Scleredema is a connective tissue disease that was recognized as a distinct entity by Buschke in 1902. The disease affects all races and appears to be more prevalent among females. In a review of 209 cases by Greenberg et al., [1] 29 percent were children younger than 10 years of age, 22 percent were between 10 and 20 years old, and 49 percent were adults.

PATHOGENESIS

The cause of scleredema is unknown. Streptococcal hypersensitivity, injury of lymph channels, alterations of pituitary function, and peripheral nerve abnormalities have been proposed as causes, but none has been substantiated. The dermis is markedly increased in thickness, although it appears that this finding is due in part to the replacement of subcutaneous tissue by connective tissue (Fig. 186-1). Chemical analysis of the dermis reveals an increase in hydroxyproline and hexosamines proportional to the increase in skin thickness. [2]

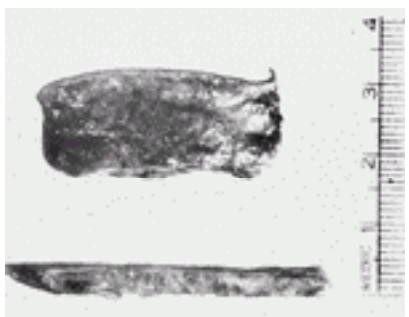

FIGURE 186-1 Scleredema skin from the back (*top*) and normal control. Note marked increase in thickness. (*From Fleischmajer et al.,* [2] *with permission.*)

Cultured fibroblasts reveal increased synthesis of total proteins and collagen and the elevation of procollagen I and III mRNA levels. [3] Fractionation of acid mucopolysaccharides shows a normal distribution of hyaluronic acid and dermatan sulfate. The water content of the skin is normal. [2] Electron microscopy reveals clumping of collagen fibrils, increase in ground substance, and collagen fibrils with reduced diameter. The urinary excretion of hydroxyproline and hydroxylysine appears normal. Scleredema has been found in association with a monoclonal gammopathy. Serum immunoglobulins are usually of the IgG type, although IgA and IgM have also been reported. The chains are either of the kappa or lambda type. [4] The association of multiple myeloma and scleredema has been documented. [5] There is some evidence that the serum of patients with scleredema may contain a factor that stimulates collagen synthesis.

CLINICAL MANIFESTATIONS

Skin involvement may be preceded by a prodrome of low-grade fever, malaise, myalgia, and arthralgia. A few days to 6 weeks before the onset, 65 percent of patients develop an infection, usually of streptococcal origin. [1] Influenza, scarlet fever, measles, mumps, tonsillitis, pharyngitis, otitis, furuncles, erysipelas, and impetigo have been observed.

The onset is frequently sudden and consists of marked, nonpitting, symmetric induration of the skin, usually affecting the posterior and lateral aspects of the neck and spreading to the face, shoulders, back, arms, and thorax (Fig. 186-2). The buttocks, legs, and abdomen are less frequently involved, and the hands and feet are affected in approximately 10 percent of the patients. The disease usually reaches maximal involvement in 1 to 2 weeks, although it may continue to spread for an additional 2 to 3 months.

FIGURE 186-2 Scleredema of 41-year duration affecting the neck and back.

The induration is of wooden-like consistency, waxy white or shiny in appearance, and rather diffuse, so that there is no sharp line of demarcation between involved and noninvolved areas. Folding of the skin is almost impossible, and the normal markings are lost. When the face is involved, there is lack of expression and, often, difficulty in opening the mouth. There is a transient, erythematous, macular or papular eruption during the early stage of the disease. Pain is absent, although paresthesia may occur. Heart abnormalities occur; in children, the most common are diastolic gallop without evidence of cardiac failure, a nonspecific S-T depression, and T-wave inversion, usually reverting to normal in 3 to 9 months. Carditis secondary to rheumatic fever has been noted. The disease may also affect the parotid gland, tongue, palate, pharynx, and upper esophagus (dysphagia). Ocular involvement may result in induration of the eyelids and conjunctiva, exophthalmos, and ophthalmoplegia. [6]

In 1970, a syndrome was recognized that consists of scleredema of long duration, obesity, maturity onset, latent or overt diabetes, and a high incidence of cardiovascular disease. [2] Diabetic retinopathy is common. [2] Most patients are quite resistant to antidiabetic therapy, including insulin and oral hypoglycemics. Antidiabetic therapy has no effect on the evolution of the scleredema.

LABORATORY FINDINGS

Most laboratory tests are usually normal except for an increase in antistreptolysin O titer in some patients. A glucose tolerance test should be performed to rule out diabetes mellitus. Hyperinsulinism may be present. [2]

PATHOLOGY

The epidermis and its appendages are normal. The dermis reveals collagen bundles separated by large interfascicular spaces (Fig. 186-3). The papillary layer is prominent and slightly edematous. In the upper dermis, there may be mild perivascular or scattered infiltrates consisting mostly of lymphocytes and histiocytic type cells. An increase in the numbers of mast cells has also been noted. The secretory coils of the eccrine sweat glands are found in the upper third or mid-dermis. The subcutaneous tissue is reduced, probably because of its replacement by connective tissue. [2] The ground substance reveals an increase in metachromatic material when stained with toluidine blue. This material also stains positive with Alcian blue at pH 2.5, but not with Alcian blue at pH 0.5, which stains sulfated acid mucopolysaccharides. Hyaluronidase digestion completely removes the Alcian blue–positive material, suggesting an increase in hyaluronic acid. However, this increase is only temporary and does not appear in all patients. Mucin deposition was also detected in extracutaneous sites including the bone marrow, nerves, liver, and salivary glands. [6]

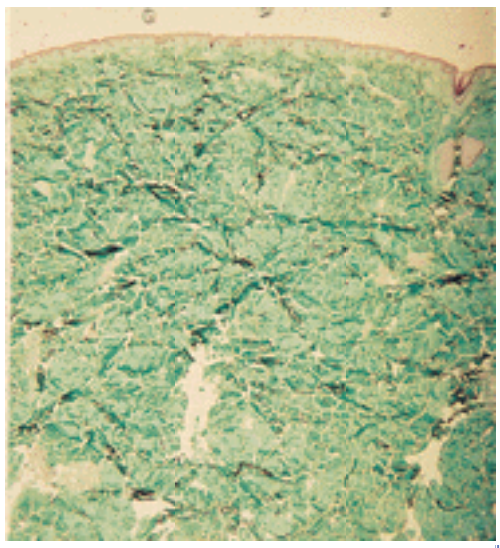

FIGURE 186-3 Scleredema. Edematous papillary layer, thick dermis, and large collagen bundles separated by interfascicular spaces.

DIFFERENTIAL DIAGNOSIS

Scleredema has to be differentiated from the early edematous stage of systemic scleroderma. In systemic scleroderma, Raynaud's phenomenon, a predilection for hands, abnormal pigmentation, telangiectasia, ischemia, and atrophic skin changes are usually present (Chap. 173); these findings are not present in scleredema. Scleredema should also be differentiated from trichinosis, dermatomyositis, scleromyxedema, myxedema, progeria, sclerema neonatorum, edema neonatorum, primary systemic amyloidosis, and edema from cardiac or renal origin.

TREATMENT

The treatment of scleredema remains difficult, although significant improvement has been reported with the use of electron-beam therapy, [7], [8] bath-PUVA, [9] and extracorporeal photopheresis. [10] Isolated reports claim some success with high-dose glucocorticoids, cyclosporine, and prostaglandin E_1.

Prognosis is usually good, and the disease undergoes spontaneous resolution in 6 months to 2 years. The disease persists indefinitely (from 2 to 41 years) [2] in those patients with associated diabetes mellitus.

Papular Mucinosis

PATHOGENESIS
CLINICAL MANIFESTATIONS
LABORATORY FINDINGS
PATHOLOGY
DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS
TREATMENT
COURSE AND PROGNOSIS

REFERENCES

Papular mucinosis, or lichen myxedematosus, is a rare disease characterized by a papular-lichenoid eruption, mucin deposition, and paraproteinemia. A clinical variant of papular mucinosis is scleromyxedema, in which the disease is more generalized and is accompanied by erythema and sclerosis. [1]

PATHOGENESIS

The pathogenesis of papular mucinosis remains unknown. This disease is frequently associated with paraproteinemia that consists of a myeloma-like, homogeneous serum globulin of the IgG type with predominantly lambda light chains, although kappa light chains have also been noted. [2], [3] Less commonly, paraproteins of the IgM and IgA types have been identified. The paraprotein in papular mucinosis is a 7S, papain-sensitive globulin, which is strongly basic because of its high content of lysine. [3] Its molecular mass of approximately 100 kDa (normal IgG has a molecular mass of 160 kDa) suggests that this IgG globulin is incomplete, missing a significant antigenic portion of the Fc fragment. [4] The initial suggestion that papular mucinosis represents a plasma cell dyscrasia has never been substantiated. However, the presence of a paraproteinemia, occasional plasma cell dyscrasia in the bone marrow, and the demonstration of skin plasma cells monotypic for lambda light chains is suggestive of a plasma cell neoplasm. [5] The association of papular mucinosis with multiple myeloma is rare, if it occurs at all. Furthermore, the paraprotein in multiple myeloma is usually a monoclonal IgG with kappa light chains. Serum from patients with papular mucinosis can stimulate DNA synthesis and the proliferation of normal human fibroblasts in vitro. [6] The removal of the paraprotein from the culture medium does not decrease fibroblast mitosis, suggesting that another serum factor may be responsible for the proliferative effect.

CLINICAL MANIFESTATIONS

The disease affects adults from 30 to 70 years of age, has no sex predilection, and usually runs a chronic course. The primary lesion is a dome-shaped papule, skin color or erythematous, 2 to 4 mm in diameter; the lesions may be densely grouped in a lichenoid fashion or may show a linear arrangement. The areas most frequently affected are the dorsa of the hands and fingers, the axillary folds, and the external surfaces of the arms and legs. The coalescence of papules on the face, particularly in the glabella area, results in longitudinal folding, giving the appearance of leonine facies (Fig. 187-1). The lesions are usually asymptomatic, although mild pruritus may be present. In scleromyxedema, large parts of the body may be involved; the skin shows erythematous, scleroderma-like induration accompanied by reduced mobility of the lips, hands, arms, and legs (Fig. 187-2). Other skin lesions include urticaria, nodules, and cysts. Although the disease primarily affects the skin, systemic manifestations such as severe proximal myopathy, inflammatory polyarthritis, central nervous system symptoms resembling acute organic brain syndrome, esophageal aperistalsis, and hoarseness have been described. [7], [8] Ophthalmic findings consist of corneal opacities, lagophthalmos, ectropion, choroidal folds, and papilledema. [9] Recently, papular mucinosis was found in association with AIDS, but without a monoclonal gammopathy. [10]

FIGURE 187-1 Papular mucinosis. Note discrete papules on the forehead and longitudinal folding of the glabella. (*Courtesy of L. Shapiro, MD.*)

FIGURE 187-2 Scleromyxedema. Diffuse skin induration and erythema involving the chest, arms, and dorsum of hands.

LABORATORY FINDINGS

Paraproteinemia, usually an IgG with lambda light chains, is present in most patients, particularly in those with the clinical form of scleromyxedema. Immunofluorescence microscopy of the skin lesions occasionally shows deposits of IgG with or without IgM in the papillary and upper reticular dermis. Other inconsistent findings include an elevated sedimentation rate, leukocytosis with eosinophilia, albuminuria, and plasma cell aggregates in the bone marrow.

PATHOLOGY

The most striking changes are in the upper dermis, which shows a horizontal band of mucinous material between collagen bundles. This material is a glycosaminoglycan that stains with Alcian blue at pH 2.5 and is susceptible to hyaluronidase digestion (Fig. 187-3). The epidermis may appear thinner due to pressure from the mucinosis deposits. There is an increase in the number of fibroblasts, which appear plump and stellate, and dermal fibrosis. Cellular infiltrates may be present around the small blood vessels and appendages and consist mostly of lymphocytes with some histiocytic types and polymorphonuclear cells. An increase in the number of plasma cells has also been noted. Electron microscopy reveals fibroblasts with long cytoplasmic processes and dilated rough endoplasmic reticulum. In addition, there are numerous thin collagen fibrils, suggestive of young collagen. Muscle biopsies reveal an atypical necrotizing myopathy with fiber necrosis, severe type II fiber atrophy, and vacuolization. Mucin deposits have also been reported in the adventitia of blood vessels in kidney, heart, adrenal glands, pancreas, and kidney papillae. Papular mucinosis has to be differentiated histologically from follicular mucinosis, amyloidosis, hyalinosis cutis et mucosae, scleredema, scleroderma, cutaneous focal mucinosis, pretibial myxedema, and colloid degeneration.

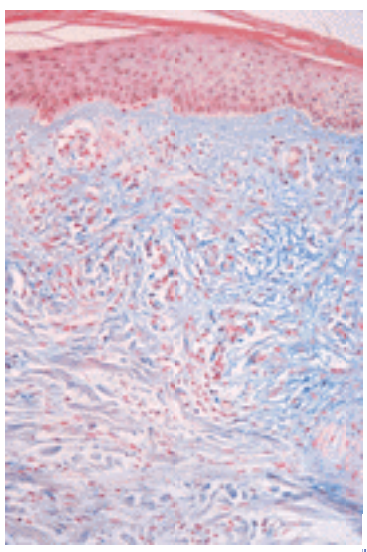

FIGURE 187-3 Scleromyxedema. Mucin and numerous plump fibroblasts in the upper dermis. Alcian blue, pH 2.5. (*Courtesy of L. Shapiro, MD.*)

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Diagnosis is based on the presence of papular lesions, the demonstration of mucin in the dermis, and the presence of paraproteinemia. Clinically, papular mucinosis should be differentiated from scleredema, scleroderma, amyloidosis, disseminated granuloma annulare, malignant lymphomas, and dermatomyositis. The more localized forms should be differentiated from colloid degeneration, lichen planus, and epithelioma adenoides cysticum.

TREATMENT

The treatment of papular mucinosis remains unsatisfactory. Topical therapy is of no help. Because the disease is rare, controlled therapeutic trials are not available. Complete clearance of lesions was reported with melphalan (1 to 10 mg/day). However, the long-term use of melphalan was associated with death from hematologic malignancy and sepsis. [11] Improvement was also noted with cyclophosphamide (200 mg/day) alone or in combination with prednisone. Glucocorticoids are particularly effective for the treatment of myopathy. Electron-beam therapy may improve skin involvement in scleromyxedema. [12] Beneficial effects were also noted with high-dose intravenous immunoglobulin (2g/kg per month). [13] More recently, cyclosporine (4 mg/kg per day) [14] and extracorporeal photopheresis [15] were found effective in scleromyxedema. Isolated reports claimed benefits from isotretinoin, plasmapheresis, chlorambucil, PUVA, interferon-a, and 2-chlorodeoxyadenosine.

COURSE AND PROGNOSIS

The disease runs a chronic course and usually has no tendency toward spontaneous resolution. The prognosis is poor, particularly in patients with diffuse disease with internal involvement. Reported causes of death appear to be unrelated to the disease and include tuberculosis, pneumonia, and vascular thrombosis.

GENERAL CONSIDERATIONS

Neurocutaneous disease can be defined in various ways. A rather broad definition would include all diseases that may show both cutaneous and neurologic lesions. For the purpose of this chapter, however, a more strict definition will be applied. Neurocutaneous diseases in this context are genetically determined disorders showing both cutaneous and neurologic involvement. This definition includes both hereditary and nonhereditary phenotypes but excludes acquired disorders.

Progress in molecular genetics supports the view that neurocutaneous diseases can be reasonably classified according to formal genetics. [1] Either they follow the established Mendelian modes of inheritance, or they represent lethal mutations surviving by mosaicism, or they belong to the group of chromosomal disorders. Clinically similar disorders may follow different modes of Mendelian inheritance, but this does not constitute a major problem.

The group of neurocutaneous phenotypes that can be explained by a lethal mutation surviving in a mosaic state contains some disorders that have been classified in the past as autosomal dominant traits showing low penetrance or variable expressivity. Today, their sporadic occurrence can be explained reasonably. [2] Some of these disorders, however, may exceptionally affect several members of a family, and for this phenomenon, the concept of paradominant inheritance has been proposed (see below). [2] Chromosomal disorders showing both neurologic and cutaneous involvement are Turner syndrome and trisomy 21.

Some clinicians still use “phacomatosis” to categorize particular neurocutaneous diseases characterized by patchy lesions involving the skin and the nervous system. Unfortunately, this term has diminished rather than increased our understanding of these disorders because the group of phacomatoses has never been well defined. Today, this term should no longer be used for the classification of neurocutaneous diseases but may be applied, together with a specifying adjective, to some genetically determined diseases characterized by the presence of multiple nevi, such as phacomatosis pigmentovascularis.

AUTOSOMAL DOMINANT PHENOTYPES

A list of autosomal dominant neurocutaneous traits is presented in Table 188-1. Some of these phenotypes are presented in detail in separate chapters of this book, e.g., neurofibromatosis 1 and 2 in Chap. 190 and tuberous sclerosis in Chap. 189

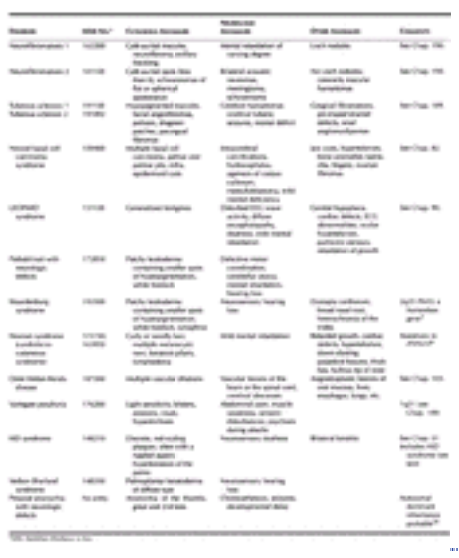

TABLE 188-1 **Neurocutaneous Syndromes: Autosomal Dominant Phenotypes**

NEVOID BASAL CELL CARCINOMA SYNDROME

This disorder is described in Chap. 82. The major CNS anomalies observed in this syndrome are presented in Table 188-1. In my experience, a remarkable neurologic feature observed in many patients with nevoid basal cell carcinoma syndrome is their good-natured, easy friendliness, or bonhomie. This good-naturedness should not be taken as a sign of mental deficiency. On the other hand, mental deficiency has been reported in about 3 percent of patients; it probably occurs more frequently in a mild form. [3]

LEOPARD SYNDROME

This syndrome also has been called *multiplel entigines syndrome* or *cardiomyopathic lentiginosis,* but the term *LEOPARD syndrome* has been firmly entrenched in the clinicians' language. The acronym was coined by Gorlin et al. [3] and stands for *l*entiginosis, *e*lectrocardiographic conduction abnormalities, *o*cular hypertelorism, *p*ulmonic stenosis, *a*bnormal genitalia, *r*etardation of growth, and sensorineural *d*eafness. Patients usually have a characteristic facial appearance with a triangular shape due to frontal bossing, hypertelorism, and low-set ears. The underlying autosomal dominant gene has a high penetrance, but the expression may vary to a large degree, often resulting in rather mild involvement or incomplete phenotypes. The typical lentigines usually develop in childhood, and their number increases with age (Fig. 188-1). In contrast to ordinary freckles, the number of melanocytes is definitely increased. Most patients tend to remain below average for height and weight. Encephalographic examination may show a disturbed wave activity. In some patients, mild mental retardation is present, but intellectual capacity may be completely normal in this syndrome.

FIGURE 188-1 Multiple lentigines as a feature of LEOPARD syndrome.

PIEBALD TRAIT WITH NEUROLOGIC DEFECTS

A piebald trait, consisting of unpigmented areas of skin showing smaller spots of hyperpigmentation in combination with a white forelock, has been described by Telfer et al. [4] in two families showing an autosomal dominant mode of transmission. Affected family members showed, in addition, defective motor coordination, cerebellar ataxia, and mental retardation of varying degree. Moreover, several affected family members suffered from hearing loss. Apparently, this association of anomalies is extremely rare, and this raises the question of whether these families were affected with a contiguous gene syndrome. In this way, the unusual co-occurrence of anomalies could be explained as a defect involving two neighboring genes.

WAARDENBURG SYNDROME

This phenotype has been mapped to 2q37.3. The mutation involves the *PAX3* gene, a homeobox gene that has been highly conserved during phylogenesis. [5] Various allelic mutations have been described.

NOONAN SYNDROME (CARDIOFACIOCUTANEOUS SYNDROME)

In the past, Noonan syndrome and cardiofaciocutaneous syndrome have been considered to represent different entities, but when the signs and symptoms of the two phenotypes are compared, it appears difficult to find any rhyme or reason to distinguish the disorders. [6], [7] Therefore, the two designations are considered synonyms. Noonan syndrome includes retarded growth and congenital cardiac defects and a peculiar facial appearance showing ptosis, hypertelorism, down-slanting palpebral fissures, thick lips, and low-set ears (Fig. 188-2). The nose shows a bullous tip. Characteristically, the scalp hair becomes more curly or woolly during childhood and adolescence. The skin may show many small melanocytic nevi, and keratosis pilaris is likewise noted frequently. Another cutaneous abnormality associated with this syndrome is lymphedema resulting from hypoplasia or aplasia of lymphatic vessels. The most common heart defects are pulmonic stenosis and atrial septal defect. Mild mental retardation is often noted, but the syndrome also may be associated with normal intelligence. The disorder is caused by mutations in *PTPN11.* [8]

FIGURE 188-2 Noonan syndrome: peculiar facies showing hypertelorism, low-set ears, thick lips, and curly hair.

OSLER-WEBER-RENDU DISEASE (HEREDITARY HEMORRHAGIC TELANGIECTASIA)

This disorder is described in Chap. 103.

VARIEGATE PORPHYRIA

For a detailed description of this disorder, the reader is referred to Chap. 149. Due to a founder effect, variegate porphyria is particularly frequent in South Africa. The high prevalence of variegate porphyria in Finland can be explained by a similar founder effect. Affected individuals may suffer from neuropathic features such as abdominal pain, muscle weakness, or sensory disturbances. During attacks, they may be disoriented or even frankly psychotic. These attacks are

often triggered by medication. Several patients homozygous for the underlying gene defect have been described. They tend to develop severe neurologic symptoms with seizures and mental deficiency.

KID SYNDROME

This phenotype is described in Chap. 51.

HID SYNDROME (HYSTRIX-LIKE ICHTHYOSIS WITH DEAFNESS)

In 1989, Traupe [9] proposed the term *HID syndrome* for a phenotype characterized by hystrix-like ichthyosis associated with bilateral neurosensory deafness (Fig. 188-3). Similar cases were published earlier under the designation “ichthyosis hystrix gravior, type Rheydt.” Today, however, molecular analysis has shown that HID and KID syndromes are associated with the same connexin 26 mutation. [10] Hence, the two disorders are identical.

FIGURE 188-3 “HID syndrome” (hystrix-like ichthyosis with deafness) has recently been found to be identical with KID syndrome. [10]

VERBOV-SHARLAND SYNDROME (PALMOPLANTAR KERATODERMA WITH NEUROSENSORY DEAFNESS)

Verbov [11] and Sharland et al. [12] described families with diffuse palmoplantar keratoderma and bilateral, progressive, high-frequency sensorineural hearing loss occurring in several consecutive generations. Molecular studies have so far not been performed in these families. [13]

PREAXIAL ANONYCHIA WITH NEUROLOGIC DEFECTS

Lynch et al. [14] described a syndrome of anonychia involving the thumbs as well as the first and the second toes combined with neurologic defects in a family showing vertical transmission of the trait.

AUTOSOMAL RECESSIVE PHENOTYPES

A list of autosomal recessive neurocutaneous traits is given in Table 188-2. For a more detailed description of the various ichthyoses associated with neurologic anomalies, such as neutral lipid storage disease, Refsum disease, Sjögren-Larsson syndrome (Fig. 188-4), as well as Tay syndrome and Amish brittle hair syndrome (IBIDS syndrome), the reader is referred to Chap. 51.

TABLE 188-2 **Neurocutaneous Syndromes: Autosomal Recessive Phenotypes**

FIGURE 188-4 Sjögren-Larsson syndrome: characteristic rippled appearance of hyperkeratotic skin. (*Courtesy of Peter*

M. Steijlen, MD, Maastricht, The Netherlands.)

MULTIPLE SULFATASE DEFICIENCY

Multiple sulfatase deficiency is a neurodegenerative disorder that usually leads to death in early childhood. The disorder is caused by a mutation that results in enhanced degradation of various sulfatases. [15] Despite some clinical similarities, the disease can be separated from metachromatic leukodystrophy on the basis of different metabolic features. Psychomotor retardation usually becomes manifest during the second year of life. A child that has already learned to walk begins to show an unsteady gait and needs help to stand upright; simultaneously, speech begins to deteriorate. In the final stage, the children are blind and unable to eat or drink. Microscopic examination of biopsies obtained from peripheral nerves shows metachromatic degeneration of myelin. Affected children usually die before their tenth year. The disease is associated with mild ichthyosis resulting from steroid sulfatase deficiency. It is usually less severe than observed in classic X-linked recessive ichthyosis. This difference may be explained by a residual activity of steroid sulfatases. [16]

STEIJLEN SYNDROME

A syndrome consisting of congenital atrichia (Fig. 188-5), transgredient palmar and plantar keratoderma (Fig. 188-6), early loss of teeth, and severe mental retardation was observed by Steijlen et al. [17] The disease occurred in four siblings. The mother had had five miscarriages. Autosomal recessive inheritance is most likely.

FIGURE 188-5 Microcephaly as a feature of Steijlen syndrome (atrichia, palmoplantar keratoderma, and mental retardation).

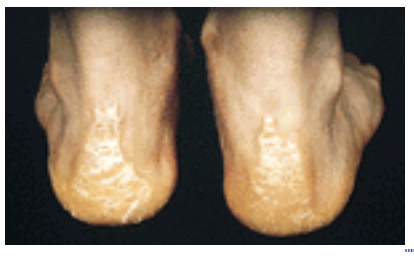

FIGURE 188-6 Steijlen syndrome: plantar keratoderma extending to the heels.

BJØRNSTAD SYNDROME

BjØrnstad syndrome is an autosomal recessive disorder characterized by pili torti and nerve deafness. [18]

SHAPIRA SYNDROME

Shapira et al. [19] described a syndrome consisting of sparse, brittle, and light-colored scalp hair; developmental delay; short stature; and mild to moderate neurologic abnormalities. Further clinical observations may show whether this combination of features represents a new entity.

ELEJALDE SYNDROME

Elejalde syndrome is a phenotype belonging to the group of silvery hair syndromes (Fig. 188-7). The disease should be distinguished from Chediak-Higashi syndrome and Griscelli syndrome. [20] Elejalde syndrome, which also has been called *neuroectodermal melanolysosomal disease,* is characterized by frequent occurrence of fatal neurologic alterations. Psychomotor impairment is a constant feature and may be observed in the newborn or during infancy. In contrast to Chediak-Higashi syndrome, microscopic examination of hair shafts shows an irregular distribution of abnormally small or large clumps of melanin (Fig. 188-8). Neuromuscular alterations consist of hypotonia, hemiplegia, quadriplegia, ataxia, and mental retardation that is usually of a severe degree.

FIGURE 188-7 Elejalde syndrome: bronzed skin and silvery hair.

FIGURE 188-8 Elejalde syndrome: hair shafts show irregular distribution of melanin clumps.

CROSS SYNDROME

This phenotype belongs likewise to the silvery hair syndromes. [20] It is characterized by generalized hypopigmentation, ocular anomalies, and neurologic defects such as mental and physical retardation, ataxia, and spasticity. [21]

XERODERMA PIGMENTOSUM

Several types of xeroderma pigmentosum are associated with neurologic abnormalities (see Chap. 155). In the past, the term *De Sanctis-Cacchione syndrome* has been used to designate this association, but this term should no longer be used because neurologic defects are not characteristic of a particular complementation group. [22] However, groups A and D appear to be especially prone to neurologic involvement. [23]

COCKAYNE SYNDROME

This disorder is described in Chap. 155.

ACRODERMATITIS ACIDEMICA

Some enzyme defects such as methylmalonic acidemia or propionic acidemia are characterized by lethargy, failure to thrive, vomiting, dehydration, dyspnea, and hypotonia. The affected infants often die in coma. These metabolic defects are often associated with cutaneous features reminiscent of acrodermatitis enteropathica, [24] and therefore, the term *acrodermatitis acidemica* has been proposed. [25] Sharply demarcated erythemas with desquamation are usually observed in a periorificial localization. [26] The scalp hair is sparse, brittle, and hypopigmented.

HARTNUP DISEASE

Hartnup disease is a metabolic disorder characterized by a transportation defect involving certain amino acids (see Chap. 147). Affected children show photosensitivity resulting in skin changes reminiscent of pellagra and progressive cerebellar ataxia.

TANGIER DISEASE

The disease is caused by *ABCA1* mutations involving cholesterol and apolipoprotein B metabolism that result in xanthomatosis of various tissues and recurrent neuropathy. [27] The disorder is named after Tangier Island in the Chesapeake Bay, where affected individuals are descendants from a small founder population. The skin may show xanthomatous papules resulting from abnormal deposition of cholesterol esters.

CHIME SYNDROME

The term *CHIME* is an acronym for colobomas of the eye, heart defects, ichthyosiform dermatosis, mental retardation, and ear defects. [28] The condition is characterized by a congenital, migratory, ichthyosiform dermatosis, hyperkeratotic palms and soles, and sparse, fine hair.

DE BARSY SYNDROME

This phenotype is characterized by growth retardation, progeroid facial appearance with pronounced nasolabial folds, and diminished subcutaneous tissue resulting in wrinkling, large dysplastic ears, corneal opacities, cataracts, hypermobility of joints, and mental retardation. [29] Microcephaly is often present.

X-LINKED MALE-LETHAL PHENOTYPES

Some X-linked neurocutaneous disorders occur almost exclusively in girls because the underlying genes exert a lethal effect on male embryos [31] (Table 188-3). In female embryos, the Lyon effect of X-inactivation accounts for survival. Exceptionally, however, male patients may be observed, and this can be explained either by a gonosome constitution XXY, by an early postzygotic mutation, or by a gametic half-chromatid mutation. [2]

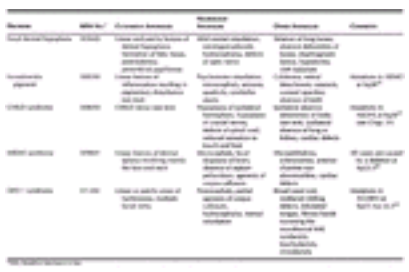

TABLE 188-3 **Neurocutaneous Syndromes: X-linked Male-Lethal Phenotypes**

FOCAL DERMAL HYPOPLASIA (GOLTZ SYNDROME)

The main features include widespread lesions of dermal hypoplasia with herniation of adipose tissue, streaks of pigmentary disturbance following the lines of Blaschko, and severe absence deformities of bones. [32] Some patients may show mental retardation, which is usually mild, and others may suffer from hearing loss. The spectrum of ocular anomalies includes defects of the optic nerve.

INCONTINENTIA PIGMENTI

Incontinentia pigmenti is caused by *NEMO* mutations. [33] During the first months of life, linear lesions showing inflammation and blistering occur and apparently reflect a selection against the functionally defective cell clone. [34] The blisters are filled with eosinophils. Later on, these lesions are replaced by hyperkeratotic verrucous areas, whereas in the older child a linear or patchy pattern of hyperpigmentation is found (Fig. 188-9). In women, a fourth stage in the form of linear hypopigmentation involves the lower legs predominantly. The disorder is associated with ocular defects such as coloboma, retinal detachment, strabismus, cataracts, optic atrophy, and corneal opacities. Dental abnormalities include absence of deciduous or permanent teeth and crown deformities. Involvement of the CNS occurs rather frequently, but it appears impossible to present the incidence in terms of percentages because all case reports and reviews contain a considerable bias of ascertainment. Neurologic abnormalities comprise psychomotor etardation, microcephaly, seizures, spasticity, and cerebellar ataxia. The great variability of these phenotypic associations can be explained by the Lyon effect of random X-inactivation. [2] Morphologic evidence of functional X-chromosome mosaicism involving the brain has been provided. [35]

FIGURE 188-9 Incontinentia pigmenti: linear arrangement of hyperpigmented skin lesions.

CHILD SYNDROME

The term *CHILD* is an acronym for congenital hemidysplasia with ichthyosiform nevus and limb defects [36] (see Chap. 51). (The term *ichthyosiform erythroderma* is misleading and should no longer be used.) The disorder is caused by mutations of *NSDHL,* a gene involved in cholesterol metabolism. [37] The phenotype is characterized by a unique inflammatory nevus that has been called *CHILD nevus*. [38] Usually this nevus shows a striking lateralization with a sharp midline demarcation (Fig. 188-10). However, a streaky arrangement following the lines of Blaschko also may be present. Ipsilateral limb defects may vary from mild hypoplasia of one finger or toe to complete absence of an arm or leg. The nails are often replaced by keratotic, clawlike material. Ipsilateral CNS abnormalities include hypoplasia of a hemisphere or hypoplasia of cranial nerves or the spinal cord; there may be reduced sensation to touch and heat on the affected side. However, in most of these girls the mental development is completely normal. Apparently, the unaffected hemisphere can take over

all the necessary functions. In one case, mild intellectual impairment was reported. [39]

FIGURE 188-10 CHILD syndrome: CHILD nevus showing striking lateralization and ipsilateral limb defects.

MIDAS SYNDROME

The term *MIDAS* is an acronym that stands for microphthalmia, dermal aplasia, and sclerocornea. [40] All the associated defects reflect functional X-chromosome mosaicism. Microphthalmia is usually bilateral, but unilateral involvement also has been reported. Dermal aplasia typically involves the face (Fig. 188-11), the scalp, and the neck, but other body areas also may be affected. In contrast to focal dermal hypoplasia, these lesions never show herniation of the underlying fatty tissue. In some of the affected girls, neurologic defects such as focal dysplasia of the brain with absence of the septum pellucidum, microcephaly, or agenesis of the corpus callosum have been reported. However, the latter also may result from a deletion that involves a neighboring gene, producing a contiguous gene syndrome that includes Aicardi's syndrome in addition to the MIDAS syndrome. [41]

FIGURE 188-11 MIDAS syndrome: microphthalmia and dermal aplasia showing linear arrangement.

OFD I SYNDROME (ORAL-FACIAL-DIGITAL SYNDROME)

This syndrome is caused by *CXORF5* mutations at Xp22.3-p22.2. [42] It includes midfacial clefting defects, lobulation of the tongue, hypoplasia of the nose, syndactyly, brachydactyly, clinodactyly, and circumscribed hairlessness that visualizes the lines of Blaschko on the scalp. [31] The upper lip is short, and the nasal root is broad. During infancy, many milia may be present on the cheeks or the ears. Typical oral manifestations are large hyperplastic fibrous bands traversing the mucobuccal fold. Many of the affected girls show mild mental retardation. Neurologic examination of the brain may reveal porencephaly, partial agenesis of the corpus callosum, or hydrocephalus.

X-LINKED NONLETHAL PHENOTYPES

In this group of disorders, women are usually more mildly affected because of the Lyon effect of X-inactivation (Table 188-4). Remarkably, however, several X-linked genes located at different regions of the X chromosome escape inactivation, and one example may be the gene for bullous dystrophy of Mendes da Costa. [43]

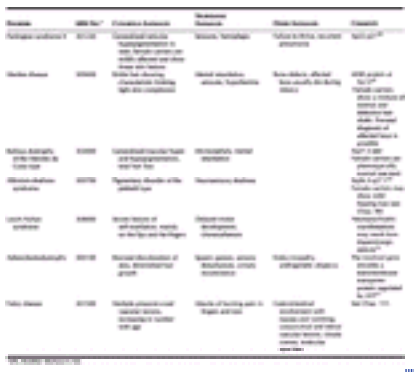

TABLE 188-4 **Neurocutaneous Syndromes: X-Linked Nonlethal Phenotypes**

PARTINGTON SYNDROME II

This syndrome is characterized by generalized reticulate hyperpigmentation, failure to thrive, recurrent pneumonia, seizures, and hemiplegia. [44] Female gene carriers are only mildly affected and show a patchy or linear pattern of hyperpigmentation.

MENKES DISEASE (See Chap. 71)

The disorder includes sparse, brittle hair showing characteristic kinking, mental retardation, seizures, hypothermia, and bone defects. The disease is caused by a defect of copper transport. [45] Affected boys usually die during infancy. Due to the Lyon effect of X-inactivation, female gene carriers show a mixture of normal and defective hair shafts and may be otherwise affected. [46], [47] There is a murine homologue of Menkes disease. [48]

BULLOUS DYSTROPHY OF THE MENDES DA COSTA TYPE

Affected boys show macular hyperpigmentation and depigmentation, total hair loss, microcephaly, and mental retardation. [49] Women heterozygous for this X-linked mutation are phenotypically normal. For this reason, it has been assumed that the underlying gene escapes X-inactivation. [43]

ALBINISM-DEAFNESS SYNDROME

This X-linked form of albinism represents a pigmentary disorder of the piebald type in combination with a profound deafness that results in deaf-mutism. [50] A less severe hearing impairment has been found in female carriers. [51]

KALLMANN SYNDROME

Kallmann syndrome is characterized by anosmia due to agenesis of the olfactory lobes and hypogonadotropic hypogonadism. [53] The underlying gene defect does not involve the skin. However, several patients affected with Kallmann syndrome display a contiguous gene syndrome that involves several neighboring gene loci, including that of steroid sulfatase. [54] Consequently, these patients are also affected with X-linked recessive ichthyosis.

LESCH-NYHAN SYNDROME

This phenotype is caused by a deficiency of hypoxanthine-guanine phosphoribosyl-transferase. [55] During the first months of life, neurologic anomalies such as delayed motor development and choreoathetosis become manifest. Affected boys usually show severe self-mutilation. The lips and fingers are involved most frequently. [56]

ADRENOLEUKODYSTROPHY

Adrenoleukodystrophy is a peroxisomal disorder characterized by progressive demyelination and adrenocortical insufficiency. [57] Affected male individuals show increased levels of long-chain fatty acids. Clinical symptoms include spastic paresis, sensory disturbances, urinary incontinence, and endocrinopathy. The cutaneous features consist of a bronzed discoloration of the skin and diminished hair growth. [58]

LETHAL AUTOSOMAL MUTATIONS SURVIVING BY MOSAICISM

Some autosomal mutations, when present in a zygote, cause early death of the embryo (Table 188-5). Cells carrying the mutation can survive only in a mosaic state, in close proximity with normal cells. [59] Such mosaics usually result from an early postzygotic mutation. The following neurocutaneous phenotypes can be best explained by this concept.

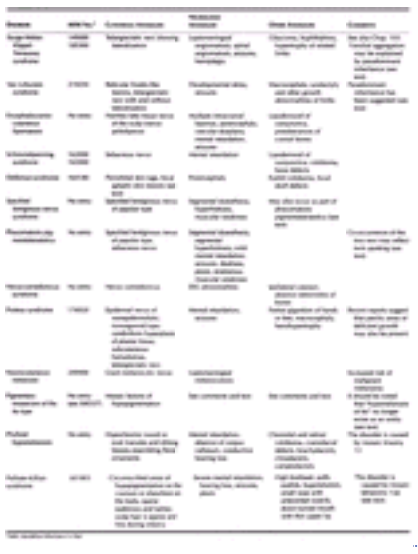

TABLE 188-5 **Neurocutaneous Syndromes: Lethal Autosomal Mutations Surviving by Mosaicism**

STURGE-WEBER-KLIPPEL-TRENAUNAY SYNDROME

According to conventional rules of classification, the Sturge-Weber syndrome and the Klippel-Trenaunay syndrome are separate entities, but from a genetic point of view, it is obvious that they are caused by the same gene defect. [59] For a detailed description of the Sturge-Weber phenotype, which is characterized by lateral telangiectatic nevi of the face (Fig. 188-12), see Chap. 103. Bilateral involvement occurs rather frequently. [60] Klippel-Trenaunay syndrome differs with regard to the location of the lesions and is characterized by lateral telangiectatic nevi associated with hypertrophy of related bones and soft tissues of one or several limbs. Again, bilateral involvement is observed frequently, and a combination of Sturge-Weber and Klippel-Trenaunay syndrome has sometimes been described.

FIGURE 188-12 Sturge-Weber-Klippel-Trenaunay syndrome. (*Courtesy of Jean Maleville, MD, Bordeaux, France*.)

Remarkably, this syndrome exceptionally may show a familial aggregation. [61], [62] To explain this phenomenon, paradominant inheritance has been proposed. [63] Heterozygous individuals would be phenotypically normal, and the trait would be expressed only when loss of heterozygosity occurs at an early stage of embryogenesis, giving rise to a mosaic population of cells that have become either homozygous or hemizygous for the underlying mutation. [64]

VAN LOHUIZEN SYNDROME (CUTIS MARMORATA TELANGIECTATICA CONGENITA)

The disease is characterized by reticular vascular lesions resulting in a bluish-red, livedo-like network that may involve large parts of the body. Extracutaneous symptoms comprise macrocephaly, seizures, and developmental delay, as well as growth anomalies of the limbs. [65] Vascular nevi similar to those observed in Sturge-Weber-Klippel-Trenaunay syndrome likewise may be present but, remarkably, do not always show lateralization. Most cases so far observed were sporadic, and for this reason they may originate from a lethal mutation surviving by mosaicism. Exceptional familial cases may be explained by paradominant inheritance. [65]

ENCEPHALOCRANIOCUTANEOUS LIPOMATOSIS

This syndrome includes an extensive fatty tissue nevus of the scalp, protuberances of the cranial bones, lipodermoid of the conjunctiva, multiple intracranial lipomas, and porencephaly. [66] It has been proposed that the associated fatty tissue nevus of the scalp should be distinguished from other connective tissue nevi such as the Hoffmann-Zurhelle nevus. [67] Involvement of the CNS may include vascular dysplasia, mental retardation, and epileptic seizures. All cases so far reported have been sporadic. [66]

DELLEMAN SYNDROME

This phenotype includes orbital cysts, porencephaly, skull defects, eyelid coloboma, and multiple skin tags that are usually arranged in the periorbital region; in addition, there are widespread aplastic skin lesions that never show herniation of the fatty tissue, as observed in focal dermal hypoplasia. [68] All these lesions suggest a mosaic arrangement, and all observations are sporadic. [59]

SCHIMMELPENNING SYNDROME

This syndrome is characterized by the presence of a systematized sebaceous nevus associated with various cerebral defects causing mental retardation and seizures, ocular anomalies including conjunctival lipodermoids or colobomas, and bone defects. [59], [69] The combination of these mosaic anomalies may vary to a large degree. There are two reports suggesting familial occurrence of this syndrome. If the clinical diagnosis was correct in these cases, they can be explained either by a coincidence or by paradominant inheritance. [64]

SPECKLED LENTIGINOUS NEVUS SYNDROME

This distinct neurocutaneous phenotype is characterized by a speckled lentiginous nevus that may be either unilateral or bilateral in association with hyperhidrosis, muscular weakness, dysesthesia, or other neurologic abnormalities. [70] The extracutaneous defects are usually ipsilateral. The disorder is most likely a paradominant trait.

PHACOMATOSIS PIGMENTOKERATOTICA

This disorder is defined by the co-occurrence of a speckled lentiginous nevus of a papular type and an epidermal nevus of a nonepidermolytic, organoid type, usually in the form of sebaceous nevus (Fig. 188-13). The coexistence of the two cutaneous lesions has been explained as a twin-spot phenomenon. [71] Associated neurologic defects include segmental dysesthesia, segmental hyperhidrosis, mild mental retardation, seizures, deafness, ptosis, strabismus, and muscular weakness of varying degrees. [72] Most likely this phenotype represents a combination of Schimmelpenning syndrome and speckled lentiginous nevus syndrome.

FIGURE 188-13 Systematized speckled lentiginous nevus in a woman who had, in addition, a large sebaceous nevus involving the scalp and the neck, in the form of phacomatosis pigmentokeratotica. Note asymmetric posture due to shortening of the left leg.

NEVUS COMEDONICUS SYNDROME

This syndrome is characterized by a nevus comedonicus in combination with ipsilateral cataract and skeletal defects. [69] In addition, electroencephalographic abnormalities and dysgenesis of the corpus callosum have been reported. [59], [73]

PROTEUS SYNDROME

This phenotype includes partial gigantism of hands or feet and other forms of hemihypertrophy, including macrocephaly; multiple subcutaneous hamartomas such as lymphangioma, hemangioma, lipoma, or fibroma; cerebriform hyperplasia of plantar connective tissue; and a linear epidermal nevus of the nonepidermolytic, nonorganoid type [74] (Fig. 188-14). Because of the marked variability of all these defects, the disorder was named after the Greek god Proteus, who was said to be able to change his outward appearance in many ways. Paradoxically, patchy areas of deficient growth have been observed in many cases. [75] Intelligence may be normal, but there is an increased incidence of mental retardation, seizures, or sensorineural hearing loss. [3], [76]

FIGURE 188-14 Proteus syndrome.

NEUROCUTANEOUS MELANOSIS

Neurocutaneous melanosis is characterized by giant melanocytic nevus in combination with leptomeningeal melanocytosis. The giant cutaneous lesion may be associated with widespread small congenital melanocytic nevi. The risk of malignant melanoma developing from either cutaneous or cerebral lesions is markedly increased. [77] Because all cases are sporadic, mosaicism of a lethal gene has been suggested. [59]

PIGMENTARY MOSAICISM OF THE ITO TYPE

Previously, such phenotypes visualizing the lines of Blaschko often were described under the designation *hypomelanosis of Ito,* but it is important to realize that this is an outdated term that does not refer to any specific neurocutaneous syndrome. [78] On the contrary, it simply describes a cutaneous symptom as observed in many different states of genetic mosaicism that may or may not involve, in addition, extracutaneous organs such as the brain or eyes. The associated neurologic anomalies vary to a large degree. Because virtually all cases are sporadic, they most likely represent mosaicism of a lethal mutation that may be a numerical chromosome aberration, a deletion, or a point mutation. Cytogenetic or molecular analysis to find one of the underlying defects is advisable.

PHYLLOID HYPOMELANOSIS

In contrast to hypomelanosis of Ito, phylloid hypomelanosis is a well-defined clinicogenetic entity that is usually caused by mosaic trisomy 13. [79] The hallmark is a pattern of hypopigmented, round or oval lesions reminiscent of the floral ornaments of art nouveau painting (Fig. 188-15). The term *phylloid* is derived from Greek *phyllon,* meaning “leaf.” The patients show CNS defects with mental retardation, absence of corpus callosum, and conductive hearing loss. In addition, choroidal and retinal coloboma, craniofacial defects, brachydactyly, clinodactyly, camptodactyly, and other osseous anomalies may be present.

FIGURE 188-15 Phylloid hypomelanosis in a 13-year-old girl with mosaic trisomy 13. (*Courtesy of Dr. Denise Horn, Berlin, Germany*.)

PALLISTER-KILLIAN SYNDROME

This disorder is caused by mosaic tetrasomy for the short arm of chromosome 12 (isochromosome 12p syndrome). [80], [81] From a heuristic point of view, the disease can be taken as a specific entity within the spectrum of so-called hypomelanosis of Ito. Clinical features are postnatal growth deficiency and severe mental retardation and a characteristic facial appearance with a high forehead, sparse eyebrows and lashes, puffy eyelids, ptosis, hypertelorism, hypoplastic nose with anteverted nostrils, and a down-turned mouth with a thin upper lip. During infancy, the hair is markedly sparse and fine, but later on, hair growth becomes normal. Circumscribed hypopigmented areas are often present on the cranium and sometimes elsewhere on the body. Apparently, these hypopigmented lesions do not follow the lines of Blaschko.

CHROMOSOMAL DISORDERS

Some phenotypes characterized by numerical chromosome aberrations are associated with characteristic cutaneous features (Table 188-6).

TABLE 188-6 **Neurocutaneous Syndromes: Disorders Caused by Numerical Chromosome Aberrations**

ULLRICH-TURNER SYNDROME

This syndrome was described in 1930 by Ullrich [82] and in 1938 by Turner. [83] The chromosome constitution 45,X results in a female phenotype with short stature, sexual infantilism, webbed neck, and various other anomalies. Remarkably, the intelligence deficit present in this syndrome does not refer to all brain functions. In general, affected women have a handicap in visual-spatial orientation and perceptual organization, whereas language skills are normal. Newborn girls may show marked lymphedema of the feet with hypoplastic toenails. Affected women show large numbers of melanocytic

nevi.

KLINEFELTER SYNDROME

The clinical features of Klinefelter syndrome result from the chromosome constitution 47,XXY. Affected men are relatively tall, and characteristically, the arm span exceeds the height. The testes are small, and gynecomastia is often present in adult individuals. Mental development is only mildly retarded. Typical cutaneous features are varicose veins and hypostatic leg ulcers. [84]

TRISOMY 21

Trisomy 21 is a well-known syndrome that will not be described in detail in this chapter. Rather, the cutaneous signs and symptoms observed in this phenotype will be mentioned. A more or less widespread ichthyosiform hyperkeratosis is often observed in adults. [85] Other typical features are elastosis perforans serpiginosa and milia-like calcinosis cutis. [86] Syringomas occur far more frequently than in the general population. [87] Moreover, individuals with trisomy show a markedly increased proneness to alopecia areata. [88]

PHENOTYPES STILL UNCLASSIFIABLE ACCORDING TO FORMAL GENETICS

Some neurocutaneous disorders are obviously genetically determined but so far cannot be categorized according to formal genetics (Table 188-7).

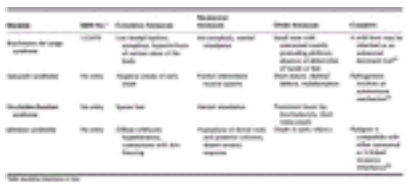

TABLE 188-7 **Neurocutaneous Syndromes: Disorders Still Unclassifiable According to Formal Genetics**

BRACHMANN–DE LANGE SYNDROME

This phenotype is characterized by low birth weight, delayed growth, and mental retardation. Affected children have a typical facial appearance with microcephaly, low frontal hair line, synophrys (meeting of the eyebrows across the midline), hypoplastic nose with anteverted nostrils, and protruding philtrum. [89] Absence deformities of hands or feet may be noted. As a characteristic cutaneous feature, pronounced hypertrichosis may be found in many areas of the body. Additional cutaneous anomalies include cutis marmorata, hypoplastic nipples, hypoplastic umbilicus, and simian crease of the palm. The genetic basis of this syndrome so far has not been fully elucidated. [90] Discordant monozygotic twins have been described. [91]

SATOYOSHI SYNDROME

Satoyoshi syndrome is of interest for the dermatologist because this genetically determined disorder is associated with early onset of alopecia areata [92] (see Table 188-7).

NICOLAIDES-BARAITSER SYNDROME

This syndrome includes mental retardation, sparse hair, prominent lower lip, and brachydactyly. [93] Further clinical research should show whether the concept of a new syndrome holds true.

JOHNSTON SYNDROME

Hyperkeratotic skin changes reminiscent of collodion baby were observed by Johnston et al. [94] in two brothers suffering from severe arthrogryposis. The two boys died shortly after birth. Autopsy performed on one of them showed severe hypoplasia of the posterior columns. The syndrome is most likely inherited as either a monogenic autosomal or an X-linked recessive trait.

REFERENCES

Tuberous sclerosis complex (TSC) is an autosomal dominant disease attributable to mutations in one of two different genes. Lesions occur predominantly in the skin, nervous system, heart, and kidney. The most commonly recognized clinical manifestations are ash-leaf hypopigmented macules, adenoma sebaceum, seizures, and mental retardation. [1], [2]

HISTORY

Although Virchow recognized scleromas of the cerebrum in the 1860s, and von Recklinghausen found a similar case with multiple myomata of the heart in 1862, Bourneville's articles, appearing between 1880 and 1900, presented the first systematic account of the disease and related the cerebral and skin lesions. Vogt, in 1908, delineated the classic triad of adenoma sebaceum, epilepsy, and mental retardation. [2]

EPIDEMIOLOGY

The prevalence of the disease is estimated to be approximately 3 to 10 per 100,000. [3], [4] There is no difference in frequency among whites, blacks, and Asians; both sexes are affected equally, although some symptoms are more predominant in women. Heredity is evident in approximately one-third of cases; the remaining cases are attributed to a de novo mutation. Prevalence data drawn from surveys of mental hospital populations probably magnified the overall incidence of mental retardation in this disorder. There is no increase in paternal age in patients with new mutations. There are several instances of mutations limited to the germ-line in parents with multiple affected children and no clinical evidence of parental disease. [5]

ETIOLOGY AND PATHOGENESIS

Mutations in two genes— *TSC1* and *TSC2*—each account for about half the cases of tuberous sclerosis. No third gene has been linked to the disease. *Tuberous sclerosis complex 1 (TSC1)* maps to 9q34, is a 8.6-kb gene and encodes hamartin, a 130-kDa protein, which is a tumor suppressor with a nuclear localization signal and a cdc2 kinase site. [6], [7]

The *TSC2* gene maps to 16p13.3 and codes for tuberin, a 1784-amino-acid protein, which has homology to a GTPase-accelerating protein (GAP) and has intrinsic GTPase activity. It colocalizes with Rap1 (a GTPase member of the Ras superfamily of GTP-binding proteins) in the Golgi apparatus. [8] Inhibition of *TSC2* expression upregulates cyclin; thus tuberin participates in regulating entrance into the S phase of the cell cycle from G1 or G0. *TSC2* mutations include deletions, insertions, missense duplications, and tandem repeats. There are no mutational hot spots in the GTPase-activating protein-related domain. [9]

Subependymal giant cell astrocytomas and angiomyolipomas associated with TSC show loss of heterozygosity in the 16p13 region, supporting a two-hit cancer-suppressor model for the pathogenesis of those tumors and for the role of *TSC2* as a tumor-suppressor gene. [10] Transgenic mice with a disrupted *TSC2* allele develop tumors in multiple sites.

CLINICAL MANIFESTATIONS

The disease may be present at birth, but not recognized. Careful examination often will reveal hypopigmented macules. Focal or generalized seizures with or without developmental delay is often the first sign of the disease. Adenoma sebaceum appears later in childhood, usually between the fourth and tenth years. [2]

SKIN LESIONS

In approximately 87 percent of the patients with tuberous sclerosis, congenital hypomelanotic macules are present (Fig. 189-1). Three hypopigmented macules are highly suspicious for the diagnosis TSC; 4.7 percent of the general population has at least one such lesion. These data and the relative incidence of tuberous sclerosis suggest that one macule per se should not prompt an extensive evaluation to rule out tuberous sclerosis. [11] Hypopigmented macules may be segmental or confetti-like on the extremities. [12] In some patients with multiple endocrine neoplasia type I, confetti-like

hypopigmented macules occur on the trunk.

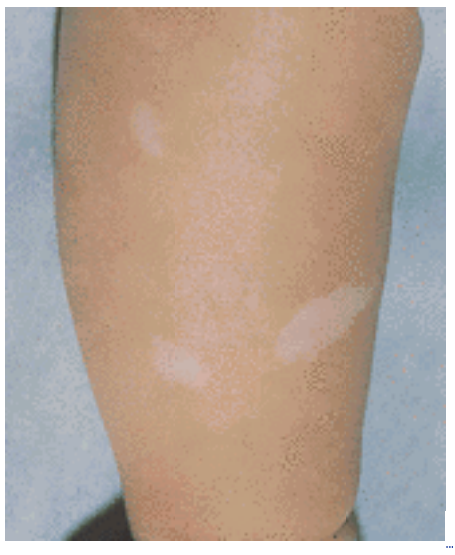

FIGURE 189-1 Hypomelanotic ash-leaf macules on the lower leg in a child with the tuberous sclerosis complex.

The contrast between normal skin and the hypopigmented macule(s) is accentuated by the Wood lamp, which may be essential when examining the skin of lightly pigmented subjects. [13] The average lesion is 1 to 3 cm in diameter with 89 percent greater than 1 cm. Individual lesions may range from 4 mm to 12 cm; large segmental lesions may occur. The lesions are often lance-ovate in shape and resemble the utline of the Eastern mountain ash leaf, hence “ash-leaf spots.” The margins are discrete and the color is not the pure white of vitiligo. Confetti lesions (2 to 3 mm), when they occur, are most commonly localized between the knees and the ankles and the wrists and the elbow. Lesions may fade with age, making use of the Wood lamp particularly helpful when trying to ascertain “asymptomatic” carriers.

Facial angiofibromas (often given the misnomer adenoma sebaceum), are diagnostic of tuberous sclerosis, and are present in 96 percent of patients. [14] The earliest manifestation of facial angiofibromatosis may be a mild erythema over cheeks and forehead, which is intensified by crying. Typically the angiofibromas are 0.1 to 0.3 mm red to pink papules with a smooth, glistening surface, localized to the nasolabial folds, cheeks, chin, and sometimes the forehead and scalp (Fig. 189-2). Segmental forms of the disease with unilateral distribution of the facial angiofibromas may occur. [15] The differential diagnosis for angiofibroma includes acne vulgaris, acne rosacea, agminated Spitz nevi, multiple trichoepitheliomas, and syringomas. Trichoepitheliomas have a similar centrofacial distribution of papules and nodules, but lack the pink vascular aspect of angiofibromas. Large connective-tissue nevi on the forehead (“fibrous forehead plaque”) represent another diagnostic feature, present in 25 percent of patients and often congenital. They are similar to facial angiofibromas, except for the absence of vascular elements.

FIGURE 189-2 Adenoma sebaceum, the classic facial lesions in the tuberous sclerosis complex. These angiofibromas are typically localized on the cheeks and the nasolabial folds; they are pink or red and have a smooth surface.

A characteristic truncal lesion is the shagreen patch, most often in the lumbosacral region (Fig. 189-3). It is a flat, slightly elevated, flesh-colored plaque with an “elephant hide” or “orange peel” appearance; the shagreen patch may vary in size from less than 1 cm to up to 10 cm in diameter.

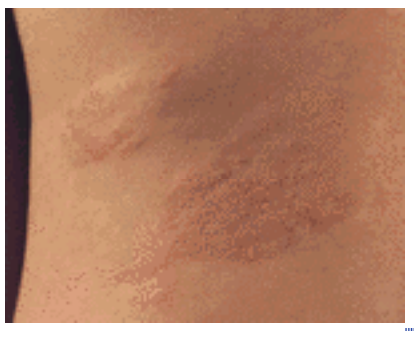

FIGURE 189-3 Shagreen patch in tuberous sclerosis. This is a flat, elevated lesion with an orange peel appearance. It corresponds to circumscribed subepidermal fibrosis.

Periungual fibromas (Koenen tumors), most often appearing after puberty, are common (50 percent) in tuberous sclerosis. They may also be subungual (Fig. 189-4). Fibromas in the matrix or nail bed lead to thinning or even destruction of the nail plate. Excision is usually curative. Gingival fibromas also occur, as do fibromas on the palate or lips. Hyperplastic gingival lesions are common if diphenylhydantoin is administered for the associated seizures.

FIGURE 189-4 Koenen tumors in the tuberous sclerosis complex. These peri- and subungual fibromas are characteristic.

NONCUTANEOUS MANIFESTATIONS

Seizures, a reliable index of cerebral lesions, most commonly begin during the first year or two of life in the form of infantile spasms with the characteristic electroencephalographic (EEG) pattern of hypsarrhythmia. Other seizure types may develop with age. The occurrence of seizures and retardation does not parallel that of the skin abnormalities. Fewer than a third of patients have the complete Vogt triad. Although some patients with recurrent seizures retain relatively normal mental function, patients with mental retardation nearly all have seizures. When only a few skin lesions or a retinal phakoma are present, the diagnosis may require additional studies such as renal ultrasound and/or cranial neuroimaging [computed tomography (CT) or magnetic resonance imaging (MRI)]. [16]

Gray or yellow plaques (single or multiple) may be found in the retina (often in or near the optic disk) in about 50 percent of cases. It is from this lesion, called phakoma, that van der Hoeve derived the term *phakomatoses,* which is applied to all neurocutaneous diseases of this class. [2], [16] Benign rhabdomyomas of the heart are common and may be associated with Wolff-Parkinson-White syndrome. Eighty percent of all children presenting with rhabdomyomas have TSC. Most rhabdomyomas regress spontaneously and do not require surgical treatment. [17] Up to 60 percent of patients have renal angiomyolipomas, although symptomatic lesions predominate in women. The lesions present early and are often multiple and bilateral, in contrast to nontuberous sclerosis-associated angiomyolipoma that are seen in older women. Cystic renal disease is seen in association with tuberous sclerosis, more frequently in patients with mutations in *TSC2*. In some cases, this is related to a contiguous gene syndrome because mutations span both the *TSC2* gene and the adjacent polycystic kidney disease gene (*PKD*). [18] Benign tumors have been found in the liver, thyroid, testes, and gastrointestinal tract. Pulmonary lymphangiomyomatosis, a proliferation of smooth muscle cells, is a rare complication of TSC, found predominantly in women, that can occur without other findings of TSC; in these cases, it may represent a form of segmental TSC. [19] Cystic bone lesions in the phalanges are common. [20]

SKIN PATHOLOGY

The skin and nail lesions contain interlacing strands of fibroblasts and dense collagen with numerous ectatic blood vessels. The papillary dermis is absent. The upper dermis in angiofibroma and periungual fibromas contains plump stellate cells (“glial-like”), which are vimentin- and factor XIIIa–positive. Melanophages are often prominent. The shagreen plaque is composed of a relatively avascular, dense, sclerotic mass of bundles of collagen fibers. The hypopigmented macules have decreased numbers of melanocytes, decreased melanosome size, and decreased melanization with fewer stage III and IV melanosomes.

BRAIN AND EYE PATHOLOGY

The brain exhibits a number of diagnostic changes that include cortical tubers, areas of increased firmness on the cortical surface that on cut surface reveal loss of normal gray-white junction. The number and size of cortical tubers correlate with the occurrence of seizures and mental retardation in TSC. Subependymal nodules along the ventricular surface, particularly at the level of the caudate nuclei and close to the foramen of Monro, are the most typical neuropathologic finding in TSC. Subependymal nodules may enlarge and obstruct the outflow of the lateral ventricles with the development of obstructive hydrocephalus. Both cortical tubers and subependymal nodules can calcify over time and be evident on plain skull radiographs.

Retinal phakomas are generally asymptomatic and consists of neuronal and glial elements. Clinically, the translucent forms, in contrast to the calcified forms, need to be distinguished from retinoblastoma.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

When a patient has the triad of retardation, seizures, and the skin abnormalities, the diagnosis is clear. [16] Epilepsy (i.e., infantile spasms) and developmental delay, however, are by no means diagnostic of tuberous sclerosis. In these cases, especially when the family history is unrevealing, a thorough examination of the skin for hypomelanotic macules, adenoma sebaceum, collagenous patches, or subungual or gingival fibromas is rewarding. The hypopigmented macules, as the earliest manifestation of the disease, are most helpful. The history of seizures and/or mental retardation is supportive in the presence of other diagnostic features of tuberous sclerosis. The radiographic demonstration of cortical

tubers and subependymal nodules by either CT or MRI are more specifically diagnostic. [21]

Localized patches of hypopigmentation should lead to the consideration of alternative diagnosis, particularly of nevus depigmentosus, hypomelanosis of Ito, and nevus anemicus. Nevus depigmentosus is usually a single lesion, although it may be large and may assume a dermatomal distribution. Usually located on the trunk or proximal extremities, nevus depigmentosus may be congenital or may first “appear” during the first few years of life as normal pigmentation darkens. The condition is almost never associated with systemic consequences. Hypomelanosis of Ito describes a heterogeneous group of mosaic conditions characterized by hypopigmented to depigmented whorl-like patterns, which tend to follow lines of Blaschko. Systemic abnormalities, especially of bones, eyes, and the central nervous system, may be associated. [22] Careful Wood light exam is essential in these patients. Nevus anemicus results from localized vasoconstriction, and should not redden with rubbing.

TREATMENT

Prenatal counseling should be recommended for a couple when one is affected, given the 50 percent risk for each pregnancy, with the caveat that the clinical phenotype can be quite variable. If the affected individual on molecular testing has a detectable mutation in either *TSC1* or *TSC2,* molecular prenatal testing may be possible. The test, although informative if a fetus is affected, is not prognostic for the severity of possible symptoms. The presence of cardiac rhabdomyomas may be detected by prenatal echocardiography and the pregnancy monitored for fetal cardiac compromise. Complications of these cardiac lesions decrease with time and the lesions usually disappear by sequential echocardiography. Seizure management is important in the eventual intellectual outcome in children who present with early onset seizures. Neurosurgery for seizure control is a consideration in children with a demonstrable dominant electroconvulsive focus whose seizures are intractable to medical management. Shunting of the obstructive hydrocephalus, related to enlarged subependymal giant cell lesions obstructing the outflow of the lateral ventricles, is quite successful, with limited morbidity in centers with experience. The cosmetic appearance of patients can be helped by dermabrasion, electrodesiccation, or laser surgery (CO_2, copper vapor) of their facial lesions, with the knowledge that they will slowly regrow. [23]

COURSE AND PROGNOSIS [24]

The increased morbidity and mortality of patients with TSC relates to the extent of systemic involvement. The cause of mortality varies based on age, with cardiovascular involvement predominant during the first decade of life, followed by brain tumors in the second decade. Mortality related to complications of renal involvement include angiomyolipomas that can be symptomatic if large and the development of renovascular hypertension; decreased renal function, catastrophic hemorrhage and, in a smaller percentage of cases, malignant transformation have been described. Status epilepticus as a source of morbidity remains a significant source of mortality. Complications of pulmonary lymphangiomyomatosis also contribute to the mortality of patients in the fourth decades and beyond.

Neurofibromatoses

NEUROFIBROMATOSIS TYPE 1
Clinical Features
Genetics of NF1
Diagnosis and Management
Related Conditions
NEUROFIBROMATOSIS TYPE 2

REFERENCES

The neurofibromatoses (NF) are a heterogenous set of genetic disorders having clinical manifestations that involve the skin, the nervous system, or both. On clinical grounds, at least two distinct autosomal dominant disorders (with somewhat overlapping features) have been definitively recognized. The most common type of NF is neurofibromatosis type 1 (NF1) (85 percent of patients), which should be distinguished from neurofibromatosis type 2 (NF2) (10 percent of patients). The other 5% have related conditions discussed below. Molecular biology confirms that NF1 and NF2 are genetically distinct: NF1 results from defects in the *NF1* gene on chromosome 17, and NF2 results from a defect in the *NF2* gene on chromosome 22. The nomenclature, definition, and diagnosis of NF1 and NF2 currently are based on the clinical criteria of the NIH Consensus Developmental Conference (Table 190-1). [1]

Neurofibromatosis Type 1
(The diagnostic criteria are met if two or more of the features listed are present)
Six or more café au lait macules over 5 mm in greatest diameter in prepubertal individuals and over 15 mm in greatest diameter in postpubertal individuals
Two or more neurofibromas of any type or one plexiform neurofibroma
Freckling in the axillary or inguinal regions
Optic glioma
Two or more Lisch nodules (iris hamartomas)
A distinctive osseus lesion such as sphenoid dysplasia or thinning of long bone cortex with or without pseudoarthrosis
A first-degree relative (parent, sibling, or offspring) with NF1 by the above criteria
Neurofibromatosis Type 2
(The criteria are met by an individual who satisfies condition 1 or 2)
1. Bilateral masses of the eighth cranial nerve seen with appropriate imaging techniques (e.g., computed tomography or MRI)
or
2. A first-degree relative with NF2 and either:
a. Unilateral mass of the eighth cranial nerve, or
b. Two of the following:
Neurofibroma
Meningioma
Glioma
Schwannoma
Juvenile posterior subcapsular lenticular opacity

SOURCE: From Stumf et al.[1]

TABLE 190-1 **Diagnostic Criteria for Neurofibromatosis Type 1 and Type 2**

NEUROFIBROMATOSIS TYPE 1

NF1 or von Recklinghausen neurofibromatosis is one of the most common autosomal dominant disorders in man, primarily affecting cells of neural crest origin and resulting in developmental, pigmentary, and neoplastic abnormalities. NF1, a distinctive inherited disease, has fascinated physicians and scholars for many centuries. The earliest known model of NF1 appears in the form of a statue, which has been dated to Hellenistic times. [2] Artistic illustrations of individuals presumed to have NF1 have been portrayed in medieval woodcarving, [3] Renaissance drawings, [4] and in the literature of the last century. [5] Tilesius was the first to record the disease in 1793. [6] Von Recklinghausen gave the first organized description of the classic syndrome in 1882. [7] Unfortunately, because of misdiagnosis, NF1 has erroneously earned the reputation of being identical with the “Elephant Man's Disease,” thereby causing enormous stress among the individuals affected with NF1. [8] A posthumous diagnosis of Joseph Merrick, the “Elephant Man,” revealed that he suffered from Proteus syndrome. [9]

NF1 is a dynamic pathologic process with physical manifestations often present at birth and becoming more apparent with age. Although the age at which NF1 is diagnosed is not predictive of the possible serious consequences of the disorder, the age of onset of serious problems means a higher lifetime burden. Early diagnosis of NF1 is important as it provides the opportunity for genetic counseling and education of the patient and family about neurofibromatosis, awareness of the serious consequences of this disorder, appropriate medical follow-up, and early intervention.

Clinical Features

The cardinal features of NF1 are multiple neurofibromas, café au lait spots (CLS), axillary and inguinal freckling, and pigmented iris hamartomas (Lisch nodules). [10] In addition, the disease can be confounded by a broad spectrum of complications, such as various kinds of osseous lesions, stenosis of the renal arteries, aqueduct stenosis, optic glioma, and learning disabilities. Malignant progression of tumors developing in NF1 patients is a major cause of morbidity and mortality. [11]

Skin involvement in NF1 has many more aspects than are often appreciated. Patches of cutaneous pigmentation and multiple cutaneous tumors create the most conspicuous findings. There are two basic types of NF1 hyperpigmentation abnormalities: focal and diffuse. The latter involves virtually all of the skin. [10]

CLS have long been known as part of the syndrome of neurofibromatosis. In fact, the first sign of this condition may be the presence of CLS (Fig. 190-1). In most of the cases, CLS are obvious at birth, although their number and definition tend to increase during the first year of life. Subsequent increases in pigmented macules largely relate to freckling. [10] In older patients with NF1, fading of the CLS may occur. [12] It is important to recognize that a few CLS do not establish the diagnosis of NF1, because approximately 10 percent of the normal population has one to five CLS. [13]

FIGURE 190-1 Multiple café au lait spots distributed over the trunk of an infant.

The CLS of NF1 may occur randomly distributed anywhere on the body except the eyebrows, scalp, palms, and soles. When CLS are limited to a single unilateral segment, other forms of NF should be taken into account, for example, segmental NF. [14]

The café au lait macules vary in size, shape, and hue, but are darker than the normal color of the surrounding skin (Fig. 190-1). The typical CLS are 10 to 30 mm in diameter, ovoid in shape, and of uniform color whose intensity is proportionate to the background skin coloration. The lesions have sharp, well-defined borders that are usually smooth. In some instances in NF1, a CLS alters the appearance of the “Mongolian spot” on which it may be superimposed. [15]

There are a number of disorders other than NF1 in which multiple CLS may occur. These mainly include NF2; Watson syndrome; McCune-Albright syndrome; multiple lentigines syndrome; multiple neuroma syndrome [multiple endocrine neoplasia 2B (MEN2B)]; Bannayan-Riley-Ruvalcaba syndrome; tuberous sclerosis; Maffucci syndrome; and familial multiple café au lait spots (FCLS). Most can be distinguished from NF1 by other clinical features, although this can be difficult in young children. Careful and thorough examination is essential. [16]

The other form of characteristic skin pigmentation in NF1 is axillary freckling. Freckling of the inguinal region and other areas limited to intertriginous zones or sites of skin-to-skin contact also appear to be features unique to NF1. Freckling is usually acquired later in childhood and adulthood. [10] Axillary freckling is found in 81 percent of children with NF1 who are younger than 6 years of age. [17] In some patients with NF1, there may be innumerable freckles over the entire body. [18] The time course and location of freckles suggests that freckling develops by a different mechanism than CLS. [19]

It has been reported that CLS of NF1 patients have more melanocytes than does the surrounding skin. There is also increased activity of the melanocytes, and giant pigment (melanin) granules can be found in the majority of cases. Patients with NF1, compared to normal individuals, also have a higher melanocyte count in their normally pigmented skin. [20] The higher melanin content of NF1 melanocytes is a result of aberrant regulation of melanogenesis. [21] It is unknown, however, how the altered function of neurofibromin (the NF1 gene product) leads to increased melanogenesis in the skin melanocytes of NF1 patients. [22] It should be noted that giant melanin granules are not unique to neurofibromatosis and can be found in conditions such as McCune-Albright syndrome and multiple lentigines syndrome. [18] Consequently, biopsy of the CLS has little or no utility in making the diagnosis of NF1.

In another type of hyperpigmentation in NF1, the edges of the hyperpigmented patch are concordant or extend the borders of an underlying plexiform neurofibroma. These patches are darker than typical CLS. Congenital localized *hypertrichosis* of varying degrees may be present simultaneously. [23] The recognition of an *aberrant hair whorl* pattern overlying a paraspinal neurofibroma or vertebral dysplasias may assist the clinician in early diagnosis of these potentially severe complications of NF1. Scalp *hypotrichosis* or *alopecia* may be seen occasionally in association with tumors of the scalp. [10]

Although *hypopigmentation* is not specific for NF1, it may occur as small punctate macules and local areas of skin hypoplasia, or as *pseudoatrophic macules*. Histopathologic examination of these macules suggests that these macules are variants of neurofibromas. [24]

Individuals with NF1 maintain a velvety quality of the skin even in adulthood. [25] Laxity of the skin often gives the face a prematurely aged appearance. Patients with NF1 often show secondary creases in their fingertip and palmar crease pattern. [26]

Juvenile xanthogranuloma (JXG) is a rare benign cutaneous abnormality that occurs in childhood in 1 percent of young children with NF1. The presence of this lesion should raise the clinician's concern because there may be an excess of juvenile chronic myelogenous leukemia (JCML) occurring in children with JXG and NF1. [27], [28]

Multiple *neurofibromas* are a distinctive feature in patients with NF1. The sometimes impressive number and size of these tumors resulted in the original term *neurofibromatosis*. Neurofibromas virtually always involve the skin. They may

become evident as skin tags or nodules located in cutaneous or subcutaneous tissues, or as subcutaneous masses involving deep tissues. Neurofibromas are benign tumors of nerve sheath origin. They consist of Schwann cells, nerve fibers, fibroblasts, vascular elements, mast cells, and myxoid matrix. [29] There is no histologic difference between the neurofibromas of neurofibromatosis and solitary neurofibromas in persons without the syndrome. Although the tumors are often seen in small numbers in childhood, they tend to appear more extensively around puberty in both sexes and during pregnancy. [17], [30] Areolar neurofibromas occur in 80 percent or more of postpubertal women. [10]

There are four distinct types of neurofibromas. *Cutaneous* neurofibromas move with the skin and are the most common tumors in NF1. These lesions may become apparent as early as 4 or 5 years of age, although their occurrence in the 8- to 12-year-old range is more typical. [31] They are soft, flesh-colored, and not painful tumors that range in size from several millimeters to many centimeters in diameter (Fig. 190-2). They can invaginate into an underlying dermal defect with light digital pressure (button-holing). [13] This feature is a useful sign in distinguishing the lesions of this disease from other surface tumors, for example, multiple lipomas. Their clinical consequences include cosmetically distressing appearance and, in approximately 10 percent of patients, varying degrees of pruritus.

FIGURE 190-2 A large number of neurofibromas (cutaneous, subcutaneous) are scattered over the entire torso of a patient.

Subcutaneous neurofibromas are firm, rubbery, often painful tumors that are deeply seated in the dermis. They may be small (a few millimeters in diameter) or as large as 8 cm (Fig. 190-2). Approximately 20 percent of patients with NF1 have at least one subcutaneous neurofibroma, and approximately 25 percent of these patients will have serious problems as a result.

Nodular plexiform neurofibromas are essentially a network clustering of large subcutaneous neurofibromas. They may be palpated as firm, usually tender, nodules along nerve plexuses or dorsal nerve roots (Fig. 190-3). As a serious consequence of neurofibromas extending through the vertebral foramina, disfigurement of the vertebra, scoliosis, vertebral collapse, and compression of the cord may occur, resulting in severe neurologic deficits. Involvement of the dorsal nerve roots and major nerves may be associated with severe pain and neurologic compromise. [10]

FIGURE 190-3 Right knee of NF1 patient showing a large, diffuse plexiform neurofibroma.

Approximately 5 percent of NF1 patients have *diffuse plexiform* neurofibromas, which are virtually always of congenital origin (though often not immediately visible) and are thought to be the hallmark of this condition (Fig. 190-4). Diffuse plexiform neurofibromas are highly vascular, and may involve all the layers of the skin, the immediately adjacent fascia, and deeper elements, at times even replacing whole sections of muscles, eroding bony structures, and infiltrating visceral elements. Small or modest-sized neurofibromas may actually be contiguous with extensive lesions in the mediastinum or retroperitoneum. [31] A common feature of plexiform neurofibroma is a localized or segmental hypertrophy of adjacent connective tissues including enlargement of the underlying bone. [18] Diffuse plexiform neurofibromas are often associated with overlying hyperpigmentation and hypertrichosis. When these skin changes overlap the neuroaxis, evaluation of spinal involvement is mandatory. [27] Visceral involvement with diffuse plexiform neurofibromas may lead to various complications such as constipation, bleeding, and obstruction. [10]

FIGURE 190-4 The left arm of NF1 patient demonstrates extensive nodular plexiform neurofibroma.

Plexiform neurofibromas tend to infiltrate diffusely the nerve and have an increased risk of progressing to neurofibrosarcoma, also termed *malignant peripheral nerve sheath tumor* (MPNST), in as many as 5 to 6 percent of affected individuals. These tumors are highly malignant and carry a poor prognosis. [11] Such malignant transformation in a known neurofibroma is often heralded by either physical or radiologic evidence of sudden growth or a rapid progression in clinical symptoms (pain and neurologic deficit).

