the normal PAP waveform. Note the beat-to-beat respiratory variation in the PAP waveform. See text for greater detail. For **A** and **B,** the ART scale is on the *left* and the PAP scale is on the *right*. **C,** *Aortic regurgitation* produces a bisferiens pulse and a wide pulse pressure. See text for greater detail. **D,** The arterial pressure waveform in *hypertrophic cardiomyopathy* shows a peculiar "spike-and-dome" configuration. The pressure waveform assumes a more normal morphology after surgical correction of this condition. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998, Figs.3-3, 17-21, and 17-24.)*

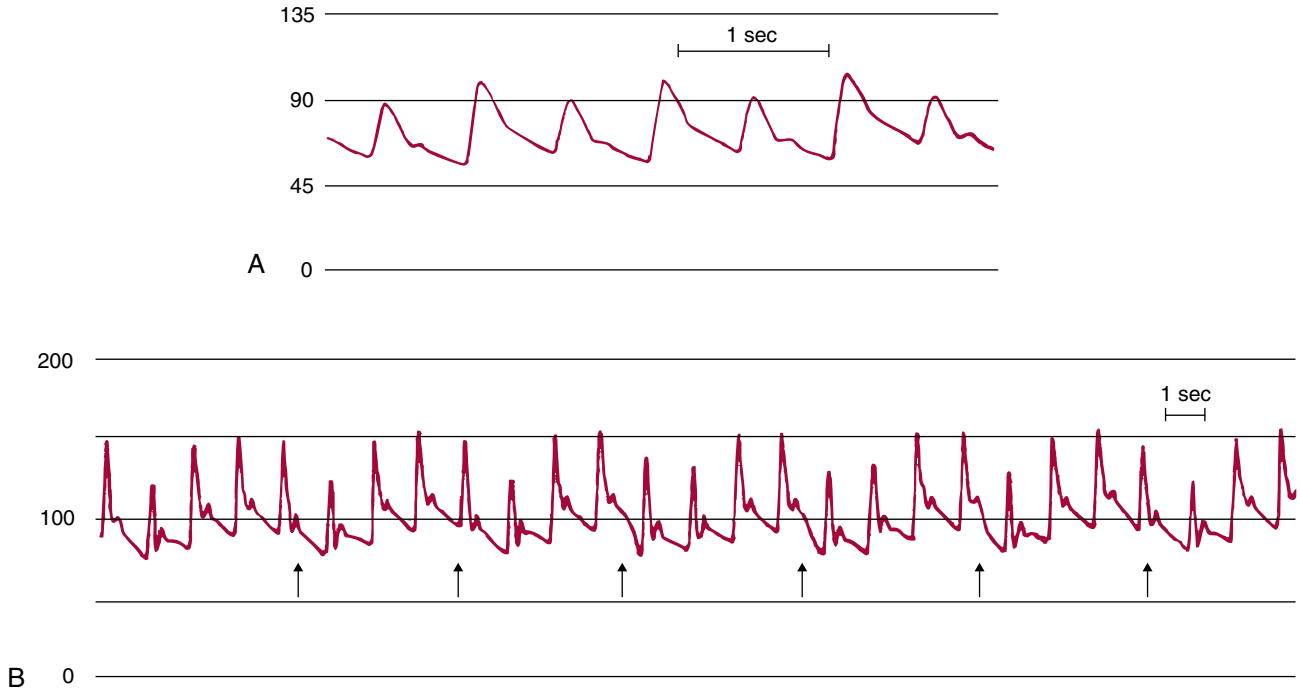

Figure 40-16 Beat-to-beat variability in arterial pressure waveform morphologies. **A,** *Pulsus alternans*. **B,** *Pulsus paradoxus*. The marked decline in systolic arterial pressure and pulse pressure during spontaneous inspiration (*arrows*) is characteristic of cardiac tamponade. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998, Fig. 18-10.)*

Arterial Pressure Monitoring for Prediction of Volume Responsiveness

The starting point for hemodynamic resuscitation begins with optimizing cardiac preload. The limitations of static indicators of preload, such as central venous pressure (CVP), have been increasingly recognized because of the many factors that confound their interpretation.[74] Newer dynamic markers of volume responsiveness have been described that provide more useful information for determining appropriate end points for fluid resuscitation. Variations in arterial blood pressure observed during positive-pressure mechanical ventilation are the most widely studied of these dynamic indicators. These changes in blood pressure are readily observed on the bedside monitor in patients who are receiving direct arterial blood pressure monitoring, and they result from the changes in intrathoracic pressure and lung volume that occur during the respiratory cycle.

During positive-pressure inspiration, increasing lung volume compresses and displaces the pulmonary venous reservoir and propels blood into the left heart chambers, thereby increasing left ventricular preload. Simultaneously, the increase in intrathoracic pressure reduces left ventricular afterload. The increase in left ventricular preload and decrease in afterload produce an increase in left ventricular stroke volume and an increase in systemic arterial pressure. In most patients the preload effects are more important, but in patients with severe left ventricular systolic failure, the reduction in afterload plays an important role in increasing left ventricular ejection. At the same time that left heart filling is increasing during early inspiration, the rising intrathoracic pressure causes a decrease in systemic venous return and right ventricular preload. The increased lung volume may also increase pulmonary vascular resistance (PVR) slightly and thereby increase right ventricular afterload. These effects combine to reduce right ventricular ejection during inspiration. During early expiration, the reduced right ventricular stroke volume that occurred during inspiration crosses the pulmonary vascular bed and leads to reduced left ventricular filling. As a result, left ventricular stroke volume falls and systemic arterial blood pressure decreases. This cyclic variation in systemic arterial pressure may be measured and quantified as the *systolic pressure variation* (SPV).

SPV is often subdivided into inspiratory and expiratory components by measuring the increase (Δ Up) and decrease (Δ Down) in systolic pressure in relation to the end-expiratory, apneic baseline pressure (Fig. 40-18). In a mechanically ventilated patient, normal SPV is 7 to 10 mm Hg, with Δ Up being 2 to 4 mm Hg and Δ Down being 5 to 6 mm Hg.[75] The greatest clinical use of SPV has been for the early diagnosis of hypovolemia.[76] In both experimental animals and patients, hypovolemia causes a dramatic increase in SPV, particularly the Δ Down component. An increase in SPV, particularly in Δ Down, may herald hypovolemia, even in patients in whom arterial blood pressure is maintained near normal levels by compensatory arterial vasoconstriction.

In a heterogeneous group of intensive care patients, Marik demonstrated that a large SPV (>15 mm Hg) was highly predictive of low pulmonary artery wedge pressure (PAWP) (<10 mm Hg).[77] Using echocardiography to measure the left ventricular cross-sectional area as a surrogate for preload, Coriat and colleagues found Δ Down to be better than wedge pressure as a predictor of preload.[78] Other uses of SPV focus on changes in the Δ Up portion of the arterial pressure trace. Just as Δ Down may

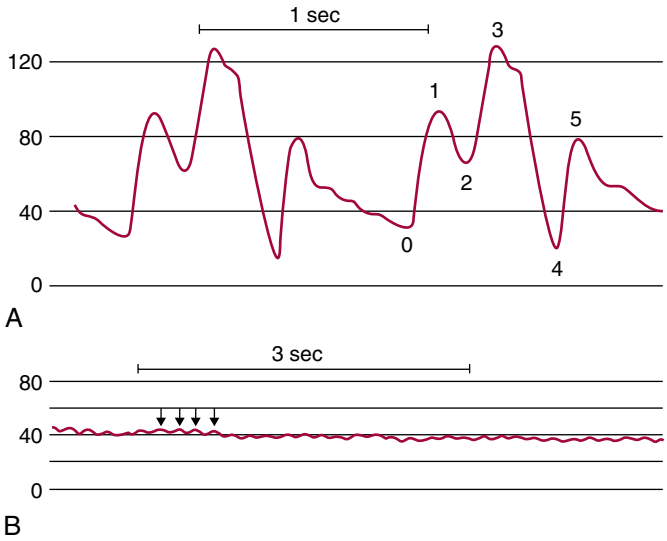

Figure 40-17 Unusual arterial pressure waveforms. **A,** *Intra-aortic balloon counterpulsation* with a 1:2 balloon-assist ratio produces a characteristic change in the arterial pressure waveform. Four cardiac cycles are shown, two with balloon assistance and two without. 0, Unassisted end-diastolic pressure; 1, unassisted systolic pressure; 2, dicrotic notch; 3, assisted or augmented diastolic pressure; 4, end-diastolic or presystolic dip; 5, assisted systolic pressure. Effective afterload reduction by the intra-aortic balloon is evidenced by the presystolic dip pressure (4) lower than the unassisted end-diastolic pressure (0) and the assisted systolic pressure peak (5) lower than the unassisted systolic pressure peak (1). **B,** Arterial pressure waveform during *cardiopulmonary bypass*. Small phasic pressure variations (*arrows*) result from the mechanical action of the bypass roller pump. The bypass pump flow rate may be estimated by measuring these pulsations. Nineteen pulsations are recorded in a 3-second time interval. In this case, the pump configured with ⅜-in tubing has an effective stroke volume of 27 mL. The pump flow rate may be calculated as follows: (19 pulsations/3 sec) × (1 pump revolution/two pulsations) × (27 mL/revolution) × (60 sec/min) = 5130 mL/min. This calculated pump flow rate should equal the flow rate displayed on the pump console (i.e., 5.2 L/min). *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998, Figs.20-3 and 19-8.)*

reveal changes in cardiac preload, the Δ Up portion of the arterial pressure trace may provide clues to the afterload dependence of the left ventricle.

As a dynamic indicator of cardiac preload, SPV and Δ Down provide valuable clinical information beyond that provided by static preload indicators such as CVP or PAWP. It appears that the magnitude of blood pressure variation accurately predicts patients who will subsequently respond to a volume challenge by increasing stroke volume and cardiac output. Using receiver-operator curve analysis, Tavernier and coworkers showed that when compared with PAWP or left ventricular end-diastolic area, Δ Down was a far better indicator of volume responsiveness.[79]

Another dynamic marker of volume responsiveness is *pulse pressure variation* (PPV), defined as the maximal difference in arterial pulse pressure measured over the course of the positive-pressure respiratory cycle divided by the average of the maximal and minimal pulse pressure[80,81] (Fig. 40-19). Normal PPV should not exceed 13%.[82] In addition to SPV and PPV, new pulse contour methods for measurement of cardiac output (see later) allow online measurement of variations in left ventricular stroke volume, so-called *stroke volume variation* (SVV). Like the other related dynamic indicators of volume responsiveness, normal SVV is approximately 10%, and greater variability accurately predicts a positive response to a fluid challenge.[83] Another approach to assessing fluid responsiveness has focused on the respiratory cycle–induced variation in the pulse plethysmogram, but this physiologic signal is even more subject to confounding influences than the arterial blood pressure waveform is.[82,84]

Despite rapidly accumulating evidence of the value of SPV and PPV and their related measures as accurate predictors of cardiac preload, they have not found widespread clinical adoption for a number of reasons. The original description of this method required transient interruption of mechanical ventilation to identify an apneic baseline for measurement of Δ Down and Δ Up.[75] Newer monitors use computerized algorithms to measure and display SPV or PPV continuously, but these automated measures are not yet routinely available in standard bedside monitors.[85,86]

A number of additional factors have precluded the wider application of SPV and PPV for monitoring volume responsiveness. The magnitude of blood pressure variation observed in any patient will be influenced by positive-pressure ventilation parameters, including tidal volume and peak inspiratory pressure. SPV and PPV cannot be used reliably in patients with cardiac arrhythmias or significant changes in chest wall or lung compliance. As noted earlier, respiratory cycle–induced variations in arterial pressure are not solely related to changes in left ventricular preload but depend in part on afterload influences. Although it is clear that the magnitude of SPV and PPV predict fluid responsiveness, precise threshold values remain uncertain, and the variety of techniques described have not been standardized.[83] Perhaps most important, all these measures have been validated only in mechanically ventilated patients and are not applicable to

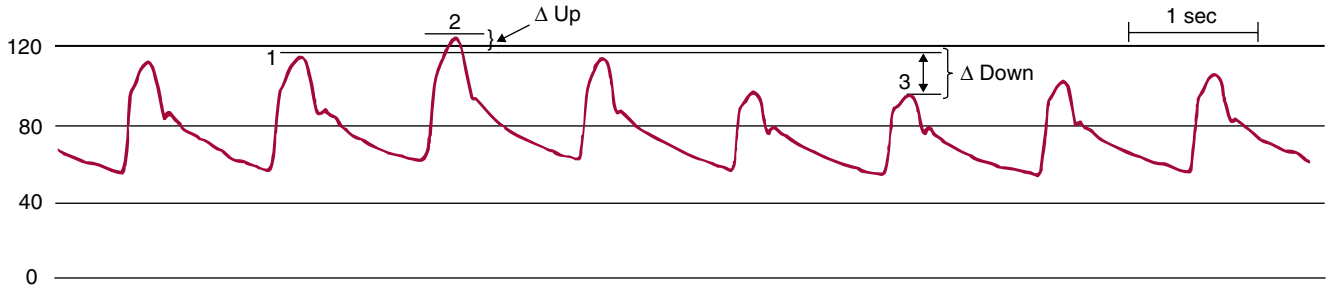

Figure 40-18 Systolic pressure variation. When compared with the systolic blood pressure recorded at alpha (1), a small increase occurs during positive-pressure inspiration (2, Δ Up), followed by a decrease (3, Δ Down). Normally, total systolic pressure variation does not exceed 10 mm Hg. In this instance, the large Δ Down indicates hypovolemia even though systolic arterial pressure and the heart rate are relatively normal. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998, Fig. 16-16.)*

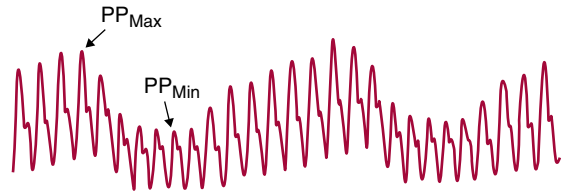

Note: The arterial blood pressure tracing is not drawn to scale

$PP_{Max} = 150 - 70 = 80$
$PP_{Min} = 120 - 60 = 60$
$PPV = (PP_{Max} - PP_{Min})/([PP_{Max} + PP_{Min}]/2)$
$PPV = 80 - 60/([80 + 60]/2) = 29\%$

Figure 40-19 Pulse pressure variation. Pulse pressure variation (PPV) is calculated as the difference between the maximal (PP_{Max}) and minimal (PP_{Min}) pulse pressure values during one mechanical respiratory cycle, divided by the average of these two values. (Note that the arterial blood pressure trace is drawn for illustrative purposes and not to scale.)

spontaneously breathing subjects, thereby precluding their use in many anesthetized and critically ill patients.

Central Venous Pressure Monitoring

Indirect assessment of CVP through physical examination of the neck veins is a fundamental aspect of cardiovascular assessment, but one that has many shortcomings. The jugular veins may be impossible to identify in up to 20% of patients, and the bedside diagnosis of low, normal, or high CVP is often inaccurate, particularly in critically ill patients.[87,88] This problem is compounded in the perioperative period, when visualization of the neck veins is further obscured and abrupt changes, sometimes of great magnitude, are not uncommon. As a result, direct measurement of CVP is frequently necessary in hemodynamically unstable patients and those undergoing major operations.

Central Venous Cannulation

Cannulation of a large central vein is the standard clinical method for monitoring CVP and is also performed for a number of additional therapeutic interventions, such as providing secure vascular access for the administration of vasoactive drugs or to initiate rapid fluid resuscitation. Frequently, the central venous location is the only site available for intravenous access of any kind. Patients at risk for venous air emboli may have central venous catheters placed for aspiration of entrained air. In addition, central venous access is required to initiate transvenous cardiac pacing, temporary hemodialysis, or pulmonary artery catheterization for more comprehensive cardiac monitoring (Box 40-4).

The decision to perform central venous cannulation before or after induction of anesthesia is guided most often by individual patient and physician preferences or institutional practice. One should consider abandoning attempts at preoperative central venous cannulation in any patient who becomes overly sedated or uncooperative during the procedure and proceed with inducing anesthesia and obtaining secure control of the airway. At that point, further attempts at gaining central vascular access are appropriate.

Choosing the Catheter, Site, and Method of Central Venous Cannulation

Central venous catheters come in a variety of lengths, gauges, composition, and lumen number.[89,90] These characteristics vary according to the purpose of the catheterization, whether for CVP monitoring or other therapeutic indications and whether intended for short- or long-term use. This makes it critical for the physician to choose the best catheter for any given application. Seven-French, 20-cm multiport catheters that allow monitoring of CVP and infusion of drugs and fluids simultaneously are the most common.[91] It should be noted that rapid fluid resuscitation is more efficient with short, large-bore intravenous catheters inserted peripherally because the smaller diameter of each individual lumen and the overall catheter length increase resistance to flow significantly. For example, according to the manufacturer's product specifications, the maximal flow rate of the 16-gauge lumen of a standard 7-Fr, 20-cm central venous catheter is a quarter that of a 16-gauge, 3-cm intravenous catheter in a large peripheral vein.

A popular alternative method for multilumen central venous access uses a large introducer sheath with an integrated T-connector sidearm for multiple drug infusions combined with a single-lumen catheter inserted through the hemostasis valve for continuous CVP monitoring. Although use of these larger introducer sheaths is not free of complications, they do allow rapid placement of a pacing wire or pulmonary artery catheter (PAC) for more intensive monitoring should the need arise.

Selecting the best site for safe and effective central venous cannulation ultimately requires consideration of the indication for catheterization (pressure monitoring versus drug or fluid administration), the patient's underlying medical condition, the clinical setting, and the skill and experience of the physician performing the procedure. In patients with severe bleeding diatheses, it is best to choose a puncture site at which bleeding from the vein or adjacent artery is easily detected and controlled with

Box 40-4 Indications for Central Venous Cannulation

- Central venous pressure monitoring
- Pulmonary artery catheterization and monitoring
- Transvenous cardiac pacing
- Temporary hemodialysis
- Drug administration
  - Concentrated vasoactive drugs
  - Hyperalimentation
  - Chemotherapy
  - Agents irritating to peripheral veins
  - Prolonged antibiotic therapy (e.g., endocarditis)
- Rapid infusion of fluids (via large cannulas)
  - Trauma
  - Major surgery
- Aspiration of air emboli
- Inadequate peripheral intravenous access
- Sampling site for repeated blood testing

local compression. In such a patient, an internal or external jugular approach would be preferable to a subclavian site. Likewise, patients with severe emphysema or others who would be severely compromised by pneumothorax would be better candidates for internal jugular than subclavian cannulation because of the higher risk with the latter approach. If transvenous cardiac pacing is required in an emergency situation, catheterization of the right internal jugular vein is recommended because it provides the most direct route to the right ventricle. Trauma patients with their necks immobilized in a hard cervical collar are best resuscitated via a femoral or subclavian approach; the latter may be used even more safely if the risk of pneumothorax is obviated by prior placement of a thoracostomy tube. The physician must recognize that the length of catheter inserted to position the catheter tip properly in the superior vena cava will vary according to puncture site, being slightly (3 to 5 cm) greater when the left internal or external jugular veins are chosen versus the right internal jugular vein.[92] Finally, a physician's personal experience undoubtedly plays a significant role in determining the safest site for central venous cannulation, particularly when the procedure is performed under urgent or emergency circumstances.

Since its introduction into clinical practice in the late 1960s, percutaneous puncture of the right internal jugular vein has been the method preferred by anesthesiologists for central venous cannulation.[93-95] Reasons for this preference include consistent, predictable anatomic location of the internal jugular vein, readily identifiable and palpable surface landmarks, and a short, straight course to the superior vena cava. An internal jugular vein catheter is highly accessible during most surgical procedures and has a rate of successful placement of approximately 90% to 99%.[94,96]

Right Internal Jugular Vein Cannulation

Many different techniques for internal jugular vein cannulation have been described, although the "central" approach described by Daily and colleagues is among the most popular and is described with minor modifications here.[97] Careful positioning will make the patient comfortable, improve identification of surface landmarks, and increase the likelihood of success. The patient is placed in the supine position with the head turned slightly to the left to expose the right side of the neck and keep the chin from interfering with the procedure. Pillows that cause the neck to be flexed should be removed, but forceful neck extension or extreme leftward rotation of the head should be avoided because this alters cervical vascular anatomy and may cause the internal jugular vein to overlie the carotid artery, thereby increasing the risk for carotid arterial puncture.[98] Anatomic landmarks, including the sternal notch, clavicle, and sternocleidomastoid muscle, should be identified before skin preparation and draping for the sterile procedure because these landmarks are more easily appreciated before they are covered by the sterile drape (Fig. 40-20). The patient should be calm, sedated, receiving supplemental oxygen if necessary, and monitored with an ECG, blood pres-

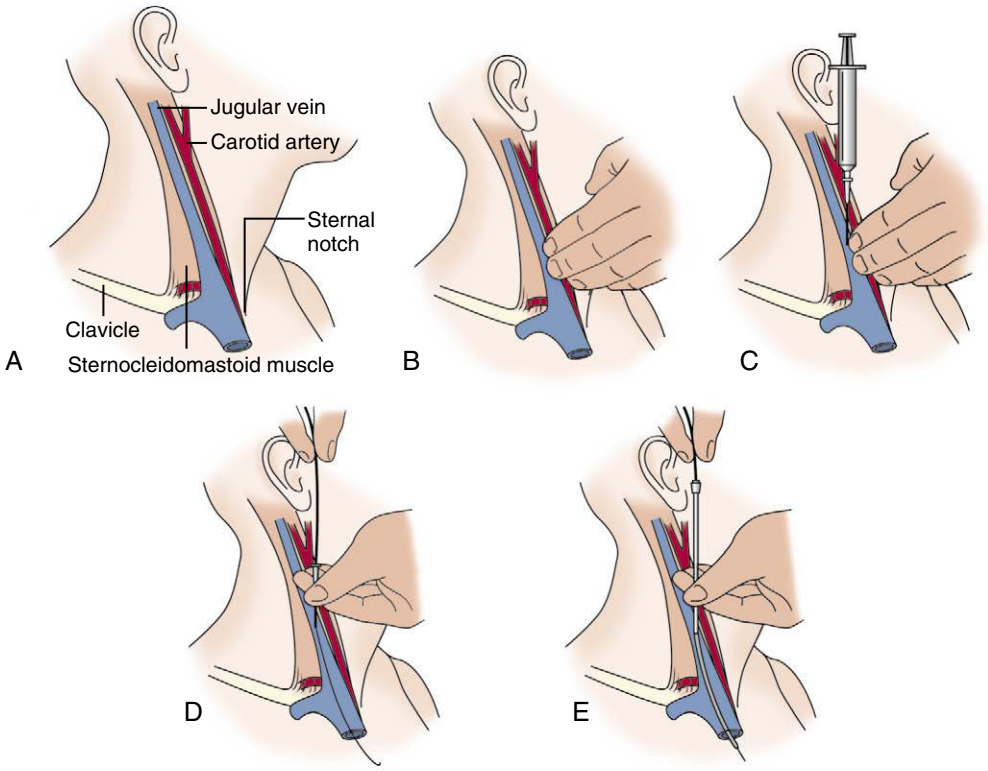

Figure 40-20 Technique for central venous cannulation of the right internal jugular vein. **A,** Important surface landmarks are identified. **B,** The course of the internal carotid artery is palpated. **C,** The internal jugular vein is punctured at the apex of the triangle formed by the two heads of the sternocleidomastoid muscle, with the needle tip directed toward the ipsilateral nipple. **D,** A guidewire is introduced through the thin-walled needle into the vein. **E,** The central venous cannula is inserted over the guidewire while making sure that the proximal end of the guidewire protrudes beyond the catheter and is controlled by the operator.

sure monitor, and pulse oximeter. Because of the frequency and serious morbidity of infectious complications from central venous catheterization, strict aseptic technique is required. Formal guidelines to reduce these complications have been published by the Centers for Disease Control and Prevention and provide prudent recommendations that should be followed during all catheterizations.[99]

Good aseptic technique begins with hand washing before the procedure. A mask, cap, sterile gloves, and gown should always be used, regardless of the procedural setting. The skin is cleaned widely from earlobe to clavicle to sternal notch, preferably with 2% chlorhexidine, an agent that has been shown to be superior to the more traditional 10% povidone-iodine.[99,100] Aseptic preparation is completed with the application of a large sterile drape that provides maximal barrier precautions, preferably a full-body drape.

Under these sterile conditions, the relevant anatomy is again identified, particularly the course of the carotid artery in the neck. The internal jugular vein lies in the groove between the sternal and clavicular heads of the sternocleidomastoid muscle, lateral and slightly anterior to the carotid artery in most cases. In many patients, venous pulsations from the internal jugular vein are observed directly within this groove and further identify the approximate site for skin puncture. An assistant then places the patient in a slight head-down (Trendelenburg) position to increase jugular vein diameter in the neck. This step may be omitted in a hypervolemic, dyspneic patient. The intended skin is anesthetized by subcutaneous infiltration of a local anesthetic solution (typically 1% lidocaine) with a 25-gauge needle if the patient is awake. Venipuncture then proceeds with a 22-gauge, 1½-inch (3.8-cm) finder needle mounted on a 5-mL syringe (see Fig. 40-20). The needle is inserted at the apex of the triangle formed by the two heads of the sternocleidomastoid muscle, at an angle of approximately 30 degrees from the plane of the skin, and directed toward the ipsilateral nipple. Gentle aspiration will identify the jugular vein when dark venous blood enters the syringe. Although use of the small finder needle is an extra step in this procedure, it presumably increases the margin of safety because unintentional puncture of the carotid artery with this small needle is less likely to result in significant bleeding and hematoma formation.[101] If blood is not aspirated as the finder needle is advanced and then withdrawn, additional needle passes may locate the internal jugular vein by fanning laterally in a small arc from the point where the needle enters the skin. If the vein is not located after several needle passes, the finder needle is withdrawn completely and checked for patency, the anatomy is reassessed, and the puncture may then proceed with the needle entering the skin several millimeters closer to the palpated carotid pulse but still directed in a sagittal or slightly lateral direction. One should resist the temptation to explore with a medial or leftward direction of the finder needle when this technique is being used because such exploration will increase the likelihood of unintentional puncture of the carotid artery.

After the internal jugular vein is located with the finder needle, the needle is gently withdrawn while the skin and surface anatomy remain fixed by the left hand. The vein is then punctured with an 18-gauge, 2½-inch (6.4-cm), thin-walled needle attached to a 5-mL syringe along the same track used with the finder needle while keeping in mind the three-dimensional location and depth of the identified internal jugular vein. It is not uncommon for the lumen of the jugular vein to be compressed as this larger thin-walled needle is advanced and both the front and back walls pierced almost simultaneously.[102,103] Consequently, the thin-walled needle should be inserted only slightly beyond the expected depth of the vein and then slowly withdrawn while maintaining gentle aspiration on the syringe. As such, venous entry of the needle is recognized during needle withdrawal by the sudden return of free-flowing venous blood.

Many individuals choose to substitute a 2-inch, 18-gauge intravenous catheter for the 18-gauge thin-walled needle for venipuncture. In this method, the catheter is advanced over the needle and into the vein immediately after blood is seen returning into the barrel of the syringe. Although this catheter can be advanced completely into the vein, it may be kinked or occluded, thereby making it more difficult to differentiate pulsatile arterial blood flow from unintentional arterial puncture. It is vital to confirm the intravenous location of this catheter. The color of the aspirated blood is examined, and it may be compared with a simultaneously obtained arterial sample, although this technique is not completely reliable.[104] A safer method is to manually transduce the pressure by attaching sterile intravenous extension tubing to the catheter and observing the fluid column.[104,105] When using this technique, it is important to allow the blood to fill more than 30 cm of the tubing and then raise it vertically and observe a fall in the column of blood. This excludes the possibility of a kinked catheter or the catheter tip abutting the arterial wall, either of which may mask an arterial puncture. Continuous pressure transduction of the thin-walled needle has been advocated as an even better method of detecting arterial puncture and preventing arterial cannulation.[96,106] Although none of these measures are foolproof, they may provide a greater margin of safety and reduce the rate of serious complications resulting from unintentional cannulation of the carotid artery with a large-bore catheter.

Once successful venipuncture is confirmed, the hub of the thin-walled needle or catheter is fixed with the fingers of the left hand, the syringe is detached, and venous blood should be observed to drip from the needle hub. A guidewire (usually 0.032 or 0.035 inch) with either a J-shaped tip or a soft, flexible straight end is inserted through the needle. The wire should advance easily into the vein with little resistance. The ECG is monitored continuously to detect arrhythmias, which are common if the wire tip is inserted too far and contacts the wall of the right atrium or ventricle.[107] From this point in the procedure, it is critical that the clinician maintain control over the guidewire and monitor its depth of insertion and continued sterility.

The puncture site is enlarged with a No. 11 scalpel blade to accommodate the greater size required for the intended catheter. A firm, tapered-tip vessel dilator may be inserted to dilate the subcutaneous tissues around the guidewire and allow a larger catheter to pass smoothly without damage to the tip of the catheter. (When an introducer sheath is to be used, the dilator and sheath form a single unit, and this separate dilation step is usually omitted.) The vessel dilator is removed, and the central venous catheter is inserted over the guidewire while countertraction on the skin is maintained. Again, the clinician must be attentive to the guidewire and ensure that a sufficient length protrudes from the catheter hub before advancing the catheter into the vein so that the wire may be extracted easily. The catheter is inserted to an appropriate depth that will place the tip in the superior vena cava, above its junction with the right atrium. This depth is typically 15 to 18 cm if the catheter is placed via the technique described. The guidewire is then withdrawn, the catheter is

attached by a Luer-Lok connector to monitoring or infusion tubing and secured in place, and sterile dressing is applied. Antibiotic ointment should not be applied to the insertion site because it may increase the risk of catheter colonization with multidrug-resistant bacteria or *Candida*.[108,109]

In patients at risk for major intraoperative blood loss and hemodynamic instability, two central venous catheters may frequently be required. Some physicians advocate double cannulation of the same central vein (usually the right internal jugular) with two catheters in close proximity. With this technique, a guidewire is introduced into the internal jugular vein by the standard method. Then, before catheter placement, a second jugular venipuncture is performed, approximately 1 to 2 cm cephalad or caudad, and a second guidewire is introduced into the vein. Placing appropriate catheters over each guidewire and securing them at the skin in the normal fashion complete the procedure. Although limited evidence suggests that the incidence of major complications with this double-cannulation technique is no greater than with single central venous catheterization, it is not clear whether this approach is safer than central venous cannulation in two separate central veins.[110] Serious complications of the double-cannulation technique include facial vein avulsion, catheter entanglement, and catheter fracture.[111,112] Double central venous cannulation must be reserved for patients whose needs for venous access and hemodynamic monitoring cannot be met through single cannulation.

Alternative Central Venous Cannulation Sites

Left Internal Jugular Vein

Cannulation of the left internal jugular vein may be accomplished with a technique similar to the one described earlier, although several anatomic details make the left side less attractive than the right. The cupola of the pleura is higher on the left, thereby theoretically increasing the risk for pneumothorax. The thoracic duct may be injured during the procedure as it enters the venous system at the junction of the left internal jugular and subclavian veins.[113] The left internal jugular vein is often smaller than the right and demonstrates a greater degree of overlap of the adjacent carotid artery during head rotation.[114] Catheters inserted from the left side of the patient must traverse the innominate (i.e., left brachiocephalic) vein and enter the superior vena cava perpendicularly, and their distal tips may impinge on the right lateral wall of the superior vena cava and thereby increase the potential for vascular injury. (This anatomic disadvantage pertains to all left-sided catheterization sites and highlights the need for radiographic confirmation of proper catheter location.) Furthermore, there is less familiarity with the technique simply because clinicians cannulate the left internal jugular vein much less often, a situation that results in more adverse events and morbidity.[98,115]

Subclavian Vein

The subclavian vein is an important site for central venous cannulation and is particularly popular among surgeons and other physicians who place central venous catheters for emergency volume resuscitation and long-term intravenous therapy or dialysis rather than for shorter-term monitoring purposes.[116,117] Advantages of subclavian venous cannulation include a lower risk of infection than with internal jugular or femoral sites, ease of insertion in trauma patients who may be immobilized in a cervical collar, and increased patient comfort, especially for long-term intravenous therapy such as hyperalimentation and chemotherapy.[99,118]

For subclavian central access, the patient is placed in a slight head-down position with the arms fully adducted and the head turned slightly away. A small roll is placed between the shoulder blades to expose the infraclavicular area fully. The skin is punctured 2 to 3 cm caudad to the midpoint of the clavicle, far enough from its inferior edge to avoid downward angulation of the needle as it is inserted just beneath the posterior surface of the clavicle. The needle tip is directed toward the suprasternal notch, which may be constantly identified by the fingers of the operator's other hand. Again, the needle is always advanced with gentle negative pressure exerted against the plunger of the syringe. If the subclavian vein is not entered in the first pass, the needle may be withdrawn and a second pass attempted in a slightly more cephalad direction while ensuring that the needle continues to hug the undersurface of the clavicle as it is advanced and avoiding the tendency to increase the downward angulation of the needle. Once the subclavian vein is punctured, catheterization proceeds in a manner similar to that described for jugular vein catheterization.

Several important technical details must be followed to ensure successful subclavian vein cannulation and avoid complications, particularly pneumothorax. Venipuncture generally proceeds without first identifying the vein with a smaller-gauge finder needle because the depth of the subclavian vein is often beyond the reach of the standard 1½-inch, 22-gauge finder needle. A thin-walled needle is preferred over an 18-gauge catheter/needle assembly because the catheter would be very easily kinked as it courses under the clavicle, thereby precluding both confirmation of venous puncture and passage of the guidewire. Of greatest importance, however, the clinician should resist the temptation to make multiple needle passes if the subclavian vein is not punctured on the second or third attempt. It is clear that complications from this procedure, particularly the incidence of pneumothorax and subclavian artery puncture, are directly related to the number of attempts.[117,119] Bilateral attempts at subclavian venipuncture are highly discouraged because of the serious morbidity of bilateral pneumothorax and the difficulty detecting and treating injury to the subclavian artery. Perhaps to an even greater degree than with internal jugular vein cannulation, the safety of subclavian venous line placement rests in the experience of the operator. In more practiced hands, the incidence of complications should be low, with pneumothorax developing in less than 2% and arterial puncture in less than 5% of cases.[117,119]

External Jugular Vein

Both the right and left external jugular veins provide a safe, albeit somewhat problematic alternative to internal jugular or subclavian vein cannulation. Because the external jugular veins are superficial, they allow central venous cannulation with essentially no risk of pneumothorax or unintended arterial puncture. In most instances, it is best to use an 18-gauge catheter rather than the thin-walled needle to introduce the guidewire because of the tortuous course of the external jugular vein and the frequent need to manipulate the guidewire repeatedly to guide it into the superior vena cava. A J-tipped guidewire should always be used because it may be advanced under the clavicle and into the central circulation more successfully than a straight-tipped wire.[120,121] When the guidewire does not advance as desired and appears to be moving peripherally into the subclavian vein, abducting the

ipsilateral shoulder beyond 90 degrees before advancing the wire may facilitate central venous passage. Alternatively, the patient's ipsilateral arm is placed at the side and an assistant applies mild caudad traction on the shoulder to straighten the course of the external jugular vein while the wire is advanced. Essentially the only factors that preclude use of the external jugular veins for CVP monitoring are an inability to visualize and cannulate the vessel in the neck and to advance a catheter into the central circulation. Care should be taken to not use excessive force when advancing catheters and stiff dilators into the external jugular vein because the sharp angle that this vein makes with the subclavian vein may increase the risk for venous injury. Unfortunately, problems with successful placement occur in approximately 20% of patients, thus limiting more widespread application of this technique.[104,122]

Femoral Vein

Femoral vein cannulation provides a useful site for CVP monitoring when the more common jugular and subclavian sites are not accessible, as is commonly the case in patients with burns or trauma, during surgical procedures that involve the head, neck, and upper part of the thorax, or during cardiopulmonary resuscitation. Use of the femoral vein obviates many of the common complications of central venous catheterization, specifically pneumothorax, but it does carry the risk of femoral artery and, more rarely, femoral nerve injury. Femoral venipuncture is performed below the inguinal ligament just medial to the palpated femoral arterial pulse in a manner similar to that used for femoral artery cannulation. Either a long (40 to 70 cm) catheter is positioned, under ECG or fluoroscopic guidance, in the inferior vena cava close to the cavoatrial junction or a shorter (15 to 20 cm) catheter is inserted from the femoral vein into the common iliac vein.[123,124] Both techniques provide intra-abdominal venous pressure measurements that appear to agree closely with pressures measured in the superior vena cava in mechanically ventilated, critically ill adults.[123,124] It is not clear whether this correlation remains valid in patients who are breathing spontaneously, those with elevated intra-abdominal or intrathoracic pressure, or those not in the supine position. Disadvantages of the femoral venous route include an increased risk of thromboembolic and infectious complications, as well as vascular injury, which may lead to intra-abdominal or retroperitoneal hemorrhage.[125] Moreover, catheters inserted at the femoral site generally preclude ambulation during recovery.

Axillary and Other Peripheral Veins

In patients with extensive, severe burn injuries, the axillary region is often spared and provides a useful site for either arterial or venous pressure monitoring.[126] Standard 20-cm CVP catheters placed in the axillary veins, approximately 1 cm medial to the palpated axillary artery, allow measurement of pressure from the superior vena cava. Even more distal pressures measured from peripheral veins in the hand and forearm may provide a reasonably accurate estimate of CVP in selected surgical patients.[127] Modified volumetric infusion pumps can even measure in-line peripheral venous pressure without the need for additional transducers and monitoring equipment.[128] Although this method of measuring CVP incurs no risk beyond that associated with placing any standard peripheral intravenous catheter, it has not been validated widely and cannot replace central venous cannulation in most circumstances.

Peripherally inserted central venous catheters (*PICCs*) have become a popular alternative to centrally inserted catheters in patients requiring long-term intravenous therapy. Advantages of a PICC include bedside placement under local anesthesia, an extremely low risk of major insertion-related complications, and safe placement by nonphysicians (i.e., registered nurses and physician assistants). This technique may be particularly cost-effective because it eliminates the need for a minor operative procedure in patients who require a Hickman or Broviac central venous catheter.[129] Venous access for a PICC is obtained through an antecubital vein, preferably the basilic vein, which is generally more successfully catheterized than the cephalic vein because of its more linear course. Early reports described only modest success positioning PICCs in an appropriate central location, as well as considerable risk for venous thrombosis, but improvements in catheter design and insertion technique now result in successful placement and few complications in most patients.[129-131] Most PICCs are placed for long-term therapeutic indications (chemotherapy or parenteral nutrition) and use very flexible, nonthrombogenic silicone catheters. Less commonly, a standard polyurethane 40-cm intravenous catheter is inserted peripherally and advanced to a central location for short-term infusion of vasoactive drugs or monitoring of CVP or pulmonary artery pressure (PAP). CVP recorded via PICCs is slightly higher than the pressure measured with centrally inserted catheters, but this difference is clinically insignificant.[132] When these standard long venous catheters are inserted from an antecubital vein, the catheter tip may advance into the heart as the arm is abducted, thereby increasing the risk for cardiac perforation or arrhythmias.[133,134] Whenever a PICC line is in place, the clinician should exercise caution when placing any additional central venous catheters because of the risk of shearing the PICC line within the central venous circulation.

Ultrasound-Guided Central Venous Cannulation

First described in 1984, ultrasound-guided placement of central venous catheters has proved beneficial in most settings, including the intensive care unit and the operating room.[135,136] Available evidence suggests that fewer needle passes are required for successful venous cannulation when two-dimensional ultrasound guidance is used. In addition, most investigators have shown that ultrasound guidance reduces the time required for catheterization, increases overall success rates, and results in fewer complications.[137,138] The benefit is most evident when the internal jugular vein rather than the subclavian or femoral vein is cannulated, when inexperienced rather than experienced operators perform the procedure, and for adult rather than pediatric patients. Based on this evidence, the Agency for Healthcare Research and Quality has listed the use of real-time ultrasound guidance for central venous catheterization as 1 of 11 practices to improve health care.[139] Nonetheless, the use of ultrasound for placement of central venous catheters continues to be low. Recent surveys show that both house staff physicians at one academic tertiary care center and a group of practicing American anesthesiologists routinely use ultrasound for central venous cannulation less than 15% of the time.[93,140] Some aspects of the use of ultrasound for placement of all central venous access remain controversial. It is still largely unknown whether the additional equipment and manipulation associated with real-time ultrasound guidance may increase the rate of catheter-related infections or whether the increased dependence on this technology by

trainees will prove detrimental in clinical settings in which it may be unavailable.

Ultrasound guidance can be used in several different ways during central venous catheterization. For example, Doppler ultrasound transforms the sound waves reflected from the moving red blood cells into an amplified audio signal that can be used to locate the artery and vein before or during cannulation.[135] Two-dimensional ultrasound can be used to confirm vessel location and patency and mark the skin, and then the catheterization can proceed in the usual fashion. Alternatively, the technology can be incorporated into the procedure itself to give real-time visualization of vessel cannulation, a method that is coming to replace the more limited, "one-look" technique.[141]

Real-time, two-dimensional ultrasound guidance for internal jugular vein cannulation requires a 7.5- to 10-MHz transducer protected by a sterile sheath. The operator holds the ultrasound probe in the nondominant hand to obtain a view of the target vessel. The vein and artery appear as two circular black structures on the ultrasound image. The vein is identified by anatomic location and by its compressibility. The artery appears mildly pulsatile (Fig. 40-21). When using ultrasound guidance, either transverse (short axis) or longitudinal (long axis) views are adequate. In general, the transverse view is easier to learn and allows simultaneous identification of the artery and vein, whereas the longitudinal view allows visualization of the needle tip at all times, which may reduce perforation of the posterior wall of the vein.[142] After positioning the vein in the center of the ultrasound screen, the vessel is punctured under direct vision with the 18-gauge needle of choice. The technique then proceeds as in the standard landmark technique described earlier, but with confirmation of the intravenous location of the guidewire with a longitudinal view before proceeding with dilation of the vessel.

Ultrasound imaging of the subclavian vessels is more difficult and often hampered by the patient's body habitus and probe configuration. When using ultrasound to guide cannulation of the subclavian vein, the transducer is placed in the infraclavicular groove at the level of the middle or lateral third of the clavicle, and the axillary vein and artery are imaged as they exit the bony canal formed by the clavicle and the first rib.[143] The artery is most commonly cephalad to the vein and noncompressible, and it does not vary in size with respiration. Either a transverse or longitudinal view can be obtained and used to guide needle insertion.[144] Another approach has been described in children in which the probe is placed in the supraclavicular space to obtain a longitudinal view of the subclavian vein while cannulation is performed via the usual infraclavicular route.[145]

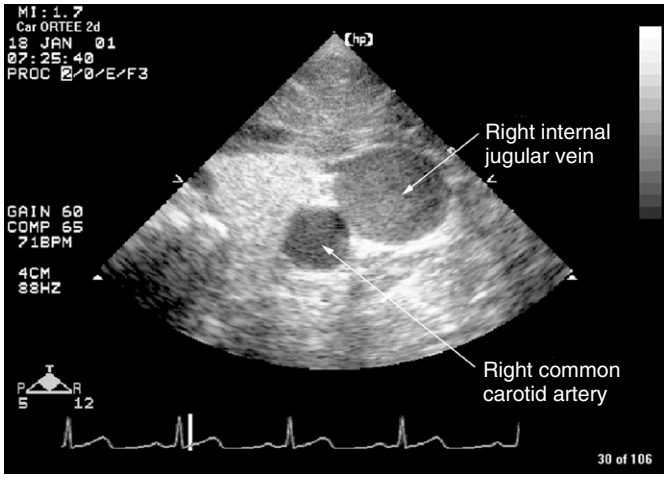

Figure 40-21 Transverse-plane ultrasound image showing the right internal jugular vein and its typical anatomic position anterior and lateral to the right common carotid artery.

Confirming Catheter Position

Central venous catheters placed in the operating room are commonly used for the duration of the surgical procedure without radiologic confirmation of the location of the catheter tip. Before monitoring or infusion commences, aspiration of blood should confirm the intravenous location of each lumen of a multilumen catheter and remove any residual air from the catheter-tubing system. After surgery, however, the position of the catheter tip must be confirmed radiographically. Catheter tips located within the heart or below the pericardial reflection of the superior vena cava increase the risk for cardiac perforation and fatal cardiac tamponade. Ideally, the catheter tip should lie within the superior vena cava, parallel to the vessel walls, and be positioned *below* the inferior border of the clavicles and *above* the level of the third rib, the T4 to T5 interspace, the azygos vein, the tracheal carina, or the takeoff of the right mainstem bronchus.[146,147] Using fresh human cadavers, Albrecht and colleagues recently confirmed that the tracheal carina was always above the pericardial reflection on the superior vena cava, thus suggesting that catheter tip should always be located superior to this radiographic landmark.[148]

Complications of Central Venous Pressure Monitoring

Complications of central venous cannulation are increasingly being recognized as major sources of morbidity, with more than 15% of patients experiencing some sort of related adverse event.[125] Although serious immediate complications are infrequent when these procedures are performed by well-trained, experienced clinicians, infectious complications are common, and the use of CVP catheters continues to result in significant morbidity and mortality. Complications are often divided into mechanical, thromboembolic, and infectious causes (Box 40-5).

Mechanical Complications of Central Venous Catheterization

The incidence of complications depends on a number of factors, including the catheter insertion site and the patient's medical condition. Large retrospective and observational studies provide the best estimates of the incidence and frequency of complications. In general, *unintended arterial puncture* is the most common acute mechanical complication, with an incidence ranging from 1.9% to 15%.[149] Many of these injuries result in localized hematoma formation, but on rare occasion even small-gauge needle punctures may lead to serious complications such as arterial thromboembolism.[150]

If arterial puncture with a small needle occurs during central venous cannulation, the needle should be removed and external pressure applied for several minutes to prevent hematoma formation. When unintentional carotid artery cannulation occurs, it can usually be managed conservatively by removing the catheter, applying local compression to the puncture site, and monitor-

  - Endocarditis
- Misinterpretation of data
- Misuse of equipment

ing the patient's airway and neurologic status. A vascular surgeon should be consulted promptly to help manage the complication. Only under exceptional circumstances should the catheter be allowed to remain in the vessel because of a high risk for arteritis, thrombus formation, and cerebral embolization.[151]

Vascular injuries from central venous catheterization have a range of clinical consequences. The most common minor complications are localized hematoma or injury to the venous valves.[152] More serious complications include perforation into the pleural space or mediastinum resulting in hydrothorax, hemothorax, hydromediastinum, hemomediastinum, chylothorax, or any combination of these sequelae.[113,153-156] Other catastrophic and thankfully rare vascular injuries have been reported, including aortic perforation and avulsion of the facial vein.[111,157] Delayed vascular complications after central venous catheterization are uncommon but should be considered consequences of this procedure. A number of these delayed complications have been described in the literature, including aortoatrial fistula, venobronchial fistula, carotid artery–internal jugular vein fistula, and pseudoaneurysm formation.[158-161]

The most important life-threatening vascular complication of central venous catheterization is *cardiac tamponade* resulting from perforation of the intrapericardial superior vena cava, right atrium, or right ventricle and subsequent hemopericardium or unintentional pericardial instillation of intravenous fluid.[162] This injury was the second most common complication related to central venous catheters in an analysis of the American Society of Anesthesiologists Closed Claims Project in 2004.[163] Cardiac tamponade resulted in death in 81% of cases in this report and often had a delayed manifestation (1 to 5 days), thus indicating that this complication is related to catheter maintenance and use more often than to the vascular access procedure itself. Most reports document the avoidable nature of this catastrophic event and highlight that patients are predisposed to this complication when central venous catheter tips are malpositioned within the heart chambers or abutting the wall of the superior vena cava at a steep angle. This latter position can be recognized radiographically as a gentle curvature of the catheter tip within the superior vena cava.[164] These observations emphasize that objective confirmation of proper catheter tip location is mandatory, regardless of whether the catheter is inserted from a central or peripheral site. In fact, many early reports of catheter-related cardiovascular perforation suggested that peripheral catheters may be associated with an unusually high risk for this complication because arm abduction may cause the catheter tip to advance into a dangerous location within the heart.[133,165] When cardiac tamponade is caused by catheter-induced cardiac perforation, symptoms develop suddenly, so a high index of suspicion is required if severe hypotension occurs in any patient with a central venous catheter in place. Cardiac arrhythmias may provide an early clue to intracardiac location of the catheter tip.[134] Occasionally, both posteroanterior and lateral chest radiographs, as well as injection of radiopaque contrast material, are required to locate the catheter tip precisely.[166]

Pneumothorax is often cited as the most common complication of subclavian vein cannulation, although it appears that unintended arterial puncture is actually more frequent.[46,119] Mansfield and coauthors reported a 1.5% incidence of pneumothorax and a 3.7% incidence of arterial puncture in 821 patients who underwent attempted subclavian vein cannulation.[119] Pneumothorax is even less frequent with the internal jugular approach. Shah and coworkers reported a 0.5% incidence of pneumothorax in their series of nearly 6000 internal jugular catheterizations.[149] This estimate is most likely high because these patients had undergone sternotomy for cardiac surgery, a procedure that may have been responsible for the pneumothorax in many cases. Small pneumothoraces may be managed conservatively, whereas tube thoracostomy is the best treatment for larger air collections or pneumothorax in patients receiving positive-pressure mechanical ventilation or scheduled for major surgery. The physician must always be prepared for the possibility of tension pneumothorax and its adverse hemodynamic sequelae. In addition to pneumothorax, other respiratory tract injuries have been reported after central venous catheterization, including subcutaneous and mediastinal emphysema, tracheal perforation, and rupture of an endotracheal tube cuff.[167]

Nerve injury is another potential complication of central venous cannulation. Damage may occur to the brachial plexus, stellate ganglion, phrenic nerve, or vocal cords.[168,169] In addition, chronic pain syndromes have been attributed to this procedure.[170]

Thromboembolic Complications of Central Venous Catheterization

Catheter-related thrombosis varies according to the site of central venous catheterization and occurs in as many as 21.5% of patients with femoral vein catheters and 1.9% of those with subclavian vein catheters.[118] Catheters that are positioned low in the right atrium may be more prone to thrombus formation, possibly because of mechanical irritation of the right atrial endocardium

by the catheter.[171] Thrombi that form at the catheter tip or adhere to the endocardium have the potential to become a nidus for infection, cause superior vena cava syndrome, or embolize into the pulmonary circulation.[172,173] Occasionally, surgical removal is required.[174]

In addition to thromboembolism, other reported embolic complications of central venous catheterization include embolism of portions of the catheter or guidewire and air embolism.[175,176] Almost invariably, these problems are the result of misuse of equipment, thus highlighting the need for proper education and training of nurses and physicians responsible for the use of these devices.

Infectious Complications of Central Venous Catheterization

By far the most common major late complication of central venous cannulation is *infection*. Bloodstream infections occur in approximately 5% of patients with standard central venous catheters and thus lead to an estimated 150,000 to 250,000 cases of catheter-related bacteremia or fungemia annually.[99,177] Given that the crude mortality of patients with nosocomial bloodstream infections is approximately 35% and the cost of these infections can exceed $50,000 per episode, even basic strategies to reduce this complication appear to be both cost-effective and lifesaving.[177,178]

As previously noted, the starting point for prevention of infection is meticulous attention to aseptic technique.[179] When more long-term central venous access is anticipated, the subclavian site is preferred because use of the jugular or femoral veins carries a higher risk for infection.[118,180] Multilumen catheters may carry a higher risk for infection than single-lumen catheters, although the added clinical functionality of such catheters often mandates their use.[99,125] Catheters are made from materials such as silicone, polyvinyl chloride, Teflon, and polyurethane. Furthermore, catheters of the same material may be manufactured differently, which influences their surfaces and the frequency of bacterial adherence to the surface.[181] Heparin-bonded central venous catheters have been shown to reduce the incidence of catheter-related thrombosis and infection in children and adults.[182] Incorporation of antimicrobial treatments onto the catheter surface, such as combinations of chlorhexidine and silver sulfadiazine or monocycline and rifampin, have been shown to reduce rates of catheter colonization and bloodstream infection.[177,183] The added expense has prevented more widespread adoption of these catheters, although an analysis has suggested their cost-effectiveness in settings in which the rate of catheter-related infection remains high (>3.3 per 1000 catheter-days).[184] The use of catheters with a silver-impregnated subcutaneous cuff has not been shown to be beneficial.[185] A chlorhexidine gluconate–impregnated sponge dressing has been shown to reduce catheter colonization in infants and children but does not reduce the rate of catheter-associated bloodstream infections.[186,187] Current guidelines from the Centers for Disease Control and Prevention do not support routine catheter site changes or scheduled changes over a guidewire and instead provide other detailed recommendations for catheter management to reduce the risk for infectious complications.[99]

Other Complications of Central Venous Catheterization

Miscellaneous other adverse sequelae of central venous cannulation have been reported (see Box 40-5), and although their incidence is not clearly known, most appear to be uncommon. All physicians performing these procedures should be familiar with them, particularly since many of these complications are related to *operator error*.[46,188]

Use of *guidewires*, *vessel dilators*, and *large-bore catheters* carries certain additional risks that mandate meticulous attention to technique. The proximal tip of the guidewire must remain under the physician's control at all times to avoid inserting the wire too far into the heart and thus causing arrhythmias or potentially losing the guidewire within the circulation.[175,189] By design, vessel dilators are stiffer than the catheters and may cause significant trauma if inserted forcefully or farther than necessary to dilate the subcutaneous tissue tract from skin to vein.[190] Large-bore introducer sheaths and multilumen catheters have become popular because of their clinical utility, yet their size may increase the risk for cannulation-associated trauma, hemorrhage from unrecognized line disconnections, and major venous air embolism. Not only may air be entrained during initial cannulation, but improperly connected large-bore cannulas may pose an additional risk because of the large site for entry of air directly into the central venous circulation.[176,191]

Although many complications of CVP monitoring relate to equipment misuse, the frequency of complications caused by misinterpretation of data remains unknown. It is extremely likely, however, that clinicians misinterpret CVP measurements and have suboptimal understanding of CVP monitoring, just as has been demonstrated repeatedly for PAP monitoring (see discussion later). Safe and effective use of CVP monitoring requires a detailed understanding of cardiovascular physiology, normal CVP waveforms, and common pathologic abnormalities in these measurements.

Physiologic Considerations for Central Venous Pressure Monitoring: Diastolic Pressure-Volume Relationships and Transmural Pressure

Cardiac filling pressures are monitored to estimate cardiac filling volumes, which in turn determine the stroke output of the left and right ventricles. According to the Frank-Starling principle, the force of cardiac contraction is directly proportional to end-diastolic muscle fiber length at any given level of intrinsic contractility or inotropy. This muscle fiber length or preload is proportional to end-diastolic chamber volume. Even though it would be ideal to monitor cardiac chamber volumes continuously in critically ill patients, this goal remains elusive in clinical practice.

When a cardiac filling pressure is measured as a surrogate for estimating cardiac volume, one must not assume that these two variables always change in direct proportion or even in the same direction. In fact, the diastolic pressure-volume relationship in cardiac muscle is not linear, but rather curvilinear, with a progressively steeper slope at higher volumes (Fig. 40-22).[192,193] This diastolic pressure-volume relationship is one limb of a pressure-volume loop that describes the relationship between pressure and volume for the left or right ventricle during an entire cardiac cycle. When a ventricle is operating along the flat portion of its diastolic filling curve, a significant increase in filling volume or preload results in a small increase in filling pressure. In contrast,

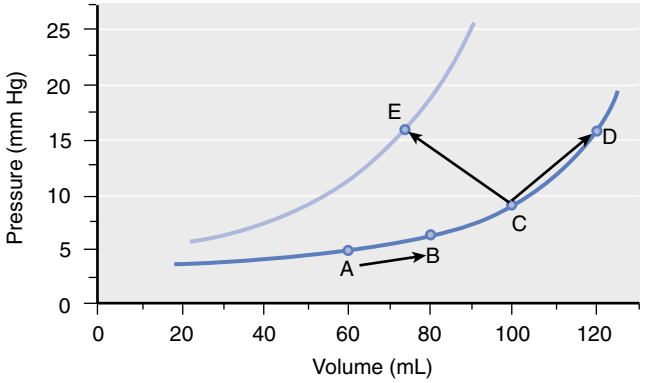

Figure 40-22 Ventricular diastolic pressure-volume relationship. Along the flat portion of the curve, a 20-mL increase in ventricular volume causes a small increase in ventricular pressure (A to B). In contrast, the same increase in volume along the steep portion of the ventricular filling curve causes a marked increase in filling pressure (C to D). Another problem associated with the use of filling pressure as a surrogate for filling volume arises when shifts in the pressure-volume relationship occur. At point C, ventricular volume is 100 mL and ventricular pressure is 8 mm Hg. An increase in filling pressure to 15 mm Hg may accompany either an increased volume (D) or decreased volume (E). The latter occurs when ventricular compliance changes and shifts the ventricular diastolic pressure-volume relationship up and to the left. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998, Fig. 15-2.)*

the same increase in filling volume causes a significant increase in filling pressure when the ventricle is operating on the steep portion of its curve.[194] An even more confusing situation arises when the diastolic pressure-volume relationship of the ventricle changes, for example, with the onset of myocardial ischemia. Rather than moving along the same diastolic pressure-volume curve, the ventricle now shifts to a different, steeper curve, where somewhat paradoxically, an increase in filling pressure may accompany a decrease in filling volume.[195] As in this example, not only can one not assume that a given measured change in cardiac filling pressure reflects a proportional change in ventricular preload, it cannot even be assumed that diastolic pressure and volume change in a similar direction.[195]

The relationship between ventricular volume and filling pressure depends on the portion of the pressure-volume curve over which the patient's heart is operating and the shape or slope of the curve. Commonly termed ventricular compliance, this change in pressure for a given change in volume ($\Delta P/\Delta V$) is actually the reciprocal of compliance and is more accurately termed ventricular elastance, distensibility, or stiffness.[196] A patient with an abnormally stiff ventricle will have a greater change in end-diastolic pressure for any given change in end-diastolic volume, and the converse is true for a patient with an abnormally compliant ventricle. By definition, diastolic dysfunction is present when changes in ventricular pressure are abnormally elevated for any given change in ventricular volume.

The ventricular diastolic pressure-volume relationship is influenced by the intrinsic properties of the ventricle, such as the passive mechanical characteristics of cardiac muscle, chamber geometry, and relaxation. In addition, external forces exerted by the pericardium, the adjacent ventricle, the coronary vasculature, and pleural pressure will further influence ventricular pressure-volume relationships.[197,198] One should not equate cardiac filling pressures with filling volumes when patients are functioning over wide ranges of their diastolic pressure-volume curve or under conditions in which diastolic stiffness is abnormal or changing rapidly.

In general, all intravascular pressures measured in clinical practice are referenced to ambient atmospheric pressure. Indeed, the first step in pressure transducer setup is to zero the transducer by exposing it to atmospheric pressure and assigning this pressure a value of zero by pressing the zero pressure button on the monitor (see "Technical Aspects of Direct Blood Pressure Measurement"). Thus, a cardiac filling pressure of 10 mm Hg is 10 mm Hg higher than ambient atmospheric pressure. Does this pressure value accurately represent the distending force across the cardiac chamber wall at end-diastole?

To answer this question, one needs to consider transmural pressure. The cardiac chambers are all contained within the pericardium and thorax. Changes in pressure in the structures surrounding the heart will influence pressures recorded within the heart. Transmural pressure is the difference between chamber pressure and juxtacardiac or pericardial pressure. This transmural pressure determines ventricular preload, end-diastolic volume, or fiber length. The same measured filling pressure, referenced to atmospheric pressure, can be associated with markedly different transmural pressures and chamber volumes, depending on whether juxtacardiac pressure is high or low. Although juxtacardiac pressure can be ignored under some circumstances, marked alterations in pleural and pericardial pressure occur commonly and must be considered when any cardiac filling pressure is interpreted. Transmural pressure is always the pressure of physiologic interest. Because juxtacardiac pressure is not measured routinely, one must always consider that the measured central venous pressure, referenced to ambient atmosphere, may be a poor estimate of transmural pressure.[194,199]

Cardiac filling pressures are measured directly from a number of sites in the vascular system. CVP monitoring is the least invasive method, followed by monitoring of PAP and left atrial pressure (LAP). Proper interpretation of all cardiac filling pressures requires knowledge of normal values for these pressures, as well as pressures in the cardiac chambers, the great vessels, and other measured and derived hemodynamic variables (Table 40-2).

Normal Central Venous Pressure Waveforms

Strictly speaking, CVP is the pressure measured at the junction of the venae cavae and the right atrium and reflects the driving force for filling the right atrium and ventricle. Because the large veins of the thorax, abdomen, and proximal extremities form a compliant reservoir for a sizable percentage of total blood volume, CVP is highly dependent on intravascular blood volume and the intrinsic vascular tone of these capacitance vessels. In other words, CVP or right atrial pressure in part reflects the relationship of blood volume to the capacity of the venous system.[200] In addition, CVP also reflects the functional capacity of the right ventricle. Based on the Frank-Starling mechanism, higher right heart filling pressures are required to maintain ventricular stroke output when ventricular contractility is impaired. Thus, in clinical practice, CVP monitoring is used for assessment of blood volume and right heart function.[201] Normal CVP in an awake, spontaneously breathing patient ranges between 1 and 7 mm Hg.