Other tumors that commonly lead to confusion in the differential diagnosis of NF1 are schwannomas, lipomas, and angiolipomas. Multiple schwannomas require the consideration of NF2, regardless of the presence or absence of skin pigmentation abnormalities, although multiple schwannomatosis may be a strong alternative. [32], [33] Multiple lipomas, often associated with other tumors, including central nervous system tumors, are exemplified in Bannayan-Ruvalcaba-Myhre syndrome. This syndrome may be similarly confused with NF1. [34]

There are no specific treatments for neurofibromas. Surgery is palliative, not curative, and multiple procedures are expected due to the progressive nature of these tumors. Surgical removal of these tumors solely for cosmetic reasons is inappropriate and unnecessary. However, there are many reasons for removing neurofibromas, including excessive size, pain, and/or prominent cosmetic disfigurement. This is true for superficial as well as deep tumors, but in the latter case, a diagnostic biopsy may be another consideration because the tumor cannot be visualized or palpated for characterization. [10]

Some of the symptoms associated with these tumors are more bothersome than the tumors themselves. Generalized itching or itching localized to newly developing neurofibromas has been described in the literature. [10] There is a significant increase in mast cells in neurofibromas. Mast cells influence the growth of neurofibromas, because some of their mediators also act as growth factors. [35] One study showed that ketotifen, a mast cell stabilizer, decreased the rate of neurofibroma growth, pruritus, pain, and tenderness. [36] Another interesting observation is that trauma seems to be the initiating or aggravating event in the growth of neurofibromas. [10] It had been shown that in NF1, trauma results in an inadequate repair process during wound healing. Strategies to confound wound healing gone awry are likely to provide the earliest effective treatments of patients with NF1. [37], [38]

Certain ophthalmic manifestations (Lisch nodules, optic glioma, and sphenoid dysplasia) account for three of the six diagnostic criteria of NF1. *Lisch nodules* (Fig. 190-5) (multiple iris melanocytic hamartomas), presenting as small yellow-brown lesions on the surface of the iris, are the most common manifestation and have crucial diagnostic value. Lisch nodules are the only ocular findings that do not cause visual dysfunction. Lisch nodules are useful for confirming or discounting the diagnosis of NF1. They are present in 94 percent of patients who are 6 years of age or older. [39] Recently, it was pointed out that choroidal abnormalities are another commonly occurring ocular complication manifested by choroidal nodules seen under infrared light. [40]

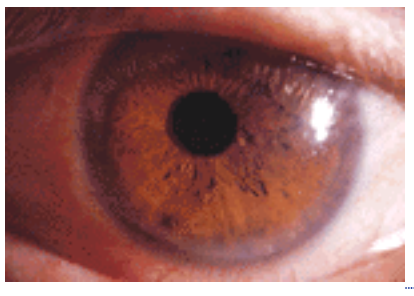

FIGURE 190-5 Lisch nodules in a patient with NF1.

Optic gliomas, a form of astrocytoma, are the most frequent central nervous system (CNS) complications in NF1 during early childhood, with an incidence of 10 to 15 percent. [41] These tumors may arise anywhere along the optic pathway. [42] The natural history of these tumors is not well understood. Two-thirds of these tumors are asymptomatic, and their mitotic activity is low and generally does not undergo malignant progression. A small subgroup of optic gliomas, however, appears with progressive vision loss, and/or proptosis associated with the expanding tumor. Mass lesions of the optic nerve and tract are neither biopsied nor treated unless clinical progression is documented. Optic gliomas are best demonstrated by magnetic resonance imaging (MRI). [43]

Characteristic congenital, and usually unilateral, bony defect in the posterior wall of the orbit is caused by *sphenoid dysplasia* and often results in pulsating exophthalmos. One may mistake this condition for an orbital tumor.

The skeletal system involvement in NF1 is also exemplified by the relative high frequency of macrocephaly and short stature. *Pseudoarthrosis* of long bones (usually the tibia or fibula) is an infrequent but distinctive congenital skeletal abnormality in NF1. [44] Appreciation of its significance should be helpful to the clinician who is faced with a patient who has subtle manifestations of this complex disease. The spectrum of this bony anomaly may range from mild bowing of the tibia to thinning of the cortex, which eventually predispose to pathologic fractures and false joint formation (Fig. 190-6). Early detection of this complication allows early treatment and prevents severe compromise of the affected limb.

FIGURE 190-6 Plain radiographs of the lower extremities of an NF1 patient. Note moderately severe tibial bowing.

Complications of NF1, other than pigmentary or tumor related, include endocrine disturbances and a variety of vasculopathies. Vascular pathology is an underestimated complication of NF1. Manifestations may include cardiovascular abnormalities, renovascular stenosis with associated hypertension, cerebrovascular occlusion, visceral ischemia, and aneurysms of smaller arteries. [45]

In NF1, the incidence of mental retardation (full-scale IQ <70) is estimated to be between 4 and 8 percent. NF1 involves a range of neurophysiologic deficits that are not limited to any one domain. Attention deficit and hyperactivity disorders are as common as impaired neuromotor skills. Cognitive difficulties include expressive and receptive language impairment, reading problems, spelling problems, deficient visual-spatial skills, and executive dysfunction. [46] These prevalent complications are estimated to occur in 30 to 50 percent of affected children. [47] The pathogenesis of learning disabilities in children with NF1 remains obscure. These special deficits may or may not be related to the severity of the clinical manifestations of NF1; therefore, mildly affected NF1 children should also be monitored for learning disabilities and behavioral problems. Care providers should attend to the psychoeducational needs of NF1 patients with the same rigor they impart to serving their physical needs.

A common neuroradiologic abnormality, high-signal abnormalities on T_2-weighted MRI, so-called UBSs (*u*nidentified *b*right *s*ignals), are found in the basal ganglia, cerebellum, and brainstem of more than 60 percent of patients with NF1. [48] These lesions are not visible with computed tomography (CT) scans. The impact of UBSs on measures of cognitive and academic performance is controversial. [49], [50]

There is an increased incidence of specific cancers in approximately 2 to 5 percent of affected NF1 individuals. These include MPNST and Triton tumor (a variant of MPNST), malignant gliomas, and extraneural malignancies such as pheochromocytoma, carcinoid tumors, rhabdomyosarcoma, and juvenile chronic myeloid leukemia. [51], [52] There is no increased incidence of malignant melanoma. Meningiomas, so characteristic of NF2, however, are not seen in NF1. [10]

Genetics of NF1

NF1 exemplifies many of the fundamental principles of classical genetics. It is inherited in an autosomal dominant manner; therefore affected individuals have a 50 percent risk of transmitting the disorder to their offspring. NF1 appears to affect all races, ethnic groups, and both sexes, and has an estimated incidence of 1 in 3000. NF1 has a rate of new mutations of approximately 1 in 10,000, one of the highest described for a human disorder. Approximately half of all index cases of NF1 have no family history of NF1 and are, therefore, thought to arise as a result of mutation in the sperm or egg of the parents. [13] Gene penetrance is virtually 100 percent by the age of 5 years. [53] The pleiotropic and protean manifestations of NF1 affect many different organ systems. Variable expression is observed in inter- and intrafamilial cases, which makes it difficult to predict clinical severity and complications of the disease in offspring of an affected parent. [54]

The *NF1* gene is located on chromosome 17 at band q11.2. [55] There is no locus heterogeneity in NF1. The gene, which is a tumor-suppressor gene, has been cloned and well characterized. Neurofibromin, the protein product of the nonmutated gene, shares sequence and functional homology with the group of Ras-GTPase-activating proteins (Ras-GAP family). Neurofibromin is capable of downregulation of the cellular p21-Ras protooncogene. [56] The loss of neurofibromin function produces increased mitogenic signaling, which may lead to uncontrolled cell growth or tumor formation. [57]

Numerous types of mutation in different parts of the *NF1* gene have been detected to date. There is no indication that the mutations are concentrated in any region of the gene (NF1 Genetic Analysis Consortium). The majority of the mutations within the *NF1* gene give rise to diminished function of neurofibromin in affected persons. No phenotype-genotype correlation has been established, except for cases in which deletion has removed the entire *NF1* gene, thereby resulting in facial dysmorphia, early onset of a large number of neurofibromas, and dull intelligence. [58]

Diagnosis and Management

A definite diagnosis of NF1 is commonly made on clinical grounds, based on NIH diagnostic criteria. Young children who present with six or more CLS, but without other physical findings or family history of NF1, may pose clinical dilemmas. Such children must be followed to look for the appearance of other manifestation of NF1. Most of these children turn out

to have NF1.

No single diagnostic test for *NF1* mutations is sufficient as a “stand-alone test,” and the identification of the majority of *NF1* mutations requires a combination of tests. Routine clinical application of DNA analysis in the diagnosis of NF1 is not yet a reality. Linkage studies using DNA markers in the molecular diagnosis of certain families with NF1 are not possible when there is only one affected individual in the family, as is often the case for NF1. [59] Recently, a new commercially available assay for *NF1* gene mutations has been developed that relies on a protein truncation test (PTT). Conformation of the *NF1* mutation in individuals with abnormal PTT fragments requires direct DNA sequencing. The use of PTT without DNA sequencing risks false-positive results. Also, the ability of the PTT to detect mosaic mutations remains untested. Unfortunately, NF1 exhibits much clinical variability within families, and these tests will tell only if an individual at risk is affected, but not how severely the individual will be affected. [60] Genetic counseling should be provided for anyone who is tested, so that the limitations of the assay are clearly understood. [61] Future research may facilitate improved DNA or biochemical diagnostic testing.

The effect of the complications in NF1 often leads to involvement of a multitude of subspecialists in the care of these patients. It is in the best interest of patients with NF1 to improve the coordination of their care by clinicians who have an expertise with the neurofibromatoses. Because there is no cure for NF1 at the present time, the main goal is the early detection of the various complications, intervention, and genetic counseling (Table 190-2). Routine follow-up is necessary, with the interval of these visits dependent on pertinent medical problems.

TABLE 190-2 **Clinical Features, Their Consequences, and Associated Complications in Neurofibromatosis Type 1 (NF1)**

Related Conditions

Segmental NF should be considered in individuals who have features of neurofibromatosis confined to a particular region of the body. [14] Segmental NF is postulated to arise from a somatic mutation in the NF1 gene early in embryo development. Segmental NF is less common than NF1, and is also more easily overlooked. Patients with segmental NF may have a child with classical NF1 because of germinal mosaicism. [62]

Watson syndrome is a variant of NF1 that features multiple CLS, only a small number of neurofibromas, short stature, pulmonary valvular stenosis, and dull intelligence. Molecular analysis in a few cases of Watson syndrome has shown a large deletion in the NF1 gene. [58]

Certain features *of Noonan syndrome* (characteristic face, pectus excavatum, short stature) have been observed in a subset of patients with NF1. Although it is likely that some features of these two common syndromes may overlap, a recent linkage study of several families showed that NF1 and Noonan syndrome are genetically distinct. [63]

NEUROFIBROMATOSIS TYPE 2

NF2, previously known as central neurofibromatosis or bilateral acoustic neuromas, is characterized by multiple slow-growing nervous system tumors, particularly schwannomas and meningiomas. The hallmark of NF2 is the development of bilateral vestibular schwannomas. NF2 is much less common than NF1, and has an estimated frequency of 1 in 50,000. [32] NF2 is an autosomal dominant disease with penetrance greater than 95 percent, so that for any offspring of an affected parent, the risk that these tumors will develop is approximately 50 percent. [64] In as many as 75 percent of NF2 cases there is no family history of the disease, and these may represent spontaneous mutations. [65] NF2 was once thought to be a form of NF1. [66] NIH Consensus Developmental Conferences (1987), however, provided clear guidelines on nomenclature, and recommended the use of the term neurofibromatosis type 2 (Table 190-1). This document also suggested substitution of the term “vestibular schwannoma” in the place of the term “acoustic neuroma,” so as to reflect the anatomic origin of these tumors. [1] Preliminary evidence suggests that there are two subtypes of NF2: a milder (Gardner) variant, and an intermediate or severe (Whishart) type. [67]

The skin manifestations in NF2 are less prominent than in NF1. Café au lait spots in NF2 tend to be fewer in number and show less distinct hyperpigmentation. Intertriginous freckling is not present. Other skin findings in NF2 include cutaneous and subcutaneous schwannomas. The most common of these is a superficial, discrete, slightly raised papule. The surface of the papule is rough, and is often pigmented and covered by excess hair. [32] Subcutaneous schwannomas are

often spherical tumors that occur on peripheral nerves. The thickened nerve can often be palpated at either end of the tumor. [65] The least-common cutaneous manifestations in NF2 are neurofibromas. Peculiarly, the palm of the hand and the lateral alae nasi are frequent sites of these tumors. Plexiform neurofibromas are distinctly unusual in NF2.

Dorsal nerve root paraspinal schwannomas are a relatively constant feature of NF2. They are the major source of morbidity from direct compromise of the involved nerves and by centripetal growth and compromise of the spinal cord. [68]

Schwannomas may occur on any of the cranial nerves except for the olfactory nerve. [65] Patients with NF2 tend to develop vestibular schwannomas, which are acoustic tumors arising from neural covering. Symptoms related to vestibular schwannomas are usually a result of pressure on the vestibulocochlear and facial nerve complex. In NF2, symptoms usually first begin in the second or third decade. However, occasionally patients may present as early as the first or as late as the seventh decade. [32] The first symptom is usually loss of hearing, which may be accompanied by intermittent tinnitus, unsteadiness, and facial weakness. Other tumors in NF2 include intracranial meningiomas, gliomas, and ependymomas. Spinal cord meningiomas and astrocytomas are common, in contrast to NF1. Meningiomas in NF2 tend to be bilateral and occur at a younger age than their sporadic counterparts. It is of interest that malignancies do not appear to be prevalent in NF2. [68] There is no evidence to suggest that mental function is impaired as a consequence of NF2.

The spectrum of ocular abnormalities of NF2 has only recently received attention. Presenile posterior cortical cataracts are highly specific for NF2. These lens opacities have little visual significance; however, their presence in an individual at risk may give a clue to the diagnosis of NF2. A host of other ocular manifestations, including retinal hamartomas, optic disk glioma, optic nerve meningioma, and eyelid ptosis, can impair the vision of patients with NF2. [69] Lisch nodules are extraordinarily rare in NF2.

The genetic defect that underlies NF2 has been localized to the long arm of chromosome 22, [70] and the gene responsible for NF2 has been cloned and characterized. The gene codes for a protein designated as “merlin” or “schwannomin,” which belongs to a superfamily of membrane organizing proteins. [71] Analysis of tumoral DNA from both NF2-associated and sporadic meningiomas and schwannomas demonstrates chromosome 22 deletions and inactivation of the merlin protein. This strengthens the argument that the *NF2* gene acts as a tumor suppressor. [72] However, the role of merlin in tumor suppression is still obscure. There is some evidence that genotype-phenotype correlation exists for certain *NF2* mutations. [73], [74]

As the course of NF2 is variable, once a patient is diagnosed as having NF2, a number of tests and procedures may be helpful to define the nature and progression of the disease in that individual. These include regular monitoring for CNS tumors (particularly, vestibular schwannoma, meningiomas, and spinal cord tumors) and for related functional impairments (hearing loss, focal neurological signs). MRI of the head and spine is the neurodiagnostic modality of choice in patients with known or suspected NF2. The natural history of NF2 is such that the onset of auditory and visual symptoms is often delayed, not infrequently until childbearing age. [75] Examination of high-risk patients may suggest the diagnosis before symptomatic CNS tumors arise, allowing genetic counseling and family planning.

Early detection of *NF2* gene mutation carriers has become possible by using linkage analysis in familial NF2. [76] For simplex cases, direct gene testing is becoming increasingly available. [77]

Treatment of vestibular schwannomas is aimed at preserving hearing. Presently the only treatments that are available for the tumors of NF2 are surgery and specialized radiation therapy. The timing of surgery is difficult to determine. However, early diagnosis allows for earlier surgical intervention and resection of subclinical vestibular schwannomas.

Multiple schwannomatosis is a disorder characterized by the development of multiple schwannomas in a variety of anatomical locations involving the skin, the spinal cord, or both, in the absence of CLS, neurofibromas, or other stigmata of NF1, and without evidence of vestibular tumor diagnostic of NF2. [78] In addition, various types of multiple schwannomatosis, including *multiple cutaneous plexiform schwannomas,* exist. These tumors have a growth pattern similar to that seen in plexiform neurofibroma, but do not have an association with progression to malignant peripheral nerve sheath tumor.

Recent molecular studies have shown that some forms of multiple schwannomatosis appear to be variant forms of NF2, but not all instances of multiple schwannomas are necessarily NF2. [79]

Familial meningiomas, without other features of NF2, represent yet another distinct entity, with its separate gene locus on the long arm of chromosome 22 (not too distant from the NF2 locus). [80]

Ataxia-Telangiectasia

ETIOLOGY AND PATHOGENESIS
CLINICAL FEATURES
PATHOLOGY
DIFFERENTIAL DIAGNOSIS
LABORATORY FINDINGS
TREATMENT

REFERENCES

Ataxia-telangiectasia (AT) [MIM 208900], also called Louis-Bar syndrome, is an autosomal recessive disorder (incidence, 1:40,000) that is characterized by cerebellar ataxia, oculocutaneous telangiectases, recurrent sinopulmonary infections including bronchiectasis, immunodeficiency, and the development of lymphoreticular malignancies. [1]

ETIOLOGY AND PATHOGENESIS

In normal mammalian cells, exposure to ionizing radiation results in a delay in both progression from G1 to S phase and of G2 into M, and transient inhibition of DNA synthesis. AT cells in culture have abnormal radioresistant DNA synthesis and fail to activate either G1/S or G2/M checkpoints in response to ionizing irradiation. [2] As a result, AT cells demonstrate chromosomal instability and hypersensitivity to ionizing radiation and radiomimetic agents such as bleomycin. Responses to ultraviolet irradiation are normal.

The identification of the *ATM* gene and the functions of the protein that it encodes enables a more complete understanding of the molecular and clinical pathophysiology of the disease. [2], [3] The gene for the ataxia-telangiectasia phenotype maps to chromosome 11q22.3, a site involved in the chromosome translocations observed in the lymphoreticular malignant cells of patient with AT. Five AT complementation groups, all mapping to 11q22.3, have been identified.

The ATM protein is a 350-kDa phosphoprotein that resembles the phosphatidylinositol-3-kinases, and participates in checkpoint regulation. The gene has 66 exons and spans 150 kb of genomic DNA. More than 400 different *ATM* mutations have been identified in patients with AT.

The tumor-suppressor protein p53 has a major role in allowing passage through the G1/S checkpoint, which tests DNA integrity before initiation of new DNA synthesis and protects against strand breaks after immunoglobulin gene rearrangement. ATM phosphorylates p53 after induction by ionizing radiation, thus allowing cell cycling. The lack of induction of p53 may explain why intrachromosomal recombinant rates in AT cells are 30 to 200 times higher than in normal cells. [4] ATM is also associated with the synaptonemal complex of meiotic chromosomes, which may explain gonadal atrophy in AT. [5] The many other possible substrates for ATM and involvement in signaling complexes such as c-Abl and NF-?B signaling, may explain many other features of AT, such as cytoskeletal defects and insulin signaling abnormalities that are difficult to relate to DNA damage responses alone.

CLINICAL FEATURES

Characteristic oculocutaneous telangiectases begin near the ocular canthi and progress across the bulbar conjunctivae (Fig. 191-1). These telangiectases usually appear when patients are 3 to 6 years of age; rarely have they been described at earlier ages. Cutaneous telangiectases subsequently may develop on the malar prominences, ears, eyelids, anterior chest, popliteal and antecubital fossae, and the dorsa at the hands and feet (Fig. 191-2). The telangiectases may be subtle and resemble fine petechiae, especially in the flexural areas. The development of telangiectases may be related to sun exposure, because ocular, but not cutaneous, telangiectases develop in affected dark-skinned children, although the underlying mechanism for any ultraviolet light induced damage is unclear.

FIGURE 191-1 Bulbar conjunctival telangiectases in a patient with ataxia-telangiectasia. (*From Paller AS: Hereditary immunodeficiency disorders, in Genetic Disorders of the Skin, edited by JC Alper. Chicago, Mosby Year Book, 1991, p 105, with permission.*)

FIGURE 191-2 Ataxia-telangiectasia. Telangiectases inside and on the helix.

Progeric changes of the skin, including xerosis and gray hair, occur in 90 percent of patients. [6] During adolescence, the facial skin may become progressively more atrophic and sclerotic, causing a masklike appearance. Occasionally, the ears, arms, and hands also become sclerodermatous. The hair may be diffusely gray by adolescence, and subcutaneous fat is generally lost in childhood. Recurrent severe impetigo often develops in patients with AT. Seborrheic dermatitis occurs in many patients, and the associated blepharitis may lead to a diagnosis of blepharoconjunctivitis rather than ocular telangiectasia. Mottled hyper- and hypopigmentation frequently occur and, together with the telangiectases and atrophy, can resemble the poikiloderma of radiodermatitis, actinic damage, or scleroderma. Other pigmentary changes include café au lait spots that may be found in a dermatomal distribution, [7] multiple ephelides, and vitiligo. Hypertrichosis of the arms and legs, alopecia areata, multiple warts, atopic dermatitis, keratosis pilaris, nummular eczema, and acanthosis nigricans have also been described in association with AT. Among the most common cutaneous manifestations are noninfectious cutaneous granulomas (Fig. 191-3). [7] These persistent, atrophic, and often ulcerative lesions are often mistaken for other granulomatous processes, including sarcoidosis, necrobiosis lipoidica diabeticorum, granuloma annulare, and granulomatous dermatitis. Intralesional injections of triamcinolone have helped to promote healing of the painful associated ulcerations, although the lesions do not clear completely with treatment.

FIGURE 191-3 Noninfectious granulomatous dermatitis of a patient with ataxia-telangiectasia. These painful persistent lesions tend to ulcerate.

Usually, the progressive cerebellar ataxia first becomes apparent during infancy (median age, 1.2 years) with swaying of the head and trunk and apraxia of eye movements often years before skin or conjunctival abnormalities develop. In childhood, dysarthric speech, drooling, choreoathetosis, and myoclonic jerks become prominent. The gradual development of a persistent cerebellar ataxia, appearing in the first few years of life, should alert the clinician to ataxia-telangiectasia. Close inspection of the limbs shows none of the usual features of cerebellar ataxia, that is, dysmetria, lack of synergism of component muscle groups involved in skilled acts, hypotonia, or intention tremor. The diagnosis of AT is usually made at a median age of 7 years, after appearance of the mucocutaneous telangiectasia. Once fully developed, the neurologic features of AT include slow, dysarthric speech, impassive face, nystagmus, choreoathetosis, occasionally myoclonic jerks of the limbs, difficulty in initiating ocular deviation from the central position, and poor voluntary control of eye movements (apraxia of gaze). Tendon reflexes are diminished or absent; intelligence may deteriorate as the disease advances. Patients usually require a wheelchair by their teenage years.

Recurrent bacterial and viral sinopulmonary infections occur in up to 80 percent of patients; these are the most common cause of death, which is usually from bronchiectasis and respiratory failure. Approximately 75 percent of patients with AT may have growth retardation and endocrine disorders, especially ovarian agenesis or testicular hypoplasia and insulin-resistant diabetes. Malignant lymphoreticular neoplasms develop in 10 to 15 percent of patients, usually by adolescence, particularly the lymphomas of B cell origin and the T cell chronic lymphocytic leukemia. [8], [9]

Heterozygotes for the *ATM* gene (1 percent of the US population) are at increased risk for neoplasia, especially female breast cancer (up to fivefold relative risk). [10], [11] Heterozygotes show increased risk of chromosomal breaks after exposure to irradiation in vitro, suggesting that mammograms in known carriers of AT are contraindicated.

PATHOLOGY

Autopsy findings indicate that approximately 50 percent of the patients die from pulmonary disease and that most of the remainder die from lymphoreticular or other malignant tumors; the thymus is absent or hypoplastic, and the spleen may be reduced in size. The significant pathologic abnormalities in the central nervous system are severe degeneration in the

cerebellar cortex, loss of myelinated fibers in the posterior columns, and degenerative cell changes in the posterior root and sympathetic ganglia.

DIFFERENTIAL DIAGNOSIS

Ataxia-telangiectasia is one of a group of diseases characterized by defects in the repair process of DNA damage. The others are xeroderma pigmentosum, Bloom's syndrome, and Cockayne's syndrome (see Chap. 155). In fibroblast cultures from patients with ataxia-telangiectasia, several complementation groups have been found, suggesting clinical heterogeneity. Patients with the Nijmegen breakage syndrome show radiation sensitivity with radio-resistant DNA synthesis, chromosomal instability, and an increased risk of cancer, but have microcephaly rather than progressive ataxia as their neurologic abnormality. Nijmegen breakage syndrome results from mutations in the *NBS1* gene, which encodes a 95-kDa protein involved in repair of double-stranded breaks that is phosphorylated by ATM. [12]

LABORATORY FINDINGS

Patients with AT tend to have both humoral and cellular immunologic abnormalities. Serum IgA and IgE are absent or deficient in the majority of patients. Circulating anti-IgA antibodies are common in patients with IgA deficiency. Defective cell-mediated immunity is found in 70 percent of patients; T cells bearing gamma/delta receptors are increased in number. Virtually all patients have elevated levels of a-fetoprotein, and many have detectable carcinoembryonic antigen. Patients with AT often have elevated hepatic transaminases (40 to 50 percent), and glucose intolerance.

Spontaneous chromosomal abnormalities (fragments, breaks, gaps, and translocations) occur 2 to 18 times more frequently in patients with AT than in normal individuals and mainly involve chromosomes 2, 7, and 14. Rearrangements of chromosomes 7 and 14, and especially 14:14 translocations, seem to predict the development of lymphoreticular malignancy including leukemia.

TREATMENT

The therapy for AT is supportive and includes administration of antibiotics for infection, physiotherapy for pulmonary bronchiectasis, physical therapy to prevent contractures in patients with neurologic dysfunction, and sunscreens and sun avoidance to diminish actinic-like changes. Lymphoreticular malignancies, including lymphoid leukemia, are the second most common cause of death, leading to the deaths of 15 percent of patients with AT. Therapeutic radiation and radiomimetic chemotherapeutic agents, especially bleomycin, may lead to extensive tissue necrosis. The administration of small doses of other chemotherapeutic drugs and low-dose, fractionated radiation is the least harmful means of managing these malignancies. Death usually occurs by late childhood or early adolescence; the oldest surviving patient died at the age of 50 years.

Prenatal diagnosis has been achieved by measurement of amniotic a-fetoprotein levels, by increased spontaneous breakage of chromosomes of fetal amniocytes, by the presence of a clastogenic factor in the amniotic fluid, [13] and by detection of the DNA defect.

COURSE AND PROGNOSIS

REFERENCES

Behçet's disease is a complex multisystem disease of unknown etiology characterized clinically by oral and genital aphthae, arthritis, cutaneous lesions, and ocular, gastrointestinal, and neurologic manifestations. The diagnosis is made by clinical criteria, as no pathognomonic laboratory tests exist. The absence of inflammatory bowel disease and collagen vascular diseases must be documented.

HISTORIC ASPECTS

Approximately 2,400 years ago Hippocrates used the designation *aphthai* to refer to common oral aphthae (canker sores), and he may have described the first patient with Behçet's disease. The disease is named after Hulusi Behçet, a Turkish dermatologist, who, in 1937, described patients with recurrent orogenital ulcerations and uveitis. [1] The first international multidisciplinary conference on Behçet's disease was organized by two dermatologists, Drs. Monacelli and Nazarro, in Rome, in 1964.

EPIDEMIOLOGY

The prevalence of Behçet's disease is highest in Japan, Southeast Asia, the Middle East, and southern Europe (along the so-called silk route from eastern Asia to the Mediterranean Basin). [2], [3] The disease is uncommon in northern Europe, the United States, and the United Kingdom. Behçet's disease most often affects patients in their twenties and thirties, but can occur at any age. [4] There seems to be a slight male predominance, but this finding varies from one country to another. [5] Behçet's disease occurs in children, albeit less frequently than in adults; girls and boys appear to be affected equally. [6]

ETIOLOGY AND PATHOGENESIS

Genetics

A significant association exists between Behçet's disease and human leukocyte antigen (HLA)-B51 in Japan, the Middle East, and the Mediterranean countries; however, this relationship is not as strong in Western countries. [5] The allele also seems to be associated with a more severe prognosis. Familial clustering of Behçet's disease is not common but is reported. [7]

Infectious Precipitants

Early theories of the pathogenesis of Behçet's disease proposed a viral or other infectious etiology. [1] Homology between the DNA of herpes simplex virus type 1 (HSV-1) and the RNA of peripheral blood lymphocytes from patients with Behçet's disease was reported. HSV-1 DNA was detected with polymerase chain reaction (PCR) in genital ulcers of patients with Behçet's disease. [4] Another study used PCR to detect HSV in saliva of patients with Behçet's disease and found no differences between those with and without oral ulceration. [8] Some evidence suggests a role of *Streptococcus* species in Behçet's disease. [9]

Immunologic Aspects

Early studies demonstrated autoantibodies reactive to oral mucosal antigens in patients with Behçet's disease. [10] The roles of immunologic mediators, including tumor necrosis factor (TNF), interleukin 1 (IL-1), IL-2 receptor, and soluble CD8 antigen, [11] ?d T cells, [12] and late expression of Fas antigen on CD4 and CD8 T cells [13] have been investigated. In addition to defective T cell immunity, B cell activation is impaired. [4]

Nazzaro [14] demonstrated that the earliest histology from aphthae, pustular vasculitic lesions, and erythema nodosum-like lesions is what we would now call a neutrophilic vascular reaction or even fully developed leukocytoclastic vasculitis, and

these findings have been confirmed. [15] Approximately 50 percent of patients with Behçet's disease have a significantly higher number of circulating immune complexes when compared to control subjects. [16] Light, immunofluorescence, and electron microscopic studies support a neutrophilic vascular reaction or even fully developed leukocytoclastic vasculitis as the earliest finding in mucocutaneous lesions. [14], [15] Pathergy lesions (cutaneous pustular vasculitis lesions induced by intradermal trauma) show a neutrophilic vascular reaction or leukocytoclastic vasculitis in a biopsy specimen obtained 24 h after histamine injection and on direct immunofluorescence usually show immunoreactants in biopsy specimens obtained 4 h after histamine injection. [15] Studies repeatedly suggest increased migration of neutrophils to chemoattractants in Boyden chamber or subagarose assays, and experiments in HLA-B51 transgenic mice show a similar phenomenon. [17], [18] Neutrophil adhesion to endothelial cells has been another important area of investigation. [19] The therapeutic benefit of colchicine, a drug that inhibits neutrophil migration and phagocytosis, may be a result of a blockade of the ability of neutrophils to hyperrespond to serum from patients with Behçet's disease.

CLINICAL MANIFESTATIONS

Mucocutaneous Lesions

Oral and genital aphthae, required for the diagnosis of Behçet's disease, are the most frequently observed mucosal manifestation and often are the presenting sign. [3], [5], [20] The typical lesion is painful, 1 to 3 cm in diameter, with a yellow fibrinous base. [11] The aphthae usually heal without scarring (Fig. 192-1A). Genital aphthae are similar in appearance to those that occur on the oral mucosa, but may not recur as often (Fig. 192-1B). [11] Herpes simplex should be excluded with appropriate Tzanck preparation, viral culture, or even skin biopsy.

FIGURE 192-1 Behçet's syndrome. *A.* On the labial mucosa there are painful aphthous-type ulcerations. *B.* Large, painful aphthous-type ulcer on the vulva.

Cutaneous lesions that should be accepted as diagnostically relevant in Behçet's disease should be confined to pustular vasculitis lesions (including pathergy lesions), erythema nodosum-like lesions, Sweet's-like lesions, pyoderma gangrenosum-like lesions, and palpable purpuric lesions of necrotizing venulitis (Fig. 192-2). All these lesions are characterized in their early stages by a neutrophilic vascular reaction. Acneiform lesions or follicle-based pustules should not be considered relevant. [21], [22]

FIGURE 192-2 Pustular vasculitic lesions on the hand of a patient with Behçet's disease.

Systemic Lesions

Ocular involvement is the major cause of morbidity in patients with Behçet's disease. The most diagnostically relevant lesion is posterior uveitis (called retinal vasculitis in Great Britain), which can lead to blindness. Other ocular lesions include anterior uveitis, hypopyon (pus in the anterior chamber of the eye, which is uncommon), and secondary complications such as cataracts, glaucoma, and neovascular lesions. [23]

The characteristic arthritis is a nonerosive, asymmetric oligoarthritis; however, symmetric polyarticular involvement is common. [3] Patients with HLA-B27–positive, erosive sacroiliitis have been included in some series of patients with Behçet's disease, but their condition is more appropriately considered as part of the Reiter's enteropathic arthritis spectrum of disease.

Significant neurologic manifestations occur in fewer than 25 percent of patients and may be delayed in onset. Meningoencephalitis, cerebral venous sinus thrombosis, benign intracranial hypertension, cranial nerve palsies, brainstem lesions, and pyramidal or extrapyramidal lesions have all been described. Poor prognosis is associated with a progressive course, relapse after treatment, repeated attacks, and cerebellar symptoms or parenchymal disease. [24], [25]

Systemic vascular involvement can be significant and includes aneurysms, arterial occlusions, venous occlusions, and varices that can be fatal. [26] Pulmonary artery aneurysms are the principal feature of pulmonary involvement in Behçet's

disease. [27] Cardiac involvement can include myocarditis, coronary arteritis, endocarditis, and valvular disease. [28] A wide spectrum of renal manifestations can occur, varying from minimal change disease to proliferative glomerulonephritis and rapidly progressive crescentic glomerulonephritis. [29] Immune complex deposition is thought to be responsible for the underlying pathogenesis in some cases of glomerulonephritis. [29] Aphthae may be present throughout the gastrointestinal tract and can result in perforation. Some patients with inflammatory bowel disease have been included in series of patients with Behçet's disease, but these cases are best excluded.

LABORATORY EVALUATION

There are no pathognomonic laboratory abnormalities in patients with Behçet's disease. Laboratory abnormalities may occur in association with dysfunction of various organ systems, depending on clinical disease manifestations.

HISTOPATHOLOGY

Characteristic histopathologic features of Behçet's disease are vasculitis and thrombosis. [11] Biopsies from early mucocutaneous lesions show a neutrophilic vascular reaction with endothelial swelling, extravasation of erythrocytes, and leukocytoclasia, or a fully developed leukocytoclastic vasculitis with fibrinoid necrosis of blood vessel walls. [14], [15], [21], [22] Although there are reports of lesions in patients with Behçet's disease that consist primarily of a lymphocytic perivasculitis, [30] most of these lesions are likely older. The neutrophilic vascular reaction should be considered the predominant histopathologic finding. [21]

DIAGNOSIS

Behçet's disease is a complex multisystem disease that must be diagnosed by clinical criteria in the absence of a pathognomonic laboratory test or histologic finding. Patients must have oral aphthae plus at least two of the following: genital aphthae, synovitis, posterior uveitis, cutaneous pustular vasculitis (see Fig. 192-2), or meningoencephalitis. The absence of inflammatory bowel disease, systemic lupus erythematosus, Reiter's disease, and herpetic infections must be confirmed.

Criteria were published in 1990 by the International Study Group and their usefulness has been validated. [31] These criteria require the presence of oral aphthae plus two of the following: recurrent genital aphthae, eye lesions, skin lesions, or a positive pathergy test. Table 192-1 explains these criteria. There are several problems with these criteria. The omission of synovitis and meningoencephalitis makes four of the five criteria variations of the same basic mucocutaneous lesion. We would require histologic confirmation that the cutaneous pustular lesions are indeed vessel-based and neutrophilic. Because 20 percent of normal young adults have oral aphthae and almost all adolescents have at least one acneiform lesion, they could practically meet the criteria if “acneiform skin lesions” are not excluded! Exclusion of inflammatory bowel disease should also be mandatory.

Criteria	Description
Oral	Minor aphthae, major aphthae, or herpetiform ulcers observed by physicians or reported reliably by patient. Recurrent at least three times in one 12-month period.
Genital	Recurrent genital aphthae or scarring, especially scrotal in males, observed by physician or reliably reported by patient.
Eye	Anterior uveitis, posterior uveitis, cells in vitreous on slit lamp examination, or retinal vasculitis, observed by qualified physician.
Skin	Erythema nodosum-like lesions observed by physicians or papulopustular lesions consistent with Behçet's disease, observed by a physician.
Pathergy	Positive pathergy test (neutrophilic vascular reaction or leukocytoclastic vasculitis) read by a physician at 24 or 48 h, performed with oblique insertion of a 20-gauge or smaller needle under sterile conditions.

*Findings are applicable if no other clinical explanation is present.

TABLE 192-1 **International Criteria for Behçet's Disease***

Several disorders need to be considered in the differential diagnosis and excluded before a definitive diagnosis of Behçet's disease can be made. Reiter's disease and the HLA-B27–positive spectrum of diseases are characterized by an axial erosive arthritis and by psoriasiform mucocutaneous lesions, but there are no aphthae and no pustular vasculitis in these patients. Patients with inflammatory bowel disease have an increased incidence of oral aphthae. These patients or those who have had bowel bypass or Billroth II surgery can have a dermatosis–arthritis syndrome that mimics Behçet's disease, including an indistinguishable pustular vasculitis. [17] However, eye disease is generally absent in these patients. Patients with complex aphthosis have recurrent oral and genital aphthae or almost ever-present, multiple (>3) oral aphthae, but no other features of Behçet's disease. [11] Patients with pustular vasculitis alone may have gonococcal or even chronic meningococcal sepsis, or the pustular vasculitis may occur as an idiopathic syndrome.

TREATMENT

The choice of treatment for patients with Behçet's disease depends on the site and severity of the clinical manifestations of the disease (Table 192-2). Aphthae are most often treated with palliative agents, such as counterirritant antipruritic agents, potent topical glucocorticoids, intralesional glucocorticoids, and local anesthetics. [11] Colchicine, 0.6 mg orally two to three times daily as tolerated by the gastrointestinal tract, can reduce the frequency and severity of mucocutaneous lesions. [15] Patients should be monitored for the infrequent neutropenia that can complicate therapy. In addition, dapsone therapy [32] has been used, as has pentoxifylline. [33] For more severe mucocutaneous lesions thalidomide has been shown to be beneficial. [17], [34] Low-dose methotrexate, interferon-a, and prednisone are also effective in treating more severe mucocutaneous disease. [11], [35], [36] Recently, a patient with a recalcitrant mucocutaneous ulceration was treated successfully with the anti–TNF-a antibody infliximab. [37] Severe ocular and systemic disease often requires

immunosuppressive treatment with agents such as prednisone, azathioprine, cyclophosphamide, chlorambucil, and cyclosporine. [11], [35] Recently, cases of gastrointestinal disease and uveitis have been treated with infliximab. [38], [39] Combination therapy with immunosuppressive agents is often used to treat the most severe disease.

Mucocutaneous disease
Topical, intralesional, or aerosolized glucocorticoids (3)
Topical tacrolimus (3)
Local anesthetics (3)
Pentoxifylline (2)
Colchicine (1)
Dapsone (3)
Combinations of the above (3)
Severe mucocutaneous disease
Thalidomide (1)
Low-dose weekly pulse methotrexate (3)
Prednisone with intermittent tapers (2)
Interferon-α (2)
Severe ocular and systemic disease
Prednisone (1)
Azathioprine (1)
Cyclophosphamide (3)
Chlorambucil (2)
Cyclosporine (1)
Infliximab (3)
Intravenous immunoglobulin (3)
Combinations of the above (3)

(1) Double-blind studies; (2) case series; (3) anecdotes.

TABLE 192-2 **Therapeutic Ladder for Behçet's Disease**

COURSE AND PROGNOSIS

The clinical course of Behçet's disease is variable. There can be a delay of up to several years before the diagnosis is made, which may influence the prognosis. Mucocutaneous and arthritic manifestations usually occur first. Ophthalmic involvement is the leading cause of morbidity. Skin lesions may be a predictive factor in vision loss, as is posterior as opposed to anterior uveitis. [40] Blindness can often be prevented with early aggressive therapy of posterior uveitis. Central nervous system, pulmonary, and large vessel involvement, as well as bowel perforation, are the major life-threatening complications. [6] Death may also result as a complication of immunosuppressive therapy. Markers of severe prognosis include HLA-B51 positivity, male gender, and early development of systemic features. Onset in childhood does not necessarily predict a poor prognosis. Spontaneous remissions of certain or all manifestations of Behçet's disease have been observed.

Antibiotic Resistance Because of "R" Factors
Topical Antibacterial Agents

REFERENCES

The patient with a fever and cutaneous lesions presents a very challenging, yet frequently rewarding, problem in medicine. The question of a treatable etiology (bacterial, fungal, herpes group viruses) should always be raised initially. The physician must actively and thoughtfully consider these possibilities and seek confirmation by appropriate studies to ensure early optimal antimicrobial therapy.

Bacterial infection involving the skin may manifest itself in either of two major forms: (1) as a primarily cutaneous process, or (2) as a secondary manifestation in the skin of infection in some other organ. The cutaneous changes associated with infection are not always suppurative but may present as a vasculitis or a hypersensitivity response (e.g., lesions in subacute bacterial endocarditis or erythema nodosum).

The importance of the skin as a mirror of systemic infection cannot be overemphasized, especially when classic clinical findings are distorted as in immunocompromised patients. The timely recognition of the cutaneous clues of bacteremia may provide the early warning to consider life-threatening infections due to organisms such as *Pseudomonas aeruginosa, Vibrio vulnificus, Salmonella typhi, Staphylococcus aureus,* and *Neisseria meningitidis*.

NATURAL RESISTANCE OF THE SKIN

The normal skin of healthy individuals is highly resistant to invasion by the wide variety of bacteria to which it is constantly exposed. It is difficult to produce localized infections such as impetigo, furunculosis, or cellulitis in laboratory animals [1] or human volunteers [2] if the integument is intact. Pathogenic organisms such as *Streptococcus pyogenes* (group A streptococcus) and *S. aureus* produce characteristic lesions of cellulitis and furunculosis in the absence of any obvious impairment of host defenses via disruption of the intact integument, that is, by insect bites, an abrasion, or the introduction of a foreign body. For example, Elek [3] demonstrated that the presence of a silk suture reduces by a factor of 10,000, in the case of *S. aureus,* the number of organisms needed to produce an abscess in the human skin. Treatment with immunosuppressive agents can predispose patients to infections by the same organisms or by others of much lower intrinsic pathogenicity (e.g., *Corynebacterium jeikeium*). The basis for this enhanced susceptibility of the compromised host is not understood but undoubtedly involves specific and nonspecific factors such as immunocompetence, nutritional state, and integrity of the cutaneous barrier. [4]

Bacteria are unable to penetrate the keratinized layers of normal skin and, when applied to the surface, rapidly decrease in number. [2] The nature and the relative importance of the factors thought to be involved in this local resistance to bacterial multiplication and to infection are not clear. [5] The low pH (approximately 5.5) of the skin environment has been suggested as one of these properties, but it does not appear to have an important role. Many virulent bacteria are capable of growing at pHs below that of normal skin. The presence of natural antibacterial substances in the sebaceous secretions may be a factor in bacterial elimination from the skin. Streptococci appear to be particularly sensitive, in vitro, to the unsaturated long-chain fatty acids of the skin lipids, but in controlled studies in humans *S. pyogenes* (gpA streptococci) grow equally well in high- or low-lipid–containing regions. [2] Areas such as the palms and soles, lacking in sebaceous glands, remain relatively free of streptococci as well. On the other hand, reduction of skin surface lipids with topical solvent treatment has prolonged the survival time of *S. aureus* on the skin. [6] Several free fatty acids (linoleic and linolenic acids) among skin lipids are more inhibitory for *S. aureus* than for coagulase-negative staphylococci, a component of the normal skin flora. [7] The role of circulating immunoglobulins, cellular immunity, and delayed hypersensitivity in the defense of the skin against certain organisms is under intense investigation (see Chap. 23). IgM has not been found in normal sweat, and IgA, IgG, and IgD have been found only in minute amounts (0.01 percent of the level in serum). However, the greater frequency with which a specific cutaneous and mucous membrane mycotic

infection, candidiasis, occurs in patients with severe combined immunodeficiency suggests a relationship. Experimental and clinical observations, summarized by Kligman et al., [5] consistently support the importance of moisture content and the indigenous cutaneous microflora in limiting colonization of the skin by potential pathogens. The relative dryness of normal skin contributes to the marked limitation of growth of bacteria, especially gram-negative bacilli with their higher moisture requirements (*Escherichia coli, Pseudomonas, Proteus*). Whereas application of 10 [6] *P. aeruginosa* alone on normal skin produced no lesions, the presence of a similar inoculum under dressings that increased local skin hydration led to a superficial papular and pustular infection. [8] Bacterial interference (the suppressive effect of one bacterial strain or species on colonization by another) exerts a major influence on the overall composition of the skin flora. Although this effect is somewhat difficult to define, its relevance, at least in the case of colonization of the nose and skin by *S. aureus,* appears clear. [9] Profound changes in these bacterial interactions may be effected by the use of antibiotics.

All of these factors allow certain bacterial species to colonize the skin surface successfully, while rapidly excluding other species. The organisms that characteristically survive and multiply in various ecologic niches of the skin constitute the "normal cutaneous flora." As an example, the distribution of different species of coagulase-negative staphylococci varies among different anatomic areas, and their relative numbers can depend on age. In adults, *S. epidermidis* is the principal staphylococcal species isolated from the scalp, face, chest, and axilla. Gram-negative bacilli are relatively rare as components of the normal resident skin flora, with the exception of members of the *Acinetobacter calcoaceticus-baumannii* complex, found on approximately 25 percent of normal adults, primarily in axillae, groins, and toe webs. [10] An appreciation of the composition of this flora and the attributes of its major elements is important in understanding and treating many bacterial infections of the skin.

PATHOGENESIS OF BACTERIAL INFECTION OF THE SKIN

The host–bacteria relationship in infections of the skin, as in infectious disease in general, involves three major elements: (1) the pathogenic properties of the organism, (2) the portal of entry, and (3) the host defense and inflammatory response to microbial invasion of the anatomic region.

Pathogenicity of the Microorganism

The disease-producing capacity of bacteria is determined to a large measure by (1) the invasive potential (often based on antiphagocytic surface components), and (2) the toxigenic properties of the organism. A few species of bacteria (e.g., pneumococcus) appear to owe their pathogenicity solely to their ability to multiply extensively and invade tissues while resisting phagocytosis. No definable extracellular products or toxins that might contribute to their invasiveness have been discovered. Conversely, a few species have toxigenic properties that account for the local lesion (*C. diphtheriae, Bacillus anthracis*) or systemic manifestations (*Clostridium tetani*) of a local infection. In the case of *C. perfringens,* elaboration of a variety of extracellular toxins and enzymes (alpha-toxin or lecithinase, proteases, collagenases) appears to play an important role in the rapidly spreading skin lesions and the systemic manifestations of clostridial myonecrosis. Although it is useful to distinguish between these two major pathogenic mechanisms whenever possible, most bacterial infections result from the combination of the invasive and toxigenic properties of the organism. Local invasiveness (dependent to a considerable extent on the antiphagocytic M protein of the bacterial cell envelope) is an important element in streptococcal pharyngitis, but the clinical features of scarlet fever result from the elaboration of the erythrogenic toxin.
For most disease-producing bacteria, including *S. aureus,* the cause par excellence of suppurative lesions, a clear understanding of the basis for pathogenicity is lacking. Recently, evidence has accumulated indicating that the capsular polysaccharides of 2 (types 5 and 8) of the 11 known *S. aureus* capsular types are both virulence factors and protective antigens. [11] This evidence is both epidemiologic (80 percent of *S. aureus* bloodstream isolates in hospitalized patients belong to types 5 and 8) and derived from in vitro testing (types 5 and 8 resist opsonophagocytosis). *S. aureus* toxins have roles in the pathogenesis of a variety of entities such as the staphylococcal toxic shock syndrome (*S. aureus* toxic shock syndrome toxin, or TSST-1; see Chap. 194) and staphylococcal scalded skin syndrome (exfoliatin A and B; see Chap. 195). The increasing prevalence of serious infections in compromised hosts, caused by "traditionally" nonpathogenic bacteria that include the resident skin flora, supports the concept that pathogenicity is the result of microorganism and host interactions.

Gram-negative bacteria (*E. coli, S. typhi, N. meningitidis, N. gonorrhoeae, Brucella melitensis,* and others) contain endotoxin, complex phospholipid-polysaccharide macromolecules [lipopolysaccharides (LPS)] as an integral part of the bacterial cell envelope. Endotoxins, unlike exotoxins, are released only upon breakdown of the bacterial cell. Their toxicity appears to be linked principally to the lipid fraction, whereas their antigenic determinants reside with the polysaccharide component. [12] Although the biologic effects of LPS in experimental animals are numerous (shock, fever, gastrointestinal hemorrhages, leukopenia, abortion) and well studied, their role in invasiveness and the pathogenesis of localized bacterial diseases until recently remained ill defined. [13] During the past 20 years, this has changed considerably. Much is now known of the mechanisms by which LPS exerts its biologic effects, in systemic infections due to gram-negative bacteria or in major localized infections that may also be capable of producing the sepsis syndrome. [14] The effects are both toxic (lethality, shock, fever, anorexia and cachexia, somnolence, complement activation, disseminated intravascular coagulation, and capillary thrombosis) and immunologic (adjuvant function, polyclonal B cell stimulation, macrophage activation, cytokine production). The two cytokines most relevant to the toxic and proinflammatory effects of LPS are produced by LPS-activated macrophages: tumor necrosis factor (TNF) and interleukin (IL)-1, the latter formerly known as leukocytic pyrogen (see Chap. 26). [15], [16]

After it enters the circulation, TNF, among its many biologic effects, acts as an endogenous pyrogen on hypothalamic centers to induce fever. [17], [18] It also acts on mononuclear phagocytes to stimulate production of IL-1 (another endogenous pyrogen), IL-6 (an inducer of production of serum amyloid A and other proteins of the "acute phase response"), and IL-8 (an inflammatory cytokine stimulating leukocyte chemotaxis and activation) (see Chap. 26). Thus, TNF initiates a proinflammatory cytokine cascade. TNF itself acts on the liver to increase synthesis of acute phase reactants, including fibrinogen. It also activates the coagulation system through its effects on vascular endothelium and

decreases blood pressure and tissue perfusion by reducing myocardial contractility and by relaxing smooth muscle.

High circulating levels of TNF are demonstrable in patients with meningococcemia and other forms of severe sepsis. [19], [20] Its direct role as a mediator of circulatory collapse in gram-negative bacillary bacteremia is supported by the fact that pretreatment with antibody to TNF can prevent mortality (associated with hypotension and cardiac and renal failure) from experimental *E. coli bacteremia* in animals. [21] In addition, infusion of high concentrations of purified TNF alone can produce shock and death.

LPS can directly trigger release of IL-1 from activated macrophages as well as act indirectly through initial induction of TNF. Like TNF, IL-1 acts on endothelial cells as a procoagulant and as a stimulator of leukocyte adhesion. It can cause fever, stimulate production of acute phase proteins, and initiate (in combination with TNF) muscle wasting and cachexia. IL-1 also acts in an immunomodulatory role to enhance proliferation of CD4+ T cells and to stimulate B cell growth and differentiation.

The Shwartzman reaction is an intensified response in experimental animals to bacteria containing LPS or to purified LPS itself. LPS injected intravenously twice, 24 h apart, causes disseminated intravascular coagulation in rabbits (systemic Shwartzman reaction); LPS injected intradermally, followed by a second (intravenous) injection, produces hemorrhagic necrosis of the skin (localized Shwartzman reaction) at the site of intradermal introduction. The necrosis stems from poor tissue perfusion as a consequence of capillary blockage by neutrophils and platelets and by local fibrin formation. TNF is the major mediator of the Shwartzman reaction; unlike TNF, IL-1 cannot directly mediate this reaction. The ability of LPS, through TNF production, to induce leukocyte adherence to capillary endothelium and to induce fibrin deposition has been suggested as the basis for development of the hemorrhagic necrotic skin lesions (with or without direct bacterial invasion) that sometimes occur during the course of gram-negative bacillary bacteremias and particularly in meningococcemia. Purpura fulminans develops in 10 to 20 percent of cases of marked meningococcal sepsis, and severe cases may develop thrombosis of large vessels with infarction of digits (see Chap. 197). Evidence indicates that this disseminated intravascular coagulation in severe meningococcemia results from downregulation of the endothelial thrombomodulin-endothelial protein C receptor pathway with consequent impairment of protein C activation. [22] A large, randomized, multicenter trial of the use of human recombinant activated protein C [drotrecogin alfa (activated)] in patients with severe sepsis indicated a reduction of mortality but with an associated potential risk of bleeding. [23]

Changing Patterns of Bacterial Infections of the Skin

In addition to the usual pathogens, a variety of “nonpathogenic” members of the cutaneous, intestinal, or respiratory tract flora are capable of producing acute disease in debilitated patients and in individuals with altered humoral or cellular defenses and with a variety of skin defects. A patient receiving immunosuppressive therapy, for example, may have an atypical streptococcal or staphylococcal lesion because of impairment of the normal inflammatory response, or an unusual organism may be causal. Pain can be the most prominent feature, and etiologic considerations should include, in addition to streptococci and staphylococci, members of the Enterobacteriaceae (*E. coli, Klebsiella- Enterobacter-Serratia, Proteus* spp.); a variety of nonfermentative gram-negative bacilli (*Pseudomonas, Aeromonas, Acinetobacter* spp., etc.); halophilic vibrios (e.g., *V. vulnificus*); and the indigenous anaerobic flora (peptostreptococci, *Bacteroides* spp., *C. perfringens,* etc.). [4], [24], [25], [26] and [27]

Portal of Entry

In laboratory animal models the pathogenic potential of many microorganisms depends, to a considerable extent, on the route of administration. Similarly, the character of the cutaneous inflammatory response to certain bacteria will be influenced by how the organisms reached the involved area. Thus, the vascular wall is often the primary site of skin involvement during bacteremic infection; hemorrhage or thrombosis with infarction is the initial manifestation. This is followed somewhat later by the cellular reaction expected from direct inoculation of the bacteria into the skin. Local inflammation and suppuration commonly accompany direct bacterial invasion of the skin, and these may, in turn, give rise to systemic spread via the rich cutaneous vascular network. Certain bacteria can produce bacteremia or distant lesions without evoking an obvious inflammatory response at the portal of entry [e.g., *Yersinia pestis, Streptobacillus moniliformis* (rat-bite fever)] even in a nonimmunosuppressed host. Occasionally, a devastating *S. pyogenes septicemia* has followed closely upon an innocuous pinprick or abrasion that has not induced a significant local lesion. Table 193-1 lists those bacterial species most frequently involved in pyogenic infections of the skin.

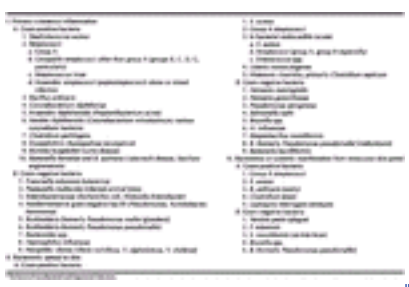

TABLE 193-1 **Bacteria Involved in Cutaneous Infection***

Specific Features of Host Inflammatory Response to Cutaneous Infection

In view of the relatively few cell types present in the skin, it is surprising that such a variety of rather distinctive clinical responses to various bacterial infections have been catalogued. In most instances, it is the anatomic site of the infection and the attendant inflammatory response pattern, rather than the specific pathogen, that provide the characteristic

clinical picture. The following brief examples are expanded upon in Chap. 194 and Chap. 196.

IMPETIGO The very superficial location of the infection, with vesicopustule formation just beneath the stratum corneum, is the specific clinical feature.
FOLLICULITIS This represents a circumscribed infectious process that originates in the hair follicle and is defined by its anatomic features. It may be located superficially in the follicle or may extend more deeply to produce perifollicular inflammation.
FURUNCLE (BOIL) This infection either complicates an antecedent folliculitis or develops as a deep-seated nodule about a hair follicle. The distinctive pathologic change results from its relation to the hair follicle; thus, it does not occur in glabrous areas such as the palms. The deep location and its containment by the relatively thick dermis prevent spontaneous early drainage to the surface and contribute to the hard, nodular, painful character of the lesion.
CARBUNCLE This is a larger, more deep-seated extension of a furuncle, with infection spreading under and between fibrous tissue septa, forming a whole series of interconnected abscesses. Drainage occurs through a number of projecting necrotic points in the skin.
CELLULITIS This is an acute, inflammatory process in the skin, particularly in the deeper subcutaneous tissues. Because of the subcutaneous location, the borders of the lesion are usually indistinct, in contrast to the sharply defined margin of erysipelas (see below).

Interplay of Morphology and Specific Bacterial Properties

ERYSIPELAS This is a superficial inflammatory process of the skin and subjacent lymphatics, characterized by marked edema of the dermis and extensive invasion of connective tissue usually, but not exclusively, caused by *S. pyogenes* (gpA streptococci). The rapid progression of the process and the prominence of edema of the affected skin relate to the biologic properties of the microorganisms and to the involvement of superficial lymphatics.

Influence of Hypersensitivity to Bacterial Antigens on Inflammatory Reaction in Skin

Although the introduction of certain bacteria in large numbers into the skin will elicit a local inflammatory reaction, the character and extent of this response may be modified by various host factors (e.g., leukopenia). In the case of skin infections caused by *S. aureus,* the tendency to recur is often quite striking. Initial lesions are usually suppurative and localized, whereas subsequent infections, when caused by the same antigenic strain, may have more prominent surrounding cellulitis. The immunologic response to *S. aureus* has been suggested as a factor in this altered inflammatory response. [28]

Vasculitis as a Cutaneous Response to Systemic Infection

Inflammatory changes in and about small blood vessels in the skin may occur in a variety of bacteremic infections in the absence of obvious localization of bacteria at these sites. The macular, papular, nodular, and petechial lesions of chronic meningococcemia (see Chap. 197) show such histologic changes. The lesions of erythema nodosum (see Chap. 109) have a prominent element of vasculitis, even though the initiating infection (e.g., streptococcal pharyngitis) is distant and has a suppurative character. The Osler nodes and petechiae of subacute bacterial endocarditis, caused by viridans streptococci, probably provide the best examples of this association of small-vessel vasculitis with bacteremia (see Chap. 166 and Chap. 194). Histologically, these lesions are more suggestive of vasculitis than of emboli. The occasional development of such lesions in profusion, localized to the lower extremities, supports the concept of cutaneous vascular inflammation rather than embolization.

CLASSIFICATION OF BACTERIAL INFECTIONS OF THE SKIN

The introduction of a variety of specific antibiotic and chemotherapeutic agents has effected rather striking changes in the management of bacterial infections. Indeed, with the availability of such drugs, attention has focused on the determination of the specific bacterial cause so that the proper choice of antibacterial agent can be made. This has rendered unnecessary, and even obsolete, descriptions of some of the dermatologic entities whose status depended on imprecise morphologic criteria rather than on etiologic considerations. Consequently, from the pragmatic (therapeutic) viewpoint, the approach has been to consider and classify these infections by bacterial causation, for example, infections caused by gram-positive organisms and infections caused by gram-negative organisms. Although the foregoing classification is helpful from the therapeutic point of view, there is still need for a system of categorizing bacterial infections of the skin so that the dermatologic picture will provide the basis for consideration of the most likely bacterial etiologies. To this end, the classification of skin infections as (1) primary infections (pyodermas), (2) secondary infections, and (3) cutaneous manifestations of systemic bacterial disease seems warranted. Primary bacterial infections are produced by the invasion of ostensibly normal skin by a single species of pathogenic bacteria. In such infections there is usually no doubt as to the primary etiologic role of the specific agent in the pathogenesis of the lesion. Treatment aimed at the bacterial pathogen almost universally results in cure of the lesion. Impetigo, erysipelas, and furunculosis are familiar examples of primary cutaneous infections; contrastingly, secondary infections develop in areas of already damaged skin. Although the bacteria present did not produce the underlying skin disorder, their proliferation and subsequent invasion of surrounding areas may aggravate and prolong the disease. Such secondary infection may occur when the integrity of the skin has been broken or bruised, primarily involved with mycotic or viral infections, or altered by sensitivity reactions or medications. In contrast to the primary infections, the secondary infections often show a mixture of organisms on culture, and not infrequently it is impossible to determine which plays the major role. Pathogenic organisms such as *S. aureus* and *S. pyogenes,* generally considered transients on the skin, can colonize such lesions and sometimes produce active secondary infection. The appearance of these lesions is not characteristic, in comparison to the primary pyodermas, but is largely dependent on the nature of the underlying skin condition. The result of antibacterial treatment is much less clear-cut, because it has no effect on the underlying process.

Table 193-2 presents an outline of infections involving the skin in a classification based upon the appearance of the lesions. In this outline, specific entities that are discussed elsewhere in detail are described only by the appropriate

chapter reference, and the more common bacterial etiologic agents are noted. This table refers exclusively to bacterial infections. Two of the categories identified in Table 193-2 present a broad differential diagnosis and warrant special consideration. These consist of infectious gangrene/gangrenous cellulitis (Table 193-3) and crepitant soft tissue wounds and cellulitis (Table 193-4). In addition, an uncommon group of infections present as chronic nodular, and sometimes ulcerative, granulomatous lymphangitis (with or without an evident initiating chancriform lesion) of a distinctive character. Because definition of the specific microbial etiology may be difficult without careful epidemiologic history, biopsy with culture, special stains of histologic sections, and an awareness of the broad variety of microorganisms (fungi, bacteria, mycobacteria, protozoa) that may be involved, a listing of the possible causes is presented separately (Table 193-5).

TABLE 193-2 **Bacterial Infections Involving the Skin***

TABLE 193-3 **Differential Diagnosis of Infectious Gangrene and Gangrenous Cellulitis**

TABLE 193-4 **Differential Diagnosis of Crepitant Soft Tissue Wounds***

Principal Considerations	Relative Frequency As Etiology
Fungi	
Sporothrix schenkii (causative agent of sporotrichosis (see Chap. 207)	Occasional
Mycobacteria	
Mycobacterium marinum (causative agent of "swimming pool granuloma" (see Chap. 200)	Occasional
M. Kansasii	
Bacteria	Rare
Nocardia brasiliensis	Rare
N. asteroides	Very rare
Francisella tularensis	Very rare
Staphylococcus aureus	Very rare
Botryomycosis (*S. aureus*)	Very rare
Protozoa	
Leishmania brasiliensis and *L. mexicana* (causative agents of new world cutaneous leishmaniasis (see Chap. 235)	Occasional

TABLE 193-5 **Causes of Chronic Nodular (Granulomatous) Sporotrichoid Lymphangitis**

DIAGNOSTIC STRATEGIES

Direct Examination of Aspirates and Biopsies

Identification of bacteria from skin lesions may provide important information as to the cause of cutaneous infections, whether primary or secondary to systemic processes. The presence of “normal skin flora” can confuse interpretation of these cultures. All too often, the finding of a potential pathogen such as *S. aureus* or *P. aeruginosa* is equated with the presence of disease. It is important to recall that damaged skin (operative incisions, exudative dermatoses, etc.) provides a medium for proliferation of certain bacteria. Only by correlating the clinical appearance of the lesion (local suppuration, cellulitis, etc.) with the bacteriologic data can one reach the proper decision concerning the presence of a bacterial disease. Examination of a Gram-stained smear of material from a suspected skin infection can guide decisions on early antibiotic therapy before a cultural diagnosis is made. For these reasons, bacteriologic investigation is an important part of the initial evaluation of patients with skin lesions and includes (1) appropriate sampling, (2) interpretation of

Gram-stained smears, and (3) use of selective growth media for culturing.

Gram staining provides a very rapid method for examining a sample for number and type of bacteria, as well as for the character of the inflammatory exudate. Skin contaminants are usually recognized by being present in low concentration, often clumped in characteristic microcolonies (growth in skin crypts) and usually not associated with polymorphonuclear leukocytes. Obtaining an appropriate specimen for microscopic study and culture requires care to avoid contamination. Results of needle aspiration of superficial erysipelas lesions have been generally unrewarding. Slightly better, but still limited, results have been obtained on aspiration culture of lesions of cellulitis. Aspirates from the advancing edge of cellulitis yielded positive cultures in only 10 percent of patients, and culture of skin punch biopsy specimens taken from the leading edge were positive in only 20 percent of patients in the study by Hook et al. [29] Positive cultures (beta-hemolytic streptococci and coagulase-positive *S. aureus*) were more likely in patients with apparent primary sites of infection associated with the cellulitis. In another study of needle aspiration cultures of the leading edge of erythema in patients with cellulitis, the yield of pathogenic bacteria was low (15 percent) as well. [30] Other studies have suggested a greater yield on needle aspiration of the leading edge of cellulitis when performed in patients with underlying conditions such as diabetes mellitus and neoplastic disease. [31] A higher yield (about 50 percent) for positive cultures has been reported in aspirates obtained from the point of maximal inflammation than that (5 percent) obtained from the leading edge of cellulitis in children. [32] The authors' personal experience is in accord with published results for sampling deeper cellulitic lesions and bullae associated with acute infections. Findings on needle aspiration, when positive, can provide an immediate useful guide to therapy. If sterile saline is injected into a lesion that initially yields no aspirate, bacteriostatic agent-free solutions should be employed. In circumstances where no data are available from needle aspiration, a surgical biopsy may yield information that is life-saving. In the recent bioterrorism-associated outbreak of anthrax infections in the United States, rapid specific diagnosis of cutaneous disease was accomplished by punch biopsy of an erythematous, indurated plaque and tissue Gram's stain demonstrating gram-positive rods, confirmed as *Bacillus anthracis* by immunohistochemical analysis. [33] Local lesions of the skin and subcutaneous tissues in immunocompromised patients should always be biopsied if aspiration fails to define a pathogen. [4] Encouraging results have been reported in a series of patients with suspected necrotizing fasciitis who had biopsies done to confirm the diagnosis early in the course of this devastating infection. [34]

Methods of Culture of Skin Material

All samples for culture should be planted routinely on blood agar and inoculated into a tube of thioglycollate (anaerobic) broth. Additional, more selective media should be used as indicated by clinical findings and evaluation of the Gram-stained smear and frozen sections if a biopsy is done. If cutaneous diphtheria is a consideration, Loeffler or tellurite agar should be inoculated. When gram-negative rod infection is suspected, an eosin-methylene blue (EMB) or MacConkey plate is used; a chocolate agar or modified Thayer-Martin plate incubated in a CO_2 atmosphere is indicated for suspected meningococcal or gonococcal lesions; a blood agar plate incubated in an oxygen-free atmosphere should be used if anaerobic streptococci, clostridia, or *Bacteroides* are suspected. When the skin lesions are thought to be part of a generalized infection, blood cultures should also be obtained prior to institution of antibiotic therapy.

Other Diagnostic Procedures

FLUORESCENT ANTIBODY The practical use of this procedure in bacterial diseases of the skin is currently of limited availability. Spirochetes can be demonstrated (by the direct or indirect techniques) in chancres, but dark-field examinations are easier to perform and more reliable (see Chap. 228). *N. gonorrhoeae, Actinomyces israelii, Legionella* spp., *Francisella tularensis,* and *Y. pestis* have been identified by this rapid direct fluorescent antibody staining method. This technique is still in the experimental development stage for identifying the etiologic agent in most common infections of the skin. [35] However, it can be extremely valuable in the specific diagnosis of uncommon but serious infections, as illustrated by the positive-immunostaining for *Bacillus anthracis* in an atypical erythematous indurated lesion on the arm of an infant infected during the recent outbreak of bioterrorism-related anthrax in the United States. [36]
OTHER IMMUNOLOGIC METHODS A variety of serologic tests may be helpful in the diagnosis of bacterial infections of the skin, particularly in those where the cutaneous manifestations are secondary to systemic disease (e.g., “rose spots” of typhoid fever). In general, these tests have value in confirming a diagnosis that has already been made by direct bacteriologic identification of the offending organism (e.g., *Salmonella* agglutination, *Brucella* agglutination, agglutination reaction for tularemia, leptospirosis complement fixation or agglutination tests). As in any serologic test, a fourfold or greater rise in titer during the course of the illness is considered significant.
POLYMERASE CHAIN REACTION Polymerase chain reaction (PCR) technology can be applied to diagnosis of material obtained on skin punch biopsy of lesional tissue or aspirates from a vesiculobullous lesion just as it has been used in diagnosis of infection in body fluids (cerebrospinal fluid, pleural fluid, blood). Appropriate precautions to exclude contamination during the acquisition of the specimen must be taken. The use of this procedure is most helpful when one particular bacterial species is being considered and appropriate primers are available. Such was the case in a patient with a cutaneous lesion during the bioterrorism-induced anthrax outbreak. [36]

ANTIBIOTIC THERAPY (See also Chap. 259)

The selection of the appropriate antibiotic should be made initially on the basis of the appearance of the skin lesion, the characteristics of any systemic illness, and a Gram-stained smear of material from a lesion if available to sample. Culture results and susceptibility testing of the isolated pathogen(s) are usually available within 48 h (Table 193-6).

TABLE 193-6 **Selection of Antibiotics**

Additional epidemiologic factors (current hospitalization or residence in a nursing home, recent antibiotic use, neutropenia, and immunocompromise) should be considered in the choice of initial antimicrobial therapy. Also, it is important to make the choice based on the latest data from the local area and from frequently updated sources (e.g., *Medical Letter*) in view of the rapidly changing patterns of antimicrobial resistance of various bacterial species, requiring alterations in the previous drugs of choice and the use of newer drugs or drug combinations.

Dosage: Methods of Administration—Excretion

Primary cutaneous infections of mild to moderate severity can be treated with local measures, topical drugs, oral antibiotics, or by a combination of these methods. In recent years, there has been a proliferation of oral cephalosporins with activity against group A streptococci and methicillin-susceptible *S. aureus,* which cause infections of the skin and soft tissues such as impetigo, cellulitis, subcutaneous abscesses, and wound infections (Table 193-7). Extensive infections of the skin, with or without systemic manifestations, should be vigorously treated with parenteral antibiotics in adequate dosages.

Drug	Adult Dosage
Cephalexin	250–500 mg q6h
Cefadroxil	500–1000 mg q12h
Cephradine	500 mg q6h
Cefaclor	250–500 mg q8h
Cefprozil	250–500 mg q12h
Cefuroxime	250–500 mg q12h
Cefpodoxime	200–400 mg q12h
Loracarbef	200–400 mg q12h

TABLE 193-7 **Oral Cephalosporins Used in Treating Skin Infections**

A number of factors must be considered in administering antibiotics: oral treatment may be limited by absorption and gastrointestinal disturbances; hypotension, severe thrombopenia, and extensive skin disease can prohibit the intramuscular route; and the proper drug selected may be suitable for administration only by a specific route. Caution must be exercised in administering intramuscular medications to avoid sterile or infected abscesses. When the intravenous route is used, a needle or “heparin-lock” is preferred. Percutaneous catheters should be changed frequently, and all line-skin sites kept clean with a topical antibiotic ointment and sterile dressing that is changed daily.

The excretory pattern of a given antibiotic should always be considered in order to avoid toxic accumulation in the face of specific organ malfunction (e.g., use of aminoglycosides or vancomycin in the presence of renal impairment).

Toxicity

The toxicity of antibiotics should be considered on an individual basis, but some problems are applicable to all antibiotics. Hypersensitivity reactions are relatively common and can include skin rashes, fever, or more severe manifestations such as acute anaphylaxis or exfoliative erythrodermas. The penicillins and sulfonamides are particularly likely to produce these problems. Questions regarding previous drug allergy should be asked whenever any antibiotic is to be administered. All antibiotics alter the relative kinds and absolute numbers of the indigenous flora, and superinfection may result from their use, especially with broad-spectrum agents such as the cephalosporins. Gastrointestinal disturbances and oral mucous membrane lesions are the major nonspecific types of problems encountered with alteration of the flora, although changes also occur on burn surfaces and other lesions. There are numerous other untoward reactions (renal, hematologic, hepatic, nervous system) to antibiotics that may represent acceptable risks if the reasons for use of these drugs are compelling (see footnotes, Table 193-6). The responsibility is the physician's, however, to be aware of the usual and unusual manifestations of toxicity to any of the antibiotics used and to be alert to possible novel effects in individual patients.

Antibiotic Resistance Because of “R” Factors

Transferable resistance to multiple antibiotics has emerged as a widespread problem. Extrachromosomal genetic elements (R plasmids) in bacteria are the basis for much of such resistance. [37], [38] Prolonged antibiotic therapy, especially in a closed environment such as a hospital, may select R-factor–carrying members of the indigenous flora (e.g., in the gastrointestinal tract), which may subsequently transfer this property to a recently acquired organism. In this way, antibiotic resistance to chloramphenicol, tetracycline, and kanamycin conferred by a plasmid in *E. coli* can be

transferred during mating to a *Klebsiella* or *Salmonella* strain. As a consequence, organisms with greater intrinsic pathogenicity can also become antibiotic-resistant. A number of studies have verified this phenomenon and its practical consequences. [39]

R plasmids (R factors) are found in most pathogenic gram-negative bacteria, including *E. coli, Klebsiella, Proteus, Pseudomonas, Salmonella,* and *Shigella*. They are also responsible for high-level resistance to the penicillins (penicillinase plasmids) and cephalosporins. R-factor–associated antibiotic resistance has been identified in *S. aureus* and *Enterococcus* spp., as well as in *Haemophilus influenzae* and *N. gonorrhoeae,* all important pathogens in skin and systemic infections.

Topical Antibacterial Agents

Topical antibacterial agents are frequently used to prevent, as well as to suppress, bacterial growth in burns and other open lesions (see Chap. 245). Their greatest usefulness is when employed along with strict aseptic techniques in preventing percutaneous line sepsis. These agents are capable of inhibiting the local flora, but, as is true of all antibiotics, they have a relatively limited spectrum of activity, which favors the emergence of bacterial resistance during treatment. In addition, topical drugs may precipitate contact dermatitis and can be absorbed to toxic levels. Furthermore, there has been very little evidence that they add a great deal therapeutically. [40] An exception to this is the result, in burn patients, of the use of Sulfamylon (mafenide) acetate cream or of 0.5% silver nitrate solution. However, even with these broad-spectrum agents, resistant species, such as *C. perfringens, Klebsiella,* and *Enterobacter,* may emerge as the dominant potential pathogen of the local flora.

Among the most useful topical antibacterial agents are acetic acid (1 to 5% for *Pseudomonas* nail and toe web infections and bacitracin (500 units per milliliter or gram) for selected superficial *S. aureus* and streptococcal lesions. Occasionally, topical bacitracin may be associated with a cutaneous hypersensitivity reaction. Neomycin (0.5% ointment) and gentamicin (0.17% cream) may be useful in selected patients when mixed gram-negative bacteria require local suppression. Mupirocin (2% ointment) has antibacterial activity against various streptococci and *S. aureus*. It is a safe and effective treatment of impetigo. [41] A number of broad-spectrum antiseptics are also available for topical use, combining antibacterial with nonirritating properties. Povidone-iodine (Betadine) is effective against most gram-positive and gram-negative bacteria but does not persist in the skin to provide a residual action. Chlorhexidine gluconate (4% solution) is an antiseptic that combines broad antibacterial properties with prolonged action due to local accumulation. An alcoholic preparation is especially effective, is not appreciably absorbed into the blood, and generally is not irritating to the skin. [42], [43] These broad-spectrum antiseptics can be used prophylactically or to treat local wounds and superficially infected dermatoses.

The topical therapy of burns is discussed in Chap. 127.

Pyodermas: Staphylococcus aureus, Streptococcus, and Other Gram-Positive Bacteria

STAPHYLOCOCCAL SKIN INFECTIONS
General Features
Superficial Staphylococcal Pyodermas
STAPHYLOCOCCAL BACTEREMIA AND ENDOCARDITIS
Syndromes Caused by Staphylococcal Exotoxins
STREPTOCOCCAL SKIN INFECTIONS
General Features
Specific Diseases Caused by Group A (and Other) Streptococci (Table 194-5)

REFERENCES

Normal human skin is colonized soon after birth by a large number of bacteria that live as commensals on the epidermis and epidermal appendages. Coagulase-negative staphylococci (*S. epidermidis*) are inoculated during vaginal passage; coryneform bacteria take up residence on neonatal skin shortly after birth; and within several weeks after birth, the flora of neonatal skin is similar to that of adults (for further reading see Chap. 193).

The majority of the primary and secondary pyodermas (cutaneous bacterial infections) are caused by either *S. aureus* or group A streptococcus. *S. aureus* pyodermas occur in individuals who are nasal carriers of the organism, which, when translocated onto the skin, is able to gain access via small breaks in the cutaneous integrity and cause superficial infections. Group A streptococcal pyodermas occur following colonization of the skin either from the skin of another individual colonized with group A streptococci or, less likely, from the patient's nasopharynx. *S. aureus* and group A streptococcus cause a broad clinical spectrum of infection, that is, superficial pyodermas and invasive soft-tissue infections (see Chap. 196), depending on the organism, on the anatomic location of infections, and on host factors.

STAPHYLOCOCCAL SKIN INFECTIONS

Staphylococci are classified into two major groups: the coagulase-negative staphylococci and coagulase-positive (*S. aureus*) staphylococci. Many different species of coagulase-negative staphylococci are found on the skin, the ratio varying according to the site. *S. epidermidis* is the most common. Individuals carry a combined minimum of 10 to 24 temporary and resident strains of *S. epidermidis*. The relatively high number of *S. epidermidis* strains is attributable in part to the wide habitat and niche range of this species; this number is usually maintained on the host even though the specific strain composition may change over time. *S. epidermidis* is a reluctant pathogen but is capable of causing superficial and invasive infections (particularly about implanted foreign bodies such as intravascular catheters).

S. aureus is a persistent member of the microbial flora in 10 to 20 percent of the population. Carriage is transient or intermittent in other individuals. Approximately 30 to 50 percent of healthy adults harbor *S. aureus* at some site at any given time. As many as 84 percent of healthy individuals have occasional carriage of *S. aureus* in their anterior nares. [1] Other sites of colonization include the axillae, perineum, pharynx, and hands. Conditions predisposing to *S. aureus* colonization include atopic dermatitis, diabetes mellitus (insulin-dependent), dialysis (hemo- and peritoneal), intravenous drug use, and HIV infection.

S. aureus is an aggressive pathogen and the most common cause of primary pyodermas and soft-tissue infections (STIs), as well as of secondary infections on disease-altered skin. *S. aureus* in pyodermas or STIs can invade the bloodstream, producing bacteremia, metastatic infection such as osteomyelitis, and acute infective endocarditis. Some strains of *S. aureus* also produce exotoxins, which cause constellations of systemic symptoms such as staphylococcal scalded-skin syndrome (SSSS), and staphylococcal toxic shock syndrome (TSS).

General Features

BACTERIOLOGY AND PATHOGENESIS Colonization by *S. aureus* may be transient or represent a prolonged carrier state. *S. aureus* produces many cellular components and extracellular products that may contribute to its pathogenicity. The role of these components in disease is not well understood, except for the variety of exotoxins that are made and secreted extracellularly. The production of coagulase, leukocidin, alpha toxin, and the like, may be the same in *S. aureus* strains isolated from staphylococcal cellulitis as in those from normal skin of the carrier. Thus, host factors such as immunosuppression, glucocorticoid therapy, and atopy may also play a major role in the pathogenesis of staphylococcal infections. Preexisting tissue injury or inflammation (surgical wound, burn, trauma, dermatitis, retained foreign body) are of major importance in the pathogenesis of staphylococcal disease. The production of coagulase, a factor capable of clotting plasma, has been employed in the past as the in vitro criterion of the potential pathogenicity of a staphylococcal strain. Coagulase may play a role in the development of the staphylococcal abscess by producing local fibrin thrombi that protect organisms and concentrate toxic factors elaborated by these pathogens. The surface of *S. aureus*, and particularly of coagulase-negative staphylococci, may be very mucoid, which facilitates adherence of the organism to surfaces of foreign bodies such as intravascular catheters or prostheses. Increased epithelial cell adherence is a factor in the increased incidence of *S. aureus* infections in individuals treated with oral retinoids. Exotoxins elaborated by *S. aureus* (Table 194-1) include enterotoxins and toxic shock syndrome toxin 1 (TSST-1), involved in TSS and related illnesses, and exfoliative toxins A and B, involved in SSSS (see Chap. 195) and bullous impetigo. These exotoxins, as

well as the similar toxins produced by group A streptococcus, are called *superantigens*. Superantigens act by binding directly to constitutively expressed human leukocyte antigen (HLA)-DR molecules [major histocompatibility complex (MHC) II] on professional antigen-presenting cells without antigen processing. While conventional antigens require recognition by all five elements of the T cell–receptor complex, superantigens require only the variable region of the ß chain (Vß). As a result, 5 to 30 percent of resting T cells may be activated where the "normal" antigenic response is only 0.0001 to 0.01 percent of T cells. [2] Nonspecific T cell activation leads to massive systemic release of cytokines, especially interleukin (IL)-2, interferon (IFN)-?, and tumor necrosis factor (TNF)-ß from T cells and IL-1 and TNF-a from macrophages. [3] Superantigen stimulation of T cells also results in activation and expansion of lymphocytes expressing specific T cell–receptor Vß region. They may activate B cells leading to high levels of IgE or autoantibodies. [4] Also, there is evidence that superantigens selectively induce cutaneous lymphocyte-associated antigen (CLA) on T cells, thereby "homing" them to the skin. [5]

Toxin	Clinical Syndrome
Enterotoxins B and C	TSS (nearly 50% of nonmenstrual cases)
TSS toxin 1 (TSST-1)	TSS (nearly all menstrual cases)
	Scarlatiniform eruption (staphylococcal scarlet fever)
Exfoliative toxins A and B	SSSS
	Bullous impetigo

TABLE 194-1 **Exotoxins (Superantigens) Produced by** *Staphylococcus aureus*

Drug resistance A major problem in dealing with staphylococcal infections has been the emergence of antibiotic-resistant strains, particularly those resistant to penicillin and the semisynthetic penicillinase-resistant penicillins. Undoubtedly, the initial introduction of the penicillinase-resistant penicillins has altered considerably the prognosis for serious staphylococcal infections. However, with ever-increasing use of such penicillins, methicillin-resistant *S. aureus* (MRSA) strains have become a major epidemiologic problem since the 1980s. Resistance to methicillin indicates pan-resistance to all beta-lactamX antibiotics. Recently, intermediate-level resistance of MRSA to vancomycin has emerged and constitutes a potential further problem in treatment. An alarming factor is that while in some countries *S. aureus* infection prevalence has not changed drastically over the years, the percentage of MRSA isolates of these infections has significantly increased. Those at higher risk for acquiring colonization or infection with MRSA are adults over 65 year of age, the chronically ill, those with prolonged hospitalizations (especially surgical), exposure to others with MRSA and prior antibiotic therapy. The main MRSA reservoirs are health care workers and hospitalized patients with subsequent transmission primarily through direct contact. [6] Attempts to eradicate MRSA have generally been unsuccessful. Treatment of anterior nares and wounds with mupirocin ointment has been shown to decrease *S. aureus* colonization but has failed to decrease the rate of transmission to a roommate in a long-term-care facility. [7] Although there are many other reports of topical mupirocin being used to reduce colonization of MRSA and methicillin-sensitive *S. aureus* (MSSA) strains, indiscriminate use of topical mupirocin must be avoided because significant mupirocin resistance has already emerged. [8]

Epidemiology At first glance, the high frequency of staphylococcal colonization of the respiratory tract and the frequency of staphylococci in our immediate environment suggest that their spread from person to person occurs principally via respiratory transmission or fomites. However, careful epidemiologic studies using phage-typing techniques suggest that transfer of organisms to patients occurs predominantly via the hands of personnel rather than through the air. This appears to be particularly true in newborn nurseries, where this route is important in the dissemination of the organisms from nasal carriers and also in the transfer of staphylococci between babies. Any individuals with open staphylococcal infections are particularly dangerous potential carriers and transmitters of infection. Nasal carriage of *S. aureus* appears to be a major risk factor for wound infection after cardiac surgery, resulting in higher mortality rates and longer postoperative stays. [9] The rate of *S. aureus* bacteremia is also higher in nasal carriers of *S. aureus*. [10] Good nursery technique, careful handling of patients, strict hand-washing procedures, and isolation of patients with open draining staphylococcal infections are important in the reduction of transmission of staphylococci. In older adults, *S. aureus* accounts for 9 percent of nosocomial infections and follows only *Escherichia coli, Pseudomonas aeruginosa*, and enterococci in prevalence. [11]

Immunity The high prevalence of staphylococci and staphylococcal infections is substantiated by the almost universal presence in adults of circulating antibody to one or more cell-wall antigens or extracellular toxins. The occurrence of staphylococcal infections in the presence of these antibodies suggests that they are not the primary determinants of resistance to such infections. Immunization of experimental animals with alpha toxin does not afford protection against staphylococcal disease following challenge. Hypersensitivity may play a role in recurrent staphylococcal skin infections in humans.

Superficial Staphylococcal Pyodermas

In industrialized nations, *S. aureus* is the most common cause of superficial pyodermas, having more of a "market share" than it did several decades ago. Group A streptococcus continues to be a common cause of pyoderma in developing countries. Pyoderma represents infections in the epidermis, just below the stratum corneum (impetigo) or in hair follicles (folliculitis) (Table 194-2). Untreated, superficial pyodermas can extend into the dermis, resulting in ecthyma and furuncle formation.

TABLE 194-2 **Infections and Toxin Syndromes Involving the Skin and Soft Tissues Caused by** *Staphylococcus aureus*

IMPETIGO Two clinical patterns of impetigo are recognized: bullous and nonbullous. Bullous impetigo is caused by *S. aureus*. Several decades ago, nonbullous impetigo was most commonly caused by group A streptococcus (see "Streptococcal Impetigo," below). Currently, in industrialized nations, nonbullous impetigo is most commonly caused by *S. aureus* and less often by group A streptococcus, or by both organisms. Group A streptococcus remains a common cause of nonbullous impetigo in developing nations.

Nonbullous impetigo This type accounts for >70 percent of cases of impetigo; it occurs in children of all ages as well as in adults. Intact skin is usually resistant to colonization or impetiginization, probably because of absence of fibronectin receptors for teichoic acid moieties on *S. aureus* and group A streptococcus. When both organisms are present, group A streptococcus appears to be the primary pathogen and *S. aureus* the secondary invader of the lesions (see "Streptococcal Impetigo," below). Production of bacteriocins, produced by certain *S. aureus* strains (phage group 71) and highly bactericidal to group A streptococcus, may be responsible for the isolation of only *S. aureus* from some lesions initially caused by streptococci. The sequence of spread of *S. aureus* is from nose to normal skin (about 11 days later) and to skin lesions (after another 11 days). Lesions commonly arise on the skin of the face (especially around the nares) or extremities after trauma. Pruritus may be present in some cases. Nasal carriers of *S. aureus* can present with a very localized type of impetigo confined to the anterior nares and the adjacent lip area (Fig. 194-1); soreness of the area is a common complaint (see Fig. 194-2). Conditions that disrupt the integrity of the epidermis, providing a portal of entry of impetiginization, include insect bites, epidermal dermatophytoses, herpes simplex, varicella, abrasions, lacerations, and thermal burns. The initial lesion is a transient vesicle or pustule (see Fig. 194-2) (usually not seen by the patient or the health care worker) that quickly evolves into a honey-colored crusted plaque that can enlarge to >2 cm in diameter (see Fig. 194-1). Surrounding erythema may be present. Constitutional symptoms are absent. Regional lymphadenopathy may be present in up to 90 percent of patients with prolonged untreated infection.

FIGURE 194-1 *S. aureus:* impetigo. Erythema and crusting on the nose and moustache area (*A*), which can spread to involve the entire centrofacial region (*B*).

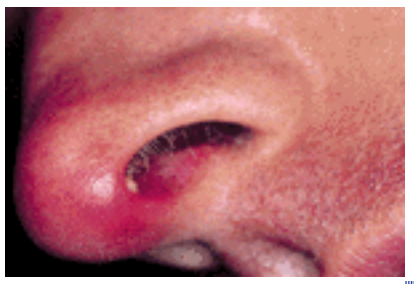

FIGURE 194-2 *S. aureus:* nasal carriage with impetigo. Erythema with a small pustule on the tip of the nose and nares in individual whose nares are colonized by *S. aureus*.

The differential diagnosis of nonbullous impetigo includes seborrheic dermatitis; atopic dermatitis; allergic contact dermatitis; epidermal dermatophyte infections; tinea capitis; herpes simplex; varicella; herpes zoster; scabies; and pediculosis capitis. Any of these disorders may occur primarily and become secondarily impetiginized with *S. aureus* or group A streptococcus. Untreated, the lesions may slowly enlarge and involve new sites over several weeks. In some individuals, lesions resolve spontaneously. In others, the lesions extend into the dermis forming an ulcer (ecthyma, see below).

Bullous impetigo Three types of skin lesions can be produced by phage group II *S. aureus*, particularly strains 77 and 55: (1) bullous impetigo, (2) exfoliative disease (staphylococcal scalded-skin syndrome), and (3) nonstreptococcal scarlatiniform eruption (staphylococcal scarlet fever). All three represent varying cutaneous responses to extracellular exfoliative toxins ("exfoliatin") types A and B produced by these staphylococci (for descriptions of the toxin and the clinical presentation see Chap. 195). Exfoliative toxin A acts as a serine protease of desmoglein 1, the desmosomal cadherin that is also the target of autoantibodies in pemphigus foliaceus. [12] In a study of bullous impetigo, 51 percent of patients had concurrent *S. aureus* cultured from the nose or throat; 79 percent of cultures grew the same strain from both sites. Bullous impetigo occurs more commonly in the newborn and in older infants, and is characterized by the rapid

progression of vesicles to flaccid bullae (Fig. 194-3). Several decades ago, extensive bullous impetigo (archaic term: pemphigus neonatorum or Ritter's disease) occurred in epidemics within neonatal nurseries.

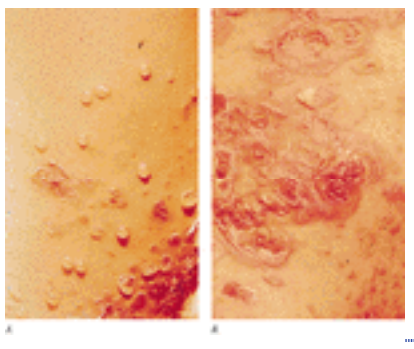

FIGURE 194-3 *S. aureus:* bullous impetigo. *A*. Multiple vesicles with clear and turbid contents that (*B*) rapidly coalesce to form flaccid bullae.

Bullae usually arise on areas of grossly normal skin. The Nikolsky sign (sheetlike removal of epidermis by shearing pressure) is not present. Bullae initially contain clear yellow fluid that subsequently becomes dark yellow and turbid (Fig. 194-3A), and their margins are sharply demarcated without an erythematous halo. The bullae are superficial, and within a day or two, they rupture and collapse, at times forming thin, light-brown to golden-yellow crusts (Fig. 195-3B). So-called bullous varicella represents superinfection by *S. aureus* (phage group II) of varicella lesions (bullous impetiginization). The differential diagnosis is that of blisters localized to one body region and includes allergic contact dermatitis (e.g., poison ivy or oak); pemphigus vulgaris; bullous pemphigoid; erythema multiforme; dermatitis herpetiformis; thermal burns; bullous fixed drug reaction; SSSS; bullous tinea pedis; and bullous insect bites. Gram stain of exudates from bullous impetigo reveals gram-positive cocci in clusters; *S. aureus* belonging to phage group II can be cultured from the contents of intact bullae. In comparison, Gram stain of exudates from lesions of SSSS do not show staphylococci, and *S. aureus* are not isolated on culture. Bulla formation in the latter condition is caused by distant production of toxin rather than local infection (see Chap. 195). Histologically, the lesions of bullous impetigo show vesicle formation in the subcorneal or granular region, occasional acantholytic cells within the blister, spongiosis, edema of the papillary dermis, and a mixed infiltrate of lymphocytes and neutrophils around blood vessels of the superficial plexus.

Course of staphylococcal impetigo Untreated, invasive infection can complicate *S. aureus* impetigo, including cellulitis, lymphangitis, and bacteremia, with resultant osteomyelitis, septic arthritis, pneumonitis, and septicemia. Exfoliatin production can lead to SSSS in infants, and in adults who are immunocompromised or have impaired renal function.

Management of staphylococcal impetigo Local treatment with mupirocin ointment or cream and removal of crusts and maintenance of cleanliness is sufficient to cure mild cases. [13] However, the results are further improved, particularly in extensive cases, by the administration of systemic antibiotics. The frequency of isolation of group A streptococcus makes such therapy a reasonable approach in most patients who have a significant degree of involvement. Staphylococcal impetigo responds quite promptly to appropriate treatment. In an adult with extensive or bullous lesions, dicloxacillin (or similar penicillinase-resistant semisynthetic penicillin) (250 to 500 mg PO qid), or erythromycin (in the penicillin-allergic patient) (250 to 500 mg PO qid) should be given. Treatment should be continued for 5 to 7 days (10 days if streptococci are isolated). Also, a single dose of oral azithromycin (in adults 500 mg on the first day, 250 mg daily on the next 4 days) has been shown to be equally as effective as dicloxacillin for skin infections in adults and children. For impetigo caused by erythromycin-resistant *S. aureus*, which is commonly isolated from impetigo lesions of children, amoxicillin plus clavulanic acid (Augmentin) (25 mg/kg per day given tid), cephalexin (40 to 50 mg/kg per day), cefaclor (20 mg/kg per day given tid), cefprozil (20 mg/kg once daily), or clindamycin (15 mg/kg per day tid or qid) given for 10 days are effective alternative therapies.

ECTHYMA Ecthyma is usually a consequence of neglected impetigo. *S. aureus* and/or group A streptococcus can be isolated on culture. Untreated staphylococcal or streptococcal impetigo can extend more deeply, penetrating the epidermis, producing a shallow crusted ulcer (Fig. 194-4). Ecthymatous lesions can evolve from a primary pyoderma or within a preexisting dermatosis or site of trauma (insect bites or excoriations). Ecthyma gangrenosum is a cutaneous ulcer caused by Pseudomonas aeruginosa and resembles staphylococcal or streptococcal ecthyma (see Chap. 197).

FIGURE 194-4 *S. aureus:* ecthyma. Multiple thickly crusted ulcers on the leg of a patient with diabetes and renal failure. Ecthymatous lesions were also present on the other leg, the arms, and the hands.

Ecthyma occurs most commonly on the lower extremities of children, or neglected elderly patients, or individuals with diabetes. Poor hygiene and neglect are key elements in pathogenesis. Multiple ecthymatous ulcers on the ankle and dorsum of the foot were the most common pyodermas seen during wartime in tropical climates. [14] The ulcer has a “punched out” appearance when the dirty grayish-yellow crust and purulent material are débrided. The margin of the ulcer is indurated, raised, and violaceous (see Fig. 194-4), and the granulating base extends deeply into the dermis. Untreated ecthymatous lesions enlarge over weeks to months to a diameter of 2 to 3 cm or more. The lesions are slow to heal, requiring several weeks of antibiotic treatment for resolution. Problems of spread by autoinoculation or by insect

vectors and of poststreptococcal sequela (glomerulonephritis) are the same as with impetigo.
Management of ecthyma Same as for staphylococcal impetigo (see above).
FOLLICULITIS This is a pyoderma that begins within the hair follicle, and is classified according to the depth of invasion, that is, superficial and deep, and by microbial etiology (Table 194-3).

Bacterial folliculitis
S. aureus folliculitis
Periporitis staphylogenes
Superficial (follicular or Bockhart's impetigo)
Deep (sycosis) (may progress to furuncle (boil) or carbuncle)
P. aeruginosa folliculitis ("hot tub" folliculitis)
Gram-negative folliculitis (occurs at site of acne vulgaris usually the face during long-term antibiotic therapy)
Syphilitic folliculitis (secondary) (acneform)
Fungal folliculitis
Dermatophytic folliculitis
Tinea capitis
Tinea barbae
Majocchi's granuloma
Pityrosporum folliculitis
Candida folliculitis
Viral folliculitis
Herpes simplex virus folliculitis
Follicular molluscum contagiosum
Infestation
Demodicidosis

TABLE 194-3 **Classification of Infectious Folliculitis**

Superficial folliculitis Superficial folliculitis has also been termed follicular or Bockhart's impetigo. A small fragile dome-shaped pustule occurs at the infundibulum (ostium or opening) of a hair follicle, often on the scalps of children and in the beard area (Fig. 194-5), axillae, extremities, and buttocks of adults. Isolated staphylococcal folliculitis is common on the buttock of adults. “Periporitis staphylogenes” refers to secondary infection of miliaria of the neonate by *S. aureus*. Staphylococcal blepharitis is an *S. aureus* infection of the eyelids, presenting with scaling (squamous type) or crusting (ulcerative type) of the eyelid margins, often with associated conjunctivitis; the differential diagnosis includes seborrheic dermatitis and rosacea of the eyelid.

FIGURE 194-5 *S. aureus:* superficial folliculitis. Multiple pustules confined to the beard area.

S. aureus folliculitis must be differentiated from other folliculocentric infections (see Table 194-3). Black men are subject to three noninfectious, inflammatory, follicular disorders: pseudofolliculitis barbae, which occurs on the lower beard area (Fig. 194-6); folliculitis keloidalis, on the nape of the neck; and perifolliculitis capitis, on the scalp. *S. aureus* can cause secondary infection in these inflammatory disorders. Exposure to mineral oils, tar products, and cutting oils can cause an irritant folliculitis. Acne vulgaris, drug-induced acneform eruptions, rosacea, hidradenitis suppurativa, acne necrotica of the scalp, and eosinophilic folliculitis of HIV disease must be distinguished from infectious folliculitis as well. Also, folliculitis caused by *P. aeruginosa* may be acquired from exposure in “hot tubs” (see Chap. 197).

FIGURE 194-6 Pseudofolliculitis barbae. Multiple papules in the lower beard area caused by ingrowing of the curved hair shaft in a black male who shaves. If pustules are present, secondary *S. aureus* infection must be ruled out.

Deep folliculitis Sycosis barbae is a deep folliculitis with perifollicular inflammation occurring in the bearded areas of the face and upper lip (Fig. 194-7). If untreated, the lesions may become more deeply seated and chronic. Local treatment with warm saline compresses and local antibiotics (mupirocin) may be sufficient to control infection. More extensive cases require systemic antibiotic therapy. Dermatophytic folliculitis must be differentiated from *S. aureus* folliculitis. In the latter fungal infection, the hairs are usually broken or loosened, and there are suppurative or granulomatous nodules rather than discrete pustules (see Chap. 205).

FIGURE 194-7 Sycosis barbae. Deep staphylococcal folliculitis of the mustache region.

Lupoid sycosis is a deep, chronic form of sycosis barbae associated with scarring, usually occurring as a circinate lesion. A central cicatrix surrounded by pustules and papules gives the appearance of lupus vulgaris (see Chap. 200).
FURUNCLES AND CARBUNCLES A furuncle or boil is a deep-seated inflammatory nodule that develops about a hair follicle, usually from a preceding, more superficial folliculitis and often evolving into an abscess. A carbuncle is a more extensive, deeper, communicating, infiltrated lesion that develops when suppuration occurs in thick inelastic skin. Furuncles arise in hair-bearing sites, particularly in regions subject to friction, occlusion, and perspiration, such as the

neck, face, axillae, and buttocks. They may complicate preexisting lesions such as atopic dermatitis, excoriations, abrasions, scabies, or pediculosis, but occur more often in the absence of any local predisposing causes. In addition, a variety of systemic host factors is associated with furunculosis: obesity, blood dyscrasias, defects in neutrophil function (defects in chemotaxis associated with eczema and high levels of IgE, defects in intracellular killing of organisms as in chronic granulomatous disease of childhood), treatment with glucocorticoids and cytotoxic agents, and immune globulin deficiency states. Whether diabetes mellitus predisposes to furunculosis is still controversial; once established, however, the process is often more extensive in patients with diabetes. The majority of patients with problems of furunculosis appear to be otherwise healthy. A furuncle starts as a hard, tender, red folliculocentric nodule in hair-bearing skin that enlarges and becomes painful and fluctuant after several days (i.e., undergoes abscess formation; Fig. 194-8A). Rupture occurs, with discharge of pus and often a core of necrotic material. The pain surrounding the lesion then subsides, and the redness and edema diminish over several days to several weeks. Furuncles may occur as solitary lesions or as multiple lesions in sites such as the buttocks (Fig. 194-8B).

FIGURE 194-8 *A*. Furuncle of the upper lip. The lesion is nodular and the central necrotic plug is covered by purulent crust. Several small pustules are seen lateral to the center of the lesion. *B*. Multiple furuncles. Multiple abscesses on the buttocks of long standing in a young man with inflammatory bowel disease. The lesions healed with scarring after a prolonged course of dicloxacillin.

A carbuncle is a larger, more serious inflammatory lesion with a deeper base, characteristically occurring as an extremely painful lesion at the nape of the neck, the back, or thighs (Fig. 194-9). Fever and malaise are often present, and the patient may appear quite ill. The involved area is red and indurated, and multiple pustules soon appear on the surface, draining externally around multiple hair follicles. The lesion soon develops a yellow-gray irregular crater at the center, which may then heal slowly by granulating, although the area may remain deeply violaceous for a prolonged period. The resulting permanent scar is often dense and readily evident.

FIGURE 194-9 Carbuncle. This lesion represents multiple confluent furuncles draining pus from multiple openings.

The differential diagnosis of furuncles and carbuncles includes “cystic acne,” kerion, a deep-seated dermatophytic infection with abscess formation of hair follicles (see Chap. 205), hidradenitis suppurativa (axillae and anogenital region), ruptured epidermal inclusion cyst, furuncular myiasis (e.g., *Dermatobia hominis*) apical (dental) abscess (face), and the external sites (on an extremity of a beginning fistulous track from an underlying osteomyelitis). Extensive furunculosis or a carbuncle may be associated with leukocytosis, particularly when there is a large amount of unliberated pus, surrounding cellulitis, or bacteremia. *S. aureus* is almost always the cause of furuncles and carbuncles. Histologic examination of a furuncle shows a dense polymorphonuclear inflammatory process in the dermis and subcutaneous fat. In carbuncles, multiple abscesses, separated by connective-tissue trabeculae, infiltrate the dermis and pass along the edges of the hair follicles, reaching the surface through openings in the undermined epidermis. The diagnosis is made on the basis of the clinical appearance. Gram stain of pus, clusters of gram-positive cocci, or isolation of *S. aureus* on culture confirms the diagnosis. The major problems with furunculosis and carbuncles are bacteremic spread of infection and recurrence. Lesions about the lips and nose raise the specter of spread via the facial and angular emissary veins to the cavernous sinus. Invasion of the bloodstream may occur from furuncles or carbuncles at any time, in an unpredictable fashion, resulting in metastatic infection such as osteomyelitis, acute endocarditis, or brain abscess. Manipulation of such lesions is particularly dangerous and may facilitate spread of infection via the bloodstream. Fortunately, these complications are not common. Recurrent furunculosis is a troublesome process that may continue for many years. Most often these lesions are limited to the area of the follicles, but sometimes they extend to produce surrounding cellulitis or bacteremia. Individuals who perspire excessively or who have poor skin hygiene appear more disposed to recurrent furunculosis.

Management of folliculitis, furuncles, and carbuncles Simple furunculosis may be treated by local application of moist heat, which relieves discomfort, aids in the localization of the infection, and promotes drainage. A carbuncle or a furuncle with surrounding cellulitis, or one with associated fever, should be treated with a systemic antibiotic. For severe infections or infections in a dangerous area, maximal antibiotic dosage should be employed by the parenteral route, the patient should be put to bed, and the involved area should be immobilized. If MRSA is implicated or suspected in serious infections, vancomycin (1.0 to 2.0 g IV daily in divided doses) is indicated. Antibiotic treatment should be continued for at least 1 week. When the lesions are large but localized, painful, and fluctuant, drainage (limited to the necrotic fluctuant area) is indicated. Antimicrobial therapy should be continued until all evidence of inflammation has regressed. After

adequate drainage (spontaneous or surgical) has occurred, moist dressings should not be applied because of the danger of local spread enhanced by tissue maceration. Application of a thin layer of 2% mupirocin ointment about the lesion protects the surrounding skin. Such draining lesions should be covered with a sterile dressing to prevent autoinoculation. Hands should be thoroughly washed after contact with the lesions. The treatment of patients with recurrent furunculosis presents a special and frequently exasperating problem (Table 194-4). There is no evidence that this disease is caused by any specific staphylococcal strains with special biologic properties. In addition to the treatment of acute lesions, as above, treatment involves steps in the prophylaxis of recurrent episodes.

TABLE 194-4 **Management of Recurrent Furunculosis**

ABSCESS As discussed above, abscesses caused by *S. aureus* commonly occur in folliculocentric infections—that is, folliculitis, furuncles, and carbuncles. Abscesses can also occur at sites of trauma, foreign bodies, burns, or sites of insertion of intravenous catheters. The initial lesion is an erythematous nodule. Often if untreated, the lesion enlarges with the formation of a pus-filled cavity (Fig. 194-10). In some cases, the portal of entry is apparent.

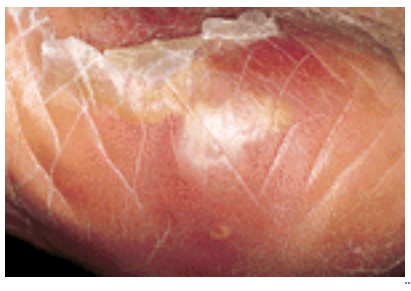

FIGURE 194-10 *S. aureus* abscess. A large painful abscess on the heel of a patient with diabetes improved clinically, however, the severe pain persisted. X-ray films of the heel revealed a broken-off sewing needle. The patient had sensory neuropathy and was unaware of stepping on this foreign body.

Management of abscess (See " Management of Folliculitis, Furuncles, and Carbuncles ," above) The initial treatment of an abscess is incision and drainage. If the abscess recurs at the same site, a foreign body should be ruled out by probing or imaging.

BOTRYOMYCOSIS (See also Chap. 201) This a very rare pyogenic disease, possibly related to a balance between numbers of organisms and host defenses. Predisposing factors include trauma, immunosuppression (HIV disease, hyperimmunoglobulin E syndrome), chronic alcoholism, and diabetes mellitus. The lesions (usually solitary) can occur in skin, bone, and liver. Cutaneous botryomycosis usually presents as a solitary or few lesions, often occurring in the genital area. The lesion has the gross appearance of a ruptured epidermal inclusion cyst (an erythematous circumscribed tender nodule), lichen simplex chronicus, or prurigo nodularis (Fig. 194-11). In the majority of reported cases, a foreign body (fish bone, broom straw, etc.) has played a role in initiating or perpetuating the lesion. For diagnosis and treatment see Chap. 201.

FIGURE 194-11 *S. aureus* botryomycosis. A plaque on the chest had been present for several months in this HIV-infected individual. The diagnosis was confirmed on lesional biopsy findings and culture.

STAPHYLOCOCCAL PARONYCHIA Individuals exposed to hand trauma or chronic moisture are predisposed to staphylococcal paronychia, as well as to other causes of paronychia (e.g., *Candida, Pseudomonas, Streptococcus,* dermatophytes). *S. aureus* is the major infectious cause of acute paronychia, usually around the fingernails, often originating from a break in the skin, such as a hangnail. Clinically, skin and soft tissue of the proximal and lateral nail fold are red, hot, and tender, and if not treated, can evolve to abscess formation (Fig. 194-12).

FIGURE 194-12 *S. aureus* paronychia. An abscess is seen in the dorsum of the finger, beginning in a small break in the cuticle. In contrast, *Candida* paronychia is a space infection, occurring in the space created by the separation of the proximal dorsal nail plate and the overlying proximal nail fold.

In contrast, chronic or recurrent paronychia caused by *Candida albicans* is an infection of the space created by separation of the proximal dorsal nail plate and the undersurface of the proximal nail fold. Candidal paronychia is most common in individuals who have their hands in water for a great deal of time; this is discussed in Chap. 206. Management of paronychia caused by *S. aureus* includes oral and topical antibiotics, and incision and drainage of abscesses.

STAPHYLOCOCCAL WHITLOW (FELON) A whitlow is a purulent infection or abscess involving the bulbous distal end of the finger. The most common causes are *S. aureus* and herpes simplex virus. The portal of entry of *S. aureus* is from a traumatic injury or possible extension of an acute paronychia. This infection is usually very painful. Clinically, an obvious portal of entry is often apparent. The finger bulb is red, hot, tender, and edematous, with possible abscess formation (Fig. 194-13). In contrast, individuals with herpetic whitlows usually have a history of prior lesions occurring in the same site, and present with grouped hemorrhagic vesicles, which may become confluent and form a single bulla (see Chap. 214). Management of a staphylococcal whitlow requires surgical drainage of loculated abscess(es) within the tissue and intravenous antibiotic therapy. X-ray examination of the involved finger is indicated to determine the presence of osteomyelitis.

FIGURE 194-13 *S. aureus* whitlow (felon). A pyogenic granuloma arose 1 week after trauma to the bulb of the thumb. A week later, the bulb became swollen, erythematous, and very tender. Abscess formation is seen with loculation of pus. X-ray films showed early osteomyelitis complicating the whitlow.

STAPHYLOCOCCAL BACTEREMIA AND ENDOCARDITIS (SeeChap. 166)

S. aureus from pyodermas and soft tissue infections can invade lymphatics and blood vessels, resulting in bacteremia and metastatic infection at distant sites, causing diverse processes such as acute bacterial endocarditis (ABE), septic arthritis, or acute osteomyelitis. *S. aureus* infection at internal sites or on the heart valves can result in dissemination to mucocutaneous sites.

Bacteremia with *S. aureus* is defined as seeding of the bloodstream in the presence (“secondary bacteremia”) or absence (“primary bacteremia”) of a defined peripheral focus of infection. The focus of infection is usually community-acquired (furuncle, carbuncle, wound infection) or nosocomial (intravascular catheter, urinary catheter, or chest tube). In the absence of localizing findings, the clinical presentation may be of a flulike syndrome and *S. aureus* may be isolated on multiple blood cultures. Presumably in this case, a small, unnoticed skin focus has been the initial source of bacteremia. Without an identifiable peripheral focus and in the presence of repeatedly positive blood cultures, endocarditis is assumed and the patient treated accordingly, even in the absence of a heart murmur, demonstrable vegetations, or embolic events.

The risk of endocarditis is probably less than 10 percent in patients with secondary bacteremia (from a defined peripheral site). Continued bacteremia increases the risk for endocarditis. In acute *S. aureus* infectious endocarditis, skin and/or mucous membrane lesions occur in 50 percent of patients, and can provide a clue to the diagnosis. These lesions include petechiae on the digits or extremities; a full spectrum of larger skin lesions with elements of infarction (Fig. 194-14), suppuration, and hemorrhage (pustules, subcutaneous abscesses, and purulent purpura); gangrenous symmetric involvement of the extremities; and purpura fulminans (see below) as a manifestation of disseminated intravascular coagulation. The purulent purpura consists of an area of purpura with a white purulent center. (Gram-stained smear of the aspirated contents from the center of the lesion shows gram-positive cocci in clusters and polymorphonuclear inflammatory cells.) Multiple tender subcutaneous nodules (2 to 4 cm) with erythema of the overlying skin may occur, with and without abscess formation. Culture of a lesional biopsy specimen often yields the causative *S. aureus*.

FIGURE 194-14 *S. aureus* endocarditis and bacteremia with cutaneous infarctions. Multiple cutaneous infections are seen on the plantar foot of the injected-drug user with acute infective endocarditis; lesions were also present on the other foot and the palms. (*Courtesy of David N. Silvers, MD.*)

Several types of lesions can be seen on the hands of individuals with acute infectious endocarditis. Janeway lesions are typically seen in *S. aureus* endocarditis and Osler's nodes are caused by microemboli leading to vascular occlusion with local vasculitis. Both Osler's nodes and Janeway lesions are escribed in more detail under subacute infectious endocarditis below. Subungual splinter hemorrhages associated with *S. aureus* acute infectious endocarditis occur in the middle third of the nail bed.

Embolization to the eye results in subconjunctival hemorrhage, petechial and flame-shaped hemorrhages in the retina, cotton–wool exudates in the fundus, Roth spots (oval or boat-shaped white areas in the retina surrounded by a zone of hemorrhage), and endophthalmitis (see Chap. 166).

Syndromes Caused by Staphylococcal Exotoxins

STAPHYLOCOCCAL SCALDED-SKIN SYNDROME This condition is described in detail in Chapter 195.
Staphylococcal scarlatiniform eruption This is identical to the generalized scarlatiniform rash with skin tenderness observed in the initial stage of SSSS (Chap. 195). Patients are febrile for the first few days. As in streptococcal scarlet fever (see below), the skin is diffusely erythematous, with a sandpaper roughness. Pastia's lines are present. Pharyngitis, strawberry tongue, and palatal enanthem, typical of streptococcal scarlet fever, are not seen. Bullae and exfoliation do not occur, although Nikolsky's sign may be present in an occasional patient. After 2 to 5 days of erythema, desquamation begins, initially on the face, and extends to involve most of the body. Healing of the skin occurs within 10 days. Staphylococci belonging to phage group II are recovered from sites of staphylococcal infection (conjunctivitis, abscesses, bacteremia, external otitis). These strains generally produce staphylococcal enterotoxins (SEs) similar to toxins responsible for TSS. Thus, staphylococcal scarlet fever may be a milder form of TSS.
STAPHYLOCOCCAL TOXIC-SHOCK SYNDROME TSS is a multiorgan systemic illness due to exotoxin-producing strains of *S. aureus*. It is characterized by a generalized erythematous eruption and a high fever. Additional elements making up the syndrome include (1) hypotension, (2) functional abnormalities in at least three organ systems, and (3) desquamation following the scarlatiniform eruption. More than 1600 cases occurred in a nationwide outbreak between 1979 and 1982, primarily, but not exclusively, in menstruating women. [15]
Bacteriology and pathogenesis Toxic shock syndrome has two forms: menstrual and nonmenstrual. *S. aureus* strains isolated from women with menstrual TSS are usually penicillin-resistant, and more than 93 percent of them produce TSS toxin 1 (TSST-1). In nonmenstrual TSS, 48 percent of isolates produce TSST-1 alone, 26 percent produce enterotoxin B, 7 percent produce enterotoxin C, and 19 percent produce both TSST-1 and enterotoxin C1 together. [16] Illness similar to TSS in humans can be produced in animals inoculated with either purified TSST-1 or with TSST-1–producing strains of *S. aureus*. The manifestations of this illness can be prevented by TSST-1 antiserum. TSST-1 stimulates release of TNF-a, and the induction of the shocklike state appears to be related to the synergistic action of TNF-a with interleukin-1. In 1980, approximately 85 to 90 percent of cases of TSS occurred in women at the time of menstruation; almost all had been tampon users (particularly of superabsorbent types). *S. aureus* has been isolated from vaginal cultures of more than 90 percent of menstruating women with TSS, but from only 10 percent of healthy menstruating women. Cervicovaginal ulcerations, possibly produced or aggravated by tampon use, may have provided the initiating infection and the portal for toxin absorption in menstruating women in whom TSS developed. Furthermore, superabsorbent tampons may allow increased oxygen tension, which results in higher amounts of toxin production. Recurrent menstrual TSS, which has been reported to occur in up to a third of TSS patients, requires two concurrent factors: persistent colonization with toxin producing *S. aureus* and persistent absence of toxin neutralizing antibodies. [17] Staphylococcal infections (skin, soft tissue, bone, lung) in children, men, and nonmenstruating women account for the remaining 10 to 15 percent of cases of TSS and clinical signs of local infection may be absent. Minor surgery, burns, trauma, and abrasions are some of the risk factors for nonmenstrual TSS. Other reported associations include sinusitis, tracheitis, IV drug abuse, HIV infection, influenza, allergic contact dermatitis, gynecologic infection, the postpartum period, and two cases of TSS in children with abrasive injuries beneath casts. [18] Between 1980 and 1990, the number of cases of menstrual TSS declined by more than 90 percent, but the number of nonmenstrual cases remained unchanged, leading to the current higher incidence of nonmenstrual TSS over menstrual TSS. The decrease in menstruation-associated TSS cases is directly related to the removal of superabsorbent tampons.
Clinical manifestations Fever, hypotension (or shock), and a rash (diffuse macular erythroderma) are the initial hallmarks of TSS (Fig. 194-15A). The cutaneous findings include a generalized scarlatiniform (resembling scarlet fever) erythema, most intense around an infected site. The rash may be indistinguishable from that of scarlet fever or may be less striking and suggest the flush associated with fever. Nonpitting edema may occur on the face and extremities. The bulbar conjunctivae show intense injection; the mucosa of the oropharynx, tongue (strawberry tongue), vagina, and tympanic membranes may show intense erythema. Less-common findings include petechiae, bullae, subconjunctival hemorrhages, and ulcerations of the mouth, vagina, esophagus, or bladder. Desquamation of palms and soles occurs 1 to 2 weeks later (Fig. 195-15 *B*). Evidence of multiple other organ dysfunctions seen in TSS include (1) muscular system—myalgias and rhabdomyolysis; (2) central nervous system—toxic encephalopathy; (3) kidney—azotemia; (4) liver—elevated levels of aspartate transaminase and serum bilirubin; and (5) blood—thrombocytopenia. Mortality is approximately 5 percent.

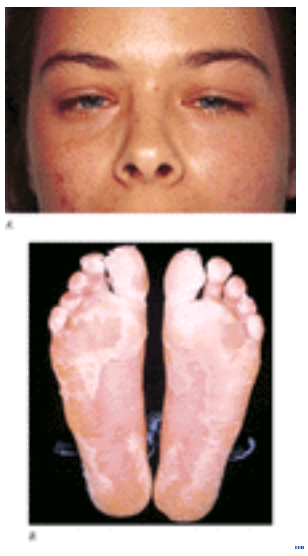

FIGURE 194-15 *S. aureus* toxic shock syndrome. *A*. Erythema and edema of the face with conjunctival injection during the acute presentation. *B*. Residual erythema and desquamation occurring 2 weeks after an episode of toxic shock syndrome; similar findings were also found on the palms. (*Courtesy of Stuart J. Salasche, MD.*)

Differential diagnosis The differential diagnosis include staphylococcal scarlatiniform eruption; SSSS (in which bullae and a positive Nikolsky sign are expected); scarlet fever (not usually associated with hypotension or shock); streptococcal toxic shock–like syndrome; a febrile drug reaction (not usually associated with hypotension); Kawasaki disease (usually in children, and features prominent lymphadenopathy; see Chap. 204); viral exanthem; systemic lupus erythematosus; acute graft-versus-host disease; and adverse cutaneous drug eruptions (confluent exanthematous, toxic epidermal necrolysis, erythema multiforme).

Laboratory findings Leukocytosis and thrombocytopenia are usually present. Microscopic hematuria may be present. Elevated blood urea nitrogen and creatinine levels occur in the majority of patients, and liver-function tests are frequently abnormal. Increased serum creatine kinase levels reflect muscle injury, and myoglobinuria occurs in some patients. Hypocalcemia occurs in many patients but the basis is unclear.

Diagnosis Diagnosis is made on the basis of the clinical constellation of findings in a patient who has an *S. aureus* infection or in a menstruating woman, particularly in a tampon user.

Management Treatment of TSS involves (1) immediate institution of vigorous fluid replacement to combat the hypotension, (2) attention to focal staphylococcal infections (drainage of abscesses, removal of tampons), and (3) systemic antimicrobial therapy aimed at penicillinase-producing *S. aureus* (nafcillin 1.0 to 1.5 g intravenously in the adult every 4 h). Intravenous gamma globulin therapy and fresh-frozen plasma containing immunoglobulins have been successful, especially when administered early in the disease course.

Recalcitrant, erythematous, desquamating disorder This was described by Cone et al. in 1992 based on a series of AIDS patients with a TSS-like syndrome. [19] Clinical features include fever, hypotension, diffuse macular erythema, ocular and oral mucosal injection, strawberry tongue, and delayed desquamation. All have TSST-1, enterotoxin A or enterotoxin B producing *S. aureus* isolates from the blood, subcutaneous tissue or sinuses. Recalcitrant, erythematous, desquamating disorder (RED disorder) is a subacute illness of about 50 days mean duration with frequent recurrences. Despite the subacute nature, it has a higher reported mortality rate than TSS, likely a result of the effect of underlying immunosuppression. Treatment includes antibiotics (nafcillin, vancomycin or cephalosporin), IV fluids, and possibly IVIG.

KAWASAKI SYNDROME (See Chapter 204)

RECURRENT TOXIN-MEDIATED PERINEAL ERYTHEMA This was described by Manders et al. [20] in 1996 as a recurrent, toxin-mediated disease sharing some of the clinical characteristics of Kawasaki syndrome but occurring in young adults, rather than small children. Clinical features include macular erythema of the perineum within 24 to 48 h of a bacterial pharyngitis, strawberry tongue, and extremity changes including erythema, edema, and convalescent desquamation. No fever or hypotension is noted and recurrences are frequent. Culture of the pharynx during the acute pharyngitis identified a TSST-1 producing *S. aureus* or a pyrogenic exotoxin A and B producing group A streptococcus.

ATOPIC DERMATITIS (See Chap. 122) In individuals with atopic dermatitis (AD), *S. aureus* was found in the anterior nares and distal subungual spaces of their fingernails 5 and 10 times more frequently, respectively, than in normal subjects. [21] In children and adults with AD, 78 to 100 percent of eczematous lesions (more commonly in exudative lesions than chronic plaques) are colonized with *S. aureus*. Colonization of noneczematous skin is significantly less frequent. Topical glucocorticoid treatment of involved skin reduces the bacterial skin flora in patients with atopic dermatitis. Approximately 60 percent of isolates from AD patients secrete exotoxins, primarily enterotoxins A and B and TSST-1. These toxins may play a role in the frequent exacerbations seen in these patients since flares often temporally correlate with heavy staphylococcal colonization of the skin.

STREPTOCOCCAL SKIN INFECTIONS

General Features

BACTERIOLOGY AND PATHOGENESIS The Lancefield classification of streptococcal groups (A to T) is based on the C carbohydrate antigens of the cell wall. Although essentially all group A streptococcal strains are beta-hemolytic streptococci (BHS), not all streptococci producing beta-hemolysis belong to group A. Because serologic grouping of streptococci is not generally available, a reasonably accurate presumptive test for group A streptococci is necessary. Bacitracin disk (“Taxos S”) sensitivity has been widely used; group A streptococci are, almost without exception, susceptible to the low concentration of bacitracin contained in the disk, whereas streptococci of other groups are often resistant. Subtyping of group A streptococci can be performed according to their M protein antigenicity (see below). Certain M protein serotypes appear to correlate with greater virulence of the organism. The M protein inhibits phagocytosis, promotes adherence to host cells and allows bacterial growth in human blood. [22] Other virulence factors are cell surface molecules including the hyaluronic acid capsule, C5a peptidase, opacity factor and streptococcal inhibitor of complement (SIC). Secreted proteins playing a role in virulence include streptolysins O and S, cysteine proteinase, pyrogenic exotoxins, streptokinase, hyaluronidase, and other enzymes. The primary invasive streptococcal pyodermas are due almost exclusively to group A streptococcus. The invasive potential of group A streptococcus is

usually considerably greater than that of other streptococci. Nonsuppurative postinfectious complications have been limited mostly to those produced by group A streptococcus. Thus, group A streptococcal infections merit antibiotic treatment and eradication. The hallmarks of invasive group A streptococcal infection (erysipelas, see Chap. 196) are profuse edema, rapid spread through tissue planes, and the relatively thin character of the exudative response. Infection may spread via the lymphatic or hematogenous routes and result in a fulminant clinical course. The presence of streptococci of groups other than A in skin lesions may represent either surface colonization or actual secondary infection in preexisting dermatoses. Group C and group G streptococci have occasionally been implicated in impetiginous lesions, secondarily infected dermatitis, wound infections with lymphangitis, and even in erysipelas and cellulitis. Streptococci of groups B and D have been isolated from infections of skin lesions secondary to ischemia or venous stasis and have particularly involved the perineal area and operative wound sites. As with most secondary infections, those due to group B and group D streptococci are frequently mixed infections with enteric bacteria or *S. aureus*. Group B streptococci may cause cellulitis and otitis in neonates and sometimes in adults. Group L streptococci (often carried by pigs, cattle, and poultry) have been responsible for impetigo, secondarily infected wounds, and paronychias in meat handlers.

EPIDEMIOLOGY OF GROUP A STREPTOCOCCAL INFECTIONS Group A streptococci are usually spread by transfer of organisms from an infected person or carrier through close personal contact. The major source of such spread is from patients with infections in the upper respiratory tract. Approximately 10 percent of the normal population carry group A streptococcus asymptomatically—a higher percentage of adults than of children in the oropharynx and less commonly in the nares and anus. While the carriage rate of group A streptococcus on normal skin is less than 1 percent, a variety of skin lesions and puerperal sepsis may also be the source of intrahospital spread of infection. Group A streptococci introduced into the operating room in the form of a minor skin infection, or even through perianal carriage by a surgeon or anesthetist, may be responsible for an epidemic of streptococcal wound infections. Although viable streptococci are found on a variety of articles in the immediate surroundings of a carrier or infected individual, the major factor in spread is not the articles in the contaminated environment but rather proximity to an individual disseminating the organisms. Because many patients with group A streptococcal skin infections harbor the same organism in their pharynxes, they are, for both reasons, potential sources for spread of infection in a hospital. Particular care must be taken to prevent spread of infection, by isolating such patients until antibiotic therapy has rendered them noncontagious. Despite the salutary effects of penicillin on morbidity and mortality, the overall incidence of streptococcal disease has surged since the mid-1980s. [23] Reports of invasive group A streptococcal infections often associated with shock and multiorgan failure have increased globally. It is possible that more virulent serotypes of group A streptococcus are now distributed in the general population. Localized epidemics continue to appear and during such outbreaks, the carrier and infection rates in the community increase. Carriers may then enter the hospital environment. In this way, streptococci can be introduced into surgical incisions and lacerations and initiate infection. Streptococcal operative infections, because of the rapidity with which they progress, may be more severe and dramatic than those caused by staphylococci. After recovery (without antibiotic treatment) from streptococcal pharyngitis, some individuals may carry the organism for prolonged periods. The carrier state may also occur in the absence of overt antecedent infection. Fifteen to 20 percent of schoolchildren carry group A streptococci in the throat.

DELAYED NONSUPPURATIVE SEQUELAE The incidence of invasive complications (lymphangitis, suppurative lymphadenitis, bacteremia) of streptococcal infections of the skin has decreased in the antibiotic era. Besides these pyogenic complications, a variety of nonsuppurative complications (acute rheumatic fever, acute glomerulonephritis, erythema nodosum) may follow group A streptococcal infections. Distinct differences exist between acute rheumatic fever and acute glomerulonephritis in the site of the antecedent infection, the length of the latent period, and the streptococcal serotypes involved. Acute rheumatic fever may be a complication of group A streptococcal pharyngitis or tonsillitis, but it does not occur following streptococcal skin infections. In contrast, acute nephritis may follow infection of either the skin or the upper respiratory tract. The latent period between streptococcal pharyngitis and the onset of rheumatic fever is 2 to 3 weeks; whereas the latent period for pharyngitis-associated nephritis is about 10 days. A longer latent period, about 3 weeks, is characteristic of acute nephritis associated with streptococcal pyoderma. Group A streptococci are classified into over 80 subtypes, based on the antigenicity of their M proteins (fibrillar structures extending out from the cell surface). While there is as yet no strong evidence of an association between infection with any specific group A serotypes and the subsequent development of rheumatic fever, several serotypes (particularly mucoid strains of types 1, 3, and 18) have been implicated in a few outbreaks of streptococcal sore throat complicated by this sequela. [24] However, there is a clear relationship between infection with certain serotypes and the subsequent occurrence of nephritis—the so-called nephritogenic serotypes. Type 12 is the classic serotype responsible for pharyngitis-associated acute nephritis, but other serotypes, such as 1, 4, 25, and 49, have been implicated. The pyoderma-associated nephritogenic strains generally belong to different serotypes: types 2, 49, 42, 55, 56, 57, and 60. [25], [26] Unlike the pharyngitis strains, the pyoderma serotypes produce lipoproteinase or opacity factor, illustrating a fundamental difference between the two. [23] The skin rather than the pharynx is the principal site of antecedent streptococcal infection causing nephritis, and impetigo is now the most common form of such predisposing skin infections. Major epidemics of pyoderma-associated nephritis have been observed in communities, and multiple cases of overt and subclinical nephritis have occurred within families. The frequency of acute glomerulonephritis following infection with a known nephritogenic strain is 10 to 15 percent; the frequency of rheumatic fever following an unrecognized or inadequately treated pharyngeal infection by any serotype of group A streptococcus is 2 to 3 percent or less. The distinction between nephritogenic and other strains of streptococci that might be associated with rheumatic fever can be seen in studies from Trinidad, a hyperendemic area for pyoderma-associated nephritis. There the streptococcal serotypes causing outbreaks of nephritis differed from the serotypes associated with sporadically occurring cases of acute rheumatic fever in the same population. [24] It has been suggested that several biologic properties are associated with broad categories of group A streptococci. Most M proteins fall into one of two antigenic classes based on the presence (class I) or absence (class II) of a highly conserved antigenic domain. Almost all rheumatic fever outbreak–associated strains belong to serotypes of class I and require a precursor nasopharyngeal infection. However, because many class I serotypes are associated with impetigo as well, and because class II serotypes are responsible for both upper respiratory and skin infections, the class of M protein alone is not a determinant of tissue tropism. Current evidence indicates differences among class I organisms that may relate to their capacities to induce rheumatic fever: class I nasopharyngeal isolates appear to lack human IgG-binding activity, whereas nearly all impetigo isolates of the same class bear human IgG receptors. [27] As in *S. aureus*, there are several group A streptococcal superantigens that have been identified. These include streptococcal pyrogenic exotoxin (or erythrogenic exotoxin) A to C, F, and G to J, streptococcal superantigen, and streptococcal mitogenic exotoxin Z. These superantigens are associated with disease (see below). [28]

ANTIBODY RESPONSE AND IMMUNITY The immune response to group A streptococcal infection depends to a large measure on site of infection. Streptococcal infection is usually defined as a positive throat culture with a serologic response to group A streptococcus and the streptococcal carrier state by a positive throat culture and no serologic response. Following streptococcal pharyngitis, specific antibodies develop to many of the extracellular enzymes of the streptococci. Eighty-five percent of patients with acute rheumatic fever and a proven preceding streptococcal infection will have an elevated or increasing antistreptolysin O (ASO) titer. The serologic demonstration of an antecedent streptococcal infection in this situation can be increased to virtually 100 percent by the simultaneous testing for several other antibodies (antihyaluronidase, anti-DNase B). Antibodies to extracellular products, with the exception of antibody to the erythrogenic toxin of scarlet fever, appear to have no effect on the manifestations of illness. Streptococcal immunity is type specific (but not group specific), long-lasting, and depends on the production of bactericidal antibodies to the specific M proteins of the over 80 different serotypes of group A organisms. Although recurrent pharyngeal infections caused by the same serotype are most unusual, repeated clinical infections caused by different types are not uncommon. Early treatment of streptococcal upper respiratory tract disease with antibiotics may suppress the appearance of type-specific antibody (and immunity), as well as the development of antibody to the extracellular products of the organism. In contrast to pharyngeal infections, the ASO response with streptococcal skin infections or pyoderma-associated nephritis is weak. To define the latter serologically, anti-DNase B titers are much more reliable. Although pyoderma strains of streptococci produce M proteins, and although type-specific antibody may develop in patients with pyoderma-associated nephritis, the frequency of production of such antibodies and their role in protection against reinfection are unclear. While pharyngeal reinfection with the same streptococcal serotype is probably unusual, some evidence suggests that the same serotype can be associated with repeated episodes of pyoderma.

Specific Diseases Caused by Group A (and Other) Streptococci (Table 194-5)

Superficial pyodermas
Nonintertriginous skin
Impetigo
Ecthyma
Blistering distal dactylitis
Intertriginous skin
Perianal streptococcal cellulitis
Streptococcal vulvovaginitis
Streptococcal intertrigo
Invasive infections
Acute lymphangitis
Erysipelas
Cellulitis
Streptococcal gangrene
Bacteremia, septicemia
Toxin-associated syndrome
Scarlet fever
Streptococcal toxic-shock–like syndrome
Streptococcal gangrene
Nonsuppurative complications
Rheumatic fever
Glomerulonephritis
Other associated cutaneous reaction patterns
Erythema nodusum
Erythema multiforme
Guttate-pattern psoriasis
Vasculitis

TABLE 194-5 **Infections and Toxin Syndromes Caused by Group A Streptococci**

SUPERFICIAL PYODERMA Streptococcal pyodermas include all types of superficial streptococcal skin infections except erysipelas—that is, impetigo, ecthyma, and secondary infections of preexisting skin lesions (e.g., insect bites, abrasions, eczema). Streptococcal intertrigo such as streptococcal perianal "cellulitis" can occur primarily or secondarily in underlying conditions such as inverse psoriasis.

SUPERFICIAL PYODERMAS IN NONINTERTRIGINOUS SKIN

Impetigo Impetigo caused by group A streptococcus presents as a crusted superficial infection of the skin; an initial vesicular phase has been described but is rarely detected. Lesions are clinically indistinguishable from impetigo caused by *S. aureus*, with the exception of bullous impetigo (see " Staphylococcal Skin Infections," above).

EPIDEMIOLOGY AND BACTERIOLOGY Impetigo caused by group A streptococcus is a highly communicable infection and occurs predominantly in preschool-aged children (usually before the age of 2 years except in highly endemic areas). It is more common in warmer, more humid climates than in temperate zones. Its peak seasonal incidence is in the later summer and early fall. Several decades ago, group A streptococcus was the single most common isolate from impetigo in the United States. [29] Mixtures of streptococci and *S. aureus* were isolated from about half the patients with nonbullous impetigo. The relative roles for these two species in any analysis will probably vary, but the role of *S. aureus* has increased in recent years. Non-group A (groups B, C, and G) streptococci may be responsible for rare cases of impetigo; group B streptococci are associated with impetigo in the newborn. Whereas many different serotypes of group A streptococci may cause pharyngitis, a limited number of newly described types predominate in impetigo (types 49, 52, 53, 55, 56, 57, 59, and 61).

PATHOGENESIS AND PATHOLOGY Group A streptococci appear on normal skin of children about 10 days prior to the development of impetigo and they are not recovered from the nose and throat of the same patients until 14 to 20 days after skin acquisition of the organism. Streptococci are recovered from the respiratory tract of about 30 percent of children with skin lesions, but there is no clinical evidence of streptococcal pharyngitis. Thus, the sequence of spread in a given patient is from normal skin to lesions and eventually to the respiratory tract. [30] In contrast, the sequence of spread of *S. aureus* (in cases of impetigo in which it is the only organism isolated) is from nose to normal skin (about 11 days later) and to skin lesions (after another 11 days). Following acquisition of a streptococcal strain on normal skin from another family member or close contact (whose skin was already colonized or contained a pyoderma), minor traumas (insect bites, abrasions) or preexisting lesions such as scabies, varicella, or eczema. predispose to the appearance of infected lesions. Crowding, poor hygiene, and neglected minor skin trauma contribute to the spread of streptococcal impetigo in families. Minor outbreaks have also occurred among athletes involved in contact sports. Although the majority of cases occur in children, particularly of preschool age, young adults are also affected. The inflammatory process of impetigo is superficial, with a unilocular vesicopustule located between the stratum corneum above and the stratum granulosum below. This is usually situated near the opening of a hair follicle. Organisms, as well as leukocytes and epithelial cell debris, fill the vesicle.

CLINICAL MANIFESTATIONS Impetigo caused by *S. aureus* and group A streptococci cannot be differentiated on clinical findings. For clinical features see above (staphylococcal impetigo, Fig. 194-1 to Fig. 194-3). Pruritus and burning

may occur, but the lesions are usually painless. Systemic response is minimal unless complications occur.
LABORATORY FINDINGS A slight leukocytosis may occur. A gram-stained smear of early vesicle fluid reveals gram-positive cocci in chains. Culture of the weeping area or of the area beneath an unroofed crust reveals group A streptococci or a mixture of streptococci and *S. aureus* (particularly from older crusted lesions). The lesions of bullous impetigo are caused by *S. aureus* of phage group II.
DIAGNOSIS The diagnosis of impetigo usually presents no difficulties when the lesions are seen at the stage of crusting, but the specific bacteriologic diagnosis requires culture.
COURSE AND PROGNOSIS Untreated, the process may persist and new lesions may develop over the course of several weeks; thereafter, the infection tends to resolve spontaneously unless there is some underlying cutaneous disorder such as eczema. Untreated some lesions become chronic and deeper, such as, ecthyma (see above). Complicating erysipelas, cellulitis, or bacteremia are unusual. The major serious sequela is acute poststreptococcal glomerulonephritis.
MANAGEMENT Topical treatment (removal of dirt, crusts, and debris by soaking with soap and water) is a valuable adjunct. Mupirocin ointment appears to be as effective as parenteral or oral penicillin for treatment of impetigo. [31] However, prophylactic application of mupirocin ointment to insect bites and abrasions in children in an endemic area during the peak season for skin infections may be useful in preventing superficial streptococcal pyodermas. In superficial pyodermas known to be caused by group A streptococcus, penicillin is the drug of choice, administered either as a single injection of long-acting benzathine penicillin (300,000 to 600,000 units for children; 1.2 million units for adults) or orally (25,000 to 100,000 units/kg per day in divided doses q6h for 10 days). Although penicillin treatment will clear the lesions of group A streptococcal impetigo and prevent recurrence for a short time, streptococci can persist on or newly colonize normal skin in spite of this therapy. Erythromycin (30 to 50 mg/kg per day by mouth in divided doses q6h for children; 250 to 500 mg by mouth q6h for adults administered for 10 days) is a suitable alternative drug in patients allergic to penicillin. However, it should be noted that 20 percent or more of group A streptococcal strains became resistant to erythromycin in areas (Japan, Finland) where this antibiotic had been extensively used (or overused) for a variety of indications. [32] Whether administration of penicillin is effective in reducing the incidence of pyoderma-associated nephritis remains a moot point. Although the latent period following impetigo is longer than that following pharyngeal infection, the mildness of the illness delays or negates the seeking of medical attention. Practically, however, the majority of cases of nonbullous impetigo are caused by *S. aureus*, and systemic antimicrobial treatment should be directed at that pathogen (see above, Management of staphylococcal impetigo).
Ecthyma (See above, staphylococcal ecthyma)
STREPTOCOCCAL INFECTIONS IN INTERTRIGINOUS SKIN SITES Streptococcal pyodermas occur much less commonly in occluded sites such as the perineum/perianal region, vulva/vagina, axillae (Fig. 194-16), inframammary region, groin, preputial sac, and web spaces of the feet. Perianal (group A) streptococcal “cellulitis” occurs principally in children, presenting with intense perianal erythema (Fig. 194-17), pain on defecation, blood-streaked stools associated with anal fissures, and chronicity if untreated. [33] It is often confused with psoriasis, candidiasis, seborrheic dermatitis, inflammatory bowel disease, pinworm infection, or a behavioral problem. The infection can also involve the penis and vulva. Treatment options include oral antibiotics or topical mupirocin. Guttate psoriasis has also occurred in children, associated with perianal streptococcal infection. [34]

FIGURE 194-16 Group A streptococcus intertrigo. A sharply marginated erythematous and oozing plaque in the axilla, which was also present in the other axilla, inframammary area, and inguinal folds, was painful in this HIV-infected woman.

FIGURE 194-17 Group A streptococcus intertrigo—perianal streptococcal cellulitis. Well-demarcated erosive erythema in the perianal region and perineum in an 8-year-old boy who complained of soreness.

Blistering distal dactylitis Group A streptococcus is responsible for the majority of cases of this disease, usually occurring in children and adolescents. However, group B streptococcus can also cause this infection. A large, tense blister develops, filled with seropurulent fluid, over the volar skin pad of distal fingers or toes (Fig. 194-18). The blisters are often surrounded by an erythematous base. The lesion may be more proximally located on the finger or extend to involve the nail folds. Group A streptococcus may be cultured from the vesicle fluid. Blistering distal dactylitis may be treated with oral penicillins or erythromycin. Staphylococcal blistering distal dactylitis has been reported with an identical clinical picture as above. [35]

FIGURE 194-18 Group A streptococcus blistering dactylitis. A blister is seen on a toe adjacent to the nail fold; the patient also had group A streptococcal intertrigo of an abdominal skin fold.

Acute lymphangitis

DEFINITION Acute lymphangitis is an inflammatory process involving the subcutaneous lymphatic channels. It is most often caused by group A streptococci, but occasionally may be caused by *S. aureus*; rarely, soft-tissue infections with other organisms, such as *Pasteurella multocida* or herpes simplex virus may be associated with acute lymphangitis.

CLINICAL MANIFESTATIONS *History:* The portal of entry is commonly a wound on an extremity, an infected blister, or a paronychia. The systemic manifestations of infection may occur either before any evidence of infection is present at the site of inoculation or after the initial lesion has subsided. The patient may notice pain over an area of redness proximal to the original break in the skin. Systemic symptoms are often more prominent than one might expect from the degree of local pain and erythema. An unusual spread of streptococcal infection of the thumb (paronychia) or of the interdigital webs between the thumb and index finger may occur occasionally. Lymphatic drainage from this area can bypass the lymph nodes at the elbow and drain into the axillary nodes, which in turn communicate with the subpectoral nodes and the pleural lymphatics. As a consequence, subpectoral abscesses and pleural effusion develop. The subpectoral infection may dissect downward and appear over the lower chest and upper abdomen as an area of cellulitis. This is a very serious illness. The clinical clues to the development of this sequence of events are provided by the location of the original infection on the thumb or medial surface of the index finger and the early occurrence of axillary pain. *Cutaneous lesions:* Red linear streaks, which may be a few millimeters to several centimeters in width, extend from the local lesion toward the regional lymph nodes, which are usually enlarged and tender.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS In the upper extremities, acute lymphangitis usually can be differentiated from subacute or chronic sporotrichoid syndrome caused by organisms such as *Sporothrix schenckii*. In the lower extremities, superficial thrombophlebitis may produce somewhat similar linear areas of tender erythema. The absence of a portal of entry and of tender regional adenopathy is helpful in distinguishing this process from lymphangitis.

LABORATORY FINDINGS The peripheral white blood cell count is elevated, with a marked increase in polymorphonuclear cells. The offending organism cannot be cultured from the skin, as the infection is restricted to the lymphatic channels. However, the primary portal of entry or a suppurative lymph node, if overt infection is present, may reveal the etiologic agent.

COURSE AND PROGNOSIS The frequent development of bacteremia with metastatic infection in various organs makes this a potentially serious disease. The infection responds readily to penicillin therapy if instituted promptly.

INVASIVE STREPTOCOCCAL INFECTIONS These are erysipelas cellulitis and streptococcal gangrene and are discussed in Chapter 196.

STREPTOCOCCAL TOXIN SYNDROMES

Scarlet fever Scarlet fever is a diffuse erythematous eruption resulting from the production and subsequent circulation of pyrogenic exotoxin (erythrogenic toxin) produced by group A streptococci usually located in a pharyngeal infection. The difference between streptococcal tonsillopharyngitis and scarlet fever is the greater toxicity and the cutaneous eruption in the latter.

BACTERIOLOGY AND PATHOGENESIS Pyrogenic exotoxin is produced by most, but not all, strains of group A streptococci, and its gene is encoded by a lysogenic bacteriophage in the streptococcus. This relationship is very similar to that involving bacteriophage infection and toxin production in *Corynebacterium diphtheriae*. There appear to be three immunologically distinct pyrogenic exotoxins (types A, B, and C) produced by approximately 90 percent of group A isolates, although several other exotoxins have been identified. A toxin-producing group A strain may contain the gene encoding for one or more of the exotoxins. In the first half of the twentieth century, when scarlet fever was more prevalent and often severe, most scarlet fever strains of group A streptococci produced type A toxin, but in the past three to four decades, strains producing either type B or combinations of type B and C toxins have predominated, perhaps related to the milder course of scarlet fever during this period. More recently, however, there has been a resurgence of severe forms of streptococcal illness resembling scarlet fever, now coined as streptococcal toxic shock syndrome or toxic shock–like syndrome (see below). [36] This increase in severity, once again, may be attributed to an increase in exotoxin type A producers. [37] The streptococcal pyrogenic exotoxins belong to a larger family of exotoxins produced by group A streptococcus and *S. aureus*. These exotoxins are involved in the pathogenesis of toxic shock–like syndromes and have been implicated in numerous autoimmune and skin disorders, including atopic dermatitis and psoriasis. They have been labeled as superantigens similar to the staphylococcal exotoxins (see above). [38] Type A toxin is a more potent stimulator of cytokine production (e.g., TNF-a) and T lymphocyte activation, which might explain its association with more severe

cases of scarlet fever. Group A streptococci can cause recurrent infections, but an individual usually has scarlet fever only once because of the development of protective antibody specific to the pyrogenic exotoxins. The few patients with documented recurrent attacks of scarlet fever may represent cases in which the episodes have been caused by either of the other two immunologically distinct toxins. The immune status of a patient will determine the response to exposure to a given pyrogenic exotoxin-producing strain of group A streptococcus; it consists of two parts: type-specific antibacterial immunity and antitoxic immunity. The responses fall into three patterns: (1) Patients with type-specific antibacterial immunity (with or without antitoxic immunity) to a given streptococcal type (e.g., type 12) will contract no clinical disease when exposed to that type. (2) Patients with no type-specific antibacterial immunity (but with antitoxic immunity) will contract streptococcal pharyngitis. (3) Patients with neither antibacterial nor antitoxic immunity will contract pharyngitis plus scarlet fever (unless treated early with appropriate antibiotics). The rash of scarlet fever requires both the presence of pyrogenic exotoxin and the existence of delayed-type skin reactivity to streptococcal products, the latter stemming from prior exposure to the organism. In support of this is the observation that although streptococcal infections are not uncommon in infants and very young children, scarlet fever is rarely seen in this age group, and these infants fail to react to intradermal injection of pyrogenic exotoxin (Dick test). This failure to react correlates with transfer of antibody from the mother. Similarly, infant guinea pigs are not susceptible to intradermal injection of pyrogenic exotoxin. Following immunization with the toxin in Freund's adjuvant, they become sensitized and the Dick test becomes positive.

CLINICAL MANIFESTATIONS *History:* The disease usually occurs in children (the maximal incidence being in the 2- to 10-year-old age group) and only rarely in adults. The clinical onset of the disease with the appearance of pharyngitis and fever is often abrupt after a 2- to 4-day incubation period. The temperature may be only slightly elevated in mild cases but it often rises rapidly to 38.9°C to 40°C (102°F to 104°F). Nausea and vomiting, headache, malaise, diffuse abdominal pain, and chilly sensations are prominent initial constitutional manifestations. The fever reaches its peak by the second day, and the temperature gradually returns to normal in 5 to 6 days in the average case. The rash appears 24 to 48 h after the onset of pharyngeal symptoms. Although the streptococcal focus of most patients with scarlet fever is in the pharynx, occasional patients have a form of the disease, surgical scarlet fever, as a consequence of operative or other wound (burn, etc.) infection. The acute manifestations of scarlet fever consist of those symptoms and signs related to the invasive streptococcal process at the portal of entry and those findings produced by pyrogenic exotoxin (malaise, nausea, vomiting, headache, fever, generalized lymphadenopathy, rash). Rabbits treated with exotoxin alone by either subcutaneous injection or slow-delivery subcutaneous mini-osmotic pump develop many classic signs of scarlet fever. [39]

Enanthem: The pharynx is beefy red in color, with edema involving the tonsillar area and extending anteriorly to include the soft palate and uvula. Manifesting the local group A streptococcal infection, the tonsils are enlarged, reddened, and often covered with discrete patches of white or yellow exudate filling the tonsillar crypts. Occasionally, the exudate becomes confluent. Bilateral tender submandibular lymphadenopathy is present, relating to the streptococcal pharyngitis. Pharyngitis and submandibular lymphadenopathy are not seen in individuals with group A streptococcal surgical wound scarlet fever or staphylococcal scarlet fever. During the first several days of the illness, the tongue is white and furred, but the edges and tip remain reddened. The papillae soon become reddened and hypertrophied and project through the white coating, producing what has been called the “white-strawberry” tongue. By the fourth or fifth day, the white coating has sloughed and the tongue assumes a bright red color punctuated with very prominent papillae, the so-called red-strawberry tongue (Fig. 194-19A). Punctate erythema and scattered petechiae are often present over the soft palate.

FIGURE 194-19 Group A streptococcus scarlet fever: Exanthem and enanthem. *A*. In this young woman with pharyngitis, the face is erythematous with perioral pallor and the tongue is a beefy or “strawberry” red. *B*. Close-up of scarlatina rash.

Exanthem: The rash usually appears first on the head and neck (Fig. 194-19A), and then rapidly encompasses the trunk, and finally spreads to the extremities. The involvement of the body is usually complete within 36 h, but the palms and soles are spared. The rash is a diffuse erythema, blanching on pressure, with numerous 1- to 2-mm punctate papular elevations, giving a rough sandpaper quality to the skin (Fig. 194-19B). There are usually no discrete lesions on the face, but only a marked flushing of the cheeks and forehead, contrasting quite sharply with the circumoral pallor. On the body the rash is most marked in the skin folds of the inguinal, axillary, antecubital, and abdominal areas and about sites of pressure such as the buttocks and sacrum. The eruption often exhibits a linear petechial character in the antecubital fossae and axillary folds (Pastia's lines). When the eruption is intense, pinhead vesicular lesions (miliary sudamina), seen in a variety of prolonged febrile illnesses, may appear on the abdomen and chest. When the rash is mild, the exanthem may be localized to the trunk and be seen as only a faint erythema. In black patients, the rash is often difficult to recognize but may be felt as punctate papular lesions resembling “gooseflesh” or sandpaper. At its peak the rash has a diffuse, bright scarlet appearance. Capillary fragility is increased in the severer cases, and the tourniquet test result is positive. Occasional frank purpura may develop, with or without thrombocytopenia. The exanthem usually persists for 4 or 5 days, but in mild cases may be very transient. One of the most characteristic features of the illness is the desquamation that begins as the rash starts to fade, commencing on the face, usually about the ears, and spreading to the trunk and extremities, involving the hands and feet last (between the second and third weeks of illness). The desquamation on the face and trunk has a brawny character, and frequently a punched-out appearance of the abdomen results from the peeling off of circular areas of skin. Skin on the hands and feet is frequently shed in large sheets. The desquamation is so prominent a feature that it may be helpful in making a retrospective diagnosis in a case in which the eruption was minimal (Fig. 194-20). Similar changes in the nail bed produce a transverse groove in the nails.

FIGURE 194-20 Group A streptococcus scarlet fever: desquamation. The patient had streptococcal pharyngitis 17 days previously that was successfully treated with ampicillin. The fingertips show the subtle desquamation that occurs in scarlet fever, related to epidermal damage and repair.

Other physical findings: Generalized lymphadenopathy is a common finding, and splenomegaly is present occasionally.
DIFFERENTIAL DIAGNOSIS Although the total clinical picture is highly suggestive of scarlet fever (caused by group A streptococci), scarlatiniform eruptions may occur in other conditions and cause confusion in diagnosis. Infection with toxin ("exfoliatin")-producing strains of *S. aureus* belonging to phage group II may produce a rash resembling that of scarlet fever (see above, " Staphylococcal Skin Infections"). Strains of *S. aureus* producing TSST-1 are responsible for TSS (see above). In infants and young children particularly, exanthem-subitum and rubella may be mistaken for scarlet fever, but the lack of a pharyngeal focus is important in distinguishing these conditions. Also, neither of these processes is followed by extensive desquamation. Patients with infectious mononucleosis (primary cytomegalovirus or Epstein-Barr virus infection) may have an erythematous eruption, and this, together with lymphadenopathy and membranous pharyngitis, may mimic scarlet fever. The typical blood picture and the heterophil agglutination test are helpful in distinguishing between these diseases. Diffuse erythroderma as part of a drug-sensitivity reaction (sulfonamides, streptomycin, penicillin) may be mistaken for scarlet fever, as may the fever and cutaneous blush associated with atropine toxicity. Sunburn in a child with pharyngitis may be a cause of confusion, but the distribution of the lesions is the crucial distinguishing point.
LABORATORY FINDINGS The hematologic findings in the early stages are of a polymorphonuclear leukocytosis, and later in the illness eosinophilia (5 to 10 percent). Throat culture reveals group A streptococci. If direct bacteriologic confirmation cannot be made during the early phases of the illness, determination of the ASO titer may provide, retrospectively, evidence of a recent streptococcal infection. Slight microscopic hematuria is found not infrequently during the peak of the exanthem and does not represent acute glomerulonephritis. It is usually transient and may be related to a generalized effect of the pyrogenic exotoxin on capillaries.
DERMATOPATHOLOGY There is an outpouring of polymorphonuclear leukocytes and scattered red blood cells into the skin about small blood vessels. The punctiform lesions are represented by dilated small blood vessels and a focal accumulation of exudate. The suppurative and nonsuppurative sequelae are the same as are seen with any group A streptococcal infection.
DIAGNOSIS The diagnosis is usually made on the basis of clinical features—fever, vomiting, exudative pharyngitis, and an erythematous punctiform eruption going on to desquamation. Confirmatory evidence is provided by isolation of group A streptococci from the pharynx.
COURSE AND PROGNOSIS The acute febrile course of the untreated, uncomplicated case lasts about 4 to 5 days; desquamation may continue for several weeks thereafter. Many cases seen currently are mild and last only a few days. The course of the illness is dramatically altered by the administration of penicillin, which produces a prompt subsidence of fever and of constitutional symptoms. Adequate, early penicillin treatment eradicates the streptococci from the pharyngeal or other foci, interferes with the development of ASO antibodies, and prevents the development of suppurative and nonsuppurative sequelae. The prognosis is excellent, and today deaths as a consequence of scarlet fever are extremely rare.
Group A streptococcus toxic shock–like syndrome ("toxic strep syndrome") Group A streptococci cause an acute multisystem syndrome coined toxic shock–like syndrome (TSLS) or streptococcal toxic shock syndrome resembling that caused by *S. aureus* (see section on " Staphylococcal Skin Infections," above). [40] The initiating streptococcal infection is commonly in soft tissues (cellulitis, necrotizing fasciitis, infection at site of liposuction); other infections include pharyngitis, suppurative phlebitis, peritonitis, osteomyelitis, endophthalmitis, and myometritis. The majority of cases occur in 20- to 50-year-old, otherwise healthy patients. Major differences between staphylococcal TSS and streptococcal TSLS are extensive soft-tissue infection and bacteremia. Staphylococcal TSS does not usually have an obvious cutaneous site of infection, nor is bacteremia common (15 percent). Streptococcal TSLS usually has an obvious soft-tissue site of infection (80 percent), and bacteremia occurs in over half of cases. A mortality rate near 50 percent has been reported for streptococcal TSLS, and it is five times more deadly than staphylococcal TSS. [41] Group A streptococcus producing pyrogenic exotoxin A is most closely linked to TSLS, although pyrogenic exotoxin B and C, streptococcal superantigen, and streptococcal mitogenic exotoxin Z have also been implicated. [2] Clinical features usually include many of the following: hypotension, chills, fever, tachycardia, myalgias, and mental changes, as well as manifestations of multiorgan dysfunction (gastrointestinal abnormalities, renal failure, adult respiratory distress syndrome). Localized erythema (usually about the face) is more commonly present than the generalized punctate erythema of scarlet fever. Injection of bulbar and palpebral conjunctivae may be present as well as a strawberry tongue; and skin desquamation may or may not be a later feature. Major risk factors for TSLS include wounds, chickenpox in children, nonsteroidal antiinflammatory drug (NSAID) use, pregnancy and multiple underlying illnesses. [3] Many patients will require extensive débridement of infected wounds. Therapy includes appropriate antibiotics, IV fluids and vasopressors. Intravenous immunoglobulin may improve survival for TSLS. [42] It is important to recognize as well that "septic scarlet fever" may be reemerging currently, after an absence during the postantibiotic era. Three cases of severe septic scarlet fever with the features of toxic shock in individuals with group A streptococcal cellulitis and bacteremia have been described. Although some clinical distinction could be made, TSLS may be a more severe form or variant of scarlet fever.
Cutaneous manifestations of subacute bacterial endocarditis A variety of skin lesions have been described in subacute bacterial endocarditis (usually caused by viridans streptococci). Although often ascribed to embolic phenomena, it appears that many of these lesions represent local areas of vasculitis.
PETECHIAE AND HEMORRHAGES (See Chap. 166) These are the most common of the skin and mucous membrane lesions in bacterial endocarditis and are found in approximately 50 percent of patients with this disease. These small, reddish-brown, flat lesions do not blanch on pressure. They occur particularly on the extremities and upper chest. Mucous membrane petechiae and/or hemorrhages on the conjunctivae (Fig. 194-21A) or palate is common. The petechiae frequently occur in small crops. Rarely, the lesions may be extremely numerous and involve primarily the lower extremities.

FIGURE 194-21 Enterococcal endocarditis with embolization. *A*. Subconjunctival hemorrhage. *B*. Subungual hemorrhages in the midportion of the nail bed. The patient had acute infective endocarditis following an enterococcal urinary tract infection with bacteremia.