Table 40-2 Normal Cardiovascular Pressures

Pressure	Average (mm Hg)	Range (mm Hg)
Right Atrium		
a wave	6	2-7
v wave	5	2-7
Mean	3	1-5
Right Ventricle		
Peak systolic	25	15-30
End-diastolic	6	1-7

End-diastolic	8	5-12
Central Aorta		
Peak systolic	130	90-140
End-diastolic	70	60-90
Mean	90	70-105

Table 40-3 Central Venous Pressure Waveform Components

Waveform Component	Phase of Cardiac Cycle	Mechanical Event
a wave	End diastole	Atrial contraction
c wave	Early systole	Isovolumic ventricular contraction, tricuspid motion toward the right atrium
v wave	Late systole	Systolic filling of the atrium
h wave	Mid to late diastole	Diastolic plateau
x descent	Mid systole	Atrial relaxation, descent of the base, systolic collapse
y descent	Early diastole	Early ventricular filling, diastolic collapse

Mechanical events during the cardiac cycle are responsible for the sequence of waves seen in a typical CVP trace. The CVP waveform consists of five phasic events, three peaks (a, c, v) and two descents (x, y) (Table 40-3, Fig. 40-23).[202,203] The most prominent wave is the *a wave* of atrial contraction, which occurs at end-diastole after the ECG P wave. Atrial contraction increases atrial pressure and provides the "atrial kick" to fill the right ventricle through the open tricuspid valve. Atrial pressure decreases after the a wave as the atrium relaxes. This smooth decline in pressure is interrupted by the *c wave*. This wave is a transient increase in atrial pressure produced by isovolumic ventricular contraction, which closes the tricuspid valve and displaces it toward the atrium. The c wave always follows the ECG R wave because it is generated during the onset of ventricular systole. (Note that the c wave observed in a jugular venous pressure trace might have a slightly more complex origin. This wave has been attributed to early systolic pressure transmission from the adjacent carotid artery and may be termed a carotid impact wave.[204] Because jugular venous pressure also reflects right atrial pressure, however, this c wave probably represents both arterial [carotid impact] and venous [tricuspid motion] origins.) Atrial pressure continues its decline during ventricular systole because of continued atrial relaxation and changes in atrial geometry produced by ventricular contraction and ejection. This is the *x descent*, or systolic collapse in atrial pressure. The *x* descent can be divided into two portions, x and x′, corresponding to segments before and after the c wave. The last atrial pressure peak is the *v wave*, which is caused by venous filling of the atrium during late systole while the tricuspid valve remains closed. The v wave usually peaks just after the ECG T wave. Atrial pressure then decreases, thereby inscribing the *y descent*, or diastolic collapse, as the tricuspid valve opens and blood flows from atrium to ventricle. (A final compo-

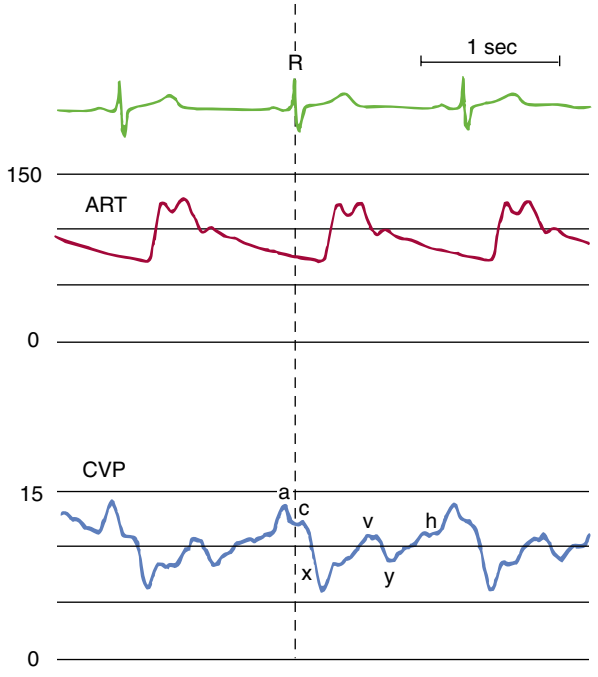

Figure 40-23 Normal central venous pressure (CVP) waveform. The diastolic components (y descent, end-diastolic a wave) and the systolic components (c wave, x descent, end-systolic v wave) are all clearly delineated. A mid-diastolic plateau wave, the h wave, is also seen because the heart rate is slow. Identification of the waveform is aided by timing the relationship between individual waveform components and the electrocardiographic R wave. Waveform timing using the arterial (ART) pressure trace is more confusing because of the relative delay in systolic arterial pressure upstroke. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998, Fig. 2-5.)*

nent of the CVP waveform, the *h wave*, occasionally appears as a pressure plateau in mid to late diastole. The h wave is not normally seen unless the heart rate is slow and venous pressure is elevated.[204,205]) In summary, the normal venous waveform components may be remembered as follows: the a wave results from atrial contraction; the c wave results from closure of the tricuspid valve and isovolumic right ventricular contraction; the x descent is the systolic decrease in atrial pressure caused by atrial relaxation; the v wave results from ventricular ejection, which drives venous filling of the atrium; and the y descent is the diastolic decrease in atrial pressure caused by flow across the open tricuspid valve.

In relation to the cardiac cycle and ventricular mechanical actions, the CVP waveform can be considered to have three systolic components (c wave, x descent, v wave) and two diastolic components (y descent, a wave). By recalling the mechanical actions that generate the pressure peaks and troughs, it is easy to identify these waveform components properly by aligning the CVP waveform and the ECG trace and using the ECG R wave to mark end-diastole and the onset of systole. When the radial artery pressure trace is used for timing of the CVP waveform instead of the ECG, confusion may arise because the arterial pressure upstroke occurs nearly 200 msec after the ECG R wave (see Fig. 40-23). This normal physiologic delay reflects the times required for spread of electrical depolarization through the ventricle (~60 msec), isovolumic left ventricular contraction (~60 msec), transmission of the rise in aortic pressure to the radial artery (~50 msec), and transmission of the rise in radial artery pressure through fluid-filled tubing to the transducer (~10 msec).[61,206]

The normal CVP peaks are designated systolic (c, v) or diastolic (a) according to the phase of the cardiac cycle in which the wave begins. However, one generally identifies these waves not by their onset or upstroke but rather by the location of their peaks. For instance, the a wave generally begins and peaks in end-diastole, but the peak may appear delayed to coincide with the ECG R wave, especially in a patient with a short PR interval. In this instance the a and c waves merge, and this composite wave is termed an a-c wave. Designation of the CVP v wave as a systolic event may be even more confusing. Although ascent of the v wave begins during late systole, the peak of the v wave occurs during isovolumic ventricular relaxation, immediately before opening of the atrioventricular valve and the y descent. Consequently, the most precise description would be that the v wave begins in late systole but peaks during isovolumic ventricular relaxation, the earliest portion of diastole. For clinical purposes, it is simplest to consider the v wave to be a systolic wave.

Although three distinct CVP peaks (a, c, v) and two troughs (x, y) are discernible in the normal venous pressure trace, heart rate changes and conduction abnormalities alter this pattern. A short ECG PR interval causes fusion of the a and c waves, and tachycardia reduces the length of diastole and the duration of the y descent, which causes the v and a waves to merge. In contrast, bradycardia causes each wave to become more distinct, with separate x and x′ descents visible and a more prominent h wave. Although there are circumstances in which other pathologic waves may be evident in the CVP trace, one should resist the temptation to assign physiologic significance to each small pressure peak because many will arise as artifacts of fluid-filled tubing-transducer monitoring systems. It is more useful to search for the expected waveform components, including those characteristic of the pathologic conditions suspected.

Abnormal Central Venous Pressure Waveforms

Various pathophysiologic conditions may be diagnosed or confirmed by examination of the CVP waveform (Table 40-4). One of the most common applications is rapid diagnosis of cardiac arrhythmias.[207] In *atrial fibrillation*, the a wave disappears and the c wave becomes more prominent because atrial volume is greater at end-diastole and the onset of systole as a result of the absence of effective atrial contraction (Fig. 40-24A). Occasionally, atrial fibrillation or flutter waves may be seen in the CVP trace when the ventricular rate is slow. Isorhythmic *atrioventricular dissociation* or *junctional* (*nodal*) *rhythm* (see Fig. 40-24B) alters the normal sequence of atrial contraction before ventricular contraction. Instead, atrial contraction now occurs during ventricular systole when the tricuspid valve is closed, thereby inscribing a tall "cannon" a wave in the CVP waveform. Absence of normal atrioventricular synchrony during ventricular pacing (see Fig. 40-24C) can be identified in a similar fashion by searching for cannon waves in the venous pressure trace. In these instances, the CVP waveform helps diagnose the cause of the arterial hypotension; loss of the normal end-diastolic atrial kick may not be as evident in the ECG trace as it is in the CVP waveform.

Right-sided valvular heart diseases alter the CVP waveform in different ways.[208] *Tricuspid regurgitation* produces abnormal systolic filling of the right atrium through the incompetent valve (Fig. 40-25A). A broad, tall systolic c-v wave results, beginning in early systole and obliterating the systolic x descent in atrial pressure. The CVP trace is said to be ventricularized and resembles right ventricular pressure. Note that this regurgitant wave differs in onset, duration, and magnitude from a normal v wave caused by end-systolic atrial filling from the venae cavae. In patients with tricuspid regurgitation, right ventricular end-diastolic pressure is

Table 40-4 Central Venous Pressure Waveform Abnormalities

Condition	Characteristics
Atrial fibrillation	Loss of a wave Prominent c wave
Atrioventricular dissociation	Cannon a wave
Tricuspid regurgitation	Tall systolic c-v wave Loss of x descent
Tricuspid stenosis	Tall a wave Attenuation of y descent
Right ventricular ischemia	Tall a and v waves Steep x and y descents M or W configuration
Pericardial constriction	Tall a and v waves Steep x and y descents M or W configuration
Cardiac tamponade	Dominant x descent Attenuated y descent
Respiratory variation during spontaneous or positive-pressure ventilation	Measure pressures at end-expiration

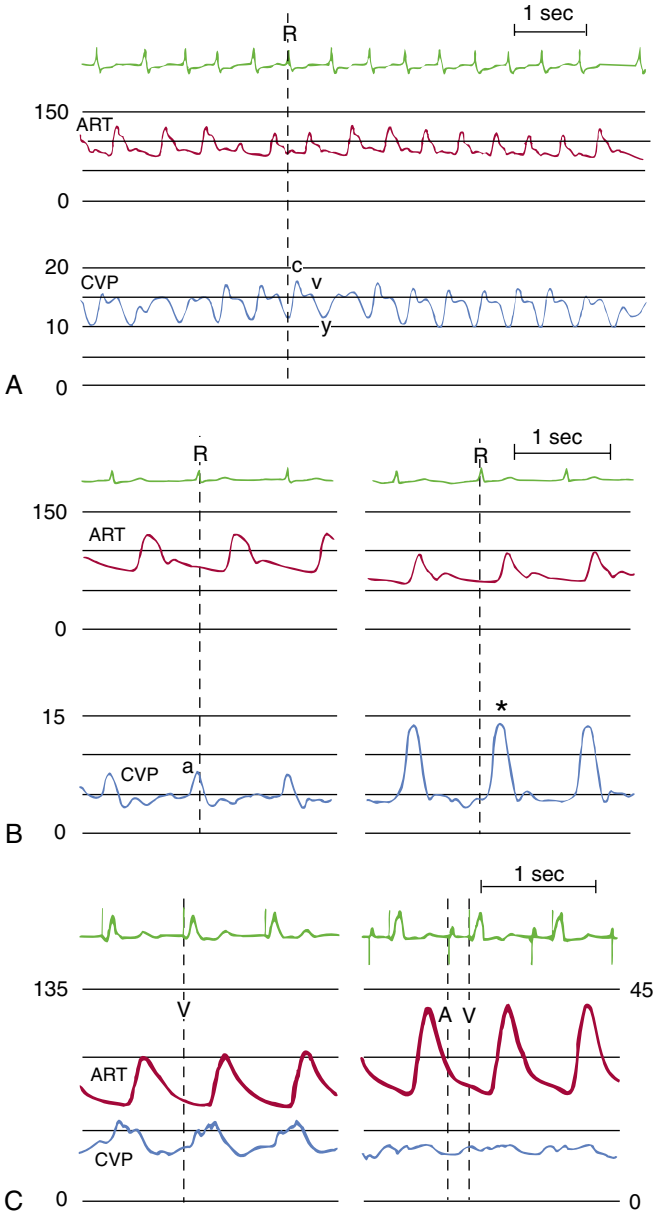

Figure 40-24 Changes in central venous pressure (CVP) caused by cardiac arrhythmias. **A,** Atrial fibrillation. Note the absence of the a wave, a prominent c wave, and a preserved v wave and y descent. This arrhythmia also causes variation in the electrocardiographic (ECG) R-R interval and left ventricular stroke volume, which can be seen in the ECG and arterial pressure (ART) traces. **B,** Isorhythmic atrioventricular dissociation. In contrast to the normal end-diastolic a wave in the CVP trace (*left panel*), an early systolic cannon wave is inscribed (*, *right panel*). Reduced ventricular filling accompanying this arrhythmia causes decreased arterial blood pressure. **C,** Ventricular pacing. Systolic cannon waves are evident in the CVP trace during ventricular pacing (*left panel*). Atrioventricular sequential pacing restores the normal venous waveform and increases arterial blood pressure (*right panel*). The ART scale is shown on the *left*; the CVP scale is on the *right*. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998, Figs.14-1, 14-5, and 14-6.)*

overestimated by the numeric display on the bedside monitor, which reports a single mean value for CVP. Instead, right ventricular end-diastolic pressure is best estimated by measuring CVP at the time of the ECG R wave, before the regurgitant systolic wave (see Fig. 40-25A). Unlike tricuspid regurgitation, *tricuspid stenosis* produces a diastolic defect in atrial emptying and ventricular filling (see Fig. 40-25B). Mean CVP is elevated, and a pressure gradient exists throughout diastole between the right atrium and ventricle. The a wave is unusually prominent and the y descent is attenuated as a result of the impaired diastolic egress of blood from the atrium. Other conditions that reduce right ventricular compliance, such as right ventricular ischemia, pulmonary hypertension, or pulmonic valve stenosis, may produce a prominent end-diastolic a wave in the CVP trace but do not attenuate the early diastolic y descent. CVP waveform morphology changes in other characteristic ways in the presence of pericardial disease and right ventricular infarction. These patterns are

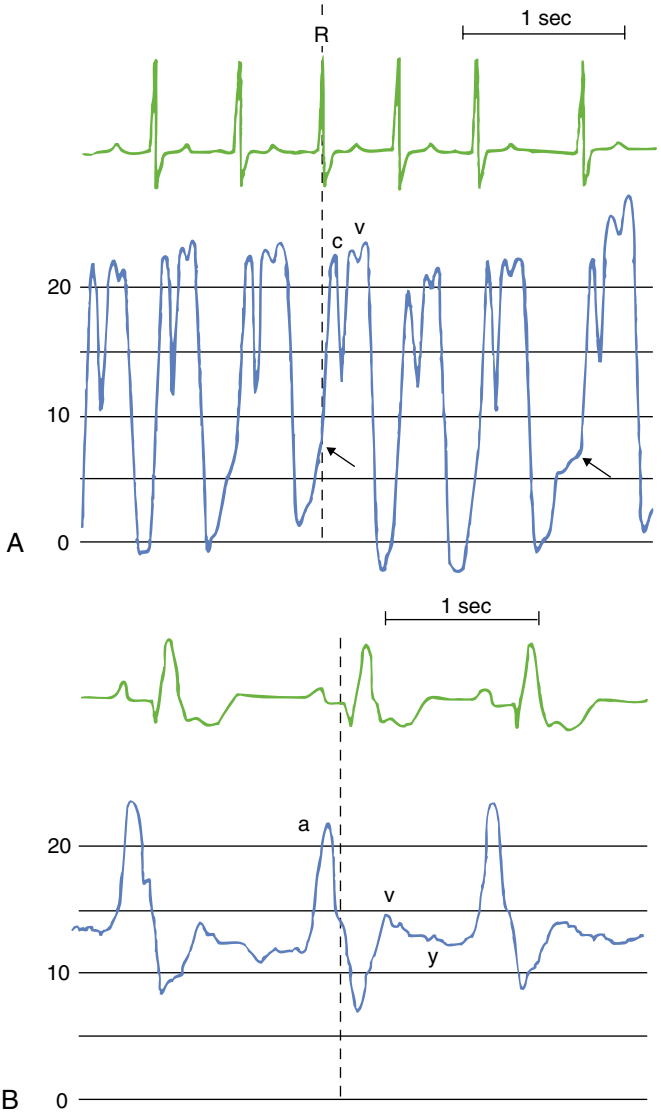

Figure 40-25 Changes in central venous pressure (CVP) in tricuspid valve disease. **A,** Tricuspid regurgitation increases mean CVP, and the waveform displays a tall systolic c-v wave that obliterates the x descent. In this example the a wave is not seen because of atrial fibrillation. Right ventricular end-diastolic pressure is estimated best at the time of the electrocardiographic R wave (*arrows*) and is lower than mean CVP. **B,** Tricuspid stenosis increases mean CVP, the diastolic y descent is attenuated, and the end-diastolic a wave is prominent. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998, Figs. 17-3 and 17-15.)*

best interpreted in conjunction with monitoring of PAP, which is discussed later.

Perhaps the most important application of CVP monitoring is to provide an estimate of the adequacy of circulating blood volume and right ventricular preload. As noted earlier, transmural CVP is the pressure of physiologic interest, although in clinical practice we measure and record pressures referenced to ambient atmospheric pressure. Consequently, accurate interpretation of CVP requires the physician to consider the alterations in intrathoracic or juxtacardiac pressure that occur during the respiratory cycle.[194,199] During spontaneous breathing, inspiration causes a decrease in pleural and juxtacardiac pressure, which is transmitted, in part, to the right atrium and lowers CVP (Fig. 40-26A). This same decrease in pleural pressure will influence other measured central vascular pressures in similar fashion. Note a subtle, but critically important observation about the measurement of central vascular pressures. Although CVP measured relative to atmospheric pressure decreases during the inspiratory phase of spontaneous ventilation, transmural CVP, the difference between right atrial pressure and juxtacardiac pressure, may actually increase slightly as more blood is drawn into the right atrium. The opposite pattern is observed during positive-pressure ventilation, in which inspiration increases intrathoracic pressure while raising the measured CVP but decreases transmural CVP because the elevated intrathoracic pressure reduces venous return (see Fig. 40-26B). As mentioned earlier, transmural pressures are rarely measured in clinical practice because of difficulty assessing juxtacardiac or intrathoracic pressure. Instead, end-expiratory values for cardiac filling pressures should be recorded in all patients to provide the best estimate of transmural pressure. At the end of expiration, intrathoracic and juxtacardiac pressures approach atmospheric pressure regardless of ventilatory status, and the CVP values will coincide (see Fig. 40-26). Proper pressure values can also be determined by visual inspection of the CVP waveform on a calibrated monitor screen or paper recording. This facilitates comparison of CVP values (and other cardiac filling pressures) obtained from the same patient under varying patterns of ventilation, a common situation in anesthesia and critical care.

Not only can individual CVP waveforms provide unique diagnostic clues about the circulation, but trends in CVP over time may also be useful in estimating fluid or blood loss and guiding replacement therapy. It is important to remember that there is a significant range of normal values and that a small change in CVP may reflect a significant alteration in circulating blood volume and right ventricular preload. Additional useful information may be derived from examining how a fluid bolus simultaneously alters CVP and other variables of clinical interest, such as blood pressure, urine output, and so forth.

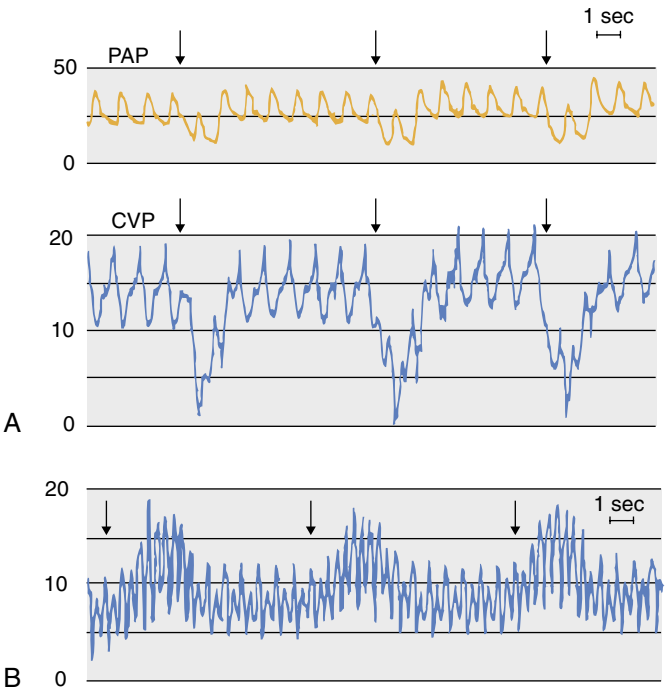

Figure 40-26 Respiratory influences on the measurement of central venous pressure (CVP). **A,** During spontaneous ventilation, the onset of inspiration (*arrows*) causes a reduction in intrathoracic pressure, which is transmitted to both the CVP and pulmonary artery pressure (PAP) waveforms. CVP should be recorded at end-expiration (mean CVP, 14 mm Hg). **B,** During positive-pressure ventilation, the onset of inspiration (*arrows*) causes an increase in intrathoracic pressure. CVP is still recorded at end-expiration (mean CVP, 8 mm Hg). *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998, Figs. 16-1 and 16-2.)*

Pulmonary Artery Catheter Monitoring

In 1970, Swan, Ganz, and colleagues introduced pulmonary artery catheterization into clinical practice for hemodynamic assessment of patients with acute myocardial infarction.[209,210] These catheters allowed accurate measurement of important cardiovascular physiologic variables at the bedside, and their popularity soared. By the mid-1990s, estimated annual PAC sales in the United States approached 2 million catheters, with an estimated cost associated with their use in excess of $2 billion each year.[211]

The PAC provides measurements of several hemodynamic variables that many clinicians, including experts in intensive care, cannot predict accurately from standard clinical signs and symptoms.[212] However, it remains uncertain whether PAC monitoring leads to improved patient outcome.[213]

Pulmonary Artery Catheterization

PACs can be placed from any of the central venous cannulation sites described earlier, but the right internal jugular vein is preferred because it provides the most direct route to the right heart chambers. The procedure is conducted in a manner similar to that for central venous cannulation. However, before PAC insertion, a slightly larger skin nick is made to accommodate a large-bore introducer sheath with a hemostasis valve at its outer end and a side-arm extension for intravenous access. A tapered-tip, stiff dilator stylet is placed inside an introducer sheath to facilitate passage into the vein. Utmost care must be exercised when introducing this large dilator-cannula assembly by advancing it only to the depth required to enter the vein and then threading the introducer into the vein. Finally, the guidewire and dilator are removed, and the introducer sheath is sutured in place.

The standard PAC has a 7.0- to 9.0-Fr circumference, is 110 cm in length marked at 10-cm intervals, and contains four

internal lumens. The distal port at the catheter tip is used for monitoring of PAP, whereas the second is 30 cm more proximal and is used for monitoring of CVP. The third lumen leads to a balloon near the tip, and the fourth houses wires for a temperature thermistor, the end of which lies just proximal to the balloon.

The steps in placing a PAC require the aid of a skilled assistant. Before insertion, the PAC is passed through a sterile sheath that attaches to the hub of the introducer and allows sterile manipulation of PAC position during use. The assistant attaches the distal and proximal port hubs to pressure transducers and flushes them to ensure proper function and exclude air from the system. The balloon is tested by filling it completely with 1.5 mL of air from a volume-limited syringe to ensure symmetry of expansion and patency. The air-filled balloon at the tip of the catheter serves to "float" the catheter forward with blood flow through the right heart chambers and into its proper position in the pulmonary artery.

It is important to check the assembly for proper function. When the tip of the PAC is held near heart level, the recorded pressure should be 0 mm Hg, thus confirming that the transducer was correctly adjusted at the beginning of the procedure. The catheter tip is then raised up straight to create a 30-cm-tall vertical fluid column, which should produce a pressure of 22 mm Hg (equivalent to 30 cm H_2O) on the bedside monitor.

The PAC is then inserted through the hemostasis valve of the introducer to a depth of 20 cm or approximately 5 cm beyond the tip of the introducer sheath. A characteristic CVP waveform should be visible. The gentle curvature of the PAC should be oriented to point just leftward of the sagittal plane (the 11-o'clock position as viewed from the patient's head) to facilitate passage through the anteromedially located tricuspid valve. The balloon is inflated and the catheter is advanced into the right atrium; through the tricuspid valve, right ventricle, and pulmonic valve; into the pulmonary artery; and finally into the wedge position. Characteristic waveforms from each of these locations confirm proper catheter passage and placement (Fig. 40-27).

After PAWP is measured, the balloon is deflated and the PAP waveform should reappear. Wedge pressure may be obtained as needed by reinflating the balloon and allowing the catheter to float distally until pulmonary artery occlusion occurs again. The clinician must recognize that the tip of the PAC advances to a smaller pulmonary artery each time that the balloon is inflated to measure wedge pressure. In some patients the PAC may migrate distally even without balloon inflation. This problem is more common during cardiopulmonary bypass because of the repeated cardiac manipulations and temperature changes, which alter the stiffness of the catheter.[214] Consequently, proper catheter position must be ensured throughout the monitoring period by frequent observation of the pressure waveform. If a PAWP trace appears without balloon inflation or with only partial balloon inflation, the balloon should be deflated and the catheter withdrawn several centimeters to reduce the risk of pulmonary vascular injury. Although the external protective sleeve covering the PAC is intended to maintain sterility during these minor adjustments, the sleeve does not preclude contamination. Therefore, PACs should be manipulated only as necessary to maintain a proper safe location.[215]

Additional Guidelines for Placement of Pulmonary Artery Catheters

From a right internal jugular vein puncture site, the right atrium should be reached when the PAC is inserted 20 to 25 cm, the right ventricle at 30 to 35 cm, the pulmonary artery at 40 to 45 cm, and the wedge position at 45 to 55 cm. When other sites are chosen for catheter placement, additional distance is required, typically an extra 5 to 10 cm from the left internal jugular and left and right external jugular veins, 15 cm from the femoral veins, and 30 to 35 cm from the antecubital veins.[216] These distances serve only as a rough guide, and waveform morphology must always be verified and catheter position confirmed with a chest radiograph as soon as practical. The tip of the PAC should be within 2 cm of the cardiac silhouette on a standard anteroposterior chest film.[217]

Keeping in mind these typical distances helps avoid complications caused by unintended catheter loops and knots within the heart. If a right ventricular waveform is not observed after inserting the catheter 40 cm, coiling in the right atrium is likely. Similarly, if a pulmonary artery waveform is not observed after inserting the catheter 50 cm, coiling in the right ventricle has probably occurred. The balloon should be deflated, the catheter withdrawn to 20 cm, and the PAC floating sequence repeated.

Although the right internal jugular vein is the primary site for catheterization of the pulmonary artery, failure to achieve venous cannulation or other medical and surgical considerations may require the use of alternative sites. For cardiac surgery, the

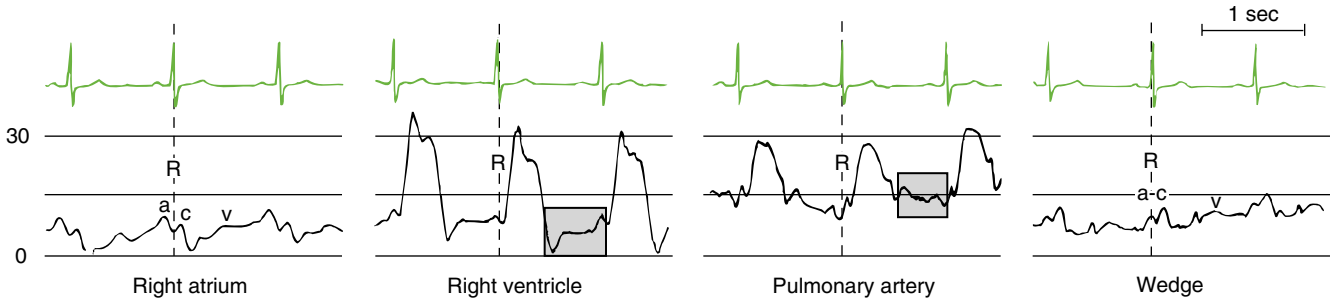

Figure 40-27 Characteristic waveforms recorded during passage of the pulmonary artery catheter. Right atrial pressure resembles a central venous pressure waveform and displays a, c, and v waves. Right ventricular pressure shows higher systolic pressure than seen in the right atrium, although the end-diastolic pressures are equal in these two chambers. Pulmonary artery pressure shows a diastolic step-up when compared with ventricular pressure. Note also that right ventricular pressure increases during diastole whereas pulmonary artery pressure decreases during diastole (*shaded boxes*). Pulmonary artery wedge pressure has a similar morphology to right atrial pressure, although the a-c and v waves appear later in the cardiac cycle relative to the electrocardiogram. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998, Fig. 3-1.)*

left internal jugular vein is often the second choice because a PAC inserted by the subclavian route may be compressed and kinked under the clavicle, thus making it extremely difficult to withdraw or advance after sternotomy.[219]

Regardless of the intended surgical procedure, whenever one plans to insert a PAC through the left internal jugular, subclavian, and particularly the external jugular veins, the more tortuous course of these vessels may make it difficult to advance the large-bore introducer sheath fully into the vessel. This is not a problem as long as the introducer cannula is withdrawn slightly to maintain a position in the vein that allows unimpeded intravenous infusion and free aspiration of venous blood. Frequently, the introducer cannula needs to remain in this partially inserted position while the PAC is introduced through its hemostasis valve. Because the tip of the PAC is more flexible and smaller than the tip of the introducer, the PAC might advance easily and completely into the central vein and right atrium. The PAC balloon may then be inflated and the procedure completed in the normal fashion with the PAC serving as the de facto guidewire. Occasionally, the introducer sheath must remain partially or completely withdrawn to avoid acute angulation and kinking of the PAC as it leaves the sheath and enters the central vein.[218,219]

After successful venous cannulation, if attempts to advance the PAC to the right ventricle prove difficult, the physician should consider whether this difficulty might result from abnormal venous anatomy. The most common abnormality of the systemic veins is persistence of the left superior vena cava, which is present in approximately 0.1% to 0.2% of the general population and 2% to 9% of patients with other forms of congenital heart disease.[220,221] A persistent left superior vena cava descends along the left mediastinum and empties into a dilated coronary sinus. As a result of its benign nature, virtually all cases are asymptomatic and discovered incidentally at the time of failed central venous or pulmonary artery catheterization. Because a normal right superior vena cava is present in most of these patients, the anomaly is recognized only when attempted PAC placement proceeds from a left-sided vein. More rarely, difficult PAC placement is encountered during attempted right-sided venous cannulation because the right superior vena cava is absent as well. In these cases, the right internal jugular vein joins the persistent left superior vena cava by a bridging innominate vein. A rare form of atrial septal defect, termed *unroofed coronary sinus*, may also be encountered in these patients and provide coronary sinus–left atrial communication and the potential for a PAC to enter the left atrium and systemic circulation.[221] With any of these venous anomalies, advancement of the PAC into the coronary sinus may disclose an unexpected pressure waveform, coronary sinus pressure. This waveform has characteristics of both the downstream right atrial pressure and an indirectly transmitted, dampened left ventricular pressure waveform.

A few additional points might aid successful positioning of the PAC. The air-filled balloon tends to float to nondependent regions as it passes through the heart into the pulmonary vasculature. Consequently, positioning a patient head down will aid flotation past the tricuspid valve, and tilting the patient onto the right side and placing the head up will encourage flotation out of the right ventricle.[222] Deep inspiration during spontaneous ventilation will increase venous return and right ventricular output transiently and may facilitate catheter flotation in a patient with low cardiac output. On occasion, a catheter may be floated to proper position when stiffened by injecting 10 to 20 mL of an iced solution through the distal lumen. Finally, a catheter that is initially difficult to place may be positioned easily when hemodynamic conditions change, as commonly occurs after induction of general anesthesia and initiation of positive-pressure ventilation.

Complications of Pulmonary Artery Catheter Monitoring

Complications of PAC use may be divided into several groups: those resulting from catheter placement, those associated with the in vivo presence of the catheter, and those resulting from catheter use and misuse. For the most part, problems encountered during catheter placement are the same for both PAP and CVP monitoring (see Box 40-5). However, catheterization of the right ventricle and pulmonary artery causes complications uniquely associated with PACs (Box 40-6).

When all adverse effects from PAC use are considered, including self-limited arrhythmias observed during catheter insertion, it appears that minor complications occur in more than 50% of catheterized patients.[211] However, major morbidity specifically attributable to PAC use is uncommon.[223] In both an initial exhaustive review of the literature and in its 2003 update, the American Society of Anesthesiologists Task Force on Pulmonary Artery Catheterization emphasized that the reported incidence of complications from PAC monitoring varies widely, although it seems that serious complications occur in 0.1% to 0.5% of PAC-monitored surgical patients.[211] In 1984, Shah and coworkers reported the use of PACs in 6245 patients undergoing cardiac and noncardiac operations.[149] Quite remarkably, only 10 patients (0.16%) had serious complications resulting in morbidity and only 1 patient (0.016%) died as a result of pulmonary artery catheterization. Furthermore, a 1998 European report of PAC use in 5306 patients undergoing cardiac surgery confirmed this low incidence of major morbidity, with injury to the right ventricle or pulmonary artery occurring in only 4 patients (0.07%).[224] Finally, only 1 of 2000 adverse events reported in the Australian Incident Monitoring Study of 1993 involved the use of a PAC, in contrast to 64 adverse events involving access to the arterial or venous

Box 40-6 Complications of Pulmonary Artery Catheter Monitoring

- Catheterization
  - Arrhythmias, ventricular fibrillation
  - Right bundle branch block, complete heart block
- Catheter residence
  - Mechanical, catheter knots
  - Thromboembolism
  - Pulmonary infarction
  - Infection, endocarditis
  - Endocardial damage, cardiac valve injury
  - Pulmonary artery rupture
  - Pulmonary artery pseudoaneurysm
- Misinterpretation of data
- Misuse of equipment

systems.[46] However, it is important to acknowledge that although these large studies indicate a low incidence of serious complications attributable to the use of PACs, the frequency of complications in a particular clinical setting or patient group remains unknown.

Arrhythmias are the primary complication observed during pulmonary artery catheterization. In fact, self-limited atrial or ventricular arrhythmias are so common during PAC passage through the heart that most clinicians do not consider them complications, but instead confirmation that the PAC is traversing the cardiac chambers appropriately. Shah and associates observed transient premature ventricular contractions in 68% and atrial dysrhythmias in 1.3% of their catheterized patients.[149] Of greater clinical significance, persistent ventricular dysrhythmias requiring treatment occurred in only 3.1% of patients, none of whom suffered prolonged hemodynamic instability. Although the balloon-tipped PAC is less arrhythmogenic when it strikes the endocardium than a standard intravenous catheter or transvenous pacing wire is, PACs have been reported to induce sustained atrial fibrillation, ventricular tachycardia, and even ventricular fibrillation.[222,224,225]

Prophylactic use of intravenous lidocaine before pulmonary artery catheterization is not effective in reducing ventricular ectopy.[226] When such problems arise, the balloon should be deflated and the catheter withdrawn to the right atrium. When hemodynamically significant dysrhythmias develop hours or even days after placement, it is unlikely that the PAC is responsible. However, the position of the catheter tip should always be checked by observation of the pressure waveform and chest radiograph to identify catheters that have migrated back into the right ventricle.

As the PAC passes through the right ventricle and strikes the interventricular septum, transient right bundle branch block occurs in up to 5% of patients.[227,228] This is of no clinical significance except in patients with preexisting left bundle branch block. In these patients, complete heart block may be precipitated, although this is rare. Shah and coworkers catheterized 113 patients with preexisting left bundle branch block, and complete heart block developed in only 1 patient (0.9%).[149] In a different population of 47 high-risk patients with left bundle branch block, many of whom had acute myocardial infarction or heart failure, Morris and colleagues inserted 82 PACs without a single episode of complete heart block for the initial 24-hour period.[227] However, transcutaneous pacing equipment, an external pulse generator, and a temporary transvenous pacing wire or pacing PAC should be readily available as a precaution, especially since the onset of heart block in this setting may be delayed.

A dizzying array of mechanical problems have been reported with PACs or introducer sheaths since their introduction into clinical use. In the setting of cardiac surgery, PACs may be damaged by surgical instruments or become entrapped in sutures or bypass cannulas.[149,229-231] Whenever right heart structures are involved, it is prudent to ensure free movement of the PAC before chest closure. Sternal retraction during cardiac surgery may pose other problems, particularly when the PAC is inserted via the external jugular or subclavian route. The PAC may kink as it exits the introducer sheath and makes an acute angle between the sheath and vessel wall.[218,219] These mechanical difficulties should be suspected whenever there is a damped appearance of the monitored pressure trace or difficulty infusing fluids or withdrawing blood through one of the catheter lumens.

Although gross structural defects in the catheter itself should be recognized by inspection of the catheter before insertion, more subtle manufacturing problems may escape detection. Some, such as communications between the PAP, CVP, and balloon inflation lumens, may be suspected only when the data are contradictory or inconsistent.[232,233]

PACs may dislodge temporary transvenous pacing wires, become entangled with other cardiac catheters, or form knots within the heart.[234,235] Arnaout and coauthors reported a PAC knot around the tricuspid valve chordae tendineae that resulted in severe tricuspid valve regurgitation after catheter removal.[234] Catheter knots should be suspected when there is difficulty withdrawing a PAC, and the diagnosis may be confirmed by chest radiography. Knots may be untied by radiologists with the use of intravascular snares and fluoroscopic guidance.[236] If the knot has already been drawn tight, surgical exploration and removal are usually required.

Although the incidence of thromboembolic complications is increased in patients who require PAC monitoring for longer periods, thrombi have been detected on PACs within hours of placement.[237] When drugs such as aprotinin and ε-aminocaproic acid are used to reduce perioperative bleeding, the risk of thrombus formation on the PAC may be increased.[238,239] Although heparin bonding to the external surface has unquestionably reduced the thrombogenicity of PACs, it does not entirely eliminate the possibility.[237,240] Fortunately, major pulmonary embolism is a rare occurrence.[241]

The incidence of PAC-related infection increases after 3 days of continuous monitoring and in patients with preexisting sepsis.[242] The most catastrophic of these infections is endocarditis, most often of the right-sided valves.[243,244] Using sophisticated microbiologic techniques in 297 critically ill patients, Mermel and associates demonstrated a 22% incidence of local infection of the introducer sheath but only a 0.7% incidence of bacteremia related to the PAC.[245] In view of these findings, it is not surprising that scheduled PACs changes do not reduce the risk for bloodstream infection, particularly when the catheter is changed over a guidewire.[246] However, cannulation at a new site carries a significant risk of vascular complications. The specific risks and benefits must be weighed in each patient.

In addition to infectious injury, mechanical injury may also result from PAC use.[243,244] In a series of 55 autopsies of patients who had been monitored with a PAC, Rowley and colleagues identified right-sided endocardial lesions in 53%.[243] Even though both severe tricuspid regurgitation and severe pulmonic regurgitation have been reported, these complications of PAC use are rare.[234,244,247] Using color flow Doppler echocardiography, Sherman and coworkers demonstrated that placement of a PAC caused a slight increase in the magnitude of tricuspid regurgitation, but in no instances did the PAC lead to severe right-sided valvular insufficiency.[248]

Pulmonary artery rupture, the most deadly but also the most preventable of complications, occurs in approximately 0.02% to 0.2% of catheterized patients and appears to carry a mortality rate of 50%.[149,249] Several factors appear to increase the risk for this catastrophic event, including hypothermia, anticoagulation, and advanced age, although many reported cases involve heart transplant procedures.[249-251] Pulmonary hypertension may also possibly predispose patients to arterial injury during balloon inflation because of the increased gradient between proximal arterial and distal wedge pressure or because pulmonary hyper-

tension distends the pulmonary vasculature and causes the PAC to wedge in a distal, less compliant vessel.[252]

Several mechanisms of pulmonary artery injury have been proposed and investigated, including forceful inflation of the PAC balloon and chronic erosion by the catheter tip abutting the vessel wall or eccentric balloon inflation forcing the uncushioned catheter tip through the vessel wall.[251,253] Regardless of the precise mechanism by which pulmonary arterial injury occurs, case reports highlight that this complication often results from suboptimal catheter insertion and management techniques. Procedural errors include unnecessary catheter manipulation, excessive insertion depth, unrecognized persistent wedge pressure, prolonged balloon inflation, or improper balloon inflation with liquid rather than air.[252-254] It is critical that the clinician recognize artifactual "overwedged" pressure recordings that indicate peripheral location of the PAC tip or impaction against the vessel wall and correct this problem immediately by withdrawing the catheter into the proximal pulmonary artery (see later).

The hallmark of catheter-induced pulmonary artery rupture is hemoptysis, which may cause life-threatening exsanguination or hypoxemia. Less commonly, occult hypotension or respiratory compromise may develop. If the visceral pleura fails to contain the bleeding, free rupture into the pleural space produces a large hemothorax. When time allows, a chest radiograph helps make the diagnosis by revealing the hemothorax or a new infiltrate near the tip of a distally positioned PAC. Although its initial appearance may be confused with catheter-related pulmonary infarction, its pattern of resolution and clinical course differentiate these diagnoses. In confusing cases the diagnosis may be made by performing a wedge angiogram, in which radiopaque dye injected through the wedged PAC will extravasate into the pulmonary parenchyma and thus identify the site of arterial disruption.[250]

Treatment of pulmonary artery rupture focuses on resuscitation and immediate control of the hemorrhage. Specific therapeutic steps are highly individualized, depending on the setting. The first priority is ensuring adequate oxygenation and ventilation, which may require endobronchial intubation with either a single- or double-lumen endotracheal tube to selectively ventilate and protect the unaffected lung. In addition, positive end-expiratory pressure (PEEP) applied to the affected lung may help control hemorrhage.[255] Any anticoagulation should be reversed unless the patient must remain on cardiopulmonary bypass and bronchoscopy is performed to localize and control the site of bleeding. A bronchial blocker may be guided into the involved bronchus to tamponade the bleeding and prevent contamination of the uninvolved lung.[256] Management of the PAC itself is more controversial. Some experts recommend removing the catheter, but others suggest leaving the PAC in place to monitor PAP and guide antihypertensive therapy targeted at lowering this pressure and reducing bleeding.[257,258] Others have suggested that the PAC balloon may be carefully reinflated and the catheter floated into the involved pulmonary artery to occlude the bleeding arterial segment as a temporizing measure.[256] Although these techniques may be effective in some cases, many patients will require definitive surgical therapy, such as oversewing the involved pulmonary artery or resecting the involved segment, lobe, or lung.[250,256] In addition, some authors have recommended distant follow-up with angiography to rule out pseudoaneurysm formation in those managed conservatively because of the high morbidity associated with secondary hemorrhage.[249,256,259,260]

A more insidious but possibly more common complication of PAC use is misinterpretation of data.[261,262] Although the magnitude of the problem is not clear, there is reason to believe that there are widespread knowledge deficits among practitioners who use PACs. In 1990, Iberti and coauthors reported the results of a 31-question multiple-choice examination taken by 496 resident and staff physicians in the medicine, surgery, and anesthesiology departments in 13 North American medical centers. The authors found a poor overall level of knowledge of PACs, as evidenced by a mean score of only 67% correct answers. Although higher scores were demonstrated by individuals with more training and more experience inserting and using catheter-derived information, none of these factors ensured a high level of knowledge.[263] These results have been duplicated in a variety of other specialty care groups.[264] It is especially concerning that PAWP measurement was performed incorrectly by 30% to 50% of the clinicians in these studies and that educational programs failed to improve performance.[265,266] Taken together, these observations highlight the fact that effective use of PACs requires a great deal of expertise and clinical experience and that even measuring the most fundamental PAC-derived variable, namely, wedge pressure, is a complicated endeavor.[267]

Physiologic Considerations for Pulmonary Artery Catheter Monitoring: Prediction of Left Ventricular Filling Pressure

Pulmonary artery catheterization allows measurement of a variety of hemodynamic variables, including cardiac output, mixed venous oxygen saturation, and most important, pulmonary artery diastolic and wedge pressure. These values, in turn, are used to estimate left ventricular filling pressure and, in combination with other clinical information, help guide administration of fluid and vasoactive drugs.

When a PAC floats to the wedge position, the inflated balloon isolates the distal pressure-monitoring orifice from upstream PAP. A continuous static column of blood now connects the wedged PAC tip to the junction of the pulmonary veins and left atrium. Thus, wedging the PAC, in effect, extends the catheter tip to measure the pressure at the point at which blood flow resumes on the venous side of the pulmonary circuit. Because resistance in the large pulmonary veins is negligible, PAWP provides an accurate, indirect measurement of both pulmonary venous pressure and LAP.[50,268]

Pulmonary artery diastolic pressure (PADP) is often used as an alternative to PAWP to estimate left ventricular filling pressure. This is acceptable in normal circumstances because when pulmonary venous resistance is low, the pressure in the pulmonary artery at the end of diastole will equilibrate with downstream pressure in the pulmonary veins and left atrium.[269,270] From a monitoring standpoint, PADP has the added advantage of being available for continuous monitoring, whereas PAWP is measured only intermittently.

For PADP or PAWP to be valid estimates of left ventricular filling pressure, the column of blood connecting the tip of the wedged catheter and the draining pulmonary vein must be continuous and static. At the microcirculatory level, this channel consists of pulmonary capillaries that are subject to external compression by surrounding alveoli. West and colleagues described a

three-zone model of the pulmonary vasculature based on the gravitationally determined relationships between relative pressure in the pulmonary arteries, the pulmonary veins, and the surrounding alveoli.[271] This model provides useful insight into conditions when PAC measurements are erroneous.

In West zone 1, alveolar pressure exceeds that in both the pulmonary artery and the pulmonary veins, whereas in zone 2, it is intermediate between these two pressures (Fig. 40-28). A PAC positioned in both zone 1 and 2 will be highly susceptible to alveolar pressure, and measurements will reflect alveolar or airway pressure rather than left ventricular filling pressure. As such, the tip of the PAC must lie in zone 3 for PAWP measurements to be accurate. In most clinical settings, a supine position of the patient favors zone 3 conditions, a finding that has been confirmed by radiographic studies.[272] However, when patients are placed in the lateral or semi-upright position, zone 2 may expand significantly. In general, zones 1 and 2 become more extensive when LAP is low, when the PAC tip is located vertically above the left atrium, or when alveolar pressure is high. Clues to an incorrectly positioned catheter include absence of normal PAWP a and v waves, marked respiratory variation in PAWP, and a PADP that exceeds the PAWP measurement without excessively tall a or v waves visible on the trace.[49]

Normal Pulmonary Artery and Wedge Pressure Waveforms

As the balloon-tipped PAC is floated to its proper position in the pulmonary artery, characteristic pressure waveforms are recorded (see Fig. 40-27). In the superior vena cava or right atrium, a CVP waveform should be observed, with its a, c, and v waves and low mean pressure. At this point the PAC balloon is inflated and the catheter advanced until it crosses the tricuspid valve to record right ventricular pressure, which is characterized by a rapid systolic upstroke, a wide pulse pressure, and low diastolic pressure. The PAC next enters the right ventricular outflow tract and floats past the pulmonic valve into the main pulmonary artery. Premature ventricular beats are common during this period as the balloon-tipped catheter strikes the right ventricular infundibular wall. Entry into the pulmonary artery is heralded by a step-up in diastolic pressure and a change in waveform morphology.

On occasion it may be difficult to distinguish right ventricular pressure from PAP, particularly if only the numeric values for these pressures are examined. However, careful observation of the pressure waveform by focusing on the diastolic pressure contours allows differentiation. During diastole, PAP will fall because of interruption of flow during pulmonic valve closure, while simultaneously, pressure in the right ventricle will increase because of filling from the right atrium (see Fig. 40-27).[216]

Under normal conditions, the PAP upstroke slightly precedes the radial artery pressure upstroke because of the longer duration of left ventricular isovolumic contraction, as well as the time required for propagation of the pressure wave to a distal monitoring site. As a practical matter, though, the pulmonary and systemic arterial pressure waveforms appear to overlap on the bedside monitor (Fig. 40-29). Understanding these temporal relationships is critically important for proper interpretation of abnormal pulmonary artery and wedge pressure waveforms, particularly when tall v waves are present (see later).

As noted previously, wedge pressure is an indirect measurement of pulmonary venous pressure and LAP and should therefore resemble these venous waveforms, with characteristic a and v waves and x and y descents. However, because of interposition of the pulmonary vascular bed between the PAC tip and left atrium, wedge pressure is a delayed representation of LAP.[268] On average, 160 msec is required for the LAP pulse to traverse the pulmonary veins, capillaries, arterioles, and arteries. As a consequence of this delay, the wedge pressure a wave appears to follow the ECG R wave in early ventricular systole even though the a wave is an end-diastolic event (see Fig. 40-29).

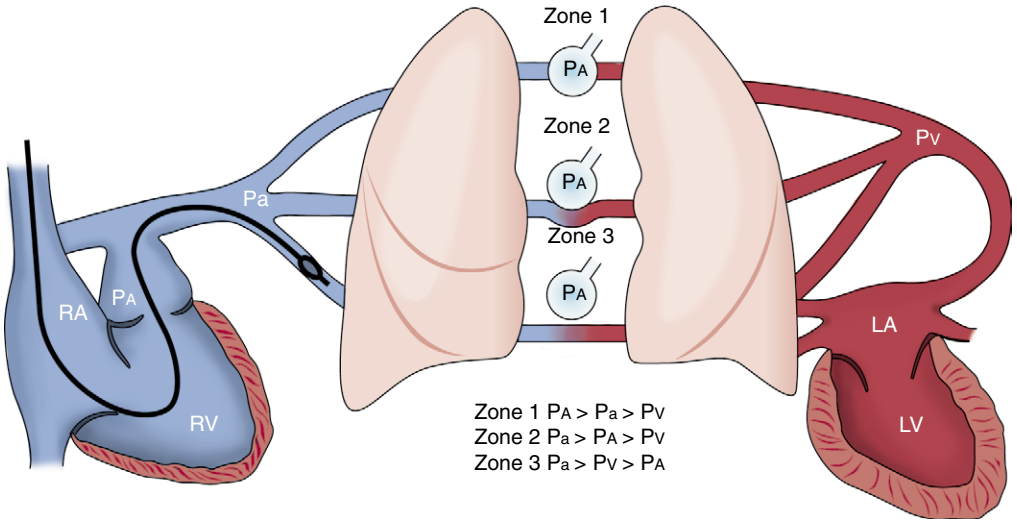

Figure 40-28 The tip of the pulmonary artery catheter must be wedged in lung zone 3 to provide an accurate measure of pulmonary venous (Pv) or left atrial (LA) pressure. When alveolar pressure (PA) rises above Pv in lung zone 2 or above pulmonary arterial pressure (Pa) in lung zone 1, wedge pressure will reflect alveolar pressure rather than intravascular pressure. LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998, Fig. 6-10.)*

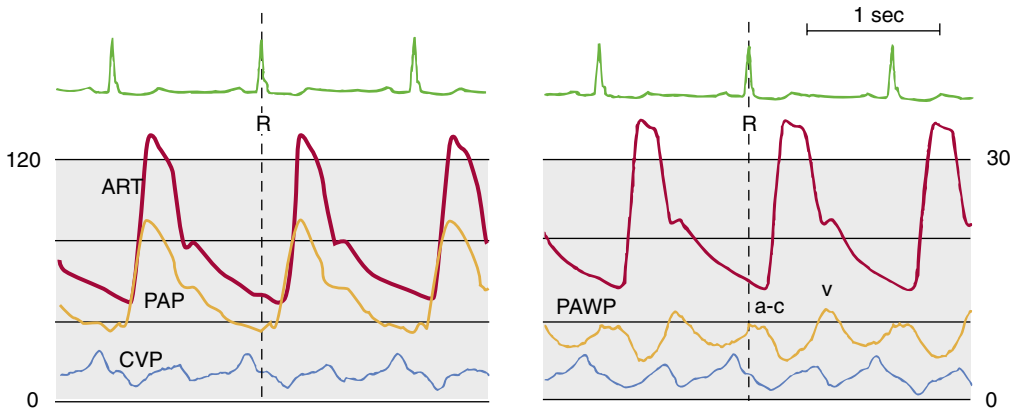

Figure 40-29 Temporal relationships between normal systemic arterial pressure (ART), pulmonary artery pressure (PAP), central venous pressure (CVP), and pulmonary artery wedge pressure (PAWP). Note that the PAWP a-c and v waves appear to occur later in the cardiac cycle than their counterparts on the right side of the heart seen in the CVP trace. The ART scale is on the *left*; the PAP, CVP, and PAWP pressure scales are on the *right*. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998, Fig. 3-3.)*

To recognize prominent a or v waves in the wedge pressure trace, it is not always necessary to inflate the PAC balloon. Because the PCWP trace reflects pressure waves transmitted in retrograde fashion from the left atrium, these waves will not normally be visible within the antegrade PAP waves produced by right ventricular ejection. In the setting of prominent a or v waves, the PAP trace becomes a composite wave that reflects both retrograde and antegrade components. Tall left atrial a or v waves will distort the normal PAP waveform appearance, with the a wave inscribed at the onset of the systolic upstroke and the v wave distorting the dicrotic notch (Fig. 40-30).[268,273] Once these waves are identified by wedging the PAC and comparing the PAP and PAWP traces, it is wise to "follow" the "wedge pressure" a and v waves in the unwedged PAP trace rather than repeatedly inflating the balloon.

In summary, PAWP measured with a balloon-tipped PAC provides a delayed, damped estimate of LAP by measuring the pressure near the junction of the pulmonary veins and the left atrium. Mean wedge pressure should be lower than mean PAP; otherwise, blood would not flow in an antegrade direction. The PAWP waveform should display small but visible a and v waves if the pressure trace is displayed with sufficient gain and resolution on the monitor screen.

Left Atrial Pressure, Pulmonary Artery Wedge Pressure, and Pulmonary Capillary Pressure

The most common technique for monitoring LAP during cardiac surgery involves catheterization of the left atrium with a thin catheter introduced through the right superior pulmonary vein and secured with a purse-string suture. The catheter is brought out through the skin beneath the xiphoid process and attached to a closed pressure monitoring system. Because LAP monitoring is discontinued simply by withdrawing the left atrial catheter through the skin, transseptal methods for LAP monitoring during surgery have been proposed to reduce the risk of bleeding after catheter removal.[274]

Today, direct LAP monitoring has largely been supplanted by PAC monitoring, no doubt because the latter provides a wider array of hemodynamic data. Furthermore, PAWP generally provides an excellent estimate of LAP after cardiac surgery.[275,276] On the other hand, there are a host of pathophysiologic conditions that alter the relationships between PADP, PAWP, and LAP and lead to erroneous measurements and potential clinical errors (see later).

Direct LAP monitoring continues to be particularly useful in pediatric patients undergoing complex congenital heart surgery, in part because of technical difficulties in this patient population. Gold and coauthors reported complications from left-sided monitoring occurring in only 0.68% of 2393 catheters.[277] However, direct access to the left heart chambers carries the grave risk of air and particulate embolization to the systemic circulation, especially during routine flushing of the lines.

Catheter removal may result in bleeding, the most common complication from LAP catheters. Consequently, these lines must be removed before the mediastinal chest drains, and if attempted withdrawal is met with resistance, surgical re-exploration is required. More unusual complications include catheter entrapment in mechanical aortic or mitral valve prostheses, fistulas between the right superior pulmonary vein and the right mainstem bronchus, and embolization of catheter fragments.[277-279]

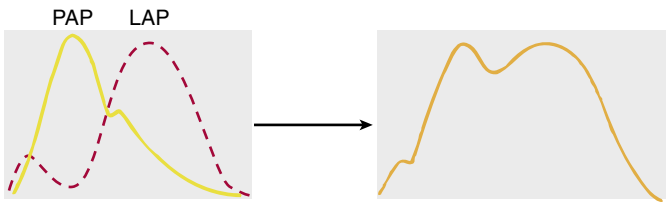

Figure 40-30 Tall left atrial pressure (LAP) a and v waves transmitted in a retrograde direction through the pulmonary vasculature distort the antegrade pulmonary artery pressure (PAP) waveform. The LAP a wave distorts the systolic upstroke, and the v wave distorts the dicrotic notch. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998, Fig. 4-10.)*

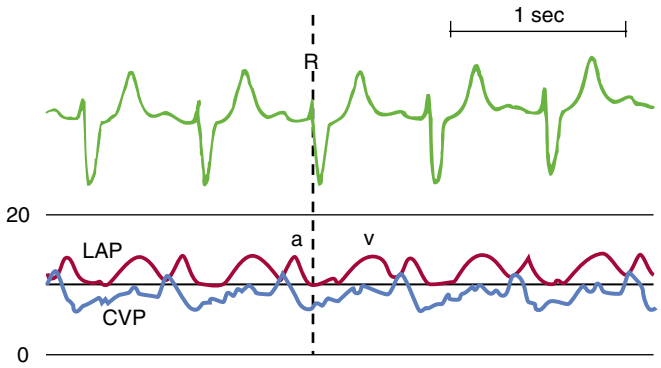

Figure 40-31 Normal temporal relationships between the electrocardiographic, central venous pressure (CVP), and left atrial pressure (LAP) traces. The LAP and CVP waveforms have nearly identical morphologies, although the CVP a wave slightly precedes the LAP a wave. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998, Fig. 2-9.)*

Normal LAP waveforms resemble those from CVP catheters, although there are a few subtle morphologic distinctions. Because atrial depolarization originates in the sinoatrial node located at the junction of the superior vena cava and the right atrium, the right-sided a wave appears slightly earlier than the left-sided a wave (Fig. 40-31). Although the a wave is the most prominent pressure peak in a normal CVP trace, the v wave is often taller than the a wave in a normal LAP waveform, thus suggesting that atrial contraction is stronger on the right than the left and that the left atrium is less distensible than the right.[61] Finally, the interval between atrial and ventricular contraction is approximately 40 msec longer on the right than on the left.[61] Consequently, a and c waves are seen as separate waves in a right atrial pressure trace, whereas on the left they merge into a composite a-c wave. In the PAWP waveform, the c wave is obscured even further by the damping effect of the lung vasculature.

The terms *pulmonary artery wedge pressure* and *pulmonary artery occlusion pressure* are used interchangeably and refer to the same measurement obtained from the tip of a PAC after balloon inflation and flotation to the wedged position. However, pulmonary capillary pressure must not be confused with wedge pressure or LAP, nor should the term *pulmonary capillary wedge pressure* be used at all. The hydrostatic pressure in the pulmonary capillaries that causes edema formation according to the Starling equation is different from LAP. This is the pressure that must exceed LAP to maintain antegrade blood flow through the lungs. Although the magnitude of the difference between pulmonary capillary pressure and wedge pressure is generally small, it can increase markedly when resistance to flow in the pulmonary veins is elevated.[280] In most situations, the major component of PVR occurs at the precapillary, pulmonary arteriolar level. However, rare conditions such as pulmonary veno-occlusive disease may cause a marked increase in postcapillary resistance to flow. Similar situations arise in conditions that disproportionately increase pulmonary venous resistance, such as central nervous system injury, acute lung injury, hypovolemic shock, endotoxemia, and norepinephrine infusion.[273,274] Under these conditions, measurement of wedge pressure will underestimate pulmonary capillary pressure substantially and thereby underestimate the risk of hydrostatic pulmonary edema. Although pulmonary capillary pressure may be measured at the bedside by analyzing the decay in the PAP trace after PAC balloon inflation, these techniques have not been adopted widely in clinical practice.[281,282] To avoid confusion, the phrase "pulmonary capillary wedge pressure" should be abandoned because it is imprecise and misleading.

Abnormal Pulmonary Artery and Wedge Pressure Waveforms

PAC monitoring is subject to the same technical artifacts inherent in all invasive pressure monitoring techniques, as well as some additional problems unique to this method.[253,283,284] Because the PAC is longer and passes through the cardiac chambers, it is more prone to distortions from clot or air bubbles, and motion-related artifacts are more problematic. Artifactual pressure spikes may be distinguished from the underlying physiologic pressure waveform by their unique morphology and timing.

At the onset of systole, tricuspid valve closure accompanied by right ventricular contraction and ejection resulting in excessive catheter motion are responsible for the most common PAC trace artifact.[283,285] Note that this pressure artifact occurs simultaneous with the CVP c wave and may produce either an artificially low pressure or a pressure peak. If the monitor detects this inappropriate pressure nadir, it may erroneously be designated as PADP (Fig. 40-32). Repositioning the PAC often solves the problem.

Another common artifact in PAC pressure measurement occurs when the balloon is overinflated and occludes the lumen orifice. This phenomenon is termed *overwedging* and is usually caused by distal catheter migration and eccentric balloon infla-

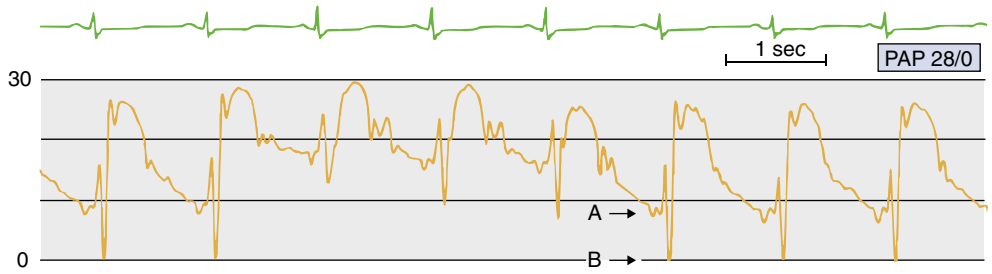

Figure 40-32 Artifactual pressure peaks and troughs in the pulmonary artery pressure (PAP) waveform caused by catheter motion. The correct value for pulmonary artery end-diastolic pressure is 8 mm Hg (A), although the monitor digital display erroneously reports the PAP as 28/0 mm Hg (B). *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998, Fig. 5-6.)*

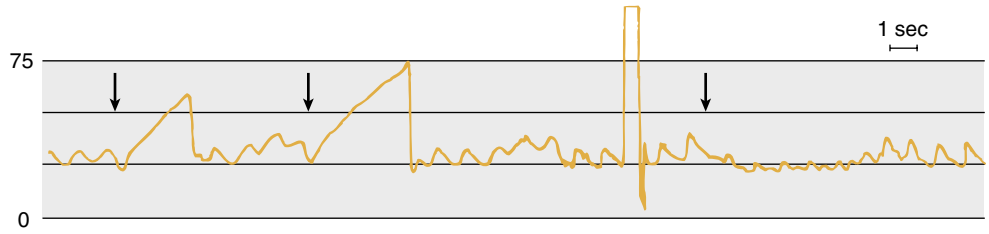

Figure 40-33 Overwedging of the pulmonary artery (PA) catheter causes artifactual waveform recordings. The first two attempts to inflate the PA catheter balloon (first *two arrows*) produce a nonpulsatile increasing pressure caused by an occluded catheter tip. After the catheter is withdrawn slightly, balloon inflation allows proper wedge pressure measurement (*third arrow*). Before the third attempt at balloon inflation, the PA pressure lumen is flushed, which restores the appropriate pulsatile pressure detailed to the PA and wedge pressure waveforms on the right side of the trace. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998, Fig. 5-7.)*

tion, which forces the catheter tip against the vessel wall. The catheter now records a gradually rising pressure produced by the continuous flush system and builds up pressure against the obstructed distal opening (Fig. 40-33). For a catheter that has migrated to a more distal position, it is possible for overwedging to occur without balloon inflation. Note that the overwedged pressure is devoid of pulsatility, is higher than expected, and rises continuously to the flush pressure. Such a pattern should arouse suspicion and prompt corrective action.

As emphasized earlier, with each PAC balloon inflation and wedge measurement, the catheter tip migrates distally. When a wedge pressure tracing appears during partial balloon inflation, it suggests that the PAC is inappropriately located in a smaller, distal branch of the pulmonary artery. The catheter should be withdrawn before overwedging results in vascular injury or pulmonary infarction.

Pathophysiologic conditions involving the left-sided cardiac chambers or valves produce characteristic changes in the pulmonary artery and wedge pressure waveforms. One of the characteristics of these waveforms is the tall v wave of mitral regurgitation. Unlike a normal wedge pressure v wave produced by late systolic pulmonary venous inflow, the prominent v wave of mitral regurgitation begins in early systole. Mitral regurgitation causes fusion of the c and v waves and obliteration of the systolic x descent because the isovolumic phase of left ventricular systole is eliminated as a result of retrograde ejection of blood into the left atrium.[208] Because the prominent v wave of mitral regurgitation is generated during ventricular systole, mean wedge pressure overestimates left ventricular filling pressure. Consequently, in cases of severe disease, left ventricular end-diastolic pressure is best estimated by measuring wedge pressure before onset of the regurgitant v wave (Fig. 40-34). Although mean wedge pressure exceeds left ventricular end-diastolic pressure in patients with severe mitral regurgitation, mean wedge pressure remains a good approximation for mean LAP. Retrograde pressure reflected by the regurgitant v wave contributes to left atrial hypertension and the subsequent risk of hydrostatic pulmonary edema.

When large v waves are present in the wedge pressure trace, it is critically important to recognize them and be able to distinguish the wedged from the unwedged pressure waveform. At first glance, a wedge trace with a tall systolic v wave resembles a typical unwedged PAP trace, but closer observation reveals a number of discriminating details. The PAP upstroke is steeper and slightly precedes the systemic arterial pressure upstroke, whereas a wedge tracing with a prominent v wave has a more gradual upstroke that begins after the radial artery pressure upstroke. Furthermore, the wedge pressure v wave reaches its peak later in the cardiac cycle, after the ECG T wave, as opposed to the simultaneous systemic and pulmonary arterial peaks (see Fig. 40-34).[208,286] Another distinguishing feature in patients with severe mitral regurgitation is the unusual morphology of the pulmonary artery waveform itself. The larger the v wave, the more the regurgitant v wave distorts the pulmonary artery waveform by giving it a bifid appearance and obscuring the normal end-systolic dicrotic notch (see Fig. 40-34).[273] Through recognition of these subtle but important diagnostic details, a clinician may assess the wedge pressure v wave by observing the unwedged PAP trace. This would eliminate the need for repeated balloon inflation and avoid the potential for catastrophic arterial rupture.

A close look at left atrial pressure-volume relationships helps explain the apparently paradoxical coexistence of severe mitral regurgitation and a normal PAWP trace.[287,288] Three factors determine whether mitral regurgitation produces a prominent v wave in the left atrial or wedge pressure traces: left atrial volume (often termed the patient's "volume status"), left atrial compliance, and regurgitant volume (Fig. 40-35). Given that the left atrial

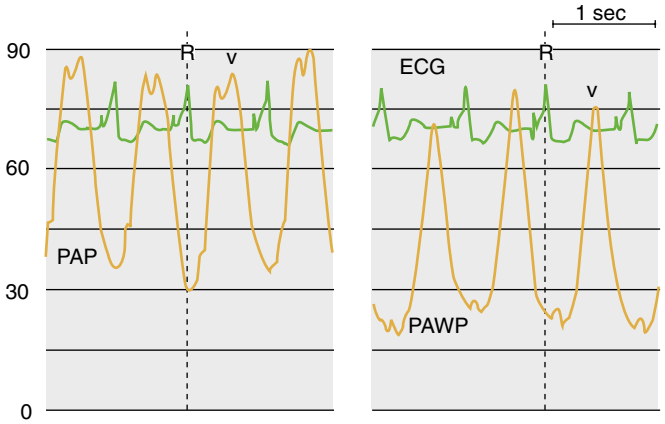

Figure 40-34 Severe mitral regurgitation. A tall systolic v wave is inscribed in the pulmonary artery wedge pressure (PAWP) trace and also distorts the pulmonary artery pressure (PAP) trace, thereby giving it a bifid appearance. The electrocardiogram (ECG) is abnormal because of ventricular pacing. Left ventricular end-diastolic pressure is estimated best by measuring PAWP at the time of the electrocardiographic R wave, before onset of the regurgitant v wave. Note that mean PAWP exceeds left ventricular end-diastolic pressure in this condition. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998, Fig. 17-11.)*

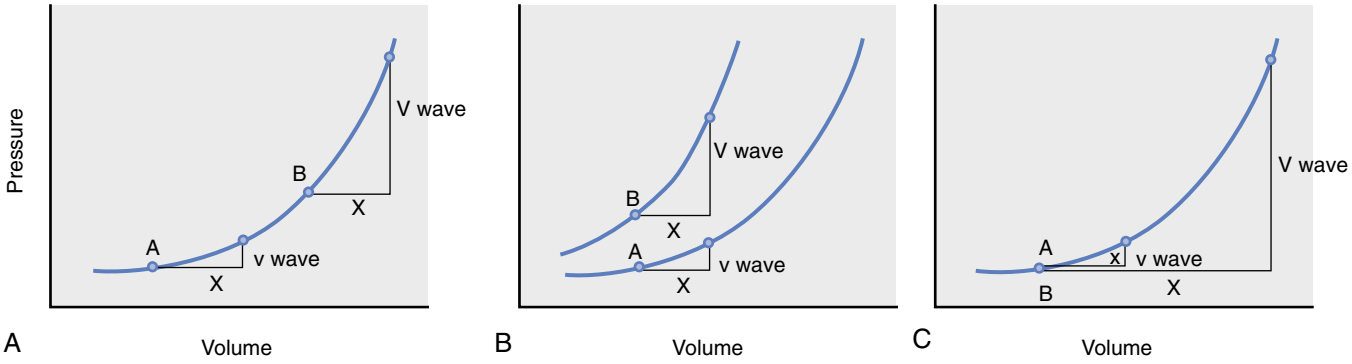

Figure 40-35 V wave height as an indicator of the severity of mitral regurgitation. Left atrial pressure-volume curves describe the three factors that determine v wave height. **A,** Influence of left atrial volume. For the same regurgitant volume (x), the left atrial v wave will be taller if baseline atrial volume is greater (point B versus point A). **B**, Influence of left atrial compliance. For the same regurgitant volume (x), the left atrial *v* wave will be taller if baseline atrial compliance is reduced (point B versus point A). **C,** Influence of regurgitant volume. Beginning at the same baseline left atrial volume (points A and B), if regurgitant volume increases (X versus x), the left atrial pressure v wave will increase (V versus v). *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998, Fig. 17-13.)*

pressure-volume relationship is not linear, the same volume of regurgitation will result in a variable increment in systolic pressure, depending on the preexisting atrial volume at the onset of systole. Furthermore, the nature of that relationship is dependent on the compliance (i.e., stiffness) of the left atrium. Although the total regurgitant volume of blood entering the left atrium will influence the height of the v wave, this clearly is not the only determinant of v wave magnitude. This may explain why patients with acute mitral regurgitation tend to have tall wedge pressure v waves—they have smaller, stiffer left atria with poorer compliance than patients with long-standing disease do. It is not surprising that wedge pressure v waves are neither sensitive nor specific indicators of the severity of mitral regurgitation, and the height of these waves should not be used in such a manner.[287] Prominent wedge pressure v waves may exist in the absence of mitral regurgitation when LAP is high, as might occur when the left atrium is compressed.[289] Tall v waves are also seen commonly in patients with hypervolemia, congestive heart failure, and ventricular septal defects.[287] Note that the giant v waves observed in patients with ventricular septal defects are not caused by retrograde flow, but rather excessive antegrade systolic flow into the left atrium as a result of the intracardiac shunt.[290]

In contrast to mitral regurgitation, which distorts the systolic portion of the wedge pressure waveform, mitral stenosis alters its diastolic aspect. In this condition, the holodiastolic pressure gradient across the mitral valve results in an increased mean wedge pressure, a slurred early diastolic y descent, and a tall end-diastolic a wave. Similar hemodynamic abnormalities are seen in patients with left atrial myxoma or whenever there is obstruction to mitral flow. Diseases that increase left ventricular stiffness (e.g., left ventricular infarction, pericardial constriction, aortic stenosis, and systemic hypertension) produce changes in wedge pressure that partly resemble those seen in mitral stenosis. In these conditions, mean wedge pressure is increased and the trace displays a prominent a wave, but the y descent remains steep because there is no obstruction to flow across the mitral valve during diastole. Because patients with advanced mitral stenosis often have coexisting atrial fibrillation, the a wave will not be present in many of these cases (Fig. 40-36).[208]

Myocardial ischemia may be detected with the PAC in several ways. Ischemia itself impairs left ventricular relaxation and thus results in diastolic dysfunction, a pattern particularly characteristic of demand ischemia associated with tachycardia or induced by rapid atrial pacing.[195,291,292] Impaired ventricular relaxation results in a stiffer, less compliant left ventricle, which leads to increased left ventricular end-diastolic pressure. Not only does this in turn increase left atrial and wedge pressure, but the morphology of these waveforms changes as well, with the phasic a and v wave components becoming more prominent as diastolic filling pressure increases.[293-295] Although myocardial ischemia will often be detectable as a rise in pulmonary artery diastolic, mean, or systolic pressure, these changes are generally less striking than the accompanying change in wedge pressure and the new appearance of tall a and v waves (Fig. 40-37). In patients with left ventricular ischemia, the tall wedge pressure a wave is produced by end-diastolic atrial contraction into a stiff, incompletely relaxed left ventricle.[296] Although the diastolic dysfunction accompanying myocardial ischemia leads to an increase in left ventricular end-diastolic pressure, this elevation in pressure often coexists with decreased left ventricular end-diastolic volume or preload.[195] The dissociation between filling pressure and filling volume in this condition must be appreciated to avoid diagnostic and therapeutic errors.

Myocardial ischemia also produces a characteristic pattern of left ventricular systolic dysfunction. Systolic dysfunction is the hallmark of supply ischemia, which is caused by a sudden reduction or cessation of coronary blood flow to a region of the myocardium.[292,297] With severe systolic dysfunction, changes in global left ventricular contractile performance may be detected by hemodynamic monitoring. As the ejection fraction falls significantly, left ventricular end-diastolic volume and pressure rise, and systemic arterial hypotension and elevated pulmonary diastolic and wedge pressure develop.[298] A more common hemodynamic manifestation of myocardial ischemia occurs when left ventricular geometry is distorted or when the region of ischemic myocardium underlies a papillary muscle and results in acute mitral regurgitation.[299] This form of mitral regurgitation is often termed "papillary muscle ischemia" or "functional mitral regurgitation." As noted earlier, PAC monitoring is particularly well suited to detect this event by revealing the onset of new regurgitant v waves in the pulmonary artery or wedge pressure traces (see Fig. 40-34).

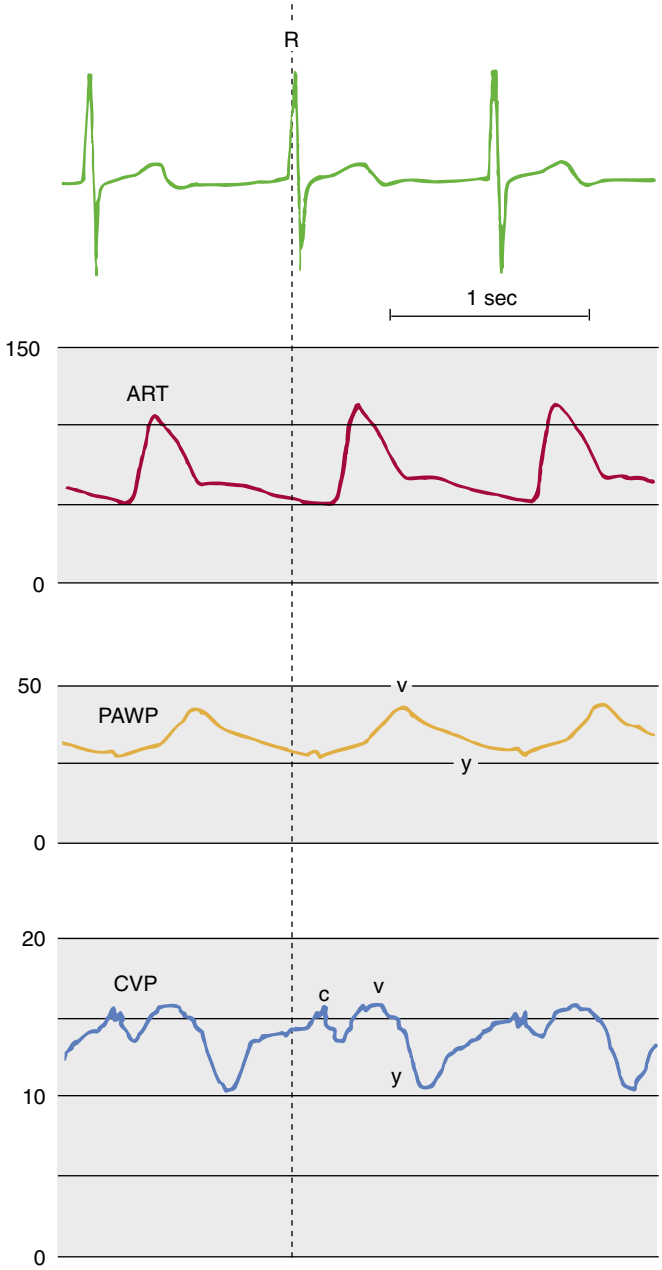

Figure 40-36 Mitral stenosis. Mean pulmonary artery wedge pressure (PAWP) is increased (35 mm Hg) and the diastolic y descent is markedly attenuated. Compare the slope of the y descent in the PAWP trace with the y descent in the central venous pressure (CVP) trace. In addition, compare this PAWP y descent with the PAWP y descent in mitral regurgitation (see Fig 40-34). A waves are not seen in the PAWP or CVP traces because of atrial fibrillation. ART, arterial blood pressure. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998,: Fig. 17-19.)*

Whether the PAC should be used in high-risk patients as a supplemental monitor for detection of myocardial ischemia remains controversial.[295,300-302] None of the current methods for detecting perioperative myocardial ischemia are perfectly sensitive or specific. Although patients with left ventricular ischemia are likely to have higher mean wedge pressure than those without ischemia, these differences are small and may be difficult to detect clinically.[295] Furthermore, clear quantitative threshold values for mean wedge pressure or a and v wave peak pressures that are diagnostic of ischemia have not been identified, perhaps because of the wide variations found in normal patients. Consequently, when a PAC is used to diagnose myocardial ischemia, the best approach is to integrate the PAC data with other clinical data.[303]

Right ventricular ischemia produces characteristic PAC trace patterns that may be helpful in diagnosis and management. Just as left ventricular ischemia increases PAWP, right ventricular ischemia increases CVP. In fact, this is one of the few situations in which CVP may be higher than wedge pressure. In addition, CVP waveforms may display a prominent a wave resulting from right ventricular diastolic dysfunction and a prominent v wave resulting from ischemia-induced tricuspid regurgitation.[304,305] This particular CVP waveform is described as having an M or W configuration, which refers to the tall a and v waves and interposed steep x and y descents. Severe pulmonary artery hypertension may also result in right ventricular ischemia and dysfunction and increases in CVP, but this can be distinguished from primary right ventricular dysfunction in that the PAP and calculated PVR are normal in primary ventricular failure.

The CVP waveform in right ventricular infarction is similar to that in restrictive cardiomyopathy or pericardial constriction, including elevated mean pressure, prominent a and v waves, and steep x and y descents.[306] The cardinal feature common to these conditions is impaired right ventricular diastolic compliance, often termed "restrictive physiology." In restrictive cardiomyopathy and right ventricular infarction, diastolic dysfunction impairs ventricular relaxation and decreases wall compliance, whereas in pericardial constriction, also termed constrictive pericarditis or pericardial restriction, cardiac filling is limited by the rigid, often calcified pericardial shell. Impaired venous return decreases end-diastolic volume, stroke volume, and cardiac output. Despite reduced cardiac volumes, cardiac filling pressures are markedly elevated and equal in all four chambers of the heart at end-diastole (Fig. 40-38). Although PAC monitoring reveals this pressure equalization, the characteristic M or W configuration is more apparent in the CVP trace, most likely because of the damping effect of the pulmonary vasculature on left-sided filling pressures.[307-309]

Another hallmark of pericardial constriction is observed in the right and left ventricular pressure traces. These traces demonstrate rapid, but short-lived early diastolic ventricular filling, which produces a diastolic "dip-and-plateau" pattern or "square root sign."[72,310] In some cases, particularly when the heart rate is slow, a similar waveform pattern may be noted in the CVP trace: a steep y descent (the diastolic dip) produced by rapid early diastolic flow from the atrium to the ventricle, followed by a mid-diastolic h wave (the plateau) from the interruption in flow imposed by the restrictive pericardial shell (see Fig. 40-38).

Like pericardial constriction, cardiac tamponade impairs cardiac filling, but in the case of tamponade, a compressive pericardial fluid collection produces this effect. This fluid collection results in a marked increase in CVP and reduced diastolic volume, stroke volume, and cardiac output. Despite many similar hemodynamic features, tamponade and constriction may be distinguished by the different CVP waveforms seen in these two conditions. In tamponade, the venous pressure waveform appears more monophasic and is dominated by the systolic x pressure descent. The diastolic y pressure descent is attenuated or absent because early diastolic flow from the right atrium to the right ventricle is impaired by the surrounding compressive pericardial

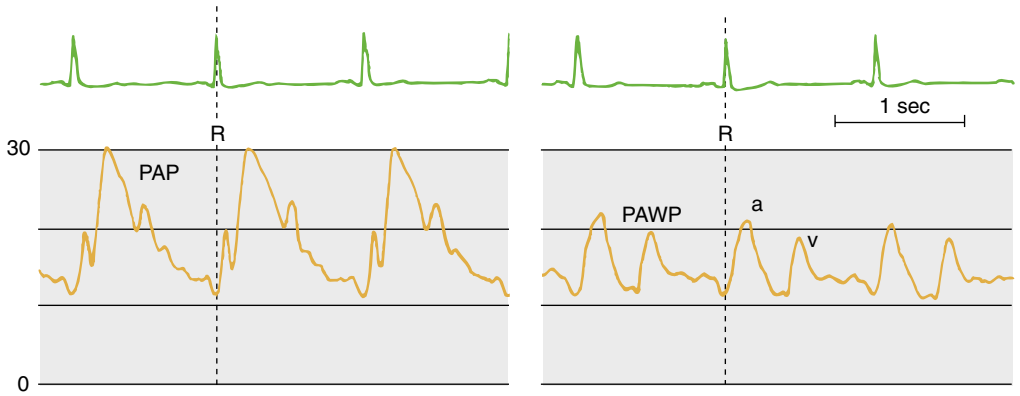

Figure 40-37 Myocardial ischemia. Pulmonary artery pressure (PAP) is relatively normal and mean pulmonary artery wedge pressure (PAWP) is only slightly elevated (15 mm Hg). However, PAWP morphology is markedly abnormal, with tall a waves (21 mm Hg) resulting from the diastolic dysfunction seen in this condition. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998, Fig. 12-4.)*

fluid collection (Fig. 40-39).[307,311,312] Clearly, other clinical and hemodynamic clues help identify these diagnoses, such as the presence of *pulsus paradoxus*, an almost invariable finding in cardiac tamponade (see Fig. 40-16).[313] Coexisting abnormalities such as tachycardia, arrhythmias, and atrial contractile failure may complicate interpretation of these waveforms. On occasion, localized pericardial constriction may simulate valvular stenosis, and hypovolemia may lower cardiac filling pressure to within the normal range and confound the diagnosis.

Probably the single most important waveform abnormality or interpretive problem in PAC monitoring is discerning the correct pressure measurement in patients who are receiving *positive-pressure ventilation* or who have labored spontaneous respiration or other causes of greatly increased intrathoracic pressure. Just as in the case of CVP monitoring, transmural cardiac filling pressures are best estimated when end-expiratory pressure values are recorded (see the earlier section "Physiologic Considerations for Central Venous Pressure Monitoring: Diastolic Pressure-Volume Relationships and Transmural Pressure"). During positive-pressure ventilation, inspiration increases pulmonary artery and wedge pressure. By measuring these pressures at end-expiration, the confounding effect of this inspiratory increase in intrathoracic pressure is minimized (Fig. 40-40).[199] Forceful inspiration during spontaneous ventilation has the opposite effect, but again, measurement of these pressures at end-expiration eliminates this confounding factor. Bedside monitors are designed with algorithms that aim to identify and report the numeric values for end-expiratory pressures but are notoriously inaccurate.[314,315] The most reliable method for measuring central vascu-

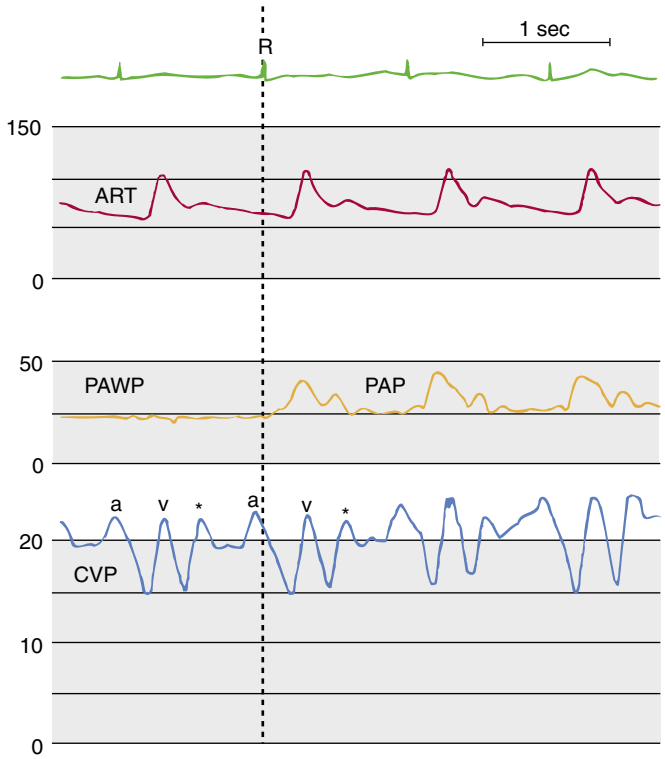

Figure 40-38 Pericardial constriction. This condition causes elevation and equalization of diastolic filling pressure in the pulmonary artery pressure (PAP), pulmonary artery wedge pressure (PAWP), and central venous pressure (CVP) traces. The CVP waveform reveals tall a and v waves with steep x and y descents and a mid-diastolic plateau wave (*) or h wave. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998, Fig. 18-1.)*

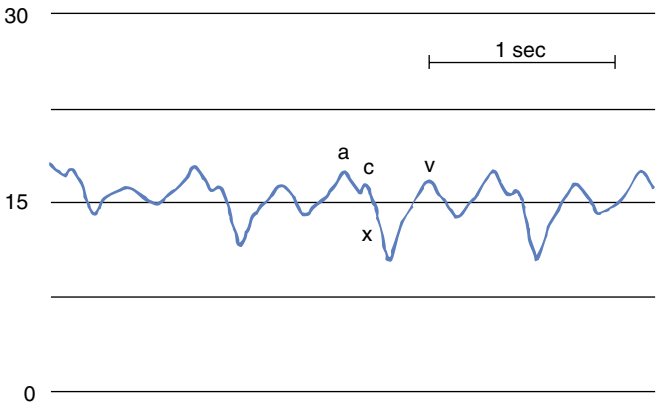

Figure 40-39 Cardiac tamponade. The central venous pressure waveform shows increased mean pressure (16 mm Hg) and attenuation of the y descent. Compare with Figure 40-38. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998, Fig. 18-5.)*

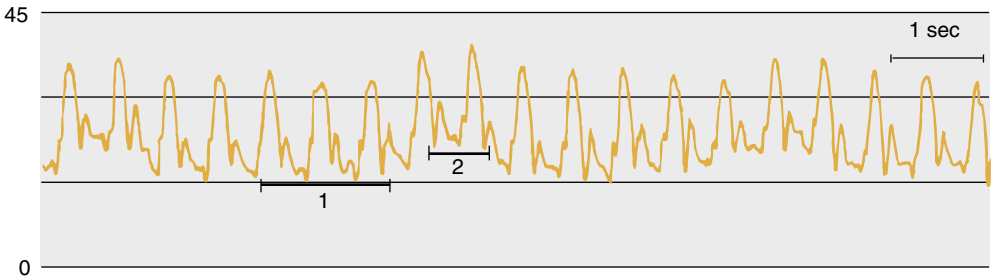

Figure 40-40 Influence of positive-pressure mechanical ventilation on pulmonary artery pressure. Pulmonary artery pressure should be measured at end-expiration #1, 15 mm Hg) to obviate the artifact caused by positive pressure inspiration (#2, 22 mm Hg). Compare with Figure 40-26. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998, Fig. 16-3.)*

lar pressures at end-expiration is examination of the waveforms on a calibrated monitor screen or paper recording.[315,316]

Use of Central Vascular Pressures to Estimate Left Ventricular Preload

A detailed understanding of the relationship between left ventricular filling pressure and preload is important for clinically meaningful interpretation of PAC-derived data. Although surrogates such as PADP and PAWP are used as measures of left ventricular filling, many factors influence the relationship between filling pressure and chamber volume. For example, a PAWP of 20 mm Hg is somewhat higher than normal, but depending on its interpretation and the clinical setting, different treatments would be indicated. Proper interpretation of this filling pressure depends on juxtacardiac pressure and ventricular compliance. Most commonly, a wedge pressure of 20 mm Hg is assumed to mean that juxtacardiac pressure and ventricular compliance are normal and the diagnosis is hypervolemia, with increased left ventricular end-diastolic volume causing the increased PAWP. However, different conclusions are reached if juxtacardiac pressure is increased by certain condition, including tamponade, constriction, or positive-pressure ventilation. Furthermore, a wedge pressure of 20 mm Hg may mean that ventricular compliance is decreased, such as might occur with diastolic dysfunction secondary to myocardial ischemia, hypertrophy, or cardiomyopathy (Fig. 40-41).

Determining an ideal central vascular pressure is often a clinical challenge. At the extremes of high and low, the appropriate intervention is more obvious. Unfortunately, things are rarely so clear-cut in critically ill patients, and the optimal wedge pressure must often be chosen empirically. A fluid challenge may be useful in determining the optimal pressure by comparison with the baseline hemodynamics of the particular patient. An intravenous bolus of crystalloid or colloid solution (250 to 500 mL) is given over a period of 15 minutes, and the change in wedge pressure is measured. Small increases in wedge pressure after the fluid challenge (e.g., <3 mm Hg) suggest that the ventricle is operating on the flat portion of its diastolic filling curve, whereas large increases in wedge pressure (e.g., ≥7 mm Hg) suggest that the steep portion of the curve has been reached and that little further increase in stroke volume and cardiac output can be achieved without a substantial risk of producing hydrostatic pulmonary edema.[50,315]

Clinicians have recognized for years that CVP is a poor indicator of volume status for a variety of reasons.[317,318] The diastolic pressure-volume curves for the left and right ventricles are different even in healthy individuals, with the left ventricle being less compliant. Although investigators have shown that CVP, PADP, and PAWP all vary in the same direction, the more important question is whether small changes in CVP are clinically meaningful or even reliably detectable.[319,320]

The shared septum of the left and right ventricles, as well as the presence of the pericardium, leads to further interpretive problems in the use of CVP for assessing ventricular preload. Ventricular interdependence and pericardial constraint couple changes in right and left ventricular function such that a primary change in right ventricular filling may produce a secondary change in left ventricular filling by altering its diastolic pressure-volume relationship.[198,321] For example, acute pulmonary artery hypertension increases right ventricular end-diastolic volume and pressure, shifts the ventricular septum leftward, and increases left ventricular end-diastolic pressure while simultaneously decreasing left ventricular end-diastolic volume because of a shift

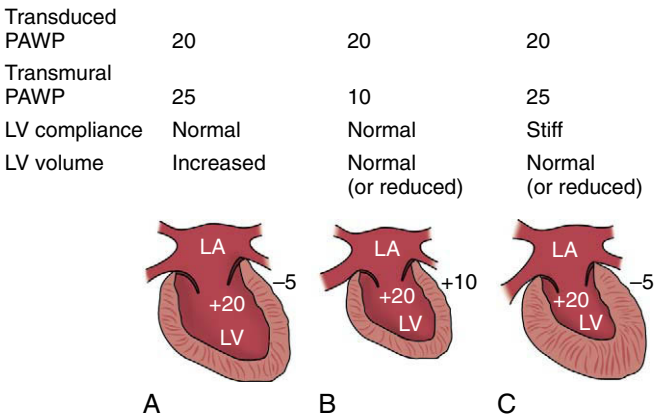

Figure 40-41 Influence of juxtacardiac pressure and ventricular compliance on left ventricular (LV) preload. There are three interpretations of increased transduced pulmonary artery wedge pressure (PAWP, 20 mm Hg). **A,** Juxtacardiac pressure (–5 mm Hg) and LV compliance are normal, transmural PAWP is increased (25 mm Hg), and LV volume is increased. **B,** Juxtacardiac pressure is increased (+10 mm Hg), LV compliance is normal, transmural PAWP is decreased (10 mm Hg), and LV volume is normal or decreased. **C,** Juxtacardiac pressure is normal, LV compliance is decreased, transmural PAWP is increased (25 mm Hg), and LV volume is normal or decreased. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998, Fig. 15-8.)*

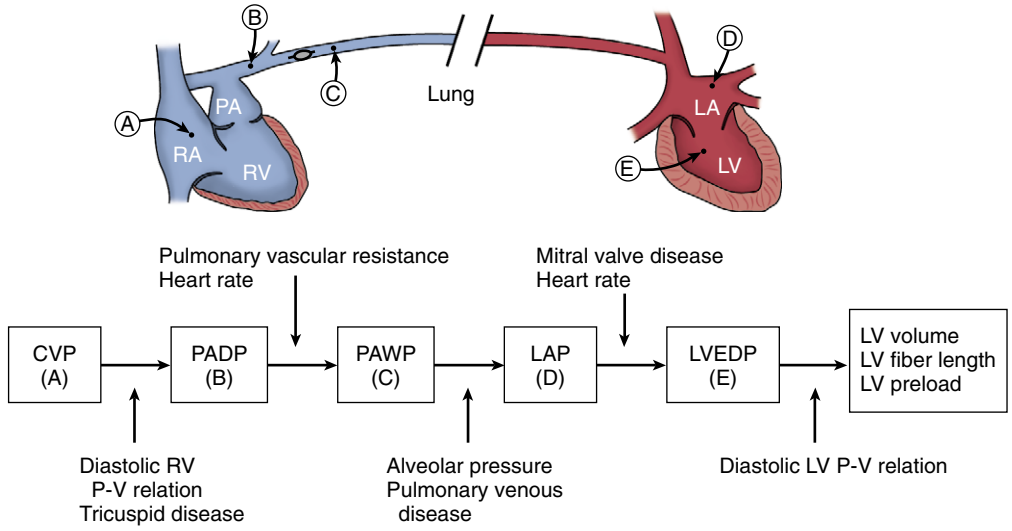

Figure 40-42 Anatomic and physiologic factors that influence the relationships between various measures of left ventricular (LV) filling and true LV preload. The further upstream filling pressure is measured, the more confounding factors may influence the relationship between this measurement and LV preload. CVP, central venous pressure; LA, left atrium; LAP, left atrial pressure; LVEDP, left ventricular end-diastolic pressure; PA, pulmonary artery; PADP, pulmonary artery diastolic pressure; PAWP, pulmonary artery wedge pressure; P-V, pressure-volume; RA, right atrium, RV, right ventricle. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998, Fig. 15-5.)*

in the left ventricular pressure-volume relationship to a steeper, stiffer curve. Conversely, primary changes on the left side can adversely affect the right heart structures in similar ways.

Finally, numerous additional factors may alter the relationship between CVP and left ventricular preload (Fig. 40-42).[194] The further upstream from the left ventricle one records the "filling pressure," the greater the multitude of factors that conspire to nullify the relationship between the monitored pressure and left ventricular preload. In view of these considerations, it should be no surprise that reliance on CVP to estimate left ventricular preload in critically ill patients is poorly placed.

Predicting Left Ventricular End-Diastolic Pressure

The first reason to measure wedge pressure is that it estimates pulmonary capillary pressure and as such offers a measure of the hydrostatic pressure within the pulmonary capillaries that largely controls the formation of pulmonary edema. Although wedge pressure and capillary pressure are not identical, changes in PAWP and capillary pressure generally mirror each other.

The second purpose for measuring wedge pressure is to estimate filling of the left ventricle. The end-diastolic wedge pressure after atrial contraction best predicts left ventricular end-diastolic filling pressure or preload.[315] Left ventricular end-diastolic pressure is measured at the Z-point (the point at which the slope of the left ventricular pressure upstroke changes, approximately 50 msec after the ECG Q wave and generally coinciding with the ECG R wave) (Fig. 40-43).[61]

PAC Underestimation of Left Ventricular End-Diastolic Pressure

When a PAC is used to estimate left ventricular filling pressure, there are a number of situations in which this pressure is either underestimated or overestimated (Tables 40-5 and 40-6, respectively). Left ventricular diastolic dysfunction leading to decreased ventricular compliance is the most common cause of underestimation of left ventricular end-diastolic pressure.[322] The atrial contribution to left ventricular end-diastolic volume and pressure is normally less than 20%, but with diastolic dysfunction, it may approach 50%.[296] Under these conditions, the wedge pressure a wave will be unusually prominent and will provide a close estimate of left ventricular end-diastolic pressure, but the mean wedge pressure will underestimate left ventricular filling (see Fig. 40-37).[269] In patients with aortic regurgitation, abnormal diastolic left ventricular filling from the aorta occurs as soon as left ventricular pressure falls below aortic pressure and continues after left atrial contraction and closure of the mitral valve. Left ventricular diastolic pressure continues to rise until end-diastolic pressure is reached at the onset of mechanical systole. Because mitral valve closure occurs before end-diastole, mean PAWP and the wedge pressure a wave both underestimate left ventricular end-diastolic pressure.[269]

In the presence of pulmonic regurgitation, diastolic flow from the proximal pulmonary artery becomes bidirectional, moving both antegrade into the left atrium and retrograde into the right ventricle. When right ventricular diastolic pressure is lower than LAP, pulmonary artery diastolic flow seeks the lower-pressure pathway toward the right ventricle, and PADP will underestimate PAWP, LAP, and left ventricular end-diastolic pressure.[323]

When PVR is normal, there is no pressure gradient across the pulmonary vascular bed at the end of diastole, and PADP equilibrates with the downstream LAP. However, when right ventricular systole is delayed because of right bundle branch block, PAP continues to fall with the x or systolic descent in LAP. In such circumstances, PADP may underestimate left ventricular end-diastolic pressure by as much as 7 mm Hg.[324]

Under normal conditions, inflation of the PAC balloon to measure wedge pressure interrupts antegrade blood flow through

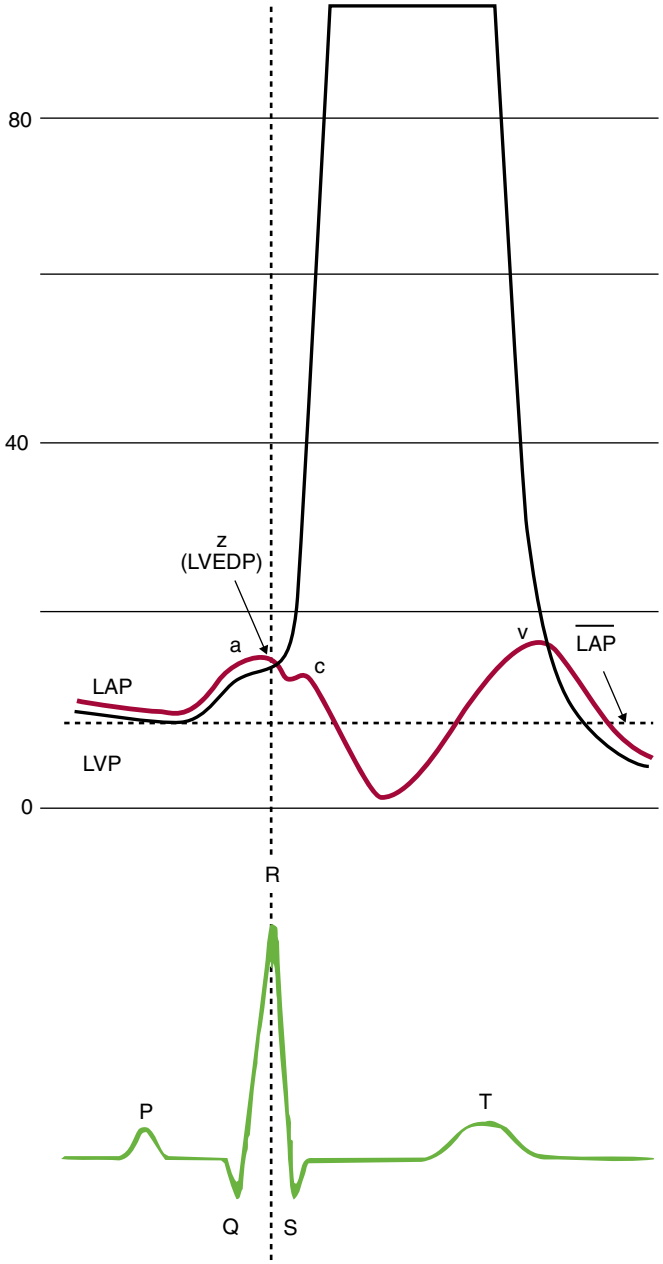

Figure 40-43 Relationship between left atrial pressure (LAP) and left ventricular end-diastolic pressure (LVEDP). LVEDP is measured at the Z-point on the left ventricular pressure (LVP) trace at the time of the electrocardiographic R wave. Mean LAP (9 mm Hg) underestimates LVEDP (15 mm Hg), but the LAP a wave pressure peak closely estimates LVEDP. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998, Fig. 6-1.)*

a small section of the lung and has no measurable effect on total pulmonary blood flow or left heart filling. However, after pneumonectomy and in other rare conditions that markedly decrease the pulmonary vascular bed, balloon inflation may occlude a significant portion of the remaining pulmonary vascular cross-sectional area. Mechanical obstruction of pulmonary blood flow ensues and causes increased CVP, as well as decreased LAP, cardiac output, and systemic blood pressure.[325] Therefore, because inflation of the PAC balloon for measurement of wedge pressure leads to obstruction of pulmonary blood flow, the measured wedge pressure underestimates the left atrial and left ventricular end-diastolic pressures that existed before balloon inflation.

Table 40-5 Underestimation of Left Ventricular End-Diastolic Pressure

Condition	Site of Discrepancy	Cause of Discrepancy
Diastolic dysfunction	Mean LAP < LVEDP	Increased end-diastolic a wave
Aortic regurgitation	LAP a wave < LVEDP	Mitral valve closure before end-diastole
Pulmonic regurgitation	PADP < LVEDP	Bidirectional runoff for pulmonary artery flow
Right bundle branch block	PADP < LVEDP	Delayed pulmonic valve opening
After pneumonectomy	PAWP < LAP or LVEDP	Obstruction of pulmonary blood flow

LAP, left atrial pressure; LVEDP, left ventricular end-diastolic pressure; PADP, pulmonary artery diastolic pressure; PAWP, pulmonary artery wedge pressure. Modified from Mark JB: Predicting left ventricular end-diastolic pressure. *In* Mark JB (ed): Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998, p 59.

PAC Overestimation of Left Ventricular End-Diastolic Pressure

Respiratory influences on the pulmonary artery and wedge pressure traces are the most common cause of overestimation of left ventricular end-diastolic pressure (see Table 40-6). Mechanical ventilation with PEEP poses a particular problem inasmuch as it may expand zone 1 or zone 2 lung conditions and allow PAWP to be influenced by alveolar pressure. In general, mechanical ventilation with PEEP increases wedge pressure by an amount less

Table 40-6 Overestimation of Left Ventricular End-Diastolic Pressure

Condition	Site of Discrepancy	Cause of Discrepancy
Positive end-expiratory pressure	Mean PAWP > mean LAP	Creation of lung zone 1 or 2 or pericardial pressure changes
Pulmonary arterial hypertension	PADP > mean PAWP	Increased pulmonary vascular resistance
Pulmonary veno-occlusive disease	Mean PAWP > mean LAP	Obstruction to flow in large pulmonary veins
Mitral stenosis	Mean LAP > LVEDP	Obstruction to flow across the mitral valve
Mitral regurgitation	Mean LAP > LVEDP	Retrograde systolic v wave raises mean atrial pressure
Ventricular septal defect	Mean LAP > LVEDP	Antegrade systolic v wave raises mean atrial pressure
Tachycardia	PADP > mean LAP > LVEDP	Short diastole creates pulmonary vascular and mitral valve gradients

LAP, left atrial pressure; LVEDP, left ventricular end-diastolic pressure; PADP, pulmonary artery diastolic pressure; PAWP, pulmonary artery wedge pressure. Modified from Mark JB: Predicting left ventricular end-diastolic pressure. *In* Mark JB (ed): Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998, p 59.

than half the value of PEEP applied (i.e., 10 cm H_2O PEEP will raise wedge pressure less than 5 cm H_2O or 4 mm Hg).[50,326] However, the ratio of chest wall compliance to lung compliance has a significant impact on the relationship between PEEP and its effect on PAWP, and simple mathematical methods to adjust for this effect are not adequate.[50,321,327] Alternative methods to correct for PEEP, such as measuring pleural pressure, are cumbersome and not generally used. Prolonged discontinuation of PEEP before measuring wedge pressure is to be discouraged. Not only might circulatory dynamics change dramatically as a result of rebound central hypervolemia caused by translocation of blood into the core, but respiratory gas exchange may also deteriorate and be slow to recover.[50] As an alternative, Pinsky and coworkers found that transient airway disconnection for 2 to 3 seconds in patients receiving mechanical ventilation with PEEP allowed measurement of nadir wedge pressure, which proved to be a better and safer way to estimate left ventricular filling pressure at higher levels of PEEP.[327] When wedge pressure measurement did not change after abrupt airway disconnection, the on-PEEP wedge pressure measurement accurately reflected left ventricular filling pressure. However, when wedge pressure decreased after airway disconnection, the nadir wedge pressure reached within 3 seconds provided a more accurate measurement. Studying patients with adult respiratory distress syndrome, Teboul and colleagues found that PAWP closely estimates left ventricular end-diastolic pressure at all levels of PEEP up to 20 cm H_2O.[328] This relative microvascular "protection" from the effects of PEEP presumably occurred because of the marked increase in lung stiffness seen in these patients.

When the pulmonary vasculature is normal, pulmonary blood flow ceases at end-diastole, and PADP equals LAP. However, if PVR increases, PAP equilibration with downstream pressure does not occur. Under these conditions, the pulmonary vascular bed begins to resemble the systemic vasculature, where a large pressure gradient between systemic arterial pressure and right atrial pressure persists at end-diastole. Therefore, in the presence of pulmonary arterial hypertension, PADP overestimates PAWP, LAP, and left ventricular end-diastolic pressure.[329]

In contrast to the precapillary pulmonary vasoconstriction that exists in patients with pulmonary arterial hypertension, postcapillary obstruction to flow in the pulmonary veins may occur in the rare condition pulmonary veno-occlusive disease. Patients with this condition have normal LAP, but some disagreement exists about whether these patients have normal or elevated PAC-derived wedge pressure measurements.[50,330,331] In part, these different observations may relate to whether the PAC has been wedged successfully because the wedge position may be difficult to obtain in these patients or in some instances the measured wedge pressure may be recorded from a totally occluded vascular channel. The most important factor, however, is whether the patient has predominantly small-vein occlusion or large-vein occlusion. Obstruction to flow in the small pulmonary veins narrows the static column of blood connecting the wedged PAC tip with the flowing column in the larger pulmonary veins. Given that the partial obstruction involves only the static column, wedge pressure will measure normal left atrial and pulmonary venous pressure because there is no pressure drop across this partially obstructed vascular segment in the absence of flow. Conversely, large-vein obstruction creates a pressure gradient across the large veins as blood flows in these vessels toward the left atrium. In this instance, wedge pressure will detect an increased pulmonary venous pressure and overestimate left atrial and ventricular diastolic pressure.[50,330,331] This model of pulmonary vein obstruction is consistent with the observations of Zidulka and Hakim, who measured wedge pressure in both large and small pulmonary arteries.[332] Other conditions may mimic the hemodynamic features of pulmonary veno-occlusive disease, including mediastinal fibrosis and intrathoracic or atrial tumors that obstruct pulmonary venous flow near the left atrium.

Mitral stenosis obstructs blood flow between the left atrium and left ventricle, and consequently LAP will exceed left ventricular pressure throughout diastole. Furthermore, all upstream pressures recorded by the PAC will overestimate left ventricular end-diastolic pressure as a result of the valvular obstruction. Because the pressure gradient across the mitral valve is directly related to flow, PADP and PAWP will overestimate left ventricular filling pressure even more when transmitral flow is increased by tachycardia or elevated cardiac output.[333]

LAP is increased in mitral regurgitation because of the abnormal leakage of blood across the incompetent valve during systole, and left ventricular end-diastolic pressure is better approximated by measuring wedge pressure before onset of the regurgitant c-v wave (see Fig. 40-34).[334] In contrast to patients with mitral stenosis, in whom LAP exceeds left ventricular pressure throughout diastole, patients with mitral regurgitation have appropriate diastolic equilibration of atrial and ventricular pressure. The problem in mitral regurgitation is choosing the appropriate end-diastolic, pre–v wave pressure to use as an estimate for left ventricular end-diastolic pressure. Mean PAWP will overestimate left ventricular end-diastolic pressure in any patient whose wedge pressure displays tall systolic v waves, including those with ventricular septal defect and left ventricular failure.[287,290]

When tachycardia develops, the duration of diastole is shortened. At both the mitral and pulmonary vascular levels, pressure gradients develop as diastole progressively shortens.[335,336] Consequently, PADP overestimates mean PAWP, which in turn overestimates left ventricular end-diastolic pressure. Patients in atrial fibrillation will have more complete equilibration of PADP and left ventricular end-diastolic pressure during longer R-R intervals. Consequently, these beats should be chosen to provide the best estimate of left ventricular end-diastolic pressure and preload.

Additional Features of Pulmonary Artery Catheters

The popularity of PACs is largely due to the fact that they are multipurpose and provide a wide range of supplementary features for therapeutic and diagnostic applications. Some catheters have a third lumen, which is often used as an additional venous infusion line that opens either 20 or 30 cm from the catheter tip. Others have specific modifications designed for monitoring continuous cardiac output, right heart function, or mixed venous oximetry, thereby vastly expanding the types of physiologic information available to those caring for critically ill patients. Specialized PACs also allow temporary endocardial pacing or intracardiac ECG recording and may even have combinations of electrodes permanently implanted along its length to allow bipolar ventricular, atrial, or atrioventricular pacing.[337] Other models have a special lumen that opens in the right ventricle, through which a

thin bipolar wire may be introduced for endocardial ventricular pacing, or have separate atrial and ventricular lumens for passage of two pacing wires for bichamber sequential pacing.[338]

Pulmonary Artery Catheterization and Outcome Controversies

Pulmonary artery catheterization has stimulated a great deal of vigorous controversy. It is an expensive, invasive technique that is widely used but still not proven to improve patient outcome. The PAC controversy has been fueled in part by strongly worded editorials written by prominent physicians debating whether PAC use should be suspended pending scientific proof of its efficacy.[339-341] Although similar controversies have surrounded the use of other widely adopted, highly technical clinical monitoring techniques such as electronic fetal monitoring, physicians who use PACs should especially appreciate the uncertainties surrounding PAC monitoring and be fully informed of the evidence that must guide patient selection.[342,343]

In 2003, the American Society of Anesthesiologists published an updated practice guideline for pulmonary artery catheterization that included a current exhaustive review of the scientific evidence for the clinical effectiveness of PAC monitoring.[211] The inconsistent findings of the many studies in the literature were striking, with evidence both supporting and refuting the benefits of this technique.[213,301,344-346] A great amount of the published literature concerning the use of PACs had been plagued by problems in study design (lack of randomization, small sample size), lack of standardization, and heterogeneity of both patients and clinical settings (medical versus surgical, cardiac surgery patients versus patients with acute congestive heart failure). Furthermore, even within a given clinical setting there is little consensus on which hemodynamic parameters are the most relevant to obtain from use of the PAC and no agreement on appropriate therapeutic interventions in response to specific findings.

Perhaps the most provocative of the early studies was published by Connors and colleagues, who examined the association between PAC use during the first 24 hours of intensive care and subsequent survival.[347] This prospective cohort study included 5735 patients in five teaching hospitals as part of a larger 9000 patient cohort.[348,349] Entry into the study required predicted 6-month mortality in excess of 50%. Patients who were in the PAC-monitored group were judged to be sicker by every measurement recorded, although to the extent statistically possible, the authors used case-matching analyses and applied a propensity score to adjust for these confounding medical covariates. These patients had increased mortality, increased length of hospital stay, and increased cost. Moreover, there was no subgroup of patients who appeared to benefit from PAC monitoring. Publication of this study was accompanied by a strongly worded editorial calling for a moratorium on PAC use or initiation of a randomized controlled trial to define its efficacy.[339]

In the intervening years, a great deal of work and energy have been devoted to determining whether patients are being helped or harmed by the use of PACs. Fortunately, a series of large, randomized, adequately powered studies have been published that specifically address this issue. Three trials enrolling a total of 3468 patients showed no effect on mortality or on hospital or intensive care unit length of stay despite a higher incidence of adverse events.[213,350,351] These complications were most commonly infection or "insertion-related" events. These trials included medical and surgical patients, elderly and high-risk patients, and those with severe heart failure. These findings were confirmed by two meta-analyses of 11 and 13 published randomized, controlled trials involving PAC use.[352,353]

Some investigators have even been able to show a treatment benefit from PAC use in selective populations, a finding that helps guide future use and research. A review of 53,312 patients from the National Trauma Data Bank showed no mortality benefit in those treated with PACs in the group as a whole. However, in patients with an injury severity scale score greater than 25, those who arrived at the hospital in severe shock, or those older than 60 years, mortality was decreased significantly.[354] In a mixed medical and surgical population, patients with Acute Physiology and Chronic Health Evaluation (APACHE) scores less than 25 showed increased mortality when treated with PACs, whereas those with scores higher than 31 showed significant benefit.[355]

Indications for Pulmonary Artery Catheterization

The most recent recommendations governing the use of PACs are the American Society of Anesthesiologists practice guideline published in 2003.[211] The task force considered PAC monitoring to be appropriate in surgical patients undergoing procedures associated with a high risk of complications from hemodynamic changes (e.g., cardiac surgery) or patients with advanced cardiopulmonary diseases that would place them at increased risk for adverse perioperative events. Furthermore, the specific practice setting, as well as the proficiency and experience of clinicians, should be considered.

PAC use must be tailored to the degree of risk for the patient and the risk posed by the procedure itself. For example, a patient with advanced ischemic cardiomyopathy who needs lower extremity amputation under regional anesthesia would not warrant PAC monitoring, whereas a patient with stable ischemic heart disease scheduled for extensive abdominal cancer resection may benefit from perioperative use. Furthermore, the individual practice setting must be considered.[211] Keats has termed this feature "the role of environment in the outcome of operation," by which he means important unmeasurable aspects of the clinical setting, including, but not limited to technical skill and experience.[356] Clearly, all physicians and nurses using a PAC must have the requisite knowledge and skills to use it safely and effectively. Unfortunately, this is a goal that eludes objective definition and remains unattained by current postgraduate training programs.[266]

Several important points should be kept in mind when indications for PAC monitoring are being considered. First, uses of the catheter are different in different patient populations. For example, whereas acute titration of fluids and inotropic agents is most relevant in the perioperative period, in the heart failure population, fine management of oral medications or delineation of drug combinations may be most important. Use of the catheter should be timely; that is, it should not be withheld until irreversible injury has occurred and therapies would be futile. Patients arriving in shock may benefit from immediate PAC placement, whereas others may warrant "watchful waiting." In addition, no

catheter should be placed unless the data will be used. Finally, it is of the utmost importance to consider the clinical expertise and experience of those manipulating the catheter and interpreting the data.

It seems a reasonable conclusion from the bulk of published research that PAC use should be limited, although a moratorium on use is ill advised. Use should be reserved to centers with significant experience and expertise. Moreover, PACs should generally be used to monitor and guide therapy in patients at high risk for hemodynamic instability, those who are judged more critically ill by a variety of clinical means, and those who are in shock, especially if older than 60 years.

There remains a great deal of uncertainty and controversy surrounding PAC use. Among the many measurements and calculations possible from a PAC, there is little consensus on which is the most meaningful and useful. Furthermore, therapies based on these findings have not been systematically studied or validated. Indeed, the variations in PAC design have moved so far beyond simple wedge pressure measurement that the PAC is becoming as much a physiologic monitor as it is a hemodynamic one. A PAC itself has no capacity to benefit and only limited risk. However, the potential for adverse outcomes from therapies based on PAC measurements is tremendous. This is the direction that future research needs to take.

Cardiac Output Monitoring

Aside from its pressure monitoring capabilities, one of the more important features of the PAC is its ability to measure cardiac output via the thermodilution method. Cardiac output is the total blood flow generated by the heart, and in a normal adult at rest it ranges from 4.0 to 6.5 L/min. Measurement of cardiac output provides a global assessment of the circulation, and when combined with other hemodynamic measurements (heart rate, arterial blood pressure, CVP, PAP, and PAWP), it allows calculation of additional important circulatory variables such as systemic vascular resistance (SVR), PVR, and ventricular stroke work (Table 40-7).

Three factors have driven efforts to measure cardiac output in clinical practice. The first is the recognition that in many critically ill patients, low cardiac output leads to significant morbidity and mortality.[357] In addition, clinical assessment of cardiac output is often inaccurate; for example, seriously ill patients with decreased cardiac output might have normal systemic arterial blood pressure.[358] Finally, newer techniques for measurement of cardiac output are less invasive than PAC monitoring and thus might provide benefit to many patients without the attendant risks associated with invasive monitoring.[358-360] The advantages and disadvantages of each technique must be appreciated for proper clinical application.

Thermodilution Cardiac Output Monitoring

The thermodilution technique has become the de facto clinical standard for measuring cardiac output because of its ease of implementation and extensive clinical experience with its use in various settings. It is a variant of the *indicator dilution* method, in which a known amount of a tracer substance is injected into the bloodstream and its change in concentration measured over time at a downstream site (see Chapter 38 for more details). For thermodilution, (negative) heat is injected, and change in temperature downstream is measured.

Table 40-7 Normal Hemodynamic Values

	Average	Range
Cardiac output (L/min)	5.0	4.0-6.5
Stroke volume (mL)	75	60-90
Systemic vascular resistance		
Wood units	15	10-20
Dynes•sec/cm^5	1200	800-1600
Pulmonary vascular resistance		
Wood units	1	0.5-3
Dynes•sec/cm^5	80	40-180
Arterial oxygen content (mL/dL)	18	16-20
Mixed venous oxygen content (mL/dL)	14	13-15
Mixed venous oxygen saturation (%)	75	70-80
Arteriovenous oxygen difference (mL/dL)	4	3-5
Oxygen consumption (mL/min)	225	200-250

In practical terms, a fixed volume of iced or room-temperature fluid is injected as a bolus into the proximal (right atrial) lumen of the PAC, and the resulting change in pulmonary artery blood temperature is recorded by a thermistor at the catheter tip. As in all other forms of cardiovascular monitoring, it is important to have a real-time display of the thermodilution curve resulting from each cardiac output measurement.[361] This allows the clinician to discern artifacts that would invalidate the cardiac output measurement, such as unstable blood temperature, recirculation, or incomplete indicator injection. Usually, a series of three cardiac output measurements performed in rapid succession are averaged to provide a more reliable result. When only a single injection was used to determine cardiac output, a difference between sequential cardiac output measurements of 22% was required to suggest a clinically significant change. In contrast, when three injections were averaged to determine the thermodilution measurement, a change greater than 13% indicated a clinically significant change in cardiac output.[362]

Even when carefully performed, some studies have found that thermodilution cardiac output measurements may not agree with other reference methods.[363,364] However, few complications are directly attributable to the technique itself, and monitoring the trend in cardiac output is probably more clinically useful than emphasizing any absolute value.

Sources of Error in Thermodilution Cardiac Output Monitoring

Several important technical issues and potential sources of error must be considered to interpret thermodilution cardiac output measurements properly (Box 40-7).[361] The thermodilution technique measures right ventricular output. In the face of an *intracardiac shunt*, right ventricular and left ventricular output will not be equal. In patients with left-to-right shunts, early recirculation of the thermal indicator can be seen to distort the downward slope of the thermodilution curve, and in patients with right-to-

Box 40-7 Factors Influencing the Accuracy of Thermodilution Cardiac Output Measurement

- Intracardiac shunts
- Tricuspid or pulmonic valve regurgitation
- Inadequate delivery of thermal indicator
  - Central venous injection site within the catheter introducer sheath
  - Warming of iced injectate
- Thermistor malfunction from fibrin or a clot
- Pulmonary artery blood temperature fluctuations
  - Post–cardiopulmonary bypass status
  - Rapid intravenous fluid administration
- Respiratory cycle influences

left shunt, some of the injected indicator will bypass the thermistor and result in overestimation of left ventricular cardiac output.

Patients with *tricuspid* or *pulmonic valve regurgitation* pose additional problems for thermodilution cardiac output measurement because of recirculation of the indicator across the incompetent valve. In patients with severe tricuspid regurgitation, the thermodilution curves have an abnormally prolonged decay time, and the measured cardiac output may be inaccurate. Unfortunately, there is no simple method to correct for this problem. In the presence of significant tricuspid regurgitation, thermodilution cardiac output techniques are simply unreliable, either underestimated or overestimated, depending on the severity of valvular regurgitation and the magnitude of the cardiac output.[361,365]

Other technical problems with thermodilution cardiac output measurement are caused by *inadequate delivery of the thermal indicator*. Mishandling of an iced injectate syringe can warm the solution and reduce the signal of the thermal indicator administered. In addition, fibrin or blood clot on the PAC tip may lead to *thermistor malfunction* and result in spurious cardiac output values.