SUBUNGUAL "SPLINTER HEMORRHAGES" These small, dark-red streaks resembling splinters in the midportion of the nail bed are suggestive of the diagnosis of subacute bacterial endocarditis (Fig. 194-21B; see Chap. 166). Similar lesions may, however, occur beneath the distal portion of the nail bed as a result of trauma (in dishwashers, carpenters, etc.) or poor hygiene. Splinter hemorrhages may also occur as part of the clinical picture in trichinosis and vasculitis. Subungual hemorrhages may occur in acute meningococcemia with extensive petechiae and purpura.
OSLER'S NODES These are split-pea–sized, erythematous, painful, nodular lesions. They appear to be in the skin and in some ways resemble an urticarial wheal, often with a whitish center. The most common location of these swellings is on the pads of the fingers and toes, on the thenar and hypothenar eminences, and over the arms. They are quite transient, lasting 12 to 24 h or perhaps several days. They are discussed in detail in Chap. 166.
JANEWAY LESIONS These lesions, consisting of minimally nodular hemorrhages, or occasionally erythematous macules, in the palms or soles, are seen in acute endocarditis (commonly caused by *S. aureus*) or, infrequently, in subacute bacterial endocarditis. They may be rather numerous and, unlike Osler's nodes, are painless. They are also discussed in Chap. 166.
POSTSTREPTOCOCCAL (GROUP A) NONSUPPURATIVE CUTANEOUS SEQUELAE
Erythema nodosum See Chap. 109.
Erythema marginatum (cutaneous lesions of acute rheumatic fever) See Chap. 179.
Purpura fulminans Purpura fulminans is an uncommon, acute, severe, usually fatal nonspecific hemorrhagic infarction and necrosis of the skin that occurs in the course of, or immediately following, a variety of infections, particularly those caused by group A streptococci. Marked depletion of multiple coagulation factors (disseminated intravascular coagulation) is responsible for this condition. Closely related, if not the identical process, is the symmetric peripheral gangrene that is sometimes seen (particularly in infants) during bacteremias.
EPIDEMIOLOGY Purpura fulminans occurs most often in children but has been seen at all ages. The antecedent or concomitant infections with which it has been associated include those due to bacteria (scarlet fever; group A streptococcal, staphylococcal, pneumococcal, and vibrio bacteremias; and meningococcemia) and, less commonly, those of a viral etiology (varicella). In patients with purpura fulminans after varicella, secondary streptococcal infection may have been an important etiologic factor.
ETIOLOGY AND PATHOGENESIS Purpura fulminans is one of several cutaneous syndromes whose common feature is a hemorrhagic tendency developing secondary to the acute intravascular activation of the clotting mechanism. The exact means of initiation of the consumption coagulopathy is not yet fully understood. However, there is evidence that endotoxin, via stimulation of IL-12, IFN-?, TNF-a, and IL-1, may lead to consumption of protein C and S and antithrombin III. [43] A host of coagulation abnormalities has been noted at one time or another. This variability probably reflects the rapid changes that occur during the evolution of the process and the effects of "secondary" fibrinolysis. The abnormalities more commonly recorded include thrombocytopenia; depression of prothrombin (factor II), fibrinogen (factor I), proaccelerin (factor V), and antihemophilic factor (factor VIII); and findings of secondary fibrinolysis (i.e., increased plasminogen levels or evidence of fibrinogen or fibrin breakdown products). The coagulopathy and microscopic pathology in purpura fulminans are very similar to those found in rabbits with generalized Shwartzman reaction (see Chap. 193).
CLINICAL MANIFESTATIONS *History:* The eruption develops during, or on convalescence from, one of the infections noted earlier. Chills and fever usually herald the onset of the hemorrhagic lesions, and the patient appears acutely ill. *Cutaneous lesions:* The lesions are localized, massive ecchymoses, often with sharp, irregular ("geographic") borders. They are usually symmetric and on the extremities, particularly in areas of pressure, but may involve the lips, ears, nose, and trunk. There may be a narrow surrounding zone of erythema. Hemorrhagic blebs may develop in the ecchymotic areas associated with edema of the areas (Fig. 194-22). The peripheral ecchymotic lesions, especially of the digits, may rapidly blacken and progress to gangrene.

FIGURE 194-22 Purpura fulminans. *A*. Hemorrhagic infarctions in a patient with diabetes with *S. aureus* septicemia and disseminated intravascular coagulation. The patient died within 24 h in spite of therapy. *B*. Purpura fulminans in disseminated intravascular coagulation following abdominal surgery. There are extensive geographic areas of cutaneous infarction involving the face, breasts, and extremities.

Other physical findings: The other findings are those of a systemically ill patient with high fever and tachycardia. The disease often rapidly progresses over 48 to 72 h, with peripheral vasoconstriction and shock supervening.
DIFFERENTIAL DIAGNOSIS All the causes of gross purpura must be considered in the differential diagnosis. The relationship of specific infections, the striking geographic nature of the lesions, and their location on the extremities are suggestive of the diagnosis. Rarely, morphologically similar lesions have been described as complications of coumarin therapy in individuals deficient in coagulation factor protein C.
LABORATORY FINDINGS There is usually a leukocytosis. The number of platelets is markedly reduced and coagulation factors V, VII, and VIII and prothrombin and fibrinogen are decreased. As a result, the prothrombin time and the partial thromboplastin time are prolonged. Split products of fibrinogen and fibrin may be present.
DERMATOPATHOLOGY The involved areas show occlusion of arterioles with fibrin thrombi. A dense polymorphonuclear reaction occurs in the dermis in the areas of infarction necrosis. Bacteria are not seen in the lesions.

Similar lesions may occur in the viscera, but they are often restricted to the skin.
COURSE AND PROGNOSIS The mortality rate is extremely high. In patients who survive, amputation of extremities or extensive skin grafting may be necessary to deal with the gangrenous areas.
MANAGEMENT Treatment includes vigorous antibiotic management of any associated infection. Only if bleeding is significant during the course of diffuse intravascular coagulation in the patient with purpura fulminans is replacement of platelets and coagulation factors undertaken and consideration given to the use of heparin (10 to 15 units/kg per h as a continuous intravenous infusion) to inhibit the intravascular clotting process. However, there is evidence mounting that early intervention with protein C concentrate may decrease morbidity and mortality associated with purpura fulminans. [44]
Other skin lesions accompanying or following group A streptococcal infections
ERYTHEMA MULTIFORME-LIKE LESIONS Round erythematous macules, up to 1.5 cm in diameter, some developing bright borders and subsequently showing clearing in the center, may occur during bacteremia caused by group A streptococci (or *S. aureus*) in infants and young children (see Chap. 58).
ACUTE GUTTATE PSORIASIS Rarely, erythematous, papulosquamous, guttate psoriasiform lesions may develop during or following group A streptococcal pharyngitis or skin infections. Children appear to be most commonly affected. Clearing of the lesions may occur within weeks of antimicrobial therapy of the streptococcal infection. Although the temporal relation of the two processes is striking, a direct causal connection has not been established, but the role of superantigens in guttate psoriasis is the subject of current research [45], [46] (see Chap. 42).
MANAGEMENT OF GROUP A STREPTOCOCCAL SKIN INFECTIONS
Antibiotic management
GENERAL PRINCIPLES Penicillin G is the drug of choice in the treatment of known group A streptococcal skin infections. When the etiology is not known immediately (e.g., in cellulitis) and when *S. aureus* is also a distinct consideration, a semisynthetic penicillin (nafcillin or oxacillin) should be employed initially. Penicillin treatment should be continued for at least 10 days to ensure eradication of the infection. Prophylactic penicillin therapy is indicated for close family contacts (particularly children) of patients with streptococcal pharyngitis.
ANTIMICROBIAL THERAPY Mild instances of infections such as impetigo, scarlet fever, or certain cases of erysipelas and cellulitis may be treated with oral penicillin V (250 to 500 mg four times daily). When staphylococcal infection is suspected, dicloxacillin (250 to 500 mg orally four times daily) should be substituted. In adults allergic to penicillin, erythromycin (250 to 500 mg orally four times daily) is a reasonable alternative. Other alternatives include azithromycin, clarithromycin, and clindamycin.
PREVENTION OF SPREAD Patients hospitalized with group A streptococcal infections should be isolated until the organisms have been eradicated by antibiotic treatment. Individuals with recurrent episodes of group A streptococcal infections can be treated with dicloxacillin or erythromycin 250 mg twice daily (penicillin-allergic individuals) as secondary prophylaxis. Where streptococcal infections are highly endemic, prophylactic antibiotics must be administered to all members of the population to reduce the incidence of group A streptococcal infections. [47]
SOFT-TISSUE STREPTOCOCCAL INFECTIONS See Chap. 196
CUTANEOUS INFECTIONS CAUSED BY MICROCOCCUS
Pitted keratolysis This bacterial infection involves the stratum corneum of the web spaces and plantar surface. Originally named keratoma plantare sulcatum by Castellani in 1910, this disease has become more commonly called by its current name after Taplin and Zaias coined it in 1967. The disease was first seen in those who went barefooted during the rainy season.
ETIOLOGY AND PATHOGENESIS The likely causative organism is *Micrococcus sedentarius*, which is a gram-positive staphylococcus-related bacterium that invades the stratum corneum softened by sweat and moisture. There is less convincing evidence that a *Corynebacterium* species or *Dermatophilus congolensis* may be involved. Pitted keratolysis tends to be much more severe in tropical climates than in temperate ones. Pitted keratolysis occurs in adults and children of both sexes, but adult males with sweaty feet are most susceptible (96 percent of cases). [48] Sliminess of the skin, often manifest by the foot sticking to the socks, is also a common complaint (70 percent of cases). The feet are typically very malodorous (89 percent) and may be mildly pruritic (8 percent). [49]
CLINICAL MANIFESTATIONS Pitted keratolysis presents a superficial erosion of the stratum corneum, composed of numerous small crateriform pits coalescing to form a large discrete defect with serpiginous borders on the plantar surface of the foot. The pits are usually >0.7 mm in diameter, but at times the pits are <0.5 mm in diameter. The pits have elongated configurations along the plantar furrows and are located predominantly on the pressure-bearing areas, such as the ventral aspect of the toe, ball of the foot, and the heel, but they are also seen on non–pressure-bearing areas. The web spaces between the toes are also commonly involved sites, and may be the only manifestation (Fig. 194-23).

FIGURE 194-23 Pitted keratolysis. The web spaces between the toes are sharply eroded. Interdigital tinea pedis and erythrasma may occur concurrently.

DIFFERENTIAL DIAGNOSIS Interdigital tinea pedis can present with erosive lesions in the web spaces. Erythrasma in the web spaces is usually hyperkeratotic but can be erosive.
LABORATORY FINDINGS Gram-staining of scraping may detect the microorganism more readily than potassium hydroxide examination. Histologically, the organisms are present in the walls and bases of the crateriform defects in the upper layer of the stratum corneum. The organisms appear as coccoid and filamentous forms with branches and septa, divided only transversely without longitudinal septation.
DIAGNOSIS The diagnosis is made on the unique clinical findings.
MANAGEMENT Prophylactic measures are aimed at keeping the feet as dry as possible. Inert antiseptic foot powders often help. A benzoyl peroxide wash and 5 percent gel are effective therapy in most cases. Other commonly used topical agents include clindamycin, erythromycin, clotrimazole, miconazole, and Whitfield's ointment.
INFECTIONS CAUSED BY CORYNEBACTERIUM

Erythrasma Erythrasma is a common superficial bacterial infection of the skin characterized by well-defined but irregular reddish brown patches, occurring in the intertriginous areas, or by fissuring and white maceration in the toe clefts.
ETIOLOGY AND EPIDEMIOLOGY *Corynebacterium minutissimum*, the etiologic agent of erythrasma, is a short, gram-positive rod with subterminal granules. The infection is more common in tropical than in temperate climates. In a study in a temperate climate, 20 percent of randomly selected subjects were found to have erythrasma by Wood lamp examination. The generalized disease is much more common in the tropics. Erythrasma is more common in men, and may occur in asymptomatic form in the genitocrural area.
CLINICAL MANIFESTATIONS Symptoms vary from a completely asymptomatic form, through a genitocrural form with considerable pruritus, to a generalized form with scaly lamellated plaques on the trunk, inguinal area, and web spaces of the feet. When pruritic, irritation of lesions may cause secondary changes of excoriations and lichenification. *Cutaneous lesions:* The most common site of involvement is the web spaces of the feet, where erythrasma presents as a hyperkeratotic white macerated plaque (Fig. 194-24), especially between the fourth and fifth toes. In the genitocrural, axillary, and inframammary regions, the lesions present as well-demarcated, reddish-brown, superficial, finely scaly, and finely wrinkled patches (Fig. 194-25). In these sites, the patches have a relatively uniform appearance as compared with tinea corporis or cruris, which often have central clearing.

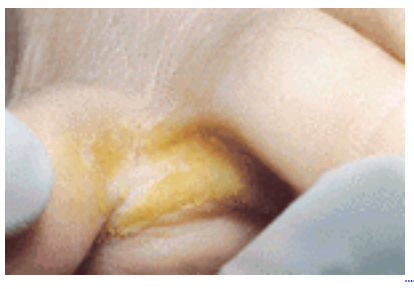

FIGURE 194-24 Erythrasma. Hyperkeratosis with a yellowish hue in the web space of the foot. The three lateral web spaces of both feet were involved. The potassium hydroxide preparation was negative; the Wood lamp examination showed a bright coral red fluorescence.

FIGURE 194-25 Erythrasma. Well-demarcated reddish-brown patches in the axilla (*A*) and groin (*B*). The potassium hydroxide preparations were negative; the Wood lamp examination showed a bright coral red fluorescence.

Wood lamp examination of erythrasma reveals a coral-red fluorescence caused by coproporphyrin III. The fluorescence may persist after eradication of the *Corynebacterium* as the pigment is within a thick stratum corneum. The red fluorescence distinguishes erythrasma from pityriasis (tinea) versicolor, where a yellow fluorescence can be seen on Wood lamp examination.
DIFFERENTIAL DIAGNOSIS Tinea versicolor is distinguished from erythrasma by the lesions on the trunk being most numerous at nonintertriginous sites. Tinea cruris tends to have an active scaling border with central clearing. Inverse pattern psoriasis usually presents as sharply demarcated plaques with a beefy shiny red color in the intergluteal cleft, inguinal folds, and axillae.
LABORATORY Culture of the specific *Corynebacterium* in abundance from the lesion corroborates the diagnosis. Gram-stained imprints of the horny layer of the skin show rod-like, gram-positive organisms in large numbers. Bacilli have been demonstrated within cells of the horny layer on examination by electron microscope.
DIAGNOSIS The diagnosis is strongly suggested by the location and superficial character of the process, but must be confirmed by demonstration of the characteristic “coral-red” fluorescence with Wood lamp illumination.
COURSE AND PROGNOSIS The disease may remain asymptomatic for years or may undergo periodic exacerbations. Relapses occasionally occur even after successful antibiotic treatment.
MANAGEMENT For localized erythrasma, especially of the web spaces of the feet, benzoyl peroxide wash and 5% gel are effective in most cases. Clindamycin (2% solution) or azole creams are several of the many effective topical agents. For widespread involvement, oral erythromycin is effective. A 1 g single dose of clarithromycin has been successfully used. [50] For secondary prophylaxis, use of an inexpensive antibacterial benzoyl peroxide bar when showering is effective and inexpensive.
Trichomycosis axillaris and pubis This bacterial infection of the hair shaft (not fungal as the name implies) is characterized by what appears to be nodular thickenings on the hair shaft, composed of colonies of aerobic *Corynebacterium*. The condition occurs both in the axillae and pubic areas, and not just in the axillae, as the name implies. The bacteria produce various pigments, giving the nodules a range of colors. In a study from the United Kingdom, axillary infection was noted in 27 percent of adult male students; in hospitalized mentally retarded patients, the finding was present in 42 percent of male patients and in 7 percent of female patients (many of the females had no axillary hair). [51] Trichomycosis is asymptomatic except for the patient's concern regarding the lesions themselves and because they are malodorous. The concretions on the hair shaft are usually a tan color but may be reddish, yellow, or black (Fig. 194-26). Lesions are most dense in and may be present only in the central portion of the axillary hair. The same lesions may occur in the pubic hair as well.

FIGURE 194-26 Trichomycosis axillaris. Tan-yellow concretions on the hair shafts of the axilla.

The diagnosis is usually made on the basis of the physical findings. The concretions can be visualized using a potassium hydroxide preparation. Pediculosis pubis infestation with multiple eggs on the hair shaft should be ruled out. The involved hair can be removed by shaving. Benzoyl peroxide wash and gel are effective as treatment and prevention against recurrence of trichomycosis.

REFERENCES

The staphylococcal scalded skin syndrome (SSSS) is a generalized exanthematous disorder with cutaneous tenderness, widespread blistering and superficial denudation/desquamation. SSSS represents the severe end of a spectrum of blistering skin disease that includes localized bullous impetigo. The disorders are caused by exfoliative (also known as epidermolytic) toxins A or B, produced by certain strains of *Staphylococcus aureus,* usually belonging to phage group 2.

HISTORY

In 1878, Ritter von Rittershain described 297 cases of “dermatitis exfoliativa neonatorum.” [1] Subsequently, a relationship of the disease to staphylococci was appreciated, and during the late 1940s and early 1950s the link between bullous impetigo and phage group 2 staphylococci became evident. The report of toxic epidermal necrolysis (TEN) by Lyell [2] drew attention to the similarity of the condition to the appearance of generalized scalding, but also led to a period of confusion between nonstaphylococcal TEN and the bacterial toxin–mediated scalded skin syndrome. [3] The situation was clarified with the development of a murine model of the staphylococcal disease. [4] SSSS is now clearly distinguished from other diseases of generalized epidermal necrolysis.

ETIOLOGY AND PATHOGENESIS

The staphylococcal exfoliative toxins A and B (ETA and ETB) are responsible for the characteristic blistering of SSSS. Although most toxigenic strains of *S. aureus* are identified by group 2 phage (types 71 and 55), toxin producers have also been identified among phage groups 1 and 3. ETA and ETB are trypsin-like serine proteases with 40 percent sequence homology. They produce blistering and denudation of skin by disruption of desmosomes in the epidermal granular cell layer, leading to intradesmosomal splitting. [5] For more than a decade it was suspected that the toxins bound directly to the desmosomal cadherin, desmoglein I (Dsg I). [6] Recently, it was demonstrated that ETA specifically cleaves Dsg I in both murine and human skin. [7] Dsg I is also the specific target of autoantibodies in pemphigus foliaceus, a disease with identical localization and histology of blistering as SSSS. Although epidermal cell separation is explained by exfoliative toxins (ETs), other clinical manifestations of SSSS are not explained by action of the toxin. Purified ETs do not cause erythema in either neonatal mice or humans, leading some to suggest that the delta-hemolysin toxin may play an important role in the full expression of the syndrome. [8] In addition, the ETs may act as lipases and activate other proteases, which, in turn, cause pathogenic effects. [9]

A controversy exists concerning whether the ETs possess superantigenic activity. The ETs display limited homology to the staphylococcal enterotoxins and toxic shock syndrome toxin-1. Recent work supports the notion of ET-induced T cell activation in a pattern consistent with other known bacterial superantigens. [10] Toxic shock–like presentations have not been described in patients with ET-producing staphylococcal infections, but it has been proposed that ETA may have properties unique from other superantigens. [10] Their unique properties could explain the discrepant clinical pattern of SSSS, when compared with the patterns of fulminant toxin syndromes such as staphylococcal toxic shock syndrome. In conflicting work, however, recombinant ET was shown to possess no T cell mitogenic or superantigenic activity, [11] which led to the proposal that reports of superantigenic activity of ET resulted from the use of preparations contaminated by minute quantities of other staphylococcal exotoxins. [12]

Children younger than 5 years of age, and particularly neonates, are most commonly affected by SSSS. This epidemiologic pattern is explained by the importance of mature renal function in the clearance of ETs. The combination of decreased ability to achieve renal clearance of toxin [13] and lack of specific immunity to the toxins make neonates the highest risk group.

There are two case reports of congenital SSSS in infants born to mothers with staphylococcal chorioamnionitis. [14], [15] Older children and adults may also develop the disease. In such cases, pathologic renal insufficiency or immunodeficiency appear to explain the susceptibility to the syndrome. Reports highlight the problem of SSSS in adults, including a case associated with HIV disease [16] and a review summarizing 32 adult cases. [17] Unlike most cases in young children, adults with SSSS are often found to have positive blood cultures for toxigenic *S. aureus* and mortality can be significant.

CLINICAL FEATURES (Table 195-1)

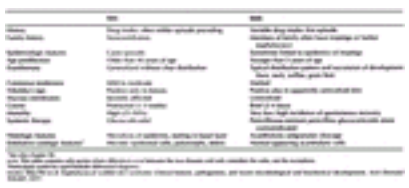

TABLE 195-1 **Differentiation of Toxic Epidermal Necrolysis (TEN) and Staphylococcal Scalded Skin Syndrome (SSSS)***

Generalized Form (Ritter's Disease)

Affected children initially have a faint, orange-red macular exanthem, typically associated with purulent conjunctivitis, otitis media, or occult nasopharyngeal infection (Fig. 195-1). Although the rash is not distinctive in appearance, cutaneous tenderness is often apparent at this stage. Tenderness may be so severe that infants stand in their beds whining because lying is too painful. Periorificial and flexural accentuation may be observed. Also, even prior to the appearance of clinical blisters, a positive Nikolsky's sign can often be elicited (Fig. 195-2). Within 24 to 48 h the rash progresses from a scarlatiniform to a blistering eruption. Characteristic tissue paper–like wrinkling of the epidermis is followed by the appearance of large, flaccid bullae in the axillae, groin, and around the body orifices. Subsequent generalized involvement occurs (Fig. 195-3A), sparing the mucous membranes. As sheets of epidermis are shed, a moist, erythematous base is revealed (Fig. 195-3B). Despite the worrisome appearance of the disease, which at this stage resembles generalized scalding, the entire process usually resolves with superficial desquamation (Fig. 195-4), and healing is usually complete within 5 to 7 days. Cultures obtained from intact bullae are usually sterile, consistent with the scenario of hematogenous dissemination of toxin produced at a distant focus of staphylococcal infection. The healing phase may be characterized by extensive desquamation with marked perioral crusting and fissuring.

FIGURE 195-1 Early stage of generalized staphylococcal scalded skin syndrome. Initial manifestation may be occult nasopharyngeal, conjunctival, or ear infection, followed by periorificial erythema and crusting.

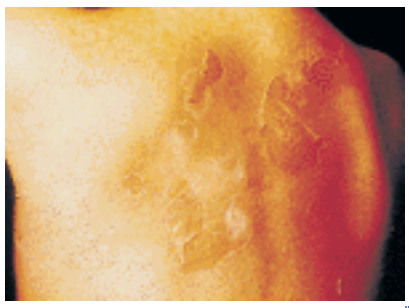

FIGURE 195-2 Generalized indistinct erythemas develop, accompanied by a positive Nikolsky's sign and superficial erosions.

FIGURE 195-3 Advanced stages show (*A*) flaccid bullae and (*B*) large denuded areas similar to scalding.

FIGURE 195-4 Late stage of generalized staphylococcal scalded skin syndrome: generalized desquamation with characteristic large sheets.

Localized Forms (See also Chap. 194)

Bullous impetigo is a localized manifestation of cutaneous staphylococcal infection by toxigenic strains, without hematogenous dissemination of toxin. Presumably, immunity to the toxin plays a crucial role in preventing dissemination, but other factors, including the total burden of toxin, and renal clearance of toxin play a role. As with generalized SSSS, bullous impetigo is predominantly a disease of children, although adult cases also occur. The early lesions are vesicles or bullae filled with cloudy fluid surrounded by an erythematous rim (Fig. 195-5), but more commonly superficial erosions with a silvery sheen and minimal crusting predominate. The lesions tend to be concentrated on exposed parts of the body and around body orifices. In contrast to generalized scalded skin syndrome, both Gram's stain and cultures of blisters reveal staphylococci, and cutaneous tenderness is absent. Rarely, localized bullous impetigo can progress to generalized scalded skin syndrome.

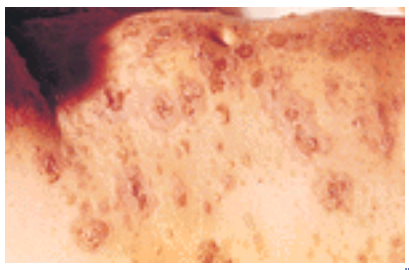

FIGURE 195-5 Bullous impetigo due to phage group 2 staphylococci. Blisters are initially filled with cloudy fluid and later rupture, leading to erosions and crusting.

Abortive Forms

Intermediate forms of SSSS may be seen that begin as localized bullous impetigo, which might evolve to produce regionally limited bullae and denuded areas that may or may not harbor staphylococci. An abortive form of SSSS known as the scarlatiniform variant is described, with features of the early erythrodermic and final desquamative stages but the bullous stage does not occur. [18] Such cases may be confused with other toxic exanthems, including toxic shock syndrome. A recent review suggests that most cases diagnosed as abortive SSSS (staphylococcal scarlet fever) actually represent mild presentations of toxic shock syndrome. [9]

LIGHT MICROSCOPIC AND ULTRASTRUCTURAL PATHOLOGY

All forms of the scalded skin syndrome are characterized by intraepidermal cleavage with splitting occurring beneath and within the stratum granulosum. [19] The cleavage space may contain free-floating or partially attached acantholytic cells (

Fig. 195-6A), but the remainder of the epidermis appears unremarkable and the dermis contains no inflammatory cells, except in cases of localized disease (bullous impetigo) (Fig. 195-6B). Cells bordering the cleavage space appear uninjured, and, ultrastructurally, separation seems to occur by simultaneous splitting of the desmosomes and interdesmosomal regions. [20]

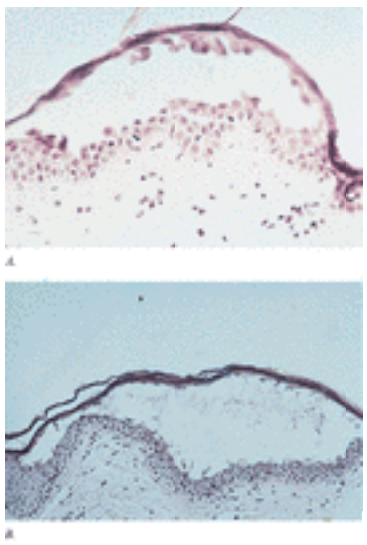

FIGURE 195-6 Generalized (*A*) and localized (*B*) staphylococcal scalded skin syndrome. In both conditions, intraepidermal cleavage occurs within or immediately beneath the stratum granulosum. However, although inflammatory cells are absent in the generalized disease, in the localized form (bullous impetigo) a leucocytic infiltrate impinges and extends from the dermis into the epidermis.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The principal diagnostic problem is distinguishing SSSS from TEN (see Table 195-1; see also Chap. 58). Although TEN is rare in infancy and childhood, distinctions based solely on age are risky because TEN can occur in children and SSSS can occur in adults. [3], [4], [17] Although the use of exfoliative cytology * (Fig 195-7) and frozen sections for the rapid bedside differential diagnosis can be particularly useful in guiding initial therapy, [21] the definitive diagnosis depends on culture and permanent section biopsy results. In contrast to the subgranular epidermolysis of the scalded skin syndrome, TEN produces full-thickness epidermal necrosis and a dermal–epidermal separation.

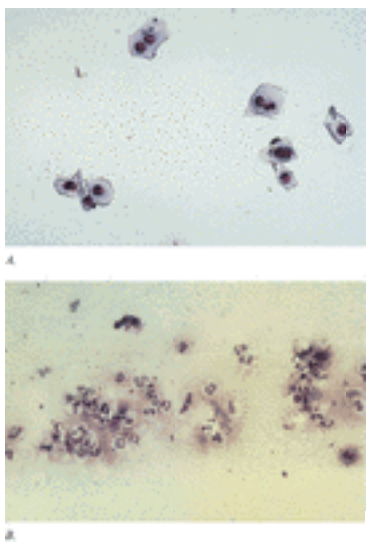

FIGURE 195-7 Giemsa-stained exfoliative cytology preparations from lesions of staphylococcal scalded skin syndrome and drug-induced toxic epidermal necrolysis. In the former (*A*), flattened, fried egg–like nucleated squamae predominate; in the latter (*B*), cellular debris, leukocytes, and occasional cuboidal keratinocytes appear.

TREATMENT AND PROGNOSIS

Therapy for SSSS should be directed toward eradication of staphylococci from the focus of infection, which generally requires intravenous penicillinase-resistant antistaphylococcal antibiotics. Usually, oral antibiotic therapy can be substituted within several days or sooner. Antibiotics, supportive skin care, and appropriate attention to fluid and electrolyte management in the presence of disrupted barrier function will usually ensure rapid recovery. The disease still carries a significant mortality (2 to 3 percent), and serious complications have been reported, including cellulitis, sepsis, pneumonia, and osteomyelitis. Adult patients with SSSS are more likely to be immunosuppressed and suffering from other medical problems. They are much more likely than children to have staphylococcal bacteremia, and they have a poorer prognosis. [17]

It is important to recognize the potential for epidemic scalded skin syndrome in neonatal care units. [22] Identification of health care workers colonized or infected with toxigenic *S. aureus* is an integral part of managing the problem. Control measures should be applied, including isolation of infected infants, barrier precautions, strict enforcement of chlorhexidine hand washing, oral antibiotic therapy for infected workers, and mupirocin ointment for eradication of persistent nasal carriage. [23]

*Smears are made from scrapings of Nikolsky-positive areas. After short fixation, the smears are stained with methylene blue or Giemsa stain. The test is considered positive when large “fried egg”–like cells are seen.

REFERENCES

Soft-tissue infections (STIs), are characterized by findings that include an acute, diffuse, tender, spreading, edematous, suppurative inflammation of the dermis, subcutaneous or muscular tissues, often associated with systemic symptoms of malaise, fever, chills, and local pain. Nonnecrotizing STIs are treated with antibiotics, drainage of abscesses, and supportive measures. Necrotizing STIs are often life-threatening and require, in addition, extensive surgical débridement.

In competent hosts these infections are usually caused by beta-hemolytic streptococci (primarily Group A), *Staphylococcus aureus,* and, in deep fascia and muscle, by mixed anaerobic and facultative gram-positive and gram-negative organisms, including histotoxic *Clostridia*. There is less predictability in compromised hosts. Organisms may include a range of traditional and rare pathogens, usual commensals, yeast, fungi, and parasites. Adding to the importance of determining an etiologic diagnosis is the observation that traditional patterns of symptoms and physical findings may be lacking or nonspecific in immunocompromised patients. [1] In both immunocompetent and compromised hosts bullae, necrosis, or gas-forming bacterial infections can lead to alarming physical findings, and signal urgency, as well as the location, in defining the cause (see Chap. 193, Table 193-3 and Table 193-4).

Erysipelas is a distinct type of superficial cutaneous cellulitis with marked dermal lymphatic vessel involvement caused by group A beta-hemolytic streptococcus (very uncommonly group C or G streptococcus) and rarely caused by *S. aureus*. In the newborn, Group B streptococci can cause erysipelas.

Cellulitis involves more of the soft tissues, extending deeper into the dermis and subcutaneous tissue. *S. aureus* and group A streptococci are by far the most common etiologic agents, but occasionally other bacteria are identified (e.g., group B streptococci in the newborn, pneumococci, gram-negative bacilli, and in immunocompromised individuals, a variety of other microorganisms, including yeasts and molds).

Gangrenous cellulitis, characterized by necrosis of the epidermis and deeper soft tissue structures including muscle, is classified as necrotizing fasciitis, clostridial STI, progressive bacterial synergistic gangrene and synergistic necrotizing cellulitis (see Chap. 193, Table 193-3 and Table 193-4).

Myonecrosis is an acute inflammatory and necrotizing infection usually caused by histotoxic *Clostridia* (including *C. perfringens, C. septicum*) as well as group A streptococci, peptostreptococci and, rarely, other microorganisms. Secondary soft tissue changes include edema, bulla formation, crepitus, skin discoloration, tenderness and pain.

ETIOLOGY OF SOFT TISSUE INFECTIONS

See Table 196-1.

TABLE 196-1 **Etiology of Soft Tissue Infections**

PATHOGENESIS

Normal intact skin plays a critical role in the defense against a wide range of pathogens. The details of the host–pathogen interaction are poorly understood, but appear to involve barrier function, bacterial factors, and host factors (Fig. 196-1). This issue is discussed in detail in Chap. 193.

FIGURE 196-1 Host–pathogen interaction.

CLINICAL SYMPTOMS OF SOFT-TISSUE INFECTIONS

In some cases, there is a history of an antecedent lesion (dermatitis, stasis ulcer, puncture wound, percutaneous catheter, or trauma). With onset of infection, patients often experience local pain and tenderness along with variable degrees of erythema and systemic symptoms (fever, chills, and malaise). Erythema, at first minimal at the site of infection, may rapidly intensify and spread. Local pain is often severe and in the absence of erythema should raise suspicions of early deeper seated infection. In some individuals, systemic symptoms may antedate localizing complaints and signs of STIs. In a study of 50 patients with cellulitis, only 26 percent had fever >38°C (>100.4°F). A potential portal of entry was identified in 66 percent of patients: 50 percent of those with upper extremity and 67 percent of those with lower extremity cellulitis. [2] Patients with early gangrenous cellulitis may experience severe pain out of proportion to the appearance of the local area.

OBJECTIVE CLINICAL FINDINGS IN SOFT-TISSUE INFECTIONS

Erysipelas

In the absence of underlying edema or other skin abnormalities, erysipelas usually begins on the face or on a lower extremity, heralded by pain, superficial erythema, and plaquelike edema with a sharply defined margin to normal tissue (Fig. 196-2 and Fig. 196-3). In the presence of antecedent edema or other anatomic abnormalities, the margin between normal and diseased soft tissue may be obscure, much like in primary cellulitis. There may not be an obvious portal of entry, and skipped areas may confuse the nature of the process. Facial erysipelas is less frequent than lower extremity disease, begins unilaterally but may spread by contiguity over the nasal prominence to involve the face symmetrically (Fig. 196-2). Inflammatory edema may extend to the eyelids but orbital complications are rare. Fever may precede local signs and occasionally patients complain of groin pain, caused by swelling of a femoral node, prior to distal extremity findings. Lymphangitis and abscess are very rare but the process may spread rapidly from the initial lesion, the pace of which can be evaluated by using a pen to define the borders. The most common pathogen identified is group A streptococcus, but cases caused by groups C, G, and B streptococci and more slowly evolving lesions secondary to *S. aureus* and other microorganisms are documented. [3], [4] Occasionally, in addition to rapid spread of the erythematous, edematous plaque, bullae may form in the involved area. [5] Recurrent erysipelas is associated with saphenous vein harvest (associated occasionally with tinea pedis) and the lymphedema complicating mastectomy with axillary node dissection.

FIGURE 196-2 Erysipelas. Painful, edematous erythema with sharp margination on both cheeks and the nose.

FIGURE 196-3 Erysipelas. Fiery-red, brawny, edematous erythema that is sharply and irregularly marginated. There is tenderness, and the patient has fever and chills. In the presence of underlying edema the margins of the cellulitis may be ill-defined and the process less confluent.

ACUTE CELLULITIS This has many of the features of erysipelas (erythema, tenderness, pain) but extends deeper into the subcutaneous tissues. Cellulitis can be differentiated from erysipelas by the lack of distinct margins between affected and normal skin, a deeper, firmer form of tender induration, fluctuance, and occasionally the presence of crepitus on palpation. In a study of 50 children with cellulitis, 16 percent of cases had facial infection with the remainder occurring on an extremity, the leg being affected three times as often as the arm. [6] In some cases of cellulitis, the overlying epidermis undergoes bulla formation or necrosis, resulting in extensive areas of epidermal sloughing and superficial erosion (Fig. 196-4A). Alternatively, with or without antibiotic therapy, infection may localize in the soft tissue, with dermal and subcutaneous abscess formation (Fig. 196-4B) or fasciitis (Fig. 196-5). Regional lymphadenopathy may be associated with cellulitis on an extremity. In older individuals, thrombophlebitis may complicate lower leg cellulitis. Most cases of spontaneous cellulitis or those secondary to skin lesions or trauma are due to *S. aureus*. Group A and other streptococci (especially groups B, C, and G), as well as *Escherichia coli* and other Enterobacteriaceae and anaerobes, are involved in cellulitis, especially in association with extremes of age, prolonged hospitalization, percutaneous intravascular lines, diabetes, immunocompromised states and glucocorticoids. [7]

FIGURE 196-4 *A*. Cellulitis following puncture trauma. The forearm is swollen, erythematous, and tender; there is abscess formation, blistering, and crusting. *B*. Cellulitis arising at the site of a surgical excision: *S. aureus*. Note discharge of pus.

FIGURE 196-5 *A*. Gangrenous cellulitis: necrotizing fasciitis. Note the black necrosis, resembling a third-degree burn, and an erythematous margin. There is severe systemic toxicity. *B*. 48 h later, there is progressive gangrene of the pubic, perigenital, and perianal tissue.

SURGICAL WOUND INFECTIONS These are classified as incisional (superficial) or deep. [8] Incisional wound infections involve the skin, subcutaneous tissue, and/or muscle. Deep infections involve structures adjacent to the surgical wound that were entered or exposed during the procedure, such as subfascial layers, viscera, and/or spaces within the peritoneum, thorax, or joints. Up to 80 percent of wound infections are incisional. A wound is considered to be infected if there is drainage of purulent material and evidence of inflammation. Incisional infections present with erythema, pain, tenderness, and local swelling (Fig. 196-4B), and often with low-grade fever. Purulent drainage reveals neutrophils and cultures most often grow *S. aureus.* Separation of the margins of the wound is usual and this allows appropriate drainage. Deep wound infections may be more subtle and delayed and often present as fever of uncertain cause. Progressive bacterial synergistic gangrene and other variants of gangrenous cellulitis can arise in surgical wounds or around sutures (see below). The complications of superficial and deep wound infections include poor healing, bacteremia, the local and systemic effects of prolonged hospitalization, poor nutrition, residual compromised tissue integrity, and the consequence of prolonged antibiotic therapy in a hospital setting. Additionally, wounds infected with toxin producing *S. aureus* or group A streptococci may result in systemic complications such as toxic shock syndrome or scarlet fever. Details of infections and intoxications secondary to pyogenic gram positive microorganisms are discussed in Chap. 194 and Chap. 195.

CELLULITIS COMPLICATING A PRESSURE ULCER Pressure ulcers, particularly those located in the sacrum in elderly, frail, malnourished individuals pose significant problems for the patient and the physician. In addition to reflecting poor skin nutrition, the location causes the site to be contaminated by a variety of facultative and anaerobic microorganisms from the skin and the bowel, including *S. aureus,* enterococci, *Pseudomonas aeruginosa,* and *Bacteroides fragilis*. In addition to pain and cellulitis, the ulcer can be undermined and may eventually be complicated by bacteremia, often polymicrobial, or the underlying bone can become infected. Like other open wounds, the identity of the active pathogen(s) may be difficult to determine.

CELLULITIS ARISING AT SITES OF ANIMAL BITES Domestic dog and cat bites are frequent and can give rise to painful and necrotizing cellulitis caused by *Pasteurella multocida, Capnocytophaga canimorsus* (especially in asplenic individuals) and a host of other aerobes and anaerobes from the animals' mouth or the skin of the infected individual. Dog bites are often accompanied by a crush injury that devitalizes tissues. The bite of cats can inject organisms (via sharp incisors) deep into tissues, including joint spaces, tendon sheaths, or below the periosteum of bone. Domestic and wild animal bite infections are discussed in detail in Chap. 199 and Chap. 237. Human bites have a higher incidence of infection than do animal bites because of the mix of oral bacteria (aerobes and anaerobes), as well as the crush injury imparted along with the bite. Organisms include various streptococci, *S. aureus,* and the anaerobic peptostreptococci and peptococci.

GANGRENOUS CELLULITIS, INFECTIOUS GANGRENE, AND CREPITANT SOFT-TISSUE WOUNDS (Table 196-2)

Necrotizing fasciitis
Streptococcal gangrene
Necrotizing fasciitis other than streptococcal gangrene
Synergistic necrotizing cellulitis (necrotizing cutaneous myositis, synergistic nonclostridial anaerobic myonecrosis)
Fournier's gangrene
Clostridial soft tissue infections
Anaerobic cellulitis
Anaerobic myonecrosis (gas gangrene)
Spontaneous, nontraumatic anaerobic myonecrosis
Progressive bacterial synergistic gangrene
Gangrenous cellulitis in the immunosuppressed individual
Localized areas of skin necrosis complicating conventional cellulitis

TABLE 196-2 **Classification of Gangrenous Cellulitis (Infectious Gangrene)**

These soft-tissue infections are characteristically rapidly developing, progressive, and accompanied by constitutional symptoms, severe pain, and tenderness, with changes in overlying skin that progress to bulla formation and frank necrosis. The process can be in the superficial or deep fascia with secondary changes in the overlying soft tissues. Palpation may reveal tenderness or gas in the area of involvement (see Chap. 193, Table 193-3 and Table 193-4; and Fig. 196-5A and Fig. 196-5B). This section focuses on the various types of necrotizing fasciitis and other necrotizing soft-tissue infections, with and without gas formation, excluding myonecrosis. During the past decade there has been increasing speculation, especially associated with necrotizing soft-tissue infections and toxic shock syndromes, that the use of nonsteroidal antiinflammatory drugs (NSAIDs) may be contraindicated. Citing examples of necrotizing fasciitis and streptococcal toxic shocklike syndrome, the arguments are interesting, but need study. [9] NSAIDs may interfere with leukocyte chemotaxis (inhibition of lipoxygenase), decrease the inflammatory response (through decreased leukotriene production), and blur cardinal symptoms of infection (fever and pain) by inhibition of prostaglandin action. [10] The above observations and speculations argue for more thoughtful and cautious use of NSAIDs in fragile patients.

Streptococcal angrene including type II necrotizing fasciitis The pathogen is almost always a group A streptococcus, although groups C and G isolates, as well as other microorganisms, are rarely identified. Occasionally, especially in newborns, but also in patients early postpartum, group B streptococci have been recovered. A recent description of seven cases (two new) of *Streptococcus pneumoniae* necrotizing fasciitis, behaving like group A streptococcal infections, is noteworthy, considering the infrequent cutaneous involvement of *S. pneumoniae,* the similarity of their inflammatory

characteristics, and the increasing problems of penicillin resistance. [10] Patients may be immunocompromised by age or illness, such as diabetes, alcoholism, or cirrhosis, but usually are healthy individuals. The location of the necrotizing lesion is most often an extremity, rarely the face. Pain, erythema, and edema with rapid formation of bullae, constitutional symptoms with high fever, and toxicity are characteristic of early progression. There is bacteremia in approximately two-thirds of patients and evolution of necrosis of the overlying skin can be rapid and dramatic with appearance of deeper structures including tendon sheaths and muscle. Streptococcal toxic shocklike syndrome often accompanies this infection, referred to in the lay press as a “flesh-eating” bacterial process. The terms *streptococcal gangrene* and *streptococcal necrotizing fasciitis* should be considered as a single disease continuum. With bulla formation, the diagnosis is apparent from a Gram stain of an aspirate. As the process evolves, necrosis and eschar formation precede sloughing of tissues. Early symptoms of local pain eventually evolve to anesthetic areas and progressive toxicity is often accompanied by mental depression. Treatment with penicillin and clindamycin as well as surgical débridement and supportive therapy can be life saving but the prognosis remains poor. [7], [11] Chapter 194 provides a detailed discussion of streptococcal toxic shocklike syndrome prognosis and therapy.

Type I necrotizing fasciitis This infection is caused by a mix of facultative and anaerobic microbes, often delivered into the subcutaneous tissues following surgery, bowel perforation secondary to neoplasm or diverticulitis, trauma, or parenteral drug abuse via skin-popping, and often occurs in patients compromised by diabetes or malnutrition. Organisms include nongroupable streptococci, enterococci, anaerobic streptococci and staphylococci, *Bacteroides* spp., and Enterobacteriaceae including *E. coli,* as well as various aquatic bacteria. Often three to five species contribute to the infection, which may have a slower pace than group A streptococci in evolving to a full-blown process with cutaneous manifestations. [12], [13] Type I necrotizing fasciitis most commonly occurs on an extremity, abdominal wall, perineum, or about operative wounds. Clinically, it is indistinguishable from streptococcal gangrene (Fig. 196-5). Although the initial pace of the illness may be slower, it is important to recognize that when this infection presents in the thigh (dissection along the psoas muscle) or abdominal wall, it may be secondary to an intestinal source (occult diverticulitis, rectosigmoid neoplasm). The involved area may be painful at first and then evolve with objective findings: swelling, erythema, warmth, and tenderness. The process is often more extensive than the overlying skin changes would suggest. Within several days, the skin color becomes purple, bullae develop, and frank cutaneous gangrene ensues (Fig. 196-5B). At this stage the involved area is no longer tender; it has become anesthetic as a result of occlusion of small blood vessels and destruction of superficial nerves in the subcutaneous tissues. Crepitus is often present, particularly in patients with diabetes mellitus or if gas-forming anaerobes, such as *Bacteroides* spp., are present. [7], [13]

Fournier's gangrene This is a localized variant of necrotizing fasciitis involving the scrotum and penis. [7], [14], [15] It is usually caused by the same mix of facultative and anaerobic organisms that are associated with type I necrotizing fasciitis. In rare cases, group A streptococci, as the single pathogen has been implicated, and this may be related to rectal ring carriage or to oral-genital sex. The average age at onset is 50 to 60 years. Most men have underlying diseases or procedures. These include diabetes mellitus, ischiorectal abscess, perineal fistula, bowel disease (rectal or colon carcinoma, diverticulitis), scrotal or penile trauma, prior hemorrhoidal or urogenital surgery, pressure ulcers of the scrotum and perineum (e.g., alcoholics sitting in a drunken stupor), and, rarely, obscure causes, such as dissection of pancreatic secretions through the retroperitoneum and into the scrotum in acute pancreatitis. The onset of Fournier's gangrene can be insidious, with a discrete area of edema, erythema, and necrosis on the scrotum, progressing to advancing skin necrosis rapidly over 1 to 2 days. Pain, swelling, and crepitus in the scrotum, perineum or suprapubic region may be marked. Foul-smelling drainage occurs, indicating a contribution from anaerobes. Purplish discoloration of the scrotum, an initial “red flag,” progresses to frank gangrene. The infection tends to be superficial, limited to skin and subcutaneous tissue and extending to the base of the scrotum, but it may spread to the penis, perineum, and abdominal wall along fascial planes. The testes, glans penis, and spermatic cord are usually spared as they have a separate blood supply. The infection may progress and invade the abdominal panniculus in obese patients, especially those with diabetes mellitus, leading to rapid and extensive destruction of tissue and requiring wide débridement and prolonged hospitalization.

Synergistic necrotizing cellulitis (necrotizing cutaneous myositis, synergistic nonclostridial anaerobic myonecrosis) This variant of necrotizing fasciitis is unique in that all soft-tissue structures, including muscle, can be involved in a painful, progressive, polymicrobial infection that is highly lethal. The poor prognosis relates to the demography of the usual patient: frail, elderly, diabetic, wasted or obese, and almost always with compromising cardiovascular and renal disease. The process may begin slowly, evolving over 7 to 10 days with mild symptoms, primarily pain. Individuals are often afebrile or have only low-grade fever, lacking systemic toxicity in the early stages. The initial skin lesion is a small area of necrosis or reddish-brown blister with extreme local tenderness; the superficial appearance belies the widespread destruction of the deeper tissues. Skin sinuses (with surrounding areas of blue-gray gangrene) form, draining a foul-smelling thin pale “dishwater” exudate containing fragments of necrotic fat. Gram stain of the drainage reveals both gram-positive and gram-negative organisms and rare or absent neutrophils. Extensive gangrene of the superficial tissues and fat can be visualized by direct inspection through skin open areas or with skin incisions. Gas can be palpated in the tissues in approximately a quarter of patients. Organisms frequently isolated included anaerobes (streptococci and/or bacteroides) and facultative bacteria, especially Enterobacteriaceae (*E. coli, Proteus, Klebsiella,* etc.). [16] The most common site of involvement in approximately half the cases is the perineum. The major predisposing causes are perirectal and ischiorectal abscesses. These localized infections track to the deeper structures of the pelvis, leading to a severe infection. A more superficial form involves the buttocks without extension to deeper muscles; 40 percent of individuals have involvement of the thigh and leg. Some infections arise in the adductor compartment of the thigh, often extending from an infected amputation stump or diabetic gangrene. The remaining 10 percent of cases are found on the lower abdomen, distal leg and rarely on the neck, often associated with severe vascular disease and diabetes. Even with rapid surgical and medical interventions, the mortality remains in the 40 to 50 percent range, in part because of accompanying diseases. Incision, drainage, extensive débridement, and amputation are the aggressive actions that must be taken, in concert with antibiotics (including one directed at bacteroides) guided initially by the Gram stain. [7]

PROGRESSIVE BACTERIAL SYNERGISTIC GANGRENE (MELENEY'S GANGRENE) This infection typically occurs in association with wire stay sutures in a drain site following an abdominal operation (ileostomy, colostomy), in an incision in the chest wall following abdominal or thoracic infection (empyema), at the exit site of a fistulous tract, or in a chronic ulcer. The infection usually is recognized as one or more shaggy, painful ulcers developing within a week or two of a procedure, especially in proximity to wires or other foreign bodies. [7] The name, synergistic gangrene, was coined by Meleney in the 1930s, based on studies done in vivo in rabbits. Clinical microbiology confirms that this rare infection usually is associated with a microaerophilic or anaerobic streptococcus at the advancing margin and *S. aureus* (or,

rarely, an enteric gram-negative bacillus) in the central, shaggy, ulcerated area. [17] The process usually starts with local redness, tenderness, and swelling that subsequently develops into a painful, superficial enlarging shaggy-based ulcer. Three zones of involvement become apparent: a central area of necrosis (ulceration); a surrounding zone of violaceous, tender edematous tissue with necrotic margins; and an outer zone of bright erythema and edema. Local pain and tenderness are nearly always present; fever and systemic toxicity, however, usually are minimal or absent. Untreated, the process progressively enlarges, ultimately resulting in enormous ulcerations (Fig. 196-6). Meleney's ulcer has the features of progressive bacterial synergistic gangrene (Meleney's gangrene), with associated burrowing necrotic tracts through tissue planes that emerge at distant skin sites. Treatment includes removal of foreign bodies and excision of the shaggy ulcer and necrotic margins, plus zinc sulfate topical cream and antibiotics, guided by Gram stains and cultures. [18]

FIGURE 196-6 Progressive bacterial synergistic gangrene. Necrosis and deep ulcerations of the genitalia and perineum in a toddler.

GANGRENOUS CELLULITIS IN THE IMMUNOCOMPROMISED INDIVIDUAL The microorganisms associated with necrotizing cutaneous infections in the normal host are joined by a variety of other traditionally pathogenic and nonpathogenic bacteria, as well as fungi in compromised patients. In the presence of thermal burns bacteremic *Pseudomonas aeruginosa* may colonize normal skin, producing ecthyma gangrenosum (see Chap. 197), or may home to burn areas, leading to extensive bacteremic *Pseudomonas* gangrenous cellulitis (see Chap. 193, Table 193-3). Mucormycotic gangrenous cellulitis can engraft onto thermal burns or complicate percutaneous catheter areas in immunosuppressed individuals. [19] In the immunocompromised host it becomes mandatory to biopsy any necrotic cellulitic lesions and to be alert to the possibility of a wide range of bacterial, viral, fungal and even parasitic pathogens.

NONCLOSTRIDIAL CREPITANT CELLULITIS The presence of a cellulitis with palpable gas raises the specter of a histotoxic *Clostridium* infection. The patient may have experienced a traumatic or surgical injury that was inadequately débrided or had an underlying local infection, a poorly performed needle stick or illicit drugs via skin popping. [20] Underlying diabetes, glucocorticoid or NSAID use and granulopenia may be present. The clinical presentation is often insidious, with low-grade fever, mild pain, and tenderness, but with early palpable gas and edema. Anaerobic isolates may include *Bacteroides* spp. or peptostreptococci, often with facultative gram-negative bacilli. In uncontrolled diabetes, the presence of gas may result from metabolism of glucose by *E. coli, Klebsiella, Aeromonas,* and other microorganisms (see Chap. 197).

CLOSTRIDIAL SOFT-TISSUE INFECTIONS The histotoxic clostridia are responsible for a variety of infections that involve the subcutaneous and muscular tissues, with changes in the overlying skin that can be abrupt and dramatic. Clostridial anaerobic cellulitis is an infection of the more superficial subcutaneous zone, usually in tissues that are already devitalized, and rarely involving the deep fascia or muscle. Clostridial myositis, or gas gangrene, is a process that is anatomically in the muscle layer but with significant changes in the skin and subcutaneous tissues via interference with vascular and lymphatic structures. The histotoxic clostridia primarily involved in these infections include the human gut commensal *Clostridium perfringens* and the environmentally resident *Clostridium septicum*. *C. perfringens* is present in approximately 90 percent of normal colons but *C. septicum* is rarely found, perhaps in 5 percent of asymptomatic individuals. Newer and traditional bacteriologic techniques allow for easy identification of these obligate anaerobes. [21]

ANAEROBIC CELLULITIS This is an infection of devitalized tissue, usually caused by *C. perfringens* with or without other bacteria, occurring in a dirty or inadequately débrided wound several days after injury or following a needle stick or surgery. The onset is more gradual than in anaerobic myonecrosis (gas gangrene). The clostridia are able to grow in the wound and extend rapidly through tissue planes, with attendant formation of large quantities of gas that is readily palpable. A thin, dark-gray to brown, foul, serous discharge is produced. Gram-stained smear of the drainage reveals short, plump, blunt-ended, gram-positive rods without spores, with a variable number of polymorphonuclear leukocytes and occasionally other bacterial forms. Unlike gas gangrene, there is relatively little local pain or edema, change in overlying skin, or toxemia. At surgery, the muscles appear normal, but gas may be readily evident throughout the exudate. Anaerobic cellulitis can be distinguished from anaerobic myonecrosis by inspection of muscle, to avoid needless mutilating surgery and amputations. Treatment consists of opening the wound, removing necrotic debris, and administering antibiotics (penicillin and either clindamycin or metronidazole). Occasionally, bacteremic *C. septicum* can spread to subcutaneous tissues. These patients are toxic, unstable and usually the suspicion of *C. septicum* is raised on finding subterminal spores in large gram-positive bacilli. [22]

ANAEROBIC MYONECROSIS (GAS GANGRENE) This is a rapidly progressing, toxemic, potentially lethal infection involving muscle but with secondary changes in the overlying skin. The infection may develop as a complication of muscle injury, a traumatic dirty wound with extensive muscle and soft-tissue damage, or following surgery on the bowel or gallbladder. *C. perfringens* is the most common pathogen and also part of the normal flora but rarely associated with spontaneous gas gangrene. The incubation period of anaerobic myonecrosis is often short (12 to 24 h) but may be delayed, rarely developing following anaerobic cellulitis. The first symptom is usually severe local pain, followed by fever, tachycardia, and hypotension. Gas formation is present, but not prominent, in subcutaneous tissues, and may be completely obscured by edema of the superficial tissues. The skin often takes on a dark yellow or bronze discoloration, with tense blebs or bullae containing dark brown fluid. A serosanguineous exudate can be expressed from the wound or aspirated from a bullous lesion. Gram stain of the exudate reveals plump gram-positive rods and rare or absent white blood cells even with a systemic leukocytosis. The overlying skin may develop patchy necrosis and desquamation. At surgery the process in the muscle is evident, with gray pallor, absence of bleeding, presence of gas and failure of muscle to respond to direct stimuli. Removal of devitalized tissue, antibiotics and supportive therapy must be quickly undertaken, and amputation can be life saving in limb involvement. Antitoxin is no longer available and hyperbaric oxygen is reserved for involvement of areas not amenable to débridement. [21]

SPONTANEOUS, NONTRAUMATIC ANAEROBIC MYONECROSIS In the absence of an external wound, septicemic gas gangrene may occur spontaneously, usually caused by *C. septicum* and often associated with hematologic malignancies or occult colon cancer, especially in the cecal area. Spontaneous *C. septicum* gas gangrene is a fulminant

disease, with a mortality approaching 100 percent and marked by a precipitous onset and progression, often with subcutaneous gas, myonecrosis, and high-grade septicemia. Overlying skin of an involved area becomes red-brown and the epidermis sloughs early in the illness. [22]

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of erysipelas, cellulitis, necrotizing cellulitis, and myonecrosis includes other infections, as well as noninfectious inflammatory disorders that have features that may be confused with STI (Table 196-3 and Table 196-4).

Noninfectious Disorders
Dissecting cellulitis of the scalp (perifolliculitis capitis abscedens et suffodiens)
Acne conglobata
Hidradenitis suppurativa
Acute allergic contact dermatitis (e.g., to poison ivy or poison oak)
Erythema nodosum
Eosinophilic cellulitis
Giant urticaria and angioedema
Fixed drug eruption
Deep venous thrombosis and lipodermatosclerosis
Vasculitis such as polyarteritis nodosa
Familial Mediterranean fever
Inflammatory breast carcinoma (carcinoma erysipeloides)
Infectious Disorders
Osteomyelitis of the maxillary or frontal bones secondary to paranasal sinusitis
Extension of subperiosteal infection from long bone osteomyelitis
Erythema migrans
Erythema infectiosum (human parvovirus B19 infection with "slapped cheek")
Early primevsicular herpes zoster

TABLE 196-3 **Differential Diagnosis of Erysipelas and Acute Cellulitis**

Factitial ulcers
Pyoderma gangrenosum
Purpura fulminans (disseminated intravascular coagulation)
Calciphylaxis
Ischemic necrosis (atherosclerosis obliterans, thromboembolism)
Fixed drug eruption, warfarin necrosis, heparin necrosis
Pressure ulcer
Amebic (Entamoeba histolytica) skin gangrene following bowel surgery
Brown recluse spider bite

TABLE 196-4 **Differential Diagnosis of Necrotizing Soft-Tissue Infections**

LABORATORY STUDIES

Smears of Pus, Exudate, and Aspirates

Although classical morphologic descriptions of STI can provide insight into the likely etiologic diagnosis, one cannot assume that typical lesions equate to specific pathogens. This is particularly true when dealing with patients that are immunocompromised by diseases or their therapies. Typical appearance of an STI, coupled with epidemiologic and clinical data, may provide help when prescribing initial antibiotics, but cannot be totally relied on. Immediate and more substantial clues can come from aspiration of fluctuant lesions or bullae and from swabs of open lesions using the Gram stain, fungal stains, and other direct methods, including immunofluorescent methods (see Chap. 193).

Cellulitic plaques, characteristic of erysipelas, are rarely successfully cultured. Nonbacteriostatic saline can be injected into the advanced border, followed by aspiration of tissue fluid that is then subjected to staining. Successful identity of pathogens is uncommon, but cultures of the material along with blood cultures is a vital part of the search for the etiologic agent in all STIs. [23] Open lesions such as postsurgical, traumatic, and pressure ulcers, may contain multiple organisms, some of which may be significant although others are contaminants. The Gram stain may help initially to identify the most significant morphologic and staining bacteria but often a biopsy as well as the inflammatory cell type of the lesion, followed by cultures, special stains and pathologic investigation, will prove most helpful compared to study of surface material. Pathogens are more likely to be seen microscopically and cultured from abscesses, surgical wounds, bullae and deeper tissue exudates from necrotizing fasciitis and myonecrosis. Open lesions will attract a variety of microorganisms, among which a pathogen may be difficult to select. [24] Refer to Chap. 193 for a discussion of other methods, many noncultural, [25] being used or developed to identify a responsible pathogen—the gold standard in effective antimicrobial therapy of STI.

Imaging

Infections with anaerobic organisms, especially *Clostridia* and bacteroides, may lead to gas formation, which can then be visualized radiographically. Conventional x-ray of anaerobic cellulitis may reveal pockets of gas confined to superficial tissues and is usually readily palpable. True gas gangrene (clostridial myositis) can be distinguished from anaerobic cellulitis by the linear feathery appearance of gas infiltrating through groups of muscle fibers, although palpation may not reveal crepitus. [7], [21]

Magnetic resonance imaging (MRI) has gained favor as a technique in diagnosing STIs. In a recent study, 23 patients with acute STIs underwent MRI evaluation. T_2-weighted images best highlighted the cutaneous disease process. In patients with pyomyositis or subcutaneous abscesses, a spindle-shaped or round, well-defined area of high signal intensity was observed in the muscle or fat, respectively. Patients with necrotizing fasciitis had deep dermal, well-defined dome-shaped areas of increased signal. Patients with nonnecrotizing cellulitis had smaller, heterogeneous areas of increased signal. [26]

Dermatopathology

In addition to direct stains and cultures, pathologic investigation with special staining can be very useful. Lesional skin punch biopsy is often helpful in ruling out a cellulitis-simulating noninfectious inflammatory lesion such as erythema nodosum, vasculitis, or eosinophilic cellulitis. In ecthyma gangrenosum (caused by *P. aeruginosa*), a septic vasculitis is seen. Direct immunofluorescent techniques have been reported to identify streptococcal pathogens in 19 of 27 cases of erysipelas and in 10 of 15 cases of cellulitis. [27]

Histologically, erysipelas is characterized by intense edema, marked vascular dilatation of the superficial dermis and a profuse infiltration of tissue spaces and lymphatic channels with streptococci and neutrophils. The streptococci are not found in the blood vessels themselves, but their presence in the lymphatics produces an inflammatory reaction about these vessels. The dermis is markedly edematous, and there is infiltration with neutrophils and mononuclear cells. The epidermis is only secondarily involved, primarily with edema.

Deep incisional biopsy and histopathologic examination on frozen sections has been shown to improve diagnosis and decrease mortality in necrotizing fasciitis by rapidly establishing the diagnosis and thus defining the need for surgical débridement. [28] Indications for an open exploration and a biopsy include confusion, pain and tenderness, tachycardia, tachypnea, ketoacidosis/hyperglycemia, bullous or gangrenous skin changes, bronzing of the skin, spreading areas of anesthesia, thin reddish discharge with undermining of wound edges, crepitus, and an abscess with multiple tracts.

In streptococcal gangrene, the prominent angiitis and focal dermal necrosis with spread along fascial planes suggest that the disease is fundamentally gangrene of the subcutaneous tissues followed by necrosis of the overlying skin. Microscopically, fibrinoid necrosis is present in the media of many arteries and veins passing through the edematous and damaged fascia. [29] Fibrin thrombi are present. The epidermis, dermis, and skin appendages in the area of gangrene undergo coagulation necrosis. Numerous polymorphonuclear leukocytes and mononuclear cells infiltrate the lesion, and the upper layers of the dermis contain large numbers of gram-positive cocci.

SPECIFIC BACTERIAL SPECIES ASSOCIATED WITH STI

See Chap. 193, Table 193-1 and Table 193-2 and the preceding material in this chapter, including Table 196-1.

Person-to-Person Spread

***STAPHYLOCOCCUS AUREUS* AND GROUPS A, B, C, AND G BETA-HEMOLYTIC STREPTOCOCCI** (See Chap. 194)
ENTEROBACTERIACEAE, HAEMOPHILUS INFLUENZAE, NEISSERIA MENINGITIDIS, AND PSEUDOMONAS AERUGINOSA (See Chap. 197)
STREPTOCOCCUS PNEUMONIAE *S. pneumoniae* is a rare cause of cellulitis and necrotizing fasciitis, perhaps occurring more frequently in recent years and behaving like group A streptococcal STI. [30], [31] Predisposing or associated conditions include chronic alcoholism, drug abuse, HIV, connective-tissue disorders, glucocorticosteroids, and the use of NSAIDs. [10] Bacteremia is an underlying mechanism in about half of the cases described but relative or absolute penicillin resistance does not appear to be a factor.

Specific Bacterial Species Associated with Aqueous Environments

Aeromonas spp. and *Vibrio* spp. (see Chap. 199).

Specific Bacterial Species Associated with Soil Exposure

Clostridium species (primarily, excluding endogenous *C. perfringens,* the most frequently isolated pathogen) was discussed earlier in this chapter.

Specific Bacterial Species Associated with Animal Exposure (See Chap. 199)

Streptococcus iniae, Erysipelothrix rhusiopathiae, Bacillus anthracis, and *Pasteurella multocida* are associated with animal exposure.

Miscellaneous Pathogens

***MYCOBACTERIUM* SPECIES (See Chap. 200)** *M. fortuitum* complex species are rapid growers and include *M. fortuitum, M. chelonae,* and *M. abscessus*. These organisms are widely distributed in soil, dust, and water. Inoculation can occur via puncture wounds (injection or traumatic) or surgical procedures (augmentation mammoplasty, median sternotomy, percutaneous catheterization) (Fig. 196-7); rarely, primary cellulitis occurs without recognizable skin trauma. [32], [33] Contaminated gentian violet used for skin marking has been the source in some outbreaks. *M. fortuitum* complex STIs characteristically occur several weeks after the inciting injury and appear as indolent wound infections (nodules, ulcers, granulomatous papules, or verrucous plaques). In immunocompromised individuals, *M. fortuitum* can disseminate hematogenously to skin (multiple recurring abscesses on the extremities) and joints. Treatment regimens are complex, require careful susceptibility testing, and may include excisional biopsies.

FIGURE 196-7 Cellulitis: *Mycobacterium chelonae.* Cellulitis occurred at operative sites following venous harvest and coronary artery bypass in a 37-year-old male with diabetes mellitus. The infection combined with peripheral vascular disease necessitated amputation of both legs above the knees.

HELICOBACTER CINAEDI A syndrome characterized by fever, bacteremia, and recurrent *H. cinaedi* cellulitis has been described in immunocompromised patients. In a series of seven patients (six HIV-infected, one with a history of alcoholism) with *H. cinaedi* STIs, cellulitis with adjacent arthritis occurred in two patients. Ciprofloxacin was effective in treatment in five cases. [34] In a series of 23 febrile patients with *H. cinaedi* bacteremia, 11 were HIV-infected; 9 had cellulitis (some with a distinctive red brown or copper discoloration with minimal warmth); the others had underlying alcoholism, diabetes, or malignancy. [35]
CORYNEBACTERIUM JEIKEIUM Skin and soft tissue infections caused by *C. jeikeium* occur primarily in granulocytopenic patients and take either of two forms: (1) primary infections (cellulitis at bone marrow biopsy sites, infection at insertion sites of intravascular catheters), and (2) secondary infections (erythematous or hemorrhagic papular rash, soft tissue abscess, or necrotic lesions) following a bacteremia from primary infection sites. [7], [36] Vancomycin intravenously is the treatment of choice.

COURSE AND PROGNOSIS

Occasionally, group A streptococci or *S. aureus* will cause a persistent superficial infection in moist intertriginous sites, such as perianal cellulitis in children. The process can become chronic, marked by perianal erythema (Fig. 196-8) and pruritus, pain on defecation, blood-streaked stools, and spread to other perineal structures. Diagnosis can be made by culture of the erythematous area followed by treatment of the offending group A streptococcus or *S. aureus,* usually with prompt resolution of the persistent superficial cellulitis. [37]

FIGURE 196-8 Perianal streptococcal cellulitis. Erythema around the anus and on the perineum. (*Courtesy of Arthur R. Rhodes, MD.*)

Uncomplicated erysipelas remains confined primarily to the lymphatics and subcutaneous tissues, occasionally complicated by bleb formation and, rarely, by the presence of an abscess. Even in the days prior to antibiotic therapy, it was often a self-limited process, subsiding over 7 to 10 days. Occasionally, untreated erysipelas or cellulitis may be complicated by bacteremia with metastatic infection in various organs. Prompt treatment prevents both suppurative and nonsuppurative complications. However, in young infants and elderly debilitated patients and in individuals receiving glucocorticoids, the disease may progress with devastating rapidity to a fatal outcome. Erysipelas or cellulitis after saphenous vein harvest may be recurrent, especially in patients with underlying tinea pedis, presenting as edema, erythema, and tenderness along the course of the saphenous venectomy.

Erysipelas has a tendency to recur in the same area, probably a result of the predisposing effects of chronic lymphatic obstruction, persistent edema, and even elephantiasis-like swelling caused by earlier infections. Such recurrent infections may produce persistent swelling of the lips (macrocheilia), cheeks (particularly the lax tissues beneath the eyes), lower extremities, or even abdomen. Chronic lymphedema of the lower extremities secondary to recurrent erysipelas may result in elephantiasis nostras verrucosa (see Chap. 167). Areas of lymphatic obstruction are predisposed to recurrent infections; for example, following radical mastectomy some patients are liable to recurrent episodes of what appears to be erysipelas in the area of lymphedema. In summary, erysipelas, especially that caused by group A streptococci, causes local injury to lymphatics that further compromise tissue defenses resulting in edema, skin and scar changes, and potential for recurrent disease. Erysipelas leads to recurrent erysipelas such that early therapy and prolonged elevation of the affected area can help to preserve better tissue resistance to reinfection. Some patients with frequent recurrences in the same area benefit from prophylactic antibiotics, usually monthly benzathine penicillin injections. [38]

Acute cellulitis, with or without abscess formation, has a tendency to spread through the lymphatics and bloodstream,

and may be a serious disease if not treated early. In older patients, involvement of a lower extremity may be complicated by thrombophlebitis. In patients with chronic edema, the process may spread extremely rapidly and recovery may be slow, despite drainage and sterilization of the lesions by antibiotics.

The mortality rate for necrotizing fasciitis is high (reported to be approximately 40 percent greater when complicated by streptococcal toxic shock–like syndrome; see Chap. 194). Early diagnosis and aggressive treatment of necrotizing fasciitis is the most important factor in determining outcome. [39] Risk factors mentioned above can impact negatively on outcome and include older age, diabetes mellitus, malnutrition, hypertension, and intravenous drug abuse. Overall, clostridial infections have a mortality of 20 to 70 percent, depending upon the location of the process, with myonecrosis associated with the more lethal prognosis. Spontaneously occurring gas gangrene tends to have an even more ominous mortality, approaching 100 percent, because of its rapid onset, without an obvious predisposing traumatic or surgical wound and the association with an underlying malignancy. The mortality for synergistic necrotizing cellulitis is at least 50 percent, the patient usually succumbing to septic shock and circulatory collapse.

In assessing prognosis, the wide ranges described for these infections depends upon many variables. The underlying health and immune status of the patients clearly are factors predisposing to all of these entities. In like manner, early recognition and definition of etiologic agents guides appropriate antibiotic usage, as well as surgical decisions. Many of these infections are life-threatening and therefore urgent evaluation and therapy are capable of improving prognosis.

TREATMENT

Antibiotics

See Chap. 193, Table 193-6 for a complete outline of antimicrobial choices and Table 196-5 for therapeutic guidelines for necrotizing infections.

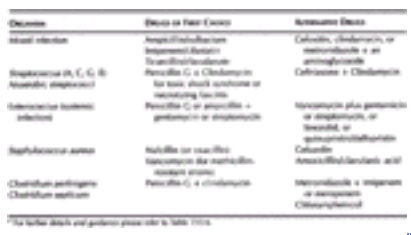

TABLE 196-5 **Antimicrobial Treatment of Necrotizing Infection of Skin, Fascia, and Muscle***

Mild cases of early erysipelas can be treated on an outpatient basis with either intramuscular procaine penicillin (600,000 units twice daily) or with oral penicillin V, 500 mg every 6 h. Erythromycin and clindamycin are also effective in penicillin-allergic individuals. [40]

Individuals with more extensive streptococcal infections and with underlying medical problems such as diabetes mellitus should be hospitalized and treated with intravenous aqueous penicillin G (1 to 2 million units every 4 to 6 h). In severe streptococcal skin infections (e.g., extensive erysipelas, cellulitis, or streptococcal gangrene), parenteral aqueous penicillin G should be administered in higher doses. In the ill patient in whom a staphylococcal etiology is identified, a penicillinase-resistant semisynthetic penicillin (e.g., nafcillin) should be employed and/or vancomycin substituted in the penicillin allergic individual. In the patient with a questionable penicillin allergy, cefazolin (1.0 g intravenously every 8 h) may be chosen. Vancomycin is the drug of choice in patients that have a methicillin-resistant organism or have a prior history of an immediate type reaction (IgE mediated) to a penicillin or a cephalosporin.

Treatment decisions for patients with crepitant or gangrenous STI, including necrotizing fasciitis, anaerobic cellulitis and myonecrosis must be based upon a rapid or presumptive identification of the etiologic agent(s) (see Table 196-5).

Local Measures

Care of the local lesions of erysipelas and cellulitis includes bed rest with immobilization and elevation of the involved area to reduce local edema. Cool, sterile saline dressings decrease the local pain and are particularly indicated in the presence of bullous lesions. The application of moist heat may aid in the localization of an abscess in association with cellulitis, but it should not be used in a patient with arterial insufficiency of the involved extremity.

Surgical Intervention

Treatment of necrotizing STIs requires early and complete surgical débridement of necrotic tissue in combination with appropriate drainage and high-dose antibiotics. Inspection of the deep fascia can confirm the presence of fat necrosis, preservation of the deep aponeurosis overlying muscle and provide material for bacterial and pathologic study. [28] Reexploration and débridement should be performed as necessary to ensure that all necrotic tissue has been removed and pockets of pus are drained.

When synergistic necrotizing cellulitis is considered a more likely diagnosis than an abscess, it becomes essential to explore the involved area including careful assessment of the area of necrosis in the deep subcutaneous tissues as well as inspection of the underlying muscle. A frozen-section soft-tissue biopsy early in the course of the illness may provide a definitive diagnosis and expedite appropriate débridement of the area of involvement until completely normal fascia is reached and muscle has been inspected. The wound is left open and if there is any question as to the adequacy of the initial débridement, a second-look procedure is indicated 24 to 48 h later. Prior to obtaining results from cultures, initial

antimicrobial therapy should be based on knowledge of the prominent role of anaerobic bacteria in this infection and on the specific findings of the gram-stained smear of the exudate.

Anaerobic clostridial cellulitis is treated with surgical débridement of all devitalized tissue. The use of hyperbaric oxygen drenching, particularly in patients with far-advanced disease involving the trunk in whom surgical excision would be mutilating, appears to have a place in current therapy. Although prospective studies are lacking, retrospective data indicate that adjunctive hyperbaric oxygen therapy may reduce morbidity and mortality in both clostridial and nonclostridial necrotizing infections. [41] Proposed mechanisms by which hyperbaric oxygen could improve outcome include enhancement of leukocyte production of bactericidal free radicals, direct inhibition of anaerobic bacterial growth, preservation of poorly perfused tissue, and promotion of wound healing.

The surgical approach to clostridial or streptococcal myonecrosis requires rapid evaluation, appropriate antibiotics with penicillin and metronidazole or clindamycin and exploration and débridement of affected muscle. Amputation of a limb can be rapidly accomplished and may be life saving in selected patients. Spontaneous myonecrosis and anaerobic cellulitis caused by *Clostridium septicum* or other histotoxic clostridia may benefit from exposure to hyperbaric oxygen because bacteremia is frequently present, toxin production may be halted and tissues still viable may be protected by an oxygen barrier. [42]

Other Therapies

Other adjunctive considerations in treatment of STI include the use of intravenous gamma globulin for type II necrotizing fasciitis caused by group A streptococci and recombinant human activated protein C in severe sepsis related to these soft-tissue infections. [43], [44] Patients with poor granulocyte production may be helped by granulocyte colony-stimulating factor. There is some evidence from the recent literature and from speculative observation that NSAIDs should be avoided in patients suspected of incubating or expressing early bacterial infections. Masking of fever and inhibition of granulocyte migration and function are arguments that deserve continued evaluation.

REFERENCES

Many of the characteristic cutaneous manifestations of infection with gram-negative organisms are due to direct microbial invasion of the skin or subcutaneous tissues. In addition, responses of host cytokines, chemokines, receptor molecules, and other effector cells and factors may contribute to fever, hypotension, and a variety of cutaneous manifestations. [1]

The typical skin lesions in meningococcal or *Pseudomonas* septicemia, often among the earliest indications of generalized infection, can provide immediate and important clues to early diagnosis. [2] However, in the immunocompromised patient, unusual organisms and atypical presentations of typical pathogens occur.

INFECTIONS DUE TO *NEISSERIA MENINGITIDIS* (MENINGOCOCCUS)

Three clinical syndromes associated with cutaneous involvement occur in meningococcal disease: meningitis, acute meningococcemia, and chronic meningococcemia. Skin lesions are frequently the most dramatic manifestations and graphically add to the aura of fear attached to these infections. The presence of areas of purpura or gross hemorrhage correlates with greater numbers of bloodstream organisms and generally indicates a poorer prognosis than a local or generalized petechial eruption. Several reviews detailing the epidemiology, pathogenesis, and clinical presentations have recently been published. [1], [3], [4]

Bacteriology and Pathogenesis

The *Neisseria* are obligate, aerobic, encapsulated, gram-negative, kidney bean–shaped cocci that pair with their long axes in parallel. *Neisseria meningitidis* grows well on blood-enriched media (chocolate agar), supplemented by an atmosphere containing 5 to 10 percent CO_2 and approximately 50 percent humidity. In potentially mixed bacterial exudates, these organisms should be grown on a selective medium (e.g., modified Thayer-Martin); they can be distinguished from *Neisseria gonorrhoeae* by their fermentation of both glucose and maltose rather than of glucose alone. Meningococci are separable into at least 13 serologic groups on the basis of capsular antigens, of which A, B, C,

Y, and W-135 are the major pathogenic groups involved in human disease today. Antigenic variation resulting from the presence of outer membrane proteins that can identify serotypes, serosubtypes, and immunotypes, not only is helpful in epidemiologic studies, but also enables organisms to evade host defenses. [3] Recent studies, including an analysis of an epidemic of meningococcal disease, have identified a shift of capsular group, in this case from group B to group C organisms and vice versa, thus facilitating the evasion of host antibodies. [5]

The presence of a virulent strain colonizing the nasal mucous membranes precedes clinical disease in a nonimmune host. Pili that attach to specific receptors on nonciliated, columnar mucosal epithelial cells and production of an IgA protease that cleaves host secretory IgA may facilitate initial colonization. [3] Additionally, antigenic variation contributing to virulence may occur through changes in the semi- and hypervariable regions of pili of organisms attaching to epithelial, endothelial, and phagocytic cells. [6]

Encapsulated organisms resist phagocytosis. With the onset of a viral respiratory infection, they may multiply locally and invade the bloodstream or be aspirated into the lower respiratory tract. Meningitis, meningococcemia, or pneumonitis can result. Predisposition to sporadic and occasionally recurrent meningococcal disease occurs in patients with congenital or acquired complement deficiencies, particularly late-acting components C5–C9. [3], [7]

The skin lesions associated with meningococcemia and meningococcal meningitis result from damage to small dermal blood vessels. Light and electron microscopy reveal bacteria within endothelial and polymorphonuclear cells. [8] Organisms are sometimes apparent when needle aspirates or punch biopsies from involved areas of skin are Gram-stained. [9] Local endothelial damage, thrombosis, and necrosis of the vessel walls occur. Immunoglobulins and complement are present, even in early vascular lesions. [3], [8] Edema, infarction of overlying skin, and extravasation of red blood cells are responsible for the characteristic macular, papular, pustular, petechial, hemorrhagic, and bullous lesions. Similar vascular lesions occur in the meninges and in other tissues. In addition to direct involvement of skin vessels by meningococci, many of the cutaneous hemorrhagic lesions may be due directly to the effects of lipo-oligosaccharide (LOS) endotoxin or indirectly to the stimulation of host cytokines. [1] A contribution to the dermal inflammatory vascular injury, independent of immune complexes and cytokine activity, may come from the interaction between vascular endothelium (intercellular adhesion molecule-1) and an adhesion glycoprotein (CD18) on leukocytes, the so-called dermal Shwartzman reaction. [10] The profound effects on small blood vessels, directly related to bacterial invasion or indirectly due to LOS endotoxin host cytokine released or the dermal Shwartzman reaction may lead to diminished blood volume, lowered cardiac output, anoxia in vital organs, myocardial failure, hypotension, acidosis, and diffuse intravascular coagulation. [4]

Meningococci can be isolated from the blood in chronic meningococcemia, usually during periodic fevers, rash, and joint manifestations. The pathogenesis of this form of disease is not as well understood as that of the acute septicemia. This chronic form of meningococcal infection has been linked to the absence of terminal components of complement in several patients and to an isolated IgA deficiency in one patient, associations that may provide insights into pathogenic mechanisms in this unusual host-parasite interaction. [11], [12] The absence of bacteria, bacterial antigenic material, and granulocytic inflammation distinguishes the findings of chronic infection from those seen in acute infections. The histopathology of a skin biopsy specimen in an immunocompetent infant revealed leukocytoclastic vasculitis, an exception to the usual absence of vascular damage found in chronic meningococcemia. [12] The chronic course of the disease, lack of endotoxin-like manifestations (even with demonstrated bacteremia), and the potentiality for an eventual complication such as meningitis or endocarditis suggest that an unusual host-parasite relationship is central to this persistent, but rare, infection.

Epidemiology

Humans are the only known natural hosts of *N. meningitidis.* Nasopharyngeal carrier rates vary (5 to 15 percent overall) with age: 1 percent in children 3 to 48 months of age, 5 percent in those 14 to 17 years of age, and 20 to 40 percent in young adults. When conditions are crowded, such as in schools or military camps, or when a carrier of a new strain develops disease in a day-care or family setting, carrier rates can increase dramatically, independent of clinical disease. [13] The recent increase in cases among first-year college students living in dormatories illustrates the impact of crowding and stress, concentration of susceptible individuals, and variations in the antigenic makeup of microorganisms. [3], [14]

Globally, group A strains have been responsible for epidemics of meningitis, especially in sub-Saharan Africa. In Europe and the Americas, Groups B and C have predominated, and in the United States, a recent surge in group Y disease has been reported. These regional differences are not readily explained, but probably are influenced by host factors such as naturally acquired immunity and immunizations; circumstances such as travel or crowding, viral illness; and smoking—as well as microbial antigenic variation.

Adult family members probably introduce the organism into the household, but secondary cases are most frequently spread from ill children aged 1 through 14 years to other family members in the same age group, especially under crowded conditions. [15] Household spread is 500 to 800 times more frequent than secondary cases in the community at large. An exception to this is the increased incidence of secondary cases in day-care centers where large numbers of susceptible children congregate. [4], [16] Absence of the spleen has been associated with fulminant meningococcal disease, as has been reported for other encapsulated organisms. *Neisseria meningitidis* has been isolated from the genitourinary tract in individuals practicing orogenital sex and in homosexuals. [17]

Asymptomatic exposure to a variety of *N. meningitidis* strains, as well as nonpathogenic *Neisseria* and *Escherichia coli* K1 strains can stimulate protective bactericidal antibody. Consequently, immunity to meningococci increases with age, and protective bactericidal antibodies, both IgG and IgM, occur in 70 to 95 percent of young adults. Newborn infants are often resistant to meningococcal disease; this protection lasts until they are approximately 3 to 6 months of age, by which time

passively acquired maternal IgG antibody levels have markedly diminished. [18]

A number of conjugate vaccines have been in use outside the United States with favorable results, [3], [4] but the quadrivalent vaccine containing polysaccharides of groups A, C, Y, and W-135 is the only currently licensed vaccine in the United States against meningococcal disease. The poor immunogenicity and the inadequate protective efficacy of the quadrivalent vaccine in young children have led to the development of conjugate vaccines that appear to have the same protective efficacy for infants as the currently available *Haemophilus influenzae,* type b conjugate. The group B capsular polysaccharide, a polysialic acid polymer similar to human fetal neural tissue, does not induce protective immunity. With the use of outer membrane proteins of group B organisms, efforts continue to develop an effective vaccine for this frequently identified pathogenic group. [19]

Acute Meningococcemia and Meningitis

CLINICAL MANIFESTATIONS
History The disease often follows a mild upper respiratory infection associated with headache, grippelike complaints, nausea and vomiting, and muscle soreness. These symptoms can be so short-lived that fever, obtundation, and other manifestations of meningitis are the initial findings. In fulminant meningococcemia, vomiting, stupor, precipitous development of a hemorrhagic rash, and hypotension may be evident within a few hours of the onset of symptoms. Milder cases, developing at a slower pace, also occur.
Cutaneous lesions The skin findings associated with acute meningococcal infections are characteristically petechial, but transient urticarial, macular, or papular lesions (Fig. 197-1A), which can resemble those seen in viral exanthems, may be evident. [20] The petechiae are small and irregular with a “smudged” appearance, and they are often raised, with pale grayish vesicular centers. Although most commonly located on the extremities and trunk, lesions can also be found on the head (Fig. 197-1B), palms, soles, and mucous membranes (including the conjunctivae). Pustular or extensive bullous and hemorrhagic lesions with central necrosis (suggillations) can develop. Gangrenous hemorrhagic areas (indistinguishable from purpura fulminans; see Chap. 194) can appear in patients with severe meningococcemia, often complicated by disseminated intravascular coagulation (DIC; Fig. 197-1C). Skin lesions and bacteremia are rarely seen with meningococcal pneumonia, [21] but cellulitis has been noted in occasional patients, especially in children with meningococcal conjunctivitis (see below).

FIGURE 197-1 *Neisseria meningitidis:* Acute meningococcemia. *A.* Transient macular and papular lesions on the upper chest. *B.* Discrete, pink-to-purple macules and papules, as well as purpura, are seen on the face of this young child. These lesions represent early disseminated intravascular coagulation. *C.* Maplike gray-to-black areas of cutaneous infarction are seen in this child with disseminated intravascular coagulation.

Other physical findings Patients with meningitis display signs of meningeal irritation and altered consciousness. Occasionally, agitated or maniacal behavior predominates. Cranial nerve palsies, long-tract signs, seizures, and alterations in vital signs associated with changes in intracranial pressure may be present. Obtundation and hypotension without meningeal signs, associated with the syndrome of DIC, are characteristic features of acute fulminating meningococcemia. Rarely, meningococcemia may result in septic foci in other areas: (1) septic arthritis with a pyogenic effusion in one or several joints; (2) purulent pericarditis with precordial pain, enlarging cardiac silhouette, and findings of cardiac tamponade; and (3) bacterial endocarditis. More commonly, a delayed immune complex–mediated syndrome can result in a sterile arthritis, pericarditis, or episcleritis. [3] The acute arthritis-dermatitis syndrome, characterized by petechiae and nontraumatic arthritis, has traditionally been identified with disseminated *N. gonorrhoeae* (see Chap. 233), especially auxotype strains requiring arginine, hypoxanthine, and uracil for growth. In recent years, there has been a decline of gonococcal cases and an increase in this syndrome due to *N. meningitidis.* [22]
LABORATORY FINDINGS A polymorphonuclear leukocytosis is present in the peripheral blood and cerebrospinal fluid (CSF) in meningitis. The CSF protein level is increased, and the glucose value is commonly reduced. Characteristic organisms may be seen on Gram-stained smears of fluid, and meningococci are usually isolated from the CSF. *Neisseria meningitidis* may be isolated from the blood of approximately one-third of patients with meningitis and from almost 100 percent of patients with acute meningococcemia. The demonstration of organisms from cutaneous lesions has been variable, and the presence of gram-negative commensal organisms on the skin makes caution necessary. Published reports describe positive results in 50 to 80 percent of aspirates, skin films, or punch biopsies of petechial lesions. [9], [24] In our experience, aspirates of bullous and pustular lesions often demonstrate characteristic gram-negative diplococci. In patients already exposed to antimicrobial agents, the development of rapid, accurate, and inexpensive procedures for detection of soluble antigens in the CSF has been a major advance in laboratory methodology. The latex agglutination and the enzyme-linked immunosorbent assay (ELISA) methods are sensitive, and very specific, but their clinical usefulness in most situations has been questioned. [24] Rapid diagnosis using a modification of the polymerase chain reaction is available in Europe currently and should be commercially available in the United States shortly. [4]
DIFFERENTIAL DIAGNOSIS Meningococcal infection always warrants consideration in a patient with fever and a petechial or purpuric eruption, even in the absence of clinical meningitis. Unfortunately, acute meningococcemia may evolve after only a brief prodrome of nonspecific flulike symptoms and in the absence of any meningeal findings. Occasionally, the characteristic rash is absent, delaying a consideration of meningococcal disease. The differential diagnosis should include the following conditions:

- Acute bacteremias and endocarditis. Petechial eruptions may be present in acute bacteremias and endocarditis, with or without changes in platelet numbers. In endocarditis, mucous membrane and conjunctival lesions, as well as

subungual “splinter” hemorrhages, occur. Very infrequently, numerous petechial and purpuric lesions, almost indistinguishable from those of meningococcal bacteremia, occur in patients with acute *Staphylococcus aureus* endocarditis. These patients may also have meningismus and pleocytosis (usually without bacteria evident on a Gram-stained smear of CSF) secondary to cerebral embolization or staphylococcal meningitis, completing the mimicry of meningococcal disease. Usually, a few skin lesions in a patient with acute *S. aureus* endocarditis are purulent purpura; aspirate from the purulent center of the lesion usually shows gram-positive cocci in clusters (rather than gram-negative biscuit-shaped diplococci) on smear, and subsequently *S. aureus* can be isolated on culture. In acute gonococcemia, the skin lesions are usually nodular, hemorrhagic, few in number, and located on the distal parts of the extremities (see Chap. 233). Occasional patients with *H. influenzae* or *Streptococcus pneumoniae* septicemia develop petechial eruptions.

- Acute hypersensitivity vasculitis. The lesions associated with acute hypersensitivity vasculitis are usually palpable, present in greatest profusion on the lower extremities, and often symmetric. Renal involvement and hypertension may be present. Pathologically, the major focus of inflammation is in postcapillary venules (see Chap. 175).
- Enteroviral infections. Fever, petechial eruptions, and aseptic meningitis are characteristic features of enteroviral disease. Echo-(e.g., type 9) and coxsackieviruses are most often implicated.
- Rocky Mountain spotted fever. The history of exposure to ticks in an endemic area, absence of an antecedent respiratory infection, delay in appearance of the rash, and the location first on the distal parts of the extremities, including palms and soles, are helpful clues to Rocky Mountain spotted fever (see Chap. 227).
- Toxic shock syndrome (see Chap. 194).
- Purpura fulminans (see Chap. 194).
- Weil's disease (leptospirosis) (see Chap. 199).

COURSE AND PROGNOSIS Untreated, acute meningococcal disease usually ends fatally. The prognosis for treated meningitis is excellent, with recovery in approximately 90 percent of patients. In severe meningococcemia, especially with the rapid emergence of cutaneous hemorrhages, hypotension, and DIC, the entire course from onset to death can be measured in hours. These cases are often associated with massive adrenal hemorrhage (Waterhouse-Friderichsen syndrome). The mortality rate approaches 100 percent. Gradations in the severity of the illness make it difficult to assign an accurate prognosis in an individual case, although a bedside predictive model has been proposed and may prove useful. [4], [25]

Chronic Meningococcemia

CLINICAL MANIFESTATIONS

History Chronic meningococcemia is a rare disease, occurring much less frequently than the more acute dermatitis-arthritis syndrome of subacute gonococcemia that it resembles. [22] The manifestations of chronic meningococcemia are indefinite and vague at the onset, but tend to establish a pattern over a period of weeks or months. [11], [26] Initially, there may be an acute febrile illness, but it wanes and leaves the patient with vague, intermittent complaints of muscle aches and pains, joint soreness, mild headache, and anorexia with weight loss. The simultaneous emergence of a localized rash with several days of fever and joint soreness are characteristic symptoms. As the fever recedes, the rash usually fades as well, and the patient may be totally free of overt skin manifestations for days or weeks at a time. This pattern of recurring fever and rash may last for a period of a few weeks to as long as 6 to 8 months. The average duration of reported cases is 6 to 8 weeks. Untreated cases may eventually evolve into acute meningococcemia, meningitis, or endocarditis. Rare case reports relate this syndrome to the absence of a terminal component of complement, a finding also observed in some sporadic and recurrent acute meningococcal infections. [11]

Cutaneous lesions Variability is the hallmark of the eruption associated with chronic meningococcemia. Several different types of skin lesions may appear, usually distributed about one or more painful joints or on pressure areas in contrast to the acral distribution of skin lesions in gonococcemia. They may vary in appearance and in size (1 to 20 mm) from one crop of lesions to the next and include (1) pale to rose-colored macular and papular lesions (the most common type), occurring in about 30 percent of cases; (2) slightly indurated and tender erythema nodosum–like nodules, mainly on the lower extremities; (3) petechiae of variable size; (4) petechiae with vesicular or pustular centers; (5) hemorrhage (minute) with an areola of paler erythema (very characteristic when it occurs); (6) grossly hemorrhagic areas with pale blue-gray centers; or (7) hemorrhagic, tender nodules located deep in the dermis.

Other physical findings Aside from the rash, the physical findings of chronic meningococcemia are minimal except for occasional joint swelling and tenderness. If the disease progresses to an acute complication such as meningitis, the new findings will be those of the complicating process.

PATHOLOGY The skin lesions in chronic meningococcemia differ pathologically from those in acute meningococcemia. Bacteria are absent, and fluorescent antibody techniques do not detect meningococcal antigens. In addition to the absence of bacteria or their recognized products, thrombi do not occlude capillaries and venules, endothelial cell swelling is absent, and the perivascular infiltrate consists of mixed polymorphonuclear and mononuclear cells rather than predominantly polymorphonuclear leukocytes, as seen in acute infections. Pathologic findings may be reported as “leukocytoclastic angiitis.” An allergic basis for the skin lesions has been suggested in chronic meningococcemia, even though bacterial antigens are not identifiable. [11]

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS During the febrile periods, blood cultures frequently show the presence of meningococci and, thus, provide the specific means of diagnosis. Serologic tests have not proved helpful, and there are no available data for the use of antigen detection procedures in chronic meningococcemia. A number of diseases with periodic fever, skin lesions, and joint involvement resemble chronic meningococcemia:

- Subacute bacterial endocarditis. A prolonged febrile course with a pleomorphic petechial rash, joint symptoms, and no overt focus make subacute bacterial endocarditis an important consideration. A prominent heart murmur, evidence of renal impairment, and blood cultures that indicate bacterial infection help to establish the diagnosis.
- Acute rheumatic fever. When the fever is prolonged, joint findings are prominent, and macular and papular rashes appear (see Chap. 179), the diagnosis may be acute rheumatic fever.
- Henoch-Schönlein purpura. The petechial hemorrhagic rash in association with symptoms of arthritis and fever suggests an illness not unlike chronic meningococcemia; the eruption in Henoch-Schönlein purpura is more often symmetric, usually only on the lower extremities, and does not have the periodicity of the rash of chronic

meningococcemia (see Chap. 175).

- Rat-bite fever. Also referred to as Haverhill fever, rat-bite fever may be acute (mimicking acute meningococcemia) or chronic (resembling chronic meningococcemia). Intermittent fever, rash, and joint manifestations are hallmarks of an illness that follows a rodent bite or ingestion of contaminated milk (see Chap. 199).
- Erythema multiforme. The symmetric distribution of the eruption and the iris-type configuration of the lesions suggests erythema multiforme (see Chap. 58).
- Gonococcemia (chronic). The cutaneous and joint manifestations of chronic gonococcemia may continue for many days or even weeks (see Chap. 233.). The presence of tenosynovitis in gonococcemia, in contrast to its usual absence in chronic meningococcemia, can be an important clue.

COURSE AND PROGNOSIS Some patients with chronic meningococcemia recover spontaneously without specific therapy, whereas others develop serious systemic complications, such as endocarditis or meningitis. The prognosis for treated infection is excellent; almost 100 percent of patients are cured with antibiotic therapy.

Primary Meningococcal Conjunctivitis

The bacterial species most commonly involved in acute bacterial conjunctivitis are *Staphylococcus aureus, Streptococcus pneumoniae,* and *H. influenzae. Neisseria meningitidis* is the infecting microorganism in up to 2 percent of cases, and the source of infection is most likely either direct inoculation of airborne organisms from close contact with carriers or manual contact with secretions from the patient's own nasopharynx. [27] A Gram-stained smear of conjunctival exudate commonly reveals gram-negative, biscuit-shaped diplococci, and culture yields *N. meningitidis*. Several microorganisms that can be found in infected body fluids and blood may appear morphologically similar to *N. meningitidis* on Gram stain, including *N. gonorrhoeae.*

Clinical features of primary meningococcal conjunctivitis include low-grade fever, conjunctival hyperemia, purulent exudate, lid edema, chemosis, photophobia, and preauricular lymphadenopathy. The majority of cases occur in children. Meningococcal conjunctivitis progresses to systemic meningococcal disease in about 20 percent of patients within a few hours to 4 days after the initial ocular symptoms. In view of the risk of systemic spread of infection, treatment should include not only topical antimicrobial agents (e.g., sulfonamides), but also systemically administered penicillin. Cellulitis of the cheek or periorbital region can complicate meningococcal conjunctivitis in children; in adults with underlying diseases, cellulitis, appears most commonly on the face, neck, or upper limb. [28]

Treatment and Prophylaxis

CHEMOTHERAPY The widespread emergence of sulfonamide-resistant strains more than 30 years ago complicated the therapy for meningococcal infections. Initially, these strains belonged predominantly to serogroup B, but in recent years, they have been from serogroups A to C, essentially eliminating the sulfonamides as systemic agents for prevention or for treatment. These variations have resulted in penicillin G supplanting the sulfonamides as the treatment of choice for acute meningococcal infections. The usual adult dosage of penicillin G for meningococcal meningitis is 4 million units given IV every 4 h until approximately 7 days after the temperature has returned to normal. Treatment of chronic meningococcemia does not require “meningeal doses” of penicillin; 6 to 12 million units divided into four to six daily doses, given IV for 7 to 10 days, should be effective therapy. In the highly penicillin-allergic patient, the use of chloramphenicol (1 g given IV every 6 h) is preferable to risking cross-reactions with a third-generation cephalosporin. In many parts of the world, such as Spain and the United Kingdom, where meningococci that are relatively resistant to penicillin have been isolated, a third-generation cephalosporin (e.g., ceftriaxone, cefotaxime) should be considered for initial therapy. All meningococcal isolates from blood, CSF, or other normally sterile body cavities should be tested for penicillin susceptibility. [4]

SUPPORTIVE THERAPY Efforts to prevent acute brain swelling are critical in patients with meningitis. These include prevention of overhydration, reduction of body temperature, and employment of agents such as mannitol or dexamethasone (if evidence of rising intracranial pressure develops). Although it has been postulated that hypotension in acute meningococcemia may be due to adrenal failure associated with the Waterhouse-Friderichsen syndrome (adrenal hemorrhage), blood cortisol levels and corticosteroid secretion rates have been found elevated in this syndrome. The modern treatment of shock in sepsis begins with a number of well accepted measures, including antibiotic selection, drainage procedures for abscesses, appropriate use of volume expanders, ß-adrenergic–stimulating drugs such as dopamine or isoproterenol, correction of severe acidosis, and in selected patients, peripheral vasodilators. Therapies still considered experimental include those directed against cell envelope components of bacteria (e.g., LOS), those that neutralize host cell–mediated cytokines (e.g., interleukin 1, tumor necrosis factor), [1] and those capable of limiting tissue damage (e.g., protein C). [29] Although numerous studies have been completed and results have been variable, on balance glucocorticoids do not appear to be indicated for septic shock. Severe meningococcal infections can be complicated by the syndrome of DIC. The basis for the diagnosis is usually a composite of associated hematologic abnormalities, including thrombopenia and hypofibrinogenemia, prolongation of the prothrombin time and partial thromboplastin time, and presence of fibrin split products. If bleeding occurs, it may be necessary to administer fresh-frozen plasma. Treatment for each case must be individualized, because therapy may be harmful and produce more problems than the DIC syndrome, especially if acute respiratory distress syndrome is also present. Data on the use of heparin in treating DIC remain unconvincing and inconclusive, and because of potential adverse effects, most septic shock therapists no longer recommend it as routine therapy. Investigators are continuing to study antibodies to various cytokines that are elevated in meningococcal septicemia, the use of protein C replacement, [1], [29] and immunomodulatory therapies. [1], [29], [30]

PROPHYLAXIS There is a critical need for reliable chemoprophylaxis to rapidly protect day-care nursery exposures, crowded household contacts, or institutional groups because secondary cases can emerge rapidly, often within 24 to 48 h of an index case. [13], [31] Currently recommended prophylactic drug regimens for children and adults favor rifampin (age-adjusted for children), 600 mg orally twice daily for 2 days. [16] Rifampin resistance occurs, however, and recent reports document its failure with the development of invasive meningococcal disease. [28] Fortunately, the fluoroquinolones, ciprofloxacin and ofloxacin, are effective single-dose substitutes, and ceftriaxone is available for parenteral single-dose use in children as well as adults. [16] The effectiveness of these agents appears to be due to their

presence in adequate concentrations in upper respiratory and salivary secretions. [32]

Immunization

Polysaccharide vaccines have been developed from groups A, C, Y, and W-135 *N. meningitidis* and have proved to be safe and effective in preventing meningococcal disease in adults and in children over the age of 2 years. [16]

The currently available single and quadrivalent vaccines, especially as they apply to protection of susceptible young children, have limitations, however. Protein conjugated vaccines, successful in protecting young children from *H. influenzae,* type b (Hib) carriage and disease, have been developed and are in use, but are not yet available in the United States. [4], [30] A protective vaccine for group B infection that has been in development uses outer membrane proteins instead of the capsular sialic acid polymer, and clinical trials, outside of the United States, continue. [4] The elucidation of the complete genome of *N. meningitidis* has led to the identification of several conserved proteins that, in an experimental mouse model, have been protective for challenge with all pathogenic *N. meningitidis.* The future for vaccine development is hopeful.

INFECTIONS DUE TO *PSEUDOMONAS AERUGINOSA*

The ubiquitous gram-negative bacilli *Pseudomonas aeruginosa* can cause serious infections, usually in individuals who have altered defenses, who are receiving intense antibiotic therapy, or who are in hospital. Cutaneous manifestations of *Pseudomonas* infections are common and characteristic. They may represent the only overt findings in septicemias, or they may be the localizing focus in serious infections of the ear. In addition, these organisms can produce trivial cutaneous lesions involving nails, toe webs, skin, and the external auditory canal.

Bacteriology and Pathogenesis

Pseudomonas aeruginosa is a nonfermentative, obligately aerobic, robust, gram-negative bacillus that can even grow in distilled water. Some strains produce a blue pigment (pyocyanin) soluble in chloroform, a water-soluble yellow-green substance (fluorescein), or black pyomelinin. With Wood's ultraviolet lamp, it is possible to detect the presence of organisms in lesions of skin or nails and in the urine, if the infecting strain produces fluorescein. Either of the pigments or their combination will impart a characteristic greenish color to the surrounding growth media or the tissue substrate involved in clinical disease (e.g., “green nail” syndrome; Fig. 197-2). Pyomelinin strains can lead to confusion between pigment and/or necrotic changes. In addition, an odor of grapes, characteristic of trimethylamine, often accompanies the growth of these microorganisms.

FIGURE 197-2 *Pseudomonas aeruginosa:* “Green nails.” This 36-year-old bartender noted a greenish-yellow discoloration of 8 of 10 fingernails during the preceding year. Several of the fingers show chronic candidal paronychia as well.

Organisms gain entry through breakdown of the skin or mucous membrane barriers at sites of maceration, dermatophytic foci, trauma, or foreign bodies (e.g., indwelling venous or urinary catheters), or via aspiration or aerosolization into the respiratory tract. Infections in otherwise healthy individuals are unusual; when they occur, the involved regions are often areas with increased moisture (e.g., toe webs, the external auditory canal). Infection may begin in the base of the nail in persons who frequently have their hands or feet in water. This can progress to paronychia, followed by development of a green-blue discoloration of the nail due to local pigment production. The ability of this organism to infect healthy, but moistened, skin is evident in the numerous reports of a rash of disseminated papules and pustules on areas of skin of people immersed in public whirlpools, hot tubs (“hot tub folliculitis,” Fig. 197-3), wading and swimming pools. [33] These ubiquitous organisms can sometimes be aggressive secondary invaders in open wounds, in decubitus and other skin ulcerations, or in association with thermal burns. Rarely, a superficial pyoderma due solely to *Pseudomonas* is engrafted upon a generalized or localized dermatitis, such as tinea pedis or eczema, producing irregular pustular areas with macerated and eroded borders. [33]

FIGURE 197-3 *Pseudomonas aeruginosa:* “Hot tub folliculitis.” This 22-year-old female noted the appearance of erythematous, pruritic papules and pustules on the trunk, buttocks, and upper thighs several days after bathing in a hot tub. The eruption resolved without antibiotic therapy.

Serious invasive infections occur in debilitated patients; malnourished infants; individuals whose normal bacterial flora has been suppressed by antibiotics; patients with neoplastic diseases, granulocytopenias of various etiologies, or impaired circulating or cellular immunity, including that associated with AIDS; [34] and individuals requiring mechanical respiratory assistance. These ubiquitous organisms frequently colonize body surfaces and survive exposure to antibiotics. *Pseudomonas aeruginosa* can spread widely via the bloodstream, producing a disseminated infective vasculitis in which organisms can appear in the periadventitia, adventitia, and media of vessels without luminal clots. Occasionally, features of the generalized Shwartzman reaction are found, but less frequently than in infections due to *N. meningitidis* or Enterobacteriaceae.

Whole dead *Pseudomonas* cells injected into experimental animals produce little, if any, toxicity compared with the effects of live bacteria. This suggested to Liu that the pathogenicity of this organism may reside in an exotoxin rather than in the classic endotoxin of gram-negative bacteria. [35] Studies during the past 25 years have confirmed the relevance of a number of enzymatic and toxic substances to pathogenesis. Among these, collagenase and elastase may be important determinants for the development of hemorrhagic lesions. A phospholipase similar to the a-toxin of *Clostridium perfringens* may have a major role in the pathogenesis of respiratory infections through destruction of pulmonary surfactant. Studies have led to the identification and characterization of a potent protein, exotoxin A. The mechanism of action of this cytotoxin is identical to that of diphtheria cytotoxin, but it differs in its cellular specificities, molecular properties, and clinical expression. Among the critical effects of these cytotoxins, their influence on polymorphonuclear leukocyte migration and function is considered vital to pathogenicity. [36] The role of the various cellular and toxic components of *P. aeruginosa* that contribute to pathogenicity has been reviewed. [37] In addition, the potential for developing immunotherapies, including conjugate polysaccharide toxin A and outer membrane protein vaccines, for life-threatening infections in compromised patients has been discussed in a recent report. [38]

Epidemiology

Because *P. aeruginosa* is widely distributed in nature (in air, water, dust particles, and soil), it is not surprising that it may contaminate plants, vegetables, hot tubs, whirlpools, swimming and wading pools, and occasionally medicinal preparations such as procaine and fluorescein eye drops. In humans, the moist regions of skin folds and the external auditory canal are the most common sites of natural colonization (approximately 3 to 5 percent of individuals). *Pseudomonas aeruginosa* is found in small numbers in the feces of 10 to 20 percent of the population, but in as many as 35 to 50 percent of patients hospitalized for longer than 1 week.

Any activity that leads to excessive local moisture—laundry work, dishwashing, or hiking for long periods in wet terrain—will enhance the presence and growth of these organisms. Moist or weeping cutaneous lesions (e.g., thermal burns) encourage the growth of *Pseudomonas* as well as that of other gram-negative bacteria. Procedures that increase humidity in the environment are frequently associated with overgrowth of these organisms. Moisture-enhancing bath materials, like loofah or synthetic sponges, easily become contaminated with gram-negative bacteria and have served as vehicles of transmission of *Pseudomonas* to skin.

Systemic infection with these indigenous gram-negative bacteria depends primarily on altered susceptibility of the host rather than on spread from individual to individual or on increased pathogenicity. However, there may be exceptions to this in newborn nurseries, respiratory care units, and occasionally, urology wards, where dissemination from a primary source may occur. Hospitalized patients who are neutropenic or immunocompromised are more likely to become colonized and develop invasive disease.

Local and Secondarily Infected Lesions

Pseudomonas produces a number of characteristic lesions. In addition, these organisms contaminate and complicate other skin diseases and open wounds. [39]

CLINICAL MANIFESTATIONS

History Painful paronychial lesions, with or without characteristic green or blue discoloration of the nails occur most often in women with a history of continual immersion of the hands in water with soaps and detergents. People with toe web infection characteristically work or live in an atmosphere of high humidity and often have wet feet. Symptoms usually include slight persistent soreness and scaling of the web tissues. There are a large number of reports of therapeutic or

recreational whirlpool-, hot tub–, and swimming pool–associated skin rashes developing in healthy individuals within 1 to 5 days after use of public bathing facilities (see Fig. 197-3). In all instances, *P. aeruginosa* was isolated in large numbers from the pool water. The skin rash is usually self-limited, clearing without therapy within 1 week, but often accompanied by fatigue, malaise, low-grade fever, external otitis, and mastitis. [33] The hot-foot syndrome, a newly described disease caused by *P. aeruginosa* contamination of a wet surface, emphasizes the organism's opportunism in infecting the ventral surface of feet abraded by a roughened floor. [40]

Cutaneous lesions In addition to a tender paronychial lesion, patients with the “green nail” syndrome may have part or all of the associated nail colored green to blue. The color may be in horizontal bands, representing intermittent activity of the infection at the nail base (see Fig. 197-2). Individuals with toe web *Pseudomonas* infections have thick, macerated, scaling, slightly green, foul-smelling discolored areas between the toes. The hot-foot syndrome is characterized by tender, painful, red, plantar nodules independent of signs of folliculitis, developing within 1 to 2 days of exposure of individuals to an abrasive wet surface, such as a wading pool. [40] External otitis due to any type of bacteria presents a characteristically swollen, macerated appearance in the local area without any specific lesion involving the eardrum. Often referred to as “swimmer's ear,” the condition produces intense swelling and discoloration with excruciating pain on movement of the pinna. If the skin is traumatized naturally or during a surgical procedure, local infection can spread to the pinna, producing a perichondritis and chondritis with intense tender swelling of the ear. Cartilagenous necrosis may result from pressure effects or inflammatory damage unless immediate drainage with through-and-through incisions and appropriate antibiotics are instituted. Organisms other than *P. aeruginosa* may be causal, including *Staphylococcus aureus* and streptococci. [41] The most severe form of *Pseudomonas* infection, malignant external otitis, has a high mortality rate if therapy is delayed or inadequate. This serious infection usually occurs in elderly people who are diabetic with significant small-vessel disease, but may also occur in healthy elderly people, as a complication of surgical trauma, after minor trauma such as water irrigation of the external canal, and in patients with AIDS. [42] The onset and early progression of infection are insidious. Swelling, erythema, moderate discharge, and pain are present without fever or constitutional symptoms. As the surface breaks down, the *Pseudomonas* invade the soft tissues at the junction of cartilage and bone, and the process then advances to involve cartilage, mastoid, and temporal bone. Inflammation at the stylomastoid and jugular foramina can lead to 7th-nerve and 9th- to 11th-nerve palsies, the 7th-nerve palsy being the earliest objective neurologic defect seen. Diagnosis is made clinically and early if there is adequate visibility, and granulation tissue can be seen erupting at the cartilage-bone interface in the posterior inferior canal wall. The pinna is often swollen, and pain is intense. [43] Patients who develop folliculitis usually give a history of exposure to warm water in a theraputic whirlpool, a public bath such as a hot tub, a recreational spa for swimming, or a water slide. The rash can be localized if a limb has been immersed in a whirlpool or generalized in distribution in swimsuit and intertriginous areas. The rash begins as papules, evolves to papulopustules (see Fig. 197-3), and eventually heals with fine desquamation. Pruritus and pain may accompany the lesions along with localized areas of mastitis and external otitis. Serotype 0-11 of *P. aeruginosa* is most commonly involved. [44] A small outbreak of *P. aeruginosa* 0-11 folliculitis occurred in granulocytopenic patients in a cancer treatment center; but the lesions in these patients, in contrast to those in healthy individuals with swimming pool folliculitis, rapidly became widespread and progressed to bullae, which became necrotic (ecthyma gangrenosum–like) unless systemic antibiotic treatment began immediately. [45] Thus, the development of ecthyma gangrenosum can result from the progression of an initial folliculitis in a compromised patient rather than the incidental occurrence of superimposed bacteremic *P. aeruginosa* lesions. Sinks and faucets in the patients' rooms were sources of *P. aeruginosa* of identical serotype. In secondarily infected open skin areas, the presence of *Pseudomonas* is sometimes associated with a prominent greenish-blue color to the purulent exudate. Widespread, irregular, superficial pustular lesions may be superimposed on the underlying skin disease; the margins of these regions are usually sharply defined and irregular and may exhibit the characteristic grapelike odor and pigmented exudate. [44]

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS Nail and skin lesions resulting from *Pseudomonas* infection are recognized by the characteristic pigment and “fruity” odor of the exudate. The organisms can be identified as thin gram-negative rods, or a mixed infection (e.g., with *Candida*) may be observed. Fluorescence, demonstrated with a Wood's lamp, can help to support the diagnostic impression. Occasionally, *Aspergillus* infection of the nails produces a greenish color, there is usually no associated paronychia. A subungual hematoma may superficially resemble *Pseudomonas* nail infection.

COURSE AND PROGNOSIS Patients with minor *Pseudomonas* infections (e.g., onychia and paronychia, toe web inflammation, whirlpool-associated skin rash, and external otitis) usually improve rapidly with topical therapy and drying of the affected area. Malignant external otitis requires the systemic use of antibiotics directed against *Pseudomonas,* utilizing a fluoroquinolone (ciprofloxacin or ofloxacin) with or without imipenem or ceftazidime. High doses and prolonged therapy are combined with local surgical debridement to limit spread to bone, nervous system structures, and the meninges. [37], [46]

Septicemia and Cutaneous Involvement

CLINICAL MANIFESTATIONS

History In individuals ill with *Psedomonas* septicemia, the history is most frequently centered around the underlying problem and antecedent therapy. A premature infant may have required resuscitation and treatment of a nonspecific pneumonitis prior to developing high fever, obtundation, and macular or hemorrhagic vesicular skin lesions. Infants may present initially with omphalitis or severe diarrhea, followed by septicemia and skin lesions. Urinary tract infections complicating congenital lesions such as exstrophy of the bladder may predispose the infant to bacteremia. In adults, there is usually a history of antibiotic therapy, treatment with glucocorticoid hormones or antitumor agents, or the use of percutaneous catheters. Frequently, the patient is granulopenic, has already had a significant febrile illness, and may still be receiving antibiotics when one of the characteristic cutaneous manifestations develops. The local lesions are rarely painful, but the patient is usually too sick to focus on the local problem. Occasionally, hemorrhagic manifestations may develop secondary to the involvement of small vessels supplying the skin, to platelet reduction, or to DIC. *Pseudomonas* involvement of the gastrointestinal tract, particularly in the tropics, may produce the picture of an acute enteric infection, with headache, high fever, diarrhea, and cutaneous manifestations. If, rose spots are present, the syndrome is described as Shanghai fever and resembles typhoid fever. The same enteric syndrome with ecthyma gangrenosum has recently been observed in previously healthy infants. [47]

Cutaneous lesions The skin lesions, the most characteristic part of the physical findings in *Pseudomonas* septicemia, consist of four types [48]:

1. Vesicles and bullae. Singly or in clusters, these lesions spread in random fashion over the skin. They frequently become hemorrhagic as they evolve. Occasionally, in infants, they may be surrounded by large erythematous halos and may be mistaken for erythema multiforme.
2. Ecthyma gangrenosum. The lesion in this disorder starts with a gunmetal gray, infarcted lesion with surrounding erythema (Fig. 197-4) and evolves into a necrotic black or gray-black eschar and surrounding erythema (Fig. 197-4 and Fig. 197-5). This lesion often evolves from a necrotic vesicle. Frequently, but not exclusively, the lesion is in the anogenital or axillary region.

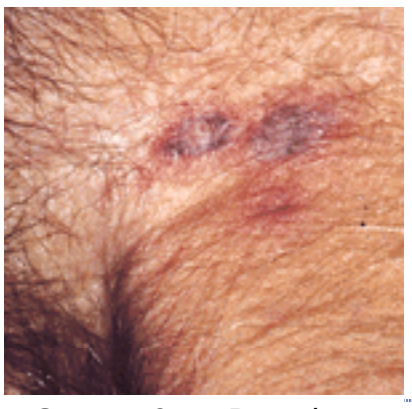

FIGURE 197-4 *Pseudomonas aeruginosa:* Ecthyma gangrenosum. Gunmetal gray, painless, infarcted lesions with surrounding erythema.

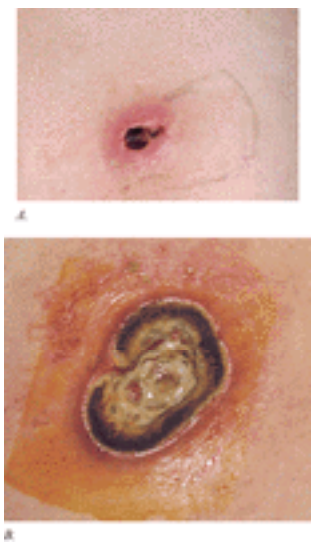

FIGURE 197-5 *Pseudomonas aeruginosa:* Ecthyma gangrenosum. This 32-year-old male with HIV disease noted the onset of a very tender plaque on the right buttock associated with fever and malaise. *A.* Five-day-old lesions with a central infarcted, necrotic area surrounded by erythema. *B.* At 5 weeks, the lesions had improved following ciprofloxacin treatment, which was discontinued owing to an adverse drug reaction. Without antibiotic treatment, the necrotic area enlarged and was associated with bacteremia. Eventually, the lesion reepithelialized, but the patient died of pseudomonal pneumonia.

3. Gangrenous cellulitis. Sometimes presenting as a sharply demarcated, superficial, painless, necrotic lesion, gangrenous cellulitis may resemble a decubitus ulcer. However, it is located in a nonpressure area and may complicate a prior area of injury, such as a thermal burn. Also, it may begin abruptly as an acute infection (with much clinical toxicity), producing local pain, swelling, and erythema, and involving deep subcutaneous tissue and fascia. Either local injury or bacteremia may introduce the infection.
4. Macular or papular nodular lesions. These are small, oval, and painless, located predominantly over the trunk. They resemble rose spots of typhoid fever.

Another cutaneous manifestation of *Pseudomonas* septicemia, usually occurring after days or weeks, is nodular cellulitis. The lesions are red, warm, sometimes fluctuant, but often situated deeply enough to feel solid. Surgical incision reveals suppuration, and *P. aeruginosa* can be cultured from the lesions. [48], [49] A variation of this process consists of numerous red, nonfluctuant, hot, nontender, subcutaneous nodules on the trunk and extremities that may be accompanied by other characteristic lesions, such as hemorrhagic bullae and ecthyma gangrenosum. Such lesions may be successfully treated by combination antipseudomonal antibiotic therapy. Other lesions that may appear in association with *Pseudomonas* infection include petechiae, ecchymoses, dermal Shwartzman-like reactions, and purpura fulminans. Occasionally, the cutaneous expression of *Pseudomonas* infection may take the form of a typical erythema multiforme reaction. Patients with extensive burns may develop lesions of the described types on areas of normal skin, as well as more florid diffuse growth secondarily infecting the burn surface with resultant necrosis.

Other physical findings Patients with *Pseudomonas* septicemia frequently exhibit physical findings associated with their underlying diseases: malnutrition, mucous membrane ulcerations, glossitis and stomatitis secondary to antibiotics and granulocytopenia, urinary tract infections, proctitis, adenopathy, hepatosplenomegaly, and hemorrhagic bronchopneumonia.

Laboratory findings Routine hematologic examination may reveal leukocytosis or leukopenia, with modifications based on underlying illnesses (e.g., aleukemic leukemia, leukemia). Platelets may be diminished, and fibrinogen and other clotting factors may be reduced in association with consumption coagulopathy, liver disease, or profound malnutrition. Characteristically, in *Pseudomonas* septicemia aspirated material from bullae, areas of cellulitis, and papular or nodular lesions reveals numerous organisms, but few leukocytes, even in patients with leukocytosis. Cultures of these lesions and of blood almost always show *Pseudomonas.*

PATHOLOGY The distinctive finding in *Pseudomonas* lesions is a necrotizing vasculitis in which a myriad of bacteria invade the walls of small arteries and veins. [50] The internal elastic lamellae may be destroyed by microbial elastase, but

the endothelial surface is rarely damaged and thrombosis is unusual. [47] Extravasation occurs around the vessels, edema and bland necrosis in the perivascular and adventitial regions are extensive, and blood flow to the region supplied by the affected vessel is decreased. This, in turn, leads to the formation of cutaneous lesions (bullae, hemorrhagic cellulitis, and gangrenous changes). Organisms tend to spread along the exterior surfaces of vessels and invade the skin. Similarly, bacteria may invade the blood vessel walls of the lungs, liver, kidneys, and brain, with the production of characteristic discrete nodular necrotic lesions.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS The characteristic ecthyma gangrenosum skin lesions in an acutely ill patient suggest the diagnosis of *Pseudomonas* septicemia. The finding of abundant, thin, gram-negative rods with rare granulocytes in vesicle fluid or in association with gangrenous or hemorrhagic cellulitis constitutes further presumptive evidence. The differential diagnosis of *Pseudomonas* septicemia includes other infections that can produce ecthyma gangrenosum and other skin lesions through direct involvement of blood vessels (e.g., those caused by *N. meningitidis, Aeromonas hydrophila, E. coli, Klebsiella pneumoniae, Morganella,* spp. and fungi of the *Aspergillus* and *Rhyzopus* groups). In addition, other gram-negative bacteria and *Rickettsia* may produce petechial, ecchymotic, or gangrenous skin lesions suggestive of the dermal Shwartzman reaction.

COURSE AND PROGNOSIS *Pseudomonas* septicemia is frequently the terminal event in a complex illness involving a patient with malignant disease or altered cellular and humoral defense mechanisms. Therapy may be effective and recovery complete in some instances, especially when the septicemia occurs in patients with more favorable underlying problems such as thermal burns, in individuals with urinary tract foci of infection, or in association with the use of percutaneous venous catheters.

TREATMENT AND PROPHYLAXIS

Local infections Superficial skin and toe web infections and onychia usually respond to acetic acid, silver nitrate, or gentian violet compresses applied two to three times daily between long periods of absolute drying. Paronychia is best treated by surgical drainage, nail trimming, and 4 percent thymol in chloroform. Acetic acid, polymyxin (0.1 percent) in acetic acid, or glucocorticoids with neomycin are effective for otitis externa. When acetic acid is used topically on chronic ulcers or burns, a 2 to 5 percent solution is often effective. [51] In addition, topical silver nitrate (0.5 percent;) or silver sulfadiazine may eradicate these organisms in burn patients (see Chap. 127).

Systemic infections *Pseudomonas* septicemia requires early and vigorous systemic bactericidal antibiotic therapy. Effective therapeutic agents include the aminoglycosides gentamicin, tobramycin, and amikacin. One of these drugs is combined with an antipseudomonas penicillin or ceftazidime and given IV for patients who are acutely ill. In the presence of hypotension or of any renal impairment, the dosage of aminoglycoside antibiotics must be drastically reduced; in such circumstances, determinations of “peak” and “trough” serum levels of the aminoglycoside drug employed should guide therapy. In addition to the parenteral administration of antibiotics, surgical drainage is appropriate for nodular and fluctuant lesions. Acute *P. aeruginosa* gangrenous cellulitis/fasciitis requires debridement (often extensive), sometimes with a surgical “second look” 1 or 2 days later. Leukocyte transfusions have been effective in granulopenic infants, and investigations are ongoing into the experimental use of human immune globulins with activity against *P. aeruginosa* or specific *Pseudomonas* exotoxin A antibody preparations. [38] The markedly granulocytopenic patient with gangrenous cellulitis due to *P. aeruginosa* alone or in polymicrobial combination presents a particularly difficult problem. Because the progression of the process can be extremely rapid, such a patient needs very prompt surgical debridement in addition to therapy with antimicrobials and granulocyte colony–stimulating factor. Complicating thrombocytopenia and DIC may supervene and add to the urgency.

Prophylaxis Infections caused by *P. aeruginosa* are difficult to treat not only because they often occur in compromised hosts, but also because the organisms are highly resistant to many antibiotics. There is no place for prophylactic antibiotics against *P. aeruginosa* because of drug toxicity and emergence of resistant strains. This reality has led to attempts to develop protective vaccines against the limited number of serotypes of *P. aeruginosa* or immuno theraputic agents. [38]

Skin Infections Due to Other *Pseudomonas* Species

Pseudomonas putrefaciens, a psychrophilic bacterium, is a rare cause of cellulitis, particularly in the setting of chronic lower extremity infection in ulcers secondary to venous stasis. [52]

SKIN INFECTIONS DUE TO *HAEMOPHILUS INFLUENZAE*

The characteristic feature of the rare infection of the skin with *H. influenzae* is a cellulitis that usually involves the face, neck, or upper extremities. Most cases occur in young children (6 to 24 months old), but the infection can occur in adults. With the early administration of protective Hib conjugate vaccines, invasive manifestations of *H. influenzae* disease have nearly disappeared in the developed world, but they persist as major disease problems in developing countries.

Bacteriology and Pathogenesis

Haemophilus influenzae is a small coccobacillary, pleomorphic gram-negative organism. It is nonmotile and has fastidious growth requirements, including heme (X factor) and nicotinamide nucleoside (V factor). There are rough and encapsulated forms, the latter divided into six serologic types (a through f) based on capsular polysaccharide antigens.

Most infections with *H. influenzae,* including meningitis, epiglottitis, and cellulitis, are caused by encapsulated type b strains (Hib). The ribosyl-ribitol phosphate capsule inhibits phagocytosis in nonimmune individuals and allows a period of unchecked bacterial growth and invasiveness to occur. Rough, unencapsulated, nontypable, noninvasive species are not involved in cellulitis.

In the majority of Hib infections, there is an antecedent upper respiratory infection or acute otitis media. The characteristic localization of the cellulitis to the upper part of the body argues for the sequence of upper respiratory infection, fallout onto or invasion of the skin locally, and then bacteremia. This sequence is evident in adult, as well as in pediatric, cases. The association of otitis media with cellulitis has led to the hypothesis that the ear may serve as the primary focus of infection in cases involving the face. A primary bacteremic mechanism with secondary localization in the skin would be favored by a more random and widespread distribution of lesions than is seen. Localization of a subclinical

bacteremia could follow trauma and has been suggested as a possible antecedent predisposing event.

Epidemiology

Humans are the only known natural host for *H. influenzae.* These potentially pathogenic bacteria are carried in the oropharynx and nasopharynx, especially in children up to age 5 years, as part of the normal indigenous flora. However, early immunization using conjugate Hib vaccines has markedly decreased nasopharyngeal carrier rates and increased herd immunity, which has certainly contributed to the overall dramatic decline of invasive clinical disease. [53] Cellulitis as well as other forms of invasive disease, including meningitis, pneumonia, and epiglottitis, have all but disappeared in populations protected by Hib conjugate vaccine.

Susceptibility to Hib disease appears to be greatest among certain ethnic groups and in socioeconomically disadvantaged populations, a relatively small issue in the Western world, but a major continuing problem worldwide. [53], [54] Genetic factors, prompt antibiotic treatment of Hib disease (aborting an antibody response) congenital and acquired complement and antibody deficiency, and asplenia may also be responsible for increased susceptibility to disease and to recurrent episodes in nonimmunized traditional age groups, as well as in adults. Spread is via droplet aerosol or close contact, and susceptibility to *H. influenzae* infection appears to be greatest between the ages of 3 months and 3 years.

Although the mechanism of protection in the newborn period remains uncertain, it probably involves transplacental IgG transfer. There is general agreement that complement-dependent anticapsular and bactericidal antibodies increase with age and are protective. Paradoxically, Hib disease may occur in individuals endowed with adequate levels of bactericidal antibody.

Clinical Manifestations

HISTORY Typically, a nonimmunized young infant or child (under age 3) develops an area of swelling and discoloration on the face or arm following several days of coryza and abruptly rising temperature. Rarely, a similar process occurs in adults as a complication of respiratory tract infection involving the upper airway. [55]
CUTANEOUS LESIONS The typical lesion is a single, circumscribed, indurated area usually located on the face, neck, upper chest, or upper extremity. Although described in infants as characteristically blue-red to purple-red in color and surrounded by a zone of edema, the early lesion may be an area of pale edema or erythema (see Fig. 197-6). The margins are indistinct, in contrast to the sharply defined borders of erysipelas. Regional adenopathy is rarely present. Occasionally, in children with Hib buccal cellulitis, erythematous buccal mucosal lesions appear on the side of the affected cheek, suggesting direct bacterial spread from the oropharynx into buccal soft tissues. [56]

FIGURE 197-6 Cellulitis: Haemophilus influenzae. Erythema and edema of the face in a child. (*Courtesy of Sandy Urioste, MD.*)

When *H. influenzae* cellulitis occurs in adults, the infection follows a striking sequence: marked pharyngitis at first; high fever; then rapidly progressive anterior neck swelling, tenderness, erythema, and dysphagia. [55]
OTHER PHYSICAL FINDINGS Associated infections of the upper respiratory tract, including otitis media, sinusitis, or epiglottitis, and pneumonia occur. The patient may appear lethargic; occasionally, metastatic infections such as septic arthritis or meningitis may occur.

Laboratory Findings

The white blood cell count is invariably elevated, usually in the 20,000/mm ^{3} range. Results of blood cultures are positive in approximately 50 percent of cases. Aspiration and culture of the margin of the cellulitis has been positive in about half the patients encountered, and Gram-stained smears should be studied.

Pathology

No information is available about the histologic changes associated with this rare lesion, but the inflammatory response is doubtless an acute pyogenic reaction.

Diagnosis and Differential Diagnosis

Haemophilus influenzae cellulitis should be suspected when a child aged 3 to 24 months develops an acute facial (buccal) cellulitis with high fever. There may be concomitant upper airway inflammation. Immediate confirmation of the diagnosis may be possible from inspection of Gram-stained smears of an aspirate of the lesion. Although cellulitis caused by other microorganisms is more common in adults, Hib disease should be considered in patients with respiratory infections and upper body cellulitis, especially in adults or in young children not fully immunized. [54]

Streptococcal (group A, C, or G) or pneumococcal cellulitis may produce discoloration of the skin similar to Hib infection. Erysipelas, which rarely occurs in infants, is usually homogeneously erythematous, and the margins of the plaquelike swelling are distinct compared with the indefinite borders of *H. influenzae* cellulitis. The presence of pustules or boils is

helpful in identifying *S. aureus* as the etiologic agent.

Course and Prognosis

Most patients do well with antibiotic therapy, even though the disease is often associated with bacteremia. The abrupt onset of high fever and easily observed cellulitis indicates the urgency of the situation and mandates an early visit to a physician. Constant vigil must be maintained for suppurative complications in the upper airways, meninges, lungs, bones, joints, or other organs. Cellulitis is a rare complication of Hib disease.

Treatment and Prophylaxis

Third-generation cephalosporins (ceftriaxone or cefotaxime) are currently the drugs of choice in the treatment of Hib disease because of their activity against both ampicillin-susceptible and ß-lactamase–producing strains of *H. influenzae* and because of their efficacy in treating any complicating meningeal spread of infection. Infections caused by ß-lactamase–negative isolates can be treated with ampicillin given IV in four to six divided doses daily. However, with plasmid-mediated ampicillin resistance at levels of 30 to 45 percent among strains of Hib, therapy should begin with a third-generation cephalosporin. Chloramphenicol is not recommended, owing to its hematologic toxicity, especially in very young children.

As noted earlier, the introduction of Hib conjugate vaccine (capsular polysaccharide covalently linked to a protein moiety) in the past decade, has dramatically decreased the incidence of invasive Hib disease in the developed world. [53] These vaccines stimulate protective antibody when given to infants prior to 6 months of age, a period of great susceptibility to Hib invasive disease. As Hib immunization becomes a global reality it is fair to assume that cellulitis, meningitis, and other invasive manifestations of Hib disease will become infections of historical interest only.

CUTANEOUS MANIFESTATIONS OF *SALMONELLA* INFECTION (ENTERIC FEVER)

Salmonella organisms are widespread in nature. Carried by cold- and warm-blooded animals, they contaminate many foods derived from animals, are global in distribution, and therefore have an impact on human health as well as economic stability. *Salmonella* infections usually manifest as gastroenteritis, enteric fever (typhoid-like illness), or septicemia. Rose spots, the classic skin lesions of systemic *Salmonella* infection, have been variably reported (10 to 60 percent) during the natural (untreated) evolution of typhoid fever, but less frequently in enteric fevers caused by other *Salmonella* species.

Bacteriology and Pathogenesis

Salmonellae are not fastidious organisms, but their isolation from stool is made difficult by the fact that, when present, they represent only a small part of the abundant fecal flora. Extragastrointestinal isolates (i.e., from abscesses, blood, skin lesions) are easier to identify, as they are usually pure cultures of a given *Salmonella* species. The use of selective inhibiting media (e.g., MacConkey, SS agar) that inhibit the growth of gram-positive organisms, as well as many gram-negative species, facilitate the isolation of the organisms from stool specimens. Salmonellae are motile, gram-negative bacilli that do not ferment lactose. From a practical viewpoint, in stool bacteriology, initial selection of non–lactose-fermenting colonies is followed by biochemical and serologic (agglutination) procedures for identification and serotyping of the organism. There are approximately 2300 serovars determined by surface and flagellar antigens. Modern molecular biology has established a revised nomenclature, with *Salmonella choleraesuis* the single species, and all serovars serotypes of this single species. Because habits are difficult to change, organisms are usually still referred to as familiar species (e.g., *Salmonella typhi, Salmonella paratyphi, Salmonella enteritidis*) rather than serotypes of *S. choleraesuis.*

There is a latent period from 3 to as long as 50 days (usually 7 to 14) between the ingestion of bacteria and the dramatic onset of the clinical symptoms of enteric fever. Shorter latent periods often follow the ingestion of larger numbers of organisms. When resulting from the ingestion of salmonellae other than *S. typhi,* symptoms tend to begin earlier and are milder. During the latent period, organisms multiply in the distal small bowel and invade and multiply in lymphoid tissues in the area of Peyer's patches in the terminal ileum. A major factor facilitating dissemination may be the ability of these organisms to resist killing by macrophages, while simultaneously they are protected from circulating antibodies and antibiotics by their intracellular residence. [57] Invasion of the bloodstream from this focus heralds the onset of the clinical illness, with chills and fever and other constitutional effects of circulating endotoxin. Manifestations of infection occur in many organs, frequently in a predictable sequence: respiratory and central nervous system symptoms during the first week; skin manifestations during the second week; diarrhea, often following a period of constipation, during the second and third weeks. Bacterial invasion of the skin, liver, gallbladder, bones, and joints, as well as manifestations of endotoxemia, usually occur during the bacteremic phase of the illness (first 10 days). The reticuloendothelial system clears the organisms, leading to hyperplasia of these elements in the liver, spleen, and lymph nodes. Persistence of organisms in the gallbladder, biliary ducts, bone marrow, or the reticuloendothelial system may lead to a chronic asymptomatic carrier state.

Epidemiology

People acquire *Salmonella typhi* and other *Salmonella* species causing enteric fever by the ingestion of contaminated water or food. Travel in developing countries and other areas of marginal sanitation places people in the proximity of enteric pathogens. Rapid transportation can bring them home healthy during an incubation period that can be 5 to 6 weeks long. A history of recent travel and unusual or suspicious food or water encounters should be sought in a patient with appropriate clinical manifestations.

Humans are the only hosts for *S. typhi* and *S. paratyphi.* The chronic carrier state that may follow clinical typhoid fever is almost always asymptomatic, except for manifestations of gallbladder disease if cholelithiasis and active cholecystitis are

present. Other serotypes of *Salmonella* can produce an enteric fever syndrome similar to, but usually milder than, typhoid fever. Unlike *S. typhi,* these other *Salmonella* serotypes are ubiquitous in nature (occurring in animals, birds, reptiles, poultry products) and are difficult to control as sources of human infection.

A number of factors, exclusive of inoculum size, determine whether disease will occur after ingestion of *Salmonella.* Achlorhydria and previous gastric surgery allow organisms to escape destruction by the acid barrier of the stomach. Rapid transit of a smaller inoculum in a liquid vehicle may allow adequate numbers of viable bacteria to reach the distal small bowel. Suppression of competing bowel flora by antimicrobials and gastric acid reduction or neutralization by the variety of pharmacologic agents available are unproven, but likely, contributing factors to the emergence of disease. Underlying illnesses such as Hodgkin's disease, which alters cellular immunity, can interfere with the host defense mechanisms that normally eradicate these pathogens; hemoglobinopathies such as sickle cell disease appear to predispose to systemic *Salmonella* infections and osteomyelitis by saturating the protective reticuloendothelial system with red cell fragments and occluding small blood vessels, leading to local chronic foci; finally, tumor immunosuppression therapy may predispose patients to salmonellosis. Infants and young children, as well as the very elderly, appear to be especially susceptible to gastroenteritis and serious disease.

Clinical Manifestations

HISTORY Symptoms begin several days to several weeks after the ingestion of contaminated water or food. Headache, fever, generalized aching, abdominal discomfort, cough, and constipation are common. Delirium or mental torpor are not unusual, especially when there is a high fever. The pulse rate may be slower than expected for the magnitude of the fever. Symptoms increase in intensity, and the fever often reaches 39.5°C to 40.5°C (103.1°F to 104.9°F) by the end of the first week. During the second week, rose spots may appear on the trunk, and diffuse abdominal cramping becomes prominent, sometimes accompanied by diarrhea. In area endemic for typhoid fever, abdominal symptoms may be present from the onset, and diarrhea can also be an early manifestation.
CUTANEOUS LESIONS After approximately 7 to 10 days of high fever, the rose spots characteristic of *S. typhi* infection may appear. These lesions are 2- to 3-mm, slightly raised, pink papules that blanch on pressure and are usually nontender. Appearing in crops of approximately 10 to 20 lesions, they are often located between the nipple area and the umbilicus on the anterior trunk, rarely on the back or extremities. Without therapy, the crops of spots usually become brownish as they fade and disappear in 3 to 4 days. New lesions emerge over the ensuing 2 to 3 weeks in untreated patients. Their presence in 63 percent of a group of 62 patients should encourage careful observation for this subtle rash. [58] Antibiotic therapy instituted early in the course of the illness may be responsible for the decreasing incidence of rose spots. The rash is less frequently reported in people of color, but this may be because of difficulty in detecting the small, scarce lesions on dark skin. Rose spots occur infrequently in enteric fevers caused by other *Salmonella* species, but when they do appear, they may be present in greater numbers and in a more widespread distribution. A variety of other skin changes have appeared in enteric fever during the acute phase of illness. Erythema typhosum, an erythematous rash that is confluent and widely scattered, may occur during the first week of the disease. Erythema nodosum and urticarial lesions have been noted and ascribed to hypersensitivity phenomena. In several recent reports from the Indian subcontinent, subcutaneous and cutaneous abscesses and skin ulcers have been described. [59], [60] Transient loss of hair, changes in nails, and posttyphoid anhidrosis reflect the acute catabolic stress. It is distinctly uncommon to observe herpes labialis in enteric fever.
OTHER PHYSICAL FINDINGS During the acute phase of the disease, at the time the cutaneous lesions are appearing, the patient may be disoriented and have signs of pneumonia. The abdomen is often distended, tympanitic, and diffusely tender, with some localization to the right lower quadrant. The spleen is often enlarged, but may be difficult to palpate because of abdominal distension and guarding.

Laboratory Findings

Leukopenia or low normal leukocyte counts are often present, but values range from 3000 to 20,000/mm ^{3}. The percentage of mononuclear cells may be increased, and atypical lymphocytes can appear in small numbers, suggesting a viral illness. Thrombocytopenia and, rarely, hemolysis may occur. During the initial week of illness, blood cultures are usually positive for *Salmonella.* During the second week, or when diarrhea begins, stool cultures become positive for *Salmonella,* and the white blood cell count may increase.

In addition to blood and stool, the typical rose spots should be cultured, preferably using the technique of skin snips. [58] Bone marrow and skin lesion material may show *Salmonella* in approximately 65 to 95 percent of cases, even when routine blood cultures done simultaneously are negative for *Salmonella* or when the patient is receiving antibiotics. Standard serologic tests like the Widal agglutination procedure become positive only after several weeks to a month of illness. The accuracy of these tests is low, with many nonspecific elevations in a variety of other infectious diseases. A specific polymerase chain reaction assay is in development for identifying a number of pathogens and will add specificity and sensitivity to laboratory testing. [62]

Pathology

The rose spot associated with *Salmonella* infection characteristically blanches on pressure, and examination of the lesion histologically reveals gross dilatation of capillaries, described by some pathologists as “capillary atony.” Extravasation of blood is not observed, but there is considerable edema and an abundant pericapillary infiltration with macrophages; organisms may be present within these cells. [63] A cutaneous leukocytoclastic vasculitis has been described in a rose spot biopsy from a patient with *S. paratyphi* enteric fever.

Diagnosis and Differential Diagnosis

The diagnosis of *Salmonella* enteric fever may be difficult in a sporadic case, especially if the characteristic rash and gastrointestinal symptoms have not yet appeared and there is no history of travel in an endemic area. Headache, cough,

and high fever are not very specific findings. However, when these symptoms are associated with delirium, relative bradycardia, and leukopenia with increased numbers of circulating mononuclear cells, the diagnosis of enteric fever should be considered. The diagnosis is usually made by obtaining blood cultures, which are positive for *Salmonella* in approximately 80 percent of untreated cases during the first week to 10 days. The results of serologic tests (e.g., Widal) are usually negative during the early phase of the illness and may not be diagnostic later. Likewise, enteric fever due to other *Salmonella* species can usually be diagnosed through blood cultures. Other cultured material (e.g., bone marrow, rose spots) may be important, especially in patients who have had prior antibiotic therapy.

The differential diagnosis includes a wide range of diseases. Prominent cough and severe headache in the early phases may suggest a viral or atypical pneumonia (disease caused by *Legionella pneumophila, Chlamydia pneumoniae,* or *Mycoplasma pneumoniae;* psittacosis; or Q fever). Typhus and Rocky Mountain spotted fever can usually be excluded by geographic and epidemiologic considerations, serologic studies, the characteristic petechial component to the rash, and, in the case of Rocky Mountain spotted fever, the distribution of the rash on the distal parts of the extremities. Miliary tuberculosis may begin as an acute febrile illness with similar symptoms, leukopenia, and splenomegaly. The diagnosis may be delayed until a secondary complication such as meningitis occurs or until biopsy material (liver, lymph node) reveals granulomas, sometimes containing acid-fast rganisms. Among the viral diseases, the diagnosis of infectious mononucleosis is suggested by headache, cough, high fever, lymphadenopathy, splenomegaly, and a blood picture with leukopenia and some atypical mononuclear cells.

Malaria and toxoplasmosis are two parasitic illnesses that deserve consideration. Epidemiologic information plus intermittency of symptoms usually suggest the diagnosis of malaria. In generalized toxoplasmosis, the symptoms may be very similar to those of early enteric fever: prominent cough, high fever, a rash that is located on the trunk, and a mononucleosis-like blood picture. The rash tends to be more florid than the crops of 10 to 20 lesions seen in enteric fever, however, and is macular with a petechial component rather than papular. Diagnosis usually requires identification of *Toxoplasma gondii* in biopsy material or a rising antibody titer (19S fluorescent antibody or hemagglutination inhibition).

COURSE AND PROGNOSIS The response of patients with enteric fever to antibiotic therapy is usually gradual, with 3 to 6 days needed for the temperature to return to normal. With prolonged treatment, the incidence of relapse has declined, but the likelihood of relapse varies with the age, nutritional condition, and general health of the patient. The major complications in the preantibiotic days were bowel perforation and hemorrhage. Although rare, these complications still occur—even with prompt, effective antimicrobial therapy—and they are responsible for approximately 75 percent of the mortality in enteric fever. Deaths have been reduced from approximately 10 percent to 1 to 2 percent with antibiotic therapy, although the mortality rate is higher in immunocompromised patients. Following typhoid fever, approximately 1 to 2 percent of patients continue to harbor organisms in the gallbladder and excrete them in the stools for an indefinite period, becoming a major potential source for infecting other individuals.
TREATMENT OF PROPHYLAXIS The emergence of multidrug-resistant *Salmonella,* including endemic and imported *S. typhi,* in many areas of the world has essentially obviated the use of chloramphenicol, ampicillin, and trimethoprim-sulfamethoxazole as first-line antimicrobials to treat typhoid fever and other enteric fevers. [64] The fluoroquinolones (ciprofloxacin, ofloxacin) are active against drug-susceptible and multidrug-resistant *S. typhi* or other salmonellae causing enteric fever. Results of many clinical trials indicate that blood cultures become sterile promptly on treatment with ciprofloxacin and that this drug appears to be a safe and effective substitute for chloramphenicol; thus, ciprofloxacin has become the treatment of choice for typhoid fever. Ciprofloxacin is administered in 500- to 750-mg doses given orally every 12 h (or 400 mg given IV every 12 h) in adults for 14 to 21 days. Third-generation cephalosporins, especially ceftriaxone or cefotaxime, are acceptable alternatives for the treatment of typhoid fever if the previously noted antimicrobials cannot be used because of resistance of the infecting strain or because of drug hypersensitivity. Glucocorticoid therapy for a period of several days has been advocated in addition to antimicrobial treatment for severely ill and febrile patients, but its efficacy is unproved and prolonged use may increase the relapse rate. A report from Jakarta in 1984 found that high doses of dexamethasone reduced mortality significantly, and a subsequent review supported the use of glucocorticoids in severe typhoid fever. [65] Among the major complications, hemorrhage usually responds to conservative management, but perforation, often in the ileocecal region, requires immediate surgery. Identification and eradication of the biliary carrier *S. typhi* is an important preventive measure for controlling enteric fever. In the presence of stones, antibiotic therapy should be combined with cholecystectomy. In the absence of stones, a prolonged course of treatment with ampicillin or ciprofloxacin may eradicate the carrier site. Individuals traveling to areas of the world endemic for *S. typhi* or *S. paratyphi*. A should receive instruction in common-sense methods of eating and drinking to avoid potentially contaminated foods. Immunization with a live attenuated oral vaccine is available for *S. typhi* and is probably effective for all but massive exposure. A virulence (vi) capsular polysaccharide vaccine requiring a single dose is also available. Careful personal hygiene and avoidance of suspicious water or foods (e.g., leafy greens) will eliminate most encounters with *S. typhi* and other salmonellae capable of causing enteric fever and remains the cornerstone of prevention for all diseases transmitted fecally or orally.

CUTANEOUS MANIFESTATIONS OF INFECTION WITH OTHER GRAM-NEGATIVE BACILLI

An acute cellulitis, with or without production of gas, may be caused by *E. coli, Proteus* spp., *Klebsiella* spp., *Enterobacter* spp., *Serratia marcescens,* a variety of other facultative and nonfermenting bacilli, and members of the obligate anaerobic group of Bacteroides. These infections have occurred often, but not exclusively, in the very elderly; in patients with diabetes following trauma, surgery, bowel or perineal inflammation; and in immunocompromised individuals. The infectious process can be limited to the superficial soft tissues or found primarily in the deep fascia, but the extent of the cellulitis is often difficult to establish. Interference with vascular integrity can influence the findings. Location can be a factor in early diagnosis, as can the extent of spread along fascial planes (e.g., Fournier's necrotizing perineal fasciitis) and treatment decisions (antibiotics and surgery). (See Chap. 196.)

Drug addicts may develop mixed infections with these organisms when “skin popping” results in lesions such as necrotizing fasciitis. [66] Prior exposure to broad-spectrum antibiotics and altered host defenses can predispose an individual to this type of infection, which is often nosocomial in origin. The finding of gas in the tissues frequently leads to

an erroneous provisional diagnosis of clostridial cellulitis or gas gangrene.

Bacteriology and Pathogenesis

The family Enterobacteriaceae is composed of a number of bacilli that grow readily on blood agar and selective media. By means of a number of biochemical reactions and growth characteristics, seven tribes of Enterobacteriaceae have been recognized. *Escherichia coli* is closely related to *Shigella; Salmonella* spp., to *Citrobacter. Klebsiella-Enterobacter-Serratia* make up a third tribe, and *Proteus-Morganella-Providencia* comprise a fourth main division. There are a variety of facultative gram-negative bacilli that do not belong to this family, metabolize sugars variably, and are identifiable by means of other specialized biochemical tests. In addition, the obligate anaerobic *Bacteroides* spp. reside in the oral cavity, colon, and female vaginal region and are speciated by their anaerobic growth requirements and by a variety of metabolites that can be identified by gas-liquid chromatography and other methods.

Infection can result from endogenous (host flora) or exogenous (e.g., fresh- or saltwater) contamination of skin or subcutaneous tissues in an area of injury, surgery, or ischemia. Bacteria can also invade the subcutaneous tissues via the circulation from a distant source or by direct spread from contiguous structures such as the colon. By dissection along fascial planes, cellulitis can erupt in areas removed from the initial focus. The process is often necrotizing, containing a mixture of facultative and anaerobic bacteria and, especially in diabetic individuals, can be associated with gas formation (mainly hydrogen). Edema, bleb formation, ischemia, and gangrene result from thrombosis of nutrient blood vessels. [67] The underlying muscle is almost always spared. Polymorphonuclear leukocytes are abundant, compared to the relative scarcity of acute inflammatory cells in clostridial infections.

Epidemiology

Cellulitis usually follows contamination of adjacent tissues by bowel contents or a breakdown of skin. The conditions predisposing patients to this type of infection include (1) bowel perforation (e.g., appendicitis, neoplasm, diverticulitis, rectal mucosal tear), (2) colon surgery, (3) chronic edema, (4) vascular insufficiency, (5) injection of addictive drugs, (6) decubitus ulcers, (7) percutaneous lines, and (8) superficial perineal dermatitis, including diaper rash. Poorly controlled diabetes, alterations in host defense mechanisms (e.g., granulocytopenia), poor nutrition, or cirrhosis often further impair the health of these patients. Crepitant (gas-containing) cellulitis results from infection with gas-forming strains of bacteria (*E. coli, Klebsiella, Aeromonas hydrophila*), especially in patients who have poorly controlled diabetes or in the presence of *Bacteroides* spp. or anaerobic streptococci. [68], [69]

Water-related lacerations may cause soft tissue infection with a variety of nonenteric bacteria. Similarly, cellulitis, subcutaneous abscess, or myonecrosis due to *A. hydrophila* may follow penetrating trauma in either a fresh- or brackish-water environment, or it may be associated with fish or other aquatic animals. Halophilic vibrios, including *Vibrio vulnificus,* are responsible for acute infections of traumatized skin or septicemic spread to skin and soft tissues from seawater exposure or ingestion of raw shellfish. (See Chap. 199 for discussion of water-borne cellulitis.) Injuries on farms, particularly from corn-harvesting machinery, have been associated with gram-negative bacilli (*Enterobacter* spp. and *Stenotrophomonas* [formerly *Xanthomonas*] *maltophilia*). [70]

Gram-negative bacillary cellulitis (due to *E. coli, Proteus* spp., or *C. freundii*) may occur in immunocompromised patients, including individuals with AIDS or with the nephrotic syndrome. Grossly, the appearance of the lesions resembles those due to the more common gram-positive pathogens.

Clinical Manifestations

HISTORY Diabetes mellitus, malnutrition, chronic conditions (e.g., paraplegia with decubitus ulcers), or other conditions described under Epidemiology are usually present at the time of infection. The onset may be insidious, over 4 to 5 days, or abrupt. Pain, often severe, frequently precedes local skin changes, especially if the infection is at the level of the deep fascia. High fever, shaking chills, increasing pain, and falling blood pressure may follow. Symptoms of gastrointestinal inflammation, such as appendicitis or diverticulitis, may precede the soft tissue illness. Rectal or perineal pain can indicate a local process that may be especially devastating in a patient deficient in granulocytes.

CUTANEOUS LESIONS The areas of infection evolve to demonstrate the typical findings of cellulitis, with warmth and brawny edema. In the early stages, the skin is rarely discolored beyond a pink hue, and vesicles and blebs or bullae are almost never present. At this juncture, unless pain is present, the process may easily be overlooked, especially if the infection lies in a less obvious area or if the patient is obtunded. As the cellulitis progresses, edema and redness increase, and areas of gangrene may appear. Palpable tenderness and crepitus, if present, can help define the anatomic extent of the process. The cellulitis may remain localized to the superficial subcutaneous tissues and skin, but progression to the deep fascia with contiguous extension, necrosis of fat, and increasing pain and toxicity suggest a diagnosis of necrotizing fasciitis. [71] (See Chap. 196.)

SUPERFICIAL NASAL LESIONS Several subspecies of *K. pneumoniae* that infect the upper respiratory tract can produce unique superficial and invasive nasal lesions. Ozena is a chronic productive rhinitis caused by infection with *K. pneumoniae,* ssp. ozaenae. The process remains internal without any cutaneous manifestations except a profuse mucopurulent, foul-smelling discharge. [72] *Klebsiella pneumoniae,* ssp. rhinoscleromatis is the etiologic agent of a hypertrophic, granulomatous infection of the external nares known as rhinoscleroma. This disease often produces changes in the overlying nasal skin (Fig. 197-7) and the contiguous surfaces of the respiratory, sinus, and posterior pharyngeal regions. Most cases seen in the United States have been in patients who have emigrated from very specific areas of eastern and central Europe (where the disease is known as “Slavic leprosy”), from Africa, from the Near East, and from parts of Central and South America. [73]

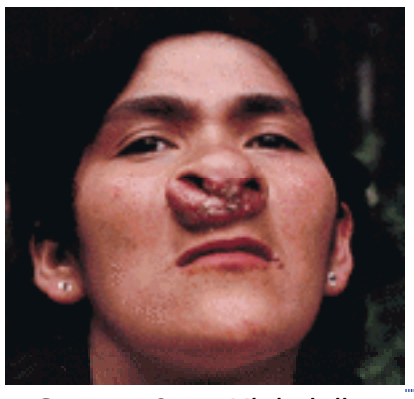

FIGURE 197-7 *Klebsiella pneumoniae rhinoscleromatis:* Rhinoscleroma. The nasal passages and nose are infected, resulting in obstructed respiration.

Dissemination of the organism is by prolonged close contact, often in family settings of crowding and poor sanitation. Infected individuals can shed organisms for years, resulting in recognized hyperendemic areas. The disease has been reported in patients with AIDs. [74] As seen in leprosy, the disease rarely becomes clinically apparent until early adulthood. Patients complain of fetid, purulent nasal discharge, epistaxis and obstructive symptoms, cutaneous nasal masses, and eventual scarring of nasal passages. Diagnosis depends upon biopsy identification of characteristic vacuolated Mikulicz cells and isolation of the organism on routine cultures, with biochemical and serologic confirmation. Both *K. pneumoniae,* ssp. ozaenae and *K. pneumoniae,* ssp. rhinoscleromatis are susceptible to ciprofloxacin, 250 to 500 mg two times daily for 1 to 3 months. A report from Mexico describes a successful outcome in all 28 patients taking ciprofloxacin (250 mg twice daily) for 1 month, compared to a group of 22 individuals treated with the more traditional combination of rifampin plus trimethoprim-sulfamethoxazole for six months. [75]

OTHER PHYSICAL FINDINGS The clinical course is often dominated by systemic manifestations of the underlying illness or decreased mental alertness, hypotension, and dehydration. Abdominal distension and other manifestations of localized or generalized peritonitis may be present. Extreme tenderness of the rectum, with or without a mass, can indicate the local source of a perineal process.

Laboratory Findings

The leukocyte count is usually elevated, in the range of 20,000 to 30,000/mm ^{3}, but may be markedly diminished in the presence of gram-negative septicemia. Elevated blood glucose values and findings of ketoacidosis are not unusual. In the presence of crepitant cellulitis, roentgenograms or magnetic resonance imaging (MRI) of the soft tissue may show the depth and extent of the gas-forming process. [76] In the absence of palpable gas, a soft tissue x-ray or MRI may indicate gas formation as part of the inflammatory process. Frozen-section biopsy materials in acute soft tissue infection can provide evidence of obliterative vasculitis, a finding suggestive of necrotizing fasciitis. [71]

Pathology

Edema, gangrene of overlying skin, fat necrosis, and a thin exudate containing visible fat droplets and polymorphonuclear leukocytes are usually present. Gas may be evident in the subcutaneous tissues. Blood vessels are often involved in a necrotic, obliterative, thrombotic inflammatory reaction. [71] The underlying muscle is usually not involved unless there is septicemia associated with major vascular thrombosis or there is myonecrosis with an organism such as *A. hydrophila.*

Diagnosis and Differential Diagnosis

A specific diagnosis can be made by needle aspiration of the cellulitis or an overlying bleb. Several morphologic forms of gram-positive as well as gram-negative organisms may be present. When gas is present, anaerobic cocci and *Clostridia* must also be considered. A foul, fetid odor may accompany the presence of anaerobes in the exudate. Radiologic and surgical evaluation can be helpful in determining a descriptive diagnosis such as crepitant cellulitis or necrotizing fasciitis.

Course and Prognosis

The process may be indolent and may respond quickly to effective antibiotic therapy. Unfortunately, especially in obese diabetic patients with perineal lesions, the progression of necrotizing fasciitis may be astonishingly rapid, even with vigorous antibiotic and surgical therapy. When the process is located centrally, in the perineal-gluteal area, the mortality rate is often as high as 50 percent. Infection of an extremity is often treated by antibiotics, drainage, and debridement, or by amputation, with more favorable results. The course is often prolonged and complex because of metabolic and nutritional complications. [69]

Treatment

Immediate antibiotic therapy and surgical drainage, guided by Gram-stained smears of the exudate and determinations of the extent of the process, are essential. Extensive debridement is usually unnecessary, and hyperbaric oxygen is not indicated in cellulitis or necrotizing fasciitis. Judgment and experience are vital in surgical decisions that include the question of amputation. The existence of a “feeding” source of contamination should be sought, especially with perineal or thigh involvement (e.g., from a ruptured appendix, diverticulum, or rectal tear). If a lower bowel leak is found, a diverting colostomy should be performed in addition to a local drainage procedure. Decubitus ulcers must be carefully evaluated for undermining necrosis, abscess formation, and cellulitis, because they may be the source of septicemias, including polymicrobial types.

Recent antibiotic usage, status of renal and hepatic function, and prior hospital exposure are factors that will help

determine the choice of antibiotics. Hospitalized patients already exposed to antibiotics and acutely ill should receive a combination of antimicrobials that includes an aminoglycoside if the presence of enteric gram-negative organisms is suspected. Crepitant cellulitis with foul exudate suggesting *B. fragilis* should be treated with metronidazole, clindamycin, or chloramphenicol. Selected second- or third-generation cephalosporins or fluoroquinolones can substitute for aminoglycosides in patients with severe renal impairment. If *P. aeruginosa, Klebsiella,* or *Serratia* is suspected in certain hospital-acquired infections, tobramycin or amikacin may be preferred to gentamicin and a broad-spectrum penicillin added if *Pseudomonas* is a major pathogen. The presence of gram-positive cocci on initial stained smears indicates the need for penicillin or ampicillin (for chaining streptococci) or nafcillin (for clusters of staphylococci). If resistant enterococci or methicillin-resistant staphylococci are suspected, then vancomycin is the drug of choice for either chaining or clustering gram-positive cocci.