Unrecognized *fluctuation in blood temperature* may also influence cardiac output measurement. In most patients, pulmonary artery blood temperature falls rapidly in the initial minutes *after cardiopulmonary bypass* when the rewarmed body core redistributes the heat gained at the end of bypass. Because of this progressive decline in central core and pulmonary artery blood temperature, the thermal baseline is unstable. Thermodilution cardiac output measurements made in the minutes after bypass are notoriously unreliable, most often leading to marked underestimation of true cardiac output.[366] Other inaccuracies in thermodilution cardiac output measurement occur when pulmonary artery blood temperature changes because of *rapid fluid infusion*.[367] Either overestimation or underestimation of cardiac output occurs, depending on the timing of the additional fluid bolus.

The choice of iced (0°C) or room-temperature injectate has been examined in detail to determine the preferred method for accurate measurement of cardiac output. Although the size of the thermal bolus (and hence the signal-to-noise ratio) is increased when an iced injectate is used, this indicator is more time-consuming, expensive, and cumbersome to prepare than a room-temperature injectate is. Because several groups have demonstrated equivalent accuracy in cardiac output determinations when iced and room-temperature injectates are compared, it appears that room-temperature injectate is preferred for almost all clinical applications.[368] In adults, an injectate volume of 10 mL should be used, whereas in children, an injectate volume of 0.15 mL/kg is recommended.[361]

One of the more controversial issues in standard bolus thermodilution cardiac output monitoring is the proper timing of measurement in relation to the *respiratory cycle*, particularly in patients receiving positive-pressure mechanical ventilation. Because the stroke output of the right ventricle varies as much as 50% during the respiratory cycle, the limited "sampling" of right ventricular stroke volumes measured with the bolus thermodilution technique may lead to widely variable measurements of cardiac output, depending on the point during the respiratory cycle when the measurements are performed.[369] Although reproducibility of consecutive measurements improves markedly when the bolus injections are synchronized to the same phase of the respiratory cycle, accurate measurement of average cardiac output is achieved more reliably by making multiple injections during the different phases of the respiratory cycle and then averaging the results.[361,369]

Continuous Thermodilution Cardiac Output Monitoring

Newer technologies applied to PAC monitoring allow nearly continuous cardiac output (CCO) monitoring with a warm thermal indicator.[370,371] In brief, small quantities of heat are released from a 10-cm thermal filament incorporated into the right ventricular portion of a PAC, approximately 15 to 25 cm from the catheter tip, and the resulting thermal signal is measured by the thermistor at the tip of the catheter in the pulmonary artery. The heating filament is cycled on and off in a pseudorandom binary sequence, and cardiac output is derived from cross-correlation of the measured pulmonary artery temperature with the known sequence of heating filament activation.[371] Typically, the value displayed for cardiac output is updated every 30 to 60 seconds and represents the average value for the cardiac output measured over the previous 3 to 6 minutes. In a laboratory investigation examining how CCO measurements responded to unstable hemodynamic conditions, such as hemorrhage and fluid resuscitation, Siegel and colleagues showed that changes in CCO were markedly slower than changes detected by ultrasonic flow probe, blood pressure, or mixed venous oxygen saturation.[372] In view of these inherent time delays, the PAC CCO method should be considered a continual rather than a continuous real-time monitor.

In general, the CCO method appears to have good agreement with standard bolus thermodilution cardiac output measurements or electromagnetic flow probe techniques.[370,373] In a small, multicenter study, Mihm and associates found that CCO provided a clinically reliable measurement in a group of 47 intensive care unit patients.[370] The device performed well in patients with a wide range of cardiac output (1.6 to 10.6 L/min) and core temperature (33.2°C to 39.8°C), and the method showed no deterioration in performance over the 72-hour monitoring period. Reproducibility and precision appear to be better with the CCO method than with the standard bolus thermodilution techniques,

probably because of the fact that the continuous method displays a time-weighted average cardiac output value as opposed to a single instantaneous measurement.[374,375]

The CCO PAC has been widely accepted into clinical use for a number of practical reasons. Although these catheters are more expensive than standard PACs, obviating the need for bolus injections reduces nursing workload and the potential risk of fluid overload or infection. Furthermore, because the CCO PAC provides a cardiac output value that is an average derived over the previous several minutes, the beat-to-beat variations in stroke volume that occur during a single respiratory cycle are all equally represented. As a result, cardiac output measured by the CCO method may provide a more accurate measurement of global cardiac output in patients receiving positive-pressure mechanical ventilation.

However, like cold bolus thermodilution techniques, warm thermal CCO has certain methodologic pitfalls that must be recognized and avoided. The CCO computer and catheter require a significant amount of time to warm up and may work poorly in an environment with a great deal of thermal noise, such as the cardiac operating room. As already emphasized, CCO monitors have an inherent 5- to 15-minute delay in responding to abrupt changes in cardiac output, and the magnitude of this delay depends on the type of physiologic perturbation, as well as the CCO computer monitor algorithm.[372] Although modifications of CCO algorithms provide a "STAT Mode" rapid response time, acute changes in cardiac output are still detected more slowly by CCO monitoring than by other methods, such as direct arterial pressure or mixed venous oximetry. In effect, the CCO technique involves a fundamental tradeoff between rapid response time and overall accuracy of measurement. Standards for these performance characteristics have not been defined but must balance the response time against the stability of the displayed value and its immunity from thermal noise.[374]

Mixed Venous Oximetry Pulmonary Artery Catheter

Although the formal Fick cardiac output method is not widely applied in clinical practice, the physiologic relationships described by the Fick equation form the basis for another PAC-based monitoring technique termed *continuous mixed venous oximetry*. Rearrangement of the Fick equation reveals the four determinants of mixed venous hemoglobin saturation:

$$S\bar{v}O_2 = SaO_2 - \frac{\dot{V}O_2}{\dot{Q} \times 1.36 \times Hb} \quad (1)$$

where $S\bar{v}O_2$ = mixed venous hemoglobin saturation (%)
SaO_2 = arterial hemoglobin saturation (%)
$\dot{V}O_2$ = oxygen consumption (mL O_2/min)
$\dot{Q}$ = cardiac output (L/min)
Hb = hemoglobin concentration (g/dL)

To the extent that arterial hemoglobin saturation, oxygen consumption, and hemoglobin concentration remain stable, mixed venous hemoglobin saturation may be used as an indirect indicator of cardiac output. For example, when cardiac output falls, tissue oxygen extraction increases and the mixed venous blood will have a lower oxygen content and lower hemoglobin oxygen saturation. However, as noted in this equation, mixed venous hemoglobin saturation also varies directly with arterial hemoglobin concentration and saturation and inversely with oxygen consumption. When any of these other variables change significantly, one cannot assume that a change in mixed venous hemoglobin saturation results solely from a change in cardiac output. Although these considerations may confound the use of mixed venous hemoglobin saturation as an indicator of cardiac output, monitoring this variable provides more comprehensive information about the balance of oxygen delivery and consumption by the body—not just the raw cardiac output, but also the adequacy of that cardiac output.[376]

Although mixed venous hemoglobin saturation may be determined by intermittent blood sampling from the pulmonary artery, a specially designed PAC can provide this information reliably and continuously. Fiberoptic bundles incorporated into the PAC determine the hemoglobin saturation in pulmonary artery blood based on the principles of reflectance oximetry using either a two- or three-wavelength system. A special computer connected to this PAC displays the mixed venous hemoglobin saturation continuously. The technology is typically incorporated into the standard PAC or the CCO PAC, in the latter case providing both CCO and venous oximetry data.

Technical problems with continuous mixed venous oximetry are generally limited to improper positioning of the PAC tip against the vessel wall or inaccurate calibration.[377] Multi-wavelength fiberoptic technology and reflection intensity algorithms help reduce wall artifacts caused by spurious reflections from a PAC thrombus or the pulmonary arterial walls. These catheters are calibrated at the bedside before use but may also be calibrated in vivo from a pulmonary artery blood gas sample if the mixed venous saturation values are questionable. Most clinical trials comparing PAC-derived continuous venous oximetry values with laboratory analysis of pulmonary artery blood samples have shown good agreement between techniques.[378] It is important to remember that mixed venous oxygenation is a global, whole-body measurement. Therefore, regionally inadequate blood flow and tissue oxygen delivery (such as limb or intestinal ischemia) can coexist with a normal or a high mixed venous oximetry value.

The continuous mixed venous oximetry PAC may be used to measure thermodilution cardiac output and arterial and mixed venous oxygen content values and thereby calculate oxygen consumption by rearrangement of the Fick equation. However, values for oxygen consumption derived from these measurements generally underestimate direct oxygen consumption measured by mass spectrometry, metabolic cart, or water-sealed spirometry.[379]

Oxygen delivery may also be calculated as shown in Equation 2:

$$\dot{D}O_2 = \dot{Q} \cdot CaO_2 \quad (2)$$

where $\dot{D}O_2$ = oxygen delivery (mL/min)
$\dot{Q}$ = cardiac output (dL/min)
CaO_2 = oxygen content of arterial blood (mL O_2/dL blood)

Many physicians have used these derived measures of oxygen consumption and oxygen delivery to guide the treatment of critically ill patients, although the success of this "goal-oriented therapy" in improving patient outcomes is still inconclusive. However, a recent randomized study in patients undergoing

cardiac surgery has shown better outcome in patients randomized to protocol-driven interventions aimed at achieving mixed venous oxygen saturation higher than 70% (and blood lactate <2 mg/dL).[380] Similarly, optimizing central venous oxygen saturation (measured in superior vena cava blood) has been shown to improve outcome in patients with early sepsis[381] and in high-risk surgical patients.[382]

It is important to note that these studies have used strict protocol-driven therapeutic interventions. A large Veterans Affairs observational trial of 3265 cardiac surgical patients noted that 49% of patients received continuous mixed venous oximetry PACs and that use of this catheter was associated with increased cost but no better outcome than achieved in the standard PAC group.[383] In this study, however, no protocol was used to guide therapeutic interventions based on monitoring results.

Right Ventricular Ejection Fraction Pulmonary Artery Catheters

Although cardiovascular monitoring has focused predominantly on left ventricular performance, in some instances, right ventricular dysfunction may be the more important factor limiting circulation. Patient populations at increased risk for right ventricular dysfunction include those with chronic obstructive pulmonary disease, adult respiratory distress syndrome, pulmonary hypertension, and right ventricular ischemia and infarction.[384] Standard techniques are available for monitoring right ventricular performance in patients with acute myocardial infarction involving the right ventricle. PAC monitoring in patients with right ventricular infarction often reveals the characteristic hemodynamic patterns described earlier. However, accurate evaluation of right ventricular performance has proved more complicated. In patients with severe respiratory failure, for example, the confounding effects of mechanical ventilation with high levels of PEEP have made interpretation of cardiac filling pressures difficult and, in some cases, misleading.[385]

Measurement of right ventricular ejection fraction (RVEF) with a specially designed PAC offers another method for evaluating right ventricular function. This method uses a standard PAC equipped with a rapid-response thermistor that detects and quantifies the small changes in pulmonary artery blood temperature that occur with each heartbeat, in a manner somewhat analogous to a standard CCO PAC. The cardiac output computer measures the residual fraction of thermal signal after each heartbeat and derives RVEF.[386] Clearly, all factors that confound standard thermodilution cardiac output measurement will also interfere with accurate determination of RVEF. In addition, because the temperature changes measured by the RVEF PAC are small beat-to-beat changes, the method will not work if the ECG R waves cannot be detected accurately, the R-R interval is short because of tachycardia, or the cardiac rhythm is irregular.[377] Comparison of PAC-based RVEF measurements with angiographic or nuclear techniques has yielded mixed results in terms of accuracy, but this may reflect, in part, the absence of a widely accepted reference standard for this measurement.[386,387] Intraoperative use of the RVEF PAC has focused primarily on detection of right ventricular dysfunction in patients with coronary artery disease undergoing surgical revascularization. Reduced RVEF has been noted after cardiopulmonary bypass, particularly in patients with preexisting right coronary artery obstruction.[388] However, RVEF is an extremely load-dependent measurement of right ventricular performance, and the clinician must keep this fact in mind to interpret this measurement properly.[377,389] Clinical use of the RVEF PAC appears to have found its greatest application to date in critically ill patients, especially those with respiratory failure.[389,390] In these applications, the measurement of greatest interest has been right ventricular end-diastolic volume, which is derived mathematically from RVEF:

$$\text{RVEDV} = \frac{\text{SV}}{\text{RVEF}} \tag{3}$$

where RVEDV = right ventricular end-diastolic volume (mL)
SV = stroke volume (mL)
RVEF = right ventricular ejection fraction

Right ventricular end-diastolic volume appears to correlate better with cardiac output than standard preload measurements such as CVP or PAWP do.[390,391] These findings are not surprising given all the interpretive problems associated with monitoring cardiac filling pressure previously discussed. It should be kept in mind, however, that the better correlation between right ventricular end-diastolic volume and cardiac output may result from the mathematical coupling of measurements because both are derivatives of stroke volume determined with the PAC. Furthermore, as in the case of standard PAC monitoring, the benefit of RVEF PAC monitoring in terms of patient outcome remains unproven.[392]

Pulmonary Artery Catheter–Derived Hemodynamic Variables

The cardiovascular system is often modeled as an electrical circuit, with the relationship between cardiac output, blood pressure, and resistance to flow related in a manner similar to Ohm's law:

$$\text{SVR} = \frac{\text{MAP} - \text{CVP}}{\text{CO}} \times 80$$
$$\text{PVR} = \frac{\text{MPAP} - \text{PAWP}}{\text{CO}} \times 80 \tag{4}$$

where SVR = systemic vascular resistance (dyne·sec·cm^{-5})
PVR = pulmonary vascular resistance (dyne·sec·cm^{-5})
MAP = mean arterial pressure (mm Hg)
CVP = central venous pressure (mm Hg)
MPAP = mean pulmonary artery pressure (mm Hg)
PAWP = pulmonary artery wedge pressure (mm Hg)
CO = cardiac output (L/min)

Normal values for SVR and PVR are given in Table 40-7. Note that these calculations of SVR and PVR are based on a hydraulic fluid model that assumes continuous laminar flow through a series of rigid pipes.[393] These calculations also use atrial pressure as the downstream pressure for systemic or pulmonary flow, with CVP used for right atrial pressure in the SVR calculation and PAWP used for LAP in the PVR calculation. Alternative methods to calculate resistance ignore the effect of these downstream pressures. For the systemic circulation, total resistance may be calculated from MAP and cardiac output alone, and for

the pulmonary circulation, total pulmonary resistance describes the ratio of mean PAP and cardiac output.

All these resistance formulas oversimplify the behavior of the cardiovascular system to a tremendous degree. A more physiologic model of the systemic circulation considers the vasculature to be a series of collapsible vessels with intrinsic tone. This model, also called the *vascular waterfall*, describes a critical closing pressure in the downstream end of the circuit that exceeds right atrial pressure and serves to limit flow—an effective downstream pressure that is higher than the right atrial pressure used in the SVR formula. Detailed consideration of these issues is beyond the scope of this discussion and is available from other sources.[394,395] The important point for clinicians, though, is that therapy focused on fine adjustment of SVR may be very misleading and should be avoided.

Additional problems arise in considering the pulmonary vasculature and using the formulas just presented as a measure of resistance to flow through the lung. The pulmonary vasculature is more compliant than the systemic vasculature, and marked increases in pulmonary blood flow may not produce any significant increase in PAP. In addition, flow usually ceases at end-diastole in the low-resistance pulmonary circuit.[396] Thus, changes in PVR may result from intrinsic alterations in pulmonary vascular tone (constriction or dilation) or vascular recruitment or from rheologic changes. For the pulmonary circuit, a better approach to evaluating changes in PVR may be to examine the end-diastolic gradient between PADP and PAWP (Fig. 40-44).[397]

Another set of common calculations derived from standard hemodynamic variables adjusts these measurements for the patient's body surface area (BSA) in an attempt to normalize these measurements for patients of different size. BSA is generally determined from a standard nomogram based on height and weight. The most commonly indexed variables are the cardiac index (cardiac index = cardiac output/BSA) and stroke volume index (stroke volume index = stroke volume/BSA). On occasion, SVR and PVR are indexed as well (SVR index = SVR/BSA; PVR index = PVR × BSA). In theory, normalizing hemodynamic values through "indexing" should help clinicians determine appropriate normal physiologic ranges to help guide therapy. Unfortunately, there is little evidence that these additional calculations provide valid normalizing adjustments. BSA is a biometric measurement with an obscure relationship to blood flow, and it does not adjust for variations between individuals based on age, sex, body habitus, or metabolic rate.[398] Although it is important to be aware of a patient's size and medical history when interpreting and treating changes in any of the measured or calculated hemodynamic variables, it is not appropriate to target therapy solely at achieving normal indexed values.

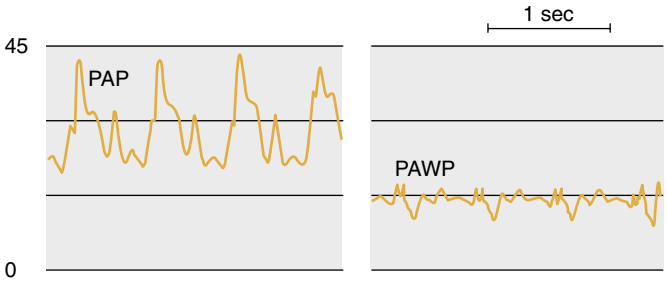

Figure 40-44 Pulmonary hypertension. The increased gradient across the pulmonary vasculature causes pulmonary artery diastolic pressure to exceed pulmonary artery wedge pressure (PAWP). PAP, pulmonary artery pressure. *(From Mark JB: Atlas of Cardiovascular Monitoring. New York, Churchill Livingstone, 1998, Fig. 6-11.)*

Other Methods for Monitoring Cardiac Output and Perfusion

Ultrasound-Based Methods for Monitoring Cardiac Output

All of the ultrasound-based methods for monitoring cardiac output use the Doppler principle. When ultrasound waves strike moving objects, these waves are reflected back to their source at a different frequency, termed the *Doppler shift frequency*, which is directly related to the velocity of the moving objects and the angle at which the ultrasound beam strikes these objects. For measurement of blood flow, the red blood cells flowing through a major artery serve as the moving objects targeted by the ultrasound beam. To measure blood flow velocity, the Doppler equation is rearranged to solve for velocity:

$$v = \frac{f \times c}{2f_0 \times \cos\theta} \quad (5)$$

where v = velocity of red blood cell targets
f = Doppler shift frequency
f_0 = transmitted ultrasound beam frequency
θ = angle between the ultrasound beam and the vector of red blood cell flow
c = velocity of ultrasound in blood (approximately 1570 m/sec)

In general, determining blood flow velocity requires just a single measurement, the Doppler shift frequency, because the velocity of ultrasound in blood and the transmitted ultrasound frequency are known and cos θ is assumed to equal 1 as long as the angle of insonation is small. This assumption requires that the ultrasound beam be oriented as much as possible in a direction that is parallel to the flow of blood. For example, for angles of less than 20 degrees, cos θ will be greater than 0.94, thereby introducing an error of less than 6% in calculation of cardiac output. Once the Doppler shift frequency is measured and blood flow velocity is calculated, stroke volume can be determined from Equation 6:

$$SV = v \cdot ET \cdot CSA \quad (6)$$

where SV = stroke volume (mL)
v = spatial average velocity of blood flow (cm/sec)
ET = systolic ejection time (sec)
CSA = cross-sectional area of the vessel (cm^2)

Several different ultrasound-based methods can be used to measure cardiac output, each using slightly different equipment and measuring blood flow from a different site in the body.

Suprasternal Doppler Cardiac Output Monitoring

This method was developed to measure blood flow velocity in the distal aortic arch with an ultrasound transducer applied to the

suprasternal notch.[399] Although the suprasternal Doppler cardiac output technique showed reasonable agreement with the thermodilution method, it is relatively labor intensive, requires a fair degree of experience and expertise, and cannot be accomplished in a significant number of critically ill medical and surgical patients.[399,400] Because it provides only an intermittent measurement at best, clinical acceptance of this method was limited.

Esophageal Doppler Cardiac Output Monitoring

The evolution of Doppler techniques into practical clinical monitoring tools required an ultrasound transducer that could be positioned and left in place for continuous monitoring without the need for repeated adjustments or time-consuming measurements by the physician or ultrasonographer. Such a transducer was incorporated into the tip of a standard esophageal stethoscope to allow continuous monitoring of cardiac output by interrogating the blood flow profile in the descending thoracic aorta. In brief, the Doppler probe is inserted into the esophagus to a depth of approximately 35 cm from the incisors. Probe position is adjusted to optimize the audible Doppler flow sound from the descending aorta. In most patients, optimal probe tip position is at the T5-T6 vertebral interspace or the third sternocostal junction because the esophagus and the descending aorta lie in close proximity and run essentially parallel to one another at this location.[401] The ultrasound transducer is mounted at a fixed angle that is anatomically defined and known by the cardiac output computer. This angle is then used to correct the resulting Doppler shift frequency to provide an accurate velocity measurement.

Several limitations of the esophageal Doppler technique must be appreciated by the physician to avoid pitfalls in interpretation of data. This monitoring method interrogates blood flow in the descending thoracic aorta and therefore measures only a fraction of total cardiac output. To report total cardiac output, either the esophageal Doppler measurement must be "calibrated" by some alternative method or an empirically determined correction constant of 1.4 must be used.[402] This constant is accurate for most patients but does not apply universally, especially in the presence of conditions that redistribute blood flow, such as pregnancy, aortic cross-clamping, and post–cardiopulmonary bypass status.[401,403] In addition, the diameter of the descending aorta is either measured by using A-mode ultrasound or calculated on the basis of the patient's age, sex, height, and weight via a nomogram.[404] When calculated, it is assumed that the diameter of the descending aorta does not change throughout the cardiac cycle.[405] Moreover, the technique is likely to be inaccurate in the presence of aortic valve stenosis or regurgitation or in patients with thoracic aortic disease, it is not easily applied in nonintubated patients, and it cannot be used in individuals with esophageal pathology. Finally, like all ultrasound techniques, the acoustic window needed to acquire the Doppler signal may not be adequate in some individuals, thereby precluding use of this method.

Advantages of the esophageal Doppler monitoring technique include its ease of use, minimal invasiveness, and inherent safety. It appears that limited experience is needed for clinical success—as few as 10 to 12 cases for accurate application of the technique.[401] In a recent review describing 25 clinical trials in which esophageal Doppler cardiac output measurement was compared with PAC thermodilution measurements, it was noted that the Doppler cardiac output values correlated well with the thermodilution measurements and showed minimal overall bias and good tracking of directional changes in thermodilution cardiac output with low intraobserver and interobserver measurement variability.[401]

The esophageal Doppler method has enjoyed renewed popularity.[402,406] Current devices provide a clear visual display of the spectral Doppler waveform, but they also calculate and display additional hemodynamic variables, including peak blood flow velocity, flow acceleration, and heart rate–corrected flow time (Fig. 40-45). Some studies have shown that these additional measures provide useful information about left ventricular preload, contractility, and SVR.[402,407] One of the more important values of the monitor may be focusing clinical attention on optimizing stroke volume rather than total cardiac output. Indeed, in critically ill patients, complications may be better predicted by low stroke volume than by low cardiac output.[408] Several studies have shown that volume resuscitation guided by maximizing esophageal Doppler–measured stroke volume in moderate-risk surgical patients reduces perioperative morbidity and shortens hospital stay.[409-411]

Bioimpedance Cardiac Output Monitoring

The technique of bioimpedance cardiac output monitoring was first described by Kubicek and colleagues and is based on changes in electrical impedance of the thoracic cavity occurring with ejection of blood during cardiac systole.[412] Their original formula relates these bioimpedance measurements to stroke volume:

$$SV = \frac{\rho L^2}{Zo^2} \times VET \times \max \frac{dZ}{dt} \qquad (7)$$

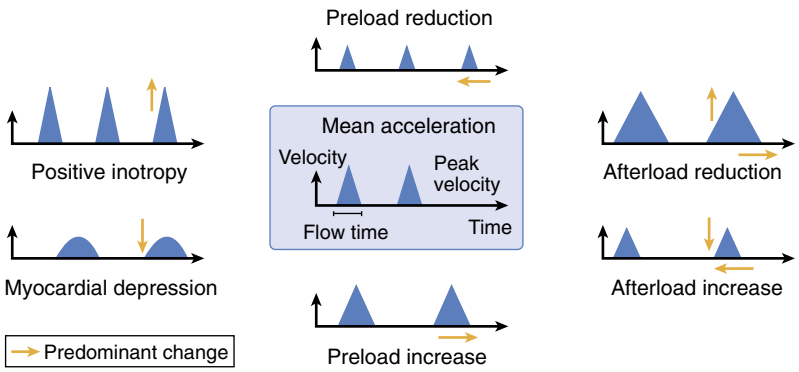

Figure 40-45 Spectral Doppler tracings of aortic blood flow recorded with esophageal Doppler cardiac output monitoring. The velocity-time waveform shape reflects alterations in contractility (mainly affecting peak velocity and mean acceleration), preload (mainly affecting systolic flow time corrected for heart rate [FTc]), and afterload (which affects FTc, mean acceleration, and peak flow velocity). *(Modified with permission from Singer M: Esophageal Doppler monitoring of aortic blood flow: Beat-by-beat cardiac output monitoring. Int Anesthesiol Clin 31:99-125, 1993.)*

where SV = stroke volume
ρ = specific resistivity of blood
L = thoracic length
Zo = basal thoracic impedance
VET = ventricular ejection time

$\max \frac{dZ}{dt}$ = maximum rate of impedance change during systolic upstroke

For performing the measurements, disposable electrodes are applied to the skin surface along the sides of the neck and lateral aspect of the lower part of the thorax, and a continuous small electrical current is applied across the chest. Patient height, weight, and gender are used to calculate the volume of the thoracic cavity. Bioimpedance cardiac output is computed for each cardiac cycle and continuously displayed as an average value over several heartbeats.

Although many studies suggest that the bioimpedance method is accurate in healthy volunteers, its reliability deteriorates in critically ill patients, including those with sepsis, increased lung water, aortic regurgitation, and electronic cardiac pacing.[413-415] More recent changes in signal processing techniques have improved the accuracy of thoracic bioimpedance measurements and might increase its clinical acceptance.[416]

Partial CO_2 Rebreathing Cardiac Output Monitoring

Another method of monitoring cardiac output that does not require pulmonary artery catheterization is the partial CO_2 rebreathing technique.[417,418] Because of the difficulty encountered in the standard Fick method involving measuring oxygen consumption and mixed venous hemoglobin saturation, this new technique is based on a restatement of the Fick equation for carbon dioxide elimination rather than oxygen uptake:

$$\dot{Q} = \frac{\dot{V}_{CO_2}}{C\bar{v}_{CO_2} - Ca_{CO_2}} \quad (8)$$

where $\dot{Q}$ = cardiac output
$\dot{V}_{CO_2}$ = rate of carbon dioxide elimination
$C\bar{v}_{CO_2}$ = carbon dioxide content of mixed venous blood
Ca_{CO_2} = carbon dioxide content of arterial blood

This method uses the change in CO_2 production and end-tidal CO_2 concentration in response to a brief, sudden change in minute ventilation. With a specially designed breathing system and monitoring computer, this measurement is easily performed in any tracheally intubated patient. Every 3 minutes a computer-controlled pneumatic valve intermittently increases dead space for a 50-second period, thereby causing partial rebreathing of exhaled gases. Changes in end-tidal CO_2 in response to the rebreathing are used to calculate cardiac output by a differential version of the Fick equation for carbon dioxide. The attractive features of this method are that it is entirely noninvasive, it can be performed every few minutes, and the brief episodes of rebreathing pose no substantial risk to most patients, with end-tidal CO_2 measurements increasing by less than 3 mm Hg. However, as currently designed, this technique requires tracheal intubation for accurate measurement of exhaled gases. Furthermore, changing patterns of ventilation may have an unpredictable influence on the measurement. As with all Fick-based techniques, the partial CO_2 rebreathing method measures pulmonary capillary blood flow as an indicator of total cardiac output and thus requires correction for pulmonary shunt.

The initial clinical trials suggested reasonably good agreement between the partial rebreathing CO_2 cardiac output method and other techniques such as thermodilution. However, as with most of these newer monitoring methods, the clinical trials are small and mainly focused on specific patient groups, particularly coronary artery bypass patients.[419] At present, the clinical role of this technique is primarily focused on short-term intraoperative applications or mechanically ventilated postoperative patients.

Lithium Dilution Cardiac Output Monitoring

The lithium dilution technique is another cardiac output monitoring method that derives its fundamental basis from indicator dilution principles.[420] In brief, after an intravenous bolus injection of a small dose of lithium chloride, an ion-selective electrode attached to a peripheral arterial catheter measures the lithium dilution curve, from which cardiac output is derived. Preliminary investigations suggest that this technique is accurate when compared with standard thermodilution methods or electromagnetic flowmetry.[421,422] As originally described, the technique required a central venous catheter for injection of lithium, but recent studies indicate comparable accuracy with peripheral intravenous bolus administration of the lithium indicator.[423] Thus, the technique seems to provide a method for accurate cardiac output measurement in a wide variety of critically ill patients who only have peripheral intravenous and arterial catheters.

Transpulmonary Thermodilution Cardiac Output

For transpulmonary thermodilution measurement, ice-cold saline is injected into a central line and the change in temperature is measured in a large peripheral artery (femoral, axillary, or brachial artery) via a special arterial catheter equipped with a thermistor.[424] Several studies have shown adequate correspondence to standard thermodilution cardiac output.[425,426] Because the measurement lasts over several cardiac cycles, respiratory effects on stroke volume are averaged and eliminated, in contrast to standard thermodilution.[427] Mathematical derivation from the thermodilution curve can produce two additional clinically useful indices: extravascular lung water, which is a measure of pulmonary edema,[428,429] and intrathoracic blood volume, which is a measure of preload. Several studies have found this index to be a better measure of cardiac preload than traditional measurements such as CVP or PAWP.[430,431]

Pulse Contour Cardiac Output Monitoring

In an attempt to provide continuous measurement of cardiac output, a number of techniques have focused on analysis of the arterial pulse pressure waveform. These methods, generally termed *pulse contour cardiac output*, determine the cardiac output from computerized analysis of the arterial pressure waveform

recorded from an arterial catheter or even a noninvasive finger blood pressure waveform.[432,433] Pulse contour methods offer the potential for continuous, beat-to-beat monitoring of cardiac output. In addition, the change in stroke volume from beat to beat can be used to evaluate volume status in ventilated patients.[434]

However, several disadvantages exist.[435] First, baseline calibration with a known cardiac output is required to account for individual differences in vascular resistance, impedance, and wave reflectance. Additionally, recalibration is required every 8 to 12 hours to account for changes in vasculature characteristics over time. A reasonably well-defined arterial pressure waveform is needed for accurate identification of systole and diastole, a condition that might not exist in patients with severe tachycardia or dysrhythmia.

Although early studies comparing these techniques showed fairly poor agreement with other cardiac output measurements, more recent clinical trials in surgical patients have shown that the pulse contour methods provide an acceptable level of accuracy.[433,436,437]

Gastric Tonometry

Gastric tonometry aims at monitoring gastric circulation as an early indication of splanchnic hypoperfusion.[438] A balloon-tipped tube is inserted into the stomach, and the saline or air in the balloon is allowed to equilibrate with the CO_2 in the gastric lumen. Intermittently, the saline or air is aspirated and the CO_2 level is measured. With the development of gastric hypoperfusion, clearance of CO_2 from the gastric mucosa decreases while CO_2 production increases from titration of acid released by anaerobic metabolism. The CO_2 from the mucosa diffuses freely to the gastric lumen and is detected by the tonometry.

Several studies have shown that gastric mucosal CO_2 and pH are a predictor of post-trauma or perioperative complications or death.[439-441] Furthermore, several studies have shown that therapy guided by gastric tonometry can improve clinical outcome in critically ill or perioperative patients.[442,443]

41 Transesophageal Echocardiography

Key Points

1. One of the category I indications for transesophageal echocardiography (TEE) is evaluation of intubated, hemodynamically unstable patients.
2. Guidelines expected in 2009 will probably recommend the use of TEE during all cardiac and other major surgical procedures in which severe hemodynamic instability is anticipated.
3. The speed of sound in the heart is assumed to be constant at 1540 m/sec.
4. The higher the transducer frequency, the better the image quality, but the more limited the depth of penetration.
5. Doppler echocardiography is used to measure the velocity of blood in the cardiac chambers and across the valves.
6. The modified Bernoulli equation transforms velocities into pressure gradients. Pressure gradient = $4V^2$, where V = velocity in m/sec.
7. Continuous wave Doppler measures high velocities but does not precisely identify their location.
8. Pulsed wave Doppler permits measurement of velocities at an exact location but is limited in its ability to measure high velocities.
9. Color Doppler codes for flow: blue away from the probe, red toward the probe (BART).
10. The abbreviated TEE examination will be adequate for the practice of basic TEE as defined by the 1996 SCA/ASA TEE guidelines.
11. TEE has been shown to be more sensitive than electrocardiography for the intraoperative detection of myocardial ischemia.

Transesophageal echocardiography (TEE) is the most powerful cardiovascular diagnostic technique available in the practice of perioperative medicine today. Thousands of published reports document its vital role in the determination of hemodynamics, detection of myocardial ischemia, evaluation of cardiovascular pathology, and assessment of cardiac surgical plans and results. With the information provided by TEE, anesthesiologists, surgeons, and intensivists can alter therapy to decrease morbidity and increase the survival of surgical patients. No other diagnostic technique has had such an impact on the practice of anesthesia and critical care. This chapter reviews the published literature documenting TEE's role in perioperative care after presenting a brief summary of TEE's history, its underlying physical principles, and the techniques required to perform it.

History

In 1976, Dr. Leon Frazin and colleagues published the results of studies using an esophageal M-mode transducer and thereby introduced the concept of transesophageal echocardiography.[1] Subsequently, Matsumoto and associates used M-mode TEE to study left ventricular (LV) function during cardiovascular surgery.[2] However, M-mode echocardiography provides too limited a view of spatial relationships to be practical for intraoperative monitoring or real-time decision-making. In the early 1980s, investigators led by Hanrath introduced a two-dimensional (2D), phased-array transducer mounted on the tip of a flexible gastroscope, and TEE's intraoperative potential became apparent.[3] However, wide adoption of TEE did not occur until the mid-1980s, when TEE transducer design was refined and color flow Doppler became commercially available. With these advances, TEE could provide the high-resolution, real-time images of structure and blood flow that we use on a daily basis today. However, the original single-plane and subsequent biplane TEE probes limited the potential imaging planes. Multiplane TEE using a rotatable 2D transducer within the probe tip resolved these limitations substantially and remains the current standard of practice.

Along with advances in probe technology, ultrasound manufacturers improved image compression algorithms, high-density digital storage, and broadband communication networks, which

has revolutionized the storage and processing of TEE images. Secure digital servers have replaced videotape libraries of clinical studies, thereby resulting in vastly faster access to and fidelity of stored images, and after decades of work on real-time three-dimensional (3D) imaging, it is finally a reality. Its impact on clinical practice remains to be determined, but we predict that it will simplify and speed mastery of the assessment of valvular anatomy and pathology.[4]

Practice Guidelines for Transesophageal Echocardiography

In 1992, the American Society of Echocardiography (ASE) Committee for Physician Training in Echocardiography published its guidelines for training in TEE.[5] They are based on previous recommendations for training in transthoracic echocardiography (TTE) and are directed at training for TEE in both operative and nonoperative applications. These guidelines require the trainee to attain at least an intermediate level of training in echocardiography and perform and interpret no less than 50 supervised TEE examinations. In 1996, a joint task force of the American Society of Anesthesiologists and the Society of Cardiovascular Anesthesiologists (SCA) published guidelines for perioperative TEE that defined two levels of practice: basic and advanced.[6] Anesthesiologists with basic training in perioperative TEE "should be able to use TEE for indications that lie within the customary practice of anesthesiology" and "must be able to recognize their limitations in this setting and request assistance, in a timely manner, from a physician with advanced training." Anesthesiologists with advanced training in perioperative TEE "should, in addition to the above, be able to exploit the full diagnostic potential of TEE in the perioperative period." These guidelines broadly defined the general principles for training in perioperative TEE, including cognitive and technical objectives. In addition, the guidelines delineated three categories of evidence-based indications for TEE, including category I indications, in which TEE was judged to frequently be useful in improving clinical outcomes in patients with hemodynamic instability, valvular pathology, cardiac source of emboli, and aortic pathology (Box 41-1). These indications were based on available data in 1995 when the task force wrote the guidelines. In 2007, the task force was reconvened to update the guidelines. Publication of their recommendations is expected in 2009. Based on the information available today, we anticipate a recommendation that TEE be used in all patients undergoing cardiac or thoracic aortic surgery and in other surgical patients in whom known or suspected cardiovascular pathology might result in significant hemodynamic, pulmonary, or neurologic compromise.

In 1999, a joint task force of the ASE and SCA published recommendations for a comprehensive TEE examination.[7] These recommendations described in detail the 20 TEE cross sections included in the comprehensive examination. In 2002, a joint task force of the ASE and SCA used the principles and recommendations published in the aforementioned guidelines to formulate guidelines for training in perioperative TEE, including the prerequisite medical knowledge and training, echocardiographic knowledge and skills, training components and duration, training environment and supervision, and equivalence requirements for postgraduate physicians already in practice.[8] A minimum number of cases are delineated; however, these numbers are less important than the depth and diversity of the clinical experience and the quality of training. Like previous published guidelines, these guidelines provide training recommendations for a basic and an advanced level of perioperative echocardiography. Unlike previous guidelines, these guidelines do not specify the duration of training. Instead, they emphasize the goals of training and the number and diversity of cases required to meet these goals (Table 41-1). The time required for perioperative training will vary markedly depending on the volume and diversity of the affiliated cardiac surgical program.

The American Heart Association (AHA), American College of Cardiology (ACC), ASE, and other professional organizations have issued other guidelines that involve TEE. In 2003, the AHA, ACC, and ASE published practice guidelines for the clinical use of echocardiography, including intraoperative and critical care TEE applications.[9] Their class I indications are essentially the

Box 41-1 Indications for Perioperative Transesophageal Echocardiography

Category I indications: Supported by the strongest evidence or expert opinion; TEE is frequently useful in improving clinical outcomes in these settings and is often indicated, depending on individual circumstances, for the following:

Intraoperative evaluation of acute, persistent, and life-threatening hemodynamic disturbances in which ventricular function and its determinants are uncertain and have not responded to treatment

Intraoperative use in valve repair

Intraoperative use in congenital heart surgery for most lesions requiring cardiopulmonary bypass

Intraoperative use in repair of hypertrophic obstructive cardiomyopathy

Intraoperative use for endocarditis when preoperative testing was inadequate or extension of infection to perivalvular tissue is suspected

Preoperative use in unstable patients with suspected thoracic aortic aneurysms, dissection, or disruption who need to be evaluated quickly

Intraoperative assessment of aortic valve function during repair of aortic dissections with possible aortic valve involvement

Intraoperative evaluation of pericardial window procedures

Use in the intensive care unit for unstable patients with unexplained hemodynamic disturbances, suspected valve disease, or thromboembolic problems (if other tests or monitoring techniques have not confirmed the diagnosis or patients are too unstable to undergo other tests)

Adapted with permission from Practice guidelines for perioperative transesophageal echocardiography. A report by the American Society of Anesthesiologists and the Society of Cardiovascular Anesthesiologists Task Force on Transesophageal Echocardiography. Anesthesiology 84:986-1006, 1996.

Table 41-1 Recommendations for Basic and Advanced Perioperative Echocardiography

	Basic*	Advanced*
Minimum number of examinations†	150	300
Minimum number personally performed‡	50	150
Program director qualifications	Advanced perioperative echocardiography training	Advanced perioperative echocardiography training plus at least 150 additional perioperative TEE examinations
Program qualifications	Wide variety of perioperative applications of echocardiography	Full spectrum of perioperative applications of echocardiography

*Totals for basic training may be counted toward advanced training provided that the basic training was completed in an advanced training environment.
†Complete echocardiographic examinations interpreted and reported by the trainee under appropriate supervision; may include transthoracic studies recorded by qualified individuals other than the trainee.
‡Comprehensive intraoperative transesophageal echocardiographic examinations personally performed, interpreted, and reported by the trainee under appropriate supervision.
Adapted from Cahalan MK, Abel M, Goldman M, et al: American Society of Echocardiography and Society of Cardiovascular Anesthesiologists task force guidelines for training in perioperative echocardiography. Anesth Analg 94:1384-1388, 2002.

same as those listed in Box 41-1. In 2005, the ASE published its recommendations for indications and performance guidelines for pediatric TEE, including intraoperative applications,[10] and in 2007, the ACC, ASE, and multiple other societies issued their appropriateness criteria (i.e., summary of proven indications) for TTE and TEE. However, in this publication, intraoperative applications were explicitly excluded.

Properties of Ultrasound

To noninvasively visualize structures inside the body, ultrasound machines generate an imperceptible vibration within a transducer that, when put next to tissue surfaces, vibrates the surrounding tissue (muscle, blood, fat, or bone). During vibration, particles within the tissue compress and then spread apart. This dual process is called *compression* and *rarefaction*. The sequence of compression and rarefaction is described by sine waves and is characterized in terms of wavelength, frequency, amplitude, and propagation velocity (Fig. 41-1).

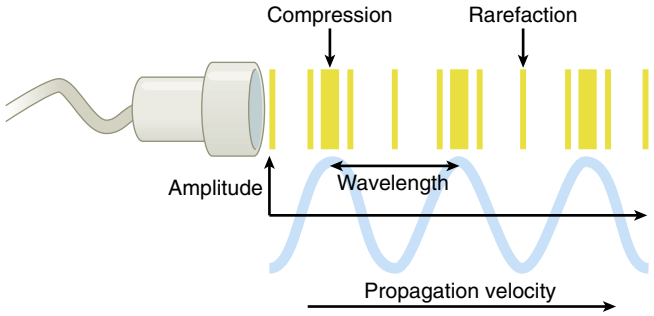

Figure 41-1 Illustration of terms used to describe transmission of ultrasound energy from a transducer into adjacent tissue. As ultrasound vibrations enter surrounding tissue, particles within the tissue compress and then spread apart (compression and rarefaction). Sine waves are used to characterize the sequence of compression and rarefaction, wavelength is the distance between two peaks of the sine wave, amplitude is a measure of tissue compression, and propagation velocity is the speed of the ultrasound wave within tissue.

Wavelength is the distance between two peaks of the sine wave. Wavelengths used in ultrasound are measured in millimeters. *Frequency* is the number of cycles that occur in 1 second. One cycle per second is defined as 1 hertz (abbreviated Hz). Ultrasound is sound with frequencies higher than the audible range for humans, or greater than 20,000 cycles per second (20 kHz). Frequencies typically used for sonographic imaging are 2 to 10 mega hertz (MHz). Wavelength is inversely related to frequency.

Amplitude is a measure of tissue compression. Amplitude represents the *loudness* of an ultrasound wave. Amplitude can vary over a large range and is described by decibels (dB). Decibels is a logarithmic transformation that allows large amplitudes to be presented next to small amplitudes (i.e., 1000 and 0.001) on the same display. A rule of thumb is that a 6-dB change is equivalent to doubling or halving of the amplitude.

Propagation velocity describes the speed of an ultrasound wave traveling through tissue. In blood it is 1540 m/sec. The relationship between propagation velocity, frequency, and wavelength is described by Equation 1:

$$\text{Propagation velocity} = \text{Frequency} \cdot \text{Wavelength} \qquad (1)$$

Assuming that propagation velocity is constant, the wavelength for any frequency can be calculated (Table 41-2).

Transducers, typically made of quartz or titanate ceramic, use crystals that exhibit the piezoelectric effect. With electricity,

Table 41-2 Relationship Among Frequency, Wavelength, and Depth of Penetration

Frequency	Wavelength	Depth of Penetration (200-400 × Wavelength)	Approximate Resolution (2 × Wavelength)
3.5 MHz	0.44 mm	9-18 cm	0.9 mm
5.0 MHz	0.31 mm	6-12 cm	0.6 mm
6.0 MHz	0.26 mm	5-10 cm	0.5 mm
7.5 MHz	0.21 mm	4-8 cm	0.4 mm

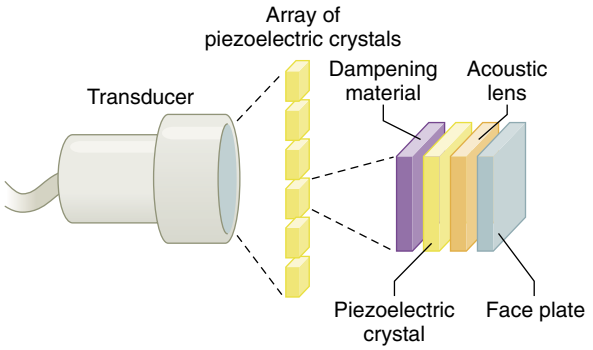

Figure 41-2 Illustration of an array of piezoelectric crystals contained within an ultrasound transducer. When pulsed with alternating current, piezoelectric crystals "ring" much like a bell. The crystal continues to vibrate after an electrical pulse has ended. To achieve a crisper pulse, a backing material is applied to the crystal to *dampen* the ring after the pulse has ended. To optimize transmission from the crystal into tissue, an *acoustic lens* focuses the ultrasound beam and an *impedance-matching face plate* improves conductance of ultrasound from the transducer into tissue.

the crystal vibrates and emits ultrasound. The reverse also holds: When ultrasound waves strike a piezoelectric crystal and make it vibrate, the crystal generates electricity. Thus, the same crystals can serve as emitters and receivers of ultrasound. The *frequency* of vibration is determined by the thickness of the piezoelectric crystal. To refine and control the emitted ultrasound beam, several layers of material are placed adjacent to the crystal (Fig. 41-2).

Transducer Frequency, Image Resolution, and Depth of Penetration

Echocardiography uses ultrasound waves with frequencies of 2.5 to 7.5 million cycles/sec (MHz). Important relationships between transducer frequency, depth, and resolution include (1) the slower the frequency, the greater the depth of penetration at the expense of resolution, and (2) the faster the frequency, the greater the resolution at the expense of depth of penetration (Table 41-3). Frequencies greater than 7.5 MHz are not used because they produce wavelengths too short for adequate penetration into tissue (an exception would be epiaortic scanning). Penetration is limited to about 200 to 400 times the wavelength. Resolution is limited to about twice the wavelength.

Image resolution is characterized in terms of axial, elevational, lateral, and temporal resolution. Axial resolution is resolution along the length of an ultrasound beam. It is a function of transducer frequency and pulse width. Long wavelengths (slow frequency) have deeper tissue penetration but are unable to resolve objects that are close together along the ultrasound beam scan line. Short wavelengths (fast frequency) do the opposite. Similarly, short-duration pulses improve and long pulses worsen axial resolution. Elevational resolution refers to the thickness of the ultrasound image: typically 8 to 10 mm.

Lateral resolution is a function of ultrasound beam formation. The initial segment (near field) of an ultrasound beam is columnar, and the length is dependent on transducer width and wavelength. Beyond the near field, the beam diverges (far field). Divergence is also a function of transducer frequency. As the frequency rises, the near field gets longer and the divergence angle decreases. For example, for transducer frequencies of 3.5 and 7 MHz, the divergence angles are 26 and 12 degrees, respectively. As the transducer width gets smaller, the angle of divergence gets larger. The lack of lateral resolution at greater depths accounts for blurring of the image in the far field (Fig. 41-3A and B).

Another descriptor of lateral resolution is the grating lobe. A grating lobe is a diverging ultrasound beam that emerges from the transducer along with the main ultrasound beam. The angle of the diverging grating lobe is determined by the spacing between the crystals in a transducer array. At angles at which the path length of an ultrasound wave between the two adjacent transducer crystals differs by one wavelength, a grating lobe is formed (Fig. 41-4).

An example of a grating lobe artifact is a properly positioned pulmonary artery catheter that appears to go through the aorta. The artifact appears as an echo-dense archlike object that traverses structures within the heart and is at equal distance from the transducer throughout the image. In this example, a diverging ultrasound beam from a grating lobe is reflected back to the transducer. The ultrasound machine cannot differentiate between reflected ultrasound from the main beam and the grating lobe beam.

Temporal resolution is the ability to accurately locate moving structures at a particular instant in time. The more images displayed per second (frame rate), the better the temporal resolution. A typical frame has 128 lines in a 90-degree 2D image. If the depth is set to 20 cm, the time required for sampling one line is 260 μsec. To scan all 128 lines requires 33 msec. In 1 second, the sector is scanned 30 times. To image moving structures inside the heart, a frame rate of at least 30 frames/sec is required. Decreasing

Table 41-3 Clinical Features of Pulsed Wave, Continuous Wave, and Color Flow Doppler

Doppler Technique	Advantages	Disadvantages	Clinical Uses
Pulsed wave	Measures blood flow velocities at selected areas of interest 3-5 mm wide along the ultrasound scan line	Cannot measure fast blood flow velocities (>1 m/sec) because of aliasing	To measure blood flow velocities through the pulmonary veins and mitral valve and in low-flow areas within the heart
Continuous wave	Detects blood flow velocities up to 7 m/sec (not subject to the Nyquist limit)	Cannot identify location of the peak velocity along the ultrasound scan line	To measure blood flow velocities through the aorta, aortic valve, stenotic valve lesions, and regurgitant valvular jets
Color flow	Presents the spatial relationships between structure and blood flow	Like pulsed wave Doppler, cannot measure fast blood flow velocities because of aliasing	To enhance recognition of valvular abnormalities, aortic dissections, and intracardiac shunts

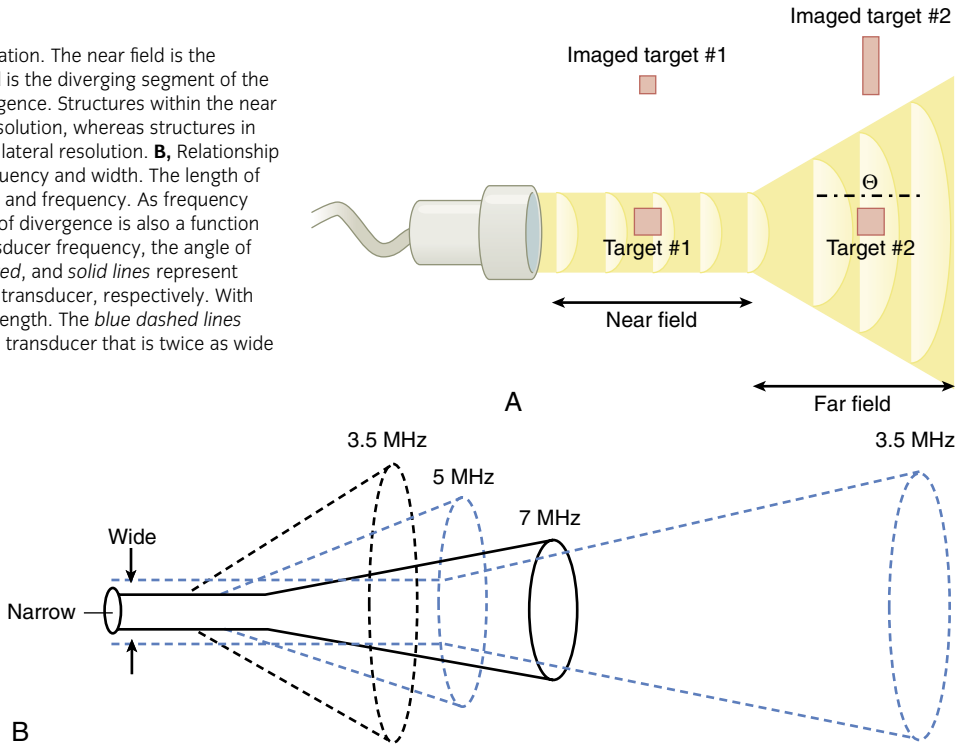

Figure 41-3 **A,** Near- and far-field beam formation. The near field is the columnar portion of the beam and the far field is the diverging segment of the beam. Theta (Θ) represents the angle of divergence. Structures within the near field (target 1) are imaged with crisp lateral resolution, whereas structures in the far field (target 2) are imaged with blurred lateral resolution. **B,** Relationship between near-field length and transducer frequency and width. The length of the near field is a function of transducer width and frequency. As frequency increases, the near field lengthens. The angle of divergence is also a function of transducer frequency. With increasing transducer frequency, the angle of divergence decreases. The *black dashed*, *dotted*, and *solid lines* represent beam divergence for a 3.5-, 5.0-, and 7.0-MHz transducer, respectively. With wider transducers, the near field increases in length. The *blue dashed lines* represent the near and far fields for a 3.5-MHz transducer that is twice as wide as the narrow transducer.

image depth will improve temporal resolution. Ultrasound machines allow the operator to zoom in on a region of interest within the 2D display. This function redistributes the number of scan lines used to generate a full 2D image into a smaller region of interest and thereby improve temporal resolution.

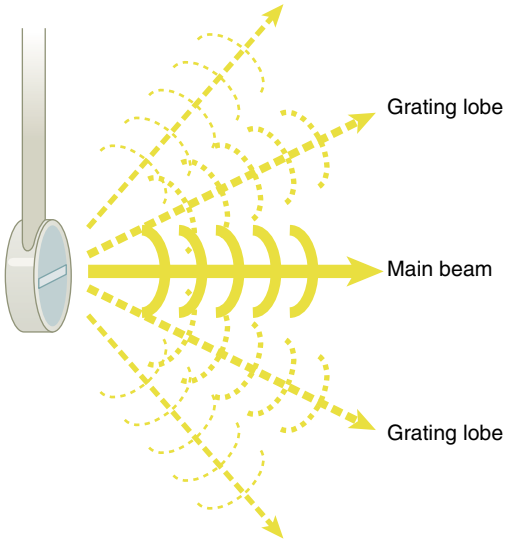

Figure 41-4 The main ultrasound beam (*solid line*) emitted from a transducer is accompanied by a series of grating lobes (*dotted lines*). The grating lobes are a phenomenon of beam formation that is a function of the array of piezoelectric crystals within the transducer. At certain angles from the main beam, the ultrasound wave from each crystal within the array is exactly one wavelength behind the wavelength from the adjacent crystal. This generates a grating lobe. The clinical implications of grating lobes are that highly echogenic objects such as a Swan-Ganz catheter or a mitral valve prosthesis can "appear" to be locations within the heart (i.e., the aorta) that are incorrect.

As ultrasound waves penetrate tissue, signal strength is attenuated. *Attenuation* is a function of tissue *absorption* (ultrasound energy converted to heat), *divergence* of ultrasound energy as it moves away from the transducer, *reflection*, and *scattering* (Fig. 41-5). Absorption is dependent on tissue type. For example, air absorbs more ultrasound energy than bone does, but bone absorbs more than blood or water does. A term used to describe absorption is half-power distance, which is the distance required

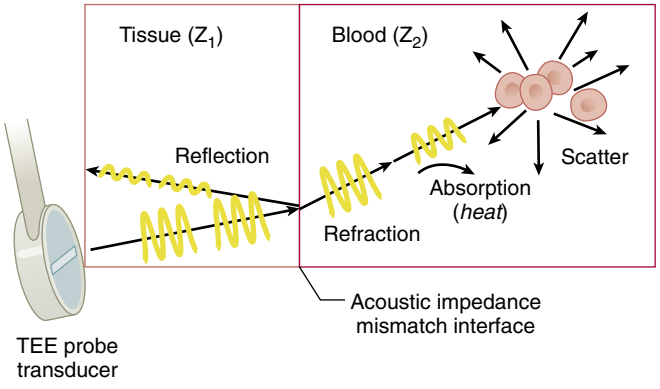

Figure 41-5 Diagram of specular reflection, refraction, absorption, scatter, and acoustic impedance. As ultrasound waves strike an interface between two different tissue types, some of it is reflected and the remainder passes through. The reflected ultrasound wave has a trajectory angle equal to the incident angle. Refraction refers to deflection of the ultrasound beam as it travels from one tissue type to another. Scattering occurs when an ultrasound wave strikes a structure that is less than one wavelength in lateral dimension (a red blood cell). Absorption represents the amount of ultrasound energy that dissipates as heat. Acoustic impedance refers to the resistance that an ultrasound wave meets when traveling though tissue. Acoustic impedance (Z) is defined as the product of tissue density and propagation velocity.

to decrease the ultrasound energy by 50%. The half-power distances for air, bone, blood, and water are 0.08, 0.8, 15, and 380 cm, respectively.

As ultrasound waves strike an interface between two different tissue types, some of it is reflected and the remainder passes through. Just as light is reflected from a mirror, the reflected ultrasound wave has a trajectory angle equal to the incident angle. The amplitude of reflected ultrasound waves is decreased by 40 to 60 dB (100- to 1000-fold). Ultrasound waves that pass through to adjacent tissue are subject to *refraction*. Refraction refers to deflection of the ultrasound beam as it travels from one tissue type to another. An example of refraction is distortion of an image of an object when partially submerged in a fish tank or swimming pool. Refraction can bend ultrasound beams and thus make objects appear in locations where they do not exist. Scattering occurs when an ultrasound wave strikes a structure that is less than one wavelength in lateral dimension (a red blood cell). The scattered ultrasound energy is radiated in all directions.

Acoustic impedance refers to the resistance that an ultrasound wave meets when traveling though tissue. It is a function of tissue density and is defined by Equation 2:

$$\text{Acoustic impedance (Z)} = \text{Tissue density} \cdot \text{Propagation velocity} \quad (2)$$

The greater the tissue density, the faster the ultrasound beam moves through the tissue. For example, ultrasound waves are much slower in air (330 m/sec), faster in blood (1540 m/sec), and very fast in bone (4080 m/sec). The extent of ultrasound beam reflection is a function of the difference in acoustic impedance between two adjacent tissues. The larger the difference in acoustic impedance, the more ultrasound energy will be reflected. Bone–soft tissue and air–soft tissue interfaces reflect most of the ultrasound beam. Imaging structures deep to these interfaces is difficult.

Mismatches in acoustic impedance and attenuation are important to consider in imaging the heart with TEE. For example, the upper aortic arch is difficult to visualize from the esophagus because of interposition of the air-filled trachea. In addition, most of the ultrasound energy that does make it to the trachea-tissue interface is reflected as a result of the large difference in acoustic impedance between air and tissue.

Basic Principles of Image Optimization: Gain, Depth, and Focus

Gain is used to amplify low-amplitude ultrasound waves reflected back to the transducer. Gain represents how well the ultrasound system *listens*. It can be used to offset the large-amplitude signals returned from proximal structures from the low-amplitude signals returned from distant structures. Many ultrasound machines have a series of sliding controls called *time gain compensation* controls that allow the operator to adjust the gain at a given depth. One temptation when structures are not readily visualized in the brightly lit operating room is to turn up the gain. Although gain increases structure brightness, it comes at the cost of amplifying background noise. A better approach is to brighten the display screen settings and keep gain at normal settings.

In echocardiography, the crystals emit very short pulses of ultrasound (0.5 to 3 µsec containing two wavelengths) and receive or "listen" for the reflected ultrasound for 250 to 500 µsec. The *pulse repetition frequency* (PRF) is the number of pulses that leave and return to the transducer in a single second. As image depth is increased, the time required to reach the target depth and return increases. Thus, the number of cycles that can be completed within 1 second is reduced. The opposite also holds: as imaging depth decreases, PRF increases. PRF is also described in hertz; it is audible and ranges from 1 to 10 kHz.

Early echocardiography displays used this principle to map out the depth of structures within the heart. The first echocardiograms, "motion" or "M-mode" studies, were one-dimensional views of cardiac structures produced by single-crystal transducers with the results traced on moving photosensitive paper. Today, M-mode echocardiography is used principally to view rapidly moving structures, such as valve leaflets, because M-mode transducers can produce up to 1800 images/sec (Fig. 41-6). However, M-mode images reveal only a small portion of the heart at one time, thus making orientation and interpretation of spatial relationships difficult.