REFERENCES

Bartonella are aerobic, fastidious, gram-negative bacilli, with the remarkable capacity for intracellular persistence and the production of bacteremia. The number of identified *Bartonella* species has been rapidly expanding. The genus includes three important species: *B. henselae,* the cause of most cases of cat-scratch disease (CSD) as well as some cases of bacillary angiomatosis (BA) peliosis, and endocarditis; *B. quintana* the cause of trench fever, urban trench fever, BA, and endocarditis; and *B. bacilliformis,* the cause of Oroya fever and verruga peruana. Other potential human pathogens are *B. clarridgeiae,* a cause of CSD, *B. elizabethae* and *vinsonii,* which causes endocarditis, and *B. grahamii,* a cause of neuroretinitis (Table 198-1). Infections caused by most Bartonella are associated with arthropod vectors. Asymptomatic bacteremia rates in primary vertebrate (reservoir) hosts may exceed 50 percent. This suggests high prevalence of infection and prolonged and persistent bacteremia as characteristics of Bartonella infection.

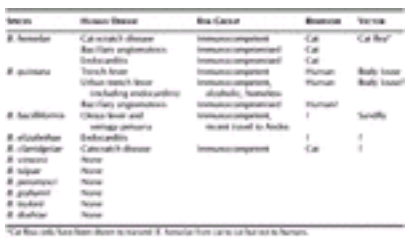

TABLE 198-1 **Diseases Caused by** *Bartonella*

MICROBIOLOGY

The genus *Bartonella* contains organisms previously in the genuses *Rochalimaea* and *Grahamella*. *Bartonella* organisms are small aerobic, fastidious, pleomorphic, gram-negative bacteria; they are difficult to culture from clinical samples. This difficulty stems in part from their slow growth rate and complex nutritional requirements. Initial clinical isolates grow slowly and visible colonies may not be detected for weeks, but subsequent passages grow much more rapidly. [1] The organisms are short rods, ranging from 0.3 to 0.5 micrometers wide by 1.0 to 1.7 micrometers long. [1] The organisms stain poorly with Gram's stain, and are best visualized in tissue using modified silver stains (Warthin-Starry).

CAT-SCRATCH DISEASE

CSD is a relatively common, benign, self-limited disease caused by *B. henselae*. It is the most common cause of localized chronic lymphadenopathy in children and young adults. [2] The disease is usually transmitted by the bite or scratch of a cat or kitten, although it has rarely been associated with other pets. CSD was originally reported by Robert Debré in 1931. An infectious etiology was long suspected, but it was not until 1983 that Wear and his colleagues, by using Warthin-Starry staining, identified bacteria in 34 of 39 lymph nodes from patients with CSD. Bacilli were also identified in primary cutaneous and ocular lesions of CSD. Significant titers of antibodies against *B. henselae* are found in 90 to 95 percent of cases that meet the clinical definition of CSD. [3] By using polymerase chain reaction (PCR)

analyses, *B. henselae* DNA sequences can be identified in 30 percent of lymph node specimens from CSD patients and in CSD skin test antigens. [4], [5] and [6]) *B. henselae* causes the overwhelming majority (>95 percent) of cases of CSD. In the United States there appears to be only one infectious genotype of *B. henselae,* but in Europe there are two. This is analogous to the differences in *Borrelia* genotypes in the different continents, although, unlike *Borrelia,* no differences in the clinical manifestations have been identified in cases of CSD in the United States and Europe. *B. clarridgeiae* is also a potential cause of CSD, but the importance of this organism worldwide is unknown. [7] *B. quintana* has been isolated in Europe from two cases of chronic lymphadenopathy following cat exposure.

Epidemiology

Approximately 29.2 million (31 percent) households in the United States own a cat, averaging close to two cats per household, for a total household cat population of 57 million. [8] Given the large population of domestic cats, more than 22,000 cases of CSD are reported. [9] Significant health care dollars are spent in diagnostic work-up of these patients.

CSD affects persons of all ages, although 60 to 90 percent of cases are reported in children and young adults. CSD is seen worldwide and does not appear to have a racial prevalence. Most patients with CSD recall a history of cat contact, but this is not absolute (90.3 to 99.1 percent). The incidence of CSD is slightly higher in males and it occurs seasonally, mostly in the second half of the year.

CSD is associated with exposure to a cat, usually a flea-infested pet cat, and frequently a kitten 12 months old or younger. The method of spread from the cat is usually a scratch or bite. In California, 39.5 percent of cats are bacteremic for *B. henselae* with a single sampling, indicating a very high infection rate. Bacteremic cats were more likely to be stray cats, young (less than 1 year old), and flea-infested. [10] The seroprevalence of *B. henselae* among pet cats is highly variable throughout regions of North America (overall, 27.9 percent positive); a higher seroprevalence is associated with increasing climatic warmth and annual precipitation. [11] When the geographic seroprevalence of *B. henselae* is compared with predicted estimates of cat flea populations based on temperature and humidity, there is considerable overlap, supporting the role of the cat flea (*Ctenocephalides felis*) as the arthropod vector maintaining infection in cats. *B. henselae* can be transmitted from cat to cat via the cat flea; cat fleas contain *Bartonella* organisms after feeding on infected cats; cat flea feces contains viable *Bartonella;* and cats can be experimentally infected by the intradermal injection of infected cat flea feces. [12] The cat flea has not been demonstrated to spread *Bartonella* infection from cats to humans.

Clinical Manifestations

The clinical spectrum of CSD has expanded since serologic diagnosis became possible. Typical CSD exhibits two components, the primary inoculation papule and adenopathy proximal to the inoculation site. The papule appears at the site of inoculation within 3 to 10 days of exposure and progresses through an edematous (vesicular) and crusted stage. The primary inoculation papule lasts 1 to 3 weeks. The lymphadenopathy, seen in at least 90 percent of patients, develops on average 2 weeks following inoculation (range 3 to 50 days) (Fig. 198-1). [13] The inoculation papule is still present in 60 to 90 percent when the adenopathy develops, making it a valuable diagnostic finding. [14] The most commonly affected lymph nodes are axillary, cervical, and submandibular, with 98 percent of patients having involvement of only one anatomic region. The nodes are generally firm, tender and between 1 and 5 cm in diameter. The lymphadenopathy usually remits spontaneously after several months, although in 20 percent of cases, the adenopathy lasts longer than 6 months. Recurrences are uncommon.

FIGURE 198-1 Cat-scratch disease. Primary lesion adjacent to mouth with associated submandibular lymphadenopathy in a woman.

Suppuration of clinical significance occurs in less than 10 percent of cases, but when affected nodes are followed with ultrasonography, suppuration is found to be the natural course of resorption of affected nodes in nearly all cases. [14] Surgical drainage is seldom necessary.

With improved diagnosis, atypical cases of CSD have increased from fewer than 5 percent of cases to more than 30 percent of cases in some series. [15] In one pediatric series, atypical mononucleosis with pharyngitis and bilateral cervical adenopathy and thrombocytosis was a common presentation of *B. henselae* infection. [16] Fever of unknown origin with or without endocarditis, hepatic and splenic granulomatosis, and massive lymph node enlargement resembling lymphoma may also occur. [15] Involvement of the terminal ileum may mimic inflammatory bowel disease; and intraabdominal lymphadenopathy may obstruct the portal vein. [17], [18] *B. henselae* infection may also be the most common cause of neuroretinitis and focal retinochoroiditis. [19], [20] The most common neurologic complication of CSD is acute encephalopathy, presenting with seizures in 66 percent and status epilepticus in 10 percent of patients. [21], [22]

In one study, up to 20 percent of immunocompetent patients with serologically confirmed CSD had PCR positivity for *B. henselae* in peripheral blood, suggesting bacteremia may be common. [23] Not surprisingly, hematogenous dissemination of *B. henselae* complicating CSD in immunocompetent persons has been reported to affect bone (osteomyelitis), liver and spleen, lungs (pneumonia, pleural effusion, pulmonary nodules), and the optic nerve. [2], [24], [25], [26] and [27] These lesions may be markedly symptomatic, or, in one case of pulmonary involvement, completely asymptomatic. [24] *B. henselae,* which may cause endocarditis in persons with known valvular heart disease, usually affects the aortic valve, and 90 percent of patients require valvular surgery as a consequence of severe damage. [28] Erythema nodosum may be triggered by CSD. [15] One patient with CSD developed erythematous papules and plaques of the anterior chest, resembling Sweet's syndrome clinically, but a dermal infiltrate of lymphocytes, plasma cells, and eosinophils histologically. The eruption responded to systemic steroids without any adverse outcome. [29]

Laboratory Findings

Routine laboratory findings are nonspecific and usually not helpful except to exclude other diseases. Patients with CSD may have a slightly elevated white blood cell (WBC) count and elevated erythrocyte sedimentation rate during the acute phase. Blood cultures are rarely positive when using current testing techniques. PCR of affected lymph nodes may be positive in 30 percent of cases. Between 80 and 90 percent of cases of CSD will have positive serology for *B. henselae* at the time of presentation, and many of the seronegative cases will be positive 2 to 8 weeks later. Serologic testing has replaced the CSD skin test as the confirmatory test of choice in cases of CSD. Cases of CSD caused by *B. clarridgeiae* are often negative on serologic tests used to detect other *Bartonella* species. [7]

Pathology

Histopathologic examination of CSD lymph node lesions is not specific. Lymph nodes undergo three stages in the formation of a granuloma: (1) enlargement with hypertrophy of the germinal centers and thickening of the cortex; (2) formation of granulomas with invasion of lymphocytes and epithelioid cells; and (3) necrosis and infiltration with neutrophils—all of which may be simultaneously present within a single lymph node. [30] Abscess formation may occur. Organisms can be detected in lymph nodes and primary skin lesions, often in clumps or filaments, in or adjacent to areas of necrosis.

In primary skin lesions, microscopic examination reveals necrosis of the epidermis and upper dermis, and dermal inflammation ranging from neutrophil and macrophage infiltration to granuloma formation. Conjunctival lesions have similar histologic findings. In a few cases, conjunctival lesions produce proliferating blood vessels and a homogenous eosinophilic to basophilic granular appearance in the background—features similar to those of bacillary angiomatosis.

Diagnosis/Differential Diagnosis

The diagnosis of CSD is presumptive if there are characteristic clinical findings and history of a cat scratch or bite. A primary inoculation papule increases the likelihood of the diagnosis, and in typical cases may be adequate. The diagnosis is confirmed if acute or convalescent serology is positive for a *Bartonella* species known to cause CSD.

The differential diagnosis of typical CSD includes other causes of unilateral or regional lymphadenopathy: other pyogenic infections, tularemia, atypical mycobacteria, and lymphoma.

Treatment

Virtually all cases of CSD remit spontaneously without therapeutic intervention. In a retrospective study of 202 patients with CSD who were treated with antibiotics, [9] commonly prescribed antibiotics, including macrolides, tetracycline derivatives, and cephalosporins, were ineffective. [28] However, antibiotic susceptibility studies have shown that *B. henselae* is highly sensitive to macrolides, tetracycline derivatives, and second- and third-generation cephalosporins, and is variably sensitive to quinolones. The failure of antibiotics in classic CSD in the immunocompetent host may relate to the small infectious burden and the frequent initiation of therapy once the disease is already improving spontaneously (in its lymphatic phase). In a recent prospective randomized trial, azithromycin for 5 days was demonstrated to reduce the lymph node volume during the first 30 days of observation. Half of azithromycin-treated patients reached 20 percent of baseline lymph node volume by 1 month, as opposed to 7 percent of untreated patients. However, there was no difference in any other symptoms or findings, or in the long term outcome, and some treated patients had increases in lymph node size after treatment. [14]

TRENCH FEVER, URBAN TRENCH FEVER, AND BACTEREMIA/ENDOCARDITIS

B. quintana is the etiologic agent of trench fever, a disease that affected more than 1 million troops of the German and Allied armies during World War I. [31] This disease is characterized by a fever lasting about a week, followed by recurrent fevers every 4 to 8 days, most commonly every 5 days (quintana fever). Clinically, patients complain of severe headaches and neck, back, and shin pain (shin bone fever). [32] There are no specific cutaneous manifestations. Although significant morbidity is associated with the disease, fatalities are rare. Trench fever is caused by *B. quintana*. As opposed to most other *Bartonella* species, humans are the only known reservoir for this organism. The disease is transmitted from human to human by the human body louse (*Pediculus humanus corporis*). Close body contact and unsanitary conditions are associated with outbreaks. The incubation period ranges from 5 to 20 days. The organism can be isolated from patients with the disease and can be transmitted from person to person by direct inoculation or through lice. Recovered patients may be bacteremic for weeks. [31]

Recently, *B. quintana* caused bacteremia and endocarditis in the United States and France (urban trench fever). [28], [31], [33]

Virtually all of the patients are HIV-negative, homeless, alcoholic men. Moreover, in cities where urban trench fever has been described, from 15 to 50 percent of the indigent alcoholic inner-city male population has serologic evidence of infection with *B. quintana*. [34], [35] Patients present with fever, weight loss, and endocarditis. Classic "trench fever" shin pain is uncommon. Endocarditis occurs in patients without a known history of previous valvular disease, and surgery is required in more than 95 percent of patients. [28] The diagnosis is usually made by blood culture, which is >90 percent positive if done specifically to isolate *Bartonella,* and before any antibiotic therapy. After even a single dose of antibiotics, blood cultures are usually negative. [4] All patients are serologically negative at presentation but become positive after several weeks, making this a useful delayed confirmatory test, but of no value in the acute setting. [4]

Treatment

For uncomplicated bacteremia, 4 to 6 weeks of doxycycline 100 mg bid, erythromycin 500 mg qid, or azithromycin 500 mg qd is recommended. For endocarditis, 4 to 6 months of therapy is required, often in combination with valve replacement.

BARTONELLA INFECTION IN THE IMMUNOSUPPRESSED (BACILLARY ANGIOMATOSIS; PELIOSIS OF THE LIVER AND SPLEEN)

BA was originally reported in 1983 by Stoler, who described a patient with AIDS and multiple angioproliferative nodules that resolved with erythromycin. [36] Histologic examination by using Warthin-Starry staining revealed small bacillary forms that were confirmed by electron microscopy. In the following year, two groups reported similarities between the organisms seen in BA and CSD and proposed that they may be caused by the same bacteria. [37], [38] In 1990, Perkocha et al. described eight patients with AIDS with bacillary peliosis (BP) hepatitis, large, blood-filled cysts in the liver that contained clumps of bacteria identical to those seen in BA. [39] Some patients had skin and liver/spleen involvement simultaneously. Both *B. henselae* (the CSD bacillus) and *B. quintana* (the agent of trench fever) have been identified as causative agents of BA and BP. [40], [41], [42] and [43])

B. henselae causes both CSD and BA. At one end of the clinical spectrum, classic CSD is seen in young, immunocompetent hosts. At the other end, BA is seen in patients who are severely immunocompromised. Thus, it is the immunocompetence of the host and the bacterial load that dictates the clinical manifestations of the disease. Immunocompetent hosts are able to mount a significant immune response, kill the vast majority of the bacteria, and contain the infection (CSD). Immunocompromised hosts are unable to control the infection and a systemic disease occurs. Moreover, immunocompromised patients with BA develop an angioproliferative response (BA, BP), probably because of an angiogenic factor produced by the bacteria.

Epidemiology

Bacillary angiomatosis is most commonly seen in patients with advanced AIDS and a CD4 count less than 50 cells/mm ^{3}, with an incidence of 1.2 cases per 1000 at-risk patients. [44] Other immunosuppressed patients with BA, including patients with leukemia and recipients of organ transplants, have been reported. [45], [46] and [47]) Several patients with BA who were HIV-negative and nonimmunosuppressed have been reported. [48] In the cases of BA in immunocompetent persons, however, although the lesions were proliferative vascular papules, they were limited in number, had limited or no systemic involvement, and followed a benign course. There is no risk factor predisposition in terms of race, sex, or age. BA is not limited to adults. [45], [49] BA caused by *B. henselae* is acquired from infected cats and is a manifestation of CSD in the immunocompromised host. Peliosis hepatitis is exclusively associated with *B. henselae* infection. [50] In contrast, patients with BA caused by *B. quintana* develop subcutaneous masses and lytic bone lesions. [51], [52] *B. quintana* infection in the immunosuppressed patient is also associated with low income, homelessness, and exposure to body lice. [44]

Clinical Manifestations

The incubation period for BA is unknown. The clinical constellation of BA in AIDS patients include fever, a low CD4 lymphocyte count (usually less than 50 cells/mm ^{3}, cutaneous or subcutaneous vascular lesions, lymphadenopathy, and/or abdominal symptoms. [52] The most common cutaneous morphologies of BA are (1) pyogenic granuloma like lesions (Fig. 198-2), (2) subcutaneous nodules, and (3) hyperpigmented indurated plaques. The same patient may have several morphologies. Lesions resembling pyogenic granuloma can range in size from 1 mm to several centimeters and are dusky-red in color with a collarette of scale and peripheral satellite lesions (Fig. 198-2). The lesions are firm, bleed easily, and are often tender, occurring in skin and mucosa. Subcutaneous nodules can range from distinct nodules to diffuse swellings with or without induration and are also often tender. Hyperpigmented plaques are most commonly seen in African Americans with BA and are oval in shape; they are several centimeters in diameter with indistinct borders. Large, fungating masses rarely occur. [53] Patients with BA may have few to thousands of lesions with the number of lesions gradually increasing over time. Additional immunosuppression with chemotherapeutic agents may be followed by a shower of miliary skin lesions.

FIGURE 198-2 Bacillary angiomatosis. Multiple grouped dusky-red and violaceous papules and nodules that resemble pyogenic granulomas.

In addition to cutaneous lesions, other organ systems may be affected. Hepatic (BP) and splenic lesions can occur concomitantly with or independently of cutaneous lesions. [39] BP can be a cause of significant blood loss and anemia. *Bartonella* infection, especially that caused by *B. quintana,* can affect bone and soft tissues. [41], [54] Lesions of the central nervous system have been reported and can result in neurologic and psychiatric disorders. [55], [56] Bacteremia, chronic fevers, and pulmonary and gastrointestinal lesions have also been reported. [57], [58] Radiologic findings usually identify areas of systemic involvement. [59]

There are several reports of patients with other cutaneous diseases concomitant with BA, as well as the simultaneous existence of BA and another disease within the same lesion. Several patients have been reported with both BA and Kaposi sarcoma. [60] Cytomegalovirus, Epstein-Barr virus, *Cryptococcus neoformans,* and *Mycobacterium avium-intracellulare* have been found within lesions of BA. [61], [62], [63] and [64]) This emphasizes the importance of looking for multiple pathologic infectious processes in patients with advanced HIV disease.

Laboratory Findings

In patients with AIDS and BA, the CD4 T helper cell count is <200/m ^{3} and usually <50/mm ^{3}. Patients are anemic and may have elevated liver function tests [characteristically, lactic acid dehydrogenase (LDH) and alkaline phosphatase are more elevated than hepatocellular enzymes]. Blood cultures are positive for *Bartonella* species in about half of BA patients. [52]

Pathology

Lesions of BA have the general features of a lobular capillary hemangioma (=pyogenic granuloma) (Fig. 198-3A), but in contrast to a pyogenic granuloma, the endothelial cells are often larger and polygonal; they may have marked atypia. There is a prominent inflammatory infiltrate, with significant numbers of neutrophils as well as leukocytoclastic debris (Fig. 198-3B). Polymorphonuclear leukocytes (PMNs) are scattered throughout the lesion, as opposed to classical pyogenic granuloma lesions in which the PMNs are at or near the surface, even if the pyogenic granuloma is eroded and impetiginized. There is usually a finely granular, pink to purple material in areas of PMN infiltration adjacent to blood vessels (Fig. 198-3B). This represents large clumps of bacteria, best visualized with a modified Warthin-Starry stain (Fig. 198-3C). Standard tissue Gram's stain and the Warthin-Starry stain used for syphilis will not stain the organisms. If the diagnosis cannot be confirmed with special stains, electron microscopy may be used. The lack of spindle cells, atypically shaped vascular channels, and hyaline globules distinguish BA from Kaposi sarcoma. Lesions of BA in tissues other than liver show similar histologic features.

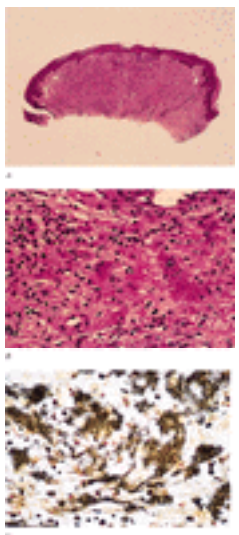

FIGURE 198-3 Histology of bacillary angiomatosis. *A*. Low-power magnification showing the architectural features of a lobular capillary hemangioma. *B*. High-power magnification showing new capillary formation and endothelial cells with cytological atypia, a prominent inflammatory infiltrate, and leukocytoclastic debris. *C*. Warthin-Starry stain showing numerous pleomorphic bacteria. (*Courtesy of P. LeBoit, MD.*)

Diagnosis/Differential Diagnosis

Because BA often resembles pyogenic granuloma, solitary lesions must be differentiated from nodular Kaposi sarcoma and pyogenic granuloma. Ulcerative BA lesions have a broad clinical differential diagnosis including pyoderma, atypical mycobacteria, *Acanthamoeba,* viral, and deep fungal infections. Clinically, widespread lesions may be indistinguishable from disseminated pyogenic granuloma or verruga peruana (see below), which can be excluded by travel history. Prior to the discovery of HIV, there were several cases of disseminated pyogenic granuloma associated with immunodeficiency; these cases may have been BA. [65], [66]

The diagnosis can usually be made histologically. *B. henselae* and *B. quintana* can be cultured from skin lesions and commonly from the blood of BA patients. The organisms grow slowly and may not be detected without prolonged culture (>1 month). PCR of affected tissue is virtually always positive if lesions are histologically characteristic and PCR is done

prior to antibiotic therapy.

Treatment

Erythromycin 500 mg four times a day or doxycycline 100 mg twice a day are the treatments of choice for BA. Other antibiotics thought to be effective are minocycline, tetracycline, chloramphenicol, azithromycin, and roxithromycin. [67] The treatment duration is unknown but should be at least 8 weeks for patients with skin lesions only and perhaps 6 months in patients with visceral infections (liver, spleen, bone). Some patients require lifelong suppressive therapy. Relapses have been reported, especially with shorter treatment courses. [50] A Jarisch-Herxheimer reaction not uncommonly occurs after initiation of therapy. Untreated BA is a fatal disease. Most patients respond rapidly to antibiotic therapy.

OROYA FEVER AND VERRUGA PERUANA

Oroya fever (also known as Carrión's disease) and verruga peruana are endemic diseases localized to Peru, Ecuador, and Colombia. The earliest recorded cases date back more than four centuries, and verruga peruana has been identified in a mummy from southern Peru. [68], [69] The disease was named after Daniel Carrión, who, as a Peruvian medical student in 1885, inoculated himself with a lesion of verruga peruana and died of the acute phase of Oroya fever, showing that both diseases are caused by the same agent. The causative organism of these diseases is *B. bacilliformis*. The arthropod vector is most commonly a sandfly, the main vector being *Lutzomyia verrucarum*.

Epidemiology

Oroya fever and verruga peruana are restricted to the South American Andes, from 2°5' latitude north to 13° south of the equator, including southern Colombia, parts of Ecuador, and Peru. [70], [71] and [72]) Seroprevalence may approach 75 percent in endemic areas, which suggests that many patients have milder disease that goes unrecognized. [72] Most cases have been reported in regions of altitude ranging from 500 to 3200 m above sea level. Recent epidemics have been reported in previously nonendemic areas of Peru, suggesting the endemic area is expanding to lower areas near the Amazon basin. Humans are the only known reservoir for *B. bacilliformis,* although verruga peruana lesions have been found in dogs, cows, mules, and chickens, and can be induced in rhesus monkeys.

Clinical Manifestations

After an incubation period between 10 and 210 days (average, 61 days), the acute stage develops, in which patients have severe fevers, headache, malaise, and a profound paleness. Other signs of hemolysis may also be present. Patients may develop signs of neurologic involvement, including coma. During the acute state, the patients are extremely susceptible to superinfection, either bacterial (*Salmonella*) or parasitic (*Toxoplasma*). Many patients will present with the eruptive lesions of verruga peruana having had no preceding acute phase. [72] The eruptive stage of verruga peruana is characterized by the appearance of red angiomatous lesions, identical to BA (Fig. 198-4). Three patterns of cutaneous lesions have been described: miliary, nodular, and mular. In the miliary form, lesions are about 3 mm in diameter (Fig. 198-4). Mular lesions are larger, fewer in number, and either sessile or pedunculated, with a superficial erosion. Nodular lesions are deeper dermal papules and nodules, and may not have overlying erythema. Mucosal lesions may be seen.

FIGURE 198-4 Bartonellosis (verruga peruana). Multiple small papules on the extremities. The lesions may ulcerate.

Laboratory Findings

During the acute hemolytic phase, a profound anemia may be present. Red blood cell (RBC) counts can reach levels below 106/mm ^{3} (two-thirds of patients have a hematocrit below 20). Oroya fever is one of the few bacterial diseases in which the agent can actually be seen on peripheral smears. Although initially the finding of bacteria within circulating RBCs was felt to be useful in confirming the diagnosis, in recent outbreaks, only one-third of patients had positive smears. It is the intracellular presence of bacteria that is thought to induce hemolysis by the liver and spleen.

Pathology

Lesions of verruga peruana are histologically identical to those of bacillary angiomatosis, showing the distinct angioproliferative pattern with areas of neutrophilic collection within the stroma. [71] The location of the proliferation varies

with the type of lesion; thus, in miliary lesions, it is in the papillary and superficial reticular dermis, and in nodular and mular lesions, it is in the deeper dermis. Old verrugas tend to lose the inflammatory component, retaining the vascular frame. At that point the lesion may look very similar to a pyogenic granuloma. In contrast to BA, the purple bodies of bacteria are hardly seen in verruga peruana lesions. However, the organisms can be seen in the tissue with modified silver-stain techniques that are similar to those used for BA.

Diagnosis/Differential Diagnosis

The differential diagnosis for verruga peruana is the same as that for BA, and includes BA, Kaposi sarcoma, pyogenic granuloma, and angiosarcoma.

Treatment

Untreated, Oroya fever may be a fatal disease. Because of the frequent concomitant infection with *Salmonella,* the treatment of choice for Oroya fever is chloramphenicol (50 mg/kg per day, maximum 3 g/day) for 10 days, although ciprofloxacin 500 mg bid also appears effective. Rifampin 10 mg/kg per day for 14 to 21 days is the treatment of choice for verruga peruana, although the macrolides and tetracyclines are also effective. Ciprofloxacin 500 mg bid for 7 to 10 days is an alternative. [71] Verruga peruana may also regress spontaneously.

Miscellaneous Bacterial Infections with Cutaneous Manifestations

DISEASES RELATED TO INTIMATE CONTACT WITH ANIMALS, FISH, FOWL, OR THEIR PRODUCTS
Anthrax
Brucellosis
Erysipeloid
Glanders
Streptobacillus moniliformis Infection (Rat-bite Fever)
Infections Caused by Streptococcus iniae
DISEASES ASSOCIATED PRIMARILY WITH A SPECIFIC GEOGRAPHIC DISTRIBUTION
Melioidosis
Plague
DISEASES ASSOCIATED WITH RANDOM ANIMAL CONTACT INDEPENDENT OF GEOGRAPHIC OR OCCUPATIONAL CONSIDERATIONS
Francisella tularensis Infections (Tularemia)
Leptospirosis
Pasteurella multocida Infections
UNCOMMON DISEASES IN WHICH ANIMAL OR WATER CONTACT OR CLIMATOLOGIC FACTORS MAY OCCASIONALLY BE RELEVANT
Listeria monocytogenes Infections (Listeriosis)
Diphtheria
Cutaneous Infections Caused by Vibrio Species
Aeromonas hydrophila Infections

REFERENCES

This chapter encompasses a group of “exotic” diseases rarely seen in urban practice in the United States. The thread of continuity that can be woven among this miscellaneous group involves epidemiologic considerations. The diagnosis can often be made expeditiously if the following are considered: (1) occupation and travel history; (2) the possibility of animal exposure; (3) the possibility of fresh, brackish, or saltwater immersion; and (4) the duration of the incubation periods. Many of the illnesses described in this chapter are systemic infections having a major cutaneous component that helps to suggest the proper diagnosis.

DISEASES RELATED TO INTIMATE CONTACT WITH ANIMALS, FISH, FOWL, OR THEIR PRODUCTS

Anthrax

The most common form of infection with *Bacillus anthracis* is an acute cutaneous lesion called “malignant pustule.” [1] Anthrax is primarily a disease of domestic and wild animals, but humans become accidentally involved through exposure to animals and their products. In addition, bioterrorism has been considered a potential source for decades. Unfortunately, this threat became a reality in October 2001 in the United States. [2]

BACTERIOLOGY AND PATHOGENIC ASPECTS

Bacteriology *B. anthracis* is a large, aerobic, encapsulated, gram-positive, square-ended rod that forms central spores in an unfavorable external environment and on culture, but not in tissues. Growth occurs readily on blood agar medium without a hemolytic reaction. This characteristic, plus pathogenicity for mice and lack of motility, helps to distinguish this organism from saprophytic *Bacillus* species.

Pathogenic aspects *B. anthracis* has two principal virulence factors. The first is a D-glutamyl polypeptide capsule, the synthesis of which depends on the presence of a specific plasmid. [3] The second is a pair of toxins, designated *edema toxin* and *lethal toxin*. Each of the toxins consists of a pair of noncovalently linked protein components: [4] edema toxin consists of edema factor (EF) plus protective antigen (PA); lethal toxin consists of lethal factor (LF) plus PA. PA binds to a surface receptor on most mammalian cells and is subsequently cleaved by furin-like proteases. The larger of the proteolytic products remains bound to its receptor, and these monomeric units of PA self-associate to form a heptameric prepore. The ligands EF and LF bind to the prepore, and this entire receptor-modified PA-ligand complex is then endocytosed and trafficked to an acidic intracellular compartment where the low PH converts the prepore to a pore. The latter allows translocation of EF and LF across the endosomal membrane into the cytosol where their toxic effects are elicited. EF is a calmodulin-dependent adenyl cyclase, which is responsible for the prominent edema at sites of infection and protects the bacilli from destruction by phagocytes [inhibiting neutrophil function and hindering production of tumor necrosis factor (TNF) and interleukin-6 by monocytes]. LF is a zinc metalloprotease that inactivates mitogen-activated protein kinase kinase, leading to inhibition of intracellular signaling. LF is capable of killing macrophages or, at lower concentrations, inducing them to overproduce cytokines (TNF-a, interleukin-1ß). [4] These actions are probably responsible for the sudden death from toxicity that occurs with high degrees of bacteremia (10^7 to 10^8 bacilli per milliliter of blood) and terminally high lethal toxin levels. Cutaneous infection usually follows introduction of spores at the site of an abrasion. Following germination, the encapsulated organisms resist phagocytosis and elaborate their toxins. Edema toxin is responsible for the characteristic gelatinous edema of the local lesion. [5] In 1881, Pasteur showed that *B. anthracis* grown at elevated temperatures were attenuated and capable of inducing immunity in animals upon subsequent challenge with virulent strains of the organism. Such vaccine strains, avirulent by virtue of their inability to produce toxins,

were shown, more than 100 years later, to have become attenuated by virtue of temperature-induced elimination of the plasmid-encoding toxin genes. However, the important protective immunogen is the anthrax toxin because vaccination with anthrax strains containing only the plasmid for capsule production, but lacking the one for toxin production, is not protective. Pasteur's vaccine was effective presumably because his attenuation procedure resulted in cultures with a relatively increased proportion of cells containing only the capsule plasmid and a relatively decreased proportion containing both plasmids. [6]

EPIDEMIOLOGY Natural infection occurs in many domestic and wild animals. Highly resistant spores persist for many years in cutaneous products of these animals and in pastures where they live. Vaccination, animal control programs, and industrial safety measures have essentially eliminated reservoirs of infection in the United States, but imported animal products from the Middle and Near East, Africa, India, and South America may still introduce spores into an unprotected industrial environment. Worldwide there are estimated to be from 20,000 to 100,000 cases of human anthrax annually. By contrast, in the United States, for two decades there has been less than 1 case annually, on average, until 2001, when over the course of a 6-week period 22 cases of anthrax (12 cutaneous, 10 inhalational with 4 deaths) were identified. [7] The cases resulted from bioterrorism acts in which “weaponized” anthrax (finely milled, nonclumping) spores that are optimal for dissemination and inhalation were sent through the mails, infecting postal workers and letter recipients and contaminating many offices. Outbreaks still occur in endemic areas. From 1979 to 1985, approximately 10,000 cases of anthrax (more than 90 percent involving the cutaneous form; the remainder representing, equally, pulmonary and gastrointestinal forms) occurred in Zimbabwe. [5] Direct cutaneous contact with carcasses of infected cattle was the major means of infection, but transmission by biting flies, which had earlier fed on carcasses of animals that had died of anthrax, may also have occurred. Infection in the United States, in the past, has been almost entirely limited to persons working in animal product–associated industries, particularly individuals handling raw materials in wool factories. However, transient exposure to infected animal products (e.g., hair) from abroad through ostensibly unrelated occupations (such as one-time air-conditioning duct repairs in a wool-sorting plant) has been incriminated in acquisition of anthrax. Shaving brushes, piano keys (ivory), hides, and raw wool have been implicated in sporadic infections in persons not related to the above industries. The use of protective vaccines, sophisticated ventilation systems, and steam sterilization of hides has drastically reduced cases from the animal product industry.

CLINICAL MANIFESTATIONS

History The patient is almost invariably employed in an animal-product industry, usually handling, for example, wool, goat, and other animal hair, hides, and bones. To this list must be added victims of bioterrorism attack, through the mail or by other means. The initial symptoms, following a 1- to 12-day incubation period, are usually low-grade fever and malaise. A painless papular lesion is usually noted on an exposed area. Itching or burning may accompany the early lesion; progressive edema, discoloration, and enlargement then occur, but the lesion and surrounding inflammatory edema remains painless (see below). The initial symptoms of inhalation anthrax are nonspecific, with fever, fatigue, and malaise, but chills, high fever, nonproductive cough, dyspnea, cyanosis, and collapse soon occur. Chest radiographs characteristically show symmetric mediastinal widening. In this form of the disease, as well as in septicemic anthrax (following cutaneous or ingestion anthrax), meningitis may develop and dominate the clinical picture. Gastrointestinal anthrax following ingestion of contaminated meat has never been reported in the United States. Although vegetative bacteria are killed by acid gastric juice, the anthrax spores are resistant. An uncommon but related form (oropharyngeal) of anthrax also results from ingestion of raw or undercooked meat from infected animals. Not surprisingly, there may be a cluster of cases in a family.

Cutaneous lesion The cutaneous lesion (“malignant pustule”) is the classic primary infection in anthrax, occurring in more than 95 percent of cases. It is most often located on an exposed area such as the hands (Fig. 199-1) or the head and neck, beginning as a papule. The painless lesion enlarges and develops into a vesicle or bulla with surrounding brawny, gelatinous, nonpitting edema. The vesicle becomes hemorrhagic and then necrotic and may be surrounded by small satellite papules and vesicles. The area of nonpitting edema increases, an eschar forms, and the red discoloration becomes more intense, but without pain. Rarely, the area of necrosis extends over most of the edematous region, or edema may be present without any detectable primary lesion or necrosis. The eschar dries and falls off in 1 to 2 weeks. Regional lymph nodes may be slightly enlarged and tender, but there is no lymphangitis unless secondary infection with streptococci or *Staphylococcus aureus* has developed.

FIGURE 199-1 Anthrax. The classic cutaneous lesion of a primary infection in anthrax is a painless papule that evolves into a hemorrhagic bulla with surrounding brawny nonpitting edema. Note the typical localization on the hand.

Other physical findings Systemic manifestations (fever, tachycardia, hypotension) may accompany either extensive cutaneous involvement or dissemination from a skin site. In woolsorter's disease, tachypnea, stridor, and cyanosis may be prominent. A thick, gelatinous, hemorrhagic nasal discharge may accompany acute sinusitis caused by *B. anthracis*.

LABORATORY FINDINGS The white blood cell count is usually elevated, with a preponderance of polymorphonuclear leukocytes. If meningitis is present, the cerebrospinal fluid is characteristically hemorrhagic and broad gram-positive bacilli may be seen. In inhalation anthrax, the chest x-ray shows significant mediastinal widening and hilar adenopathy because of edema and hemorrhagic necrosis of draining nodes. The pulmonary parenchyma is usually spared.

PATHOLOGY The prominent features of cutaneous anthrax are hemorrhagic edema, dilatation of lymphatics, and necrosis of the epidermis; gram-positive bacilli may be seen in the area of the eschar.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS The diagnosis is usually suspected on the basis of the character of the lesion and the hobby exposure, occupational history, or likelihood of bioterrorism. Demonstration of large gram-positive rods in vesicle fluid on aspiration beneath the eschar, or on skin punch biopsy, also using a direct fluorescent antibody technique supports the diagnosis. Definitive diagnosis requires culture of the organism and demonstration of its susceptibility to specific bacteriophage lysis. Occasionally, the organism can be isolated from the blood during the acute cutaneous illness as well as in disseminated anthrax. Retrospective serodiagnosis is possible with the demonstration of a

titer rise in electrophoretic-immunotransblots of antibody to PA and enzyme-linked immunosorbent assay (ELISA) for detection of anticapsule antibodies. Acute staphylococcal cellulitis with a central pustular lesion or a carbuncle with necrotic eschar may be confused with early anthrax, but the former are usually very painful and tender, and the etiologic agent is usually present on Gram-stain examination. Differential diagnosis of cutaneous anthrax includes ecthyma (caused by *Streptococcus pyogenes* and usually without edema or systemic manifestations), ecthyma gangrenosum (usually in the setting of neutropenia and *Pseudomonas aeruginosa* bacteremia), orf (caused by a parapoxvirus through contact with sheep or goats; vesicopustular lesions without gelatinous edema), and a brown recluse spider bite (causes pain with incipient necrosis).

TREATMENT Parenteral crystalline penicillin G (2 million units every 6 h) was the treatment of choice prior to the 2001 bioterrorism outbreak. In one study, smears and cultures from vesicles or from the necrotic tissue beneath the eschar became negative within 6 h of initiation of penicillin therapy. [8] Similarly, for systemic infection (inhalation, gastrointestinal, meningeal), higher doses of penicillin (2 million units every 2 h for the adult) were the previously recommended therapies. Treatment of conventional cutaneous anthrax is continued until the local edema disappears or the lesion dries up, that is, for 7 to 14 days. After resolution of the edema, penicillin therapy may be switched to the oral route to complete the treatment course. Because a strain of *B. anthracis* had been produced overseas that was resistant to multiple antibiotics (penicillin, doxycycline, chloramphenicol, macrolides, and rifampin) ciprofloxacin was the drug of choice recommended for initial postexposure prophylactic therapy in the 2001 American episode. [9] Isolates from that outbreak were found susceptible to ciprofloxacin, doxycycline, imipenem, chloramphenicol, clindamycin and rifampin, but resistant to extended-spectrum cephalosporins. Although susceptible to penicillin in vitro, these isolates produced an inducible beta-lactamase resistant to beta-lactamase inhibitors. Thus, the most recent recommendations for treatment of inhalation anthrax involve the initial use of ciprofloxacin or doxycycline plus one or two additional antibiotics with known activity against *B. anthracis.* [5], [10] Current treatment of cutaneous anthrax in adults in the setting of bioterrorism involves the use of ciprofloxacin (500 mg po bid) or doxycycline (100 mg po bid) for 60 days because of the possibility of simultaneous exposure to inhalation anthrax. [10] Incision and débridement of the cutaneous lesion should be avoided because this increases the opportunity for bacteremia. The disease does not appear to impart permanent immunity. Two types of vaccine are available for immunization against anthrax. [6] The first vaccine is licensed for human use in the United States to protect workers in occupations that might expose them to *B. anthracis;* it has been given to members of the armed forces of the United States since 1998. The vaccine is a sterile culture filtrate (primarily PA) of an attenuated strain of *B. anthracis* adsorbed to an aluminum hydroxide adjuvant and administered in 6 doses over 18 months. The second vaccine is for immunization of livestock against anthrax and consists of viable spores of an attenuated, nonencapsulated, toxigenic strain.

COURSE AND PROGNOSIS Rapid defervescence and clinical improvement follow the institution of appropriate antibiotic therapy. In inhalational, intestinal, septicemic, and meningeal anthrax the prognosis has been exceedingly grave. Whereas the mortality rate from inhalational anthrax had been approximately 90 percent in the past, it was only 40 percent in the 2001 bioterrorism-associated outbreaks, probably reflecting early diagnosis and treatment. [5]

Brucellosis

Brucellosis is an acute or chronic infection (caused by any one of four species of the genus *Brucella*) transmitted to humans from contact with animals or animal products. Such infections may be acute with bacteremia, or chronic with a variety of symptoms and signs.

BACTERIOLOGY AND PATHOGENIC ASPECTS

Bacteriology The brucellae are nonmotile, coccobacillary gram-negative rods that require enriched media and an atmosphere containing 8 to 10 percent CO_2 for optimal growth.

Pathogenic aspects The common portal for these organisms is ingestion of contaminated unpasteurized milk or cheese. Also, contact with infected animals or contaminated excretions may allow organisms to enter through small skin abrasions. Inhalation of droplets occurred among abattoir workers. The organisms can multiply intracellularly in a variety of tissues and produce acute symptoms. They may persist within cells for prolonged periods, leading to chronic brucellosis.

EPIDEMIOLOGY Domestic animals are the reservoir of brucella; humans are infected primarily by direct contact with animal material or by ingestion of raw milk or unpasteurized cheese. In the past, most infections in the United States were due to *B. abortus* secondary to contact with infected cattle. More recently, 70 percent of blood culture isolates from meat-processing-plant employees with brucellosis have been *B. suis.* [11] Another important group of patients with brucella infection are travelers who were infected in endemic areas (countries of the Mediterranean littoral, the Middle East, Mexico) through ingestion of unpasteurized cow's or goat's milk or cheese. In recent years, *B. canis,* a *Brucella* species that produces abortion or prostatitis and epididymitis in dogs, has been recognized as a cause of infection in individuals (pet owners, veterinarians) in contact with infected canines.

CLINICAL MANIFESTATIONS

History In the majority of cases, contact with animals or their products is an essential feature of the history. The incubation period is usually 1 to 3 weeks, followed either by an acute febrile illness with headache (sometimes with involvement of liver, joints, or meninges) or an indolent disease with weakness, anorexia, and low-grade fever, which may persist for weeks or months. *Brucella* involvement of the spine is not infrequent. Rarer forms of infection include suppurative lymphadenitis and endocarditis. [11] Unlike adults, children frequently exhibit skin rashes, pharyngitis, and enlarged nodes. Relapses occur in approximately 15 percent of patients. They are often associated with less-effective antibiotics, positive blood cultures, and treatment begun too early to allow cell-mediated immunity to develop. [12]

Cutaneous lesions Characteristic cutaneous lesions have been described, especially in children, usually associated with bacteremic disease. The most frequently observed rash is a violet, erythematous, papulonodular eruption that is located primarily on the trunk and lower extremities. Other lesions have included erythema nodosum, purpura, and macular and papular eruptions, some extending into subcutaneous fat and producing a panniculitis. Histology may show dermal perivascular infiltration with histiocytes and lymphocytes arranged into pseudogranulomas. Skin cultures may be positive. [13] Rarely, subcutaneous abscesses or cutaneous sinus tracts may develop as a result of extension of suppuration from infected lymph nodes or sites of osteomyelitis, or following introduction of organisms through a skin abrasion. A severe hypersensitivity reaction to brucella antigen may occur among veterinarians and animal handlers, and may manifest as an acute febrile reaction and the appearance of discrete, elevated, red papules on the hands or arms

that may progress to ulceration.
Other physical findings Among the characteristic findings are lymphadenopathy, hepatosplenomegaly, suppurative arthritis, and evidence of osteomyelitis or spondylitis.
LABORATORY FINDINGS The white blood cell count is usually normal or depressed, and anemia is frequently present. Blood cultures may be positive during the acute illness. Histologically, lesions in the liver, spleen, and other organs consist of small, noncaseating granulomas. Rarely, larger areas with caseation necrosis and calcification occur in infections due to *B. suis*.
DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS The diagnosis is usually based upon epidemiologic information (animal contact), cultures (blood, bone marrow, organ granulomas), and rising serum agglutination titer. A titer of greater than 1:160 should raise the possibility of this disease and warrant repetition of the test 7 to 14 days later. *B. canis* will not be detected by the routine agglutination test for *Brucella* spp. The antibody response to brucella infection is initially that of IgM followed by IgG antibodies. The IgM response may last for many months up to several years, but the IgG antibodies decrease rapidly following antimicrobial therapy. In patients with chronic symptomatology, the presence of IgG antibodies indicates continuing or recrudescent active infection. [11] Recently, use of IgM and IgG ELISA has suggested that they are very sensitive methods for detecting antibody to *Brucella* and that a secondary increase in IgG, but not IgM, ELISA occurs in patients undergoing clinical relapse. [14] Cross-reactions with *Francisella tularensis* occur uncommonly, and vaccination within the year for cholera may stimulate a brucella agglutinin titer. The differential diagnosis includes other acute bacterial infections such as salmonellosis, listeriosis, tuberculosis, and endocarditis. Hodgkin's disease may mimic many of the findings of brucellosis. Vertebral osteomyelitis may sometimes be the primary or sole manifestation of brucellosis.
TREATMENT Use of antimicrobials that penetrate into cells and treatment prolonged for 6 weeks constitute optimum therapy. The “gold standard” consists of a combination of doxycycline and either streptomycin or gentamicin. Equally effective results have been recorded with the combination of doxycycline and rifampin.
COURSE AND PROGNOSIS Early treatment results in rapid improvement. Brucellosis relapses in approximately 10 to 15 percent of patients who are treated suboptimally.

Erysipeloid

Erysipeloid is an acute infection of traumatized skin caused by *Erysipelothrix rhusiopathiae,* occurring most frequently in fishermen, butchers, and others, such as housewives, who handle raw fish, poultry, and meat products. [15]

BACTERIOLOGY *E. rhusiopathiae* is a thin, gram-positive, microaerophilic, nonmotile bacillus that is hardy enough to survive drying, putrefaction of tissue, and saltwater or freshwater exposure. [15] Growth occurs best on media fortified with serum at temperatures between 30°C and 37°C (86°F and 98.6°F) and in an atmosphere of 5 to 10 percent CO_2.
EPIDEMIOLOGY *E. rhusiopathiae* is the cause of a cutaneous and systemic infection of swine. It is present in rats and birds and in the slime of saltwater fish, on crabs and other shellfish, or associated with poultry, meats, hides, and bones. Occurrence of the disease is limited almost exclusively to persons handling contaminated products, primarily during summer months. Usually the organisms are inoculated through a break in the skin of the hands. Human infection takes one of four clinical forms: (1) localized cutaneous infection (erysipeloid); (2) diffuse cutaneous form, consisting of multiple serpiginous lesions with sharply defined borders; (3) subacute bacterial endocarditis; or (4) bacteremic form without endocarditis, usually in immunocompromised patients. [16] The disease does not seem to confer lasting immunity.
CLINICAL MANIFESTATIONS
History Usually the patient is employed in fishing or animal product industries. The incubation period is 2 to 7 days. Initially, there is burning pain at a site of injury. A violaceous, raised area appears and enlarges. Lymphangitis and regional lymphadenopathy occasionally occur. Constitutional symptoms include low-grade fever and malaise. Occasionally, an adjacent joint is involved. Rarely, bacteremia, and even endocarditis, may follow. [17]
Cutaneous lesion The distinctive “erysipeloid” lesion is usually on a finger or hand, is violet or purple-red in color, warm and tender, and has well-defined, raised margins (Fig. 199-2). As the lesion advances peripherally, the central region clears without desquamation or ulceration. [18] Rarely, dissemination occurs with multiple lesions distant from the original site of injury. Brownish discoloration develops as the lesion resolves.

FIGURE 199-2 Erysipeloid. Characteristically, the violaceous sharply marginated lesion is composed of macules and plaques and is localized on the hand.

Other physical findings Arthritis may be associated with the local lesion, and, rarely, distant joints are involved. Bronchitis may follow inhalation of organisms. Conjunctivitis also occurs. Typical peripheral stigmata, as well as cardiac findings of endocarditis or septicemia, have been reported, including prosthetic valve involvement. [15], [17]
LABORATORY FINDINGS There are no characteristic findings, and the organism is seldom seen on Gram-stained material from the surface of the lesion or from aspirated material. Culture of a biopsy from the advancing edge of the lesion may reveal the organism.
PATHOLOGY Dilatation of vessels in the papillary and subpapillary areas and perivascular cellular infiltrates deep in the

dermis are present. The depth of the process may explain why organisms are rarely seen or cultured from the lesion.
DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS The character of the local lesion in a person handling fresh meat or fish products suggests the diagnosis. Other forms of bacterial cellulitis or erysipelas may be confused with erysipeloid. Erysipelas is very superficial with a raised border, there is only moderate pain, and the central area remains the most affected region compared to central clearing in erysipeloid. “Seal finger” may be mistaken for erysipeloid, but there is a history of a recent seal bite or contact. In addition to cultures, the diagnosis can be confirmed by using agar-gel diffusion precipitation or fluorescent antibody. [15]
TREATMENT Penicillin, in doses of 2 to 3 million units daily, orally or ntramuscularly, for 7 to 10 days, is the treatment for erysipeloid. In the penicillin-allergic patient who has not had anaphylaxis or angioedema, a third-generation cephalosporin, imipenem, or ciprofloxacin can be given. This recommendation is based primarily on in vitro studies, not clinical experience. [19] If arthritis, septicemia, or endocarditis is present, the dose of penicillin should be raised to 2 to 4 million units every 4 h, administered intravenously (for 4 weeks in the case of endocarditis). Vancomycin should not be used because most isolates are resistant.
COURSE AND PROGNOSIS In the untreated patient, the lesion usually lasts for 2 to 3 weeks but may persist, with cycles of improvement and worsening over several months. If penicillin is administered, the improvement is dramatic and recurrence is rare. In systemic infection, prognosis depends on early and appropriate treatment.

Glanders

Glanders is an equine disease caused by the bacterium *Burkholderia mallei* (formerly *Pseudomonas mallei*) and is rarely transmitted to humans. The clinical picture takes one of two forms: (1) an acute, febrile, disseminated, infectious process whose entire course may encompass only 10 to 30 days; or (2) an indolent, relapsing, chronic infection, with multiple cutaneous and subcutaneous abscesses and draining sinuses. “Farcy,” the name given to the disease in horses, refers to the nodular subcutaneous abscesses occurring along the course of lymphatics. Control measures have nearly eradicated this previously common equine infection and eliminated transmission to humans in the United States. Occasional cases still occur in Asia, Africa, and South America. Humans are infected by direct contact with horses. *B. mallei* has long been considered an ideal agent for biologic warfare because of the contagiousness and severity of glanders and has been studied in laboratories worldwide. The first case of human glanders in the United States in more than 50 years was reported in a microbiologist at an Army Research Laboratory who developed axillary lymphadenopathy and bacteremic infection with hepatic and splenic abscesses. [20]

In acute glanders, a nodule or cellulitis appears at the site of inoculation. Local swelling and suppuration occur, and the lesion ulcerates. The ulcer is painful and has irregular edges with a gray-yellow base. Nodular sores rapidly develop along lymphatics draining the lesion; they become necrotic and ulcerated, and sinuses form. Regional lymphadenopathy is present. Widespread dissemination quickly follows, with multiple nodular necrotic abscesses in subcutaneous tissues and muscle. Lesions frequently coalesce into gangrenous areas. During bacteremic spread, a characteristic eruption appears, which may be generalized or localized to the face and neck. Papules, bullae, and pustules appear in crops. Involvement of the nasal mucosa, either initially or by secondary spread, is prominent. Mucopurulent, bloody nasal discharge is commonly noted. Infection may spread to the paranasal sinuses, pharynx, and lung.

In chronic glanders, cutaneous and subcutaneous nodules appear on the extremities and occasionally on the face. The lesions ulcerate, and draining sinuses develop. Ulceration of the hard palate and perforation of the nasal septum can occur.

The pathologic picture is that of a suppurative, necrotic process, containing numerous intracellular and extracellular bacteria. In the chronic form of glanders, a granulomatous process is usually observed.

The diagnosis is made on the basis of the epidemiologic background, examination of Gram-stained smears of pus, and isolation of the organism from abscesses or blood. Acute glanders may resemble miliary tuberculosis or typhoid fever during the initial stages. The multiple subcutaneous abscesses suggest staphylococcal or mycotic infections or melioidosis. Lymphatic nodularity resembles the lesions of *Mycobacterium marinum, Sporothrix schenckii,* and *Francisella tularensis*.

There are almost no data on the antimicrobial treatment of glanders, because the disease largely had disappeared by the antibiotic era. In vitro data indicate susceptibility to ceftazidime, gentamicin, doxycycline, imipenem, and ciprofloxacin. [21] The most recent case of glanders responded well to a combination of imipenem and doxycycline. [20]

Streptobacillus moniliformis Infection (Rat-bite Fever)

Rat-bite fever is an acute infection that is usually acquired from rodents and is characterized by fever, polyarthralgias or arthritis, and a rash. [22]

BACTERIOLOGY *S. moniliformis* is a gram-negative, pleomorphic bacillus. Growth in culture occurs as chains of bacilli and filamentous forms, interspersed with swollen bodies that look like *Candida* (*Monilia*), hence the name *moniliformis*. In blood cultures these microaerophilic organisms typically grow as small “puff balls.” On occasion, growth may occur as an L form on initial culture.
EPIDEMIOLOGY *S. moniliformis* is found in the nasopharynx of wild and laboratory rats. In recent years, the latter have been an increasing source of infection. Infection may also occur following ingestion of contaminated food. One such milk-borne outbreak occurred in Haverhill, Massachusetts, 75 years ago, and this illness was designated “Haverhill fever” (erythema arthriticum epidemicum). [23]
CLINICAL MANIFESTATIONS
History The incubation period averages 1 to 5 days. The rat bite has often healed by the time the illness begins suddenly with fever, chills, headache, and myalgias.
Cutaneous lesions An erythematous macular or papular rash may develop within 2 to 3 days of the onset of symptoms.

It is most marked on the extremities (often involving palms and soles), particularly about joints, but may become generalized, resembling measles. Sometimes the lesions are petechial.
Other physical findings Within a week of onset arthritis can develop, involving larger joints such as the knee. This takes the form of either an asymmetric polyarthritis, resembling rheumatoid arthritis, [24] or a septic arthritis. Regional lymphadenopathy may be present.
LABORATORY FINDINGS Polymorphonuclear leukocytosis is common. *S. moniliformis* can usually be isolated from blood or joint fluid, or sometimes from an abscess developing at the bite site. Serologic diagnosis involves use of agglutination, fluorescent antibody, or complement fixation tests.
DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS The diagnosis should be suspected in any febrile patient with a history of a recent rat bite. Blood cultures are the best way to establish the diagnosis. The other form of rat-bite fever (*Spirillum minus*) (sodoku) may cause a similar illness, but several features are helpful in distinguishing between the two conditions: [22] *S. moniliformis* infection has a shorter incubation period (usually less than 10 days); the bite site has usually healed by the time of onset of fever in *S. moniliformis* infection; and the incidence of arthritis is low in *S. minus* infection. The differential diagnosis should also include meningococcemia, gonococcemia, viral exanthems, and Rocky Mountain spotted fever.
TREATMENT Penicillin, 600,000 units intramuscularly every 6 h for 10 to 12 days, is the drug of choice. Doxycycline, erythromycin, or clindamycin are alternatives in the penicillin-allergic patient.
COURSE AND PROGNOSIS Untreated, the disease may last from a few days to several weeks. Rarely, it is complicated by endocarditis. Penicillin produces a prompt clinical response.

Infections Caused by *Streptococcus iniae*

S. iniae is a recently recognized fish pathogen that causes cellulitis and invasive infections in individuals handling fish from aquaculture farms. [25]

BACTERIOLOGY *S. iniae* is a beta-hemolytic, nongroupable, streptococcus capable of growth at 10°C (50°F) [but not at 45°C (113°F)]; most isolates do not grow in 6.5% sodium chloride.
EPIDEMIOLOGY *S. iniae* infection occurs in the setting of percutaneous injury while handling fresh aquacultured fish, particularly tilapia (Hawaiian sunfish). *S. iniae* colonizes the surface of aquacultured fish and can cause epizootic meningoencephalitis in cultured-fish ponds.
CLINICAL MANIFESTATIONS
History Cellulitis is initiated by a skin puncture wound while preparing fresh fish from aquaculture ponds. Most reported cases have been in individuals of Asian origin, perhaps related to the volume of tilapia consumed by this population.
Cutaneous lesions Characteristically, cellulitis involves the hand and develops within 16 to 24 h after injury. Neither skin necrosis nor bullae occur, but lymphangitis extending from the site of injury and fever are early features.
Other physical findings Bacteremia is frequent with *S. iniae* cellulitis. Metastatic infections may occur in the form of septic arthritis, meningitis, and endocarditis. [25]
LABORATORY FINDINGS Leukocytosis is usually present, with neutrophils predominating.
DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS Diagnosis is made on the basis of the setting, clinical findings, and cultures of blood or wound exudate. The common causes of cellulitis (*S. pyogenes, Staphylococcus aureus*) as well as other freshwater and fish-borne pathogens (*Aeromonas hydrophila*) should be considered in the differential diagnosis.
TREATMENT *S. iniae* is susceptible to penicillin, cefazolin, ceftriaxone, erythromycin, clindamycin, and trimethoprim-sulfamethoxazole (TMP-SMX).
COURSE AND PROGNOSIS With prompt initiation of an appropriate antibiotic, the infection responds within 2 to 4 days. Treatment is continued for 10 days for the cellulitis/bacteremia, and longer if extracutaneous complications are present.

DISEASES ASSOCIATED PRIMARILY WITH A SPECIFIC GEOGRAPHIC DISTRIBUTION

Melioidosis

Melioidosis is an infectious disease of animals and humans, endemic in Southeast Asia but also occurring in Africa, the Caribbean, South America, and the Middle East, between 20° north and south latitudes, and caused by the gram-negative bacillus *Burkholderia pseudomallei* (formerly *Pseudomonas pseudomallei*). [26] Apart from rare laboratory-acquired infections, melioidosis has occurred in only those United States residents who have traveled abroad. During the war in Vietnam, extensive exposure to this organism resulted in cases of melioidosis among American servicemen. The clinical manifestations of the disease take one of two principal forms: (1) acute melioidosis with suppurative skin infection, pneumonia, or septicemia; or (2) chronic melioidosis, the most common form of the disease, which involves the lung (unresolved pneumonia or cavitary lesions), skin (subcutaneous abscesses and draining sinuses), bones, joints, liver, and spleen.

BACTERIOLOGY The etiologic agent is a small, pleomorphic, gram-negative bacillus with bipolar staining that can be grown aerobically on common laboratory media.
EPIDEMIOLOGY The etiologic agent of melioidosis can be isolated widely from soil, vegetables, and water in the rice-growing areas of Southeast Asia. Melioidosis appears to be transmitted by contamination of abraded skin with infected soil or water. [27] The prominence of pulmonary findings in many patients, and of diarrhea in some, suggests that it may be transmitted by inhalation or ingestion.
CLINICAL MANIFESTATIONS
History The incubation period is variable. It has been as short as 3 days, and the disease has also remained latent for years. The acute pneumonic form may begin with a short prodrome (malaise, anorexia, and diarrhea), but more commonly its onset is abrupt, with chills, fever, cough, dyspnea, and chest pain. The acute septicemic form may start with an ulceration at the site of inoculation, lymphangitis, and regional lymphadenitis. In northeastern Thailand, septicemic melioidosis occurs mainly in the rainy season, primarily in rice farmers. Predisposing factors are present in approximately 50 percent of patients and include diabetes mellitus and renal failure, as well as glucocorticoid therapy, leukemia, cirrhosis, and tuberculosis. In half the patients, no source for the bacteremia can be identified, but many have minor abrasions about the feet. [28] Chronic melioidosis may follow the acute disease. More often it develops as an indolent

pulmonary infection or as a low-grade febrile illness with multiple superficial abscesses. Recrudescence of a previous latent or clinical infection months or years after initial exposure to the organism may be precipitated by various subsequent illnesses (e.g., thermal burns, diabetic ketoacidosis) and may take the form of localized infections such as splenic abscess, osteomyelitis, subcutaneous abscesses, or lung abscess, as well as septicemia. It may also take the form of persistent, unexplained fever. [29]

Cutaneous lesions Cutaneous manifestations are not a specific or diagnostic feature of melioidosis. The acute septicemic form may complicate a superficial ulceration and cellulitis. Multiple superficial pustules may be present or, rarely, ecthyma gangrenosum. In chronic melioidosis, subcutaneous abscesses and draining sinuses are common.

Other physical findings In acute pulmonary melioidosis, the findings range from those of bronchitis to those of acute pneumonia or lung abscess. Septicemic spread of the disease leads to jaundice, hepatosplenomegaly, miliary pulmonary densities, myocarditis, and severe gastroenteritis. Chronic pulmonary melioidosis produces signs suggestive of fibrocavitary tuberculosis or lung abscess. The disseminated form of chronic disease may extend over many months with septic arthritis, osteomyelitis, suppurative lymphadenopathy, and visceral abscesses. In Thailand, acute suppurative parotitis is a common form of localized melioidosis in children.

LABORATORY FINDINGS The peripheral white blood cell count is usually normal or only moderately elevated. By histopathology, sharply circumscribed abscesses are found in many organs and in the subcutaneous tissues. There may be a surrounding granulomatous response.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS The disease is a great imitator. Acute melioidosis may mimic typhoid fever, staphylococcal pneumonia, mycotic infections, or septicemia. In its chronic form, it must be differentiated from pulmonary tuberculosis, nocardiosis, fungal infections, and lung abscess. Chronic skin infections and draining sinuses in individuals from endemic areas should raise the possibility of melioidosis. The diagnosis is suspected on epidemiologic grounds and on the finding of bipolar-stained gram-negative bacilli in exudates or pus. Culture of the organism establishes the etiology. Hemagglutination, direct agglutination, and complement-fixation tests are helpful when a rise in titer is demonstrated. A positive serologic test, in the absence of a rising titer, may suggest the diagnosis but it is not definitive. The indirect hemagglutination assay (IHA) is the most commonly used test in Southeast Asia because it is simple to perform and cheap. An IHA titer of >1:80 is 80 to 90 percent sensitive and specific in the diagnosis of active melioidosis, but titers of 1:40 to 1:60 are frequently found in healthy individuals in endemic areas. [27]

TREATMENT Antibiotic susceptibility must be determined on each isolate. Most strains of *B. pseudomallei* are susceptible to some of the newer antibiotics in vitro: ceftazidime, piperacillin-tazobactam, imipenem, and amoxicillin-clavulanic acid. A recent multicenter clinical trial in Thailand, comparing ceftazidime with amoxicillin-clavulanate favored the former. [30] The combination of ceftazidime plus TMP-SMX is the initial therapy of choice. Surgical drainage of abscesses should be carried out, but only after initiation of appropriate antimicrobial therapy, in order to avoid a sudden septicemic episode. Antimicrobial treatment should be continued for from 6 to 20 weeks (the longer periods in the case of osteomyelitis or multiple suppurative foci). Following an initial period of intravenous therapy, amoxicillin-clavulanic acid is continued orally.

COURSE AND PROGNOSIS The mortality rate in melioidosis depends on the clinical form of illness: [30] (1) in disseminated septicemic melioidosis (with shock and evidence of dissemination to skin and viscera), it is approximately 50 percent; (2) in nondisseminated septicemic melioidosis it is 17 percent; and (3) in localized melioidosis (nonbacteremic slowly progressive focal infection), it is 9 percent.

Plague

Plague is a severe, acute, febrile infection in humans caused by *Yersinia pestis*. Transmission between the reservoir of this disease (wild and commensal rodents) and human beings is effected by fleas. Infection occurs in three forms: (1) bubonic plague; (2) bubonic-septicemic plague (a more acute and severe form of bubonic plague with bacteremia and delirium); and (3) pneumonic plague (fulminant form of infection resulting from respiratory spread of *Y. pestis*). [31]

BACTERIOLOGY *Y. pestis* is an aerobic gram-negative bacillus with “safety-pin” bipolar staining. It produces an intracellular toxin (plague toxin) that is plasmid-encoded and an important virulence factor. Two other plasmids encode other virulence factors. One mediates the “low calcium response,” which occurs when *Y. pestis* is transferred from the lower temperature of the flea to the 37°C (98.6°F) host whose intracellular (leukocytic) environment has a relatively low Ca^{2+} concentration, and which initiates synthesis of virulence factors. [32] The second plasmid encodes temperature-dependent coagulase and fibrinolysin activities, which also serve as virulence factors. Most strains produce an antiphagocytic capsule, and all have a potent cell envelope–associated lipopolysaccharide.

EPIDEMIOLOGY Endemic (sylvatic) plague is firmly established among wild rodents in the western United States. In this country, human plague is almost always flea borne and is usually of the bubonic type. Between 1956 and 1983, more than 200 cases of plague were reported in the United States. Most occurred during the warmer months and were transmitted by flea bites. “Off-season” (October to February) plague occurs during rabbit-hunting season in the western states and is associated with direct contact (skinning, dressing) with animal (rabbits, bobcats) carcasses. In recent years, epizootics have occurred among prairie dogs in the southwest, and sporadic human cases have been identified on several Indian reservations. Plague has also been transmitted by domestic cats via bites, scratches, or aerosol. Infected fleas can be carried significant distances and into households. Domestic dogs have become infected in endemic areas, but no human cases have resulted. The disease is also endemic in Vietnam and Africa. Rarely, plague pneumonia secondary to bacteremia complicating bubonic plague may initiate respiratory spread to other persons.

CLINICAL MANIFESTATIONS

History The incubation period is approximately 1 to 6 days, followed by the sudden onset of malaise, myalgias, backache, tachycardia, and high fever.

Cutaneous lesions In bubonic plague, the initial skin manifestation is related to the flea bite. Usually this cannot be seen, but occasionally, a small papule or vesicopustule persists. Painful, tender, enlarged lymph nodes are present in the area draining the bite site. The nodes become matted (buboes), and there is extensive surrounding subcutaneous gelatinous edema. Bacteremia may lead to overwhelming systemic illness. Petechiae and ecchymosis often occur because of the effects of plague toxin or because of the development of a disseminated intravascular coagulopathy. Eschars and ecthyma gangrenosum can complicate systemic disease or appear at the site of the flea bite. [31], [33]

Other physical findings Chills, fever, headache, and hypotension of septicemic plague are similar to those of gram-negative bacillemia. Abdominal pain is a feature of almost half the cases. [34] The onset of pneumonic plague is

abrupt, with high fever, tachycardia, and tachypnea. Signs of consolidation may appear, and within 24 h of onset, the patient is critically ill, raising bloody sputum loaded with *Y. pestis.* Meningitis may complicate all three forms of plague.
LABORATORY FINDINGS Leukocytosis occurs in all forms of the disease. In septicemic plague, bacilli can sometimes be seen on stained smears of venous blood (buffy coat). Histopathologically, in the bubonic form, acute inflammatory changes are seen in the involved nodes.
DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS Bubonic plague should be distinguished from tularemia, lymphogranuloma venereum, cat-scratch disease, Eastern Hemisphere spotted fever, and suppurative lymphadenitis. Plague pneumonia must be differentiated from other acute bacterial pneumonias. Epidemiologic considerations and the tempo of the illness are major points in the differential diagnosis. The diagnosis is firmly established by examination of Gram-stained (or specific fluorescent antibody-stained) smears of infected material and by culture of the organism from blood, sputum, or aspirated buboes. Serologic methods can be used for retrospective diagnosis through demonstration of a fourfold or greater rise in titers. A convalescent passive hemagglutination titer of >1:16 is strongly suggestive of the diagnosis.
TREATMENT Streptomycin is the drug of choice, administered intramuscularly (2 g daily in divided doses in the adult) for 10 days. Chloramphenicol or tetracycline are alternatives, or may be added initially as strains resistant to streptomycin have been recovered. Preliminary results suggest that gentamicin may be effective. Strict isolation of pneumonia cases is essential to prevent spread via the respiratory route. Ordinarily, buboes should not be drained until the lesion is well localized and the patient has been treated with antibiotics.
COURSE AND PROGNOSIS Pneumonic and septicemic plague, if untreated, are almost invariably fatal. Untreated bubonic plague has a mortality rate of 30 to 70 percent. Early antibiotic therapy has reduced the mortality rate to 5 to 10 percent.

DISEASES ASSOCIATED WITH RANDOM ANIMAL CONTACT INDEPENDENT OF GEOGRAPHIC OR OCCUPATIONAL CONSIDERATIONS

Francisella tularensis Infections (Tularemia)

Tularemia is a disease of humans caused by *F. tularensis,* an organism that normally resides in a wide range of animal species and their immediate environments. In humans, most cases follow direct animal contact or transmission by insect vectors. The clinical manifestations fall into eight major patterns: glandular, ulceroglandular (most common form), chancriform, oculoglandular, typhoidal, pulmonary, oropharyngeal, and meningeal.

BACTERIOLOGY *F. tularensis* is a pleomorphic, gram-negative coccobacillus that grows best on cysteine blood agar or in thioglycollate heart infusion medium. Intracellular parasitism of the reticuloendothelial system of humans and experimental animals is characteristic.
EPIDEMIOLOGY Infection in humans, particularly among hunters, most commonly follows contact with infected rabbits but may follow exposure to foxes, squirrels, skunks, and pheasants. Aquatic animals (muskrats, beavers) and mud and water from streams may also be a source of infection. The organisms are commonly introduced through a minimal abrasion or puncture wound or by bites of infected deerflies or ticks that are responsible for maintaining the disease in animals. [35] Domestic cats may spread the organism via direct contact, bite, or aerosol. Rarely, ingestion of meat or conjunctival contamination leads to infection.
CLINICAL MANIFESTATIONS
History After an incubation period of 2 to 10 days, the onset of any of the forms of disease is characterized by headache, malaise, myalgias, and high fever. A primary lesion develops at the site of inoculation, accompanied by regional adenopathy. Tick-transmitted disease frequently occurs on the head or trunk or may be transmitted to the conjunctivae by careless handling of an engorged arthropod.
Cutaneous lesions In ulceroglandular tularemia, a reddish, tender, painful papule appears at a site of trauma or arthropod bite. Lesions are usually found on a finger or hand. A small vesicular pustule may develop, and the area rapidly enlarges and becomes necrotic. Nodular lymphangitis may complicate the initial lesion. The lesion then evolves to an ulcer with raised margins, often covered by a black eschar, which later is shed. It appears chancre-like (Fig. 199-3). Regional nodes are enlarged and tender. Systemic signs of toxicity may be marked and pneumonia may accompany dissemination of infection. A macular and papular or petechial exanthem, erythema nodosum, and erythema multiforme are occasional manifestations.

FIGURE 199-3 Tularemia. A chancre-like ulcer with raised margins on the dorsum of the fourth digit with accompanying axillary lymphadenopathy. The rash on the chest is unrelated and is pityriasis versicolor.

In oculoglandular tularemia, the organism is directly introduced via the conjunctivae. The findings are those of a purulent conjunctivitis with marked pain, edema, and congestion. Small yellow nodules may appear on the conjunctivae and ulcerate. Preauricular and submaxillary adenopathy are prominent.
Other physical findings Splenomegaly and generalized lymphadenopathy are relatively common, and hepatomegaly may occur. Ulcerative or exudative pharyngotonsillitis with cervical lymphadenopathy may follow ingestion of the organism, which may also be associated with the “typhoidal” form of the disease. Tularemic pneumonia may occur occasionally following inhalation of organisms but is more often secondary to bacteremia. Pleural effusion and mediastinal node enlargement are sometimes evident. Meningitis can occur.
LABORATORY FINDINGS The white blood cell count is normal or low, but a polymorphonuclear leukocytosis may be seen. Blood cultures are only rarely positive. [36]
PATHOLOGY The pathogen survives intracellularly in phagocytes, and small granulomatous lesions develop in lymph

nodes, liver, and spleen. Some of the lesions may caseate, progress to frank abscess formation, or become necrotic.
DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS The primary lesion resembles a furuncle, paronychia, ecthyma, the initial lesion of anthrax, *Pasteurella multocida* infection, or sporotrichosis. The prominent regional adenopathy suggests cat-scratch disease, plague, melioidosis, or Eastern Hemisphere spotted fever. A febrile illness occurring after a tick bite might suggest Rocky Mountain spotted fever, but an exanthem is usually present in that condition, without a local chancriform lesion. A febrile illness with hepatomegaly and granulomas (on liver biopsy) resembles tuberculosis, brucellosis, or other causes of granulomatous hepatitis. Isolation of *F. tularensis* from tissues and blood requires special media and is difficult to accomplish. The diagnosis is usually made by serologic (agglutination or microagglutination) tests showing a fourfold or greater rise in titer. Cross-reactions occur in brucellosis.
TREATMENT Streptomycin (1.0 to 2.0 g intramuscularly per day in adults) is curative in all forms of tularemia if administered early in the course of the disease. Gentamicin appears to be an acceptable alternative. [37] Clinical improvement is evident within 24 to 48 h, but treatment should be continued for at least 7 to 10 afebrile days. Tetracycline and chloramphenicol are alternative drugs, but clinical relapses are more frequent, particularly if given for less than 14 days.
COURSE AND PROGNOSIS Untreated, the course may be weeks. Prior to the use of antibiotics, the mortality rate was about 5 percent in ulceroglandular disease and about 30 percent in typhoidal and pulmonary forms. Recovery provides immunity to systemic tularemia, but reinfection may produce a recurrent primary ulcer.

Leptospirosis

Leptospirosis is an acute febrile illness caused by any one of the serovarieties (serovars) of the species *Leptospira interrogans*. Although specific serovars have been reported with specific syndromes (canicola fever, Weil's disease, pretibial fever), any serovar may be responsible for a variety of clinical pictures, and a given clinical picture may be produced by many different serovars. [38], [39]

BACTERIOLOGY These organisms are spirochetes that can be cultured on special (Fletcher semisolid) media. More than 200 antigenically different serotypes have been described. They are now defined as serovarieties of the species *L. interrogans*. Thus, for example, a specific antigenic serotype would bear a designation such as *L. interrogans* serovar *canicola*. The most common serovars in the United States are *canicola, icterohaemorrhagiae, pomona, autumnalis,* and *grippotyphosa*.
EPIDEMIOLOGY The reservoir of leptospira is worldwide in the animal population: farm animals (cattle, swine); laboratory animals (mice); domestic animals (hamsters, dogs); wild animals (squirrels, rats); and reptiles. Infection in humans occurs as a result of direct contact with an animal (either a sick animal or an asymptomatic urinary “shedder”) or indirectly through contaminated water or soil. This is especially important considering travels to exotic places, and the risk of entering contaminated water to “cool off.” [40] Organisms usually enter the body through a break in the skin or, less often, through mucous membranes (including conjunctiva). The disease is most prevalent among children (from playing in contaminated puddles or ponds), farmers, hunters, or abattoir workers.
CLINICAL MANIFESTATIONS
History The incubation period is usually between 7 and 14 days, and the illness typically has a biphasic course. The onset is sudden, with headache, fever, chills, nausea, vomiting, abdominal pain, and myalgias. This initial nonspecific phase continues for about a week, when defervescence occurs. After several relatively asymptomatic days, the second phase of illness begins with low-grade fever. Meningeal symptoms may begin and persist for another 2 to 4 days or for several weeks. In the initial phase (leptospiremic), leptospiral organisms are present in the bloodstream, cerebrospinal fluid, and other tissues. The second (“immune”) phase coincides with the appearance of IgM antibodies. Clinically, this phase is characterized by the onset of meningitis, rash, uveitis, and, in more severe cases, by hepatic and renal involvement.
Cutaneous lesions Scleral conjunctival injection appears on the third or fourth day of illness. Skin lesions, usually on the trunk (consisting of macules, papules, urticaria, and petechiae), occur in fewer than 50 percent of cases. Peripheral desquamation and infarction of portions of the hands and feet have been observed in a few children with leptospirosis. [39] Weil's disease, often but not exclusively because of serovar *icterohaemorrhagiae,* is a form of infection with prominent hepatic (jaundice) and renal (hematuria, azotemia) involvement. Hemorrhagic manifestations occur in a variety of organs, including the skin. Pretibial (Fort Bragg) fever is a form of leptospirosis (serovar *autumnalis*) that has a rather distinctive rash occurring on the fourth or fifth day of illness and consisting of slightly raised, 1- to 5-cm, tender, erythematous lesions on the pretibial areas. [41] The rash subsides within 4 or 7 days. Erythema nodosum has occurred in association with infection caused by *L. interrogans*.
Other physical findings These depend on the particular syndrome that is presented: pyrexia of unknown origin with localizing signs lacking so that epidemiology is critical to diagnosis; aseptic meningitis—nuchal rigidity; Weil's disease—jaundice and hepatomegaly with interstitial nephritis; generalized hemorrhagic tendency with epistaxis, hematuria, and gastrointestinal bleeding; and pretibial fever with splenomegaly are common. In up to 20 percent of patients with leptospirosis, generalized lymphadenopathy may be observed. Pulmonary involvement with radiologically demonstrable infiltrates occurs rarely. In children, acalculous cholecystitis has been observed occasionally. Rarely, myocarditis occurs.
LABORATORY FINDINGS The white blood cell count varies from a leukopenia to a mild leukocytosis, and thrombocytopenia can occur. In Weil's disease, white blood cell count may reach levels of 40,000/mm^3. A cerebrospinal fluid pleocytosis, with up to several hundred mononuclear cells, may be present. Abnormalities of liver function are common. Azotemia and hematuria occur in patients with renal involvement, and jaundice is usually present.
DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS Skin manifestations are not specific but may suggest leptospirosis in the context of jaundice and aseptic meningitis. Conjunctival suffusion with petechiae or hemorrhages may be helpful clues. The differential diagnosis includes viral hepatitis, all the causes of a lymphocytic aseptic meningitis, nephritis, and the causes of a fever of unknown origin. The diagnosis is established most commonly by serologic means: a fourfold or greater rise in microagglutination titer (to >1:100), an IHA, or an IgM-specific dot-ELISA. [40] It can also be confirmed by isolation of the organism from blood during the first 10 days of illness. In a series of cases of leptospirosis among military personnel in Panama, leptospires were isolated from blood cultures of 23 of 29 patients studied. [42]
TREATMENT In a controlled trial in anicteric leptospirosis, doxycycline, when administered early in the course of the disease, proved effective, and it has been used successfully by the military as a prophylactic measure for short-term

exposure in a hyperendemic area. [43] Penicillin has also been recommended, but no controlled studies of its efficacy are available. The Jarisch-Herxheimer reaction has been reported in several patients who were treated with penicillin. [44]
COURSE AND PROGNOSIS Recovery is the rule in anicteric cases. In the presence of jaundice, the mortality rate may be as high as 40 percent, although a recent report describes 100 percent survival in 32 patients, only 14 of whom received adequate therapy. [40]

Pasteurella multocida Infections

Infections produced by *P. multocida* follow one of several patterns: local skin infection with adenitis following animal bites (the most common form of infection); septic arthritis and osteomyelitis following an animal bite (usually of the hand); respiratory tract infections or colonization; systemic infections such as meningitis, bacteremia, or spontaneous bacterial peritonitis. [45]

BACTERIOLOGY *P. multocida* is a small, ovoid, gram-negative rod. It grows readily on nutrient blood agar, but not on MacConkey agar.
EPIDEMIOLOGY Although this organism is primarily a pathogen among birds and animals, it occasionally infects humans. *P. multocida* can be isolated from the upper respiratory tract of healthy cats, dogs, rats, and mice. Animal exposure has occurred in 70 to 80 percent of patients with *P. multocida* bacteremia. Predisposing conditions (alcoholic cirrhosis, neoplastic disease, chronic obstructive pulmonary disease) could be identified in the majority of patients. [46]
CLINICAL MANIFESTATIONS
History Local pain and swelling occur within a few days of a cat or dog bite. There is little if any fever.
Cutaneous lesions Redness, swelling, ulceration, and seropurulent drainage develop at the bite site. Cellulitis may progress rapidly and extensively, with associated lymphangitis. Local necrosis and abscess formation may follow, and necrotizing fasciitis has been reported, accompanied by septic shock.
Other physical findings Regional adenopathy may be present. Complicating osteomyelitis and septic arthritis may occur as a result of the introduction of organisms beneath the periosteum or into a joint space by the biting animal.
LABORATORY FINDINGS Mild leukocytosis is present. After several weeks, an x-ray of underlying bone may show osteomyelitis. Histopathologically, an acute pyogenic response is seen.
DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS The diagnosis is suspected when a painful infection develops at the site of an animal bite. It must be distinguished from cat-scratch disease. Local ulceration and proximal lymphadenitis mimic ulceroglandular tularemia, but the lesion is characteristically a necrotizing cellulitis and not chancriform in appearance. The diagnosis is established by isolation of the organism.
TREATMENT Most strains of *P. multocida* are susceptible to penicillin, the drug of choice. In patients with simple cellulitis, oral penicillin (penicillin VK at 500 to 750 mg orally four times daily for adults), ampicillin, or amoxicillin-clavulanate may reasonably be used, but close follow-up is mandatory. If a prior animal bite is suspected to have penetrated deeply close to periosteum, parenteral penicillin should be administered until the local lesion is well healed. *P. multocida* is also susceptible to third-generation cephalosporins. For the penicillin-allergic patient, doxycycline is a suitable alternative. Chloramphenicol or TMP-SMX may be effective therapy for the rare patient unable to tolerate either penicillin or doxycycline. Ciprofloxacin has activity against *P. multocida* in vitro. Abscesses should be surgically drained.
COURSE AND PROGNOSIS The infection responds to local measures and antibiotic therapy.