To generate 2D images, ultrasound machines were configured to sequentially redirect the beam over an area (sector) of interest. Transducers contain a row of piezoelectric crystals (a linear array). By introducing a small delay in the firing of adjacent crystals in the array (a phased array), the ultrasound machine is able to steer the resultant ultrasound beam. Hence, by varying the time delay between crystals, ultrasound machines are able to steer

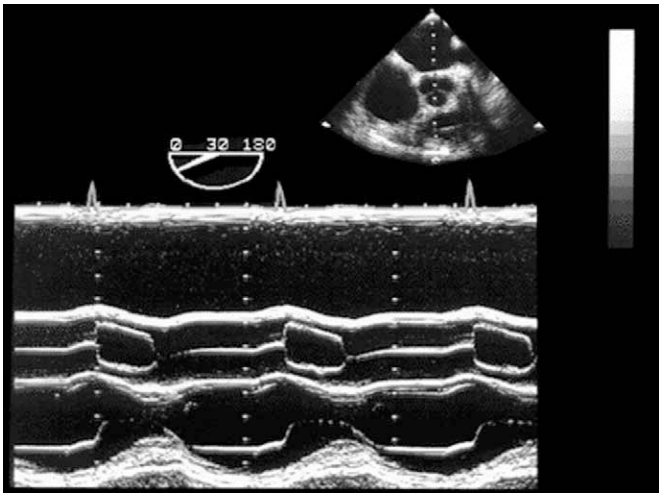

Figure 41-6 M-mode transesophageal echocardiogram of a normal aortic valve. For reference, a single frame (stop action) of the two-dimensional cross section is shown at the top right of the figure. The *dotted vertical line* through the two-dimensional echocardiogram depicts the single line of sampling provided by the M-mode echocardiogram over time (the horizontal axis for the lower two thirds of the figure). The electrocardiogram defines systole and diastole. Note in the middle of the M-mode image the three tilted *rectangles* connected by the slightly *undulating line*. These rectangles and lines are formed by the motion of the leaflets of the aortic valve as they open and close during the cardiac cycles shown. From top to bottom in this M-mode echocardiogram, the structures indicated by the *white lines* are the posterior wall of the left atrium (just under the electrocardiogram), the posterior wall of the aortic annulus, the aortic valve (as described above), the anterior wall of the aortic annulus, a pulmonary artery catheter, and the myocardium of the right ventricular outflow tract. *(Reproduced with permission from Cahalan MK: Intraoperative Transesophageal Echocardiography. An Interactive Text and Atlas. New York, Churchill Livingstone, 1997.)*

the beam through a sector of interest (typically a 90-degree sector). Although 2D techniques produce only about 30 images/sec, definition in two dimensions provides an enormous advantage in recognizing anatomic and pathologic landmarks (Fig. 41-7). Images are displayed in "real time" on a monitor screen and digitally recorded for later review. In a similar fashion to steering the ultrasound beam, the *focal depth* of an ultrasound beam can be adjusted by triggering the piezoelectric crystals to concentrate the ultrasound beam at a desired depth (Fig. 41-8). The focal depth is typically set at or just below the structure of interest in a 2D image.

The advance from 2D to real-time 3D echocardiography has proved difficult. The time needed to acquire the requisite 2D images, the computing challenge of collating them into 3D images, and the display challenge of depicting 3D images on a 2D video screen all contributed to the difficulty. Matrix-array transducers solved the image acquisition problem. Typically, they contain over 3000 imaging elements and electronically rotate the 2D ultrasound beam through 180 degrees in milliseconds to acquire the requisite 2D images in a fraction of the time possible with mechanically rotated multiplane transducers. Computing power and commercially patented display algorithms solved the other problems (Fig. 41-9).[11]

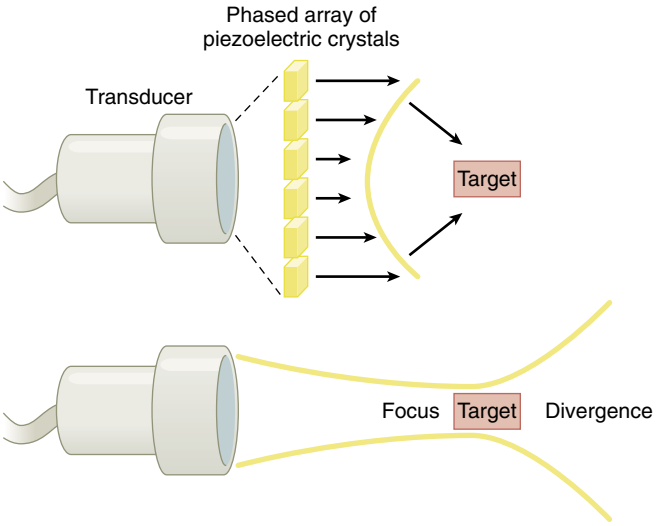

Figure 41-8 Schematic illustration of phasing the start of an array of piezoelectric crystals to focus an ultrasound beam. Crystals are sequentially fired from the outer edge to the middle of the array. The resultant concave wave converges at a point some distance from the transducer. The focal distance from the transducer is a function of the time delay between firing crystals from the edge to the middle of the array.

Integration of Flow and Structure

Christian Doppler, a physicist, studied a band playing a specific pitch on a moving train. He observed a change in pitch as the train passed by. In this experiment he characterized the relationship between train velocity and frequency (pitch), known as the Doppler shift. When applied to echocardiography, Doppler shift provides a significant enhancement to 2D imaging. With Doppler, blood flow velocity can be measured as blood flows through structures inside the heart. The ultrasound that bounces off moving red blood cells is reflected back to the transducer at a slightly different frequency than that emitted from the transducer. The shift in frequency allows the ultrasound machine to estimate blood flow velocity and direction of flow. Blood flow toward a transducer increases the frequency and vice versa with blood flowing away from the transducer. Doppler shifts are between 20 and 2000 Hz (within the audible range). Many ultrasound machines allow the user, if interested, to listen to the Doppler shift.

One important feature of assessing Doppler shift is the intercept angle (i.e., θ). To get the most accurate estimate of red blood cell speed, Doppler shift should be measured with an ultrasound beam that travels in the direction of blood flow. As the intercept angle deviates from zero degrees, blood flow will be underestimated. To compensate for this, the cosine of θ is used to account for the sampling angle. Most ultrasound machines

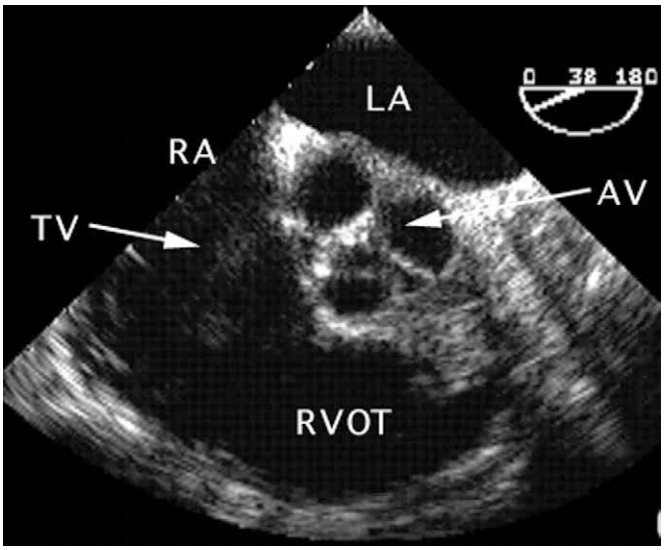

Figure 41-7 Stop-action short-axis two-dimensional cross section of a normal aortic valve (AV). This midesophageal view of the AV reveals the morphology of the three cusps of this normal valve. LA, left atrium; RA, right atrium; RVOT, right ventricular outflow tract; TV, tricuspid valve. *(Reproduced with permission from Cahalan MK: Intraoperative Transesophageal Echocardiography. An Interactive Text and Atlas. New York, Churchill Livingstone, 1997.)*

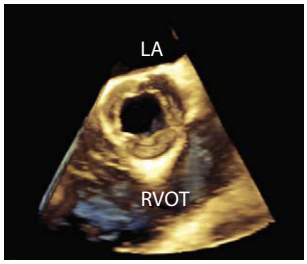

Figure 41-9 Stop-action image of a short-axis three-dimensional cross section of a normal aortic valve during systole. The partially open leaflets of aortic valve are seen in the center of the figure. Shadowing and color variation are used to depict the actual three-dimensional contours and shape of the valve and surrounding structures. In stop-action mode, these techniques are not as effective as when the real-time images are displayed. LA, left atrium; RVOT, right ventricular outflow tract.

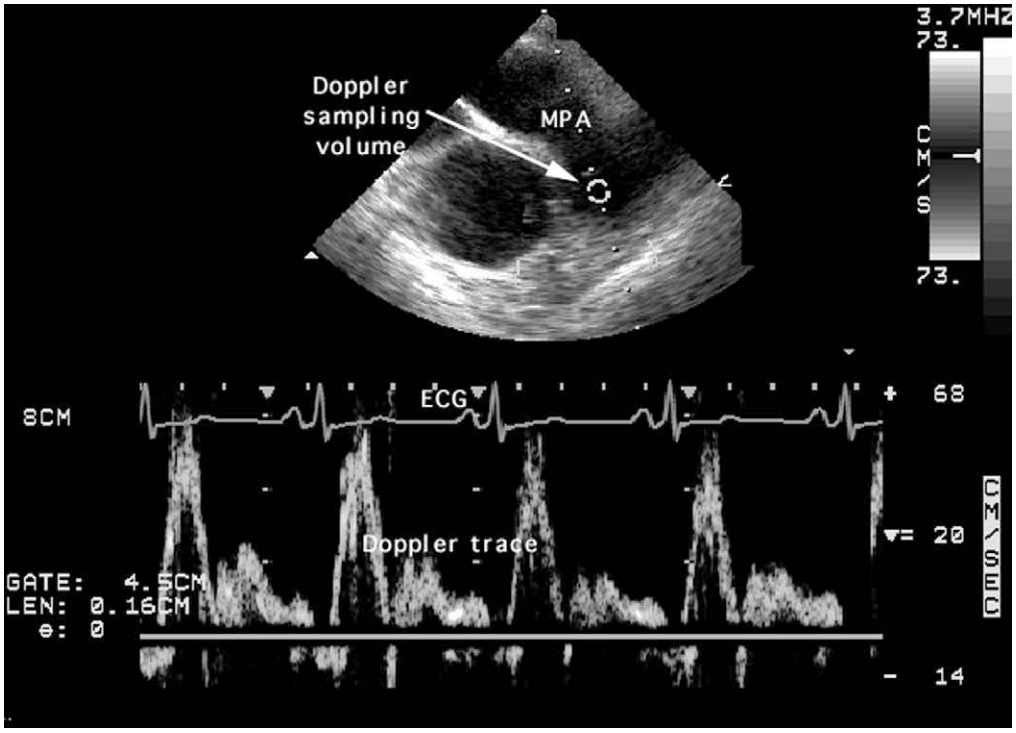

Figure 41-10 Pulsed wave Doppler echocardiogram of the main pulmonary artery (MPA). At the top of the echocardiogram is a still-frame image of the two-dimensional cross section used to position the Doppler sampling volume (*broken circle* at point of *white arrow*). On the bottom two thirds of the echocardiogram is the display in white of the instantaneous blood flow velocities (vertical axis) versus time (horizontal axis) occurring in that sample volume. The electrocardiogram (ECG) provides timing, and the *bold horizontal line* is the baseline (zero flow) for the flow velocities. Flow velocities above this line are positive (i.e., toward the transducer) to a maximum of 68 cm/sec. Flow below this line is negative (i.e., away from the transducer) to a maximum of –14 cm/sec. *(Reproduced with permission from Cahalan MK: Intraoperative Transesophageal Echocardiography. An Interactive Text and Atlas. New York, Churchill Livingstone, 1997.)*

ignore the cosine term (assume that $\theta = 0$ and cosine $\theta = 1$). At angles of 20, 30, and 60 degrees, Doppler shift will underestimate the velocity by 6%, 13%, and 50%, respectively. An intercept angle of up to 30 degrees is usually acceptable.

Doppler shifts are presented in three ways: pulsed wave Doppler (PWD), continuous wave Doppler (CWD), and color flow Doppler (CFD). The clinical features of each are presented in Table 41-3. With PWD, a small sampling volume (cursor) is placed in an area of interest within a 2D image. The transducer generates a pulse of ultrasound and then switches to the receive mode and awaits the arrival of a reflected portion of the ultrasound pulse from the sampling area (Fig. 41-10). The ultrasound machine then measures the frequency shift (or Doppler shift) to estimate the speed of blood cells in the sample volume.

One limitation of PWD is that it may be too slow to capture the velocity of fast-moving blood cells. This phenomenon is known as *aliasing*. An example of aliasing is when one watches the spokes on a wagon wheel in a western movie. As velocity increases, the movie camera detects an increase in rotational velocity of the wheel up to a point, and then the wheel appears to start spinning backward. As rotational velocity increases beyond the movie camera's sample rate, the wheel appears to be slowing down even though in reality it is speeding up.

The limit at which the sampling rate fails to accurately capture the true velocity is called the *Nyquist limit*. The sampling frequency, in this example the movie camera's sampling rate, must be at least twice the speed of the rotational velocity of the wagon wheel. With PWD, if the velocity of blood flow exceeds the Nyquist limit for the PRF (defined as PRF/2), blood flow will appear to reverse direction (Fig. 41-11).

For PWD, the maximal detectable velocity is a function of depth and transducer frequency. For depth, the farther the ultrasound pulse has to travel, the slower the maximal detectable velocity. For transducer frequency, the faster the frequency, the slower the maximal detectable velocity. To minimize aliasing with PWD, the slowest transducer setting is used. Aliasing of PWD occurs at blood flow velocities greater than 0.8 to 1.0 m/sec. Normal flow within the heart may reach 1.4 m/sec and pathologic flow up to 6 m/sec. To measure such velocities, CWD is needed.

CWD uses two sets of separate crystals: one to continuously emit ultrasound and one to continuously receive it. CWD has an infinite PRF, which eliminates the problem of aliasing (Fig. 41-12). However, this infinite pulse repetition rate allows insufficient time for the first pulse to return to the transducer before the next is emitted. Consequently, the ultrasound machine cannot precisely define the location of the moving blood cells.

CFD is based on PWD and uses multiple sample volumes along a scan line. The operator selects an area of interest ("color sector"). Scan lines are sequentially scanned through this sector. Blood flow velocity measurements are taken at several points along each scan line. A color code is used to depict flow toward (red) and away (blue) from the transducer; lighter and darker shades of red and blue, respectively, denote relatively faster and slower velocities. Continuous color maps of flow are superimposed on gray-scale cross-sectional echocardiograms. CFD has the same limitations as described previously for PWD. The

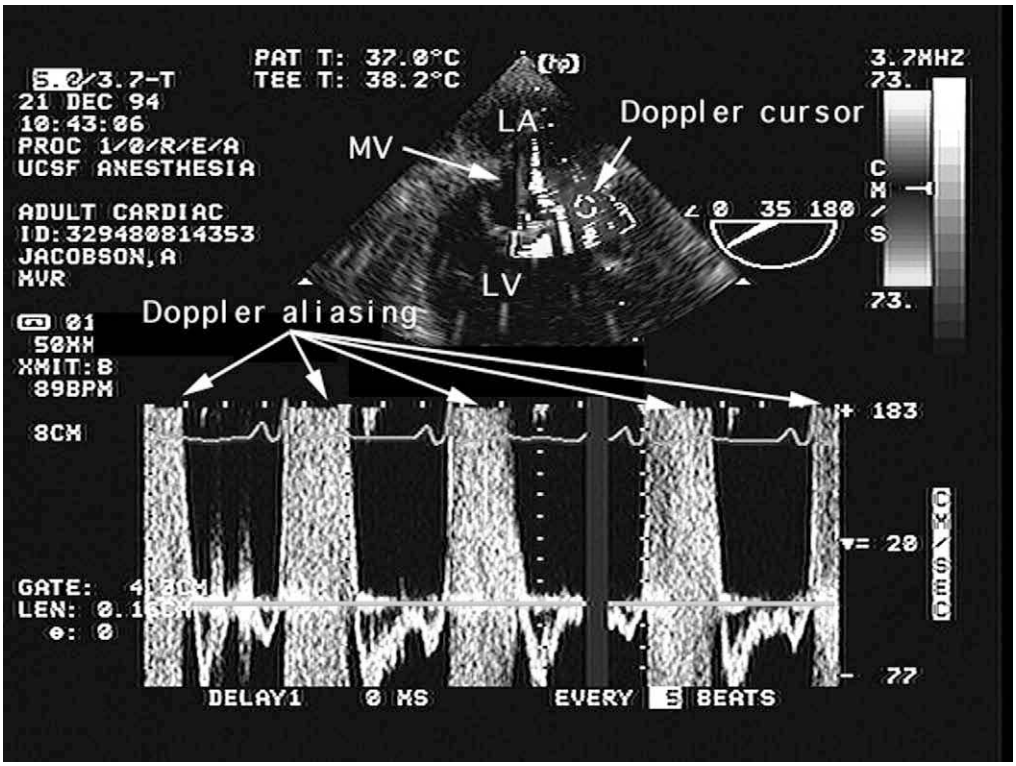

Figure 41-11 Pulsed wave Doppler (PWD) echocardiogram with aliasing at high velocities. PWD measurement of blood flow velocities in a mitral valve (MV) orifice during four cardiac cycles is shown. At the top of the figure is a still-frame image of the two-dimensional cross section used to position the Doppler sampling volume (indicated by the Doppler cursor–labeled *arrow*). On the bottom two thirds of the figure is the display in white of the instantaneous blood flow velocities (vertical axis) versus time (horizontal axis) occurring in that sample volume. The electrocardiogram provides timing, and the *bold horizontal line* is the baseline (zero flow) for the flow velocities. Flow velocities above this line are positive (i.e., toward the transducer) to a maximum of 183 cm/sec. Flow velocities below this line are negative (i.e., away from the transducer) to a maximum of –77 cm/sec. This tracing documents significant mitral regurgitation (the positive systolic velocities) but does not measure the peak velocity of regurgitant flow because it is beyond the Nyquist limit—the systolic velocities off the top of the scale are said to alias; that is, they go off scale and wrap around into the domain of negative velocities. LA, left atrium; LV, left ventricle. *(Reproduced with permission from Cahalan MK: Intraoperative Transesophageal Echocardiography. An Interactive Text and Atlas. New York, Churchill Livingstone, 1997.)*

maximal blood velocity that can be detected with CFD is a function of sector depth and PRF. PRF is considerably longer with CFD because of the numerous series of samples taken throughout the sector of interest, so the Nyquist limit is typically lower than with PWD.

Two aliasing patterns are easily recognized. The first is "normal" aliasing, in which the area of apparent flow reversal forms one or more broad, relatively homogeneous color surfaces (Fig. 41-13). Blood flow velocities within a normal heart often produce this type of aliasing because they exceed the Nyquist limit for color Doppler (0.6 to 0.8 m/sec). The second type of aliasing results from disturbed or turbulent flow within the heart (e.g., mitral regurgitation) and is never normal (Fig. 41-14). When the ultrasound machine detects two different velocities within the same small sample volume (as a result of disturbed flow), it displays a mixture, or mosaic, of colors. In most cardiovascular abnormalities these mosaics form jetlike configurations and are called "color jets." Minimizing the color sector area or reducing the distance between the transducer and the sector (or both) increases the overall PRF and thus allows an increase in the maximal measurable flow velocity before aliasing occurs. When evaluating color jets caused by valvular regurgitation, jet size is affected markedly by the Nyquist limit and gain settings. To facilitate consistent interpretation, the ASE recommends using a Nyquist limit (aliasing velocity) of 50 to 60 cm/sec and a color gain that just eliminates random color speckle from nonmoving regions.[12]

Tissue Doppler

Tissue Doppler imaging is a relatively new use of PWD technology adapted to measure myocardial velocity instead of blood flow velocity.[13] During normal LV contraction, the mitral annulus descends toward the apex of the heart. Tissue Doppler imaging measures the velocity of this descent (S_m), and S_m correlates with traditional measures of LV function, including ejection fraction and the rate of rise in LV systolic pressure (dP/dt).[14,15] In addition, S_m decreases in the presence of myocardial ischemia and responds as expected with changes in inotropy.[16,17] The four-chamber cross-sectional view is best for measuring S_m; the sampling volume is placed at the lateral insertion point of the mitral valve into the left ventricle and the cross section is aligned so that the sampling cursor is directly parallel to the motion of the annulus. S_m is an easy and reproducible measurement. However, like fractional area change and fractional shortening, it should be interpreted with caution when preload changes. Ama and associates tested its load dependence in 42 hemodynamically stable patients with normal

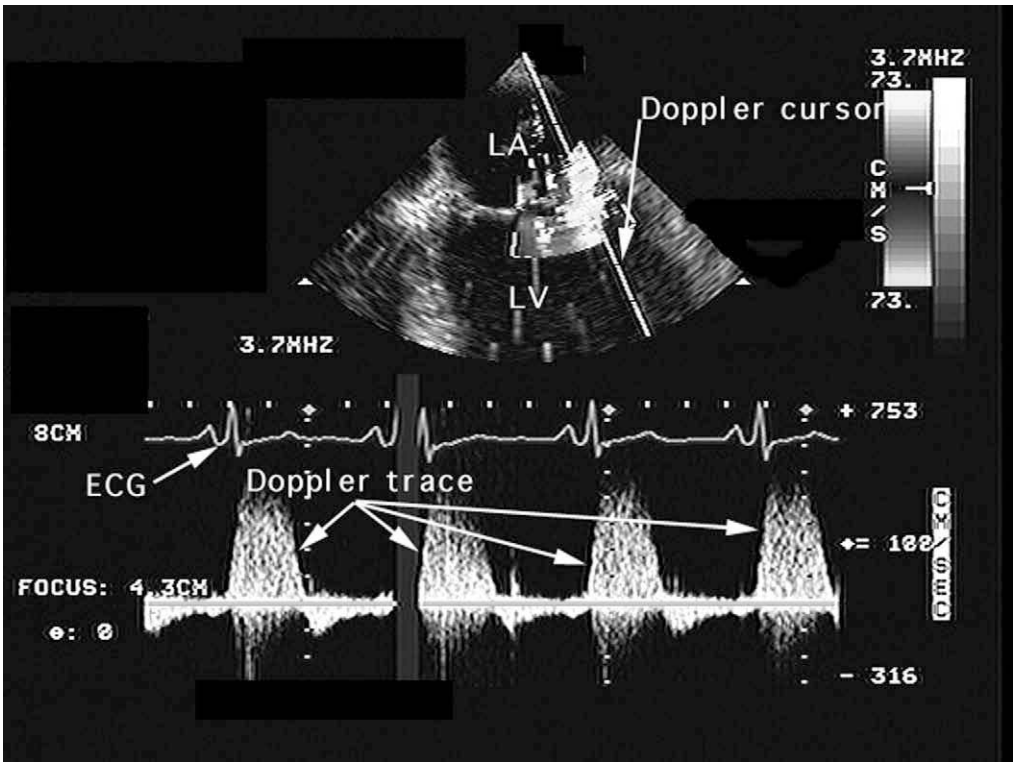

Figure 41-12 Continuous wave Doppler (CWD) measures high-velocity flow without aliasing. CWD measurement of blood flow velocities in a mitral valve orifice during four cardiac cycles is shown. At the top of the figure is a still-frame image of the two-dimensional cross section used to position the Doppler sampling cursor (the *diagonal white line*). On the bottom two thirds of the figure is the display in white of all the instantaneous blood flow velocities (vertical axis) versus time (horizontal axis) occurring anywhere along that cursor. The electrocardiogram (ECG) provides timing, and the *bold horizontal line* is the baseline (zero flow) for the flow velocities. Flow velocities above this line are positive (i.e., toward the transducer) to a maximum of 753 cm/sec. Flow velocities below this line are negative (i.e., away from the transducer) to a maximum of –316 cm/sec. This tracing documents significant mitral regurgitation (the positive systolic velocities) with a peak blood flow velocity of approximately 5 m/sec (each *white dot* on the vertical axis equals 100 cm/sec or 1 m/sec). LA, left atrium; LV, left ventricle. *(Reproduced with permission from Cahalan MK: Intraoperative Transesophageal Echocardiography. An Interactive Text and Atlas. New York, Churchill Livingstone, 1997.)*

segmental LV function after coronary surgery. S_m did not change significantly in response to a 20% increase or decrease in mean arterial pressure induced by phenylephrine or nitroglycerin. However, it increased significantly when preload was augmented by rapid infusion of colloid.[18] In summary, S_m is less dependent on afterload than fractional area change and fractional shortening are but, like these other two measures, remains critically dependent on preload. The few measures of LV function that appear to be independent of both preload and afterload (e.g., preload-recruitable stroke work) are not practical for clinical use.

Equipment Design and Operation

TEE probes are a marvel of engineering: a miniaturized echocardiographic transducer (about 40 mm long, 13 mm wide, and 11 mm thick) mounted on the tip of a gastroscope. Typically, the transducer is a phased-array configuration with 64 piezoelectric elements operating at 3.7 to 7.5 MHz. With sequential firing of the elements and an acoustic lens in the transducer housing, the ultrasound waves are formed into a 90-degree beam approximately 2 to 10 mm in thickness that emanates at right angles to the transducer. Like standard gastroscopes, two rotary knobs ("wheels") control movement of the tip of the scope. One wheel anteflexes and retroflexes the transducer (i.e., moves the transducer toward and away from the heart). The other wheel flexes the transducer rightward and leftward (Fig. 41-15).

Currently, most multiplane transducers use the same transducer technology but mount the transducer on a rotating device that allows it to spin on its axis from 0 to 180 degrees within the tip of the gastroscope (transducer housing). Because cardiac structures and blood flow are not precisely aligned relative to the transducer, this design has significantly refined imaging capability. Matrix transducers accomplish the same rotation of the beam but do so electronically (i.e., without mechanically moving the transducer). The size of the probes has been decreased for pediatric application by reducing the number of crystals, and probes are now small enough for use in infants and neonates.

Ultrasonographs contain high-powered computers capable of initiating the ultrasound beam and processing the returning data. A series of electronic transforms (some guarded commercial secrets) produce the real-time images displayed on the video screen. All ultrasonographs share common technical aspects, including gain, depth, and Doppler controls. However, the differences in technical aspects between manufacturers and even between models from the same manufacturer are sufficiently great to prevent formulation of any universal operating instruc-

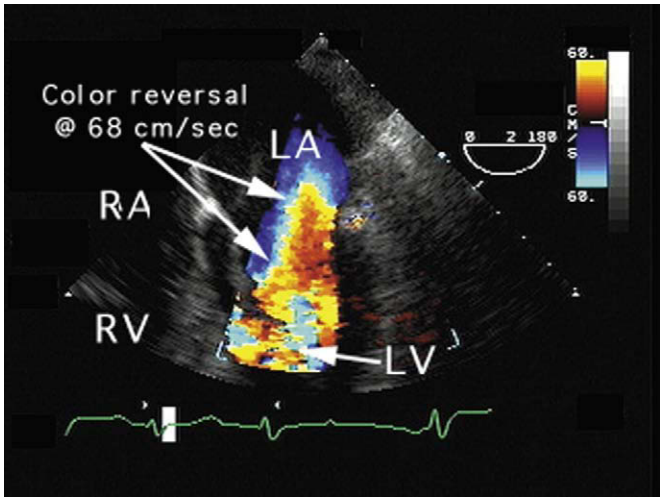

Figure 41-13 "Normal" color Doppler aliasing. In this echocardiogram, "normal" color Doppler aliasing is seen because laminar flow of blood through the mitral valve and into the left ventricle (LV) exceeds the Nyquist limit (68 cm/sec in this example—see the color reference icon at the upper right of the figure), thereby resulting in reversal of the color coding of flow direction. Notice that this color reversal occurs across fairly broad, regular areas and not in a random or point-by-point fashion as occurs with turbulent flow (always abnormal). In this example, follow the blue flow from high in the left atrium (LA) as it accelerates into the mitral orifice, and notice how color Doppler depicts the increasing flow velocities: the blue color becomes lighter and lighter until the Nyquist limit is reached. Color reversal then occurs, with light blue becoming yellow. Just at that reversal point, the velocity equals the Nyquist limit, in this example 68 cm/sec. Subsequent reversals may occur at that limit or multiples of that limit. RA, right atrium; RV, right ventricle. *(Reproduced with permission from Cahalan MK: Intraoperative Transesophageal Echocardiography. An Interactive Text and Atlas. New York, Churchill Livingstone, 1997.)*

tions. Fortunately, detailed instructions for each model are available in the operator's manual supplied with each ultrasonograph. Alternatively, cardiac sonographers are often excellent sources of instruction in the operation of these machines.

Basic Transesophageal Examination

Before performing TEE, the operator must determine that the benefits of TEE outweigh the risks. Except in the presence of esophageal disease or injury, the risk is quite low. Absolute contraindications include previous esophagectomy, severe esophageal obstruction, esophageal perforation, and ongoing esophageal hemorrhage. Relative contraindications include an esophageal diverticulum, varices, fistula, and previous esophageal surgery, as well as a history of gastric surgery, mediastinal irradiation, unexplained swallowing difficulties, and other conditions that might be worsened by placement and manipulation of the TEE probe.

In some studies, TEE is associated with a low incidence of oral and pharyngeal injuries (0.1% to 0.3%), but in other studies, the incidence of postoperative gastrointestinal complaints did not differ significantly from that in comparable patients who had not undergone TEE.[19,20] Uncontrolled studies have reported a 0.1% to 12% incidence of transient hoarseness after TEE. Serious pharyngeal or esophageal injury after TEE has been reported but is rare.[21] Two case reports indicate the possibility of TEE-associated splenic injury.[22,23] Among 10,218 patients (European multicenter study) undergoing TEE (primarily outpatients), esophageal perforation occurred in 1, who subsequently died; autopsy revealed a malignant tumor invading the esophagus.[24] Although bacteremia during TEE is uncommon, endocarditis has been reported in outpatients.[25,26] Endocarditis from intraoperative TEE has not been reported, and the risk is probably near zero because antibiotics are usually administered for prevention of surgical wound infection. In infants, TEE has a low complication rate, but even an appropriately sized TEE probe may obstruct the airway distal to the endotracheal tube or compress the descending aorta.[27]

Once the patient is anesthetized and the trachea securely intubated, the contents of the stomach are suctioned. Gentle massage of the left upper quadrant of the abdomen during suctioning may help remove air, which can otherwise degrade the imaging. The patient's neck is then extended and the well-lubricated TEE probe is introduced into the midline of the hypopharynx with the transducer side facing anteriorly. Usually, with minimal force the probe will pass blindly into the esophagus, especially if the neck is extended. If the probe does not pass blindly, a laryngoscope is used to lift the larynx anteriorly and the probe is placed into the esophagus under direct vision. During insertion or withdrawal of the transducer, the controls of the gastroscope must be in the neutral or relaxed position to allow the transducer to follow the natural course of the esophagus, thereby potentially minimizing the chance for injury.

Because of time constraints and relatively narrow diagnostic goals, anesthesiologists often perform a more limited intraoperative examination than described in the ASE/SCA's task force recommendation for a comprehensive TEE examination (see the

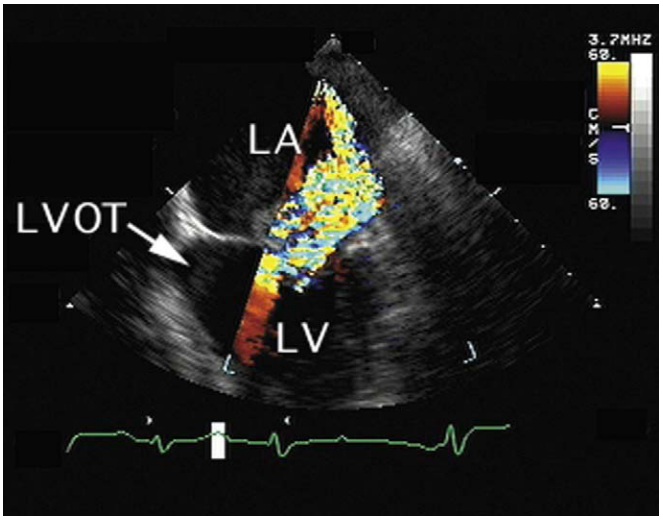

Figure 41-14 Color Doppler aliasing depicting turbulent flow. In this echocardiogram, color Doppler reveals aliasing caused by severe mitral regurgitation: a broad-based systolic color jet emanating from the mitral valve and extending far into the left atrium (LA). This jet is composed of a mosaic of colors mixed in a seemingly random, point-by-point fashion because the jet results from the turbulent flow of mitral regurgitation. Turbulence is never normal in the heart, and thus mosaic jets such as the one shown here are highly valuable diagnostic signs of underlying pathology. LV, left ventricle; LVOT, left ventricular outflow tract. *(Reproduced with permission from Cahalan MK: Intraoperative Transesophageal Echocardiography. An Interactive Text and Atlas. New York, Churchill Livingstone, 1997.)*

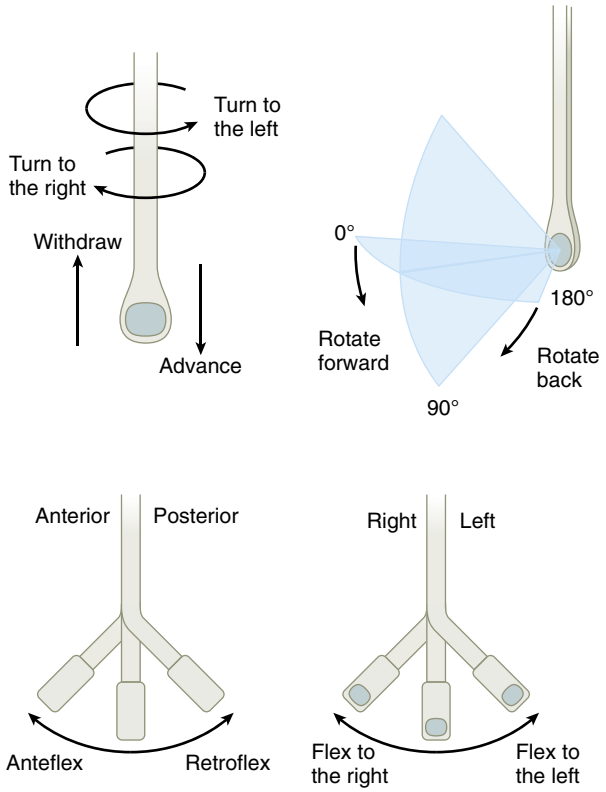

Figure 41-15 Terminology used to describe transesophageal echocardiography probe movements. *(Reproduced with permission from Shanewise JS, Cheung AT, Aronson S, et al: ASE/SCA guidelines for performing a comprehensive intraoperative multiplane transesophageal echocardiography examination: Recommendations of the American Society of Echocardiography Council for Intraoperative Echocardiography and the Society of Cardiovascular Anesthesiologists Task Force for Certification in Perioperative Transesophageal Echocardiography. Anesth Analg 89:870-884, 1999.)*

subsequent section).[7,28] However, even when time is critical, the examination performed should allow at least the basic applications of TEE as outlined in the 1996 guidelines for perioperative TEE: detection of markedly abnormal ventricular filling or function, extensive myocardial ischemia or infarction, large air embolism, severe valvular dysfunction, large cardiac masses or thrombi, large pericardial effusions, and major lesions of the great vessels.[6] A minimum of eight different cross sections drawn from the 20 cross sections delineated in the comprehensive examination are required to meet these diagnostic goals. Four of the cross sections are imaged in both 2D and color Doppler to assess valvular function. The next paragraph describes the probe manipulations required to achieve these cross sections. The reader should review Figure 41-15 to understand the terms used in this description.

After the TEE probe is introduced safely into the esophagus, it is advanced to the midesophageal (ME) level (28 to 32 cm measured at the upper incisors), and the aortic valve (AV) is imaged in the short axis (SAX) by turning the probe, adjusting its depth in the esophagus, and rotating the multiplane transducer 25 to 45 degrees until the three cusps of the valve are seen as being approximately equal in size and shape (Fig. 41-16H). Image depth is set at 10 to 12 cm as required to position the AV in the center of the video screen. This cross section is ideal for detection of aortic stenosis. This and all subsequent cross sections are digitally recorded. Next, the probe is turned slightly to position the AV in the center of the video screen, and then the multiplane angle is rotated forward to 110 to 130 degrees to bring the long axis (LAX) of the AV in view (see Fig. 41-16I). This cross section is best for detection of ascending aortic abnormalities, including type I aortic dissection. Color Doppler is used for assessment of AV competence. For detection of valvular stenosis and regurgitation, the Nyquist limit is set to 50 to 60 cm/sec.[12] Next, Doppler is discontinued and the probe is turned rightward until the ME bicaval cross section comes into view (see Fig. 41-16L). This cross section is usually seen best at a multiplane angle between 90 and 110 degrees and is ideal for assessing caval abnormalities, as well as compression of the right atrium from anteriorly located masses or effusions and compression of the left atrium from posteriorly located masses or effusions. In addition, the bicaval cross section may reveal collections of air located anteriorly in the left or right atrium, as well as the structure of the interatrial septum, including the foramen ovale. Next, the multiplane angle is rotated back to 60 to 80 degrees and the probe is turned leftward just past the AV to bring the ME right ventricular (RV) inflow and outflow cross section into view (see Fig. 41-16M). Usually, an image depth of 12 to 14 cm is required to position the RV outflow tract in the center of the video screen. This cross section reveals RV contractile function, the outflow tract, and pulmonary valve function with the application of color Doppler. Next, the transducer is rotated back to 0 degrees and the probe advanced 4 to 6 mm into the esophagus and gently retroflexed until all four cardiac chambers are visualized (ME four-chamber cross section) (see Fig. 41-16A). Rotating the transducer 10 to 15 degrees will often enhance the view of the tricuspid annulus. Usually, an image depth of 14 to 16 cm is required to include the LV apex in the sector scan. In 2D imaging, the free wall of the right ventricle and the lateral and septal LV wall segments are evaluated for contractile function. With color Doppler, both the mitral and tricuspid valves are assessed. Stenotic and regurgitant lesions can be diagnosed accurately. During this assessment, image depth is decreased to 10 to 12 cm to afford a magnified view of the valves and color Doppler flow patterns. Next, color Doppler is discontinued, the left ventricle is positioned in the center of the screen, and the multiplane angle is rotated forward to 90 degrees to bring into view the ME two-chamber cross section (see Fig. 41-16B). Image depth is returned to 14 to 16 cm. This cross section is best for revealing the function of the basal and apical segments of the anterior and inferior LV walls, as well as anterior and inferior pericardial collections. When air emboli collect in the left ventricle, they can generally best be seen in this view as very echogenic areas located along the anterior apical endocardial surface. The transducer is then rotated forward to 135 degrees to reveal the ME LAX cross section, which is best for assessment of the anteroseptal and posterior wall segments for contractile LV function (see Fig. 41-16C). Together, the ME four-chamber, two-chamber, and LAX cross sections reveal all 16 segments of the left ventricle (Fig. 41-17). However, the next and last of the basic cross sections provides a second look at the midventricular segments, as well as other benefits. To achieve this cross section, the transducer is rotated back to 0 degrees, the left ventricle is centered in the screen, and the probe is advanced 4 to 6 cm into the stomach. It is then gently flexed anteriorly to reveal the transgastric (TG) SAX cross section (see Fig. 41-16D). This cross section is ideal for monitoring LV filling and contractile function. All major coronary arteries supplying the myocardium are viewed in this cross section. Moreover, changes in preload cause greater changes

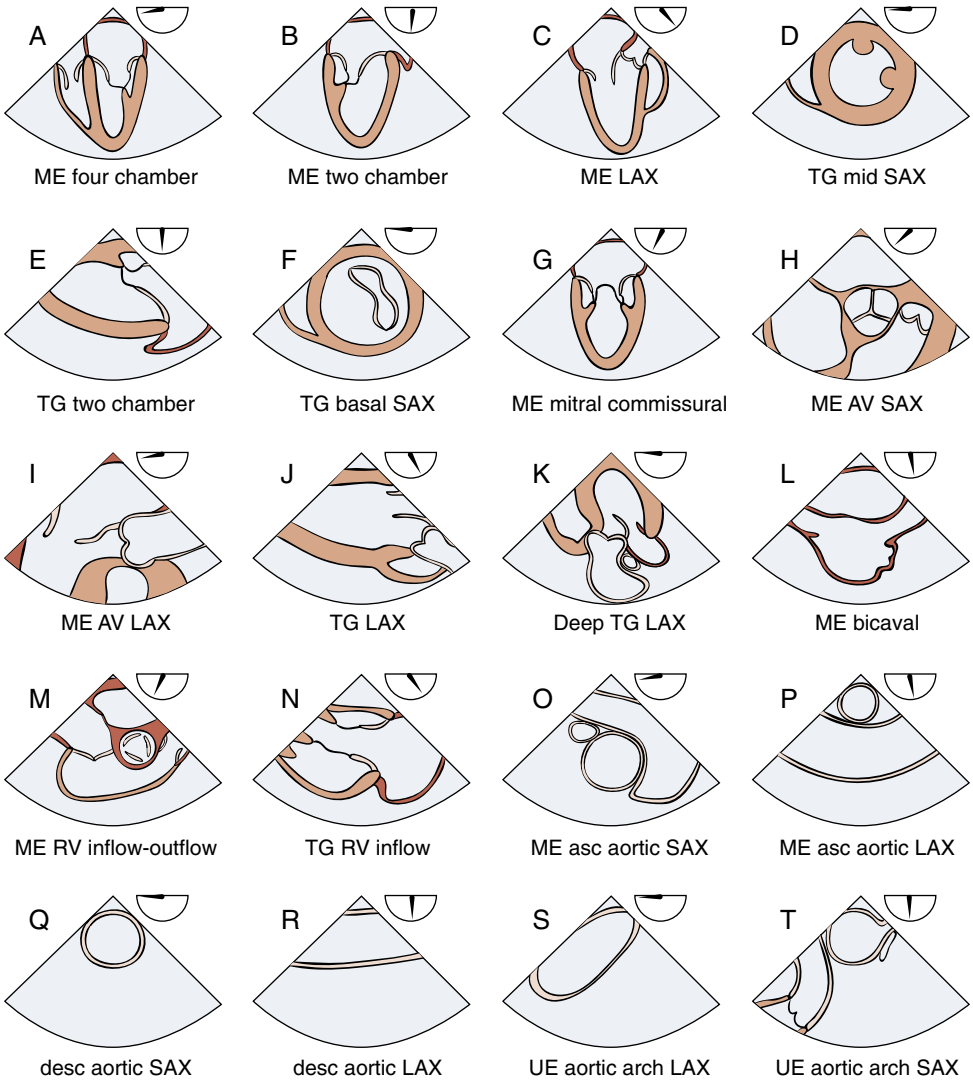

Figure 41-16 Transesophageal echocardiography cross sections in a comprehensive examination. Twenty standard cross sections and their abbreviated names are depicted by the line drawings. The text describes the probe manipulations required to produce each of these cross sections. *(Reproduced with permission from Shanewise JS, Cheung AT, Aronson S, et al: ASE/SCA guidelines for performing a comprehensive intraoperative multiplane transesophageal echocardiography examination: Recommendations of the American Society of Echocardiography Council for Intraoperative Echocardiography and the Society of Cardiovascular Anesthesiologists Task Force for Certification in Perioperative Transesophageal Echocardiography. Anesth Analg 89:870-884, 1999.)*

in the LV SAX than in the LAX dimension, and movement of the probe from this cross section is readily apparent inasmuch as the papillary muscles provide prominent landmarks. Because this cross section is used to judge filling and ejection, image depth is consistently set to 12 cm so that the size and function of the heart can easily be judged relative to previously examined hearts.

Comprehensive Transesophageal Examination

In addition to the 8 cross sections described in the preceding paragraph, 12 other cross sections are required to complete the comprehensive perioperative TEE examination delineated in the 1999 ASE/SCA task force recommendations.[7] When time permits or the diagnostic questions require, the comprehensive examination can be completed in any order deemed most appropriate by the operator. Shanewise and colleagues described an examination sequence based on anatomic structures, and the reader is referred to this very detailed reference for one excellent approach.[7] However, when a single individual is responsible for anesthetic care and the TEE examination, the comprehensive examination is completed as time permits after the basic examination has been recorded. When such is the case, the operator can use 3 of the 8 basic cross sections as takeoff points for the other 12 cross sections, thus making completion of the comprehensive examination a relatively easy sequence to remember and quick to perform.

With the probe positioned for the AV SAX cross section, the other six cross sections of the aorta are easily achieved. First, the probe is withdrawn slowly 1 to 3 cm while keeping the aorta in the center of the video screen to view the ascending aorta in SAX (see Fig. 41-16O). As the probe is withdrawn, the operator progressively views more superior SAX cross sections of the aorta beginning with the sinotubular junction until the image is lost

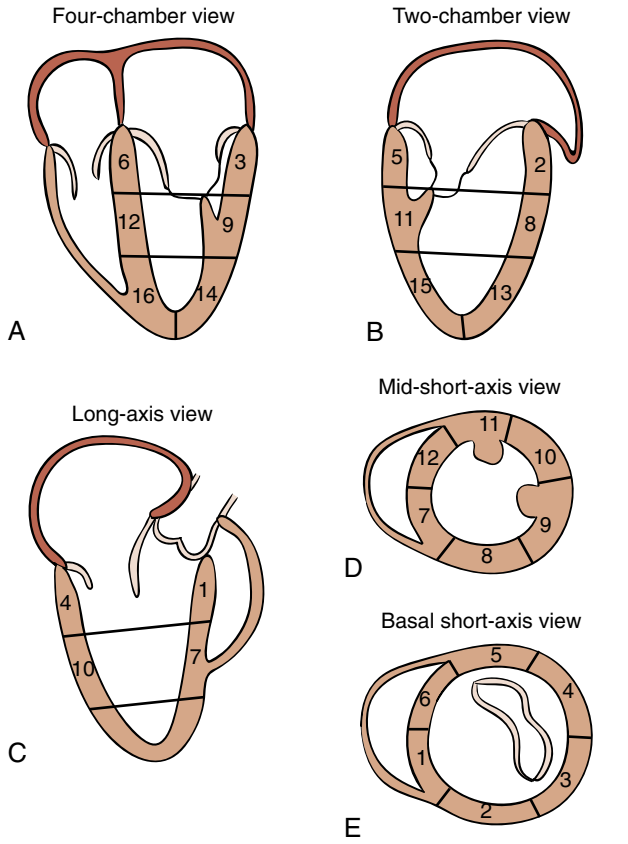

Figure 41-17 Five transesophageal echocardiography cross sections with myocardial segments identified. A total of 16 myocardial segments are identified and named according to standards adopted by the American Society of Echocardiography and the Society of Cardiovascular Anesthesiologists. *(Reproduced with permission from Shanewise JS, Cheung AT, Aronson S, et al: ASE/SCA guidelines for performing a comprehensive intraoperative multiplane transesophageal echocardiography examination: Recommendations of the American Society of Echocardiography Council for Intraoperative Echocardiography and the Society of Cardiovascular Anesthesiologists Task Force for Certification in Perioperative Transesophageal Echocardiography. Anesth Analg 89:870-884, 1999.)*

because of interposition of the trachea between the esophagus and aorta. Next, the multiplane angle is rotated forward to 100 to 120 degrees and advanced slowly 1 to 3 cm while keeping the aorta in the center of the video screen to view the ascending aorta in LAX (see Fig. 41-16P). These two cross sections are ideal for assessment of pathology of the ascending aorta, such as type I aortic dissection and aortic atheromas. However, the most superior aspect of the aorta is rarely seen, including the takeoff of the innominate artery, because of the aforementioned tracheal interposition. Next, the transducer is returned to 0 degrees, the image depth decreased to 6 cm, and the probe turned leftward past the cardiac structures to reveal the descending aorta in SAX (see Fig. 41-16Q). The probe is withdrawn and advanced with the aorta maintained in the center of the screen until the entire descending aorta has been examined in SAX. This maneuver is repeated with the transducer at 90 degrees to examine the descending aorta in LAX (see Fig. 41-16R). Next, the transducer is returned to 0 degrees and the probe withdrawn until the distal aortic arch in LAX comes into view (see Fig. 41-16S). Rotating the transducer to 90 degrees reveals the distal arch in SAX (see Fig. 41-16T). The probe is turned leftward until the aorta just disappears from view and then turned slowly rightward to identify the takeoff of the left subclavian artery (well seen in most patients) and the left carotid (well seen in a minority of patients). These cross sections of the descending aorta and distal aortic arch reliably reveal dissections and atheromatous disease.

With the probe positioned for the ME four-chamber cross section, the ME mitral commissural cross section is easily achieved by centering the coaptation point of the mitral valve in the center of the video screen and rotating the multiplane angle forward to about 60 degrees (see Fig. 41-16G). This maneuver positions the ultrasound beam parallel to the closure line of the mitral leaflets and completes the LAX examination of the mitral valve. Although a detailed discussion of mitral leaflet structure and function is beyond the scope of this chapter, Figure 41-18 summarizes an excellent approach to this challenging task.[29]

With the probe positioned for the TG mid SAX, the remaining five cross sections of the comprehensive examination are achieved easily in most patients. First, the left ventricle is centered in the video screen and the multiplane angle is rotated forward to 90 degrees to reveal the TG two-chamber cross section (see Fig. 41-16E). Although this cross section reveals the same structures as the ME two-chamber cross section, the viewing angle is orthogonal to the former viewing angle, and as a result, subvalvular structures are seen better. Next, the transducer is rotated to 100 to 120 degrees to reveal the TG LAX cross section (see Fig. 41-16J). Again, this cross section reveals the same structures as the ME LAX, but the TG LAX permits a more parallel alignment of the ultrasound beam with blood flow through the LV outflow track and AV. Next, the TG RV inflow cross section is achieved by returning the probe to the TG mid SAX position, turning it rightward until the right ventricle is centered in the video screen, and then rotating the multiplane angle to 100 to 120 degrees to bring the RV apex into view (see Fig. 41-16N). This cross section is ideal for viewing the RV inferior free wall. Next, the TG basal SAX is achieved by returning the probe to the TG mid SAX, releasing the flexion of the probe, withdrawing 1 to 2 cm, and then flexing the probe gently until the orifice of the mitral valve is seen in SAX (Fig. 41-16F). This cross section can prove vital in determining the precise location of mitral regurgitation.[29] Finally, the TG deep LAX cross section is achieved by returning the probe to the TG mid SAX position, releasing the flexion of the probe, advancing it 6 to 8 cm into the stomach, fully flexing it once in the stomach, gently withdrawing it until minimal resistance is met at the gastroesophageal junction, and then slightly turning it leftward or rightward to reveal the LV outflow tract and AV (Fig. 41-16K). Usually, this cross section does not resolve structures as well as the ME LAX does, but it provides optimal beam alignment for Doppler interrogation of the LV outflow tract and AV. Frequently, this cross section is the most difficult of the cross sections to visualize. If a few gentle attempts fail to accomplish it, it should be abandoned.

5-Chamber Allows localization of pathology to the anterior or posterior leaflet. Specific scallops difficult to identify based only on this view, but generally shows anterior elements of the valve.		4-Chamber Allows localization of pathology to the anterior or posterior leaflet. Specific scallops difficult to identify based only on this view, but generally shows posterior elements of the valve.		2-Chamber Anterior Shows a long anterior leaflet (A2/A3) and a short segment of the posterior leaflet (P3). Note that the part of the anterior leaflet that coapts with the P3 scallop is the A3 segment.		2-Chamber Mid Three scallops and two coaptation points are seen: P3, P1, and a variable amount of A2, which disappears during diastole.		2-Chamber Posterior No coaptation point seen. The plane cuts through the posterior leaflet only. Usually demonstrates mostly P2, with some P1 and P3.		Short Axis This view is most useful with color Doppler to localize the site of regurgitation. However, it rarely demonstrates the nature of the pathology.		
Figure 41-18 A systematic examination of the mitral valve is depicted. In this examination, the mitral valve is viewed in multiple cross sections to delineate the leaflet anatomy. The five-chamber cross section is accomplished by withdrawing the probe slightly from the standard four-chamber cross section until the left ventricular outflow track is in view. The *center column* shows the planes of the different cross sections as viewed from directly above the base of the heart. The two-chamber anterior, mid, and posterior cross sections are variations on the standard two-chamber cross section that are accomplished by turning the probe from the patient's right to left. P1, P2, and P3 refer to the three scallops of the posterior mitral leaflet, and A1, A2, and A3 refer to the juxtaposed segments of the anterior mitral leaflet. The *right column* shows the leaflet segments seen in the corresponding cross section. *(Reproduced with permission from Lambert AS, Miller JP, Foster E, et al: Improved evaluation of the location and mechanism of mitral valve regurgitation with a systematic transesophageal echocardiography examination. Anesth Analg 88:1205-1212, 1999.)*

Basic Transthoracic Examination

In patients with an unsecured airway, TTE is easier to perform than TEE because TTE is entirely noninvasive. TTE uses frequencies lower (1 to 3 MHz) than TEE does to penetrate the greater distances inherent in the transthoracic technique, but all previously discussed modalities (M-mode, spectral Doppler, color Doppler, and tissue Doppler) can be performed with TTE. Transthoracic cardiac probes are significantly different from the linear probes used to identify superficial vascular structures and nerve bundles. Thus, the probes used for ultrasound-guided nerve

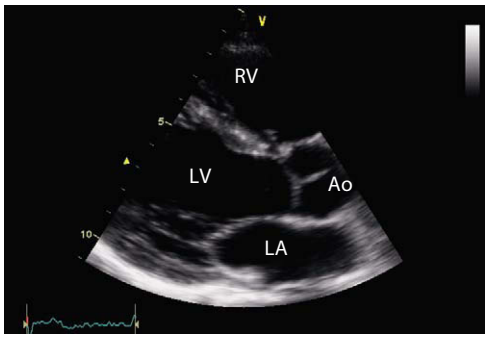

Figure 41-19 Transthoracic parasternal long-axis two-dimensional cross section of a normal heart. This cross section reveals a small triangular segment of the right ventricle on the upper section of the display and left ventricular chamber (LV), the left atrium (LA), and the aortic root (Ao) in the middle section of the display. This cross section shows the same tomographic view as with the midesophageal long-axis view described in the transesophageal examination (see Fig. 41-16C). RV, right ventricle.

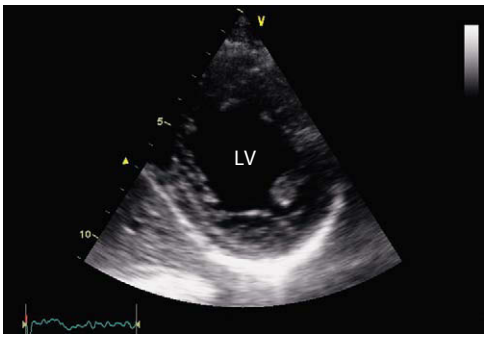

Figure 41-20 Transthoracic parasternal short-axis two-dimensional cross section of a normal heart. This cross section reveals a small part of the crescent-shaped right ventricle at the top of the display and the left ventricle (LV) in a short-axis view in the rest of the image. This cross section shows the same tomographic view as with the transgastric short-axis view described in the transesophageal examination (see Fig. 41-16D).

blocks and vascular access are not appropriate for TTE. TTE uses three standard "windows" (soft tissue points that avoid interposition of bone between the transducer and heart): parasternal (PS), apical (AP), and subcostal (SC). The next paragraphs describe the probe manipulations required at these windows to achieve the TTE cross sections.

The examination begins with the patient turned halfway onto the left side with the left arm elevated alongside the head. Optimal imaging requires ultrasound gel between the probe and chest wall. Patients should be warned of the cold sensation of the gel on the skin. The parasternal long-axis (PS LAX) cross section is acquired first (Fig. 41-19) by placing the probe on the left side of the sternum at the level of the fourth intercostal space and directing the ultrasound beam toward the patient's right shoulder. Appropriate adjustment of image depth (15 to 18 cm), rotation, and angulation of the transducer reveals a small triangular segment of the right ventricle on the upper section of the display and the LV chamber, left atrium, and aortic root in the middle section of the display. This cross section shows the same tomographic view as the ME LAX described in the TEE examination (see Fig. 41-16C). Like the ME LAX, the PS LAX cross section permits assessment of the structure and function of the AV, mitral valve, and basal segments of the anteroseptum and the posterior wall of the left ventricle. Sclerocalcific changes in the AV and reduction of cusp excursion are seen with aortic stenosis. Reduction of motion of the anterior leaflet of the mitral valve during diastole can be an indication of mitral stenosis, LV dilation, LV dysfunction, elevated filling pressure, or any combination of these pathologies. In this cross section, color Doppler allows the diagnosis of stenotic and regurgitant lesions of both atrioventricular valves. Next, the parasternal short-axis (PS SAX) cross section is obtained (Fig. 41-20) by rotating the transducer 90 degrees clockwise and angling it inferiorly toward the left hip until the right ventricle appears as a crescent-shaped structure at the top of the display and the left ventricle in SAX is viewed at the bottom. This cross section shows the same tomographic view as the TG SAX described in the TEE examination (see Fig. 41-16D). In the absence of segmental dysfunction in the apical or basal segments of the heart, LV and RV size and contractile function can be assessed accurately from the PS SAX cross section.

The next cross sections are acquired from the apical window by placing the transducer in the fourth or fifth intercostal space lateral to the nipple line with the transducer marker (the notch or other landmark on the transducer indicating beam orientation) pointing toward the floor. Appropriate adjustment of the rotation and angulation of the transducer reveals the apical four-chamber (AP-4C) cross section (Fig. 41-21) with the apex of the heart on the top of the display and the right and left atria on the bottom. This cross section shows the same tomographic view as with the ME four-chamber cross section described in the TEE examination (see Fig. 41-16A). The AP-4C cross section reveals the size and global contraction of the ventricles, as well as the segmental function of their lateral walls and interventricular septum. Color Doppler of the tricuspid and mitral valves facilitates the diagnosis of valvular stenosis and regurgitation. In addition, the right upper pulmonary vein is visualized, and PWD estimates of flow there can help in fluid management (see the subsequent section on ventricular diastolic function). The next cross section is the apical two-chamber (AP-2C) view, which is acquired by rotating the transducer 60 degrees counterclockwise

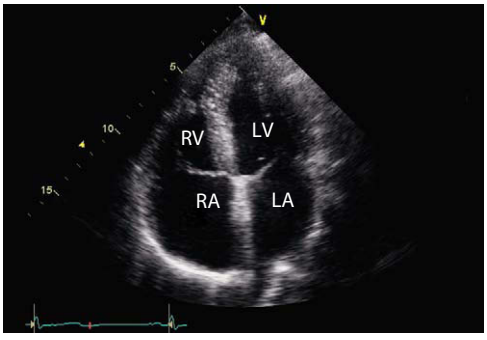

Figure 41-21 Transthoracic apical four chamber two-dimensional cross section of a normal heart. This cross section reveals the apex of the heart on the top of the display and the right and left atria (RA, LA) on the bottom. This cross section shows the same tomographic view as with the midesophageal four-chamber view described in the transesophageal examination (see Fig. 41-16A). LV, left ventricle; RV, right ventricle.

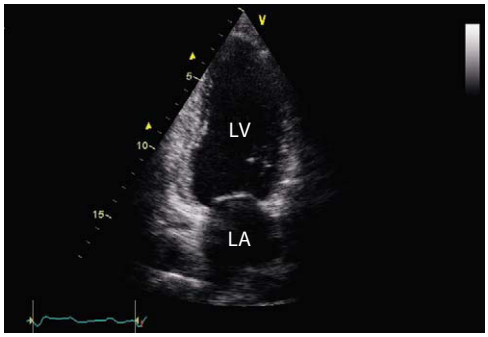

Figure 41-22 Transthoracic apical two-chamber two-dimensional cross section of a normal heart. This cross section reveals the left ventricle (LV) on the top (apex) and middle of the display and the left atrium (LA) on the bottom. This cross section shows the same tomographic view as with the midesophageal two-chamber view described in the transesophageal examination (see Fig. 41-16B).

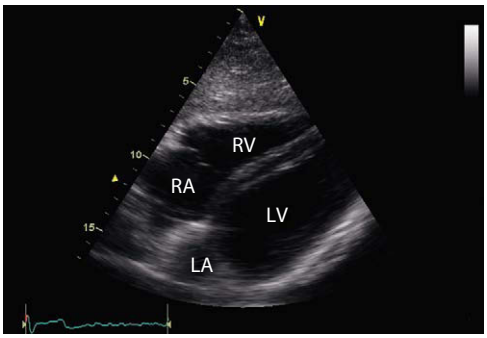

Figure 41-24 Transthoracic subcostal four-chamber two-dimensional cross section of a normal heart. The liver occupies the upper third of the display and the heart the lower two thirds. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

(Fig. 41-22). This cross section shows the same tomographic view as the ME two-chamber cross section described in the TEE examination and reveals segmental function of the anterior and inferior walls of the left ventricle (see Fig. 41-16B). The last apical cross section is the apical long-axis (AP LAX) view (Fig. 41-23), which is obtained by rotating the transducer counterclockwise another 60 degrees until the LV outflow tract and AV are seen in the bottom of the display. This cross section shows the same tomographic view as with the ME LAX described in the TEE examination (see Fig. 41-16C). The AP LAX provides an ideal vantage point for Doppler quantification of aortic stenosis and regurgitation because of the parallel direction of the ultrasound beam and blood flow.

The last two cross sections are acquired from the subcostal window with the patient in the supine position. The transducer is positioned flat under the right costal ridge next to the xiphoid appendix and pointed toward the patient's left shoulder with the transducer marker pointing leftward. The subcostal four-chamber (SC-4C) view is seen (Fig. 41-24), with the upper third of the display occupied by the liver and the heart below. RV free wall contractility and hemodynamically significant pericardial effusion are assessed best from this view. Finally, the subcostal inferior vena cava (SC IVC) cross section is obtained by rotating the transducer 90 degrees counterclockwise (Fig. 41-25). The IVC is seen on the left side of the display as a rectangular echolucent structure inside the liver connecting to the right atrium. This view allows assessment of right-sided filling pressure by evaluating the size and collapsibility of the IVC in spontaneously breathing patients.[30]

When TEE is impracticable and cardiovascular status must be evaluated reliably, these basic TTE cross sections can provide much of the same information as TEE does and thereby extend the benefits of echocardiography to many more surgical and critical care patients than when only TEE is available. We predict that TTE will become the stethoscope of the future for cardiovascular anesthesiologists and other perioperative physicians who regularly care for critically ill patients.

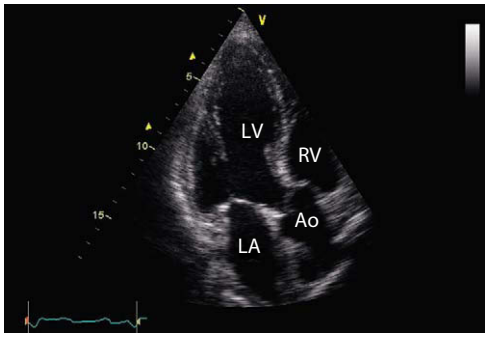

Figure 41-23 Transthoracic apical long-axis two-dimensional cross section of a normal heart. This cross section reveals the left ventricle (LV) at the top (apex) and middle of the display and the left ventricular outflow tract and aortic valve at the bottom of the display. This cross section shows the same tomographic view as with the midesophageal two-chamber view described in the transesophageal echocardiographic examination (see Fig. 41-16C). Ao, aorta; LA, left atrium; RV, right ventricle.

Assessment of Hemodynamics

Evaluation of Ventricular Filling

TEE reveals changes in LV preload more reliably than filling pressure. In 30 patients scheduled for cardiac surgery, Cheung and

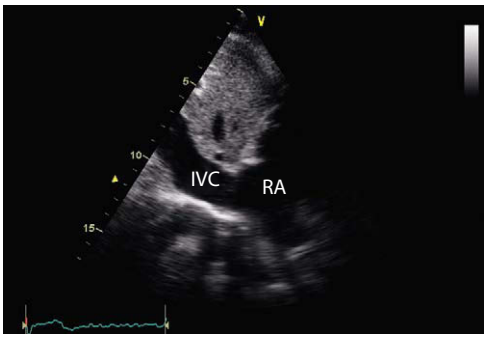

Figure 41-25 Transthoracic inferior vena cava (IVC) two-dimensional cross section of a normal heart. The IVC is seen on the left side of the display as a rectangular echolucent structure inside the liver connecting to the right atrium (RA).

colleagues removed 15% of each patient's blood volume in six equal aliquots before bypass.[31] TEE demonstrated a significant decrease in cross-sectional area at end diastole (EDA) after removal of the first aliquot (about 200 mL) and a linear decrease with subsequent aliquots. Pulmonary artery occlusion and central venous pressure also declined but correlated poorly with EDA. In most adults, an EDA of less than 12 cm^2 indicates hypovolemia, but values between 12 and 15 cm^2 may not because of variations in patient size and diastolic compliance. However, when a volume challenge increases EDA, stroke volume also increases.[32] Although quantitative TEE measurements of ventricular preload are well validated as noted earlier, they are tedious and impractical to perform intraoperatively. Instead, clinicians assess LV filling and function subjectively with the "trained eye." This approach is a valid method to guide fluid administration, and in patients with concentric hypertrophy, it may identify the need for higher than normal filling pressure to achieve optimal LV filling and function.[33]

In addition to estimating LV filling volume, TEE provides practical ways to estimate LV filling pressure. Placing the Doppler cursor at the junction of the left atrium and left superior pulmonary vein, Kuecherer and associates demonstrated that a systolic fraction of flow of less than 55% was a specific and sensitive sign of left atrial pressure greater than 15 mm Hg. This sign is easily detected as predominance of flow during diastole (Figs. 41-26 and 41-27).[34] Significant mitral regurgitation, the presence of non–sinus rhythm, and extremes of cardiac output affect pulmonary venous flow and therefore limit this application of TEE. Alternative methods have been described that obviate these limitations.[35,36] Accordingly, TEE cannot estimate left atrial pressure precisely but can reliably identify clinically significant elevations.

Estimation of Cardiac Output

Real-time TEE images of LV filling and ejection permit qualitative, immediate detection of extreme changes in cardiac output. However, TEE can quantify cardiac output more precisely by measuring both the velocity and the cross-sectional area of blood flow at appropriate locations in the heart or great vessels. The product of these measurements is stroke volume. Appropriately performed TEE estimates of cardiac output should fall within 0.3 to 0.8 L/min of thermodilution estimates, except in patients with severe tricuspid regurgitation, in whom thermodilution may underestimate output.[37,38]

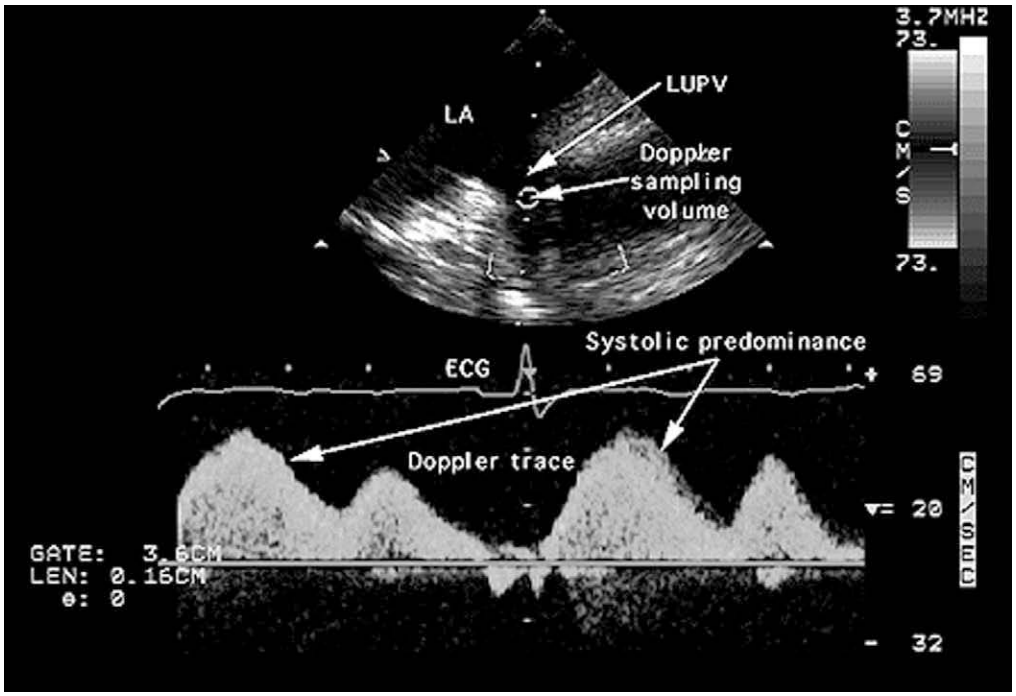

Figure 41-26 Pulsed wave Doppler measurement of normal blood flow velocities in the left upper pulmonary vein. At the top of the figure is a still-frame image of the two-dimensional cross section used to position the Doppler sampling volume (*broken circle* at point of *arrow*). On the bottom two thirds of the figure is the display in white of the instantaneous blood flow velocities (vertical axis) versus time (horizontal axis) occurring in that sample volume. The electrocardiogram (ECG) provides timing, and the *bold horizontal line* is the baseline (zero flow) for the flow velocities. Flow velocities above the *bold line* are positive (i.e., toward the transducer) to a maximum of 69 cm/sec. Flow below the *bold line* is negative (i.e., away from the transducer) to a maximum of –32 cm/sec. In this patient with normal left atrial pressure, systolic predominance of flow is evident; that is, more flow enters the atrium during the period of ventricular systole than during ventricular diastole as evidenced by the greater peak and average flow velocities during systole than during diastole. LA, left atrium; LUPV, left upper pulmonary vein. *(Reproduced with permission from Cahalan MK: Intraoperative Transesophageal Echocardiography. An Interactive Text and Atlas. New York, Churchill Livingstone, 1997.)*

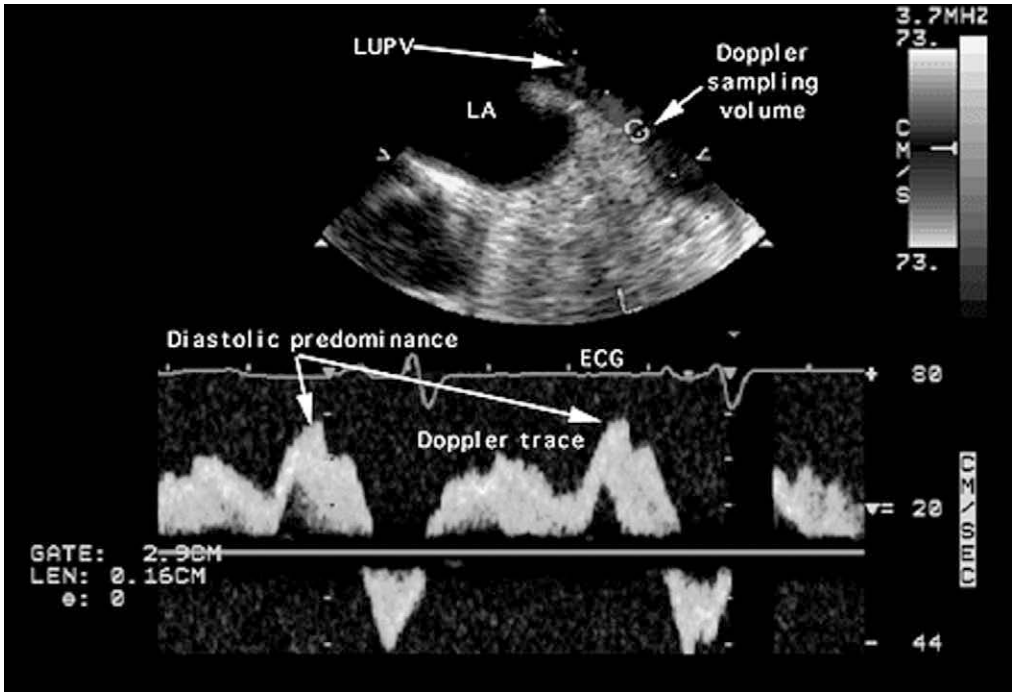

Figure 41-27 Pulsed wave Doppler measurement of blood flow velocities in the left upper pulmonary vein (LUPV) in a patient with abnormally high left atrial pressure. At the top of the figure is a still-frame image of the two-dimensional cross section used to position the Doppler sampling volume (*broken circle* at point of *arrow*). On the bottom two thirds of the figure is the display in white of the instantaneous blood flow velocities (vertical axis) versus time (horizontal axis) occurring in that sample volume. The electrocardiogram (ECG) provides timing, and the *bold horizontal line* is the baseline (zero flow) for the flow velocities. Flow velocities above the *bold line* are positive (i.e., toward the transducer) to a maximum of 80 cm/sec. Flow below the *bold line* is negative (i.e., away from the transducer) to a maximum of –44 cm/sec. In this patient with abnormally high left atrial pressure, diastolic predominance of flow is evident; that is, more flow enters the left atrium (LA) during the period of ventricular diastole than during ventricular systole as evidenced by the greater peak and average flow velocities during diastole than during systole. The negative flow velocities are due to atrial contraction pushing blood back into the pulmonary vein. *(Reproduced with permission from Cahalan MK: Intraoperative Transesophageal Echocardiography. An Interactive Text and Atlas. New York, Churchill Livingstone, 1997.)*

Assessment of Ventricular Systolic Function

Fractional area change (FAC) during systole is a commonly used measure of global LV function. It is measured by using the simple formula (EDA − ESA)/EDA, where EDA is the cross-sectional area at end diastole and ESA is the cross-sectional area at end systole. Marked changes in FAC are apparent by simply viewing the real-time images. Thus, severe LV depression is easy to detect with TEE. Although FAC correlates reasonably well with other approximations of ventricular function, significant limitations apply. First, TEE often underestimates the LV LAX (it foreshortens the left ventricle). Second, the midventricular SAX view may be a poor guide to overall ventricular ejection if other areas of the ventricle have markedly different function. Third, FAC, like other traditional echocardiographic indices of systolic function, is load dependent: changes in preload and afterload markedly alter FAC without changing the intrinsic function of the ventricle.

Measurement of RV function is more difficult than LV function because of the right ventricle's complex shape and response to changes in loading. However, severe RV dysfunction is not difficult to recognize. The hallmarks are severe hypokinesis or akinesis of the RV free wall, enlargement of the right ventricle so that it exceeds the size of the left ventricle, and a change in shape of the right ventricle from crescent to round. When RV dysfunction is due to acute pulmonary hypertension, as occurs in pulmonary embolism, the intraventricular septum flattens or bulges leftward.

Assessment of Ventricular Diastolic Function

Approximately a third of patients with symptomatic heart failure have normal LV systolic function. Their heart failure is due to diastolic dysfunction: abnormal diastolic relaxation and filling. TEE is an ideal tool for assessment of diastolic function because of its unobstructed view of the mitral valve and pulmonary veins.[39] Normal flow across the mitral valve in diastole has an early higher-velocity component generated by atrial pressure and ventricular relaxation (E wave on the Doppler echocardiogram) and a second lower-velocity component generated by atrial contraction (A wave). At slower heart rates, these two waves are separated by a period of relatively little flow (diastasis). Three severities of diastolic dysfunction are diagnosed by the combination of flow patterns in the mitral valve and pulmonary veins (Fig. 41-28).[40] The least severe is "impaired relaxation," which is characterized by a decrease in E-wave velocity, a decrease in the deceleration of early filling (seen as decreased slope of the E wave and termed "deceleration time"), and an increase in A-wave velocity to greater than E-wave velocity, thereby reversing the E-to-A ratio. In

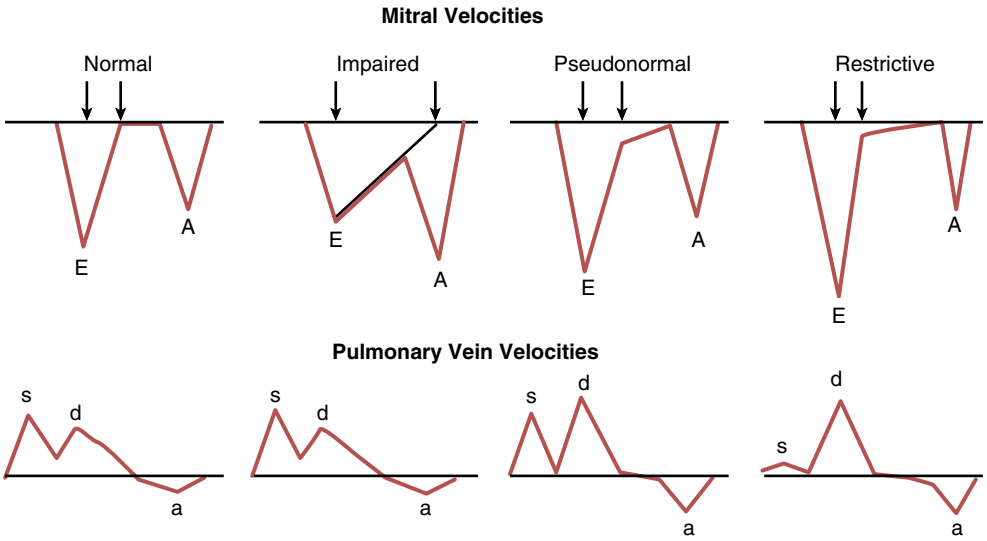

Figure 41-28 Line drawings representing simultaneous transesophageal pulsed wave Doppler recordings from the mitral annulus and right upper pulmonary vein are shown for normal, impaired, pseudonormal, and restrictive left ventricular diastolic function. The *solid black line* represents the slope of the E-wave velocity. From the start of the line at the inflection point of the E wave until its intercept at the base line is the deceleration time. This time is depicted in each of the mitral velocity drawings by *black arrows*. Please see text for further details. *(Adapted From Zile MR, Brutsaert DL: New concepts in diastolic dysfunction and diastolic heart failure: Part I: Diagnosis, prognosis and measurements of diastolic function. Circulation 105:1387-1393, 2002.© 2002 American Heart Association, Inc.)*

impaired relaxation, left atrial pressure is normal, and therefore so is the pattern of pulmonary venous flow: the S wave is greater than the D wave. The second and more severe degree of diastolic dysfunction is termed "pseudonormal" and is characterized by return of the normal E-to-A ratio because of a pathologic increase in left atrial pressure that results in abnormal pulmonary venous flow: the D wave is greater than the S wave. One simple way to confirm that the mitral flow pattern is pseudonormal and not normal is to transiently reduce left atrial filling with a Valsalva maneuver. If diastolic function is pseudonormal, the E-to-A ratio will transiently reverse, with A being greater than E. If diastolic function is normal, the normal ratio of E greater than A will persist and both waves will decrease in size. The third and most severe degree of diastolic dysfunction is termed "restrictive" and is characterized by very high E-wave velocity, a short deceleration time, and low A-wave velocity. In restrictive diastolic function, left atrial pressure is very high and results in a very small S wave and large D wave in the pulmonary veins. Patients with this pattern have a poor prognosis and suffer symptoms of congestive heart failure regardless of their systolic function.[41]

Transesophageal Echocardiography During Life-Threatening Hypotension

Ultimately, hypotension has only two possible causes: inadequate cardiac output or inappropriately low systemic vascular resistance. TEE is remarkably well suited for addressing this differential diagnosis. During severe hypotension, qualitative TEE estimates of ventricular filling and function serve as practical guides for the administration of fluids, inotropes, and vasopressors. An experienced observer can differentiate severe ventricular dysfunction from other life-threatening causes of hypotension. In severe LV failure, ventricular filling (as assessed by end-diastolic area) is increased and ejection is decreased, whereas in inappropriately low systemic vascular resistance, ventricular filling is usually normal or slightly decreased and ejection is markedly increased. Hypovolemia is easily recognized as a marked decrease in ventricular filling and a marked increase in ejection. Although inappropriately low systemic vascular resistance, severe aortic regurgitation, severe mitral regurgitation, and ventricular septal defects can manifest the same LV filling and ejection pattern on the TG SAX cross section, distinguishing these causes of hypotension is not difficult with the use of other cross sections and color Doppler. A dramatic example of the use of TEE in hypotensive patients is provided by a study of 60 consecutive patients with severe, persistent hypotension after cardiac surgery despite intensive therapy guided by invasive monitors.[42] TEE confirmed the presumed etiology of the hypotension in only 30 of these patients. In two patients, TEE revealed unsuspected cardiac tamponade and in six others unsuspected hypovolemia. In five patients, TEE prevented unnecessary reoperations by proving that tamponade was not present despite hemodynamic data suggesting that it was. In another study, unstable cardiac surgical patients in the operating room ($n = 57$) or intensive care unit ($n = 83$) underwent emergency TEE.[43] Based on TEE findings alone, 22 of these patients underwent urgent surgical interventions. The average time to diagnosis was 11 minutes. In still another study involving critically ill surgical patients, TEE proved to be more cost-effective than TTE because the latter so often fails to reveal diagnostic images.[44] Moreover, TEE has prognostic value in hypotensive, critically ill patients: when it reveals nonventricular causes of hypotension (e.g., valvular or pericardial), patients are twice as likely to survive as those with other causes of hypotension.[45] Even in the setting of prolonged cardiopulmonary resuscitation, TEE may reveal crucial diagnostic information.[46]

Detection of Myocardial Ischemia

Within seconds after the onset of myocardial ischemia, affected segments of the heart cease contracting normally. In 50 patients undergoing cardiovascular surgery, new intraoperative segmental wall motion abnormalities (SWMAs) diagnostic of myocardial ischemia (see later) occurred in 24 patients and ischemic ST-segment changes in only 6.[47] In three patients who sustained intraoperative myocardial infarction, SWMAs developed in the corresponding area of myocardium and persisted until the end of surgery, but only one of these three had ischemic ST-segment changes intraoperatively. Subsequent studies in comparable patients confirmed these advantages of TEE over electrocardiographic monitoring.[48] Moreover, when multiple TEE cross sections are monitored (not just the one cross section as was done in the aforementioned studies), the detection rate of SWMAs more than doubles.[49] Limitations of TEE in the detection of ischemia should be recognized. When an area of myocardium is clearly in view, segmental contraction can be difficult to evaluate if the heart rotates or translates markedly during systole or if discoordinated contraction occurs because of bundle branch block or ventricular pacing. Consequently, a valid system for assessment of SWMAs must evaluate both regional endocardial motion and myocardial thickening. Marked worsening of segmental wall motion and wall thickening (in the absence of similar global changes) is required to make the diagnosis of ischemia; even experts do not consistently interpret less pronounced changes. Not all SWMAs are indicative of myocardial ischemia. Myocarditis, myocardial infarction, and myocardial stunning also cause SWMAs. In coronary surgery, differentiating infarction, stunning, and ischemia is vitally important. When TEE reveals LV wall thickness of less than 0.6 cm, an old infarction in that thinned area is almost certain.[50] If inotropic stimulation improves the segmental motion of an SWMA, stunning, not ischemia, is likely.[51] One other cause of SWMA is severe hypovolemia in patients with preexisting SWMAs.[52] However, with the exception of myocardial stunning and severe hypovolemia as noted earlier, a sudden, severe decrease in segmental contraction is almost certainly due to myocardial ischemia.

Transesophageal Echocardiography in Cardiac Surgery

New Diagnoses

TEE can reveal new diagnostic findings before incision that prompt changes in surgical management (also see Chapter 60). In one prospective study of 474 consecutive patients undergoing coronary artery surgery, the surgical plan was changed in 3.4% of patients based on TEE.[53] In a different prospective study involving 3245 patients, the surgical plan was changed in 14% of patients based on TEE; the most common new finding prompting change was the discovery of a patent foramen ovale.[54] In a third prospective study involving 5016 patients, pre-bypass information from TEE led to modification of the surgical procedure in 27% of patients undergoing coronary surgery and 11% undergoing valvular surgery.[55] The divergent findings in these three studies are due to different patient populations, utilization criteria for TEE (selected versus consecutive use), and surgical practices, especially the treatment of patent foramen ovale and ischemic mitral regurgitation. Hemodynamic changes caused by general anesthesia alter the degree of mitral regurgitation (usually lessening it), thereby complicating surgical decision-making. Restoring intraoperative blood pressure with phenylephrine to preoperative levels improves the concordance between preoperative and intraoperative assessment of mitral regurgitation, but discrepancies remain.[56] In coronary surgery patients, even mild mitral regurgitation identified by intraoperative TEE predicts a significantly greater likelihood of death or hospitalization for heart failure over the subsequent 3 years than in coronary surgical patients without mitral regurgitation.[57] However, no definitive data are available to determine whether surgical repair of mild mitral regurgitation during coronary surgery is worth the added acute risk. Numerous case reports document that TEE can detect other problems necessitating changes in perioperative management, including intracardiac shunts and masses, great vessel obstruction, pulmonary embolism, and other conditions.

Aortic Diseases

TEE may have a crucial role in surgical diseases of the aorta. In a study of 160 consecutive patients with suspected thoracic aortic injury after blunt chest trauma, TEE was diagnostically superior to and faster than aortography for detection of the injury.[58] In a different study, TEE reliably distinguished between subadventitial disruptions, which require emergency surgery, and intimal tears, which do not.[59] In acute aortic dissection, TEE has proved superior to aortography and computed tomography.[60] It is associated with a shorter time to diagnosis, less morbidity (renal dysfunction and neurologic events), and shorter hospital stays than aortography is.[61] Though marginally less specific than magnetic resonance imaging (MRI) for some dissections (those originating in the aortic arch, where TEE imaging is partially obstructed by the trachea), TEE requires less time and expense than MRI or any other comparably reliable alternative.[62] Moreover, TEE can delineate the mechanisms and severity of associated aortic regurgitation and thereby identify patients in whom valve repair is likely to be successful.[63] Similarly, TEE-detected aortic atheromas have important implications. In 130 patients older than 65 years undergoing coronary artery bypass grafting, TEE detection of protruding atheroma of the ascending aorta proved to be the only independent predictor of stroke.[64] When these atheromas are detected by TEE, alteration of the aortic cannulation technique or increasing blood pressure during cardiopulmonary bypass may reduce the incidence of stroke.[65,66] Although TEE is not as sensitive as epiaortic scanning for detection of atheromas of the aortic arch, it is a good screening tool: if TEE reveals no significant atheromas in the ascending or descending aorta, none are likely to be present in the arch.[67] When intraoperative TEE reveals severe atheromatous disease of the aorta, off-pump coronary surgery results in a lower risk of death and stroke than on-pump surgery does.[68,69]

Valvular Diseases

TEE has profoundly affected valvular heart surgery by providing the surgical team with a definitive evaluation of their intervention while still in the operating room, where any needed revisions can be accomplished immediately. In 205 consecutive patients undergoing posterior mitral leaflet quadrangular resection (the most common mitral repair technique) for the treatment of mitral regurgitation, TEE revealed immediate failures in 24 patients (11.7%).[70] In 20 of these patients, TEE identified the mechanism of the failure and guided immediate further repair, and 1 patient required valve replacement. In a different study, 437 patients underwent mitral valve repair by a variety of techniques.[71] During a mean follow-up period of 29 months, 41 patients (9.4%) required a reoperation for failure of the repair. Successful initial repair as assessed by intraoperative TEE was the most important predictor of repair durability. Systolic anterior motion (SAM) of the mitral leaflet as diagnosed by intraoperative TEE is a known complication of mitral repair surgery. In a third study of 2076 patients undergoing mitral repair, TEE identified this complication in 174 patients (8.4%).[72] Four of these patients required immediate reoperation to relieve severe persistent SAM. In the others, it was managed medically. During a median follow-up period of 5.4 years, echocardiograms were available for 93 of these patients. SAM was present in 13 of them, and in 4 patients it was severe enough to cause partial LV outflow tract obstruction. Thus, when TEE reveals SAM immediately after mitral repair, it can be managed medically in most patients by preload augmentation, arterial vasoconstriction, β-blockade, or any combination of these treatments. During valve replacement surgery, TEE reliably detects periprosthetic leaks (surprisingly common). Although moderate or severe periprosthetic leaks should almost always undergo immediate repair, almost half of the small leaks resolve with the administration of protamine. However, surgically correctable prosthesis malfunction occurs in other patients and will be missed without the use of TEE. In a study of 417 patients undergoing valve replacement, immediate surgical correction was required in 15 patients (3.6%): periprosthetic leak ($n = 8$), immobilized leaflet ($n = 4$), coronary obstruction ($n = 2$), and xenograft incompetence ($n = 1$).[73]

Although a comprehensive review of valvular assessment is beyond the scope of this chapter, a brief overview of the most commonly used techniques should prepare the reader to fulfill at least the requirements for basic TEE practice so that gross valvular dysfunction can be recognized. The degree of aortic stenosis is appreciated easily in the ME AV SAX cross section, where the extent of leaflet opening can be estimated visually or measured directly by planimetry.[74] Severe stenosis is characterized by marked thickening of the leaflets and severely reduced leaflet motion (valve opening area of <1 cm^2). In the deep TG LAX cross section, CWD allows reliable estimation of the gradient across the AV (Fig. 41-29).[75] In severe stenosis, the peak instantaneous gradient will exceed 64 mm Hg (CWD velocity exceeding 4 m/sec), provided that cardiac output has not been markedly compromised. Noteworthy is the fact that the echocardiographically derived AV gradient may be higher than the peak-to-peak gradient reported from a catheterization study because the latter does not measure the instantaneous gradient as Doppler echocardiography does. Additional information on the morphology of the AV, including the dimensions of the annulus, sinotubular junction, and ascending aorta, can be garnered from the ME AV LAX cross section. The degree of aortic regurgitation is appreciated best in this cross section. With color Doppler positioned over the leaflets and outflow tract, aortic regurgitation is recognized as a color jet emanating from the valve during diastole. Even modest degrees of aortic regurgitation can be clinically significant during cardiac surgery and produce LV distention during cardiopulmonary bypass and diminish the effectiveness of antegrade cardioplegia.[76] Mild regurgitation is characterized by a narrow-based, diastolic color jet (<2 mm at its origin in the valve) that occupies less than a third of the cross-sectional area of the LV outflow tract and extends minimally into the left ventricle (1 to 2 cm). Moderate regurgitation is a broader-based, diastolic color jet (3 to 5 mm) occupying less than two thirds of the cross sectional area of the LV outflow tract and extending moderately into the left ventricle (3 to 5 cm). Severe regurgitation is a broad-based, diastolic color jet (>5 mm) occupying the entire LV outflow tract and extending well into the left ventricle (Table 41-4).

The presence and severity of mitral stenosis are determined easily with TEE on the ME four-chamber, two-chamber, commissural, or LAX cross section (or any combination of these views), as well as the basal TG SAX cross section. 2D imaging reveals thickened leaflets that dome toward the left ventricle and open poorly. Color Doppler reveals laminar flow acceleration into the stenotic orifice and a turbulent jet emerging into the ventricle (Fig. 41-30). PWD and CWD traces display a characteristic flow pattern consisting of increased peak and mean velocities (Fig. 41-31). Mathematical calculation from these traces, such as pressure half-time, are the most precise methods to assess the severity of mitral stenosis, and formulas for these evaluations are built into the software of virtually every ultrasonograph.[77] In addition to the signs just noted, severe mitral stenosis always causes marked left atrial enlargement and left atrial spontaneous contrast. Spontaneous contrast is a swirling, smokelike appearance of 1- to 2-mm densities not attributable to exogenously administered

Table 41-4 Simplified Grading for Aortic Insufficiency*

	Jet Width at Origin (mm)	Jet Area (% LVOT)	Jet Depth into the LV (cm)
Mild	<2	<33	1-2
Moderate	3-5	<66	3-5
Severe	>5	100	>5

*Diastolic jet width is assessed with color Doppler in the ME AV LAX view at the closure point of the aortic valve (the origin of the regurgitant jet). The transducer should be repositioned until the origin of the jet is clearly imaged. Failure to image the origin of the jet may lead to overestimation of its severity. The diastolic jet area is assessed with color Doppler. % LVOT is the percentage of the LVOT occupied by the plume of the color jet (the area of turbulent flow depicted by the mosaic of color pixels). This parameter is markedly affected by aortic diastolic pressure. Failure to adjust color or two-dimensional gains correctly may lead to underestimation or overestimation of the severity of the regurgitation. Color gain should be set just below the level that results in random color sparkle, and two-dimensional gains should be set at the minimum levels allowing adequate visualization of cardiac structures. Diastolic jet depth is assessed with color Doppler. The length of penetration of the jet from the LVOT into the LV is estimated in centimeters. This parameter is also markedly affected by aortic diastolic pressure and gain settings.
LV, left ventricle; LVOT, left ventricular outflow tract.

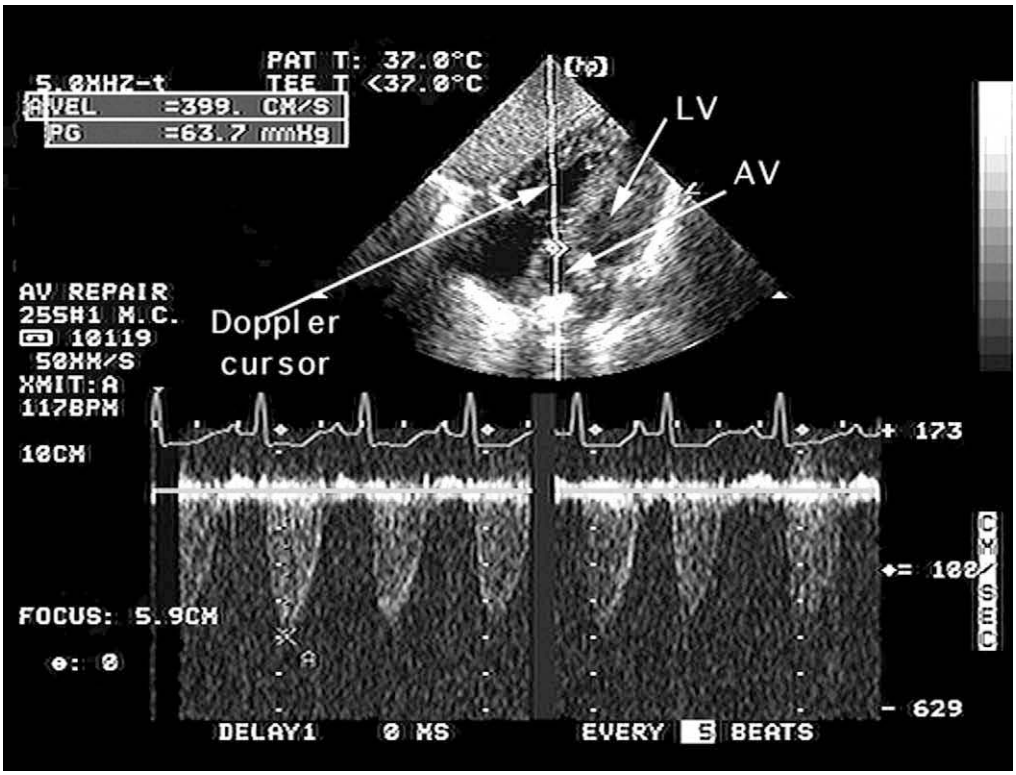

Figure 41-29 Continuous wave Doppler measurement of blood flow velocities immediately above the aortic valve (AV) during seven cardiac cycles. At the top of the figure is a still-frame image of the two-dimensional cross section used to position the Doppler sampling cursor (the *diagonal white line*). On the bottom two thirds of the figure is the display in white of the instantaneous blood flow velocities (vertical axis) versus time (horizontal axis) occurring anywhere along that cursor. The electrocardiogram provides timing, and the *bold horizontal line* is the baseline (zero flow) for the flow velocities. With this Doppler alignment, all flow velocities are negative (i.e., away from the transducer). The Doppler scale has been set to a maximum of –629 cm/sec, and this tracing documents significant aortic stenosis: a peak blood flow velocity of approximately 4 m/sec (each *white dot* on the vertical axis equals 100 cm/sec or 1 m/sec), corresponding to a peak gradient across the AV of 64 mm Hg. LV, left ventricle. *(Reproduced with permission from Cahalan MK: Intraoperative Transesophageal Echocardiography. An Interactive Text and Atlas. New York, Churchill Livingstone, 1997.)*

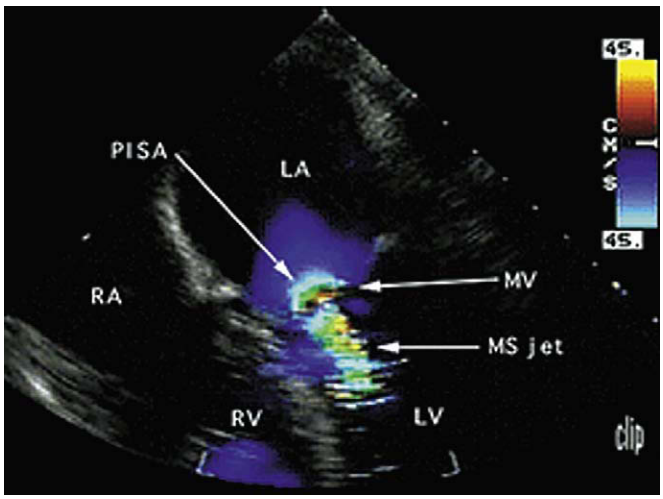

Figure 41-30 This four-chamber echocardiogram reveals a thickened and narrowed mitral valve (MV) indicative of mitral stenosis (MS). Color Doppler demonstrates (1) acceleration of blood flow into the stenotic valve (a light blue semicircular area immediately above the valve [PISA (proximal isovelocity surface area)]), (2) a narrow color jet across the valve itself, and (3) a 1- by 4-cm color jet extending from the undersurface of the valve into the left ventricle (LV). LA, left atrium; RA, right atrium; RV, right ventricle. *(Reproduced with permission from Cahalan MK: Intraoperative Transesophageal Echocardiography. An Interactive Text and Atlas. New York, Churchill Livingstone, 1997.)*

contrast agents but to aggregation of red cells in areas of low flow. Whenever left atrial enlargement and spontaneous contrast are noted, thrombus in the left atrium and, in particular, the left atrial appendage should be suspected and investigated carefully.

The presence and severity of mitral regurgitation are evaluated from the same cross sections used for evaluation of mitral stenosis and with the same grading strategy used for aortic regurgitation (Table 41-5). Mild regurgitation is characterized by a narrow-based, systolic color jet (<2 mm at its origin in the valve) that occupies less than 25% of the left atrial cross-sectional area and extends less than half the distance to the posterior wall of the left atrium. Moderate regurgitation is a broader-based, systolic color jet (3 to 5 mm at its origin in the valve) occupying less than 50% of the left atrial cross-sectional area and extending 50% to 90% of the distance to the posterior wall of the left atrium. Severe regurgitation is a broad-based, systolic color jet (>5 mm) occupying most of the left atrium and extending into the pulmonary veins and left atrial appendage (Fig. 41-32). Eccentrically directed jets of mitral regurgitation that hug the wall of the atrium are generally associated with more severe valvular regurgitation than their cross-sectional area might suggest (see Fig. 41-32). Moreover, eccentrically directed jets usually point away from the defective leaflet (i.e., laterally directed jets are typically associated with anterior leaflet defects and medially directed jets with posterior leaflet defects), provided that the mechanism of regurgitation is leaflet prolapse or flail.[78] Severe mitral regurgitation is invariably

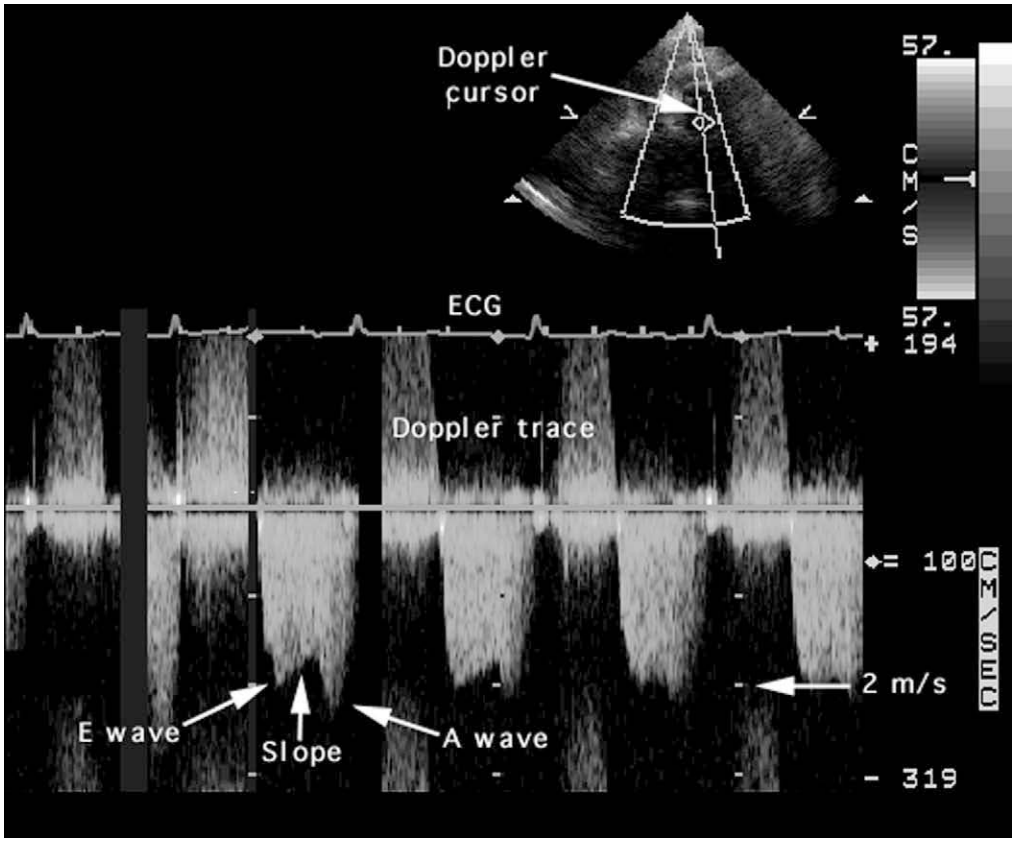

Figure 41-31 Continuous wave Doppler measurement of blood flow velocities through a stenotic mitral valve. At the top of the figure is a still-frame image of the four-chamber cross section used to position the Doppler cursor. On the bottom two thirds of the figure is the display in white of the instantaneous blood flow velocities (vertical axis) versus time (horizontal axis) occurring anywhere along that cursor. The electrocardiogram (ECG) is shown for timing purposes, and the *bold horizontal line* running through the Doppler tracing is the baseline (zero flow) for the flow velocities. Velocities displayed above the baseline are positive and represent flow toward the transducer. These velocities are due to mitral regurgitation and are so high they exceed the scale used in this example. Velocities displayed below the baseline are negative and represent flow away from the transducer. These velocities are due to severe mitral stenosis and average about 2 m/sec, indicative of a 16 mm Hg gradient across the mitral valve. Also note how slowly flow velocity decreases after the peak of the E wave (i.e., the Slope). The pressure half-time can be calculated from this slope and is markedly increased in the presence of severe mitral stenosis. *(Reproduced with permission from Cahalan MK: Intraoperative Transesophageal Echocardiography. An Interactive Text and Atlas. New York, Churchill Livingstone, 1997.)*

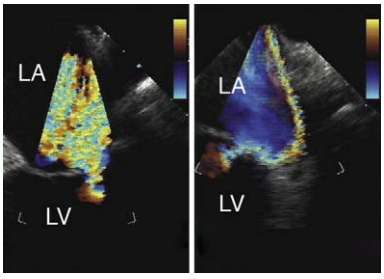

Figure 41-32 Two honed-down stop-action four-chamber transesophageal echocardiograms demonstrating severe mitral regurgitation. The one on the *left* reveals a large color jet depicting turbulent flow emanating from the center of the mitral valve at its coaptation point. The mechanism of the regurgitation in this patient is annular dilatation. Notice the broad base of the jet at the level of the valve leaflet and the extent of the jet's penetration into the left atrium (LA). The stop-action echocardiogram on the *right* reveals another broad-based jet with eccentric direction indicative of prolapse of the anterior leaflet of the mitral valve. Wall-hugging jets such as this one have a small cross-sectional area because much of their energy is absorbed by the wall of the atrium. LV, left ventricle.

associated with systolic reversal of pulmonary venous inflow (Fig. 41-33).[79] The general guidelines listed earlier are widely used, but many more criteria have been described for assessment of mitral regurgitation.[12] Of most importance, the degree of regurgitation is exquisitely dependent on LV loading conditions. For practical purposes, quantitative measures of regurgitation, such as the regurgitant orifice area based on the theory of proximal isovelocity surface area, are less often used in operating rooms because of time restriction.

Pulmonary and tricuspid valve pathology is assessed in a fashion analogous to that described previously for the aortic and mitral valves.

Coronary Disease

In a study of 82 high-risk patients undergoing coronary artery surgery, the investigators used staged blinding of the cardiac surgeons and anesthesiologists at critical points during surgery to document the clinical impact of TEE. After these clinicians docu-

Table 41-5 Simplified Grading for Mitral Regurgitation*

	Jet Width at Origin (mm)	Jet Area (% LA_a)	Jet Depth (% LA_d)
Mild	>2	<25	<50
Moderate	3-5	25-50	50-90
Severe	>5	<50	>100

*Systolic jet width is assessed with color Doppler in the five- or four-chamber view at the closure point of the mitral valve (the origin of the regurgitant jet). The transducer should be repositioned until the origin of the jet is clearly imaged. Failure to image the origin of the jet may lead to overestimation of its severity. Systolic jet area is assessed with color Doppler in the five- or four-chamber view. % LA_a is the percentage of the LA_a occupied by the plume of the color jet (the area of turbulent flow depicted by the mosaic of color pixels). This parameter is markedly affected by left ventricular systolic pressure. Failure to adjust color or two-dimensional gains correctly may lead to underestimation or overestimation of the severity of the regurgitation. Color gain should be set just below the level that results in random color sparkle, and two-dimensional gains should be set at the minimum levels allowing adequate visualization of cardiac structures. Systolic jet depth is assessed with color Doppler in the five- or four-chamber view. % LA_d is the depth of penetration of the jet into the left atrium expressed as a percentage of the distance from the mitral annulus to the posterior wall of the left atrium. This parameter is also markedly affected by left ventricular systolic pressure. In severe mitral regurgitation, the regurgitant jet may extend into one or more pulmonary veins and cause transient reversal of pulmonary venous blood flow.
From Cahalan MK: Intraoperative Transesophageal Echocardiography: An Interactive Text and Atlas. New York, Churchill Livingstone, 1996.

mented their planned management at each stage, the TEE results were revealed and led to at least one significant change in anesthetic management in 51% of patients and surgical management in 33% of patients, including additional unplanned or revised grafts (15%) and unplanned valve procedures (20%).[80] These high-risk patients had postoperative infarction and mortality rates below predicted (1% versus 3% predicted, difference not statistically significant). In the study noted in the section earlier involving 457 consecutive patients undergoing coronary artery surgery, TEE identified 71 new findings in 13% of patients. The new finding resulted in a change in surgical management in 6% of patients. After bypass, surgical management, including graft evaluation or revision and mitral repair, was initiated in 10 patients.

Congenital Heart Surgery

Pediatric TEE probes are used in infants as small as 3 kg (also see Chapter 83). Stevenson and coauthors reported that intraoperative TEE reliably detected residual cardiac defects in 17 (7.4%) of 230 consecutive patients undergoing congenital heart surgery.[81] These patients were reoperated on immediately for revision of the residual defects. However, a subsequent publication from the same center reported that the number of residual defects missed

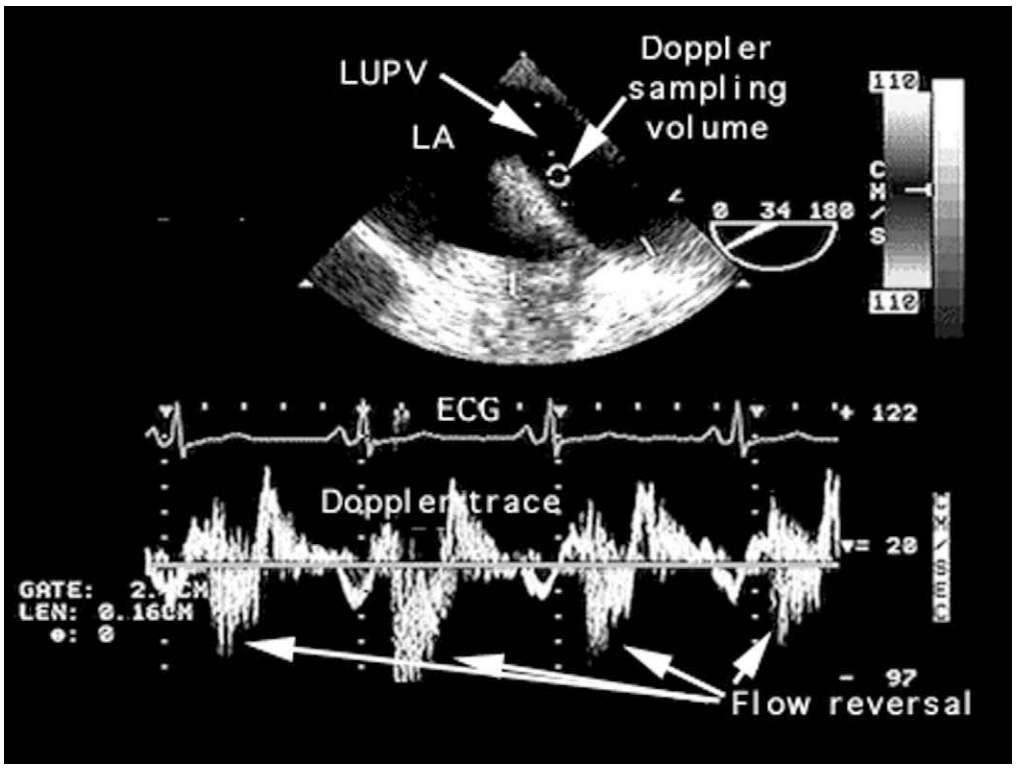

Figure 41-33 Pulsed wave Doppler measurement of blood flow velocities in the left upper pulmonary vein (LUPV). At the top of the figure is a still-frame image of the two-dimensional cross section used to position the Doppler sampling cursor (*broken circle* at point of *arrow*). On the bottom two thirds of the figure is a display of the instantaneous blood flow velocities (vertical axis) versus time (horizontal axis) occurring in the LUPV. The electrocardiogram (ECG) is shown for timing purposes, and the *bold horizontal line* running through the Doppler tracing is the baseline (zero flow) for the flow velocities. Velocities displayed above the baseline are positive and represent flow toward the transducer (in this case, into the left atrium [LA]). Velocities displayed below the baseline are negative and represent flow away from the transducer (in this case, into the LUPV). This Doppler tracing documents systolic flow reversal (normally it is positive, that is, toward the LA in systole) and confirms the presence of severe mitral regurgitation. *(Reproduced with permission from Cahalan MK: Intraoperative Transesophageal Echocardiography. An Interactive Text and Atlas. New York, Churchill Livingstone, 1997.)*

by intraoperative TEE increased from 2% to 13% when the attending anesthesiologist and not a separate echocardiographer performed TEE.[82] This study generated considerable controversy. Although it does not resolve the issue of whether a separate echocardiographer is required to perform TEE adequately in patients undergoing congenital heart repair, it does amply demonstrate that patients can suffer severe consequences when intraoperative TEE is not expertly performed, interpreted, and acted on. In this study, the deaths of seven patients may have been related to the delayed recognition of residual defects. With progress in pediatric congenital heart surgery, more and more children with palliated congenital heart disease will survive to adulthood and undergo cardiac and other kinds of surgery. For an excellent update on TEE in adult congenital heart disease, please see the recent review by Russell and associates.[83]

Other Cardiac Diseases and Applications

In addition to use in valve repair, congenital heart surgery, and thoracic aortic surgery and in hemodynamically unstable patients, the 1996 ASA/SCA guidelines identify intraoperative use of TEE during surgery for hypertrophic cardiomyopathy, endocarditis, and pericardial window procedures as category I indications.[6] Subsequent publications have documented the critical role that TEE may provide in minimally invasive cardiac surgery and in placement of cardiac support devices.[84,85] Thousands of other published reports have documented that TEE can reveal virtually any significant morphologic or functional pathology of the heart. TEE is particularly sensitive for abnormalities involving the left atrium and mitral valve, including masses, thrombi, and emboli, because of the proximity of the left atrium and mitral valve to the TEE transducer. In contrast, pathologies of the RV and LV apex are less reliably detected. TEE is exquisitely sensitive to air embolism, and as a result, even insignificant amounts of air in the circulation give rise to impressive densities on the video display. Currently, accurate estimation of the amount of air in the circulation is impossible with TEE. However, large amounts typically opacify the involved chambers until collections (very bright densities) are formed in the most superiorly positioned parts of the chambers (e.g., the anterior endocardial surface of the left ventricle in a supine patient). Pulmonary emboli may be seen with TEE if they lodge proximal to the bifurcation of the main pulmonary artery.

Transesophageal Echocardiography in Noncardiac Surgery and Critical Care

TEE has many of the same applications in noncardiac surgical patients and critically ill patients as in cardiac surgical patients (also see Chapter 91). Numerous case reports and case series have documented the impact that it can have on patient management and outcome. In our practice, the leading indications are hemodynamic instability and massive blood loss, where TEE has a vital role in determining the etiology of the instability (see the previous section on this topic) and in guiding volume resuscitation.[86,87] In the intensive care unit, TEE has similar applications, and these have been reviewed recently.[88,89]

Data Storage, Documentation, and Quality Assurance

Traditionally, echocardiograms were stored on videotape and written reports of the results were placed in the patient's medical record. Currently, digital recording of individual cardiac cycles or multiple cycles is the standard. The resulting "loops" are transported via hospital networks or the Internet to secure servers, where the studies can be retrieved rapidly. The SCA has published guidelines for TEE reporting (http://www.scahq.org/sca3/peri_op_report4-02.rtf) and a recommended report form (http://www.scahq.org/sca3/TEEREPORfin4-02.rtf).

The ASE and SCA have published guidelines for continuous quality improvement (CQI) in perioperative echocardiography.[90] However, even relatively simple CQI interventions may produce dramatic results in the consistency of image acquisition and storage.[28] Periodic expert review of TEE interpretations is essential if practitioners are to reach and maintain their diagnostic potential. Collaboration between the departments of anesthesiology and cardiology is one approach to this review process that minimizes the duplication inherent in the formation of independent CQI programs.

Certification

The SCA and ASE formed the National Board of Echocardiography (www.echoboards.org). This new board offers a written examination and certification in perioperative echocardiography. The written examination is open to all licensed physicians. Certification requires additional documented experience for physicians who completed their training before 2009. For physicians completing their training after 2009, certification will require fellowship training in perioperative echocardiography (http://www.echoboards.org/certification/pte/reqs.html).

42 Electrocardiography

Key Points

1. Electrocardiographic monitoring is mandatory and a standard of care.
2. Electrocardiography permits detection of electrical disturbances that may influence the mechanical function of the heart.
3. With carefully selected lead combinations, most arrhythmias and myocardial ischemic events can be detected in the perioperative setting.
4. Appropriate diagnosis of arrhythmias and ischemia will allow proper and effective treatment.

The electrocardiogram (ECG) was first invented by William Einthoven in 1901, who used a string galvanogram for his recordings. This time-honored and relatively simple tool remains, even today, a mainstay in clinical cardiac diagnosis and therapy. In the perioperative setting, electrocardiography serves two main functions: diagnosis and monitoring. In the preoperative period, the standard 12-lead ECG is performed mainly for risk assessment. It is used to provide information on the patient's baseline (chronic) cardiac status with regard to myocardial ischemia and conduction or rhythm abnormalities as part of the whole preoperative clinical assessment. Occasionally, the preoperative ECG may reveal acute or new abnormalities, especially when dealing with urgent or emergency operations, and in such cases comparing current with previous ECGs is of extreme importance. During and after surgery the ECG is used mainly for monitoring to detect changes in rate and rhythm or myocardial ischemia. With many patients undergoing surgery with pacemakers or implantable cardiac defibrillators in place, the ECG enables the anesthesiologist to monitor the proper function of these devices during the surgical procedure. Perioperative management of these devices is described in Chapter 43. During cardiac surgery, both myocardial ischemia and different types of arrhythmia are common, especially after separation from cardiopulmonary bypass. Proper diagnosis and management of intraoperative ischemia and arrhythmias are part of the expertise of the anesthesiologist. A postoperative 12-lead ECG is often obtained in patients at high cardiac risk when new ischemic or rhythm changes are suspected. In all these scenarios, a good understanding of the principles of interpretation of the ECG is vital for the clinical anesthesiologist. This chapter is intended to cover most aspects of interpretation of the ECG, with special emphasis on issues relevant to anesthesia and perioperative care.

Electrocardiographic Lead Systems

Standard Recording Electrodes and Leads

The small electric currents produced by the electrical activity of cardiac muscle spread an electrical field throughout the body that behaves as a volume conductor, which allows it to be recorded at various sites on the surface of the body as electrocardiographic signals. The electrical potentials reaching the skin are recorded by electrodes (leads) placed at specific locations, and the output of these leads is amplified, filtered, and displayed on various electronic devices. There are two types of electrocardiographic leads: *bipolar* and *unipolar*. A bipolar lead consists of two electrodes placed at different sites to measure the difference in potential between them. Unipolar leads measure the "absolute" electrical potential at one site in relation to a *reference*, or *remote site*, at which the potential is deemed to be zero. The standard clinical ECG includes recordings from 12 leads. These 12 leads include three *bipolar* (leads I, II, and III), six *unipolar precordial* (leads V_1 through V_6), and three *modified unipolar limb leads* (the augmented limb leads aVR, aVL, and aVF) (Table 42-1).

Standard Electrocardiographic Recordings

The ECG is normally recorded on special paper consisting of grids of horizontal and vertical lines. Distances between vertical lines represent time intervals, whereas distances between hori-

Table 42-1 Location of electrodes and lead connections for the standard 12-lead electrocardiogram and additional leads

Lead Type	Positive Input	Negative (Reference) Input
Bipolar Limb Leads		
Lead I	Left arm	Right arm
Lead II	Left leg	Right arm
Lead III	Left leg	Left arm
Augmented Unipolar Limb Leads		
aVR	Right arm	Left arm plus left leg
aVL	Left arm	Right arm plus left leg
aVF	Left leg	Left arm plus left arm
Precordial Leads		
V_1	Right sternal margin, 4th intercostals space	Wilson central terminal
V_2	Left sternal margin, 4th intercostal space	Wilson central terminal
V_3	Midway between V_2 and V_4	Wilson central terminal
V_4	Left midclavicular line, 5th intercostal space	Wilson central terminal

zontal lines represent voltage. The lines are 1 mm apart, with every fifth line intensified. The speed of the paper is standardized to 25 mm/sec. On the horizontal axis, 1 mm represents 0.04 second, and 0.5 cm represents 0.20 second. On the vertical axis, 10 mm represents 1 mV. On every recording, a 1-cm (1-mV) calibration mark should indicate that the ECG is appropriately calibrated.

Normal Electrical Activity

P Wave

Under normal circumstances, the sinoatrial (SA) node has the most rapid spontaneous depolarization rate and is therefore the dominant cardiac pacemaker. From the SA node, the impulse normally spreads to the atrioventricular (AV) node through one left-sided and two right-sided pathways. The P wave is the result of normal depolarization of the atria, and identification of this wave is important for determination of normal sinus rhythm. The anatomically anterior right atrium is activated earlier, and only later does the signal shift posteriorly as activation proceeds over the left atrium. Therefore, the P wave in the right precordial leads (V_1 and, occasionally, V_2) is commonly biphasic, a positive deflection followed by a negative one, whereas in the lateral leads, the P wave is upright and reflects right-to-left spread of the activation front.

PR Interval

The PR interval is the temporal bridge between atrial and ventricular activation, during which the AV node, the bundle of His, the bundle branches, and the intraventricular conduction systems are activated (Fig. 42-1). Most of the conduction delay during this segment is due to slow conduction within the AV node. The normal PR interval is 120 to 200 msec in duration.

Myocardial Activation—The QRS Complex

The QRS complex is the manifestation of left and right ventricular muscle depolarization. Its pattern in each electrocardiographic lead represents the sum of all electrical forces emanating from the wavefront propagation of ventricular electrical excitation aimed in the direction of that lead. Ventricular excitation spreads within several milliseconds from the bundle branches to the His-Purkinje fibers, which are dispersed broadly throughout the entire endocardial surfaces of both ventricles. Excitation of the Purkinje–ventricular muscle junctions in the endocardium then proceeds by conduction from muscle cell to muscle cell to activate the entire ventricle thickness toward the epicardium. The normal pattern of activation of the ventricles starts in the interventricular septum with a vector oriented from left to right in the frontal plane and anteriorly in the horizontal plane (as determined by the anatomic position of the septum within the chest). This produces an initial small positive R wave in the right-sided leads (aVR and V_1) and small negative waves (septal q waves—less than 30 to 40 msec) in the left-sided leads (I, aVL, V_5, and V_6). Subsequent QRS complex elements reflect activation of the free walls of the left and right ventricles. Because the right ventricular muscle mass is considerably smaller than that of the left ventricle, the QRS primarily represents left ventricular (LV) activity with its main vector proceeding from right to left in the axial plane and anterior followed by posterior vectors in the horizontal plane (R wave followed by a small S wave in the left-sided leads). The

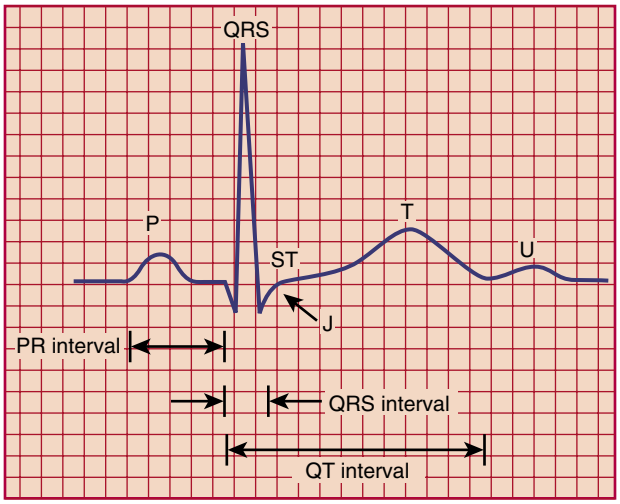

Figure 42-1 Waves and intervals of a normal electrocardiogram. *(From Goldberger AL: Clinical Electrocardiography: A Simplified Approach, 6th ed. St Louis, CV Mosby, 1999; and Zipes DP, Libby P, Bonow R, Braunwald E: Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine, 7th ed. Philadelphia, WB Saunders, 2005.)*

main vector of the QRS complex in the frontal plane serves to calculate the electrical axis of the heart, which is normally between −30 and +90 degrees. An axis more negative than −30 degrees is called *left axis deviation*, and an axis higher than +90 degrees is termed *right axis deviation*. The duration of the normal QRS complex is less than 120 msec.