UNCOMMON DISEASES IN WHICH ANIMAL OR WATER CONTACT OR CLIMATOLOGIC FACTORS MAY OCCASIONALLY BE RELEVANT

Listeria monocytogenes Infections (Listeriosis)

Infection with *L. monocytogenes* produces characteristic acute disease in infants (neonatal septicemia, meningitis, and septic granulomatosis) and in both healthy and immunosuppressed adults (septicemia, meningitis, vaginal infection, pneumonitis, and oculoglandular syndrome). [47]

BACTERIOLOGY *L. monocytogenes* is a small, thin, gram-positive rod that often appears coccoid in infected tissues and body fluids. The organism may resemble a chaining streptococcus, a diplococcus, or a diphtheroid. It is non–spore-forming, beta-hemolytic, and exhibits a characteristic tumbling motility when grown in broth at room temperature. This is the classic facultative intracellular bacterium against which host resistance is mediated by thymus-derived lymphocytes (and macrophages).
EPIDEMIOLOGY *L. monocytogenes* is found in the feces of many wild animals and birds, and in soil and vegetation. Approximately 5 percent of humans (this is probably a minimal figure as it is difficult to isolate the organism from stool) appear to be fecal carriers of the organism. Higher rates of carriage have been observed in family contacts of patients with listeriosis. Food-borne (unpasteurized or improperly pasteurized milk or cheese; coleslaw made from cabbage grown on a farm where sheep manure had been used as fertilizer) outbreaks have been described. [48] Sporadic cases of *Listeria* meningitis have occurred in immunocompromised individuals one or two days after gastroenteritis in which *L. monocytogenes* has been found in large numbers in the stool. The highest incidence of infections is in the perinatal period, suggesting that the fetus either becomes infected in utero or on passing through the birth canal. Many, but not all, adult cases occur on a background of altered cellular immunity (Hodgkin's disease, immunosuppression for organ transplantation, etc.) or cirrhosis. [49] Transfusional iron overload may also be a predisposing factor for listeriosis. *L. monocytogenes* produces a protein in culture supernatants that mobilizes iron from transferrin. [48]
CLINICAL MANIFESTATIONS
History and cutaneous lesions Neonatal listeriosis occurs in two clinical forms: early and late onset. Early onset neonatal listeriosis develops in infants infected in utero from mothers who were undergoing a bacteremic illness with nonspecific symptoms shortly before the onset of labor. Findings are evident at birth or become apparent within the first several days of life. Widespread granulomas (placenta, liver, spleen, lung, etc.) are characteristic of the syndrome known as *granulomatosis infantiseptica*. Neonatal infection would be suggested in an acutely ill, moribund infant who was meconium-stained at birth and who subsequently exhibited generalized pustular, papular, or petechial skin lesions. Late

onset neonatal listeriosis usually occurs several weeks after a normal birth, presumably resulting from postpartum acquisition. Meningitis rather than sepsis is the clinical picture. Listeriosis in the adult is not accompanied by skin lesions. Veterinarians may develop an acute febrile illness with headache, malaise, and tender, red papular lesions on the hands and arms, some of which evolve into pustules 2 to 3 days after handling infected bovine fetuses. Characteristic gram-positive rods can be demonstrated in these skin lesions. Tender axillary adenopathy is frequently present. In oculoglandular infection, there is acute conjunctivitis with preauricular adenitis.

Other physical findings In infants, meconium staining of the skin, hepatosplenomegaly, and lethargy are commonly present. Acute meningitis is accompanied by typical signs in infants and adults.

LABORATORY FINDINGS In adults with meningitis, the inflammatory reaction is usually a predominantly neutrophilic pleocytosis; in infants, the response in the cerebrospinal fluid may be mononuclear in approximately one-third of cases.

PATHOLOGY Skin lesions show focal necrosis and infiltration by polymorphonuclear leukocytes and monocytes about blood vessels. Abscesses are found in viscera, and granuloma formation may also be evident.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS Listeriosis should be suspected in any newborn with meconium-stained skin who exhibits intrauterine growth retardation, fails to thrive, or develops a papular skin eruption. Gram's stain of meconium shows the characteristic gram-positive rods. The skin lesions, cerebrospinal fluid, or blood cultures reveal the etiologic agent. The differential diagnosis includes other forms of in utero neonatal infection such as toxoplasmosis, cytomegalovirus infection, rubella, disseminated herpes simplex infection, and a variety of disseminated bacterial infections. The latter include those caused by group B streptococci, *Escherichia coli, Salmonella,* and *Pseudomonas*.

TREATMENT Ampicillin (or penicillin) is the antibiotic of choice, administered by the intravenous route in neonates in two or three divided doses. Care must be exercised in adjusting the dosage of penicillin in the newborn period to 50,000 to 250,000 units/kg per day; ampicillin is administered in a dosage of 100 to 200 mg/kg per day. In adults with meningitis or bacteremia, the dosage of penicillin G should be 12 to 24 million units intravenously daily (in divided doses every 2 to 4 h) and that of ampicillin should be 12 g intravenously (in divided doses every 3 to 4 h).

COURSE AND PROGNOSIS In neonatal septicemia and meningitis, morbidity and mortality are high (up to 50 percent). In adult infections, treatment is effective and recovery is the rule, unless the underlying disease prevents this.

Diphtheria

Diphtheria is an acute febrile illness involving primarily the pharynx and mucous membranes of the upper respiratory tract. The major manifestations of this disease are a result of (1) local membranous obstruction of the airway and (2) the effects of a potent cytotoxin on the myocardium and peripheral nervous system. The hallmark of the local lesion is a gray, leathery membrane. Rarely, the primary lesion may be located on the skin, or the infection may complicate a preexisting wound. This is characteristically seen in tropical areas. The early 1990s saw an upsurge of cases of diphtheria, primarily in the newly independent states of the former Soviet Union, but also in other areas of the world, including the United States. An awareness of its epidemiologic features, including cutaneous disease, argues for its inclusion in this chapter. [50]

BACTERIOLOGY The causative organism (*Corynebacterium diphtheriae*) is a gram-positive club-shaped rod that exhibits metachromatic bipolar granules on staining with methylene blue. It grows well on ordinary media, but its presence may be obscured by other bacteria and for this reason, selective media, such as Loeffler's or tellurite agar, should be used.

EPIDEMIOLOGY Humans are the only natural host for *C. diphtheriae*. The organism is carried in the pharynx of asymptomatic individuals. Infection occurs when a nonimmune person is infected by a toxigenic strain of *C. diphtheriae*; epidemics occur when such a strain becomes widespread in a population of nonimmune individuals. Cutaneous diphtheria and wound diphtheria occur in tropical areas (“jungle sore”) and in association with poor hygiene. There has been an increase in skin diphtheria in the United States in the Pacific northwest and in the south. [51] The contagiousness of cutaneous diphtheria may be greater than that of respiratory infection among school children. [52] Diphtheria is primarily a disease of young children and the elderly. In the United States, most cases occur among poor, crowded, unimmunized individuals. Because of the widespread use and protective effect of toxoid immunization, the disease is rare in this country. It should be stressed, however, that this protection does not prevent the development of the carrier state and subsequent spread of organisms to susceptible individuals. In the past several decades, increasing numbers of cases have occurred in unimmunized migrant farm worker families, in older alcoholics living in “skid row” situations, and among Native Americans in the western United States and Canada. Three outbreaks, involving a total of 1100 infections (40 percent caused by toxigenic strains), occurred in indigent alcoholics in Seattle between 1972 and 1982; 86 percent of these infections were cutaneous. In underdeveloped and overcrowded parts of the world, diphtheria remains an important health problem. The majority of cases of cutaneous and wound diphtheria occur in this setting and are associated with poor hygiene and skin trauma.

CLINICAL MANIFESTATIONS

History Faucial diphtheria usually presents with pharyngitis and low-grade fever. Toxicity is disproportionate to the degree of fever and local findings. As the disease progresses, swelling and pain in the neck, symptoms of airway obstruction, or unilateral nasal discharge may develop. Cutaneous diphtheria occurs in the presence or absence of pharyngeal disease. However, 20 to 40 percent of patients with cutaneous diphtheria carry the identical strain of *C. diphtheriae* in their respiratory tract. Symptoms of cranial or peripheral neuritis or of myocarditis may complicate the course. The latter usually occurs 5 to 14 days after the onset of the illness, whereas the former may develop any time from 2 weeks to several months after the primary lesion. Myocarditis is extremely rare as a complication of cutaneous diphtheria. Neurologic symptoms such as blurred vision, diplopia, numbness of the tongue, palatal paralysis, long-tract sensory and motor findings, and the Guillain-Barré syndrome have occurred in 3 to 5 percent of patients with ulcerated diphtheritic skin lesions.

Cutaneous lesions There are basically two types of skin involvement. [53] The first is wound diphtheria, which is a secondary infection of a preexisting wound that occurs in temperate as well as tropical climates and may involve any part of the body. This type accounts for almost all cases of cutaneous diphtheria reported in the United States. Underlying (primary) skin lesions include those caused by abrasions, chronic dermatitis (eczema, scabies, etc.), and various pyodermas. A latent period of up to 3 weeks transpires between initiation of the primary lesion and evidences of superimposed diphtheritic infection (pain, erythema, tenderness, exudate). The lesion is usually partially covered with a membrane; a purulent exudate is present, and a zone of edema and erythema surrounds the area. In the Seattle outbreak, coinfection with *S. pyogenes* occurred in 73 percent of diphtheritic skin lesions. [54] The second type is primary

cutaneous diphtheria, which begins acutely as a tender, pustular lesion, and then breaks down and enlarges to form an oval punched-out ulcer with a gray membrane at the base. (A similar appearance may be the result of secondary infection by *C. diphtheriae* of a primary lesion of streptococcal ecthyma.) Later, the membrane becomes dark brown. This ulcer has edematous, rolled, bluish margins, is usually located on a lower extremity, and is most often seen in the tropics. Skin lesions with the appearance of impetigo, ecthyma, infected insect bites, etc., have been described as yielding *C. diphtheriae* on culture. [51] Whether these represent true infections with *C. diphtheriae* or are the cutaneous equivalent of the respiratory carrier state is unclear.

Other physical findings A membranous pharyngitis may accompany cutaneous diphtheria. Cranial or peripheral nerve palsies may be present.

LABORATORY FINDINGS The organism can be isolated on appropriate media from the skin ulcer or pharyngeal membrane. There is nothing characteristic about the histopathologic picture of the diphtheritic lesion. The membrane is composed of coagulation necrosis and inflammatory cells.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS A presumptive diagnosis is usually based on the findings of membranous pharyngitis in faucial diphtheria and of a shallow membrane-covered ulcer in cutaneous involvement. In methylene blue–stained smears of material from the edge of the membrane, the characteristic beaded metachromatically stained rods can be seen, but proof of the diagnosis must await culture results and demonstration of toxin production. However, the presence of a pharyngeal membrane, should be presumptive evidence of infection with *C. diphtheriae,* and treatment should be started immediately. Membranous infectious mononucleosis can mimic the picture of faucial diphtheria or be complicated by diphtheria. Tropical ulcers may be confused with diphtheritic skin lesions, but they penetrate below the fascia, involving muscle and tendons. Bacterial infections in ulcerated wounds and following trauma are usually purulent and without membrane formation. Cutaneous mycotic infections are frequently more proliferative, and their margins are irregular, without surrounding reactive edema. Nonpathogenic (nontoxigenic) diphtheroids may be present in open skin lesions as superficial contaminants. Impetigo-like lesions and nondistinctive secondary pyodermas should be cultured in any contacts of a patient with diphtheria. An organism closely related to corynebacteria, *Rhodococcus equi* (formerly *C. equi*), has been identified as a cause of inhalation lung disease in AIDS patients. Rarely, this organism, which resembles *C. diphtheriae* on Gram's stain, can be responsible for skin and subcutaneous infections in healthy individuals, especially those exposed to horse manure or following an injury contaminated with soil. [55]

TREATMENT In faucial diphtheria, treatment consists of both specific equine antitoxin and penicillin. Treatment is initiated on the basis of clinical suspicion without awaiting cultural confirmation, as toxin elaborated in the intervening period could lead to irreversible myocardial damage. In ulcerative cutaneous diphtheria of the lower extremities, bed rest is essential for healing. Antitoxin in doses of 20,000 to 40,000 units is given intravenously after careful testing for horse serum hypersensitivity. Diphtheria antitoxin is no longer commercially available but may be obtained, in appropriate cases, through the Centers for Disease Control and Prevention. Injection of antitoxin into the subcutaneous area around the ulcer and surface application on the lesion have been suggested. Penicillin (2 to 4 million units intramuscularly daily) or erythromycin (2.0 g orally daily) is administered for 7 to 10 days. A few inducible erythromycin- and clindamycin-resistant strains of *C. diphtheriae* were recently isolated from the lesions of cutaneous diphtheria. The lesion should be débrided and kept clean after antitoxin and antibiotics have been administered. Close contacts of a case of cutaneous diphtheria should be examined for any skin lesions (which should be cultured for *C. diphtheriae*); the pharynx should be cultured regardless of the presence of pharyngitis or a membrane. Prophylactic treatment of contacts with erythromycin (or penicillin) should be initiated. In addition, if the immunization status of close contacts is unclear or incomplete, they should receive proper immunization against diphtheria. For children, 7 years of age and older, and adults, the adult formulation of the combined diphtheria-tetanus toxoid (Td) preparation should be used rather than the pediatric DPT vaccine.

COURSE AND PROGNOSIS If treatment is begun early, the prognosis is excellent. In untreated, unimmunized persons with cutaneous diphtheria, ulcers may persist for as long as 6 months. Neuritic symptoms and signs may occur as late as 5 months after the onset of illness and are almost always completely reversible.

Cutaneous Infections Caused by *Vibrio* Species

Infections caused by *Vibrio* species produce several different clinical syndromes: gastroenteritis (the most common primarily caused by *V. parahaemolyticus* and *V. cholerae* non-01); wound (and ear) infections; and septicemia (either “primary” or secondary to a wound infection). [56] There has been an upsurge of reports of the septicemia syndrome caused by many *Vibrio* species, including their distribution to areas of more temperate climate (e.g., Cape Cod, MA, and Denmark). This appears to be associated with ingestion of raw shellfish, cutaneous injuries before or during ocean water exposures, and the potential for systemic disease in individuals with cirrhosis and immunodeficiencies. [57]

BACTERIOLOGY AND PATHOGENIC ASPECTS

Bacteriology Nine *Vibrio* species in addition to *V. cholerae* are associated with human disease. Five species are capable of producing wound infections: *V. parahaemolyticus, V. vulnificus, V. alginolyticus, V. cholerae* non-01, and *V. damsela*. Of these, *V. vulnificus* is the most pathogenic, causing severe wound infections and a “primary septicemia” syndrome with a mortality rate approaching 50 percent. The *Vibrio* species grow in regular blood culture media and are hemolytic on sheep blood agar; they are curved gram-negative rods.

Pathogenic aspects Markers for pathogenicity have been described for some *Vibrio* species. Almost all *V. parahaemolyticus* strains associated with disease (diarrhea) in humans produce a hemolysin. *V. vulnificus* produces extracellular collagenolytic, proteolytic, and elastolytic activities that may be important in the invasiveness of this pathogen. A metalloprotease exotoxin may be an important factor causing gross edema and cellulitis. *V. cholerae* non-01 secretes a dermonecrotic factor that may be of pathogenic significance in the development of hemorrhagic bullous skin lesions. Among the *Vibrio* species, *V. vulnificus* exhibits a striking pathogenicity when introduced into animal models by either the gastrointestinal or parenteral routes.

EPIDEMIOLOGY *V. parahaemolyticus* and *V. vulnificus* are commonly found in saltwater and estuarine sediments and are adherent to fish and concentrated within shellfish. *V. parahaemolyticus* has been implicated in 24 percent of reported cases of food-borne gastroenteritis in Japan; it also has been involved in shellfish-associated outbreaks of gastroenteritis in the United States. [58] *V. vulnificus* is responsible for occasional wound infections incurred following lacerations from shellfish or in seawater as well as for septicemia with metastatic skin lesions after ingestion of raw clams. *V. vulnificus* (and other *Vibrio* species) are endemic along the Gulf of Mexico, to a lesser extent along the Atlantic and Pacific coasts, and in regions of northern Europe (Denmark), particularly in the summer when seawater temperatures exceed 20°C

(68°F). Primary septicemia caused by *V. vulnificus* is associated with the eating of raw oysters and clams and particularly in the setting of hepatic cirrhosis, hemochromatosis, diabetes, glucocorticoid use, or prior gastric surgery.

CLINICAL MANIFESTATIONS

History Gastroenteritis is most commonly associated with *V. parahaemolyticus*. *V. vulnificus* may occasionally cause a similar gastroenteritis. More typically it is responsible for a wound infection with occasional secondary bacteremia occurring several days after a laceration sustained in seawater or brackish inland lakes. Primary septicemia with *V. vulnificus* (or other *Vibrio* species) may follow 24 to 48 h after consumption of raw oysters. Fever, chills, nausea, vomiting, abdominal pain, and diarrhea are frequent symptoms in patients with primary septicemia, suggesting an initial gastrointestinal site of infection.

Cutaneous lesions Traumatic wound infections caused by *V. vulnificus* may consist of pustular lesions, lymphangitis and lymphadenitis, or cellulitis. These infections may be mild or develop into rapidly progressive, painful cellulitis with myositis, extensive skin necrosis, and gangrene requiring amputation. Secondary bacteremia may ensue, complicated by metastatic cutaneous lesions. Skin lesions, in the form of large hemorrhagic bullae on the extremities (Fig. 199-4) or trunk, develop commonly in the course of primary *V. vulnificus* septicemia and are seen with other vibrios, including *V. cholerae* non-01. [57], [59] These progress to necrotic ulcers and necrotizing fasciitis and can eventuate on the lower extremity in muscle necrosis in the anterior compartment.

FIGURE 199-4 *V. vulnificus* cellulitis with hemorrhagic plaque and bullae on the legs of an older diabetic with cirrhosis.

Other physical findings Systemic manifestations (high fever, tachycardia, hypotension) are common in *V. vulnificus* septicemia. One-third of patients are in shock on presentation or shortly thereafter.

LABORATORY FINDINGS Although *V. parahaemolyticus* usually produces a watery diarrhea, occasional patients will have a dysentery-like syndrome with leukocytes and blood present in the stool. In *V. vulnificus* primary septicemia, leukopenia is more frequent than leukocytosis. Thrombocytopenia is common and may progress rapidly to disseminated intravascular coagulation. *V. parahaemolyticus, V. vulnificus,* and other *Vibrio* species can be grown on blood agar media and isolated from routine blood cultures.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS Infection with a pathogenic *Vibrio* species should be suspected when gastroenteritis occurs in the summer months associated with a history of recent ingestion of raw shellfish or exposure to seawater, especially, along the Gulf Coast. The development of unexplained fever, shock, and bullous skin lesions in a patient with cirrhosis who has recently eaten raw oysters should alert the physician to the possible diagnosis of limb- or life-threatening primary *Vibrio* septicemia. Wound infections sustained in freshwater would suggest *A. hydrophila* rather than *Vibrio* species. Bullous lesions occurring in a hypotensive febrile patient could be secondary to bacteremic *P. aeruginosa* infection or even clostridial myonecrosis. Clostridial myonecrosis would be suggested by the presence of crepitus in the involved area and finding typical gram-positive blunt-ended bacilli in the contents of the bullae. *Pseudomonas* bacteremia would be unlikely in a nonleukopenic, nonhospitalized patient without a prior history of infection and antibiotic usage.

TREATMENT *V. parahaemolyticus* gastroenteritis is usually a mild to moderately severe form of diarrheal disease that requires no treatment other than oral fluid replacement. Management of *V. vulnificus* (or other *Vibrio* species) septicemia involves the reversal of hypotension with fluid replacement and treatment of systemic infection with both doxycycline (or chloramphenicol) and ceftazidime. Débridement of necrotic lesions is indicated.

COURSE AND PROGNOSIS *V. parahaemolyticus* gastroenteritis is a self-limited disease. In contrast, the mortality rate for *V. vulnificus* primary septicemia is approximately 50 percent, about three times as high as the mortality for wound infections caused by the same organism. In view of this, patients with cirrhosis, diabetes, AIDS, and other immunocompromising illnesses or treatments should be advised against consuming raw shellfish or exposure of preexisting wounds to contact with warm seawater.

Aeromonas hydrophila Infections

Clinical infections with aeromonads are usually associated with exposure to contaminated fresh or brackish water. The most common form of disease is gastroenteritis but, during the past several decades, many reports have documented the importance of one species, *A. hydrophila,* in skin, soft-tissue, and muscle infections, as well as in septicemic disease. [60] Except for the freshwater habitat of the causative organism, the diseases and patient population infected resemble those caused by *Vibrio* species.

BACTERIOLOGY AND PATHOGENESIS

Bacteriology Aeromonads are widespread in nature. The major pathogen, *A. hydrophila,* is a facultative gram-negative bacillus that grows well on basic blood and MacConkey agar.

Pathogenesis In healthy individuals not exposed to trauma in a freshwater setting, acute gastroenteritis is the most common expression of *Aeromonas* infection. Virulence factors, combined with trauma and fresh- or brackish-water exposure, and cirrhosis, malignancy, or immunodeficiencies, can lead to severe soft-tissue and septicemic disease.

EPIDEMIOLOGY Aeromonads are found worldwide, especially in fresh and brackish water. They are the cause of disease in many aquatic inhabitants, including fish, amphibians, and reptiles. The upswing in use of leeches for medical purposes has resulted in a number of cases of soft-tissue disease. Fish tanks, swimming pools, and tap water have been contaminated with these organisms; common source infections and nosocomial spread and disease have occurred.

CLINICAL MANIFESTATIONS

History The epidemiology may direct the clinician to consider a water-related disease, especially if there has been a laceration or dermatitis. Gastroenteritis is the major clinical complaint associated with *Aeromonas,* but, compared to *V. vulnificus,* it is unusual to have bacteremia and metastatic skin and soft-tissue complications. Fever and hypotension, jaundice, and local disease, such as spontaneous peritonitis, occur in patients with underlying cirrhosis, cancer, and

immunocompromising diseases or therapies.

Cutaneous lesions The most common lesion is cellulitis associated with a laceration, often followed by evidence of an underlying abscess or spread to deeper subcutaneous tissues, with or without palpable gas; localized in healthy individuals but progressive with bacteremia in debilitated patients. [61] The exudate often has a foul or fishy odor. Myonecrosis or necrotizing fasciitis may develop rapidly and mimic clostridial gas gangrene in its rapid onset (24 to 48 h after the initiating wound) and swift progression with severe pain, marked swelling, serosanguineous bullae, crepitation, and systemic toxicity. Occasionally, macular, papular, and ecthymatous lesions occur, indistinguishable from those caused by *P. aeruginosa*.

Other physical findings Evidence of cirrhosis or other underlying disease may be present, and jaundice is often apparent. A distended and tender abdomen may indicate spontaneous peritonitis.

LABORATORY FINDINGS Gram's stains of material aspirated from abscesses or bullae may contain gram-negative bacilli. Cultures are polymicrobial in over half of the patients; blood cultures may be positive, but less frequently than in *V. vulnificus* infections. Liver function tests may be abnormal; peritoneal fluid shows polymorphonuclear leukocytes, elevated protein concentration, and organisms on Gram's stain or culture. The presence of gas in deeper soft tissues may be appreciated by MRI, CT, or overpenetrated standard radiographic techniques.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS The diagnosis is usually suspected from the epidemiologic history of a traumatic or an existing wound exposed to fresh or brackish water, followed by local cellulitis (often with gas formation), increasing pain, and foul discharge. Culture results are confirmatory; bacteremia is rarely demonstrated. The differential diagnosis includes infections caused by *Vibrio* species, streptococcal cellulitis including that caused by *S. iniae,* and necrotizing fasciitis caused by mixed flora in patients with underlying conditions such as diabetes.

TREATMENT Prompt surgical exploration and débridement are essential, often guided by radiologic studies. Most isolates are susceptible to fluoroquinolones and TMP-SMX. The third-generation cephalosporins and aminoglycosides, other than streptomycin, are also effective. Consideration must be given to the polymicrobial nature of these infections, and Gram's stain and culture are essential for antimicrobial decisions.

COURSE AND PROGNOSIS With extensive surgical intervention and appropriate antimicrobial therapy, patients improve rapidly. Prognosis is excellent except when bacteremia is present, which often indicates severe underlying disease and metastatic complications such as peritonitis.

REFERENCES

It has been estimated that the genus *Mycobacterium* causes more suffering for humans than all the other bacterial genera combined. Twenty years ago it was assumed that tuberculosis would become extinct in the developed countries, as its incidence decreased at an average rate of 6 percent in the United States and 10 percent in Europe between 1953 and 1985. However, by 1983 tuberculosis was declared a "global emergency" by the World Health Organization because of a sharp increase in incidence (e.g., doubling in sub-Saharan Africa) largely due to the HIV pandemic. One-third of the world's population is thought to be infected; in the United States, this figure is estimated at 15 million. Currently, tuberculosis accounts for an estimated 8 million new cases and 3 million deaths per year, 98 percent of them in developing countries. It also accounts for 1.5 million new cases and for 500,000 deaths per year among children. It is thought to be responsible for 25 to 30 percent of avoidable deaths and thus has the highest morbidity and mortality rates of all infectious diseases. With respect to mycobacterial skin disease, the so-called atypical mycobacteria may be the cause of skin disease more frequently than *M. tuberculosis*. [1]

There are obligate and facultative pathogenic mycobacteria. In contrast to the obligate pathogens, the environmental, facultative pathogenic mycobacteria do not cause disease by person-to-person spread. Infections caused by the latter depend primarily on their occurrence and on individual susceptibility for infection. The immune and tissue responses of the host play a decisive role in determining the type and extent of disease produced by mycobacterial infection.

CLASSIFICATION OF MYCOBACTERIA

Mycobacteria are acid-fast, weakly gram-positive, nonsporulating, nonmotile rods. The family Mycobacteriaceae consists of only one genus, *Mycobacteria,* which includes the obligate human pathogens *M. tuberculosis* and the closely related *M. bovis, M. africanum,* and *M. microti,* as well as *M. leprae* and a number of facultative pathogenic and nonpathogenic species, the atypical mycobacteria. Runyon, in the first and still often used classification of atypical mycobacteria, distinguished a slow-growing and a fast-growing group. The slow-growing group was subdivided according to pigment-forming properties in culture: group I—photochromogens, capable of pigment formation on exposure to light; group II—scotochromogens, capable of pigment production without light exposure; and group III—nonchromogens. Group IV includes the rapid growers.

Today, approximately 60 species are named, 41 of which were included in the Approved Lists of Bacterial Names in

1980. [2] New species continue to be identified. Species may be cultivable or not (e.g., *M. leprae, M. genavense*). The main distinction in the group of cultivable mycobacteria, that between the slow growers and the rapid growers, seems to have occurred early in the development of the genus.

For clinical purposes, the organisms may be further subdivided into obligate and facultative pathogens and nonpathogens; Table 200-1 presents a classification scheme of the genus. *M. leprae* and *M. genavense* are not included because they are not available for biochemical testing. The listing is neither exhaustive nor definitive.

	Runyon Group
Slow-growing mycobacteria	
Obligate human pathogens†	
M. tuberculosis-bovis group including bacillus Calmette-Guérin (BCG) and *M. africanum*	
Facultative human pathogens	
M. kansasii	I

M. abscessus	IV
Nonpathogens	
M. smegmatis	IV
M. phlei	IV
M. vaccae	IV
Others	

M. leprae and *M. genavense* are not included in this table.
†Obligate human pathogens are not included in the Runyon classification.

TABLE 200-1 **Classification of Mycobacteria***

MYCOBACTERIA AND THE AIDS PANDEMIC

The pandemic of AIDS, with its profound and progressive suppression of cellular immune functions, has led to a resurgence of tuberculosis and the appearance or recognition of new mycobacterial pathogens. In the United States, the *M. avium-intracellulare* complex is the most common cause of disseminated bacterial infections in patients with AIDS, accounting for 20 to 40 percent of cases [3]; it is found much less frequently in European patients. *M. kansasii* is more common than *M. tuberculosis*. [4] The incidence of tuberculosis in patients with AIDS is almost 500 times that of the general population.

The sharp increase in pulmonary and bacteremic or disseminated mycobacterial infections has not been paralleled by an equal increase in mycobacterial skin disease. Cutaneous disease in these patients is caused most typically by *M. marinum, M. scrofulaceum, M. haemophilum, M. gordonae,* and the rapid growers.

TUBERCULOSIS OF THE SKIN

Definition and Classification

Tuberculosis of the skin is caused by *M. tuberculosis, M. bovis,* and, under certain conditions, the bacillus Calmette-Guérin (BCG), an attenuated strain of *M. bovis*. The clinical manifestations comprise a considerable number of skin changes, usually subclassified into more or less distinct disease forms. Classification is based on morphology and, more recently, the mode of infection or the immunologic state of the host, but none of them satisfies completely. The classification used in this chapter distinguishes between exogenous infection and endogenous spread of *M. tuberculosis/bovis*; conditions caused by vaccination with BCG; and a group of eruptions, the tuberculids, whose pathogenesis is poorly understood (Table 200-2). Some entities of a nontuberculous nature, which were once thought to be related to tuberculosis and were thus included with the tuberculids, are mentioned briefly at the end of this section.

Exogenous infection	Primary inoculation tuberculosis (infection of the nonimmune host)
	Tuberculosis verrucosa cutis (infection of the immune host)
Endogenous spread	Lupus vulgaris
	Scrofuloderma
	Metastatic tuberculous abscess (tuberculous gumma)
	Acute miliary tuberculosis
	Orificial tuberculosis
Tuberculids	Tuberculids
	Lichen scrofulosorum
	Papulonecrotic tuberculid
	Facultative tuberculids
	Nodular vasculitis
	Erythema nodosum
	Nontuberculids
	These conditions are not related to tuberculosis but for completeness are briefly discussed in the text
Tuberculosis caused by BCG vaccination	

TABLE 200-2 **Classification of Cutaneous Tuberculosis**

Epidemiology and Incidence

Even though diseases caused by mycobacteria are widespread and serious, the organisms are neither very virulent nor very infectious. Only approximately 5 to 10 percent of infections with *M. tuberculosis* lead to disease; the rate is similarly low for *M. leprae* and is very much lower for the facultative pathogens. Tuberculosis of the skin has a worldwide distribution; once more prevalent in regions with a cold and humid climate, it now occurs mostly in the tropics. In

European and North American countries, the incidence of skin tuberculosis has declined steadily over the past decades, paralleling the decreasing incidence of pulmonary tuberculosis. So far, there has been no increase of skin tuberculosis proportional to the resurgence of pulmonary tuberculosis.

The two most frequent forms of skin tuberculosis are lupus vulgaris and scrofuloderma. In the tropics, lupus vulgaris is rare, whereas scrofuloderma and verrucous lesions predominate. Lupus vulgaris is more than twice as common in women as in men, while tuberculosis verrucosa cutis is most often found in men. Generalized miliary tuberculosis is seen in infants (and adults with severe immunosuppression or AIDS), as is primary inoculation tuberculosis. Scrofuloderma usually occurs in adolescents and the elderly, while lupus vulgaris may affect all age groups.

Etiology and Pathogenesis

M. tuberculosis, M. bovis, and, under certain conditions, the attenuated BCG organism cause all forms of skin tuberculosis. Mycobacteria multiply intracellularly and are initially found in large numbers in the tissue. The mere presence of mycobacteria in the skin, however, does not necessarily lead to clinical disease, and colonization with *M. tuberculosis* is not synonymous with tuberculosis.

THE MYCOBACTERIUM Different mammalian species vary in their susceptibility to infection with different mycobacteria. In humans, *M. tuberculosis* and *M. bovis* cause identical skin manifestations. The incidence of skin tuberculosis elicited by these two organisms depends on the exposure to either organism. In more than 50 percent of cases of lupus vulgaris, the bacteria exhibit a virulence that may be as low as that of the attenuated BCG organism. In many forms of skin tuberculosis, the number of bacteria in the lesions is so small that it may be difficult to find them in histologic sections, whereas large numbers of bacteria can be demonstrated in the affected tissues of a primary chancre or of acute miliary tuberculosis. *M. tuberculosis* may become dormant in the host tissue. These dormant bacilli are resistant to antimycobacterial drugs and may be responsible for latency and reactivation of mycobacterial disease. [5]
THE HOST The human species is quite susceptible to tuberculous infections, but differences exist among populations and individuals. Populations whose contact with tuberculosis spans many generations are, in general, less susceptible than those who have come into contact with mycobacteria more recently; genetic factors also play a role. Age, state of health, and somatic type of the individual are of importance, as are environmental factors. In Africans, tuberculosis frequently takes an unfavorable course, but tuberculin sensitivity may be more pronounced than in whites. After mycobacteria have invaded the host, either they may multiply and lead to progressive disease or their multiplication is checked or completely arrested. The balance between bacterial multiplication and destruction is determined not only by the properties of the invading organisms but also by the ability of the host to control such an infection. Thus, with an increasing number of patients with a compromised immune system, caused either by infection or by therapy, the emergence of hitherto unusual clinical presentations of mycobacterial disease may be expected. The skin of an individual previously infected with tuberculosis shows an altered inflammatory response on a second exposure to the organism. An extract containing the specific protein of the mycobacteria (tuberculin) is able to elicit the same, so-called Koch phenomenon, or tuberculin reaction.
THE TUBERCULIN REACTION (KOCH PHENOMENON) The tuberculin reaction is a result of delayed-type hypersensitivity, mediated by sensitized T lymphocytes that, when injected into a nonsensitized individual, transfer the hypersensitivity. Sensitization is induced by mycobacteria during primary infection. The substance eliciting this reaction in sensitized individuals was designated tuberculin by Robert Koch. This “old tuberculin” (OT) was widely used for skin testing but has now been replaced by a purified derivative [purified protein derivative (PPD)], which is preferable to OT because its potency and composition are more consistent. More recently, purified species-specific antigens were developed. The tuberculin reaction of a sensitized individual may vary in expression, depending on the test dose used and the route of administration. Local intradermal injection (the method most widely used) leads to the local tuberculin reaction, which usually reaches its maximum intensity after 48 h. It consists of a sharply circumscribed area of erythema and induration and, in highly hypersensitive recipients or after large doses, may lead to a pallid central necrosis. In an attempt to make the tuberculin reaction quantifiable, a test system based on the measurement of specific antigen-driven interferon (IFN)-? synthesis by whole-blood cells has been developed, but its usefulness remains to be determined. [6] In approximately 95 percent of individuals, tuberculin sensitivity develops from 2 to 10 weeks after infection with *M. tuberculosis* and persists throughout life. Its intensity may be reduced by conditions that diminish delayed hypersensitivity reactions. The state of sensitivity of an individual infected with *M. tuberculosis* is of considerable significance in the pathogenesis of tuberculous skin lesions. A primary infection of the skin (tuberculous chancre) will result in clinical manifestations that are quite different from those occurring after inoculation of mycobacteria into the skin of a previously sensitized individual (tuberculosis verrucosa cutis). Similarly, the hematogenous spread of mycobacteria in individuals with low or greatly diminished sensitivity will evolve into a skin disease (miliary tuberculosis of the skin) unlike that occurring in persons in whom sensitivity is high (lupus vulgaris). In patients with clinical tuberculosis, an increase of skin sensitivity usually indicates a favorable prognosis; and in tuberculous skin disease with high levels of skin sensitivity, the number of bacteria within the lesions is small. However, tuberculin sensitivity is not necessary for immunity against *M. tuberculosis,* and sensitivity and immunity do not always parallel each other. There is now sufficient evidence that they are dissociable and that a high degree of tuberculin sensitivity may even be antagonistic to protection. Mycobacterial infection seems to elicit at least two distinct cell-mediated immune responses, very likely of the T_H1 and the T_H2 types; both produce positive tuberculin tests but vary in their protective efficacy and thus play a role in the course and severity of the ensuing disease.
ROUTE OF INFECTION The mode of introduction of mycobacteria into the skin and the properties of the tissue components affected are also essential pathogenic factors. The infection may be exogenous (i.e., from an outside source), may occur by autoinoculation, or may be endogenous. Exogenous infection will lead to the tuberculous chancre or to tuberculosis verrucosa cutis, depending on the immunologic state of the host. Lupus vulgaris at the site of BCG vaccination represents another example of exogenous infection, in this instance by attenuated mycobacteria (see below). Endogenous spread of mycobacteria may occur by continuous extension of a tuberculous process underlying the skin (scrofuloderma), by way of the lymphatics (lupus vulgaris), or by hematogenous dissemination (acute miliary tuberculosis of the skin or lupus vulgaris). Finally, the structure and vascular supply of the tissue invaded by mycobacteria must also be considered. Lesions developing in the upper dermis assume a clinical appearance and course different from those developing in the subcutaneous tissues. Impairment of local blood supply may have an important additive effect, and local injury may act as a localizing factor.

Histopathology

The hallmark of tuberculosis and infections with some of the slow-growing atypical mycobacteria is the tubercle. It consists of an accumulation of epithelioid histocytes with Langhans-type giant cells among them and a varying amount of caseation necrosis in the center. This formation is surrounded by a rim of lymphocytes and monocytes. Although this tuberculoid granuloma is highly characteristic of several forms of tuberculosis, it is not pathognomic. Deep fungal infections, syphilis, and leprosy, among other diseases, can produce a similar and, at times, identical lesion. As in leprosy, the histopathology of skin tuberculosis may be reflective of the host's immune status.

Polymerase Chain Reaction

Polymerase chain reaction (PCR) has been increasingly used in recent years to ascertain the mycobacterial etiology of mycobacterial DNA in skin specimens from patients with various tuberculous skin diseases (e.g., lupus vulgaris, papulonecrotic tuberculid, nodular vasculitis). [7], [8] While the detection of specific DNA in tissues has yielded valuable information and some surprising results, and will conceivably gain importance in the future, scrupulous interpretation of the results of these tests in individual patients has yet to be done. [9] In one recent study, samples from 16 of 20 patients with sarcoidosis contained mycobacterial DNA, both tuberculous and nontuberculous. [10] In another study of skin biopsies from 105 patients with confirmed or highly probable cutaneous tuberculosis or with erythema induratum, PCR was 100 percent sensitive and specific in multibacillary disease and 55 percent sensitive and specific in paucibacillary disease. Skin biopsy specimens from 54 percent of patients with erythema induratum also contained mycobacterial DNA, and this finding correlated with response to antituberculous therapy in 80 percent of patients. [8] Thus, although PCR currently is useful to distinguish multibacillary tuberculosis from infections with atypical mycobacteria, it cannot as yet be used as a tool to unequivocally prove or exclude a role of mycobacteria in the pathogenesis of a clinical entity. Mycobacterial culture remains the most reliable method to determine the presence of live mycobacteria and their sensitivity to antibiotics and to monitor response to therapy. [11]

SKIN DISEASE CAUSED BY *M. TUBERCULOSIS/BOVIS* INFECTION

Primary Inoculation Tuberculosis (Tuberculous Chancre; Tuberculous Primary Complex)

Primary inoculation tuberculosis results from the inoculation of mycobacteria into the skin of a host not previously infected with tuberculosis. The tuberculous chancre and the affected regional lymph nodes constitute the tuberculous primary complex of the skin.

INCIDENCE Primary inoculation tuberculosis is estimated to constitute a very small proportion of all primary tuberculous lesions; however, it may be not quite as rare as generally believed. In some regions, particularly in Asia where the incidence of tuberculosis is still high and where living conditions and hygiene are poor, primary inoculation tuberculosis of the skin is not unusual. Most affected individuals are children, but the lesions may also occur in adolescents and young adults. All parts of the body may be affected, but sites of predilection are the face, hands, and lower extremities, which are readily injured. One-third of the lesions are found on the mucous membranes of the conjunctiva and oral cavity.
PATHOGENESIS Because tubercle bacilli cannot actively penetrate intact skin, they are introduced into the tissue at the site of minor abrasions or wounds. Rarely, infection may occur in healthy individuals after sexual contact with patients suffering from genitourinary tuberculosis. Oral lesions may be due to bovine bacilli from nonpasteurized milk and occur after mucosal trauma or tooth extraction. The skin lesion appears 2 to 4 weeks after inoculation. Infection spreads to the regional lymph nodes, producing tuberculous lymphadenitis; with increasing acquired immunity, the process is localized to the particular region involved. Primary inoculation tuberculosis is initially a multibacillary type of skin tuberculosis that becomes paucibacillary as immunity develops.
CLINICAL MANIFESTATIONS The tuberculous chancre initially presents as a small papule, scab, or wound with little tendency to heal. A painless ulcer develops, which may be quite insignificant or may enlarge to a diameter >5 cm (Fig. 200-1). The lesion is shallow with a granular or hemorrhagic base studded with miliary abscesses or covered by necrotic tissue. The ragged edges are undermined and of a reddish-blue hue; as the lesions grow older, they become more indurated, with thick adherent crusts.

FIGURE 200-1 Primary inoculation tuberculosis. Note tuberculous chancre on the thigh and regional lymphadenopathy. A positive tuberculin test is noted on the arm.

Wounds inoculated with tubercle bacilli may heal temporarily but break down later, giving rise to granulating ulcers. Mucosal infections result in painless ulcers or fungating granulomas. Inoculation tuberculosis of the finger may present as a painless paronychia; inoculations of mycobacteria in puncture wounds have resulted in subcutaneous abscesses. Slowly progressing, regional lymphadenopathy develops 3 to 8 weeks after the infection (see Fig. 200-1) and may rarely be the only clinical symptom. After weeks or months, cold abscesses may develop that perforate to the surface of the skin and form sinuses; the lymph nodes draining the primary glands may also be involved. Body temperature may be slightly elevated; occasionally, lymph node enlargement, abscess formation, and perforation may take a more acute course. Fever, pain, and inflammatory swelling of the surrounding tissues simulating a pyogenic infection are present in half the cases.

HISTOPATHOLOGY In the early phase, there is an acute nonspecific inflammatory reaction in both skin and lymph nodes, and mycobacteria are easily detected. After 3 to 6 weeks, the infiltrate and the regional lymph nodes acquire a tuberculoid appearance and caseation may occur.
DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS Lack of awareness of the condition is probably the most common reason for diagnostic error. Any ulcer with little or no tendency to heal and unilateral regional lymphadenopathy in a child should always arouse suspicion. Acid-fast organisms can be demonstrated in histologic sections or in smears obtained from the primary ulcer and draining nodes in the initial stages of the disease, but may be difficult to find in older lesions. The diagnosis is verified by bacterial culture. The reaction to intradermal PPD is negative initially and later converts to positive (see Fig. 200-1). A previous tuberculous infection should be excluded. The differential diagnosis includes the primary complexes of syphilis, tularemia, cat-scratch fever, sporotrichosis, and ulcerative lesions of other mycobacterioses as well as other forms of skin tuberculosis.
COURSE Without treatment, the condition may last up to 12 months. Lesions heal by scarring, but in rare cases, lupus vulgaris develops at the site of a healed tuberculous chancre; in more than 50 percent of patients the regional lymph nodes calcify. Usually, the primary tuberculous complex yields satisfactory immunity, but reactivation of the disease may occur. Hematogenous spread may give rise to tuberculosis of other organs, particularly of the bones and joints. Depending on the size of the inoculum and the age and resistance of the host, primary inoculation tuberculosis may progress to acute miliary disease with fatal outcome. Erythema nodosum is a feature in approximately 10 percent of the cases.

Tuberculosis Verrucosa Cutis (Warty Tuberculosis)

This disorder is verrucous skin tuberculosis caused by exogenous reinfection in previously sensitized individuals.

INCIDENCE In Western countries, tuberculosis verrucosa cutis is rare. It is the most frequent form of tuberculous skin disease in Hong Kong, accounting for more than 40 percent of cases.
PATHOGENESIS Tuberculosis verrucosa cutis is inoculation tuberculosis occurring in persons who have acquired a certain degree of immunity; thus, skin tests are highly positive and it is a paucibacillary type of skin tuberculosis. Inoculation occurs at sites of minor wounds or abrasions or, rarely, from the patient's own sputum. In the past, certain professional groups, particularly physicians, pathologists, medical students, and laboratory attendants, were most liable to acquire warty tuberculosis from tuberculous patients or from autopsy material ("verruca necrogenica," "anatomist's wart," "postmortem wart"). Farmers, butchers, and knackers contracted the disease from tuberculous cattle, and in these cases, *M. bovis* was responsible. Children can become infected by playing on contaminated ground, a frequent occurrence in underdeveloped countries.
CLINICAL MANIFESTATIONS Tuberculosis verrucosa cutis usually occurs on the hands. In children, the sites of predilection are the lower extremities. The lesions are asymptomatic and start as a small papule or papulopustule with a purple inflammatory halo; they become hyperkeratotic and are often mistaken for a common wart. Slow growth and peripheral expansion lead to the development of a verrucous plaque with an irregular outline and a papillomatous horny surface (Fig. 200-2). Clefts and fissures discharging pus extend into the underlying brownish-red to purplish infiltrated base. The lesion usually is solitary, but multiple lesions may occur. The regional lymph nodes are rarely affected but may become enlarged from secondary bacterial infection.

FIGURE 200-2 Tuberculosis verrucosa cutis on the back of the hand.

HISTOPATHOLOGY The most prominent histopathologic features (Fig. 200-3) are pseudoepitheliomatous hyperplasia with marked hyperkeratosis, a dense inflammatory infiltrate, and abscesses in the superficial dermis or within the pseudoepitheliomatous rete pegs. Epithelioid cells and giant cells are found in the upper and middle dermis; typical tubercles are uncommon. Mycobacteria can occasionally be seen. At times, the dermal infiltrate may be nonspecific.

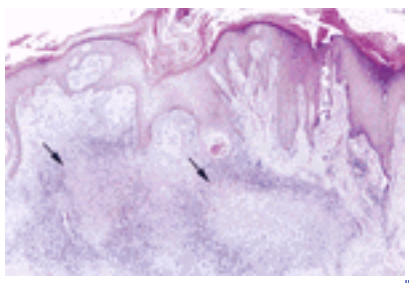

FIGURE 200-3 Tuberculosis verrucosa cutis. There is pronounced epidermal hyperplasia. Below the epithelium there is tuberculoid granulation tissue surrounded by lymphocytes (*arrows*).

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS Early lesions resemble warts or keratoses. Hyperkeratotic lupus vulgaris exhibits "apple-jelly" nodules at the periphery and occurs in sites where tuberculosis verrucosa cutis is rare (see below). Blastomycosis, chromomycosis, and bromoderma may be similar clinically and histopathologically but can be excluded by

special stains and by culture. Negative fungal cultures and small tuberculoid foci are diagnostic aids. Chronic vegetating pyoderma and hyperkeratotic lesions due to other mycobacteria may be difficult to exclude. Hypertrophic lichen planus is pruritic and more disseminated, and usually other cutaneous and mucosal lesions are found. Tertiary syphilis is not quite as verrucous and is accompanied by diagnostic serology.
COURSE The lesions progress slowly, and, if untreated, persist for many years. Secondary pyogenic infection may temporarily lead to more acute inflammatory changes, with lymphangitis and regional lymphadenitis. Spontaneous involution does occur and results in sunken atrophic scars. Occasionally, ulcerative and sclerotic lesions or fungating granulomas are seen.

Tuberculous Cellulitis

Two cases of “cellulitis” caused by *M. tuberculosis* were recently described in patients on long-term systemic glucocorticoid therapy. [12] A mode of infection was not determined, although one of the patients had been treated previously for pulmonary tuberculosis. Histopathologically, multinucleated giant cells, granulomas, and acid-fast bacilli were present. Both patients responded to antituberculous antibiotics.

Lupus Vulgaris

Lupus vulgaris is an extremely chronic and progressive form of tuberculosis of the skin occurring in individuals with moderate immunity and a high degree of tuberculin sensitivity.

INCIDENCE Although the incidence of lupus vulgaris has steadily declined during the past decades, it was estimated in 1960 that some 50,000 new cases occur throughout the world every year. It has always been less common in the United States than in Europe. Females appear to be affected two to three times as often as males; all age groups are affected equally.
PATHOGENESIS Lupus vulgaris is a postprimary, paucibacillary form of skin tuberculosis arising in previously sensitized individuals with only moderate immunity. It originates by hematogenous, lymphatic, or contiguous spread from tuberculosis elsewhere in the body, most often from cervical adenitis or pulmonary tuberculosis, but sometimes from an old, apparently quiescent primary complex. Rarely, it follows primary inoculation tuberculosis or BCG vaccination [13] (see below). The lesions progress steadily. Spontaneous involution may occur and new lesions may arise within old scars. Complete healing occurs only rarely without therapy.
CLINICAL MANIFESTATIONS The lesions are usually solitary, but two or more sites may be involved simultaneously; in patients with active pulmonary tuberculosis, multiple foci may develop. In approximately 90 percent of patients, the head and neck are involved. Lupus vulgaris usually starts on the nose or cheek and slowly extends onto adjacent areas. The earlobes are often affected, and solitary patches may be encountered on the scalp. Only a small percentage of the lesions occur on the extremities, and, except for patients with disseminated lupus vulgaris, the trunk is rarely involved. In general, lupus vulgaris is asymptomatic. The initial lesion is a brownish-red, soft or friable lupus macule or papule with a smooth surface or covered by a scale. On diascopy the infiltrate exhibits a typical apple-jelly color. Progression is characterized by elevation, a deeper brownish color (Fig. 200-4), and formation of a plaque. Involution in one area and simultaneous expansion in another result in a gyrate outline.

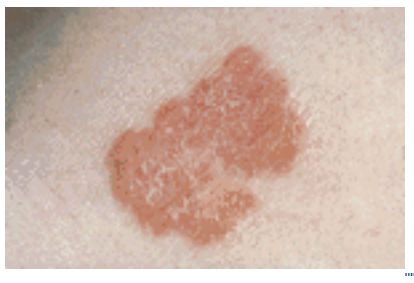

FIGURE 200-4 Slightly raised, brownish plaque of lupus vulgaris.

Lesions may become flat plaques with a serpiginous or polycyclic outline and a smooth surface (Fig. 200-4 and Fig. 200-5) or psoriasiform scaling; there may be erosions, ulceration, and scarring. Hypertrophic forms appear as a soft mass with a nodular (Fig. 200-6), hyperkeratotic surface (Fig. 200-7). Edema, lymphatic stasis, recurrent erysipelas, elephantiasic thickening, and vascular dilatation may lead to gross deformity. In ulcerative forms, the underlying tissue may be affected by progressive necrosis; involvement of the nasal or auricular cartilage results in extensive destruction and disfigurement (Fig. 200-8).

FIGURE 200-5 Lupus vulgaris. Large plaque of lupus vulgaris of 10 years' duration involving the cheek, jaw, and ear.

FIGURE 200-6 Hypertrophic form of lupus vulgaris involving the ear. There is a soft, brown, tumor-like thickening of the earlobe, which is partially eroded.

FIGURE 200-7 Hyperkeratotic lupus vulgaris on the thigh.

FIGURE 200-8 Lupus vulgaris of long duration, having led to the destruction of the nose. Ulcerating squamous cell carcinoma has developed on the upper lip.

Atrophic scarring, with or without prior ulceration, is a prominent feature of lupus vulgaris. Recurrence within a scar is characteristic. Sometimes, fibrosis is very pronounced and leads to deformations, mutilations, and contractures.

Lupus vulgaris of mucous membranes The mucosae may be primarily involved or become affected by the extension of skin lesions. They show small, soft, gray or pink papules, ulcers, or granulating masses that bleed easily. A dry rhinitis is often the only symptom of early nasal lupus, but progressive lesions destroy the cartilage of the nasal septum. Scarring of the soft palate and stenosis of the larynx may also result.

Lupus postexanthematicus After a transient impairment of immunity, particularly after measles (thus the term *lupus postexanthematicus*), multiple disseminated lesions may arise simultaneously in different regions of the body as a consequence of hematogenous spread from a latent tuberculous focus. During and after the eruption, a previously positive tuberculin test may become negative but will usually revert to positive as the general condition of the patient improves. Clinically and histopathologically, the lesions of postexanthematic lupus are typical for lupus vulgaris, and their appearance distinguishes the condition from acute miliary tuberculosis of the skin.

HISTOPATHOLOGY The most prominent histopathologic feature is the formation of typical tubercles (Fig. 200-9). Secondary changes may be superimposed: epidermal thinning and atrophy or acanthosis with excessive hyperkeratosis or pseudoepitheliomatous hyperplasia; acid-fast bacilli are usually not found. Nonspecific inflammatory reactions may partially conceal the tuberculous structures. Old lesions are composed chiefly of epithelioid cells and may be impossible to distinguish from sarcoidal infiltrates.

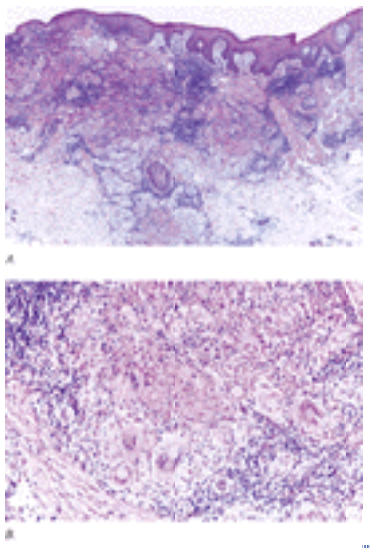

FIGURE 200-9 Lupus vulgaris. *A*. Epithelioid cell tubercles surrounded by dense lymphocytic infiltration but without caseation. There are some giant cells of the Langhans type. *B*. Higher magnification of a sarcoid-like epithelioid cell tubercle.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS Typical lupus vulgaris plaques do not present diagnostic problems; they have to be distinguished from lesions of sarcoidosis, lymphocytoma, discoid lupus erythematosus, tertiary syphilis, leprosy, blastomycosis or other deep mycotic infections, lupoid leishmaniasis, and chronic vegetating pyodermas. Criteria helpful in the diagnosis are the softness of the lesions, the brownish-red color, and the slow evolution. The apple-jelly nodules revealed by diascopy are highly characteristic; finding them may be decisive, especially in ulcerated, crusted, or hyperkeratotic lesions. Histologic examination and a positive culture for *M. tuberculosis/bovis* confirm the diagnosis. The tuberculin test is strongly positive except for the early phases of postexanthematic lupus.

COURSE Lupus vulgaris is extremely chronic, and without therapy its course usually extends over many years or even decades. Thus, adults or older patients tend to have more extensive lesions than children. The disease is progressive and leads to considerable impairment of function and to disfiguration. Contractions result in a reduction of joint mobility, and ulceration and destruction of the cartilages of the face and scarring lead to disfigurement (see Fig. 200-8), to ectropion with its complications, to microstomia with impairment of speech and food intake, and to other severe mutilations. The most serious complication of long-standing lupus vulgaris is the development of carcinoma (see Fig. 200-8). In the early 1900s, carcinoma was estimated to occur in almost 10 percent of patients. Squamous cell carcinomas outnumber basal cell carcinomas by far, and the incidence of metastases is surprisingly high.

RELATIONSHIP OF LUPUS VULGARIS TO TUBERCULOSIS OF OTHER ORGANS In 40 percent of patients there is associated tuberculous lymphadenitis, and 10 to 20 percent have pulmonary tuberculosis or tuberculosis of the bones and joints. The rate of occurrence of pulmonary tuberculosis is 4 to 10 times higher in patients with lupus vulgaris than in the general population. In some cases, lupus vulgaris may be regarded as a symptom of another tuberculous disease running a more serious course.

Scrofuloderma (Tuberculosis Colliquativa Cutis)

Scrofuloderma is a subcutaneous tuberculosis leading to cold abscess formation and a secondary breakdown of the overlying skin.

PATHOGENESIS Scrofuloderma results from contiguous involvement of the skin overlying another tuberculous process, most commonly tuberculous lymphadenitis, tuberculosis of bones and joints, or tuberculous epididymitis. It may affect all age groups, although there is a higher prevalence among children, adolescents, and the aged. It may be either a multibacillary or a paucibacillary form of skin tuberculosis.

CLINICAL MANIFESTATIONS Tuberculosis colliquativa most often occurs in the parotidal, submandibular, and supraclavicular regions, as well as on the lateral aspects of the neck; lesions may be bilateral. Lesions on the extremities or on the trunk accompany tuberculous disease of the phalangeal bones, the joints, the sternum, and the ribs. Skin lesions first present as firm, subcutaneous nodules or as a well-defined, freely movable asymptomatic infiltrate. As the infiltrate enlarges it softens, but it may take months before there is liquefaction with subsequent perforation (Fig. 200-10). Ulcers and sinuses develop and discharge watery and purulent or caseous material. The ulcers are linear or serpiginous with undermined, inverted, bluish edges and uneven, soft, and granulating floors. Sinusoidal tracts undermine the skin, and clefts and dissecting subcutaneous pockets alternate with soft nodules; scar tracts develop and bridge ulcerative areas or even stretches of normal skin. Tuberculin sensitivity is usually pronounced.

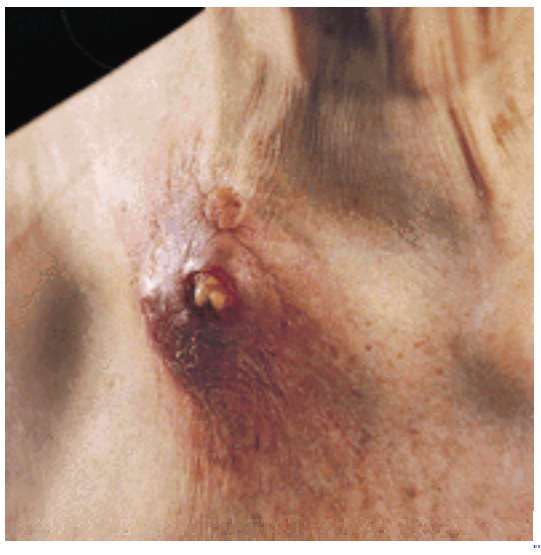

FIGURE 200-10 Scrofuloderma in the clavicular region. Note abscess formation, ulceration, and extrusion of purulent and caseous material.

HISTOPATHOLOGY Massive necrosis and abscess formation in the center of the lesion are nonspecific. However, the periphery of the abscesses or the margins of the sinuses contain tuberculoid granulomas and true tubercles, and *M. tuberculosis* can be found by acid-fast stains.
DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS *M. avium-intracellulare* lymphadenitis and the more benign *M. scrofulaceum* infection have to be excluded by bacterial cultures. If there is an underlying tuberculous lymphadenitis or bone and joint disease, the diagnosis usually presents no difficulty. Syphilitic gummas, deep fungal infections, particularly sporotrichosis, actinomycosis, severe forms of acne conglobata, and hidradenitis suppurativa have to be excluded. The clinical diagnosis is confirmed by bacterial culture.
COURSE Spontaneous healing does occur, but the course is very protracted; it may take years before the inflammatory and ulcerative lesions have been completely replaced by scar tissue. The typical cribriform or criss-crossed scars permit a correct diagnosis, even after the process has become quiescent. Lupus vulgaris may develop at the site of scrofuloderma or in its vicinity.

Metastatic Tuberculous Abscess (Tuberculous Gumma)

DEFINITION AND PATHOGENESIS The metastatic tuberculous abscess is caused by hematogenous spread of mycobacteria from a primary focus during a period of lowered resistance, resulting in single or multiple cutaneous and subcutaneous lesions. It usually occurs in undernourished children or in immunodeficient or severely immunosuppressed patients. Occasionally, it may cause a carpal tunnel syndrome. It is a multibacillary type of skin tuberculosis.
CLINICAL MANIFESTATIONS Subcutaneous abscesses, which are generally nontender and fluctuant, arise either singly or as multiples on the trunk, extremities, or head (Fig. 200-11A); the lesions may invade the overlying skin and break down, forming fistulas and ulcers. Metastatic tuberculous abscesses may occur with progressive organ tuberculosis or in miliary tuberculosis but also without an underlying focus. Tuberculin sensitivity is usually lower than in other forms of skin tuberculosis and may be absent in severely ill patients.
HISTOPATHOLOGY As in scrofuloderma, massive necrosis and abscess formation are found. Acid-fast stains usually reveal copious amounts of mycobacteria (Fig. 200-11B).
DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS All forms of panniculitis, deep fungal infections, syphilitic gumma, and hidradenitis suppurativa have to be excluded. The clinical diagnosis is confirmed by histopathology and bacterial culture.

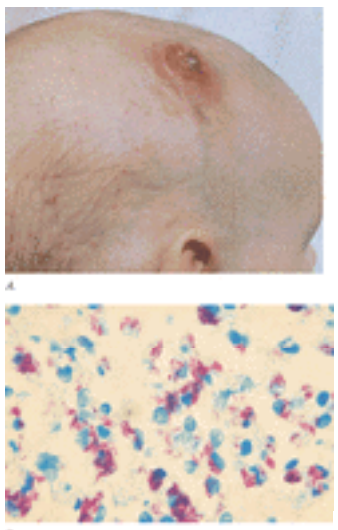

FIGURE 200-11 Metastatic tuberculous abscess on the scalp in an infant with combined immunodeficiency. *A*. Note abscess formation and discharge of purulent material but little inflammation. *B*. Histopathology of the lesion shown in (*A*) stained for acid-fast bacteria. There are hundreds of intracellular bacteria in this low-power field.

Orificial Tuberculosis (Tuberculosis Ulcerosa Cutis et Mucosae)

Orificial tuberculosis is a rare form of tuberculosis of the mucous membranes and the skin of the orifices due to autoinoculation of mycobacteria from progressive tuberculosis of internal organs.

PATHOGENESIS The underlying disease is far advanced pulmonary, intestinal, or, rarely, genitourinary tuberculosis. Mycobacteria shed from these foci in large numbers are inoculated into the mucous membranes, usually after trauma. Most patients show a positive intradermal tuberculin reaction, but in terminal stages anergy develops. Orificial tuberculosis is a multibacillary type of skin/mucous membrane tuberculosis.
CLINICAL MANIFESTATIONS In orificial tuberculosis of the mouth, the tongue is most frequently affected, particularly the tip and the lateral margins, but the soft and hard palates are also common sites. In advanced cases the lips are involved and the oral condition often represents an extension of ulcerative tuberculosis of the pharynx and larynx. In patients with intestinal tuberculosis, lesions develop around the anus, and in females with active genitourinary disease, the vulva is involved. A small yellowish or reddish nodule appears on the mucosa and breaks down to form a soft circular or irregular ulcer with a typical punched-out appearance, and undermined edges (Fig. 200-12). Its floor is covered by pseudomembranous material, and it often exhibits multiple yellowish tubercles and bleeds easily as a result of erosions of vessels. The surrounding mucosa is swollen, edematous, and inflamed. Lesions may be single or multiple and are extremely painful. The tenderness is often out of proportion to the size of the ulcers and results in dysphagia and inability to eat.

FIGURE 200-12 Orificial tuberculosis in advanced cavitary pulmonary tuberculosis.

HISTOPATHOLOGY There is a massive nonspecific inflammatory infiltrate and necrosis, but tubercles with caseation may be found deep in the dermis. Mycobacteria are easily demonstrated.
DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS Painful ulcers of the mouth in patients with pulmonary tuberculosis should arouse suspicion. Large numbers of acid-fast organisms can be detected in smears, and bacterial culture confirms the diagnosis. Syphilitic lesions, aphthous ulcers, and carcinoma have to be excluded.
COURSE Orificial tuberculosis is a symptom of advanced internal disease with a most unfavorable prognosis. Affected individuals run a downhill course; and as the internal condition progresses, the orificial lesions enlarge and spread.

Acute Miliary Tuberculosis of the Skin (Tuberculosis Cutis Miliaris Disseminata)

DEFINITION AND PATHOGENESIS Miliary tuberculosis of the skin is an extremely rare skin manifestation of fulminating miliary tuberculosis caused by hematogenous dissemination of mycobacteria. [14] The initial focus of infection is either meningeal or pulmonary. The disease may follow immunosuppressive infections such as measles and HIV [15]; it most often occurs in babies and infants. Tuberculin sensitivity is usually absent. It is a multibacillary form of tuberculosis of the skin.
CLINICAL MANIFESTATIONS Disseminated lesions occur on all parts of the body, particularly on the trunk. They consist of minute erythematous macules or papules and purpuric lesions. Sometimes umbilicated vesicles or a central necrosis and crust develop.
HISTOPATHOLOGY Initially, necrosis, nonspecific inflammatory infiltrates, and small abscesses are prominent; occasionally signs of vasculitis may appear. Mycobacteria are present both in and around blood vessels. In later stages (if the patient develops immunity), lymphocytic cuffing of the vessels and even tubercles may occur.
DIAGNOSIS The eruption occurs in individuals already gravely ill, and because of the severity of the underlying process, it often goes unnoticed. A multitude of maculopapular and purpuric rashes must be excluded, but the diagnosis is usually suggested by the evidence of acute miliary disease of the internal organs.
COURSE The prognosis is poor, but a favorable outcome after treatment is possible.

BCG Inoculation

Vaccination with the attenuated bovine BCG appears to protect infants and young children from the more serious forms of tuberculosis, but its ability to prevent disease in adults remains uncertain. In the United States BCG immunization is recommended only in the following situations [16]:

1. For infants and children with negative tuberculin skin tests who (a) are at high risk of intimate and prolonged exposure to persistently untreated or ineffectively treated patients with infectious pulmonary tuberculosis, cannot be removed from the source of exposure, and cannot be placed on long-term preventive therapy; or (b) are continuously exposed to persons with tuberculosis who have bacilli resistant to both isoniazid and rifampin.
2. For tuberculin-negative infants and children in groups in which the rate of new infections exceeds 1 percent per year and for whom the usual surveillance and treatment programs have been attempted but are not operationally feasible. These groups include persons without regular access to health care, those for whom usual health care is culturally or socially unacceptable, or groups who have demonstrated an inability to effectively use existing accessible care. In view of the recent outbreaks of multidrug-resistant tuberculosis, these recommendations are currently under review.

Vaccination should be administered only by the route indicated in the package labeling and only in the suggested dose. If a newborn is vaccinated, one-half the usual dose should be used. Depressed host immunity (from illness such as HIV infection or therapy with immunosuppressive drugs) is a contraindication to BCG administration. However, untoward reactions are rare, even in HIV-infected persons. [17]

The normal course of BCG vaccination is as follows: After about 2 weeks, an infiltrated papule develops; after 6 to 12 weeks, the papule attains a size of about 10 mm, ulcerates, and then slowly heals, leaving a scar. Vaccination may provoke an accelerated reaction if given to a person who was previously infected but has a negative tuberculin test. The regional lymph nodes may enlarge but usually heal without breaking down. Tuberculin sensitivity appears 5 to 6 weeks after vaccination.

“Specific” complications caused by the BCG organism are lymphoglandular and skin reactions that mimic cutaneous responses to “natural” mycobacterial infection (Table 200-3). Their true incidence is difficult to ascertain, but it is extremely low in comparison to the great number of vaccinations performed in Europe in the past 50 years. Nonfatal generalized complications occurred in 1 or 2 persons per million; a perforating regional adenitis appeared in 2 percent of vaccinated children in Denmark, and the incidence of postvaccinal lupus vulgaris was estimated to be from 5 to 10 per million. Usually the BCG reactions run a milder course than “spontaneous” tuberculosis of the skin, and they occur more often after revaccination.

- Lupus vulgaris may develop at or in the vicinity of the vaccination site after a latency period of several months or after 1 to 3 years.[11,40]
- Individuals previously sensitive to tuberculin may exhibit a type of Koch phenomenon. Necrosis and ulceration occur as in normal nonsensitive individuals but with a shorter time course. Regional adenitis is common, and general symptoms may be present.
- Local subcutaneous abscesses may form if the vaccination material has been injected too deeply into the skin, and excessive ulceration may ensue.
- Severe regional adenitis is definitely the most common complication and occurs more often in the younger age groups. Scrofuloderma may develop, and suppuration may persist for 6 to 12 months.
- Generalized tuberculid-like eruptions are rarely observed.
- Generalized adenitis, osteitis, and tuberculous foci in distant organs (e.g., the joints) occur occasionally.

TABLE 200-3 **Specific Lesions after BCG Vaccination**

“Nonspecific” complications of BCG vaccination include keloid formation, epithelial cysts, granulomas, eczema, generalized hemorrhagic rashes, erythema nodosum, and other eruptions. After repeated vaccinations, fever, chills, arthralgia, and malaise may occur; anaphylactic shock may be fatal. Hepatic dysfunction and noncaseous granulomas containing the organisms have been observed.

Fatal disease caused by generalized BCG tuberculosis occurs in 1 in 10 million immunizations.

THE TUBERCULIDS

Originally considered to represent recurrent disseminated or systemic skin reactions to toxins of tubercle bacilli, with a tendency to spontaneous involution, the tuberculids were distinguished from “true” cutaneous tuberculosis. They included lichen scrofulosorum, erythema induratum, papulonecrotic tuberculids, lupus miliaris disseminatus faciei, and other eruptions with rather exotic designations.

During the first half of the twentieth century, tuberculids were eruptions quite familiar to dermatologists, but with the sharp decline and effective chemotherapy of tuberculosis in the developed countries, the tuberculids have also become rare. This does not appear to apply to areas where tuberculosis is still common, and with the recent resurgence of tuberculosis in some Western countries, some tuberculids have also been observed again.

Their pathogenesis and their relationship to tuberculosis are still poorly understood. While there is no doubt that such a relationship exists for some of them, there are good reasons to doubt it for others.

By using PCR, *M. tuberculosis* DNA was detected in skin lesions of erythema induratum (nodular vasculitis) and of papulonecrotic tuberculid. [18] In another series, however, 42 specimens from patients with erythema induratum, erythema nodosum, and papulonecrotic tuberculid were uniformly negative. [7] Thus, a positive PCR result still is rather weak proof for a pathogenic link to *M. tuberculosis*. [9]

Tuberculostatics have been found beneficial in some cases, and the involution of tuberculid lesions concomitant with the improvement of underlying tuberculosis has been described. However, some tuberculids tend to involute spontaneously, some cases do not respond to antituberculous treatment, and many react equally well to other antibiotics or even to plain rest and nonspecific measures.

The following discussion therefore employs a restrictive classification that acknowledges as tuberculids only those conditions for which a reasonable amount of evidence supporting a tuberculous etiopathogenesis exists (Table 200-4). Under this criterion, tuberculids comprise only lichen scrofulosorum and papulonecrotic tuberculid. Facultative tuberculids are conditions in which *M. tuberculosis* or its antigens can be considered as one of several possible causes; they comprise nodular vasculitis (erythema induratum) and erythema nodosum. Finally, nontuberculids are all those conditions that were formerly regarded as tuberculids but are, in fact, unrelated to tuberculosis.

Tuberculids (conditions in which M. tuberculosis/bovis appear to play a significant role)	1. Lichen scrofulosorum 2. Papulonecrotic tuberculid
Facultative tuberculids (conditions in which M. tuberculosis/bovis may be one of several etiopathogenic factors)	1. Nodular vasculitis (erythema induratum) 2. Erythema nodosum
Nontuberculids (conditions formerly designated tuberculids; there is no relationship to tuberculosis)	1. Lupus miliaris disseminatus faciei 2. Rosacea-like tuberculid 3. Lichenoid tuberculid

TABLE 200-4 **Tuberculids**

Lichen Scrofulosorum

Lichen scrofulosorum is a lichenoid eruption of minute papules occurring in children and adolescents with tuberculosis.

INCIDENCE AND PATHOGENESIS This uncommon disorder, first recognized by von Hebra, is ascribed to a hematogenous spread of mycobacteria in an individual strongly sensitive to *M. tuberculosis*. Lichen scrofulosorum is usually associated with chronic tuberculous disease of the lymph nodes and bones or with specific pleurisy, but is rare in phthisic patients; it has been observed after BCG vaccination and in association with *M. avium-intracellulare* infections. [19]

CLINICAL MANIFESTATIONS The eruption is asymptomatic and is usually confined to the trunk. The lesions consist of symptomless, small, firm, follicular or parafollicular papules of a yellowish or pink color; they have a flat top or bear a minute horny spine or fine scales on their surface. Lichenoid grouping is pronounced and results in the formation of rough, discoid plaques that tend to coalesce. The lesions persist for months, but spontaneous involution eventually ensues. Antituberculous therapy results in complete resolution within a matter of weeks.
HISTOPATHOLOGY Superficial tuberculoid granulomas develop around hair follicles but may also occur independent of the adnexa. Mycobacteria are not seen in the sections and cannot be cultured from biopsy material.
DIFFERENTIAL DIAGNOSIS Lichen planus, lichen nitidus, lichenoid secondary syphilis, and micropapular forms of sarcoidosis should be excluded.

Papulonecrotic Tuberculid

Papulonecrotic tuberculid is a symmetric eruption of necrotizing papules appearing in crops and healing with scar

formation.

INCIDENCE Reports on papulonecrotic tuberculids are rare. Today, the condition still appears to be not so uncommon in populations with a high prevalence of tuberculosis. It occurs preferentially in children or young adults.
PATHOGENESIS As a rule, bacteria cannot be demonstrated in lesions. In most cases, the tuberculin test is positive, and associated pulmonary or extrapulmonary tuberculosis is frequently found. [20] Lupus vulgaris was seen to evolve with papulonecrotic tuberculid. [21] This suggests that mycobacteria may have been present in the papulonecrotic lesions, but does not exclude the possibility that they may have lodged in these lesions secondarily. A prompt response to antituberculous therapy—irrespective of whether or not a tuberculous focus was known to exist—has been described. In several studies of skin lesions from patients with papulonecrotic tuberculid, [18], [22], [23] *M. tuberculosis* DNA was detected in approximately 50 percent of patients. It was also found in a patient with cutaneous *M. kansasii* infection. [24] Some forms of papulonecrotic tuberculid have been associated with discoid lupus erythematosus, arthritis, or erythema nodosum and may therefore be triggered by antigens other than those of *M. tuberculosis*.
CLINICAL MANIFESTATIONS Sites of predilection are the extensor aspects of the extremities, buttocks, and lower trunk (Fig. 200-13), but the eruption may become widespread. Distribution is symmetric and consists of disseminated crops of dusky red, symptomless, pea-sized papules with a central depression and an adherent crust over a crater-like ulcer. If the lesions are seated more deeply, they may enlarge to a diameter of 1 cm and acquire a more livid color. There is spontaneous involution, and pitted scars result. Usually there are no systemic symptoms.

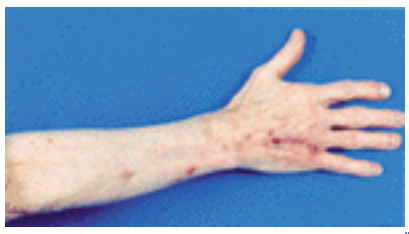

FIGURE 200-13 Papulonecrotic tuberculid on the forearm.

HISTOPATHOLOGY The most characteristic feature is a wedge-shaped necrosis of the upper dermis extending into the epidermis. The inflammatory infiltrate surrounding this necrotic area may be nonspecific but is usually tuberculoid. Involvement of the blood vessels is a cardinal feature and consists of an obliterative and sometimes granulomatous vasculitis leading to thrombosis and complete occlusion of the vascular channels. Recanalization of the vessels may be observed.
DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS The diagnosis should be confirmed by histology. The exclusion of pityriasis lichenoides et varioliformis acuta may present difficulties as will eruptions caused by leukocytoclastic necrotizing vasculitis. The history, clinical appearance, and histology help to make the diagnosis. Lichen urticatus, prurigo, and secondary syphilis are easily excluded.

Nodular Vasculitis (Erythema Induratum of Bazin) See Chap. 109)

INCIDENCE Nodular vasculitis is quite common, particularly in Europe. The disease affects women in 90 to 95 percent of cases. The age of onset varies from the early teens to old age, but incidence peaks in adolescence and in menopause. There is a seasonal prevalence in winter and early spring.
PATHOGENESIS Active tuberculosis is found only rarely in these patients. Similarly, the tuberculin test is of no pathogenic significance; many patients exhibit high sensitivity, but up to 60 percent do not react to a 1:10,000 dilution of OT. PCR testing for mycobacterial DNA has so far not been helpful to clarify the issue. The introductory comments on the relationship of the tuberculids to tuberculosis are particularly relevant to the problem of “erythema induratum.” Nodular vasculitis now is considered to be a multifactorial syndrome of lobular panniculitis in which tuberculosis may or may not be one of a multitude of etiologic components. Today, most authors accept a subdivision of the erythema induratum-nodular vasculitis complex into two groups: one with and one without tuberculous etiology. At the same time, however, it is agreed that the term *erythema induratum* should be reserved for the first group, that is, for those cases in which the tuberculous origin can be proved. The demonstration of mycobacteria emerges as the only reliable criterion.
CLINICAL MANIFESTATIONS Most patients present with erythrocyanotic changes of the lower extremities and have heavy legs, with thick and firm but not edematous skin, and follicular perniosis. Cutis marmorata is common, and the histologic pattern reveals features of vasculitis. The vessels of the patients react abnormally to changes in ambient temperature. Thus, the eruptions are usually associated with exposure to cold. Clinical features are described in Chap. 109.