ST Segment and T Wave

Repolarization of the ventricles generates the ST segment and T wave. Repolarization, like activation, occurs in a characteristic geometric pattern. Because the endocardial action potential lasts longer than that of its overlying epicardium, repolarization of the epicardium often starts earlier than in the endocardium. However, under normal conditions, there are regional differences in electrical recovery properties of the ventricles, and the transmural gradients predominantly determine the ST patterns.

Normally, there is concordance between the orientation of the QRS complex and the T wave, with both deflecting in the same direction. The junction of the QRS and the ST segment is called the J junction. The QT interval—the duration from the Q wave to the end of the T wave—is highly dependent on heart rate, and formulas have been developed to calculate the corrected QT interval (QTc), which if prolonged may be associated with serious ventricular arrhythmias. The T wave is sometimes followed by a small U wave, which may be associated with hypokalemia or hypomagnesemia (see Fig. 42-1). An example of a normal 12-lead electrocardiogram is shown in Figure 42-2.

The Abnormal Electrocardiogram

Atrial Abnormality

Initiation of atrial electrical activation from a site other than the SA node occurs in one of two ways: either as an escape rhythm if the normal SA nodal pacemaker slows or fails or as an accelerated atrial ectopic rhythm if the automaticity of the ectopic site is associated with a rate higher than the SA node. Ectopic atrial activation is often manifested by an abnormal morphology of the P wave (different from the native P). Most commonly, negative P waves are seen in the leads where the P wave is normally upright (leads I, II, aVF, and V_4 through V_6), with or without shortening of the PR interval. The exact site of an ectopic atrial pacemaker is usually of little clinical significance except that left-sided atrial ectopy is seen more often in association with LV or left heart valvular abnormalities, whereas right-sided ectopy is more common in patients with chronic obstructive lung disease or other causes of right heart dysfunction.

Ventricular Hypertrophy and Enlargement

Left ventricular hypertrophy (LVH) or enlargement produces changes throughout the QRST complex. The most characteristic change is increased voltage of the QRS complex: tall R waves in the left-sided leads (I, aVL, V_5, and V_6) and deep S waves in the right-sided leads (V_1 and V_2). ST-segment and T-wave amplitudes can be normal or increased. ST-segment depression with downsloping from a depressed J point and inverted asymmetric T waves are common in long-standing and severe LVH. Similarly, a QRS duration prolonged beyond 110 msec reflects the longer duration of activation of the thickened ventricular wall. Many sets of diagnostic electrocardiographic criteria for LVH have been developed, although their diagnostic importance in the era of echocardiography has obviously diminished. For example, Sokolow and Lyon found the following voltage criteria to correlate best with postmortem pathologic findings of LVH: SV_1 + (RV_5 or RV_6) > 3.5 mV or RaVL > 1.1 mV (or both) (Fig. 42-3).

Right ventricular hypertrophy is manifested on the ECG by abnormally tall R waves in the rightward-directed leads (aVR, V_1, and V_2), reversal of normal R-wave progression in the precordial leads, deep S waves with abnormally small R waves in the left-sided leads (I, aVL, V_5, and V_6), and marked right axis deviation (>110 degrees). Chronic obstructive pulmonary disease can lead to right ventricular hypertrophy, changes in the position of the heart within the chest, and hyperinflation of the lungs. Acute right ventricular pressure overload, such as that caused by pulmonary embolism, can produce a characteristic pattern on the ECG: a QR or qR pattern in the right-sided leads, an $S_1Q_3T_3$ pattern, and an acute incomplete or complete right bundle branch block (RBBB). However, even the classic $S_1Q_3T_3$ pattern occurs in only about 10% of cases of acute pulmonary embolism (Fig. 42-4).

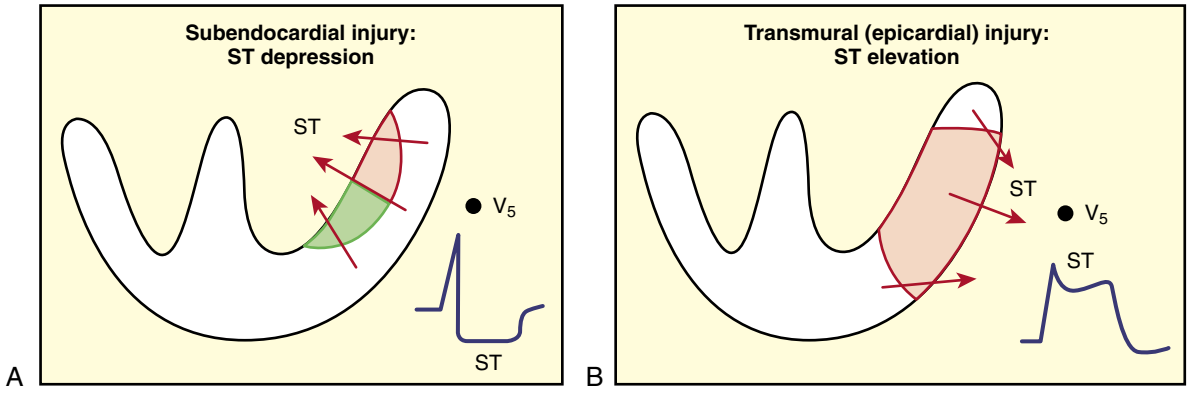

Figure 42-5 Patterns of injury currents. **A,** Acute subendocardial, ST-depression type. **B,** Transmural, ST-elevation type (ischemia). *(From Zipes: Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine, 7th ed.)*

Myocardial Ischemia

The ST-T segment, representing myocardial repolarization, is the component of the ECG most sensitive to acute myocardial ischemia. ST elevation, which may be accompanied by tall positive (hyperacute) T waves, indicates transmural ischemia and is most often the result of acute coronary artery occlusion caused by either coronary thrombosis or vasospasm (Prinzmetal's variant angina). Reciprocal ST depression may appear in the contralateral leads. Ischemia confined to the subendocardial area is usually denoted by ST-segment depression. Subendocardial, ST depression–type ischemia typically occurs during episodes of symptomatic or asymptomatic ("silent") stable angina pectoris. It is characteristic of ischemia occurring during exercise, tachycardia, or a pharmacologic stress test in patients with significant but stable coronary artery disease (CAD) (Fig. 42-5).

Myocardial Infarction

With prolonged ischemia, there is a risk of developing myocardial necrosis or myocardial infarction (MI). The electrocardiographic manifestation of MI includes decreased R-wave amplitude and pathologic Q waves (>1 mm in depth and >40 msec in duration), which may develop as a result of loss of electromotive forces in the infarcted area. Transmural infarctions are more likely to culminate in pathologic Q waves, whereas subendocardial (nontransmural) infarcts are less likely to produce Q waves. However, pathologic studies have shown such a wide overlap between the two entities and their electrocardiographic expression that "Q-wave" or "non–Q-wave" infarction is not synonymous with transmural or nontransmural infarction. Pathologic Q waves usually develop days after the onset of acute MI, and once they develop, they infrequently disappear and serve as an indicator of the location of the infarction. Persistent T-wave inversion may also be the only sign of chronic ischemia and recent or old MI. Pathologic Q waves with ST elevation that persists for weeks or longer after MI correlate strongly with severe myocardial mechanical dysfunction, akinesis, or ventricular aneurysm.

Electrocardiographic leads demonstrating ST-T changes or Q waves may help define the location and the coronary artery responsible for the ischemia or MI. For example, precordial leads V_1 to V_3 correspond to the anteroseptal or apical walls of the left ventricle; leads V_4 to V_6 to the apical or lateral LV walls (Fig. 42-6); leads II, III, and aVF to the inferior LV wall (Fig. 42-7); and the

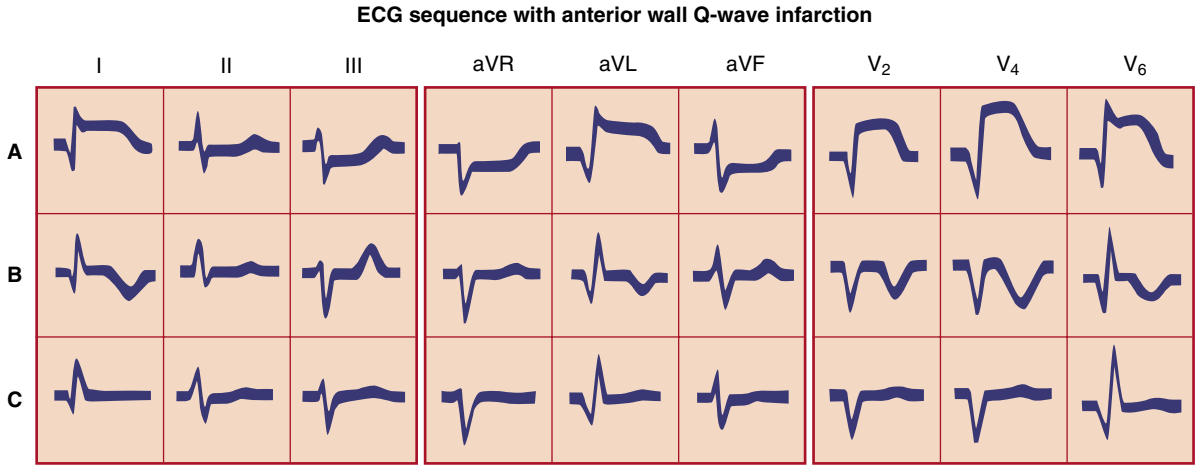

Figure 42-6 Acute, ST-elevation–type anterior wall myocardial infarction. **A,** Acute phase: ST elevations and new Q waves. **B,** Evolving phase: deep T-wave inversions. **C,** Resolving phase: partial or complete regression of the ST-T changes (and sometimes Q waves). Notice the reciprocal ST-T changes in the inferior leads (II, III, and aVF). *(From Goldberger AL: Clinical Electrocardiography: A Simplified Approach, 7th ed. St Louis, CV Mosby, 2006.)*

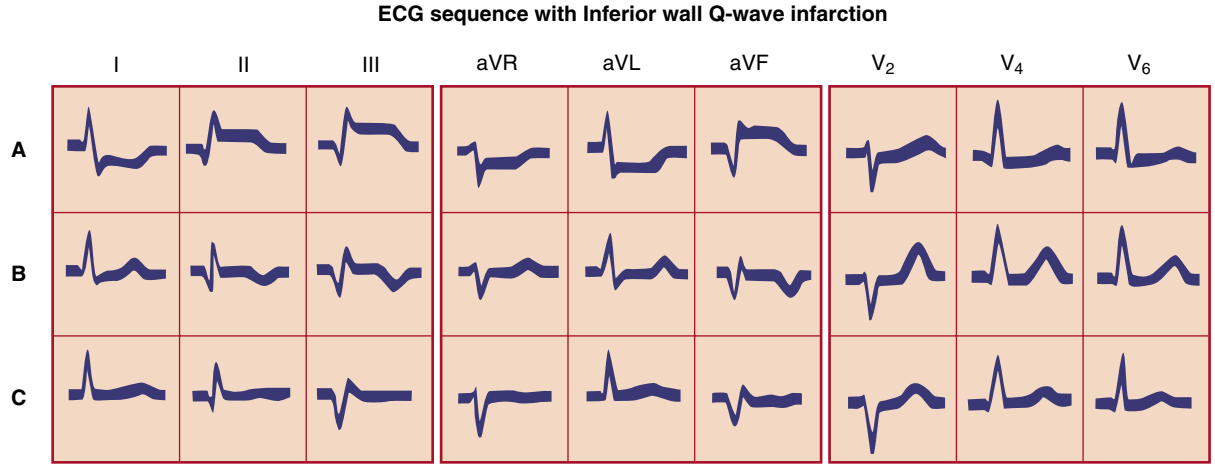

Figure 42-7 Inferior wall myocardial infarction. **A,** Acute phase: ST elevations and new Q waves. **B,** Evolving phase: deep T-wave inversions. **C,** Resolving phase: partial or complete regression of the ST-T changes (and sometimes Q waves). right-sided leads to the right ventricle. Posterior wall infarction induces ST elevation or Q waves in leads placed over the left side and back (V_7 to V_9), and reciprocal ST depression or tall R′ waves may develop in leads V_1 to V_3.

Electrolyte Abnormalities

The ECG is affected not only by structural or functional myocardial abnormalities but also by numerous metabolic and electrolyte aberrations (see Chapter 54).

CALCIUM. Hypercalcemia shortens and hypocalcemia prolongs phase 2 of the action potential duration, thus leading to abbreviation or prolongation of the QT interval, respectively. Severe hypercalcemia (e.g., total serum Ca^{2+} >15 mg/dL) causes a decrease in T-wave amplitude or T-wave inversion, and hypercalcemia may produce a high-takeoff ST segment in leads V_1 and V_2 simulating acute ischemia.

POTASSIUM. Hyperkalemia leads to a distinctive sequence of changes on the ECG, starting with narrowing and peaking of the T wave and shortening of the QT interval. Progressive hyperkalemia causes widening of the QRS complex, a low P-wave amplitude, and prolongation of the PR interval with the possibility of a second- to third-degree AV block (Fig. 42-8). Severe hyperkalemia results in sine-wave ventricular flutter and eventually asystole. Hypokalemia, in contrast, may cause ST depression, flattened T waves, and a prominent U wave that may sometimes exceed the amplitude of T waves. Hypokalemia prolongs repolarization and leads to long QT(U) syndrome, which predisposes to a torsades de pointes–type ventricular fibrillation.

MAGNESIUM. Mild to moderate hypermagnesemia or hypomagnesemia is not associated with specific changes on the ECG. Yet severe hypermagnesemia can cause AV and intraventricular conduction disturbances, including complete heart block and cardiac arrest (Mg^{2+} >15 mEq/L). Hypomagnesemia is often associated with hypocalcemia or hypokalemia

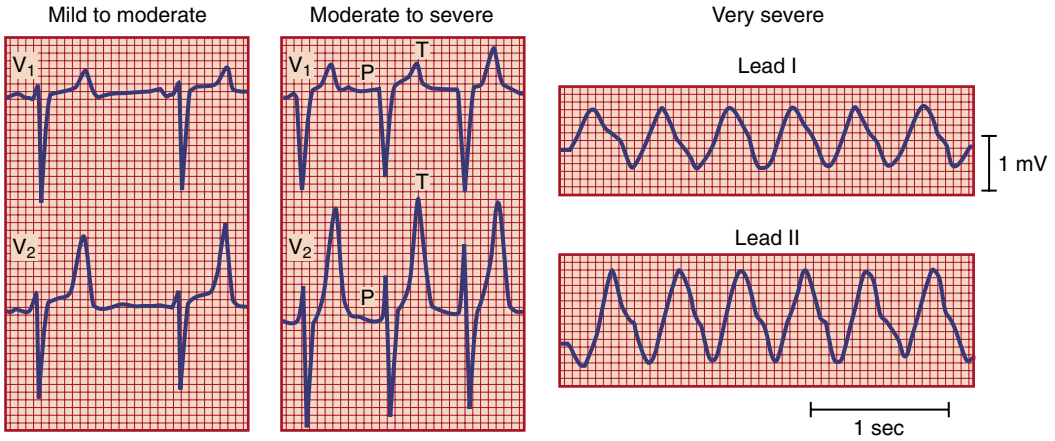

Figure 42-8 Electrocardiographic signs of hyperkalemia. The earliest change with hyperkalemia is peaking ("tenting") of the T waves. With progressive increases in the serum potassium concentration, the QRS complexes widen, the P waves decrease in amplitude and may disappear, and finally a sine-wave pattern leads to asystole unless emergency therapy is initiated. *(From Goldberger AL: Clinical Electrocardiography: A Simplified Approach, 7th ed. St Louis, CV Mosby, 2006.)*

and may predispose to long QT(U) syndrome and torsades de pointes.

Electrocardiographic Monitoring Systems

Noise Filtering

Low-Frequency Filtering. All electrocardiographic monitors use filters to narrow the signal bandwidth in an attempt to reduce environmental artifacts and improve signal quality. Low-frequency noise, such as that produced by respiration or any other patient motion, causes the tracing to wander above and below the baseline. Therefore, low-frequency filters are used in electrocardiographic monitoring. The heart rate in beats per minute forms a rough lower bound for the frequency content in hertz (Hz, cycles per second). Because heart rates below 40 beats/min (0.67 Hz) are uncommon, traditional low-frequency analog filters are used to cut signals off at frequencies below 0.5 Hz. However, such filters introduce considerable distortion on the ECG, particularly with respect to the level of the ST segment. It results in phase nonlinearities in areas of the electrocardiographic signal where frequency content and wave amplitude change abruptly, as occurs where the end of the QRS complex meets the ST segment. The 1975 American Heart Association (AHA) recommendations included a 0.05-Hz low-frequency cutoff for diagnostic electrocardiography. This recommendation preserves the fidelity of repolarization, but it does not eliminate the problem of baseline drift. Current modern digital filtering provides more sophisticated methods to achieve a higher cutoff for low-frequency filtration without the phase distortions seen with analog filtering. Thus, current AHA recommendations[1] to reduce artifactual distortion of the ST segment are that the low-frequency cutoff should be (1) 0.05 Hz for monitors with analog filters and (2) 0.67 Hz or lower for monitors and electrocardiographic recording devices with linear digital filters and zero phase distortion.

High-Frequency Filtering. High-frequency filters are needed to reduce distortions from muscle fasciculations, tremors, and electromagnetic interference from other electrical equipment. Older monitors used a 40-Hz filter to reduce the interference from electrical current. However, the higher the frequencies contained in the filtered signal, the more accurate the measurement of rapid upstroke velocity, peak amplitude, and waves of short duration. A high-frequency cutoff of 100 Hz was considered adequate by the AHA in 1975 to maintain diagnostic accuracy during visual inspection of the ECG, even though it has long been recognized that higher-frequency components of the QRS complex may have clinical significance in patients with various forms of heart disease. According to current AHA recommendations, an upper frequency cutoff of at least 150 Hz is required to accurately measure routine duration and amplitudes in adults, adolescents, and children, and an upper frequency cutoff of 250 Hz is more appropriate for infants.

Most modern electrocardiographic monitors allow the operator a choice of several bandwidths. The actual filter frequencies tend to vary among manufacturers. One manufacturer allows a choice of three different filtering modes: (1) a diagnostic mode with a bandwidth of 0.05 to 130 Hz for adults and 0.5 to 130 Hz for neonates, (2) a monitoring mode with a bandwidth of 0.5 to 40 Hz for adults and 0.5 to 60 Hz for neonates, and (3) a filter mode with a bandwidth of 0.5 to 20 Hz. The importance of bandwidth selection for detection of perioperative myocardial ischemia was evaluated by Slogoff and coworkers, who showed that the position of the ST segment was similar in all systems using the lower filter limit (0.05 Hz) recommended by the AHA.[2]

Three-Electrode Electrocardiographic Monitoring

In contrast to the standard 12-lead ECG, in which the four limb electrodes are placed on the wrists and ankles, electrode placement for continuous cardiac monitoring is on the torso to reduce artifacts from limb movement, as well as to avoid tethering the patient. Therefore, the right and left arm (RA/LA) electrodes are placed in the infraclavicular fossae close to the right and left shoulders, respectively, and the left leg (LL) electrode is placed below the rib cage on the left side of the abdomen. The ground or reference electrode (RL), if present, can be positioned anywhere, but it is usually placed on the right side of the abdomen.

The three-electrode system is the simplest and most common mode of electrocardiographic monitoring in operating rooms and intensive care units (ICUs). It allows monitoring of three bipolar leads by recording the potential difference between each of three pairs of electrodes: lead I (positive electrode, LA; negative electrode, RA), lead II (positive electrode, LL; negative electrode, RA), lead III (positive electrode, LL; negative electrode, LA), or other modified chest leads.[3] Three-electrode monitoring is usually good enough to track the heart rate, detect R waves for synchronized direct-current (DC) shock in cardioversion, and detect ventricular fibrillation. However, it is inadequate for diagnosing more complex arrhythmias, such as distinguishing between RBBB and left bundle-branch block (LBBB) or between ventricular tachycardia (VT) and supraventricular tachycardia (SVT) with aberrant ventricular conduction, for which a "true" V_1 lead is necessary. The three-electrode system is also inadequate for ST-segment monitoring because it does not provide multilead monitoring or precordial leads, which are frequently the most sensitive for detecting ischemia. The older literature[4] suggested that modified chest leads such as CS_5 (RA electrode placed under the right clavicle and LA electrode placed in the V_5 position) or CB_5 (RA electrode over the center of the right scapula and LA electrode in the V_5 position) may be suitable for detection of anterior wall myocardial ischemia; however, these leads are currently considered not accurate enough and are not recommended for monitoring myocardial ischemia.

Five-Electrode Electrocardiographic Monitoring

In the five-electrode monitoring system, the four limb electrodes, LA, RA, LL, and RL placed at their corresponding monitoring locations, allow any of the six limb leads to be obtained (leads I, II, III, aVR, aVL, and aVF), and a fifth chest electrode can be placed in any of the standard V_1 through V_6 locations (Fig. 42-9).

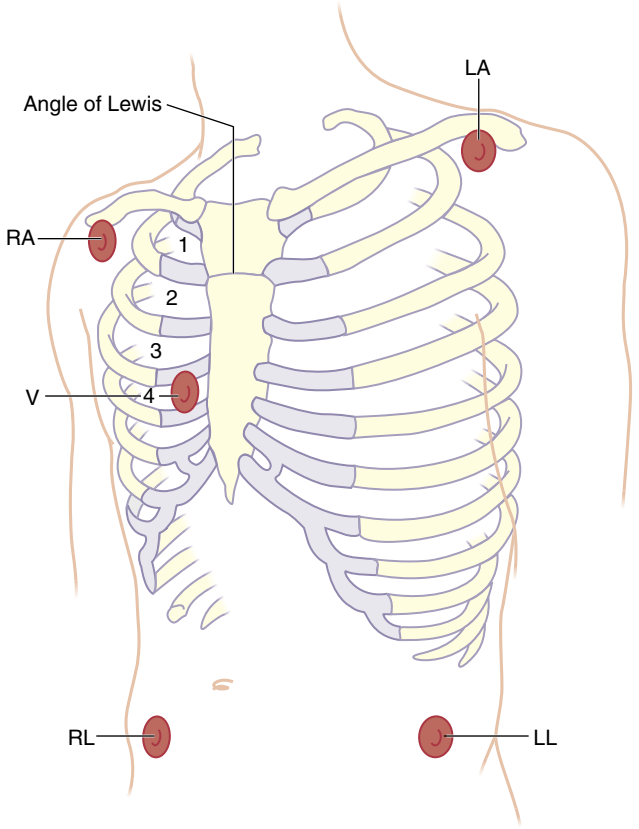

Figure 42-9 Commonly used five-electrode lead system that allows recording any of the six limb leads plus one precordial (V) lead. Shown here is lead placement for recording V_1. A limitation of this system is that only one precordial lead can be recorded. *(From Drew BJ, Califf RM, Funk M, et al: Practice standards for electrocardiographic monitoring in hospital settings: An American Heart Association Scientific Statement from the Councils on Cardiovascular Nursing, Clinical Cardiology, and Cardiovascular Disease in the Young. Circulation 110:2721-2746, 2004.)*

V_1 is the preferred lead for special arrhythmia monitoring, whereas the other precordial leads, especially V_3 to V_5, are the preferred leads for ischemia monitoring. The five-electrode monitoring system is currently the standard for monitoring patients with suspected perioperative myocardial ischemia. Differences in sensitivity and specificity among the different electrocardiographic leads in detecting myocardial ischemia are discussed later.

Ten-Electrode, Twelve-Lead Electrocardiographic Monitoring

Mason and Likar in 1966 introduced a variation on positioning the standard limb electrodes of the 12-lead ECG during exercise stress testing to minimize artifacts in the limb leads caused by movement.[5] In this design, the RA and LA electrodes were attached to the right and left infraclavicular fossae, and the LL electrode was attached to the left iliac fossa. The RL electrode could be placed anywhere but was usually placed on the right iliac fossa for symmetry. Studies have shown that although the limb lead QRS complexes are slightly different in amplitude and axis and the precordial leads may also vary slightly from the standard 12-lead recording, the ST-segment measurements during exercise stress testing were only incidentally affected when the Mason and Likar 12-lead electrocardiographic system was used as compared with the standard 12-lead ECG.[6] A major advantage of cardiac monitors using the Mason-Likar 12-lead system is that ST-segment monitoring software has been developed to analyze all 12 leads and to sound an alarm for ST-segment changes, regardless of whether multiple leads are being displayed on the bedside or central monitor. Therefore, if lead II is being displayed but the patient has a transient ischemic event involving lead V_5, an ST alarm would be triggered. Not all manufacturers who offer the Mason-Likar lead system perform full 12-lead ST-segment analysis, nor do they store all 12 leads for printing at a later time. Another advantage of the Mason-Likar lead system is that more than one precordial lead can be displayed at the same time. The disadvantage of the system for cardiac monitoring is that 10 electrodes are required and the 6 precordial electrodes often interfere with diagnostic (e.g., echocardiography, chest radiography) and emergency (defibrillation sites) procedures. In addition, the precordial sites are difficult to maintain on patients with large breasts or hirsute chests (Fig. 42-10).

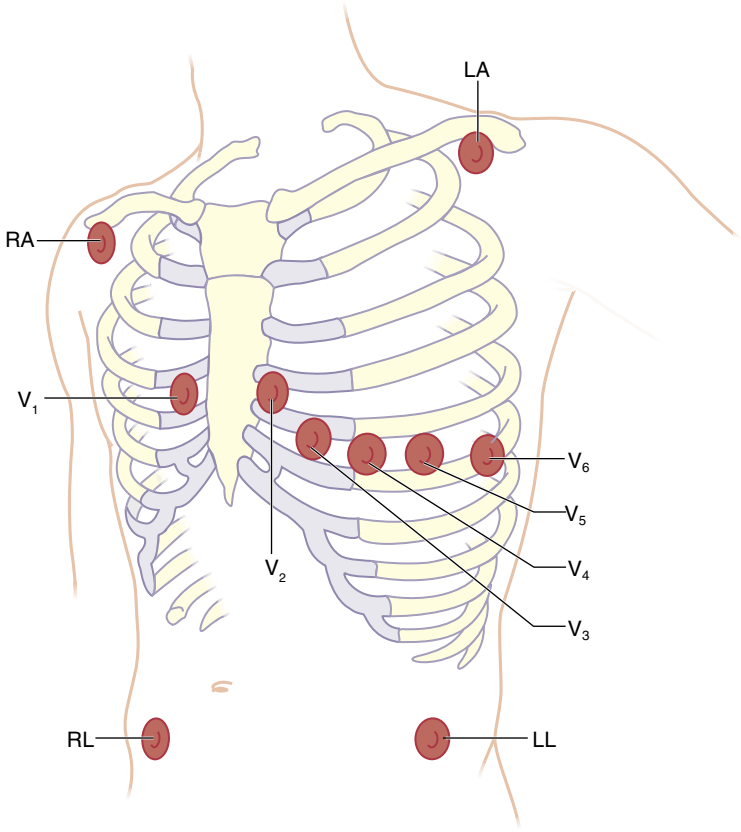

Figure 42-10 Mason-Likar 12-lead electrocardiographic (ECG) system. Anatomic locations for precordial leads are the same as for recording a standard 12-lead electrocardiogram, except that the limb leads are relocated from standard 12-lead ECG positions on the wrists and ankles to the torso. *(From Drew BJ, Califf RM, Funk M, et al: Practice standards for electrocardiographic monitoring in hospital settings: An American Heart Association Scientific Statement from the Councils on Cardiovascular Nursing, Clinical Cardiology, and Cardiovascular Disease in the Young. Circulation 110:2721-2746, 2004.)*

Holter Monitoring

Holter monitoring, originally a cardiologist's tool, has been used by a number of anesthesiologists to document the perioperative incidence of arrhythmias or ischemia. In Holter monitoring, electrocardiographic information from two or three bipolar leads is recorded by a miniature recorder. Up to 48 hours of electrocardiographic signals can be collected. Subsequently, the data are processed via a playback system, and the electrocardiographic signals are analyzed. On most modern systems, the playback unit includes a dedicated computer for rapid analysis and automatic recognition of arrhythmias and ischemia.

A significant early obstacle to the widespread use of conventional Holter monitoring in the perioperative period was the delayed, retrospective analysis and interpretation. This limitation was to some extent overcome by real-time Holter monitors, which both record specific electrocardiographic segments for later playback and also analyze the rhythm and ST segment in real time to alert the user to an acute event.[7,8] Despite significant technical progress, Holter monitoring devices continue to be limited primarily to clinical investigations.

Interpretation and Management of Arrhythmias

There is little doubt that during prolonged visual electrocardiographic monitoring on a video display, arrhythmias may go undetected. It has been demonstrated long ago that coronary care unit staff failed to detect serious ventricular arrhythmias in 84% of their patients.[9] Subsequently, computerized monitors have been designed for the automatic detection of arrhythmias in an attempt to increase the rate of detection of abnormal, potentially dangerous rhythms. These monitors use proprietary sophisticated algorithms such as pattern recognition, measurements of QRS width, onset, offset, and amplitude, and calculations of area to classify complexes into morphologic families.[10,11] Most monitors are capable of detecting potentially fatal arrhythmias such as severe bradycardia or asystole and dangerous tachyarrhythmias such as VT or ventricular fibrillation. Yet no published study has evaluated the accuracy, sensitivity, and specificity of these automated, real-time arrhythmia detection monitors. It has been shown, though, that detection of clinically important arrhythmias in the cardiac ICU improves significantly if a nurse watches the monitor and pays attention to the alarms.[12] Thus, today's computerized monitoring systems still have not achieved the level of accuracy sufficient to eliminate the need for human surveillance; the alarms must be recognized and the ECG interpreted and acted on by a knowledgeable person in a timely fashion.

Diagnosis of Arrhythmias

Arrhythmias are common during and after surgery and have numerous causes. Postoperative dysrhythmias are most likely to occur in patients with structural heart disease. The initiating factor for an arrhythmia after surgery is usually a transient insult such as hypoxemia, cardiac ischemia, catecholamine excess, or electrolyte abnormality.[13] Using perioperative Holter recordings, Mahla and colleagues[14] evaluated how anesthesia and surgery affect the course of ventricular dysrhythmias (premature ventricular beats and repetitive forms of ventricular beats: couplets and nonsustained VT) noted preoperatively in patients with structural heart disease undergoing noncardiac surgery. They concluded that the frequency of ventricular dysrhythmias was not associated with adverse cardiac outcomes. The incidence of perioperative dysrhythmia in patients with an adverse outcome (8%) did not differ from the incidence in those with a good outcome. Patients undergoing cardiac surgery obviously have a higher incidence of cardiac dysrhythmias. The incidence of new-onset atrial fibrillation after cardiac surgery approaches 33%, such arrhythmias are associated with a worse outcome.[15] Several major factors contribute to the development of perioperative arrhythmias:

1. *General anesthetics*: Volatile anesthetics, such as halothane or enflurane, produce arrhythmias, probably by a reentrant mechanism.[16] Halothane also sensitizes the myocardium to endogenous and exogenous catecholamines. Drugs that block the reuptake of norepinephrine, such as cocaine and ketamine, can facilitate the development of epinephrine-induced arrhythmias (see Chapter 23). In contrast, volatile anesthetics may have an antifibrillatory effect in response to acute coronary occlusion and reperfusion, at least in a canine model.[17] Sevoflurane may cause severe bradycardia and nodal rhythm when used in high concentrations during induction in infants,[18] and desflurane may prolong the QTc within the first minute of anesthesia in patients with a normal heart.[19]
2. *Local anesthetics*: Regional anesthesia by central neuraxial blockade, the goal of spinal or epidural anesthesia, may be associated with profound, albeit transient pharmacologic sympathectomy. This phenomenon may cause parasympathetic nervous system dominance leading to mild to very severe bradyarrhythmias, especially when the blockade extends to very high thoracic levels (see Chapter 51). Inadvertent intravascular injection of a large dose of local anesthetic may lead to asystole and cardiac arrest, which are very difficult to treat.[20] One proposed treatment is the administration of 20% Intralipid.[21,22]
3. *Abnormal arterial blood gases or electrolyte levels*: Excessive hyperventilation, particularly in the presence of low serum potassium levels, may precipitate severe cardiac arrhythmias.[23] Alterations in blood gases or electrolytes may lead to arrhythmias by producing reentrant mechanisms or by altering the phase 4 depolarization of conduction fibers. Electrolyte disturbances associated with cardiopulmonary bypass can also result in intraoperative arrhythmias (see Chapters 54 and 60).
4. *Endotracheal intubation*: This maneuver may be the most common cause of arrhythmias during surgery and is frequently associated with hemodynamic disturbances by eliciting autonomic reflexes (see also Chapter 50).
5. *Autonomic reflexes*: Vagal stimulation may produce sinus bradycardia and allow ventricular escape mechanisms to occur. It may also produce AV block or even asystole. These reflexes may be related to traction on the peritoneum or direct pressure on the vagus nerve during carotid surgery (see Chapter 62). During jugular vein cannula-

tion, stimulation of the carotid sinus by palpation of the neck can lead to bradyarrhythmias. Specific reflexes, such as the oculocardiac reflex, can also produce severe bradycardia or asystole.

6. *Central nervous system stimulation and dysfunction of the autonomic nervous system*: Many electrocardiographic abnormalities can occur in patients with intracranial disease, especially subarachnoid hemorrhage. These abnormalities are most commonly ST-T wave changes and may easily mimic myocardial ischemia and infarction (see Chapter 63).[24] The mechanism of these arrhythmias appears to be related to changes in autonomic nervous system tone.
7. *Preexisting cardiac disease*: This is probably the most common background for arrhythmias during anesthesia and surgery.[25] Patients with a preexisting tendency for atrial or ventricular arrhythmias are more likely to exhibit them during or after surgery in response to perioperative stress or secondary to acute withdrawal of oral antiarrhythmic medications, most commonly β-blockers.
8. *Central venous cannulation*: Insertion of catheters or wires into the central circulation frequently leads to arrhythmias (see Chapter 40).
9. *Surgical manipulation of cardiac structures*: Arrhythmias are frequently observed during insertion of atrial sutures or placement of venous cannulas for cardiopulmonary bypass during cardiac surgery (see Chapters 60 and 83). They are usually self-limited and cease at the end of manipulation.
10. *Location of surgery*: Dental surgery is often associated with arrhythmias because profound stimulation of the sympathetic and parasympathetic nervous systems frequently occurs.[26] Junctional rhythms are often seen and may be caused by stimulation of the autonomic nervous system by the fifth cranial nerve. The oculocardiac reflex leads to severe bradycardia in response to traction on the rectus muscles of the orbit. This reflex, which is mediated by the trigeminal nerve as the afferent limb and the vagus nerve as the efferent limb, is especially sensitive in *neonates* and children and common during strabismus operations.

After an arrhythmia is recognized, does it produce a hemodynamic disturbance, what type of treatment is required, and how urgently should therapy be instituted? Treatment should be initiated promptly if the arrhythmia results in marked hemodynamic impairment. Prompt treatment should also be instituted if the arrhythmia is a precursor for a more severe arrhythmia (e.g., frequent multifocal ventricular premature beats [VPBs] with an R-on-T phenomenon can lead to ventricular fibrillation). Immediate attention is required for arrhythmias in a patient with underlying cardiac disease (e.g., any tachycardia in a patient with mitral valve stenosis, aortic valve stenosis, or ischemic heart disease). Arrhythmias can be classified by heart rate or by anatomic origin within the heart. By heart rate criteria, arrhythmias can be broken down into three categories: bradyarrhythmias (heart rate <60 beats/min), tachyarrhythmias (heart rate >100 beats/min), and conduction blocks (at any heart rate). The anatomic origin of an arrhythmia can be ventricular, supraventricular, junctional, or elsewhere. Diagnosis and treatment of arrhythmias can be simplified by using the following checklist when looking at an electrocardiographic display:

1. What is the heart rate?
2. Is the rhythm regular?
3. Is there one P wave for each QRS complex?
4. Is the QRS complex normal?
5. Is the rhythm dangerous?
6. Does the rhythm require treatment?

The following is analysis of some common intraoperative arrhythmias.

Sinus Bradycardia

Sinus bradycardia is diagnosed when the pacemaker site is in the sinus node but the rate is slower than normal. Etiologic factors include drug effects, acute inferior MI, hypoxia, vagal stimulation, and high sympathetic blockade. Sinus bradycardia accounts for roughly 11% of intraoperative arrhythmias.

1. *Heart rate*: Slower than 60 beats/min. In patients maintained on chronic β-blocker therapy, it is defined as a heart rate of less than 50 beats/min.
2. *Rhythm*: Regular, except for occasional escape beats from other pacemaker sites.
3. *P/QRS*: Ratio of 1 : 1.
4. *QRS complex*: Normal morphology.
5. *Significance*: Heart rates lower than 40 beats/min are poorly tolerated, even in healthy patients, and should be evaluated on the basis of their effect on cardiac output. Treatment is recommended if hypotension, ventricular arrhythmias, or signs of poor peripheral perfusion are observed. Sinus bradycardia may be part of the sick sinus syndrome in which sinus node dysfunction can precipitate bradycardia, heart block, tachyarrhythmia, or alternating bradyarrhythmia and tachyarrhythmia.[27]
6. *Treatment*: Usually none is necessary. When treatment is deemed necessary, the following approach may be considered: (1) atropine, 0.5 to 1.0 mg by intravenous bolus repeated every 3 to 5 minutes, up to 0.04 mg/kg or approximately a 3.0-mg total dose for the average 75-kg male patient; (2) ephedrine, 5 to 25 mg by intravenous bolus; (3) dopamine or dobutamine (if blood pressure is adequate), 5 to 20 μg/kg/min by intravenous infusion; (4) epinephrine, 2 to 10 μg/min by intravenous infusion; (5) isoproterenol, 2 to 10 μg/min by intravenous infusion. Temporary transcutaneous or transvenous pacing may be necessary for severe, drug-refractory sinus bradycardia. Immediate institution of transcutaneous pacing is especially important in symptomatic patients.

Sinus Tachycardia

The pacemaker site in patients with sinus tachycardia is in the sinus node, and the rate is faster than normal. Sinus tachycardia is the most common arrhythmia in the perioperative period. It occurs with such frequency that it is not included in most studies of the incidence of arrhythmias. Common causes include pain, inadequate anesthesia, hypovolemia, fever, hypoxia, hypercapnia, heart failure, and drug effects.

1. *Heart rate*: Faster than 100 beats/min in adult patients and may be as high as 170 beats/min. Patients with significant CAD may not tolerate heart rates even as low as 70 to 80 beats/min, and subendocardial ischemia can develop. Similarly, patients with severe mitral or aortic stenosis may be sensitive to even moderate increases in heart rate.
2. *Rhythm*: Regular.
3. *P/QRS*: Ratio of 1:1.
4. *QRS complex*: Normal but there may be associated ST-segment depression with severe increases in heart rate and resulting myocardial ischemia.
5. *Significance*: Prolonged tachycardia in patients with underlying heart disease can precipitate MI and congestive heart failure (CHF) as a result of the increased myocardial work required and decreased myocardial oxygen supply because of decreased diastolic coronary perfusion time. A major diagnostic problem is encountered when the heart rate is 150 beats/min because this is a common rate for sinus tachycardia, paroxysmal atrial tachycardia, or atrial flutter with a 2:1 block. These three arrhythmias can sometimes be distinguished by the use of carotid sinus massage or intravenous administration of edrophonium or adenosine phosphate.
6. *Treatment*: The underlying disorder should be treated. Hypovolemia and light anesthesia are the most common causes. In patients with ischemic heart disease in whom tachycardia develops, β-adrenergic blockers should be used judiciously to prevent myocardial ischemia regardless of whether ST-segment changes are present. Hypovolemia or other causes should also be addressed in these patients.

Sinus Arrhythmia

In sinus arrhythmia, the impulses arise from the SA node, and the rhythm is characterized by a variable rate. The PR interval is normal, as is the QRS complex. Most commonly, but not invariably, the rate increases with inspiration and decreases with expiration. This arrhythmia occurs more often in children than in adults. The heart rate is 60 to 100 beats/min, the rhythm is irregular, the P/QRS ratio is 1:1, and the QRS complex has normal morphology. Sinus arrhythmia has little clinical significance, is considered a normal finding, and requires no treatment.

Atrial Premature Beats

An ectopic pacemaker site in the left or right atrium initiates an atrial premature beat (APB). The shape of the P wave is different from the usual SA node P wave and may be inverted. The PR interval may be shorter or longer than normal, depending on the site of the ectopic focus and the refractoriness of the AV nodal pathway. The APB spreads through the AV node and ventricular conduction system and, in retrograde fashion, reaches the SA node and resets the sinus pacemaker. The interval from the APB to the next sinus beat is therefore a normal sinus cycle (i.e., no compensatory pause). The absence of a compensatory pause is an important distinguishing feature between APBs and VPBs. Occasionally, APBs may find part of the ventricular conduction system refractory, in which case they travel down an aberrant pathway and create an abnormal QRS complex. They are then called APBs with aberrant ventricular conduction and can easily be confused with VPBs. Because the recovery period of the right ventricular conduction system is longer than that of the left, the most common form of aberration appears as an RBBB. Helpful points in differentiating APBs with aberrant ventricular conduction from VPBs include (1) the presence of a preceding P wave, usually abnormally shaped; (2) an RBBB configuration of the QRS complex; (3) the presence of an rsR′ ventricular complex in V_1; and (4) the finding that the initial vector forces are identical to the preceding beat, which is usually the opposite with a VPB. Other characteristics of APBs are as follows:

1. *Heart rate*: Variable, depending on the frequency of the APBs.
2. *Rhythm*: Irregular.
3. *P/QRS*: Usually 1:1. The P waves have various shapes and may even be lost in the QRS or T waves. Occasionally, the P wave is so early that it finds the ventricle refractory, and a nonconducted beat occurs.
4. *QRS complex*: Usually normal unless ventricular aberration is present.
5. *Significance*: In one study, APBs represented 10% of all intraoperative arrhythmias. They have little clinical significance, but frequent APBs may lead to other, more serious supraventricular arrhythmias or may be a sign of digitalis intoxication.
6. *Treatment*: Rarely necessary.

Paroxysmal Supraventricular Tachycardia

Paroxysmal SVT (PSVT) is characterized by a rapid regular rhythm, generally with a narrow QRS complex and lacking the normal SA node P wave. Inclusion of tachycardias involving the AV node (Fig. 42-11) allows a useful classification of tachycardias as being caused by reentry in the AV node, by apparent or concealed accessory AV pathways, or less often, by SA node reentry. Ectopic atrial or ectopic nodal tachycardias are among the less frequent SVTs. Inappropriate or persistent sinus tachycardia is another variant. PSVT rhythms are usually abrupt in onset and termination. PSVT is easily distinguished from rapid atrial fibrillation, which is an irregular rhythm, and from rapid atrial flutter, which has flutter waves.

1. Heart rate: 130 to 270 beats/min.
2. *Rhythm*: Usually regular unless the impulse originates from multiple atrial foci.
3. *P/QRS*: 1:1 relationship, although the P wave may often be hidden in the QRS complex or T wave.
4. *QRS complex*: Generally normal, but ST-T changes indicative of ischemia may be observed. Aberration of ventricular conduction may occur and complicate the differential diagnosis with VT. SVT may also be confused with sinus tachycardia, atrial flutter, and atrial fibrillation. In differentiating these rhythms, carotid sinus massage or edrophonium (5 to 10 mg given intravenously) was traditionally used. More recently, adenosine (6 to 12 mg by intravenous bolus) has been used to slow the rate by transiently enhancing the normal degree of AV block or to terminate the arrhythmia.[28] Esophageal electrocardiographic leads may also be helpful to better define atrial activity.[29]

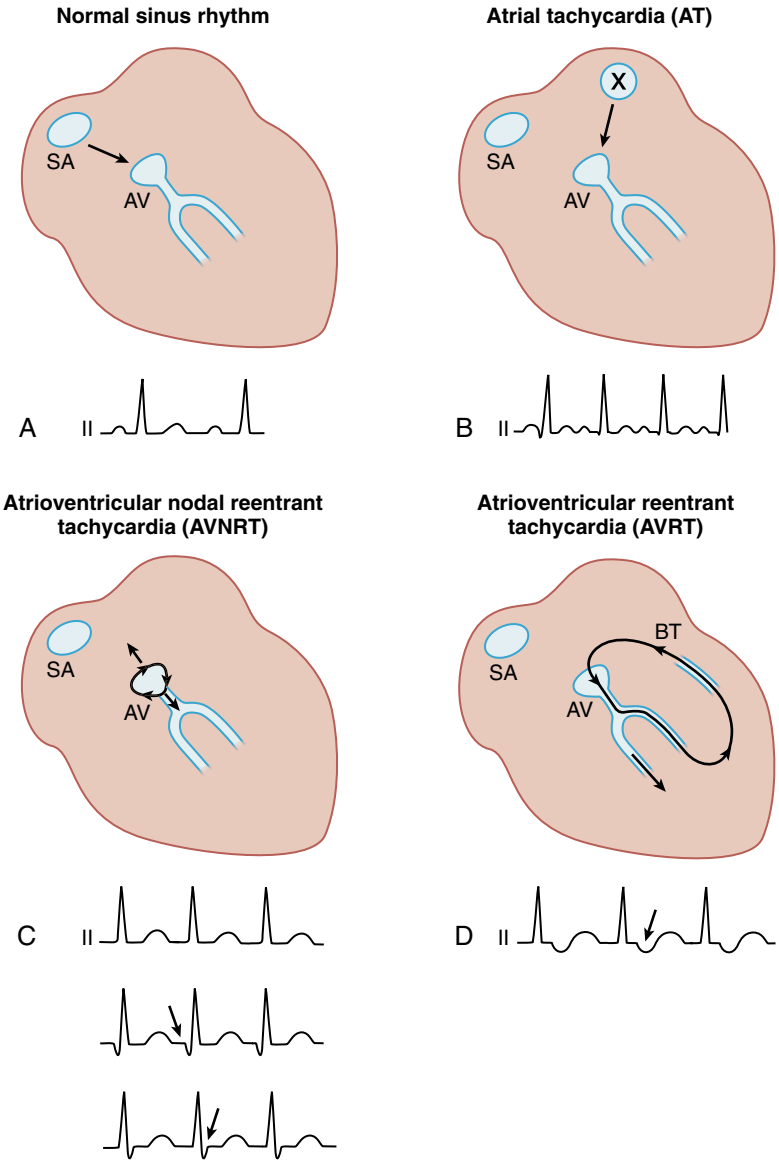

Figure 42-11 Major types of paroxysmal supraventricular tachycardia. **A,** Normal sinus rhythm. **B,** Atrial tachycardia. A focus (X) outside the sinoatrial (SA) node fires off automatically at a rapid rate. **C,** Atrioventricular (AV) nodal reentrant tachycardia. The cardiac stimulus originates as a wave of excitation that spins around the AV nodal (junctional) area. As a result, retrograde P waves may be buried in the QRS or appear immediately before or just after the QRS complex (*arrows*) because of nearly simultaneous activation of the atria and ventricles. **D,** A similar type of reentrant (circus-movement) mechanism may occur with a bypass tract (BT) of the type found in Wolff-Parkinson-White syndrome. This mechanism is referred to as atrioventricular reentrant tachycardia (AVRT). Note the negative P wave (*arrow*) in lead II, somewhat after the QRS complex. (With AVRT, the P wave in lead II may be negative or isoelectric.) *(From Goldberger AL: Clinical Electrocardiography: A Simplified Approach, 7th ed. St Louis, CV Mosby, 2006.)*

5. *Significance*: PSVT can be seen in 5% of normal young adults and in patients with Wolff-Parkinson-White syndrome or other pre-excitation syndromes. During anesthesia, PSVT accounts for up to 2.5% of all arrhythmias. This arrhythmia has no association with any intrinsic heart disease or systemic illness. When a patient is anesthetized, PSVT can be precipitated by changes in autonomic nervous system tone, by drug effects, or by intravascular volume shifts and can produce severe hemodynamic deterioration. Sometimes the PSVT may be associated with AV block because of the fast atrial rate and slow AV conduction. PSVT with a 2:1 block represents digitalis intoxication in many patients.
6. *Treatment*: Even though this arrhythmia is not usually associated with hemodynamic deterioration, the following can be undertaken to treat it:
   a. Vagal maneuvers such as carotid sinus massage should be applied only to one side.[30]
   b. Adenosine, which is the drug of choice, is given by 6-mg rapid (2 seconds) intravenous bolus, preferably through an antecubital or central vein. If no response is elicited, second and third doses of 12 to 18 mg of adenosine may be administered by rapid intravenous bolus.[31]
   c. Verapamil (2.5 to 10 mg given intravenously) terminates AV nodal reentry successfully in about 90% of cases.[32] Unlike adenosine, verapamil has the advantage of providing long-term relief.
   d. Amiodarone (150-mg infusion over a 10-minute period for the loading dose) is a recent addition.[33]
   e. Esmolol (1 mg/kg by bolus and 50 to 200 mg/kg/min by infusion) has been shown to be effective.[34]
   f. Edrophonium or neostigmine can be given by intravenous bolus.[35]
   g. Phenylephrine (100 µg by intravenous bolus) is administered if the patient is hypotensive.[36]
   h. Intravenous digitalization is performed with one of the short-acting digitalis preparations: ouabain (0.25 to 0.5 mg given intravenously) or digoxin (0.5 to 1.0 mg given intravenously).[36]

i. Rapid overdrive pacing may be done in an effort to capture the ectopic focus.[37]
j. Synchronized cardioversion may be performed with incremental doses of energy of 100, 200, 300, and 360 J, preferably after light sedative premedication.[38] Electrode catheter ablation with radiofrequency energy has evolved as the definitive, long-term treatment of most persistent AV reentrant or focal atrial SVTs.[39]

Atrial Flutter

Atrial flutter most commonly represents a macro-reentrant arrhythmia that circulates in a specific manner in the right atrium (i.e., counterclockwise rotation as viewed in the angiographic left anterior oblique view). Because it is associated with very fast heart rates, it is generally accompanied by AV block. Classic sawtooth flutter waves (F waves) are usually present (Fig. 42-12). The characteristics of atrial flutter are as follows:

1. *Heart rate*: The atrial heart rate is 250 to 350 beats/min with a ventricular rate of about 150 beats/min (2:1 or varying AV conduction block).
2. *Rhythm*: The atrial rhythm is regular. The ventricular rhythm may be regular if a fixed AV block is present or irregular if a variable block exists.
3. *P/QRS*: Usually there is a 2:1 block with an atrial rate of 300 beats/min and a ventricular rate of 150 beats/min, but it may vary between 2:1 and 8:1. F waves are best seen in leads V_1 and II and the esophageal lead.
4. *QRS complex*: Normal. T waves are lost in the f waves.
5. *Significance*: Atrial flutter does not always indicate severe heart disease. It can be seen in patients with CAD, mitral valve disease, pulmonary embolism, hyperthyroidism, cardiac trauma, cancer of the heart, and myocarditis.
6. *Treatment*: Pharmacologic or synchronized DC cardioversion, when indicated, should be performed only after careful consideration or evaluation of a possible thromboembolic event. Initial treatment should consist of control of the ventricular response rate with drugs that slow AV node conduction:

a. β-Blockers such as esmolol (1 mg/kg by intravenous bolus) or propranolol.
b. Calcium channel blockers such as verapamil (5 to 10 mg given intravenously) or diltiazem.[40] β-Blockers and calcium channel blockers are also effective as pharmacoprophylaxis for the prevention of postoperative atrial tachyarrhythmias after thoracic and cardiac surgery.[41]

If the ventricular response is excessively rapid or hemodynamic instability is present, or both, the following guidelines should be used:

c. Synchronized DC cardioversion starting at a relatively high energy of 100 J and gradually increasing to 360 J is indicated.
d. The class III antiarrhythmic agent ibutilide (Corvert, 1 mg in 10 mL saline or 5% dextrose in water [D_5W] infused slowly intravenously over a 10-minute period) has been documented to convert atrial flutter to sinus rhythm in most patients with relatively new-onset atrial flutter.[42] This may be repeated once, and although it is highly effective, life-threatening torsades de pointes (discussed later) may occur hours after ibutilide administration, thus making 4- to 8-hour monitoring after treatment highly desirable.
e. Procainamide (5 to 10 mg/kg for the intravenous loading dose, infused no faster than 0.5 mg/kg/min) may rarely be used in an attempt to restore sinus rhythm after the ventricular response has been adequately controlled.[43]
f. Amiodarone (150-mg intravenous loading dose infused over a 10-minute period, followed by 1 mg/min intravenously for 6 hours, a 0.5-mg/min intravenous infusion for 18 hours, and then a reduced intravenous dose or switching to an oral dose) has recently been shown to be effective.

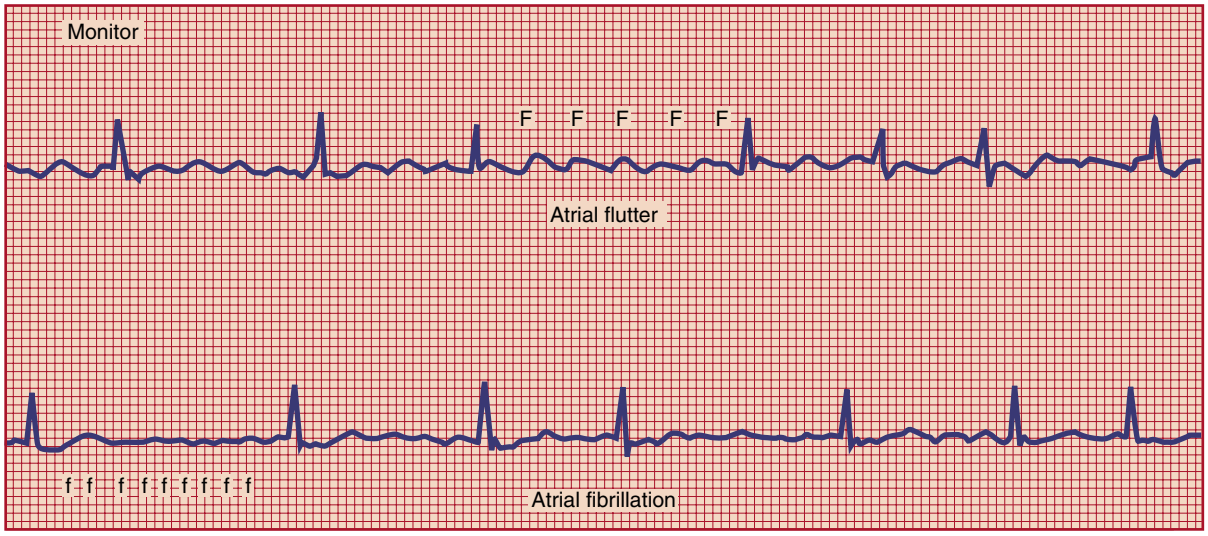

Figure 42-12 Atrial flutter and fibrillation. Notice the "sawtooth" waves (F waves) with atrial flutter and the irregular fibrillatory waves (f waves) with atrial fibrillation. *(From Goldberger AL: Clinical Electrocardiography: A Simplified Approach, 7th ed. St Louis, CV Mosby, 2006.)*

Atrial Fibrillation

Atrial fibrillation is an excessively rapid and irregular atrial focus with no P waves appearing on the ECG; instead, fine fibrillatory activity is seen (f waves, see Fig. 42-12). This is the most commonly encountered irregular rhythm. It is often described as irregularly irregular and may be associated with a pulse deficit. Its characteristics are as follows:

1. *Heart rate*: The atrial rate is 350 to 500 beats/min, and the ventricular rate is 60 to 170 beats/min.
2. *Rhythm*: Irregularly irregular.
3. *P:QRS*: The P wave is absent and replaced by f waves or no obvious atrial activity at all.
4. *QRS complex*: Normal.
5. *Significance*: The causes of atrial fibrillation are similar to those of atrial flutter. This rhythm is often associated with significant cardiac disease; however, idiopathic, paroxysmal atrial fibrillation has become increasingly recognized. The clinical significance and treatment of atrial fibrillation are similar to that for atrial flutter, except for two important considerations. The loss of atrial "kick" from inefficient contraction of the atria may reduce ventricular filling and significantly compromise cardiac output. After 24 to 48 hours, atrial fibrillation may be associated with the development of atrial thrombi, possibly resulting in pulmonary or systemic embolization.

   Atrial fibrillation is the most common postoperative arrhythmia and has significant consequences on patient health. Postoperative atrial fibrillation complicates up to 8% of all noncardiac surgeries, between 3% and 30% of noncardiac thoracic surgeries, and between 16% and 46% of cardiac surgeries. It has been associated with increased morbidity, mortality, and longer, more costly hospital stays. The risk of atrial fibrillation after cardiac and noncardiac surgery may be affected by several epidemiologic and intraoperative factors, as well as by the presence of preexisting cardiovascular and pulmonary disorders. It is typically a transient, reversible phenomenon that may develop in patients who possess an electrophysiologic substrate for the arrhythmia that is present before or as a result of surgery. Numerous studies support the efficacy of β-blockers in the prevention of postoperative atrial fibrillation. Perioperative administration of amiodarone, sotalol, nondihydropyridine calcium channel blockers, and magnesium sulfate has also been associated with a reduction in the occurrence of atrial fibrillation.[44]
6. *Treatment*:
   a. *Acute atrial fibrillation*: Treatment of acute atrial fibrillation is very similar to that for atrial flutter. Primary attention should be focused on controlling the ventricular response, especially with the administration of diltiazem or esmolol intravenously. Ibutilide may restore sinus rhythm, but it is less effective than in the treatment of flutter. Synchronized DC cardioversion should be relied on in patients with pronounced hemodynamic instability. However, if fibrillation is present for longer than 48 hours, attempts to restore sinus rhythm may be associated with a heightened risk for thromboembolism. In a patient with a normal coagulation profile, adequate anticoagulation for 3 to 4 weeks should be considered before attempting to restore sinus rhythm. Alternatively, transesophageal echocardiographic examination to rule out atrial thrombi may be substituted. New developments in electrophysiologic techniques for ventricular defibrillation consisting of biphasic current shocks have shown superiority to the conventional monophasic current techniques (discussed later). However, data regarding the efficacy of biphasic shocks for conversion of atrial fibrillation are still emerging. A randomized, double-blind, multicenter trial by the BiCard investigators[45] demonstrated that for the cardioversion of atrial fibrillation, a biphasic shock waveform has greater efficacy, requires fewer shocks and lower delivered energy, and results in less dermal injury than a monophasic shock waveform does. These results mirror those seen in the ventricular fibrillation trials.
   b. *Long-term therapy*: Long-term therapy for atrial fibrillation varies and depends on factors such as whether the arrhythmia is constant or paroxysmal, the nature of the underlying heart disease, and the state of ventricular function or hemodynamic stability or reserve. In an older individual or in the setting of specific risk factors (e.g., hypertension, diabetes mellitus, severe LV systolic dysfunction), anticoagulation with warfarin (Coumadin) should be strongly considered. When control of ventricular response is difficult with standard agents (e.g., β-blockers, calcium channel blockers, digitalis), electrode catheter ablation of the AV junction and permanent pacemaker insertion have seen increased use. This method is not a curative, merely a rate-controlling procedure. It also produces a regular ventricular contraction rhythm. For patients who are in and out of atrial fibrillation, implanted atrial defibrillators that function much like their ventricular counterparts (see Chapter 43) were considered a therapeutic option. Today, these devices see very limited application. The current "curative" electrophysiologic procedure is transseptal pulmonary vein isolation via radiofrequency catheter ablation (see Chapter 61).[46]

      In the absence of coronary artery disease or significant LV systolic dysfunction, class Ic antiarrhythmic agents (i.e., flecainide or propafenone) have become the agents of choice.[47] Use of class Ia drugs (i.e., quinidine, procainamide, and disopyramide) has sharply diminished because of concern about their significant proarrhythmic function and their systemic and organ side effects. Use of antiarrhythmic drugs that block repolarizing potassium currents (i.e., sotalol[48] and amiodarone[49]) has gained popularity for the suppression of atrial fibrillation in individuals with significant structural heart disease. Sotalol, however, has much lower efficiency in converting atrial fibrillation than class Ic agents do. New class III agents show good efficacy in converting atrial fibrillation. Ibutilide converts rapidly, can be effective in up to 50% of cases,[50] and is more effective than sotalol or procainamide. All of the drugs mentioned for treating atrial fibrillation have significant adverse cardiovascular effects, torsades de pointes (ventricular fibrillation), CHF, bradycardia, and hypotension being the most prominent.[51]

Junctional Rhythms

The AV node itself and sites just above and below it can act as pacemakers. It makes sense to consider this ectopic activity as arrhythmias of the AV junction. The resultant P wave is abnormal and, depending on the position of the ectopic pacemaker, may be very close to, buried in, or after the QRS complex. Depending on the rate of fire of the ectopic pacemaker, the resultant rhythm is nodal premature; nodal quadrigeminy, trigeminy, or bigeminy; nodal rhythm; or nodal tachycardia.

1. *Heart rate*: Variable, 40 to 180 beats/min (i.e., nodal bradycardia to junctional tachycardia).
2. *Rhythm*: Regular.
3. *P/QRS*: 1 : 1, but there are three varieties:
   a. *High nodal rhythm*: The impulse reaches the atrium before the ventricle; the P wave therefore precedes the QRS but has a shortened PR interval (0.1 second).
   b. *Mid nodal rhythm*: The impulse reaches the atrium and the ventricle at the same time. The P wave is lost in the QRS.
   c. *Low nodal rhythm*: The impulse reaches the ventricle first and then the atrium, so the P wave follows the QRS complex.
4. *QRS complex*: Normal, unless altered by the P wave.
5. *Significance*: Junctional rhythms are common in patients under anesthesia (about 20%), especially with halogenated anesthetic agents. Junctional rhythms frequently decrease blood pressure and cardiac output by about 15%, but they can decrease it up to 30% in patients with heart disease.[52]
6. *Treatment*: Usually, no treatment is required, and the rhythm reverts spontaneously. If hypotension and poor perfusion are associated with the rhythm, treatment is indicated. Atropine, ephedrine, or isoproterenol can be used in an effort to increase the activity of the SA node so that it will take over as the pacemaker. Dual-chamber electrical pacing at a rate faster than a slow nodal rhythm is another option.

Ventricular Premature Beats

VPBs result from ectopic pacemaker activity arising below the AV junction. The VPB originates in and spreads through the myocardium or ventricular conducting system, thereby resulting in a wide (>0.12-second), bizarre QRS complex. The ST segment usually slopes in the direction opposite the main deflection of the QRS complex. There is no P wave associated with a VPB, but retrograde depolarization of the atria or blocked sinus beats may obscure the diagnosis.

The most important entity in the differential diagnosis is APB with aberrant ventricular conduction. The distinction should be made whenever possible.

Although an APB normally reaches the SA node and resets the sinus rhythm, such an occurrence is rare when the ectopic pacemaker is in the ventricle. A VPB often blocks the next depolarization from the SA node, but the following sinus beat occurs on time. The result is a fully compensatory pause consisting of the interval from the VPB to the expected normal QRS, which is blocked at the AV node, plus a normal sinus interval.

VPBs are common during anesthesia, where they account for 15% of observed arrhythmias. They are much more common in anesthetized patients with preexisting cardiac disease. Other than heart disease, known etiologic factors include electrolyte and blood gas abnormalities, drug interactions, brainstem stimulation, and trauma to the heart.

1. *Heart rate*: Depends on the underlying sinus rate and frequency of the VPBs.
2. *Rhythm*: Irregular.
3. *P/QRS*: No P wave with the VPB.
4. *QRS complex*: Wide and bizarre, with a width of more than 0.12 second. If it is of an RBBB nature, prominent R forces are present in V_1. If it is an LBBB in appearance, notching of the S wave and less acute downward sloping of the ST segment are common.
5. *Significance*: The new onset of VPBs must be considered a potentially serious event because in certain clinical situations, the arrhythmia may progress to VT or ventricular fibrillation. Such situations include coronary artery insufficiency, MI, digitalis toxicity with hypokalemia, and hypoxemia. VPBs are more likely to precede ventricular fibrillation if they are multiple, multifocal, or bigeminal; occur near the vulnerable period of the preceding ventricular repolarization (i.e., R-on-T phenomenon)[53]; or appear in short-long-short coupling sequences. VPBs are markers, not the cause of more severe arrhythmias.
6. *Treatment*: In most patients, VPBs (occurring as single, bigeminy, or trigeminy but excluding nonsustained VT) do not need to be treated, particularly if the patient does not have an acute coronary syndrome, and treatment is generally dictated by the presence of symptoms attributable to the VPBs. The first step in treatment is to correct any underlying abnormalities such as decreased serum potassium or low arterial oxygen tension. If the arrhythmia is of hemodynamic significance or if it is believed to be a harbinger of worse arrhythmias, lidocaine is the treatment of choice, with an initial bolus dose of 1.5 mg/kg. Recurrent VPBs can be treated with a lidocaine infusion at 1 to 4 mg/min; additional therapy includes esmolol, propranolol, procainamide, quinidine, disopyramide, atropine, verapamil, or overdrive pacing.

Ventricular Tachycardia

The presence of three or more sequential VPBs defines VT. Diagnostic criteria include the presence of fusion beats, capture beats, and AV dissociation. The specific morphologic appearance of the QRS complex may also be helpful in distinguishing VT from other arrhythmias. VT is classified by its duration and morphology. In duration, nonsustained VT lasts three beats and up to 30 seconds, and sustained VT lasts 30 seconds or longer. With monomorphic morphology, all complexes have the same pattern, and with polymorphic morphology, complexes constantly change patterns. Polymorphic VT with a long QTc is also called "torsades de pointes."

The characteristics of VT are as follows:

1. *Heart rate*: 100 to 200 beats/min.
2. *Rhythm*: Generally regular, but may be irregular if the VT is paroxysmal.

3. *P/QRS*: Usually there is no fixed relationship because VT is a form of AV dissociation in which the P waves can be seen marching through the QRS complex.
4. *QRS complex*: Wide, more than 0.12 second in width, with similar morphologic criteria in lead V_1 as for VPB.
5. *Significance*: Acute onset is life threatening and requires immediate treatment.
6. *Treatment*: If the patient is hemodynamically stable, amiodarone administered as one or more intravenous doses of 150 mg in 100 mL saline or D_5W over a period of 10 minutes, followed by an intravenous infusion of 1 mg/min for 6 hours and 0.5 mg/min thereafter, is the recommended current treatment (maximum intravenous dose, 2.2 g/24 hr). Although amiodarone is associated with substantially less hypotension than bretylium is, hypotension and bradycardia are its main side effects. Amiodarone's pharmacologic effects persist for more than 45 days. Lidocaine and procainamide have been used in the past with varying degrees of success to treat VT. Synchronized cardioversion is the indicated nonpharmacologic intervention in any wide-complex tachycardia, whether monomorphic VT or a wide-complex SVT. Polymorphic VT with a normal QT interval is treated with amiodarone and cardioversion. Metabolic abnormalities and drug toxicity must be considered and treated. Polymorphic VT with a prolonged QT interval is a more serious rhythm disturbance, and the recommended current treatment is an intravenous infusion of 1 g of magnesium administered over a 2- to 3-minute period. Precipitating metabolic or toxic causes should be treated. Overdrive pacing may also be helpful in this setting (Fig. 42-13).

Ventricular Fibrillation

Ventricular fibrillation is an irregular rhythm that results from a rapid discharge of impulses from one or more ventricular foci or from multiple wandering reentrant circuits in the ventricles. The ventricular contractions are erratic and are represented on the ECG by bizarre patterns of various size and configuration. P waves are not seen. Important causes of ventricular fibrillation include myocardial ischemia, hypoxia, hypothermia, electric shock, electrolyte imbalance, and drug effects (Fig. 42-14).

Its characteristics are as follows:

1. *Heart rate*: Rapid and grossly disorganized.
2. *Rhythm*: Totally irregular.
3. *P/QRS*: None seen.
4. *QRS complex*: Not present.

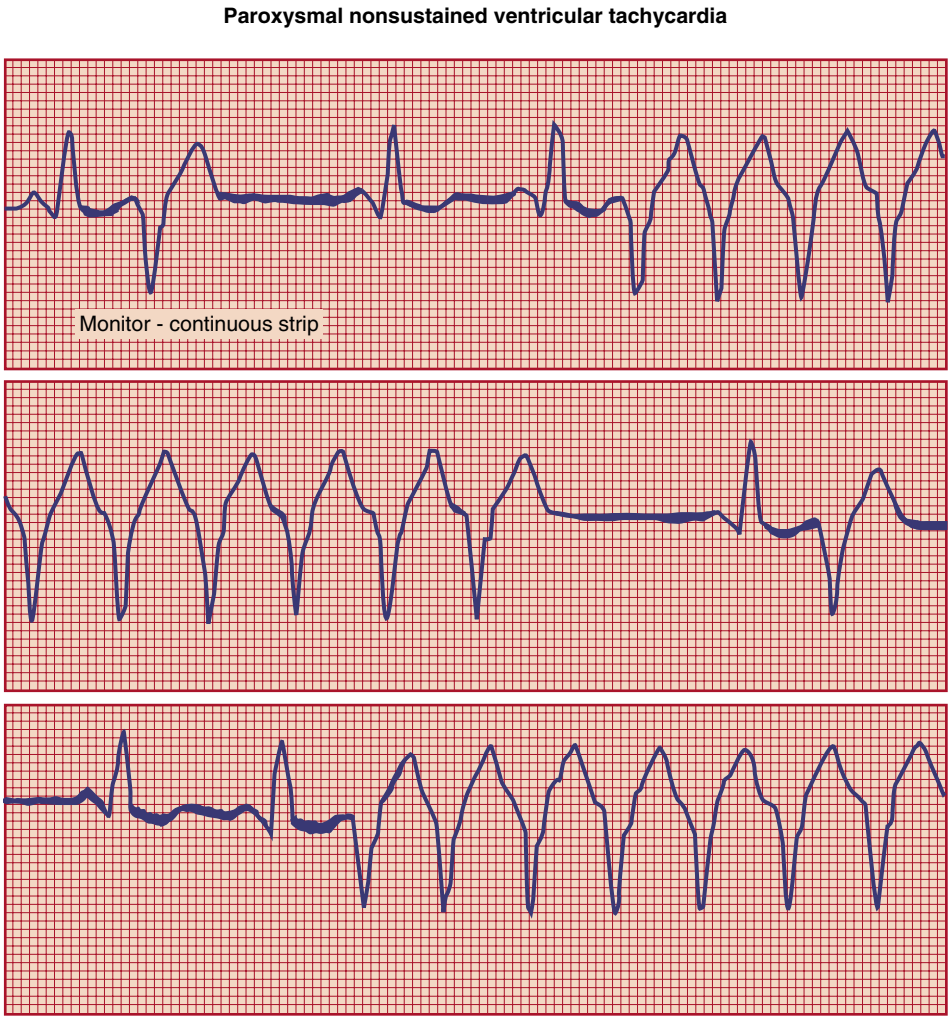

Figure 42-13 Short bursts of ventricular tachycardia. *(From Goldberger AL: Clinical Electrocardiography: A Simplified Approach, 7th ed. St Louis, CV Mosby, 2006.)*

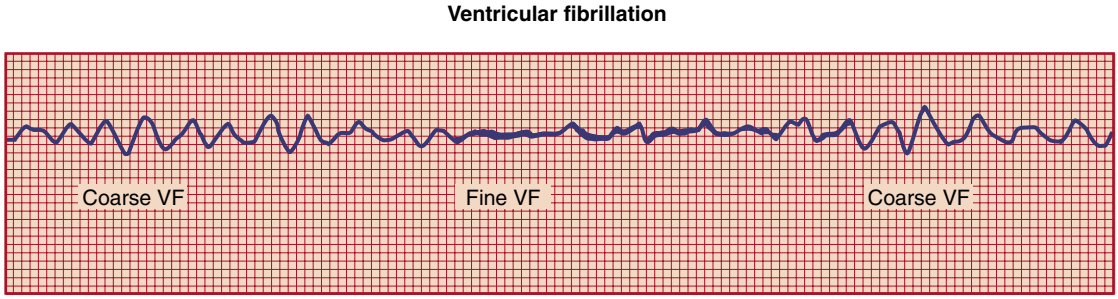

Figure 42-14 Ventricular fibrillation (VF) in the form of coarse and fine waves. *(From Goldberger AL: Clinical Electrocardiography: A Simplified Approach, 7th ed. St Louis, CV Mosby, 2006.)*

5. *Significance*: There is no effective cardiac output, and life must be sustained by artificial means, such as external cardiac massage.
6. *Treatment*:
   a. Cardiopulmonary resuscitation must be initiated immediately, and then defibrillation must be performed as rapidly as possible. Asynchronous external defibrillation should be performed with a DC defibrillator using incremental energies in the range of 200 to 360 J. The introduction of biphasic (and rectilinear) transthoracic shocks has reduced the energy levels required and increased the efficacy of ventricular defibrillation. In a prospective, randomized, multicenter trial conducted by the ZOLL investigators,[54,55] 120 J of biphasic current was superior to 200 J of monophasic current, especially in patients with increased chest wall impedance.
   b. Early administration of 1 g of magnesium sulfate may facilitate defibrillation. In some instances, epinephrine has been used for coarsening the fibrillation to facilitate defibrillation. Vasopressin has been added as a drug for the treatment of ventricular fibrillation. The vasopressin dose is a single 40-unit intravenous bolus. Subsequent administration of epinephrine should be delayed for at least 5 minutes after vasopressin. Supportive pharmacologic therapy may include lidocaine, amiodarone, bretylium, procainamide, phenytoin, or esmolol.
   c. Torsades de pointes, which may mimic ventricular fibrillation or VT, is a life-threatening arrhythmia that occurs in the presence of disturbed repolarization (hence its association with prolonged QT intervals).[56] Discontinuation of drugs that predispose to prolongation of the QT interval and correction of electrolyte abnormalities are essential in the treatment of torsades de pointes. Acute therapy may include defibrillation, 1 to 2 g of intravenous magnesium sulfate, intravenous isoproterenol, and overdrive pacing.[57]

Conduction Defects

Conduction defects are most often chronic, are present on the baseline preoperative ECG, and represent the underlying disease state of the myocardium or conduction system. However, conduction defects may be observed for the first time during surgery and anesthesia. They can occur as a result of simple manipulation, such as passage of a pulmonary artery catheter through the right ventricle, but they can also be a manifestation of myocardial ischemia. Because high-grade (second- and third-degree AV blocks) conduction defects often have deleterious effects on hemodynamic performance, intraoperative recognition is important.

Three types of conduction system blocks are possible: SA block, AV heart block, and intraventricular conduction block. The His bundle ECG used by cardiologists has greatly improved the understanding of conduction through the heart. In an SA block, the block occurs at the sinus node. Because atrial excitation is not initiated, P waves are not found on the ECG. The next beat can be a normal sinus beat, a nodal escape beat, or a ventricular escape beat.

The second type of heart block is an AV heart block, or AV block, which may be incomplete or complete. First- and second-degree AV blocks are generally considered incomplete, whereas a third-degree AV block is considered to be a complete heart block. First-degree AV block is often found in healthy hearts, but it is also associated with CAD or digitalis administration. It is characterized by a PR interval longer than 0.21 second. All atrial impulses progress through the AV node to the Purkinje system. This form of heart block ordinarily requires no treatment. Second-degree AV block is associated with the conduction of some of the atrial impulses to the AV node and into the Purkinje system. It is further subdivided into two specific types. A Mobitz type I block, or a Wenckebach block, is characterized by progressive lengthening of the PR interval until an impulse is not conducted and the beat is dropped (Fig. 42-15). This form of block is relatively benign and often reversible, and it does not require a pacemaker. It may be caused by digitalis toxicity or MI and is usually transient. A Mobitz type I block reflects disease of the AV node.

The other form of second-degree heart block is a Mobitz type II block, which may reflect disease of the bundle of His and Purkinje tissues, especially when the QRS complex is broad. In this, the less common and more serious form of second-degree heart block, dropped beats occur without any progressive lengthening of the PR interval (Fig. 42-16). This type of block has a serious prognosis because it frequently progresses to a complete heart block and may require pacemaker insertion before major surgical procedures.

Third-degree AV block, also called a complete heart block, occurs when all electrical activity from the atria fails to progress into the Purkinje system. The atrial and ventricular contractions have no relationship with each other, although each chamber

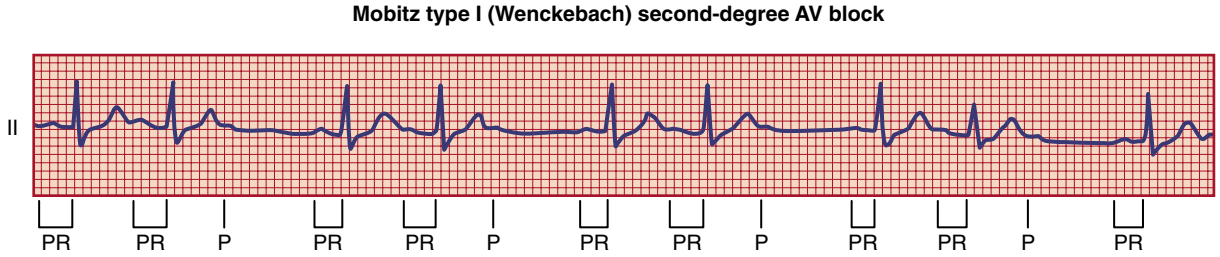

Figure 42-15 A Mobitz type I (Wenckebach) block produces a characteristically syncopated rhythm with grouping of the QRS complexes (group beating). Notice the progressive increase in PR intervals, with the third sinus P wave in each sequence not followed by a QRS complex. AV, atrioventricular. *(From Goldberger AL: Clinical Electrocardiography: A Simplified Approach, 7th ed. St Louis, CV Mosby, 2006.)*

contracts regularly. The ventricular rate is approximately 40 beats/min. The QRS complex may be normal if the pacemaker site is in the AV node, but it is usually widened to longer than 0.12 second when the pacemaker site is located in the ventricle (Fig. 42-17). The heart rate is usually too slow to maintain adequate cardiac output, and syncope or Adams-Stokes syndrome may occur, as well as heart failure. These patients generally require insertion of a transvenous endocardial or epicardial pacemaker to increase their heart rate and cardiac output.

Intraventricular blocks

Under normal conditions, activation of the left ventricle spreads simultaneously through both the left anterior and left posterior fascicles. Blockage or even a modest delay in conduction in one of these fascicles results in sequential rather than simultaneous activation of the corresponding sites and produces characteristic abnormal patterns on the ECG.

Left Anterior Fascicular Block. The left bundle branch of the bundle of His itself bifurcates distally into two fascicles, the anterior and posterior fascicles. A left anterior fascicular block (LAFB) is relatively common because of the delicate structure of the left fascicle. It causes delayed activation of the anterosuperior LV wall and is characterized by marked (−45- to −90-degree) left axis deviation. LAFB may occur in persons without overt cardiac disease but is it found mainly in patients with a wide range of diseases of the myocardial and conduction system, such as CAD or LVH. It has minimal to no independent prognostic significance.

Left Posterior Fascicular Block. A left posterior fascicular block (LPFB) is considerably less common than an anterior fascicular block because of the thicker structure of the right fascicle. It is also at a less vulnerable location near the LV inflow tract. LPFB results in delayed activation of the inferoposterior aspect of the left ventricle, and the electrocardiographic features of LPFB are marked right axis deviation (>120 degrees). LPFB can occur in patients with almost any cardiac disease but is unusual in otherwise healthy people. As in the case of LAFB, the overall QRS duration remains normal (<120 msec) (Fig. 42-18).

Left Bundle Branch Block. Caused by a serious delay or block of the main left bundle branch or both of its two fascicles, an LBBB results in a prolonged QRS duration, abnormal QRS complex, and ST-T wave abnormalities. A basic requirement is a QRS duration of 120 msec or longer. There is also a broad, sometimes notched R wave in the left-sided leads (I, aVL, V_5, V_6) with deep S waves in the right precordial leads and absent septal Q waves. The QRS axis is highly variable. It can be normal or devi-

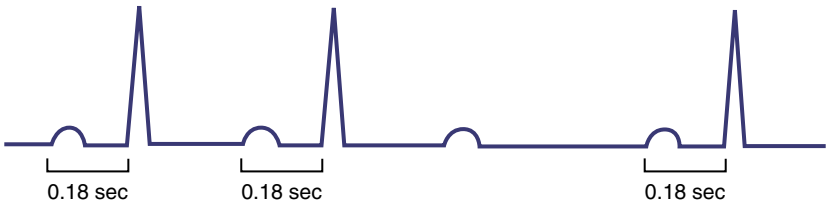

Figure 42-16 Mobitz type II atrioventricular block. Notice that the PR intervals remain constant as long as the QRS is not dropped, as in Mobitz type I. *(From Goldberger AL: Clinical Electrocardiography: A Simplified Approach, 7th ed. St Louis, CV Mosby.)*

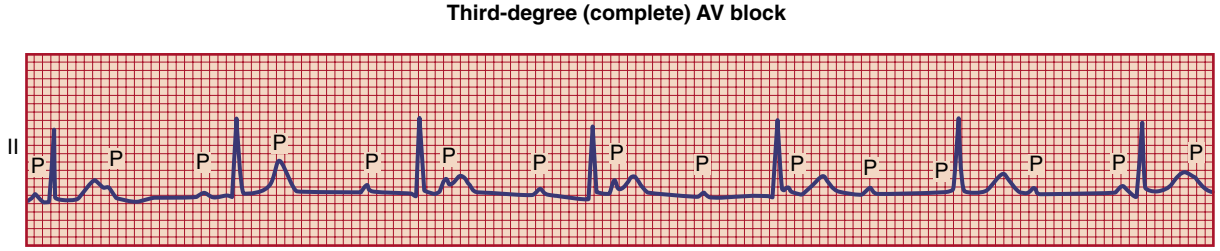

Figure 42-17 A complete heart block with underlying sinus rhythm is characterized by independent atrial (P) and ventricular (QRS complex) activity. The atrial rate is almost always faster than the ventricular rate. The PR intervals are completely variable. AV, atrioventricular. *(From Goldberger AL: Clinical Electrocardiography: A Simplified Approach, 7th ed. St Louis, CV Mosby, 2006.)*

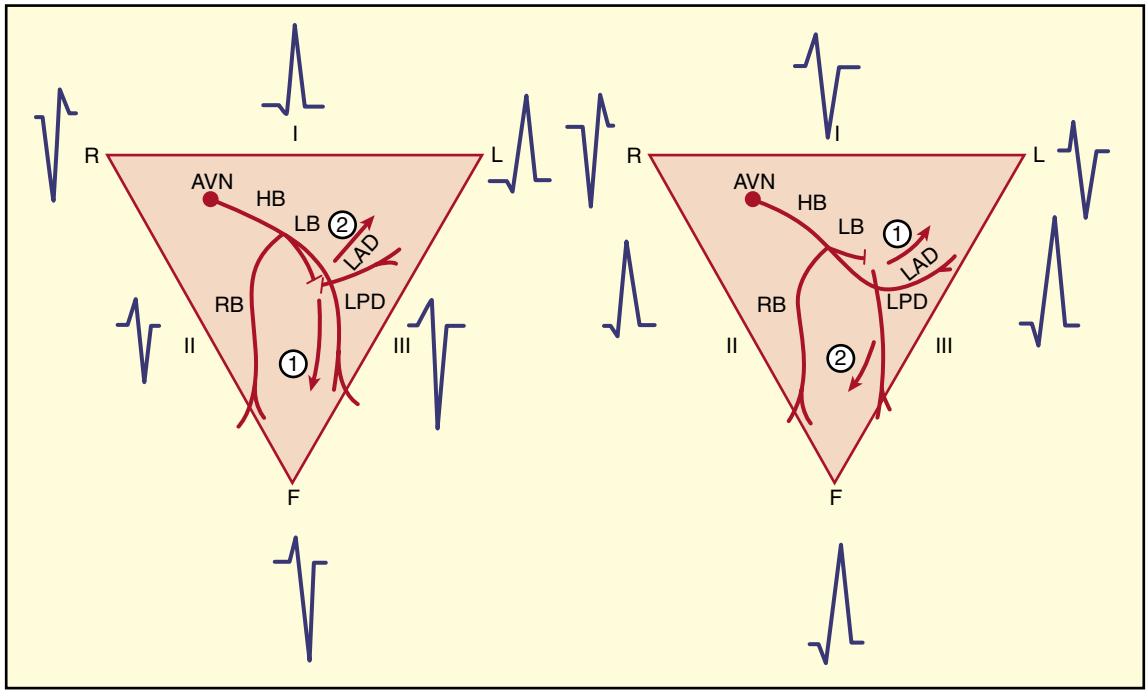

Figure 42-18 Diagrammatic representation of fascicular blocks in the left ventricle. Interruption of the left anterior fascicle (*left*) results in an initial inferior (1) followed by a dominant superior (2) direction of activation (negative in lead II and positive in leads I and aVL). Interruption of the left posterior fascicle (*right*) results in an initial superior (1) followed by a dominant inferior (2) direction of activation (negative in lead I and positive in leads II and III). AVN, atrioventricular node; HB, His bundle; LAD, left anterior descending artery; LB, left bundle; LPD, left posterior descending artery; RB, right bundle. *(Courtesy of C. Fisch, M.D.; From Zipes DP, Libby P, Bonow R, Braunwald E: Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine, 7th ed. Philadelphia, WB Saunders, 2005.)*

ated to the left or even the right. The ST-T waves are usually discordant with the direction of the QRS complex. LBBB is an ominous prognostic sign and has associated survival rates as low as 50%, probably reflecting the severity of the underlying cardiac disease. The QRS duration correlates inversely with the LV ejection fraction and is one of the criteria for current ventricular resynchronization therapy (biventricular pacing).

LBBB obscures or simulates other patterns on the ECG. In the presence of LBBB, the diagnosis of LVH, acute ischemia, or MI may be difficult or impossible (Fig. 42-19).

Right Bundle Branch Block. An RBBB is caused by a conduction delay anywhere in the right-sided intraventricular conduction system. The high prevalence of RBBB corresponds to the relative fragility of the right bundle branch, as suggested by the development of RBBB after minor trauma produced by right ventricular catheterization. The electrocardiographic manifestation of RBBB consists of prominent and notched R waves with rsr′, rsR′, or rSR′ on the right-sided leads and wide S waves on the left-sided leads, along with QRS prolongation (≥120 msec). If the QRS duration is not prolonged, it is termed an incomplete RBBB. As with LBBB, the ST-T waves are discordant with the QRS complex.

RBBB is common in the general healthy population without clinical evidence of structural heart disease and has no prognostic significance in this group. However, in patients with organic heart disease, new onset of RBBB does predict a higher rate of CAD, CHF, and mortality (Fig. 42-20).

Trifascicular blocks usually consist of one of the foregoing bilateral bundle branch blocks (i.e., RBBB plus LAFB or LPFB), in addition to a prolonged PR interval. Bundle of His ECGs are necessary to determine whether the AV conduction disturbance is localized in the AV node or whether it is distal and possibly represents an incomplete fascicular block in the last remaining fascicle.

Electrocardiographic Criteria for Acute Myocardial Ischemia

ST Depression–Type Ischemia

The criteria most accepted for detecting myocardial ischemia on continuous electrocardiographic monitoring are those established and validated during exercise stress testing.[58] During stress testing and with acute subendocardial ischemia, the electrical forces responsible for the ST segment are deviated toward the inner layer of the heart, thereby causing depression of the ST segment. With acute transmural (epicardial) ischemia, the electrical forces in the ischemic area are deviated toward the outer layer of the heart, thereby causing ST-segment elevation in the overlying leads (see Fig. 42-5). As the heart rate increases, the J point, or junctional up-sloping depression, occurs normally. In patients with myocardial ischemia, however, the ST segment typically becomes horizontal (flattens) as the severity of ischemia increases. With progressive exercise or tachycardia during ischemia, the ST-segment depression may worsen, the ST segment may become down sloping, even causing T-wave inversion in more than one lead, and angina may develop. In about 10% of patients, especially asymptomatic ones, ischemia may appear only in the recovery phase after exercise.

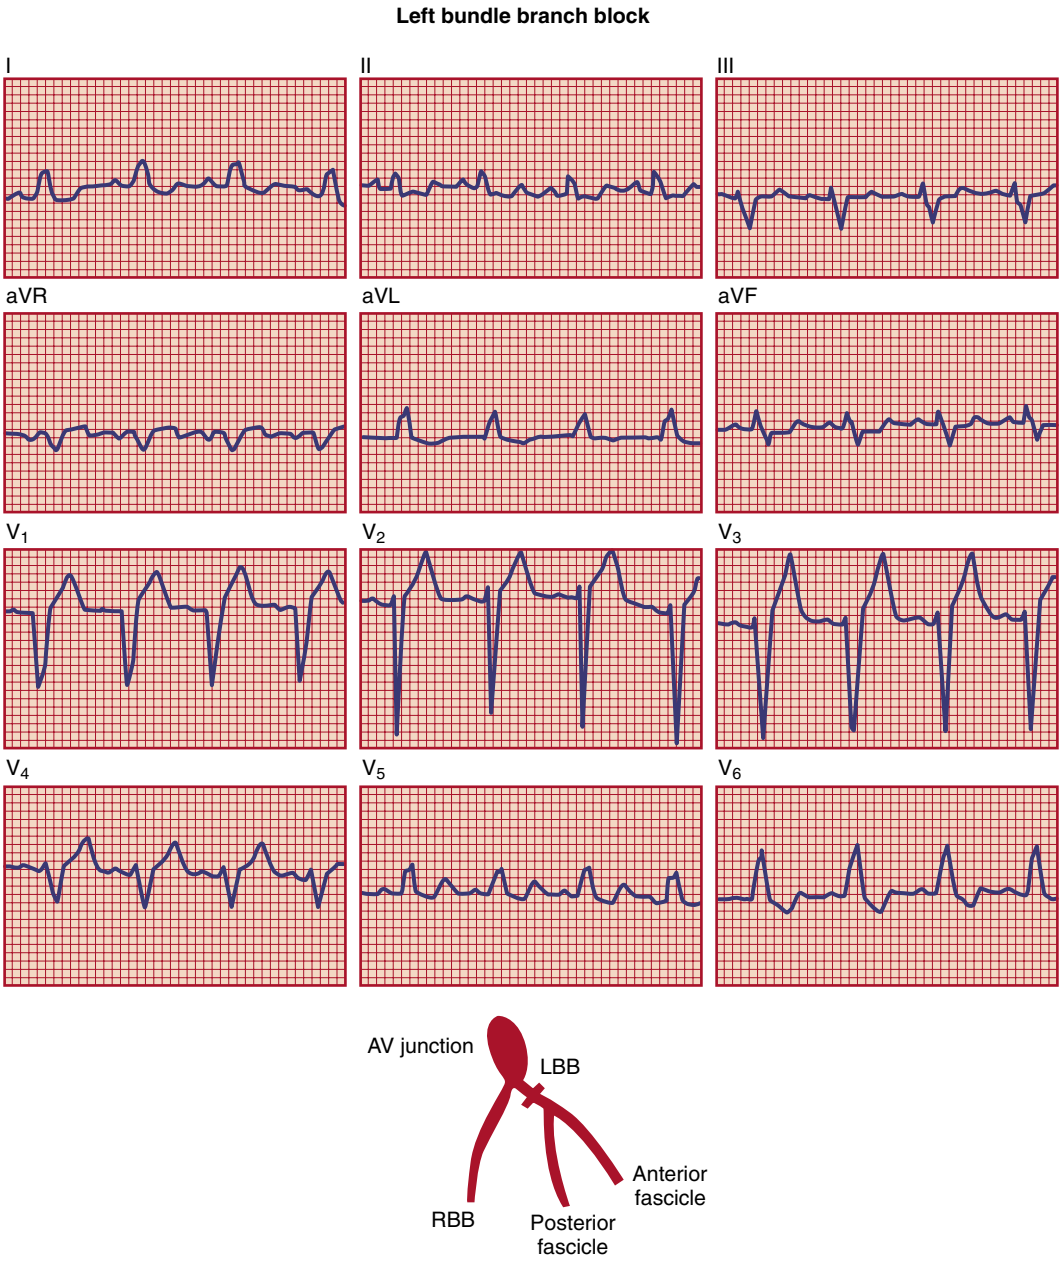

Figure 42-19 Left bundle branch (LBB) block with a characteristic wide QS complex in lead V_1 and a wide R wave in lead V_6 with slight notching at the peak. The inverted T waves in leads V_5 and V_6 (secondary T-wave inversions) are also characteristic of an LBB block. AV, atrioventricular; RBB, right bundle branch. *(From Goldberger AL: Clinical Electrocardiography: A Simplified Approach, 7th ed. St Louis, CV Mosby, 2006.)*

The criteria established for stress-induced ischemia are 1 mm (0.1 mV) or more of horizontal or down-sloping ST-segment depression measured 60 to 80 msec after the J point in at least three consecutive beats with a stable baseline. The ST depression may be accompanied by T-wave flattening or inversion. Junctional or J-point depression is normal during exercise. In addition, a *rapidly up-sloping* ST segment (>1 mV/sec) that is also *depressed less than 0.15 mV* (1.5 mm) is considered normal. In patients with *slowly up-sloping* ST-segment depression in which the ST segment is *depressed 0.15 mV (1.5 mm) or more* at J+80 msec, the slowly up-sloping ST depression may signify CAD (Figs. 42-21 and 42-22).

Some patients have preexisting ST-segment abnormalities from previous MI, bundle branch blocks, or LVH that make ST-segment interpretation more difficult. In these patients, additional horizontal or down-sloping ST-segment depression of 1 mm or greater from baseline is required to be considered myocardial ischemia. Causes of ST-segment changes other than myocardial ischemia include drugs (most notably digitalis), temperature changes, hyperventilation, and positional changes. The distribution of ST depression–type ischemia correlates poorly with the specific location of CAD.

ST Elevation–Type Ischemia

ST-segment elevation in a non–Q-wave lead is very uncommon during stress testing; it occurs in approximately 1% of patients

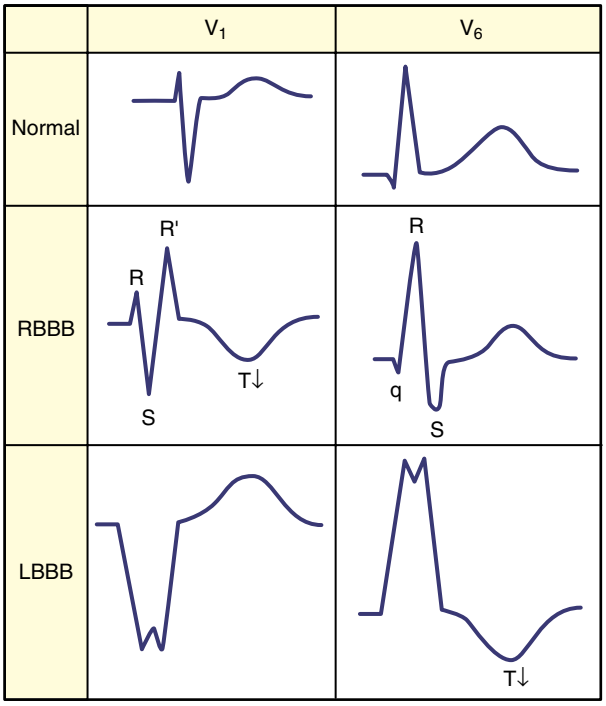

Figure 42-20 Comparison of QRST changes in left bundle branch block (LBBB) versus right bundle branch block (RBBB). *(From Zipes: Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine, 7th ed; and Goldberger AL: Clinical Electrocardiography: A Simplified Approach. 6th ed. St Louis, CV Mosby, 1999.)*

with CAD and suggests transmural myocardial ischemia caused by coronary vasospasm or high-grade coronary narrowing. The electrocardiographic site of ST-segment elevation is relatively specific for the myocardial territory involved, in contrast to ST depression–type ischemia. ST elevation occurring during exercise testing in electrocardiographic leads with pathologic Q waves does not indicate myocardial ischemia but does correlate with reduced LV function and a worse prognosis.

T-Wave Changes

T-wave morphology is largely influenced by body position, respiration, hyperventilation, and drug therapy, as well as by myocardial ischemia/necrosis. Therefore, T-wave changes not accompanied by significant ST-segment displacement rarely signify myocardial ischemia. Pseudonormalization of T waves (inverted at rest, becoming upright during exercise) may in rare instances also be a marker for myocardial ischemia. In a meta-analysis that included 147 reports of patients who underwent both angiography and exercise testing, the sensitivity and specificity of the exercise electrocardiographic stress test for detection of CAD were 68% and 77%, respectively.[59]

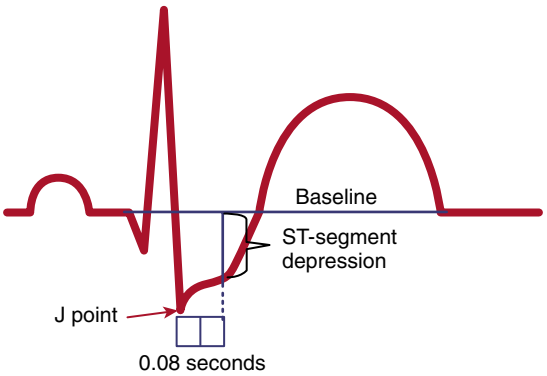

Figure 42-21 Illustration demonstrating how the ST-segment deviation is measured at 80 msec after the J point (J+80 msec).

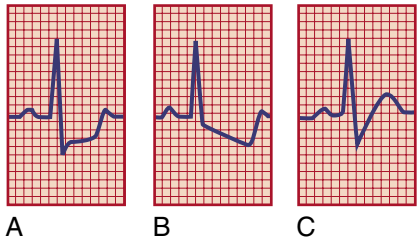

Figure 42-22 Horizontal ST depression (**A**) and down-sloping (**B**) ST depression—indicative of myocardial ischemia. Up-sloping ST depression (**C**) may be a normal finding.

Real-Time Myocardial Ischemia Monitoring

Real-time ST-segment analysis first appeared in cardiac monitoring in the mid-1980s, and currently this feature is standard in most electrocardiographic monitors. On some monitors, ST-segment analysis is automatic when a five-electrode system is used. However, the five-electrode monitoring system with automatic ST-segment analysis is primarily used by anesthesiologists in the operating room but widely underused postoperatively in the postanesthesia care unit or ICU. A recent study has shown that even among coronary care units, fewer than than 50% of clinicians routinely use ST-segment monitoring for the detection of myocardial ischemia in patients admitted with acute coronary syndromes.[60] Chief among the reasons for underuse of ST analysis are (1) a high number of false alarms, (2) lack of education on how to use the technology, and (3) what to do in response to ST alarms. In addition, there are no published randomized clinical trials to determine whether the addition of computerized ST-segment ischemia monitoring improves outcomes in patients with acute coronary syndromes or in postsurgical patients.[12]

The algorithm for ST-segment analysis is relatively simple. In each electrocardiographic lead, the computer determines the voltage of the ST segment at 60 or 80 msec after the J point (termed J+60 or J+80 msec) and compares it with the isoelectric point measured normally during the PR interval. One millimeter of ST-segment deviation is equivalent to a 100-mV difference. The changes in ST-segment level over time in each lead are displayed as ST-segment trends. To overcome problems of noise and artifacts, most monitors use filters to exclude erroneous or abnormal beats on the ECG. Averaging processes are used to calculate the mean ST-segment level over a period of 8 to 15 beats. Current monitors automatically detect the J point and calculate the J+60 msec ST-segment level. However, they also allow the operator to manually adjust the J point and the ST-segment measurement point in patients with abnormal patterns on the ECG.

One major advantage of continuous ST-segment monitoring over serial 12-lead ECGs is that the electrodes stay in place and do not vary as standard 12-lead ECGs may do between different measuring sessions. However, for improved diagnostic accuracy of ST-segment monitoring, the following points should be recognized:

1. Changes in body position may cause ST-segment changes and lead to false ST-segment deviations. However, these positional ST-segment changes are almost always accompanied by changes in QRS and therefore can easily be distinguished from true ST-segment deviations. In addition, returning the patient to the supine position may help distinguish true from positional ST-segment deviation. Changes in position of the heart in the mediastinum were also shown to affect the ST segment. Mark and coworkers[61] observed that placement of a Canadian sternal retractor during cardiac surgery was associated with a reduction in V_5 R-wave amplitude from 15 ± 1 to 10 ± 1 mm. Simultaneously, V_5 S-wave amplitude and absolute ST-segment deviation were reduced from 3.5 ± 0.4 to 1.7 ± 0.3 mm and from 0.50 ± 0.04 to 0.39 ± 0.05 mm, respectively (Table 42-2). These investigators concluded that inclusion of an R-wave gain factor may improve perioperative electrocardiographic ischemia monitoring.
2. Many patients with CAD do not have perfectly isoelectric ST segments. Early repolarization (a normal variant), intraventricular conduction delays, ventricular hypertrophy, digitalis, and nonspecific ST-T wave abnormalities may cause baseline ST-segment abnormalities. It is therefore important to tailor the ST alarm trending to the patient's baseline ST level. Many current cardiac monitors with ST-segment monitoring software allow clinicians to set alarm parameters manually. If alarm parameters are set 1 to 2 mm around the isoelectric (0 μV) line rather than at the patient's baseline ST level, frequent false alarms will occur. It is recommended that alarm parameters be set 1 mm above and below the baseline ST level in patients at high risk for ischemia. It should also be remembered that underlying electrocardiographic abnormalities may hinder ST analysis in about 10% of patients. Such abnormalities include hypokalemia, digitalis, LBBB, Wolff-Parkinson-White syndrome, LVH with strain, and acute pericarditis. In these patients, other modalities for diagnosis of myocardial ischemia should be considered, such as transesophageal echocardiography.
3. Most cardiac monitors with ST-segment monitoring software provide displays of ST-segment trends in a single lead or summated leads. Although such graphic trends are convenient for quick identification of potential ischemic events, it is of paramount importance to also print the electrocardiographic tracing in question to confirm that the ST-segment changes are the result of ischemia rather than a transient arrhythmia (e.g., an accelerated ventricular rhythm or a new bundle branch block) or other abnormality of the electrocardiographic complex, which can lead to inaccurate calculation.

Electrocardiographic Lead Sensitivity for Detecting Perioperative Myocardial Ischemia

During the perioperative period, electrocardiographic monitoring most commonly identifies stress-induced, ST-segment depression–type ischemia. Such electrocardiographic changes do not provide information about the location of the ischemic myocardial area. In contrast, ST-segment elevation indicating transmural ischemia, seen particularly during cardiac surgery, provides useful information about the myocardial segment and coronary perfusion territory responsible for the ischemic episode. Because the majority of modern patient-monitoring systems do not monitor all 12 electrocardiographic leads simultaneously, selecting which chest leads to monitor is of great importance, particularly in noncardiac surgery. During exercise stress testing, investigators have identified leads V_4 and V_5 as the most sensitive leads to detect exercise-induced ischemia (90% to 100% sensitivity).[62] London and colleagues[63] studied high-risk patients undergoing noncardiac surgery and showed that the greatest sensitivity for ischemia was obtained with lead V_5 (75%), followed by lead V_4 (61%). Combining leads V_4 and V_5 increased the sensitivity to 90%, whereas with the standard lead II and V_5 combination, the sensitivity was only 80%. They also suggested that if three leads (II, V_4, and V_5) could be examined simultaneously, the sensitivity would rise to 98%. More recently, Landesberg and associates[64] monitored continuous 12-lead ST-segment changes greater than 0.2 mV from baseline in a single lead, or greater than 0.1 mV in two contiguous leads at J+60 msec, lasting longer than 10 minutes in patients undergoing major vascular surgery. Troponins were used as markers for MI. They showed that in fact leads V_3 and V_4 were more sensitive than V_5 in detecting perioperative ischemia

Table 42-2 Electrocardiographic Changes during Sternal Retractor Placement in 83 Patients

Variable	Period	Mean ± SEM	*n* Increase	*n* Decrease	χ^2	*P*
V_5 RWA	Baseline	15.1 ± 0.8	—	—	—	—
	Retractor	9.9 ± 0.7	9	69	44.6	.001
V_5 SWA	Baseline	3.5 ± 0.4	—	—	—	—
	Retractor	1.7 ± 0.3	3	59	48.8	.001
V_5 ST-ABS	Baseline	0.05 ± 0.04	—	—	—	—
	Retractor	0.40 ± 0.05	20	51	12.68	.001

n, number of patients showing the indicated change; RWA, R-wave amplitude; ST-ABS, absolute value of ST displacement; SWA, S-wave amplitude; χ^2, comparison between *n* increase and *n* decrease.
Adapted from Mark JB, Chein GL, Steinbrook RA, et al: Electrocardiographic R-wave changes during cardiac surgery. Anesth Analg 74:26, 1992.

(87%, 79%, and 66%, respectively). Among the patients who experienced MI, V_4 was the most sensitive for ischemia (83.3%), followed by V_3 and V_5 (75% each). Combined monitoring of two of these leads (e.g., V_3 and V_5) increased the sensitivity to about 97%.[62] It was also demonstrated that on average, the baseline, preanesthesia ST segment was above the isoelectric point in V_1 through V_3 and below isoelectric in V_5 through V_6. Lead V_4 was closest to the isoelectric level on the baseline ECG, thus rendering it most suitable for detection of ischemia. Lead V_4 also detects ischemia earlier and shows a greater ST-segment deviation. These main findings were corroborated by Martinez and colleagues,[65] who also used the same method to monitor postoperative ischemia in ICU patients after major vascular surgery.

For patients with acute coronary syndromes (e.g., those with atherosclerotic plaque disruption), the recommendation is to monitor limb lead III and leads V_3 and V_5 as the most sensitive combination for detection of ischemia.[66] Monitoring of a right-sided precordial lead (V_4R) may be of benefit in patients with occlusive disease of the right coronary artery,[67] as might inspection of posterior leads (V_7 to V_9) in patients with suspected posterior ischemia.

It is commonly believed that monitoring for intraoperative myocardial ischemia is unnecessary in neonates. Whereas electrocardiographic lead systems for adults are concerned with detection of ischemia and arrhythmias, neonatal electrocardiographic monitoring has focused on recognition of arrhythmias alone. The results of some studies, however, suggest that the neonatal heart is more susceptible to ischemia than the adult heart is.[68] These studies have demonstrated the importance of calibrated electrocardiographic monitoring in neonates with congenital heart disease (see Chapter 83).

Perioperative Myocardial Ischemia and Infarction

Perioperative monitoring for myocardial ischemia in patients undergoing cardiac or noncardiac surgery started about 30 years ago. In 1980, Tinker[69] noted the importance of intraoperative ST-segment monitoring via lead V_5 and that large fluctuations in systolic blood pressure, heart rate, or hypothermia with postoperative shivering are associated with ischemia. Coriat and colleagues,[70] pioneers in using Holter monitoring in patients undergoing major vascular surgery, showed that the presence of intraoperative ischemia on Holter monitoring was strongly associated with the severity of preoperative angina pectoris. Slogoff and Keats[71] first demonstrated in 1985 an association between intraoperative ischemia and postoperative MI. They demonstrated that MI detected before induction of anesthesia or before the onset of cardiopulmonary bypass during coronary artery bypass graft surgery is strongly associated with ischemia on Holter monitoring. Several studies using perioperative (preoperative, intraoperative, and postoperative) Holter monitoring in patients undergoing major vascular surgery showed that early postoperative tachycardia-induced silent myocardial ischemia was frequent after vascular surgery and significantly associated with postoperative clinical ischemic events.[72-74] Mangano and coworkers[75] (1990) demonstrated that postoperative Holter-detected ischemia was common (41%) and predictive of adverse postoperative cardiac events, with a ninefold increase in the odds of postoperative cardiac morbidity and mortality when compared with intraoperative or preoperative ischemia.

Table 42-3 summarizes all the studies that were published in the English literature on perioperative ischemia and postoperative cardiac morbidity after major noncardiac surgery.[76-90] Altogether, these studies included more than 2400 patients. The majority of the studies involved major vascular surgery and Holter monitoring for detection of perioperative ischemia (except for the studies by Landesberg and colleagues, which used continuous on-line 12-lead electrocardiographic monitoring). The data revealed that perioperative ischemia was common in high-risk patients, with an incidence between 24% and 63%, and was almost exclusively ST depression consistent with ischemia (97% to 100%). The average postoperative MI rate in these studies was 3.9% (range, 0.6% to 15%), the majority of which were non–Q-wave infarctions (66% to 100%). The incidence of all ischemic postoperative cardiac events was 7.3% (range, 3% to 37%), and the average mortality was 1.04% (range, 0% to 2.8%). Another important observation was that the duration of postoperative ischemia was strongly associated with postoperative ischemic cardiac events. Patients with prolonged, often long hours of postoperative ST depression–type ischemia were likely to experience postoperative MI and elevated serum troponin levels, whereas short episodes of ischemia (<30 minutes) were unlikely to culminate in MI.[87] Additional studies have shown that perioperative ischemia is associated not only with early but also with long-term (5 years) postoperative morbidity and mortality.[88,91]

Examples of Perioperative Ischemia and Infarction

Example 1. Frank and coauthors[76] published one of the first and most detailed cases of postoperative cardiac mortality related to heart rate–induced prolonged postoperative ST depression–type ischemia detected on Holter monitoring. A patient who underwent lower extremity arterial bypass surgery was monitored with a Holter monitor before, during, and after the operation. His records show that he had heart rate–related silent myocardial ischemia preoperatively that subsided intraoperatively, immediately after anesthesia was instituted, only to recur as soon as the patient woke up from surgery. Figure 42-23 shows the ischemia worsening progressively after surgery until the patient died suddenly 10 hours after the operation. The ST depression–type ischemia of this patient occurred at a relatively low heart rate of 80 to 85 beats/min and in the absence of significant alterations in blood pressure. Two snapshots of electrocardiographic disclosure are presented at around 12 midnight: one at a heart rate of approximately 90 beats/min, which showed deep ST-segment depression, and the other a short while later with temporary slowing of the heart rate to around 60 beats/min, which showed almost complete but transient resolution of the ST depression. Although cardiac markers were not measured and no data were provided on myocardial function by echocardiography, it is very suggestive that the patient died as a result of prolonged, silent, heart rate–related ST depression–ischemia, which was at least temporarily reversible by slowing his heart rate (Fig. 42-23).

Example 2. A 70-year-old patient with a history of CAD (treated by coronary artery bypass grafting 7 years earlier), reduced LV function, insulin-dependent diabetes mellitus, and

cTn, cardiac troponin; ECG, electrocardiogram; MI, myocardial ischemia.

peripheral vascular disease exhibited prolonged myocardial ischemia and infarction immediately after carotid endarterectomy. On arrival at the operating room the patient was connected to a continuous, 12-lead electrocardiographic monitor with online ST-segment analysis. During surgery no ischemia was observed (Fig. 42-24). Immediately after surgery and on emergence from anesthesia, significant ST depression occurred in association with a moderate increase in heart rate to a maximum of 102 beats/min, in accordance with vague pain in his jaw. The ischemic ST-segment changes lasted 193 minutes, after which the ECG reverted completely to its baseline. Nevertheless, an increase in troponin I to 10.2 ng/mL was measured 6 hours after surgery and up to 32.1 ng/mL on the morning after surgery (see Fig. 42-24).[90] The figure insert depicts all 12-lead electrocardiographic complexes during peak ischemia superimposed on their baseline, preoperative pattern. Significant ST depression occurred in all the

chest leads and was deepest in lead V_4 (−3.7 mm at peak ischemia). It is interesting to notice the marked abnormality of this patient's baseline ECG (LVH, RBBB, left anterior hemiblock, and baseline ST-T changes). Despite these baseline abnormalities on the ECG, the continuous ST trend monitoring in 12 leads combined with the marked troponin I elevation strongly suggests that the patient had prolonged (>3 hours) ischemia that culminated in elevation of troponin and MI.

EXAMPLE 3. A 65-year-old patient was admitted for surgery because of an asymptomatic abdominal aortic aneurysm (7 cm) and exhibited prolonged postoperative ischemia and infarction with chronic total occlusion of a coronary artery. His past medical history was significant for hypertension, mild obesity (85 kg), and smoking until 12 years before admission. He had no clinical history of ischemic heart disease, but because of shortness of breath on climbing stairs, a preoperative thallium scan was performed (Fig. 42-25) and demonstrated a moderate to severe, large reversible defect in the entire LV anterior wall.

On echocardiography, the size and function of both ventricles were normal with moderate mitral regurgitation. In light of the thallium scan findings, the patient underwent preoperative coronary angiography (Fig. 42-26), which showed total ostial occlusion of the left anterior descending artery with retrograde filling through a large collateral from the right coronary artery.

Based on these findings, a decision was made to proceed to surgery without coronary revascularization. The patient was given bisoprolol (β_1-selective blocker), 50 mg daily for a month, before he returned for surgery (aortobifemoral bypass).

As in the previous example, this patient was monitored during and after surgery by continuous 12-lead electrocardiography with on-line ST-segment monitoring. Intraoperatively, the heart rate was 50 to 70 beats/min, and no significant ST-segment changes were observed. However, immediately at the end of surgery and extubation, significant ST-depression consistent with ischemia developed in association with an increase in heart rate to a maximum of 98 beats/min (Fig. 42-27) and blood pressure of 155/86. Intravenous esmolol and labetalol were administered immediately, and the ischemia subsided within 15 minutes. The patient was transferred extubated and comfortable to the ICU under continuous infusion of esmolol. In the ICU, the doses of esmolol had to be escalated gradually because of a persistent increase in heart rate. Postoperative pain was managed with the epidural catheter. Nevertheless, 5 hours after the end of surgery, severe ST depression recurred in the entire anterior wall. The ischemia lasted longer than 5 hours and responded poorly to β-adrenergic blocking agents (see Fig. 42-27). The patient became delirious and shortness of breath developed. Treatment included intravenous diuretics and a slow

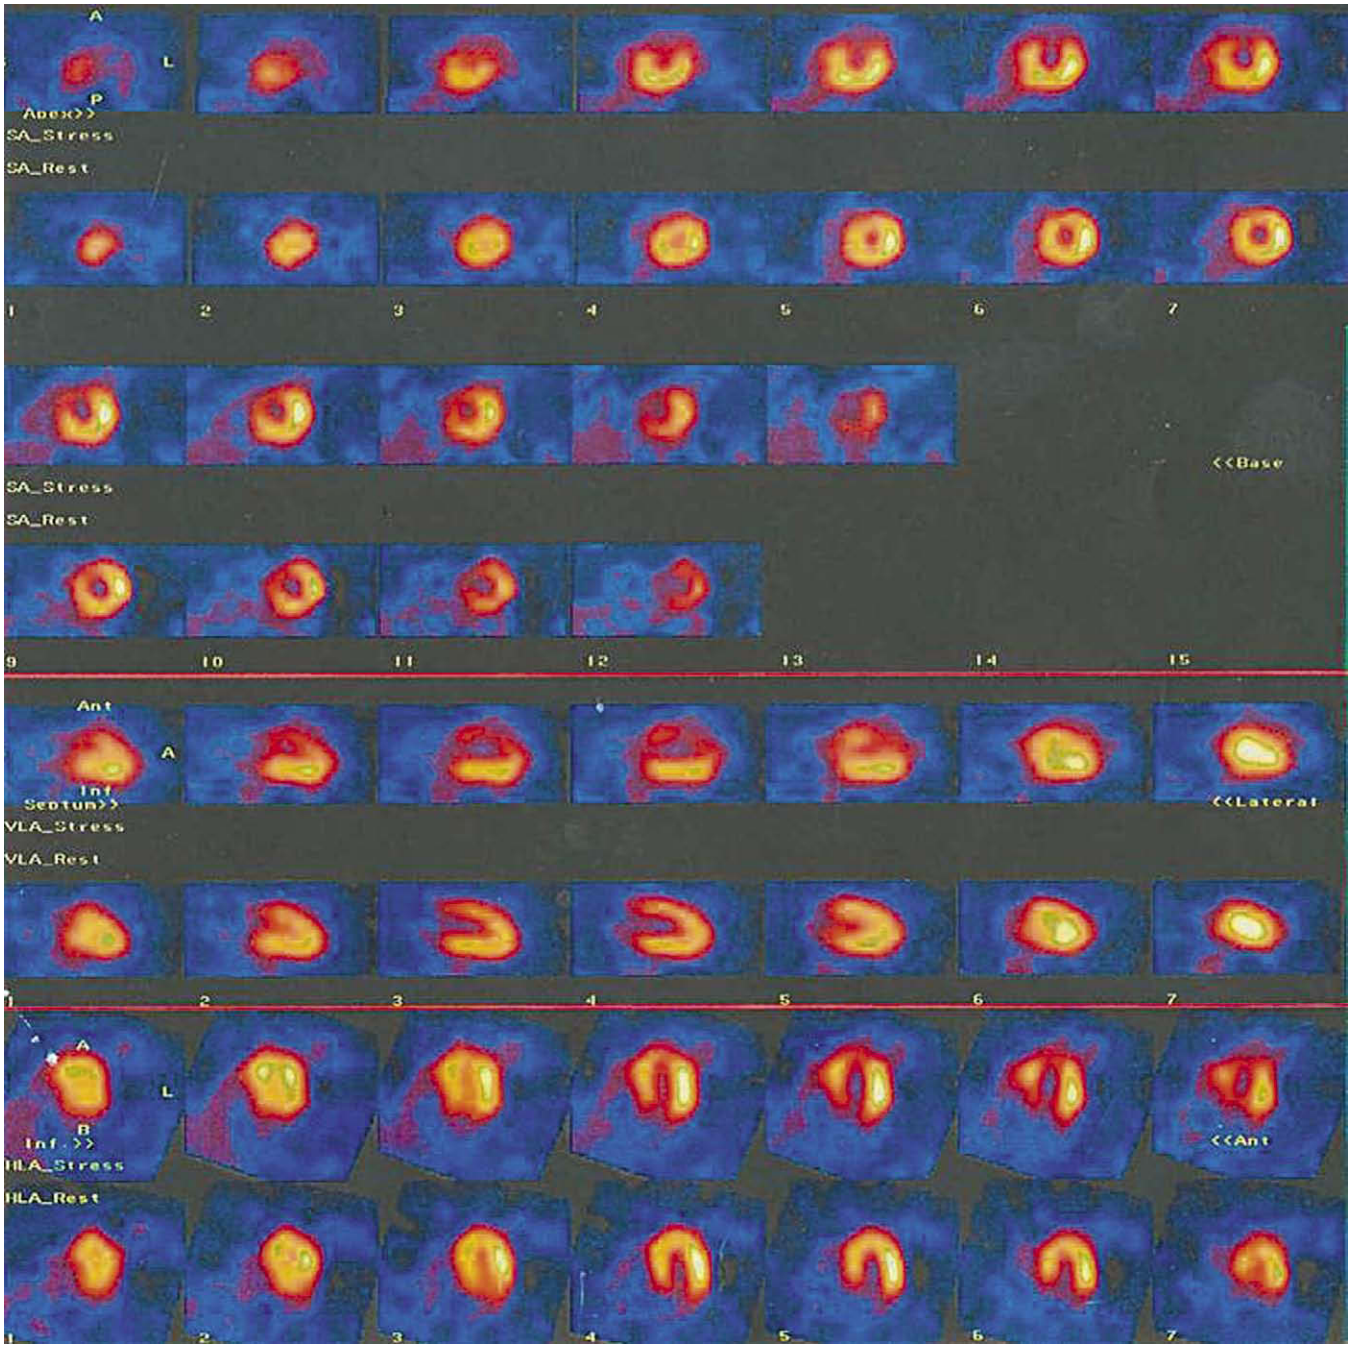

Figure 42-25 Preoperative dipyridamole-thallium single photon emission computed tomography scan of a patient scheduled for abdominal aortic surgery. A moderate to severe reversible defect is present in the entire anterior wall.

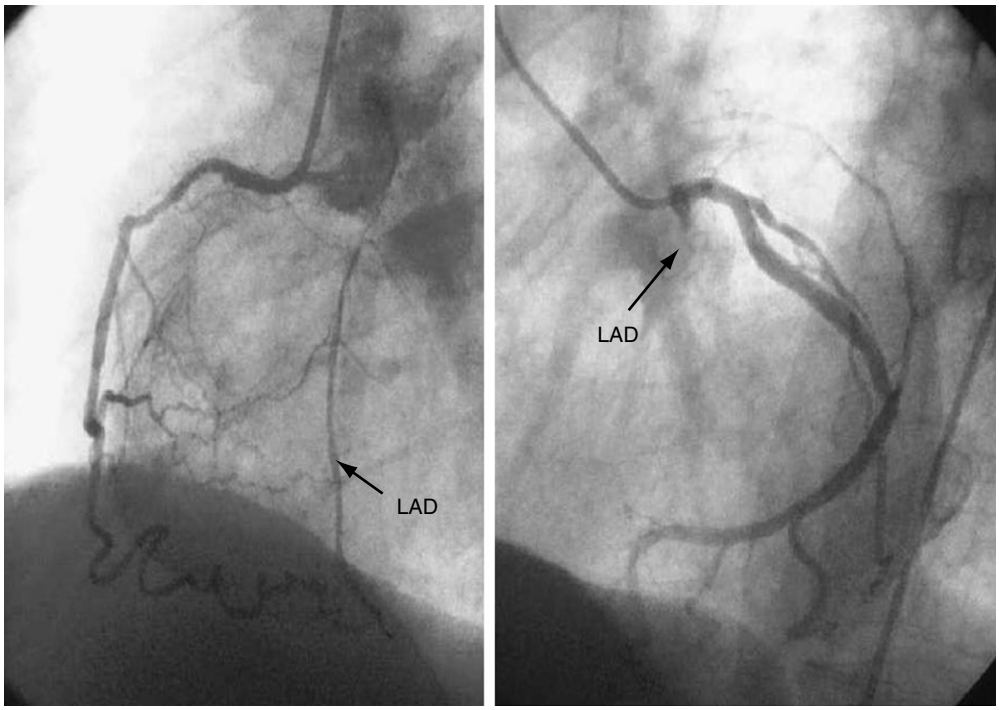

Figure 42-26 Coronary angiogram of the patient in Figure 42-25 showing chronic total ostial occlusion of the left anterior descending (LAD) artery with excellent filling of the distal LAD artery by a collateral from the right coronary artery. A possible mild stenosis is also noted in the first marginal coronary artery.