Erythema Nodosum (See Chap. 109)

Erythema nodosum is a septal panniculitis of the subcutis; it is associated with a variety of disease processes and results from inflammatory reactions that may be triggered by a multitude of antigenic stimuli including viral, bacterial, and mycobacterial antigens.

“NONTUBERCULIDS”

“Nontuberculids” are conditions with nontuberculous etiology that were previously considered to be tuberculids (Table 200-5).

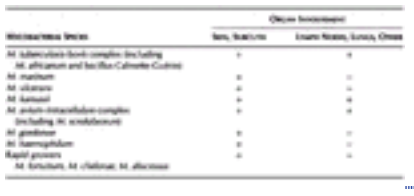

TABLE 200-5 **Mycobacterial Infections**

The older dermatologic literature abounds with entities that were considered tuberculous in nature. Great significance was attached to nomenclature, and the resulting confusion is still reflected in the literature. In none of these conditions was the tuberculous etiology proved.

To avoid a perpetuation of the terminologic jumble, many of the older designations are not mentioned in this text. Most of them are synonymous.

Lupus Miliaris Disseminatus Faciei

Originally considered a variant of lupus vulgaris or a tuberculid, there is no evidence supporting a link to tuberculosis. Because the cause and pathogenesis of this condition are unknown, the designation lupus miliaris disseminatus is inappropriate. Some cases may represent a distinct entity, tentatively named "facial idiopathic granulomas with regressive evolution." [25] Others may be a micropapular forms of sarcoidosis. However, most represent a sarcoidal form of rosacea and respond to treatment with tetracyclines.

The eruption is uncommon and occurs in adults and adolescents of both sexes. It consists of multiple brownish-red, indolent papules with a smooth surface, 1 to 3 mm in diameter, symmetrically distributed in the centrofacial regions (Fig. 200-14); occasionally, more widespread dissemination occurs. The papules develop quite rapidly, may be follicular or nonfollicular, and are distributed at random. Diascopy reveals an infiltrate similar to the apple-jelly nodules of lupus vulgaris. Histopathology reveals well-defined globular masses of tuberculoid structures in the upper dermis. In the center, there may be frank necrosis, and thus the similarity to true tubercles may be striking. The condition runs a self-limited course. Individual papules regress, leaving pitted atrophic scars, and new crops of lesions arise. After a period of months or up to 2 years, the condition disappears spontaneously.

FIGURE 200-14 Condition formerly termed *lupus miliaris disseminatus faciei,* with the characteristic distribution of small follicular and nonfollicular papules. This disorder represents a sarcoidal form of rosacea.

Rosacea-Like Tuberculid

This condition was separated from ordinary rosacea on the basis of its tuberculoid histopathology. It is largely agreed that rosacea-like tuberculid is simply a micropapular form of rosacea with pronounced tuberculoid features (see Chap. 74).

Lichenoid Tuberculid

Lichenoid tuberculid is a sudden symmetric eruption, preferentially localized on the extremities but with a tendency toward generalization. [26] The lesions are brown to violaceous papules, with a diameter of 3 to 5 mm. They may be capped by an adherent scale, and telangiectases are present. Grouping and coalescence are prominent, and annular lesions may be formed. Involution results in brownish macules but no scarring. The condition probably also represents a sarcoidal reaction.

THERAPY OF SKIN TUBERCULOSIS

In many respects, the management of skin tuberculosis follows the same guidelines and has similar implications as that of tuberculosis of other organs. Chemotherapy is usually the treatment of choice, but ancillary measures may be required to provide the patient with optimal care. The type of cutaneous involvement, the stage of the disease, the level of immunity, and the general condition of the patient are important factors to be considered. Cutaneous tuberculosis associated with mycobacterial disease of internal organs requires a well-coordinated, multidisciplinary plan of therapy. The current guidelines for the treatment of tuberculosis are found in Ref. 27.

Chemotherapy

First-line drugs that are highly effective and which are used mainly in the initial treatment of susceptible organisms are isoniazid, rifampin, aminoglycosides, and ethambutol. Second-line drugs used mainly in the treatment of patients with

drug-resistant mycobacteria are pyrazinamide, ethionamide, viomycin, kanamycin, capreomycin, and cycloserine. The quinolones and particularly their fluorinated derivatives are active against *M. tuberculosis* and a number of other mycobacteria in vitro, and thus eventually may gain therapeutic importance.

Isoniazid remains the mainstay of antituberculous therapy. It is both tuberculostatic and tuberculocidal in vitro. It penetrates into all body fluids and cells and also into sclerotic tissue so that it is effective even in old fibrotic lesions. The common daily dose of the drug is 5 mg/kg, with a maximum of 300 mg. Side effects occur in 5.4 percent of patients treated and include fever (1.2 percent), skin eruptions (2.0 percent), peripheral neuritis (0.2 percent), hepatotoxicity, and hematologic complications (agranulocytosis, eosinophilia, anemia, and thrombocytopenia). Pyridoxine should be given concomitantly to prevent peripheral neuropathy, which may otherwise occur in as many as 20 percent of patients.

Pyrazinamide should be given in a dose of 15 to 30 mg/kg, with a maximum of 2 g daily.

Ethambutol, primarily a bacteriostatic drug given in doses of 15 to 25 mg/kg, is always used in combination with other drugs, usually rifampin and isoniazid. It accumulates in patients with impaired renal function and should not be given to children younger than 13 years of age. The incidence of side effects is low.

Rifampin is one of the most effective drugs for the treatment of tuberculosis. It should not be used alone because mycobacteria rapidly develop resistance in a one-step process. Although it produces a number of side effects, the incidence of these is low, seldom necessitating interruption of treatment. Rifampin is administered as a single oral dose of 600 mg/day, and patients should be warned that the drug may impart an orange stain to excretions, including saliva.

Streptomycin, a time-honored antibiotic in the treatment of tuberculosis, is bactericidal for *M. tuberculosis* in vitro, but in vivo its activity is essentially suppressive; it does not penetrate cell membranes (and thus cannot kill intracellular organisms). The toxicity of streptomycin prohibits continuous long-term therapy; nearly 75 percent of patients taking 2 g of streptomycin daily for 60 to 120 days develop vestibular disturbances and impairment of hearing. Other side effects include peripheral neuropathy, dysfunction of the optic nerve, rashes, fever, exfoliative dermatitis, and blood dyscrasias; but there is less nephrotoxicity than with other aminoglycoside antibiotics. Streptomycin is never used alone in the treatment of tuberculosis, and its use has been sharply reduced since other drugs have become available. It is given in doses of 1 to 2 g/day; it is usually combined with two other drugs to treat the more serious forms of tuberculosis.

Drug Combinations and Regimens

The aim of chemotherapy for tuberculosis is to cure the disease as rapidly as possible, to prevent the emergence of resistant strains, and to prevent relapses. The American Thoracic Society and the Centers for Disease Control and Prevention recommend the following regimen, [27] which comprises an initial, intensive phase and a continuation phase. Phase I is directed toward the rapid destruction of large populations of multiplying mycobacteria and therefore consists of initial, intensive chemotherapy: daily isoniazid, rifampin, pyrazinamide, and either ethambutol or streptomycin for 8 weeks; ethambutol or streptomycin may be discontinued if the mycobacteria prove susceptible to isoniazid and rifampin, or in areas where isoniazid resistance is less than 4 percent. Phase II aims at the elimination of remaining, “dormant” organisms: if they are susceptible to isoniazid and rifampin, these drugs are given either daily, three times weekly, or twice weekly for 16 weeks. If resistant mycobacteria are cultivated, the treatment regimen must be adapted accordingly.

Other treatment options on the basis of drug administration only two or three times weekly are also available but may be instituted only if “directly observed therapy” is possible.

Cytokines and Thalidomide

Although not yet established as a therapeutic option, cytokines [e.g., interleukin 2 (IL-2), interferon-?, IL-12, granulocyte/macrophage colony-stimulating factor] may help to control intracellular pathogens and thereby shorten the duration of therapy and overcome drug resistance. [28]

The immunomodulatory drug thalidomide (see Chap. 264) may prove to be useful to control the tumor necrosis factor a–related problems of the immune response in severe mycobacterial infection, [29] and could thus become an important adjunctive drug, as it is in leprosy.

Special Considerations in Treating Tuberculosis of the Skin

Essentially, the treatment of tuberculosis of the skin is that of tuberculosis in general. A full antituberculous regimen is administered, even in localized forms of skin tuberculosis where a primary focus or evidence of an underlying organ tuberculosis or tuberculosis of lymph nodes exists. Special considerations may apply to tuberculosis verrucosa cutis and localized forms of lupus vulgaris without evidence of associated internal tuberculosis, for which isoniazid has been given alone with a high cure rate. Prolonged treatment, extending up to 12 months, is necessary in these forms of lupus vulgaris, and total doses of 80 to 140 g may be required. Because viable mycobacteria have been cultured from clinically healed lesions, treatment should be continued for at least 2 months after complete involution of the lesions. If, however, there is concomitant internal tuberculosis, or if drug resistance emerges, then combination therapy is mandatory.

Careful observation and follow-up are essential. Surgical intervention is quite important in the treatment of scrofuloderma. It reduces morbidity and shortens the period necessary for chemotherapy. Small lesions of lupus vulgaris or of tuberculosis verrucosa cutis are also best excised, but tuberculostatics should be given concomitantly. Plastic surgery is important as a corrective measure in long-standing lupus vulgaris with mutilation.

OTHER MYCOBACTERIAL DISEASES

In addition to the overshadowing problem of infectious disease caused by *M. leprae* or *M. tuberculosis,* the pathogenic potential of other slow-growing mycobacterial species has been recognized only in the past five decades. The reasons are in part that these infections usually closely mimic infections with *M. tuberculosis* or, in rare instances, with other organisms, and in part that they have strict and often unusual requirements for culture.

M. ulcerans was identified as the cause of an ulcerating skin condition in Australia in 1948, and in the Buruli district of Uganda (hence the name Buruli ulcer) in 1958. *M. marinum,* which has been known since 1926, was isolated from patients with swimming-pool granuloma in 1954. Several other mycobacteria have since been identified as pathogens, producing a wide variety of clinical symptoms. [1], [30] Additional mycobacterial species may be found to cause disease in the future. The rapid growers have been known as human pathogens since 1938, when Da Costa isolated an organism, which he named *M. fortuitum,* from a postinjection skin abscess.

A current classification of these mycobacteria is found in Table 200-1, and is discussed at the beginning of this chapter.

Identification of Mycobacteria

As in other infectious diseases, the diagnosis of mycobacterial infection depends on the identification of the microorganism isolated from the host. Specimens should be sent to a special laboratory familiar with the culture requirements of mycobacteria, which vary somewhat from those of other microorganisms. Correct incubation temperatures, special media, and prolonged times in culture, as well as proper identification procedures, are needed.

Antigens for intradermal skin testing (PPDs) of many of the clinically relevant mycobacterial species have been prepared in analogy to PPD from *M. tuberculosis,* but are of very limited use.

As mentioned above, PCR testing for mycobacterial DNA is not yet reliable enough to play a role in the diagnosis of mycobacterial disease, but can be useful in the identification of the organism.

Pathology and Pathogenesis

These infections are thought to be the cause of mycobacterial skin disease more often than *M. tuberculosis* [1]; they tend to occur as sporadic cases, but certain types of exposure may lead to small community outbreaks. As in *M. tuberculosis* infection, any organ or organ system may be affected (see Table 200-5), but there seems to be much less tendency to dissemination.

Pulmonary infections, which most frequently occur in patients with a ventilatory defect (e.g., after long-term silica exposure), are pathologically indistinguishable from tuberculosis. Only two organisms, *M. ulcerans* and *M. marinum,* cause a disease with a distinct clinical picture. In contrast to *M. tuberculosis,* atypical mycobacteria are usually acquired from environmental sources (water, soil), and their occurrence reflects their natural distribution. These mycobacteria are widely distributed in different environments and are usually commensals or saprophytes rather than pathogens. An immunosuppressed state of the host or damage to a particular organ (e.g., in *M. kansasii* infection of the lung) facilitates these infections.

In recent years, a number of patients have developed infections with fast-growing mycobacteria after minor or major surgical procedures. Infections with atypical mycobacteria usually run a more benign and limited course than those with *M. tuberculosis*. As a rule, they are much less responsive to antituberculous drugs, but may be sensitive to other chemotherapeutic agents.

New mycobacterial pathogens are described from time to time, suggesting that we do not yet appreciate the full pathogenic potential of this genus. It seems desirable to develop a unifying concept of mycobacterial disease and its treatment, but at the present time, our knowledge in this area is not advanced enough to allow us to do so. Thus, mycobacterial skin infections are discussed here according to their causative organisms.

Bartralot et al. [31] discuss the general pattern of histopathologic features of these infections.

Skin Infections with Atypical Mycobacteria

M. MARINUM *M. marinum* occurs in fresh and salt water, including swimming pools (thus the older name *M. balnei*) and fish tanks.

Clinical manifestations [32] Risk factors for *M. marinum* infection are a history of trauma and water- or fish/seafood-related hobbies and occupations. The disease begins as a violaceous papule at the site of a trauma about 2 to 3 weeks after inoculation. Patients may present with a nodule or a psoriasiform or verrucous plaque at the site of inoculation, usually the hands, feet, elbows, or knees (Fig. 200-15); the lesions may ulcerate. Usually the lesions are solitary, but occasionally sporotrichoid spread occurs. Lesions frequently heal spontaneously within 1 to 2 years, with residual scarring. Sometimes penetration to underlying structures (bursae, joints) may occur. Regional lymph nodes are, as a rule, not involved. Occasionally the lesions are suppurative rather than granulomatous and may be multiple in normal or immunosuppressed hosts. Probably many of the cases described in the older literature and thought to represent “inoculation lupus vulgaris” as well as “swimmer's lupus,” have in fact been caused by *M. marinum* infection, as sea urchin granulomas possibly can be.

FIGURE 200-15 *A*. *M. marinum* infection on the back of the hand. Granulomatous nodular lesion with central ulceration at the site of inoculation. (*Courtesy of A. Kuhlwein, MD.*) *B*. Verrucous, violaceous plaque with central spontaneous clearing occurring at the site of an abrasion sustained in a fish tank. The lesion was caused by *M. marinum.*

Histopathology There is a tuberculoid inflammatory infiltrate in the dermis, sometimes with abscess formation.
Diagnosis and differential diagnosis As in all mycobacterial diseases, the diagnosis requires a high index of suspicion. An appropriate history (handling of fish, use of swimming pools) and the presence of a tuberculoid granuloma on histopathologic examination are suggestive. Skin testing with PPD is generally not helpful. Many other granulomatous infectious processes of the skin have to be considered in the differential diagnosis. Depending on the geographic area, other mycobacterial infections, blastomycosis, coccidioidomycosis, histoplasmosis, and sporotrichosis as well as nocardiosis, tertiary syphilis, and yaws have to be ruled out.
Treatment Like most atypical mycobacteria, *M. marinum* is poorly susceptible to antituberculous drugs, but spontaneous healing occurs frequently. Minocycline, 200 mg/day for 1 to 2 months, is the treatment of choice. In refractory cases the diagnosis should be reevaluated, and surgical therapy may be considered.
M. ULCERANS The natural habitat of *M. ulcerans* is still not known, and it has never been found outside the human body; but *M. ulcerans* infection occurs in wet, marshy, or swampy areas. *M. ulcerans* is the third most frequent mycobacterial pathogen in immunocompetent people.
Clinical manifestations [33] The disease is found most often in children and young adults; there is a female prevalence. After an incubation period of about 3 months, a painless subcutaneous swelling develops. The nodule gradually enlarges and eventually ulcerates; a blister may develop before ulceration. The ulcer is deeply undermined, and necrotic fat is exposed (Fig. 200-16). The nodule as well as the ulcer are painless, and the patient continues to feel well. The lesions may occur anywhere on the body but tend to be limited to the extremities in adults; they may be large, involving a whole limb. The ulceration may persist for months and years, and healing and progression of the ulceration may occur in the same patient. This process may lead to an appreciable and sometimes disabling amount of scarring and to lymphedema. Neither lymphadenopathy nor any constitutional signs appear at any time if the disease process is not complicated by bacterial superinfection.

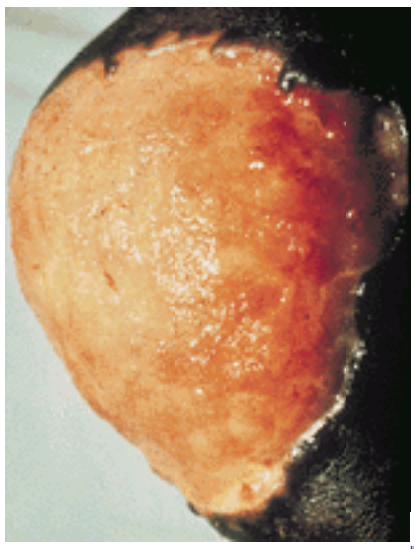

FIGURE 200-16 *M. ulcerans* infection in a child in Uganda. The knee bears an ulcer with an infiltrated undermined margin and a base of necrotic adipose and connective tissue. (*Courtesy of M. Dietrich, MD.*)

Histopathology Central necrosis, originating in the interlobular septa of the subcutaneous fat, is surrounded by granulation tissue with giant cells, but no typical caseation necrosis or tubercles. Acid-fast organisms can always be demonstrated in tissue sections.
Diagnosis and differential diagnosis Diagnosis is confirmed on the basis of histopathology and microbial culture from a subcutaneous node or an ulcer in an individual with an appropriate history. The differential diagnosis of *M. ulcerans* infection depends on the stage of the disease. The subcutaneous nodule must be distinguished from foreign body granuloma, phycomycosis, nodular fasciitis, panniculitis, nodular vasculitis, sebaceous cysts, or appendageal tumors. When the ulcerative stage is reached, necrotizing cellulitis, blastomycosis and other deep fungus infections, pyoderma gangrenosum, and suppurative panniculitis have to be considered.
Treatment The treatment of choice is simple excision of the early lesion; when ulceration has developed, wide excision and skin grafting are necessary. Local heat therapy, hyperbaric oxygen, and chemotherapy with rifampin and trimethoprim-sulfamethoxazole are of some value. BCG vaccination of exposed populations seems to provide about the same amount of protection as in tuberculosis and tuberculoid leprosy. Clofazimine is ineffective.
M. KANSASII *M. kansasii* is the atypical mycobacterium most closely related to *M. tuberculosis*. The organism is usually acquired from the environment; it has been found in tap water and in wild and domestic animals. In the United States, *M. kansasii* infection is endemic in Texas, Louisiana, the Chicago area, and California. It is also endemic in Japan. Skin disease caused by *M. kansasii* usually occurs in adults with or without an underlying condition such as Hodgkin's disease, immunosuppression for renal transplantation, or AIDS. The route of entry is usually through minor trauma such

as a puncture wound.
Clinical manifestations *M. kansasii* infection may present in several forms. Most frequently, there are papules in a sporotrichoid distribution; sometimes, subcutaneous nodules extend to deeper structures and may result in a carpal tunnel syndrome or joint disease; an ulcerated plaque may also develop as a metastatic lesion. Disseminated disease caused by *M. kansasii* infection occurs in immunosuppressed patients, and such patients have cellulitis and abscesses rather than granulomatous lesions. The most commonly affected organ is the lung, usually in patients with other pulmonary conditions (silicosis, emphysema). It may also cause cervical lymphadenopathy. As with *M. tuberculosis, M. kansasii* present in nasopharyngeal secretions can lead to periorificial cutaneous infection. These infections usually progress slowly, although a chronic persistent lesion or even spontaneous regression may occur. Consequently, drug therapy should be initiated as soon as the diagnosis is made.
Histopathology *M. kansasii* infection is histopathologically indistinguishable from tuberculosis.
Diagnosis and differential diagnosis The diagnosis can be confirmed only by the demonstration of *M. kansasii* in bacterial culture. The differential diagnosis includes sporotrichosis, tuberculosis, and other granulomatous infections of the skin (e.g., with *M. marinum* or *M. chelonae*).
Treatment *M. kansasii* is more susceptible than other atypical mycobacteria to antituberculous drugs, particularly to streptomycin, rifampin, and ethambutol. Multiple-drug regimens are of value, and the in vivo response does not always parallel in vitro sensitivities. As in *M. marinum* infection, treatment with minocycline hydrochloride, 200 mg daily, has resulted in complete resolution of sporotrichoid *M. kansasii* infection in one case, but more extensive studies of this regimen are not yet available. In localized skin disease, or in cervical lymphadenitis, surgical excision should be performed.
M. SCROFULACEUM This organism is widely distributed and has been isolated from tap water, soil, and other environmental sources. Infection probably occurs in children by accidental infestation or inhalation.
Clinical manifestations The usual manifestation of *M. scrofulaceum* infection is cervical lymphadenitis in young children, mainly between the ages of 1 to 3 years. Submandibular and submaxillary nodes are typically involved, rather than the tonsillar and anterior cervical nodes characteristic for *M. tuberculosis* infection. The disease is frequently unilateral. There are no constitutional symptoms except mild pain in the neck, but the involved lymph nodes enlarge slowly over several weeks, and eventually ulcerate and fistulate. There is no evidence of lung or other organ involvement. However, in older individuals with preexisting lung disease, pulmonary infection may rarely occur; and AIDS patients may have disseminated infection. [34] In most cases, the disease is benign and self-limited.
Histopathology *M. scrofulaceum* lymphadenitis is indistinguishable histopathologically from tuberculosis.
Diagnosis and differential diagnosis Unilateral cervical lymphadenitis in a young child with a normal chest roentgenogram should suggest this diagnosis. Skin testing with PPDs is usually negative. The diagnosis needs confirmation by bacterial culture of a biopsy specimen. Differential diagnoses include all causes of cervical lymphopathy, both infectious and neoplastic.
Treatment *M. scrofulaceum* is not very sensitive to antituberculous drugs; the treatment of choice for cutaneous lymph node disease is surgical excision. For more widespread disease, combinations of antituberculous drugs have to be tried until results from bacterial sensitivity testing are available.
M. AVIUM-INTRACELLULARE This species complex encompasses organisms with a wide variety of microbiologic and pathogenic properties. Well over 20 subtypes can be separated by immunologic techniques, although this is not necessary for clinical purposes. These organisms are usually grouped together with *M. scrofulaceum* in the so-called MAIS (*M. avium-intracellulare–scrofulaceum*) complex, but are separated here for clinical reasons. Whereas *M. scrofulaceum* produces only a benign, self-limited lymphadenopathy with no organ involvement, *M. avium-intracellulare* usually causes lung disease or, less frequently, osteomyelitis. It may also cause a cervical lymphadenitis with sinus formation that is clinically indistinguishable from tuberculous scrofuloderma.
Clinical manifestations Primary skin disease caused by *M. avium-intracellulare* has been reported in rare instances, presenting as single or multiple painless, scaling, yellowish plaques, sometimes resembling lupus vulgaris [35] or subcutaneous nodules, with a tendency to ulceration and a slowly progressing, chronic course. Sometimes, skin involvement occurs secondary to disseminated infection with *M. avium-intracellulare*. Skin lesions have included generalized cutaneous ulcerations, multiple cutaneous granulomas, infiltrated erythematous lesions on the extremities, pustular lesions, or soft tissue swelling. *M. avium-intracellulare* infections are an important cause of morbidity in patients with AIDS (see Chap. 225).
Histopathology Histopathologic examination of skin lesions shows noncaseating tuberculoid granulomas. Acid-fast bacilli can be found within giant cells and extracellularly.
Diagnosis and differential diagnosis Demonstration of *M. avium-intracellulare* in bacterial culture is necessary to establish the diagnosis. The differential diagnosis includes all chronic granulomatous conditions of the skin.
Treatment Where feasible, surgical treatment of *M. avium-intracellulare* infection is advisable as the organism seems to be poorly susceptible to chemotherapeutic agents. If dissemination of the disease does not allow curative surgery, combination therapy should be tried. Clarithromycin is the most effective antimicrobial agent against *M. avium-intracellulare* and should always be included in the therapeutic regimens. [36] Ethambutol, rifampin, amikacin, streptomycin, ciprofloxacin, clofazimine, azithromycin, and rifabutin are also highly active against *M. avium-intracellulare,* but isoniazid and pyrazinamide are not.
M. SZULGAI Cervical lymphadenitis as well as cellulitis or draining nodules and plaques are associated with *M. szulgai*. The organism causes bursitis and pneumonia; it is more susceptible to antituberculous drugs than most other atypical mycobacteria.
M. HAEMOPHILUM *M. haemophilum* was identified as the cause of a subcutaneous granulomatous eruption in several immunosuppressed and HIV-infected patients. Histopathologically, skin lesions show a mixed polymorphonuclear and granulomatous inflammation, the so-called dimorphic inflammatory response, with no caseation necrosis, similar to that seen in *M. fortuitum* complex infection (see below). The organism may be sensitive to *p*-aminosalicylic acid and rifampin.
M. GENAVENSE Little is known about the characteristics of *M. genavense*. It can cause disseminated disease similar to that caused by *M. avium-intracellulare* in patients infected with HIV. [37]
M. FORTUITUM, M. CHELONAE, M. ABSCESSUS These three species of rapid-growing, facultative pathogenic mycobacteria were usually grouped in the *M. fortuitum* complex. They now are recognized as distinct species. These organisms seem to be widely distributed and can commonly be found in soil and in water supplies. Contamination of various materials, including surgical supplies, occurs and does not always result in clinical disease.
Clinical manifestations These organisms cause similar clinical diseases. [38], [39] Infection usually follows a puncture wound or a surgical procedure. In one large series, it was found that cutaneous disease was present in 60 percent of

cases; of those, approximately one-half were a result of surgery and the other half were a result of accidental inoculation. The disease manifests itself as a painful red infiltrate at the site of inoculation; there are no signs of dissemination and no constitutional symptoms. This type of infection has followed augmentation mammoplasty, median sternotomy, and a variety of other procedures usually involving percutaneous catheterization. Cold postinjection abscesses, especially when occurring in the tropics, may also be caused by fast-growing mycobacteria. An outbreak of localized cutaneous postinjection abscesses or cellulitis in 350 patients was observed in Colombia. [39] It was suggested that the so-called fixation abscesses found in tuberculosis patients after intramuscular injections were often a consequence of inoculation with these organisms. Primary cutaneous inoculation occurs through skin injuries, in all age groups, without immunosuppression. The lesion presents as a dark red infiltrated node, often with abscess formation and clear fluid drainage. Disseminated disease involving the skin also occurs, usually in patients undergoing hemodialysis or those who are immunologically compromised. The skin lesions consist of multiple recurrent episodes of abscesses on the extremities or in a generalized macular and papular eruption. Other manifestations of infection with these organisms include pneumonitis or osteomyelitis, lymphadenitis, and postsurgical endocarditis.

Histopathology The lesions are characterized by the simultaneous occurrence of polymorphonuclear leukocyte microabscesses and granuloma formation with foreign body–type giant cells, the so-called dimorphic inflammatory response. There is usually necrosis but no caseation. Acid-fast bacilli may occasionally be found within microabscesses.

Diagnosis and treatment Organisms of the *M. fortuitum* complex may be identified by special laboratories. This is important for therapy because *M. fortuitum* is more susceptible to amikacin, cefoxitin, ciprofloxacin, and imipenem; *M. abscessus* is usually sensitive to amikacin, cefoxitin, and clarithromycin; *M. chelonae* is usually resistant to cefoxitin, and tobramycin is more effective than amikacin. Thus, a rational treatment has to await the identification of the organism and the results of in vitro susceptibility testing. In the Colombian series of 350 patients with postinjection abscesses caused by *M. abscessus,* a combination of surgical excision of the lesions and 3 to 6 months of clarithromycin resulted in a 95 percent cure rate, whereas either measure alone was successful in fewer than 30 percent of patients. Actinomycosis, nocardiosis, and actinomycetoma are chronic infections caused by human pathogenic species of filamentous bacteria. Actinomycosis is an infection caused by anaerobic *Actinomyces,* whereas aerobic actinomycete species cause nocardiosis and actinomycetoma. Actinomycosis is a chronic infection frequently of the cervicofacial area, thorax, or abdomen, usually caused by *Actinomyces israelii* and *A. gerencseriae,* but at least four other *Actinomyces* species (*A. naeslundii, A. viscosus, A. odontolyticus,* and *A. meyeri*), *Propionibacterium propionicum* (formerly *Arachnia propionica*), and *Bifidobacterium dentium* (formerly *Actinomyces eriksonii*) may also be responsible for similar or identical clinical symptoms. [1] Nocardiosis is primarily an infection of the lungs with a marked tendency to disseminate to multiple organs, particularly the brain. Members of the *Nocardia asteroides* complex (now separated into *N. abscessus, N. asteroides* sensu stricto type VI, *N. farcinica,* and *N. nova*) are the most common causes of nocardial disease in humans, but other species, including *N. brasiliensis, N. otitidiscaviarum,* and *N. transvalensis,* may also be etiologic agents. Actinomycetoma is a chronic infection of the subcutaneous tissues, skin, and bone. Actinomycosis, nocardiosis, and actinomycetoma may be occult at onset, progress in a chronic, indolent fashion, and be difficult to diagnose because of the similarity of their clinical features and, in cutaneous disease, their close resemblance to several other chronic dermatologic disorders.

In addition to the patient's clinical presentation, the demonstration of the microorganisms in smears of clinical material or in stained tissue sections may suggest the presumptive diagnosis; however, confirmation of the diagnosis depends upon the culture isolation and identification of the etiologic agents to the genus level (Table 201-1).

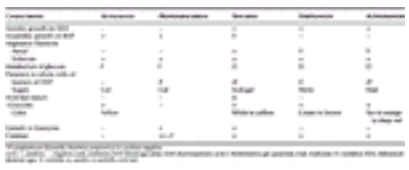

TABLE 201-1 **Presumptive Identification of the Major Medically Important Aerobic and Facultative Anaerobic Actiomycetes to the Genus Level**

The aerobic and facultative anaerobic actinomycetes belong to the order Actinomycetales. Phylogenetic investigations of 16S rRNA gene sequence clustering and the presence of unique signature nucleotides proposed by Stackebrandt et al. [2] generated a classification system for the genera described in this chapter: the genus *Actinomyces* and the related genus *Arcanobacterium* are classified in the family *Actinomycetaceae*; the genus *Propionibacterium* is classified in the family *Propionibacteriaceae*; the genus *Nocardia* in the family *Nocardiaceae*; and the genera *Streptomyces* and *Actinomadura* in the families *Streptomycetaceae* and *Thermomonosporaceae,* respectively. These taxa are in the lineage of the class *Actinobacteria,* order *Actinomycetales.* [2]

ACTINOMYCOSIS

Epidemiology

Actinomycosis is a rare infection that is worldwide in distribution. In the United States, it is more common in males. The disease's incidence is difficult to estimate because it is not a reportable disease and there is no skin test available for population surveys. The most common agents are *A. israelii* and *A. gerencseriae,* but at least four other *Actinomyces* species (*A. naeslundii, A. viscosus, A. odontolyticus,* and *A. meyeri)*, *Propionibacterium propionicum* (formerly *Arachnia propionica)*, and *Bifidobacterium dentium* (formerly *Actinomyces eriksonii*) may also be responsible for similar or identical clinical symptoms. Furthermore, eight new *Actinomyces* species (*A. europaeus, A. funkei, A. graevenitzii, A. neuii, A. radicidentis, A. radingae, A. turicensis,* and *A. urogenitalis*) [3] as well as the related taxon *Actinobaculum schaalii* [4] were recently isolated from patients with clinically less-specific inflammatory conditions, and two former *Actinomyces* species (*A. bernardiae* and *A. pyogenes*) were placed in the genus *Arcanobacterium.* [5] *Actinomyces bovis* causes granulomatous infections in cattle; however, this species is considered to be an unlikely human pathogen and earlier reports of human *A. bovis* infections might, in fact, have been caused by *A. israelii*. Of importance, characteristic actinomycotic lesions usually develop in the presence of concomitant flora that may consist of aerobic and/or anaerobic species. [6] Aerobic cultures chiefly yield coagulase-negative staphylococci, *Staphylococcus aureus,* alpha-hemolytic and beta-hemolytic streptococci as well as *Enterobacteriaceae* from abdominal and pelvic actinomycoses, whereas, anaerobic cultures chiefly yield *Actinobacillus* (*Haemophilus*) *actinomycetemcomitans* (25 percent of cases), so-called microaerophilic streptococci (mainly *S. milleri*), *Fusobacterium* spp., *Bacteroides, Prevotella* and *Porphyromonas* spp., *Leptotrichia buccalis, Eikenella corrodens,* and *Capnocytophaga* spp. [6]

The etiology of human actinomycoses is complex in two respects: the principal etiologic agents of the disease do not belong to a single species, but to a variety of different members of the genera *Actinomyces*, *Propionibacterium,* and *Bifidobacterium*. Furthermore, essentially all of the typical actinomycotic lesions contain between 1 and 10 bacterial species, in addition to the pathogenic actinomycetes. [1], [6] These concomitant bacteria apparently act as synergistic pathogens that strengthen the comparatively low invasive power of the pathogenic actinomycetes and are in particular responsible for the early symptoms of the disease and for treatment failures. [7] Because the etiologic term *actinomycosis* describes a polyetiologic inflammatory syndrome rather than a disease attributable to a single pathogen, it appears to be more appropriate to refer to this group of closely related conditions as “actinomycoses” in the plural.

Clinical Disease

Actinomycosis is a subacute to chronic bacterial disease that is characterized by slowly progressing, suppurative, fibrosing inflammation, development of draining sinus tracts that may discharge characteristic “sulfur granules,” and direct dissemination via contiguous tissues. It most commonly involves the cervicofacial area (Fig. 201-1), thorax (Fig. 201-2) or abdomen, including the pelvis, but rarely also the central nervous system (CNS), or bone.

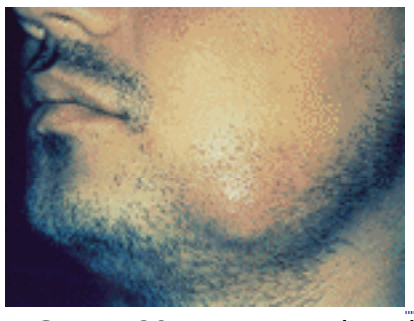

FIGURE 201-1 “Lumpy jaw” in a patient with cervicofacial actinomycosis. (*Courtesy of Maria Cecilia Albornoz, MD, Instituto de Biomedicina, Caracas.*)

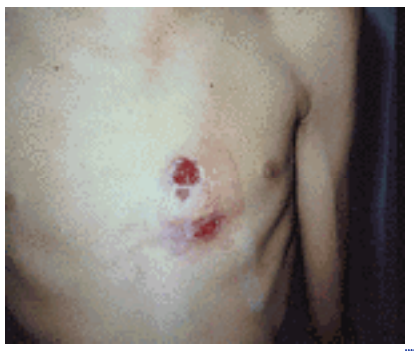

FIGURE 201-2 Ulcerated chest wall lesion from a patient who died from invasive actinomycosis. Note minimal drainage.

Cervicofacial actinomycosis is the most common form. Characteristic risk factors are poor oral hygiene resulting in periodontal abscesses or dental decay; orofacial trauma; foreign bodies penetrating the mucosal barrier such as bone splinters, fish bones, or spicules of grass or grain; and dental procedures. One to several weeks after dental extraction or mouth trauma, or spontaneously, the infection typically causes a painful, indurated cutaneous and soft tissue swelling (“woody” fibrosis) or presents as typical odontogenic abscess. The slowly enlarging inflammatory mass is most frequently located in tissue adjacent to the body of the mandible (54 percent), but may also involve cheek (16 percent), chin (13 percent), ramus and angle of the mandible (11 percent) (Fig. 201-1), upper jaw (6 percent), and mandibular joint (0.3 percent). [6], [8] Over ensuing weeks to months, the overlying skin may develop a bluish discoloration and become adherent, and the mass may become fluctuant and develop draining extra or intraoral sinuses that may extrude sulfur granules. Trismus may be prominent early in the patient's course; however, cervical lymphadenopathy is uncommon. Direct

extension may involve the tongue, sinuses, and meninges and, rarely, contribute to periostitis or osteomyelitis of the mandible. [6] Thoracic infection involving the lung and pleura is usually secondary to aspiration, but rarely may result from bloodstream dissemination. Pleuropulmonary infection may be complicated by mediastinal invasion with involvement of the pericardium and thoracic vertebrae. Actinomycosis of the gastrointestinal tract most commonly develops in the ileocecal region, but may also primarily involve the esophageal, gastric, or anorectal areas. Pelvic actinomycosis has been recognized with increasing frequency and predisposing factors have been identified to include intrauterine devices, contaminated pessaries, prolapse of the uterus, and septic abortion. [9], [10]

Differential Diagnosis

The most important conditions to consider in the differential diagnosis are other diseases that cause fistulae. These include granulomatous diseases such as Crohn's disease, foreign-body granulomas, tuberculosis, and certain pyogenic bacterial infections.

Actinomyces infections should be considered whenever there are chronic soft tissue orocervical lesions. However, the diagnosis of actinomycosis may be difficult when areas such as the pelvic, perigluteal, or perianal regions are affected. Steps in making the diagnosis include careful clinical examination, stained smear of exudate and culture isolation of the etiologic agent. In infected patients, the presence of an underlying immunodeficiency state should also considered, and evidence of polymicrobial infections should also be sought in histologic and microbiologic diagnostic tests.

Laboratory Diagnosis

A definitive diagnosis cannot be made solely on clinical grounds. The diagnosis of actinomycosis can be difficult and might depend on a heightened level of clinical suspicion and prior notification of the clinical laboratorian and pathologist. Detection of these microorganisms on Gram stain and culture from an appropriately obtained specimen is needed. Exudates and biopsy material are particularly suitable for laboratory examination. Bronchoscopy and bronchoalveolar lavage fluid smear examination and culture may be important in the diagnosis of thoracic actinomycosis. [8], [11], [12] After a sample is obtained, it should be examined by standard histologic methods and by immunofluorescence. In addition, a 2-week anaerobic culture should be performed.

CULTURE Culture is the least-reliable method of verifying infection (in Fiorino's series, only 35 percent of cultures were positive for *Actinomyces*) [10]; although an 86 percent success rate has been reported for samples cultured in the presence of metronidazole, which inhibits the growth of faster growing anaerobes. [13] Culture of abscess aspirates and vaginal and cervical swabs frequently grow multiple other species of microorganisms. Members of the genera *Actinomyces, Actinobaculum, Propionibacterium,* and *Bifidobacterium* are morphologically similar—anaerobic to less-stringently anaerobic bacteria. They are best isolated in prereduced anaerobic media such as thioglycollate with 0.5 mL sterile rabbit serum and may require 14 days of anaerobic incubation at 35°C (95°F). [14] Characteristically, they appear as gram-positive branched filaments (Fig. 201-3); however, fragmentation of these filaments readily occurs, producing bacillary or coccoid forms that are nonacid fast and nonmotile. Filamentous, microscopic colonies of *Actinomyces* species can be detected within 2 to 4 days of anaerobic incubation at 35°C (95°F). Mature colonies require 7 to 14 days to develop. Characteristics that differentiate these four genera from each other and from other anaerobically growing nonsporulating gram-positive bacteria are derived from cell wall or whole-cell analysis, acid end-product analysis, and certain physiologic tests that include fermentation of carbohydrates. These last tests are particularly necessary for differentiating between the various *Actinomyces* species, [14] but rapid and reliable identification to the species level may also be achieved by using direct or indirect immunofluorescence.

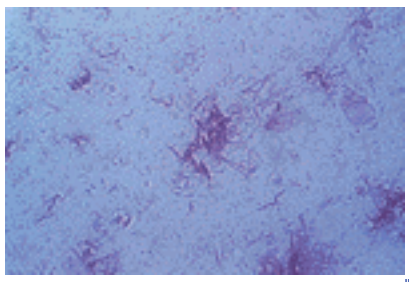

FIGURE 201-3 *Actinomyces israelii* filaments. Gram stain. Magnification, × 1022. (*Courtesy of Maria Cecilia Albornoz, MD, Instituto de Biomedicina, Caracas.*)

Actinomycosis-producing actinomycetes may be distinguished from aerobic, filamentous bacteria such as *Nocardia* species, *Rothia dentocariosa,* or *Corynebacterium (Bacterionema) matruchotii* by the type of carbohydrate metabolism (nocardiae are aerobes), by differences in cell wall composition (nocardiae and *C. matruchotii* contain *meso*-diaminopimelic acid, arabinose and galactose as well as mycolic acids in their walls), by partial acid-fastness and aerial filaments (nocardiae), and by resistance to penicillin (nocardiae). *R. dentocariosa,* which is often difficult to distinguish from aerobically growing *Actinomyces* species, is characterized by its ability to reduce nitrate as well as nitrite.

BIOCHEMISTRY *A. israelii* differs from the other *Actinomyces* species on the basis of acid production from anaerobic fermentative carbohydrates. [14] *P. propionicum* differs from the *Actinomyces* species biochemically on the basis of production of large amounts of propionic acid from glucose fermentation, the presence of ll-diaminopimelic acid in the cell wall, growth in the presence of lysozyme, and acid production from carbohydrates. [15] Differentiation of *Actinomyces* from other anaerobic nonsporulating gram-positive bacilli, such as *Bifidobacterium, Eubacterium,* and *Propionibacterium,* is based on acid production from carbohydrates, hydrolysis of esculin and gelatin, reduction of nitrate, production of indol and catalase, reaction in milk, and gas chromatographic analysis of the organic end products of glucose fermentation (Table 201-2).

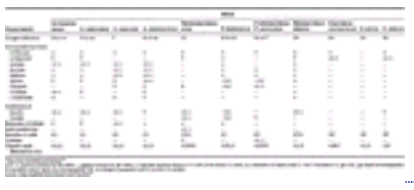

TABLE 201-2 **Comparison of** *Actinomyces* **and** *Propionibacterium* **Species to Others of Related Genera***

Pathology

The organisms stain in tissue with Gomori methenamine silver (GMS) and the Brown and Brenn modification of the Gram stain (B&B). They are usually pleomorphic, gram-positive bacilli that appear beaded in older cultures because they take up stain irregularly. The presence of “sulfur granules” is highly suggestive but not diagnostic of actinomycosis. “Sulfur granules” comprise masses of matted, interconnected bacterial filaments that appear in vivo in a characteristic radial arrangement (see “ Actinomycetoma” later in this chapter). Microorganisms may be scarce in pathologic specimens, so detection may require diligent searching of multiple tissue sections. [16]

Serodiagnosis

Serodiagnosis of actinomycosis by detection of precipitating antibodies has not been a particularly useful diagnostic test. However, presumptive identification can be achieved by direct or indirect modification of the immunofluorescence technique. [17] Unfortunately, the fluorescein isothiocyanate-labeled (direct) and unlabeled (indirect) antisera needed for these tests, and used in research laboratories, are not commercially available. Expectorated sputum may be culture positive for *Actinomyces* because of contamination from upper airway secretions. In addition, it is important to collect specimens before initiation of antibiotics and to alert the laboratory to the clinical suspicion of actinomycosis so that anaerobic cultures may be observed for an appropriate period.

Therapy

Penicillin is the antimicrobial therapy of choice for deep-seated actinomycosis. Prolonged treatment with large doses of penicillin is required to achieve serum drug concentrations high enough to ensure drug penetration into areas of fibrosis and suppuration and possibly to penetrate the granules themselves. The goal of therapy is to administer intravenous penicillin G (150,000 to 200,000 U/kg per day or 10 to 20 million units per day in divided doses for adults) for 4 to 6 weeks (or for at least 3 to 4 weeks after the patient appears cured), followed by oral penicillin (e.g., phenoxymethyl penicillin, 2 to 4 g per day, to patient tolerance) for 6 to 12 additional months, or even longer, to prevent relapse. In a given patient, complications including disseminated infection, critical organ involvement (e.g., CNS), and/or associated inability to perform definitive surgery, may alter or extend this regimen. [18] Clinical resistance to penicillin may not be a major problem; however, there have been occasional reports of clinical failures and apparently considerably more therapeutic problems that were not published in the literature following penicillin therapy alone. [19], [20] Although there is some in vitro evidence to support the development of acquired resistance to penicillin, in vivo development of acquired antimicrobial resistance by *Actinomyces* species, particularly to penicillin G, has not been reported. When the clinical response to penicillin is poor, a search should be made for an undrained abscess; in addition, the possibility of a resistant concomitant bacterial species should be considered.

The therapeutic concept outlined above is primarily based on the view that the pathogenic fermentative actinomycetes are the principal or even sole target against which the antimicrobial chemotherapy has to be directed. Considering the impressive amount of bacteriologic data that indicate that human actinomycoses are essentially always synergistic mixed infections, perhaps this concept should be modified. Pulverer and Schaal, [7] as well as several other authors, have reported on characteristic clinical treatment failures of penicillin G therapy. These findings could be related to the presence either of *A. actinomycetemcomitans* or of beta-lactamase producing *Bacteroides* species, *Staphylococcus aureus,* or *Enterobacteriaceae*. Because *Bacteroides* species or *Enterobacteriaceae* are commonly found as concomitant organisms in abdominal and pelvic actinomycoses, the latter usually do not respond well to penicillin G treatment. In contrast, beta-lactamase producers, as well as penicillin G-resistant strains of *A. actinomycetemcomitans,* are less common in the cervicofacial form of the disease so that many of these cases may be effectively treated with high doses of benzoyl penicillin.

Compared with narrow-spectrum penicillins, the aminopenicillins are similarly active against the pathogenic fermentative actinomycetes, but clearly much more effective against *A. actinomycetemcomitans,* both in vitro and in vivo. Thus, therapy with comparatively high doses of aminopenicillins such as ampicillin or amoxicillin (4 to 8 g/day for adults) effectively helps to avoid the characteristic treatment failures or relapses of cervicofacial infections caused by *A. actinomycetemcomitans*. However, aminopenicillins are also susceptible to beta-lactamases so that the presence of bacterial beta-lactamase producers may impair their therapeutic efficacy. Consequently, general treatment schemes for human actinomycoses should include drugs that are effective not only against the causative actinomycetes and *A. actinomycetemcomitans,* but also against potential producers of beta-lactamases such as *Staphylococcus aureus,* various gram-negative anaerobes of the family *Bacteroidaceae,* and, in case of abdominal and pelvic actinomycoses, certain *Enterobacteriaceae*.

On the basis of the above considerations, the current recommendations for antibiotic treatment of human actinomycoses in Germany, according to which several hundred cases were treated essentially without any therapeutic failure or relapse, are as follows [20]: for cervicofacial actinomycosis, a combination of amoxicillin and clavulanic acid is the treatment of choice. The standard dose is 2.2 g amoxicillin plus clavulanic acid every 8 h for 1 week and then a lower dose of 1.1 g of the same combination every 8 h for another week. Only rarely will delayed clinical improvement of long-term chronic cervicofacial infections indicate that antibiotic treatment of 3 or even 4 weeks duration is required. Parenteral administration of the drugs is recommended; prolonged oral treatment was never found to be necessary. [20] For thoracic actinomycosis, the same therapeutic scheme may be sufficient. Although no reduction in the initial dose is

needed, antimicrobial therapy is usually continued for 3 to 4 weeks. In addition, patients with either advanced chronic pulmonary or abdominal disease may require the addition of 2 g ampicillin every 8 h to increase the aminopenicillin tissue levels (ampicillin is used in addition to amoxicillin to avoid possible side effects associated with high doses of amoxicillin). Treatment of abdominal and pelvic actinomycoses occasionally demands the combination of amoxicillin/clavulanic acid with an aminoglycoside such as tobramycin or gentamicin to inhibit resistant concomitant *Enterobacteriaceae.* [20]

In addition to antimicrobial therapy, surgical drainage of empyema and large abscesses and excision of sinus tracts, underlying foreign bodies, necrotic tissues, sequestra, and recalcitrant fibrotic lesions may be indicated in these infected patients.

NOCARDIOSIS (See also Chap. 207)

Epidemiology

Nocardia species are soil bacteria found worldwide as saprophytes on decaying matter and are not normal inhabitants of the respiratory or gastrointestinal tracts. Disease occurs by inhalation and males are three times more likely than females to become infected.

Nocardia spp. infections are rare in humans, occurring most frequently in patients who are severely immunocompromised. [21], [22] Most clinical infections in temperate countries were caused by *N. asteroides* complex, *N. brasiliensis* (Table 201-3), and, rarely, *N. otitidiscaviarum*. *N. asteroides* complex [comprised of *N. abscessus* (formerly *N. asteroides* sensu stricto type I), *N. asteroides* sensu stricto type VI, *N. farcinica, N. nova,* and possibly other unnamed taxa] is considered to be responsible for the majority of serious invasive infections. *N. brasiliensis* is associated particularly with subcutaneous infections and is predominant in tropical countries. [23], [24] A new taxon, *N. pseudobrasiliensis,* was separated from *N. brasiliensis* and appears to be generally associated with noncutaneous (pulmonary, CNS, or systemic) nocardiosis and differs in susceptibility to ciprofloxacin and resistance to minocycline. [25] *N. otitidiscaviarum* is rare and has no typical geographic distribution. [26] *N. transvalensis* is an unusual emerging human pathogenic *Nocardia* species. [22] Four new species of *Nocardia* were recently described: *N. africana,* [27] *N. brevicatena* complex, [28] *N. paucivorans,* [29] and *N. veterana.* [30]

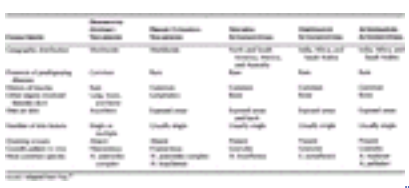

TABLE 201-3 **Distinguishing Features of Systemic and Primary (Cutaneous) Forms of Aerobic Actinomycetes Infections Affecting the Skin**

Nosocomial Infection

Although nocardiosis is most often considered a late-presenting, community-acquired infection, nosocomial outbreaks of nocardiosis in immunocompromised patients attributed to airborne bacterial transmission have been reported. [31], [32], [33] and [34] These outbreaks of nocardiosis have affected patients in a renal transplant unit, [31] children with nocardiosis complicating hematologic malignancies, [32] severely immunocompromised heart transplant patients, [35], [36], [37], [38] and [39] and patients in a special care unit for patients with acute and chronic liver disease and liver transplants. [33]

Recently, three nosocomial endemic or epidemic outbreaks of *N. farcinica* surgical-site infections occurred. [37], [38] and [39] In one outbreak, the transmission of the infection was via an asymptomatic, colonized health care worker and the infectious source was confirmed epidemiologically by genetic methods to be the environment of the health care worker's home. [39] Although definitive sources of the infectious agents could not be identified in the other two outbreaks, it appeared that aerogenic transmission of *N. farcinica* occurred endemically during operative or postoperative treatment in a health care center in Germany. [37] The increase in the number of patients with *N. farcinica* of the same genotype (18 of 20), as identified by pulsed-field gel electrophoresis, correlated with increased construction work during a specific time frame. [37] These authors recommended that because of this correlation, precautions against nocardial infections should be taken in hospitals where renovation work is planned. [37] In the other outbreak involving three heart transplant recipients in France, randomly amplified polymorphic DNA analysis showed one pattern for the epidemiologically related isolates. [38] These outbreaks illustrate the importance of using epidemiologic and laboratory data as the basis for formulating effective control interventions for terminating nosocomial transmission of pathogenic organisms.

Patterson et al. also reported a pseudo-outbreak at a university hospital, in which 18 patient blood cultures were found to be falsely positive for *N. asteroides.* [40] An epidemiologic investigation revealed that the source of contamination was a malfunctioning automated radiometric blood culture machine, and the epidemic strain was confirmed by DNA fingerprinting. Control measures that were instituted and shown to be effective in halting the pseudo-outbreak were changing the needle sterilizer and prolonging needle sterilization time on the machine. [40]

An unusual cluster of nocardiosis cases was also reported among cancer patients who had received therapy in a clinic in the Bahamas. An investigation by the US Centers for Disease Control and Prevention (CDC) determined that the probable cause was contamination of parenterally administered cancer medications. [41] There are also reports of

cutaneous nocardiosis in patients following intravenous heroin abuse. [42], [43]

Clinical Disease

In immunocompromised patients, localized respiratory infection is thought to result from inhalation of *Nocardia* spp. However, in up to half the infected patients, dissemination may occur with a predilection for the CNS and subcutaneous tissues. The clinical manifestations, severity, and prognosis of disease in the infected patient are extremely variable, and may be determined by factors such as the route of infection and the presence or absence of a properly functioning immune system. In immunocompetent hosts, localized subcutaneous infection may result. In severely immunocompromised patients, principal predisposing factors include immunosuppressive therapy, particularly steroid drugs, neoplastic diseases, solid organ and bone marrow transplantation, chronic bronchopulmonary diseases, and the acquired immunodeficiency syndrome (AIDS); the most common clinical presentations are invasive pulmonary infection and disseminated disease. [35], [36], [43], [44] and [45] However, invasive disease may also occur in nonimmunocompromised patients. Underlying pulmonary disorders (e.g., malignancy, tuberculosis) may predispose to respiratory tract colonization with *Nocardia*. In addition, primary cutaneous and subcutaneous infections may develop from inoculation of these microorganisms at the time of surgery or from traumatic inoculation as a result of outdoor activities.

There are four clinical types of cutaneous nocardiosis: mycetoma; lymphocutaneous infection; superficial skin infection (abscess or cellulitis); and secondary cutaneous involvement with disseminated disease.

Localized cutaneous nocardial infections may also present as either a chronically draining, ulcerative lesion or a slowly expanding nodule and, less commonly, pustules, abscesses, cellulitis, or pyoderma. Frequently, there may be spread beyond the initial cutaneous infective focus to involve the regional lymphatics and, in up to one-third of cases, the disease may progress to form lymphatic abscesses. When regional lymph node involvement occurs, this form of the disease is referred to as the lymphocutaneous syndrome and because it bears a striking clinical resemblance to a superficial infection with the dimorphic fungus *Sporothrix schenckii,* it has also been termed the sporotrichoid form of cutaneous nocardiosis. More localized infections may also be misdiagnosed as staphylococcal skin infections. Because skin manifestations may be complications of disseminated disease, the finding of a cutaneous lesion in a patient should not always be attributed to local inoculation.

Differential Diagnosis

The differential diagnosis of cutaneous nocardiosis includes other infections causing granulomas, for example, eumycotic mycetoma; dermal tuberculosis and cutaneous nontuberculous mycobacterial infections; keloid blastomycosis and certain forms of leishmaniasis; sporotrichosis; and botryomycosis. Noninfectious conditions to consider include foreign-body granulomas, soft-tissue sarcomas, and lethal midline granuloma.

Clinical history, epidemiologic considerations, and general pathologic features should alert the clinician to include nocardiosis in the patient's differential diagnosis. A confirmation of the diagnosis may be provided by the presence of granules, histopathologic findings, and culture identification of causative microorganisms. Deep organ involvement may pose more of a diagnostic problem because invasive biopsy procedures may be required and interpretation of the results may be complicated by the occurrence of a mixed infection. Imaging procedures (radiography, and computerized tomographic and nuclear magnetic resonance scans); and invasive procedures (e.g., bronchoscopic biopsy and bronchoalveolar lavage) may be important. A heightened level of clinical suspicion and prompt notification of the clinical microbiology laboratory to perform appropriate tests to screen for the causative organisms may provide the key for early diagnosis of nocardiosis.

Pathophysiology

Nocardia infection is usually acquired by inhalation; rarely, however, direct skin inoculation may be implicated. Inhalation allows establishment of a focal pneumonitis that progresses to necrosis and abscess formation. Rarely, colonization of the skin or respiratory tract by *Nocardia* may occur. Invasive infection in an immunocompetent patient may result in a minimal inflammatory response and negligible residual tissue scarring; however, in immunocompromised hosts, particularly those infected by *N. brasiliensis,* there may be a marked tissue response together with true granuloma formation. The immune status of the patient is crucial in determining whether and to what extent disease progression occurs.

Laboratory Diagnosis

Because *Nocardia* spp. are ubiquitous in nature, the isolation of these microorganisms from microbiologic specimens may be clinically nonsignificant. In a patient's sputum culture, their presence may not always indicate invasive infection and may reflect either laboratory contamination or respiratory colonization. The diagnosis of invasive *Nocardia* species infections is often hindered by their often nonspecific clinical presentation, the requirement for invasive diagnostic biopsy procedures, the difficulty in isolating organisms, and the imperfect taxonomic classification.

DIRECT EXAMINATION If clumps of bacteria or granules are present in the exudate, these should be selectively removed and crushed between two glass microscope slides. In addition, some of the exudate should be examined in a wet mount to exclude the presence of fungal hyphae. Two smears should be stained prior to microscopic examination of the material; one with Gram's stain and the other with modified Kinyoun's stain. [46] The presence of gram-positive filaments with some degree of acid fastness is suggestive of *Nocardia*. Although the gross and microscopic characteristics of the granules may suggest the etiologic agent, definitive identification is dependent upon culture isolation and identification.
ISOLATION Culture isolation of *Nocardia* may be difficult because growth can take up to 3 weeks on routine culture media and *Nocardia* colonies can be obscured by the rapid overgrowth of concomitant bacterial species. Additionally, *Nocardia* is inhibited by antibiotics in fungal culture media and often do not survive the digestive procedures used in

mycobacterial culture isolation. The observation that some nocardial isolates may not survive in respiratory specimens has prompted studies of recovery procedures for aerobic actinomycetes from these sources. [47], [48] Digestion-decontamination of respiratory tract specimens with *N*-acetyl-L-cysteine, sodium hydroxide, and benzalkonium is toxic to *Nocardia.* [49] The Thayer-Martin medium containing vancomycin, colistin, and nystatin, a selective medium commonly used in clinical laboratories for the isolation of *Neisseria* species, is useful as a selective medium for the growth of *Nocardia* species. [49] Other promising media include buffered-charcoal-yeast extract (BCYE) agar, and selective BCYE media containing polymyxin, anisomycin, and vancomycin; these media are commonly used in clinical microbiology laboratories for the isolation of *Legionella* species from respiratory specimens. [50] Pretreatment of clinical specimens with a low pH (2.2) KCL-HCL solution for 4 min is necessary for adequate isolation of *Nocardia* species. [50] Although no optimal methods for isolating the aerobic actinomycetes from potentially contaminated specimens exist, the methods discussed above likely represent an improvement for the recovery of these microorganisms when compared to direct plating of specimens to conventional media (e.g., Sabouraud-dextrose agar, brain–heart infusion agar, blood agar, or Lowenstein-Jensen).

BIOCHEMICAL IDENTIFICATION The final identification of the aerobic actinomycetes depends upon the results of a battery of tests including the hydrolysis of different substrates (e.g., *N. brasiliensis* hydrolyzes casein and tyrosine, but not xanthine, Fig. 201-4), and acid production or utilization of carbohydrates. Importantly, routine identification methods in use in many clinical laboratories often misidentify *N. farcinica* as *N. asteroides* complex, *Rhodococcus*/ *Gordona* complex, or *Mycobacterium* species. Therefore, additional supplemental tests that include comparison of growth on agar slants at 35°C (95°F) and 45°C (113°F), the hydrolysis of acetamide, arylsulfatase production, and antimicrobial susceptibility testing may be needed for the definitive identification of *N. farcinica.* [51], [52], [53], [54], [55], [56] and [57] Table 201-4 lists the characteristics that differentiate the medically important species of the genus *Nocardia*. In addition, newer, rapid, sensitive identification techniques (e.g., use of chromogenic enzyme substrates) have been developed. [58] The diagnostic future will probably rest on DNA amplification and restriction endonuclease analysis. [59]

TABLE 201-4 **Characteristics Used to Differentiate the Medically Important** *Nocardia* **Species**

Diagnostic Immunology

Diagnosis by immunologic methods [60], [61] has been hampered by the antigenic complexity of the aerobic actinomycetes, cross-reactivity with other species and genera (including *Mycobacteria*), and development of a generally poor immunologic response against many nocardiae during the infectious process. With the use of affinity chromatography, Boiron and Provost recently purified a 54-kDa antigen from *N. asteroides* for a Western blot assay and found little cross-reactivity with *N. brasiliensis, Rhodococcus rhodochrous, M. tuberculosis,* and *M. leprae.* [60] Although there have been many previous immunologic studies with *N. asteroides,* only recently were data on a sensitive *N. brasiliensis* immunodiagnostic assay published. Salinas-Carmona described an enzyme-linked immunosorbent assay that used the 26- and 24-kDa proteins for the diagnosis of *N. brasiliensis* mycetoma infections and showed its usefulness in assessing the patient's response to treatment. An additional advantage of this particular assay might be its demonstrated cross-reactivity with *N. asteroides.* [61]

Therapy

Sulfonamides or trimethoprim-sulfamethoxazole (TMP-SMX) is the therapy of choice for proven or presumed nocardiosis. [21] Antimicrobial therapy must be adjusted to the particular species of *Nocardia* present, to individual strain antimicrobial susceptibility patterns, and to the site and type of infection. Certain strains of *N. asteroides* complex may be susceptible to sulfonamides or TMP-SMX, and response to treatment may be attained in greater than 90 percent of cases, if the infection is confined to pleuropneumonia. However, in patients with disseminated disease to the CNS, and/or renal transplant recipients and HIV-infected patients, optimal drug therapy is difficult. [22] First, these patients frequently develop side effects (skin rash, fever, neutropenia, hepatotoxicity) with TMP-SMX that may be aggravated by prolonged use of TMP-SMX as prophylactic therapy. Second, the infecting microorganism may develop resistance to prolonged therapy with TMP-SMX, alternative agents, or drug combinations. Third, there are scant data on the efficacy of newer oral alternative antimicrobial agents or combinations that might improve the outcome of patients infected with *Nocardia* species and avoid the problems of TMP-SMX.

Sulfonamides have good penetration into the cerebrospinal fluid (CSF) and achieve high CSF concentrations. [62]

Sulfadiazine is the most commonly prescribed drug, but sulfisoxazole and triple sulfonamide combinations are also effective. Drug therapy should be continued for 6 to 18 months depending on the extent of the disease because of the high incidence of relapse and metastatic abscesses with shorter duration of therapy. [21] For most patients with nocardiosis, clinical improvement is expected within 7 to 10 days after the initiation of empiric therapy with sulfonamides (with or without trimethoprim). For infected patients the exact route of drug administration may be influenced by the assessment of their overall clinical status. In addition, a serum level estimation at least once following institution of antimicrobial therapy may be useful to establish that adequate drug absorption is occurring and provide a basis for any necessary adjustment of the patient's drug dosage to achieve recommended levels in blood of 100 to 150 µg/mL approximately 2 h after an oral dose. It is recommended that therapy with sulfonamides be given at high doses (3 to 6 g/day) for extended periods 6 to 12 months. While primary cutaneous nocardiosis may be cured by a 1- to 3-month course of antimicrobial therapy and uncomplicated pulmonary nocardiosis may respond to therapy for 6 months or less, therapy for 12 months or more is usually required for disseminated infection or if the patient is immunocompromised. Alternative antimicrobial agents in sulfonamide sensitive patients include ampicillin, clindamycin, erythromycin, and minocycline. Minocycline reaches excellent concentrations in the brain and can penetrate into phagocytes to kill intracellular organisms. [21] Ampicillin plus erythromycin or sulfonamide have demonstrated synergism in vitro. [21] Although amikacin is an effective agent in vitro, it does not cross the blood-brain barrier and prolonged outpatient therapy is impractical. Surgical drainage of abscesses and débridement of avascular tissue may be an important adjunct in the successful management of infected patients.

ACTINOMYCETOMA (See also Chap. 207)

Epidemiology

Mycetoma is a late-stage clinical manifestation of a subcutaneous infection produced by either bacteria (actinomycetes causing actinomycotic mycetoma, or actinomycetoma) or fungi (eumycotic mycetoma, or eumycetoma). [63] Patients with these chronic infections may have a history of a specific minor localized traumatic injury. Walking barefooted may be the major mode of acquisition of these infections, because this practice potentially exposes the feet to repeated soil-contaminated puncture wounds. Only actinomycetoma is discussed further in this chapter.

Microorganisms reported to cause actinomycetomas include *N. brasiliensis, Actinomadura madurae, A. pelletieri, Streptomyces somaliensis,* and, less commonly, *N. asteroides, N. otitidiscaviarum, Nocardiopsis dassonvillei,* and *N. transvalensis*. In North America, South America, Mexico, and Australia, *N. brasiliensis* is the chief cause of actinomycetomas; in Africa, Saudi Arabia, and India, *S. somaliensis* and *A. madurae* predominate. These infections most commonly affect patients in the rural areas in third world countries (Table 201-3).

Clinical Disease

Actinomycetoma is a chronic, localized, slowly progressive and often painless subcutaneous disease. The foot is the most common site of involvement; but, the hands (Fig. 201-5 and Fig. 201-6), face, neck, and upper back (Fig. 201-7, Fig. 201-8, and Fig. 201-9) may also be involved. The pathology of the disease is characterized by tumefaction, subcutaneous nodules, destructive granulomata, deformity, and discharging sinus tracts with intercommunicating channels that exude pus, often with macroscopically visible granules of various sizes and colors. Macroscopically, the granules of *Nocardia* usually appear white or yellowish in color, and those of *A. madurae* usually appear tan, orange to deep red. In contrast, *A. pelletieri* granules appear red and those of *S. somaliensis* are usually a cream to brown color macroscopically (Table 201-1).

Histopathology

Actinomycetomas, eumycotic mycetomas and botryomycosis are all associated with a similar tissue response. Typically, in hematoxylin and eosin (H&E)-stained tissue sections, deeply basophilic granules may be present, surrounded by evidence of chronic inflammation (i.e., palisading epithelioid cells and multinucleated giant cells mixed with smaller numbers of plasma cells, lymphocytes, and macrophages). Amorphous, deeply eosinophilic, radially arranged Splendore-Hoeppli material may also be present on the periphery of these granules (Fig. 201-10). Usually, neither the filaments of actinomycetoma and eumycotic mycetoma nor the bacterial agents causing botryomycosis are seen in H&E-stained tissue sections. To further define a granule as being actinomycotic or eumycotic, special stains (i.e., B&B stain for bacteria, the GMS method for both bacteria and fungi, and PAS for fungi only) are needed. If either the B&B- or the GMS-stained sections reveal gram-positive branched bacterial filaments (<1.0 µm in width), this finding suggests a diagnosis of actinomycetoma; however, the presence of a pure population of nonfilamentous bacteria (bacilli, cocci, or coccobacilli) suggests the diagnosis of botryomycosis. If either a GMS- or PAS-stained section shows broad (2 to 6 µm) hyphae, often in addition to the presence of numerous chlamydospores in the mycelium, these findings suggest a diagnosis of eumycotic mycetoma.

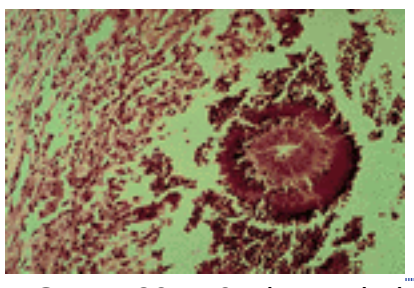

FIGURE 201-10 Histopathologic section of mycetoma featuring a granule of *Nocardia brasiliensis*. Note homogenous center, peripheral clavate area, and surrounding tissue reaction with infiltration by polymorphonuclear leukocytes. Hematoxylin and eosin stain. Magnification, × 100. (*Courtesy of Oscar Reyes-Flores, MD, Instituto de Biomedicina, Caracas.*)

Other nonspecific histopathologic findings include localized abscesses in the dermis that contain granules that may be interspersed with areas of intense infiltration with polymorphonuclear leukocytes, necrotic debris, and dense granulation tissue. Among the agents causing actinomycetomas, the granules of *Nocardia* are small (about 100 µm in diameter) and the granules of *A. madurae* are variable in size (0.5 to 5 mm), whereas the granules of *A. pelletieri* and *S. somaliensis* range from 300 to 500 µm and from 0.5 to 5 mm, respectively. Although several earlier references suggested that the

histologic appearance may enable a species-specific diagnosis, [64] the histopathologic findings, including the appearance of granules, if present, are markedly nonspecific, and culture isolation and identification of the causative agent are essential for confirmation of the diagnosis of aerobic actinomycete infection. This is because recent taxonomic studies (using DNA hybridization and rRNA gene sequencing) have confirmed marked heterogeneity among the genera of aerobic actinomycetes. [59] In addition, the macroscopic granules that may be seen to emerge in the exudate from the sinus tracts in actinomycetoma patients may or may not simulate the corresponding microorganism's colonial characteristics on microbiologic culture.

BOTRYOMYCOSIS

This is usually a chronic or subacute inflammation of the skin and subcutaneous tissues. The bacteria most commonly implicated in causing botryomycosis include *Pseudomonas aeruginosa, Actinobacillus lignieresii, Staphylococcus aureus, Proteus* species, and *Escherichia* species. [65]

Diagnosis

Clinical history, epidemiologic considerations, and general pathologic features should alert the clinician to the possible diagnosis of actinomycetoma. The detection of suggestive microorganisms in stained histologic sections obtained by deep wedge surgical biopsies or preparations from fine-needle aspiration may be of value. [65], [66] Table 201-1 lists the criteria for presumptive microbiologic diagnosis to the genus level. However, it has been suggested that patient isolates should be sent to a specialized reference laboratory for species identification and in vitro susceptibility testing. [21]

Treatment

Therapy for patients with actinomycetoma should be individualized. Economic considerations may influence the choice of therapy, particularly in developing countries. Parenteral treatment is difficult in ambulatory patients. Patient follow-up is always important and clinical progress can be monitored by biopsy or by aspiration and culture. Dapsone (diaminodiphenylsulfone) reportedly is effective and has been used in combination with other antimicrobials. Dapsone is usually prescribed in an oral daily dosage of 3 to 5 mg/kg for periods of 1 to 2 years following clinical cure. [67] In the last two decades, therapy with other sulfonamides (e.g., TMP-SMX) has been reported to be successful. The recommended therapeutic dose of TMP-SMX is 8 and 40 mg/kg per day for periods ranging from 6 months to several years with a reported average success rate of more than 60 percent. [67] This drug should be used with caution in AIDS patients as they may be intolerant of this combination. The use of other agents (e.g., amikacin) has been proposed, but there is no widespread consensus on their use. There are additional reports of patients unresponsive to sulfonamide therapy who were successfully treated with a combination of amikacin (15 mg/kg per day total dose, divided and administered as two intramuscular injections every 12 h) and oral TMP-SMX, each for a total of 3 weeks, followed by oral TMP-SMX alone for an additional 2 weeks. [67], [68] This constitutes “a cycle.” One to three cycles are usually required (5 to 15 weeks of treatment). [67] The patient should be monitored for the development of amikacin-associated ototoxicity. Surgery is effective in early or small lesions and may be the last recourse in extensive mycetomas. Extension of the infection to involve bone may be an important determinant in deciding the extent of surgical debridement. Medical treatment should precede and continue after surgical treatment. Stopping any immunosuppressant medications and other specific measures to enhance the patient's immune status (e.g., antiviral treatment for HIV infection) and surgery (e.g., removal of infected prostheses or foreign bodies) may have an important adjunctive role in the patient's therapy. In a more recent case series of actinomycotic mycetoma patients, Ramam et al. used a two-step regimen that consisted of an intensive phase of therapy with intravenous penicillin (1 MU every 6 h), intravenous gentamicin (80 mg two times per day), and oral TMP-SMX (80 to 400 mg two times per day) for 5 to 7 weeks. [69] One patient with associated leprosy received dapsone (100 mg two times per day) as a substitute for TMP-SMX. After the initial therapy in the hospital, patients were discharged and treatment was continued at home with amoxicillin (500 mg two times per day) and TMP-SMX/dapsone at the same doses as before. Maintenance therapy was continued 2 to 5 months after the lesions became completely inactivated.

Leprosy (Hansen's disease) can be defined as a chronic granulomatous infection and its sequelae, caused by *Mycobacterium leprae,* and affecting primarily skin and nerves. Leprosy is an important clinical problem, with more than 600,000 new cases yearly, worldwide. Also, despite apparently curative antibacterial therapy, one-quarter to one-third of all patients will have a debilitating and permanent neurologic deficit. Because of its diverse host responses, for clinicians, leprosy is a challenging diagnostic problem, and for immunologists, it is an exemplary model for understanding cell-mediated immunity in humans.

HISTORICAL ASPECTS

Leprosy is an ancient disease; sacred writings from India in the sixth century B.C. give a good description of a similar or identical illness. Greek soldiers returning from Asia in third century B.C. are thought to have introduced the disease into Europe. Stigmatization of patients with leprosy remains an unfortunate but enduring legacy of the European pandemic (1000 to 1500 A.D.). Hansen's attribution of *M. leprae* as its etiologic agent in 1873 marks the beginning of scientific leprology. [1]

Effective chemotherapy began with the introduction of sulfones in 1943. The limited growth of *M. leprae* in the mouse foot pad, in 1961, provided a way to screen for therapeutic agents and to identify drug resistance. [2] Rifampin, in 1970, was the first drug to be identified as bactericidal for *M. leprae* and is now the cornerstone of most therapeutic regimens.

In 1919, the lepromin skin test inaugurated systematic study of host resistance as the source of disease diversity, [3] lymphocyte transformation tests being established in the 1960s as an in vitro correlate. The recognition of leprosy in the nine-banded armadillo, in 1971, provided a source of large quantities of highly purified *M. leprae* for a wide variety of investigations, culminating in the sequencing of the entire genome of *M. leprae* in 2001. [4] This landmark achievement will provide novel avenues of investigation, which, in turn, will provide new methods of intervention.

EPIDEMIOLOGY

Leprosy, primarily a disease of developing countries, is endemic in all continents, except Antarctica. In the Americas, only Canada and Chile are not endemic areas, with Texas and Louisiana being endemic states in the United States. The southern-most nations of Europe have a very low incidence, while leprosy is endemic in many Pacific islands. The Indian subcontinent has two-thirds of the world's leprosy burden. The highest case detection rates are in India, Brazil, Madagascar, Nepal, and Tanzania. During the decade of the 1990s, the prevalence of leprosy fell by 90 percent, because patients completing a course of multiple-drug therapy have been considered to be cured, but the incidence of the disease has remained unchanged. [5]

In all populations studied, lepromatous disease is more common in men than in women by a 2:1 ratio. The tuberculoid form dominates wherever the disease is common. The median age of onset is less in tuberculoid than in lepromatous patients, but in both groups, leprosy is predominantly a young person's disease, the majority of cases occurring before age 35 years. However, age is not protective; new cases of each type occur in the eighth and ninth decades of life. The incubation time for tuberculoid leprosy is up to 5 years and for lepromatous may be 20 years or longer.

The preponderance of opinion supports the traditional view that *M. leprae* is transmitted from human-to-human, but the presence of an *M. leprae* caused lepromatous-like illness in wild armadillos, [6] evidence of armadillo exposure as a risk factor for leprosy in people, [7] and the presence of an *M. leprae*-like organism on sphagnum moss, [8] suggest that nonhuman sources for *M. leprae* may be important. The route of infection is unknown, but current evidence favors

respiratory transmission; evidence for congenital and percutaneous transmission has been presented, but these are probably rare. [9] In leprosy endemic areas, subclinical infection is common, as judged by serologic studies identifying *M. leprae*-specific antibodies. [10]

ETIOLOGY AND PATHOGENESIS

M. leprae, the cause of leprosy, is a noncultivable, gram-positive, obligate intracellular, acid-fast bacillus. The union of bulk extracted *M. leprae* from armadillos with the techniques of molecular biology has proven to be a fruitful marriage, its crowning accomplishment being the sequencing the bacillary genome. [4] The genome of *M. leprae* (3.27 megabases) is notably shorter than that of *M. tuberculosis,* (4.41 megabases). Even more striking, the *M. leprae* genome codes for 1600 genes, *M. tuberculosis* codes for 4000. The two species share 1439 genes in common. In *M. leprae* only one-half of its genome is coding sequence, this evident gene deletion and decay leaving *M. leprae* with few respiratory enzymes, but offering a reasonable explanation for the failure to cultivate the organism in cell-free media, as well as for its obligatory intracellular environment.

The bacillary cell wall consists of a peptidoglycan backbone linked to arabinogalactan and mycolic acids. Immunogenic proteins are associated with the cell wall, and also present in the cytoplasm. These include highly conserved heat shock proteins of molecular weight 10, 65, and 70 kDa, each bearing species-specific and cross-reacting epitopes. A lipoglycan target of both antibody and cellular immune responses, lipoarabanomannan, courses through the outer membrane and inserts into the cell membrane. Phenolic glycolipid I is a major, species specific and immunogenic, constituent of the highly nonpolar outer layer of the bacillus. Entry into nerves is mediated by the binding of the species-specific trisaccharide in phenolic glycolipid I to laminin-2 in the basal lamina of Schwann cell-axon units, [11] providing a rationale as to why *M. leprae* is the only bacterium known to invade peripheral nerves.

In tissues or smears, *M. leprae* is quantified by the biopsy index (BI), a logarithmic scale as to the numbers of bacilli per oil immersion field (OIF): a BI of 6 is 1000 or more bacilli/OIF; a BI of 5 is 100 to 1000/OIF; a BI of 4 is 10 to 100/OIF; a BI of 3 is 1 to 10/OIF; a BI of 2 is 1 bacillus/1 to 10 OIFs; a BI of 1 is 1/10 to 100 OIFs; and a BI of 0 is no bacilli in 100 OIFs.

GENETICS

A twin study has provided compelling evidence that both genetic and environmental factors are important in determining disease susceptibility and disease expression. [12] The recent report of a susceptibility locus for leprosy in India, located on chromosome 10p13, may be the beginning of going beyond the vague rubric of “polygenetic susceptibility.” [13] Major histocompatibility complex class II antigens appear to influence disease expression, that is tuberculoid versus lepromatous, but not susceptibility. [14]

PREVENTION

Protocols endeavoring to control leprosy by vaccination usually consists of BCG alone, viable BCG in combination with killed *M. leprae,* or killed *M. leprae* alone. [15] Most studies support a reduction in leprosy incidence, roughly one-third in tuberculoid cases, considerably less in lepromatous. The recent observation that lipid and lipoglycan antigens are presented to T cells (CD4–, CD8–, CD3+) by CD1+ cells opens the door to entirely new vaccination protocols. [16] Other preventive measures, such as isolation of patients or treatment of patient contacts with antimicrobials, have been disappointing.

CLINICAL MANIFESTATIONS

The diverse clinical manifestations of leprosy can be reduced to two kinds of changes, a granulomatous spectrum and the reactional states.

A Granulomatous Spectrum

The most detailed description of the granulomatous spectrum of leprosy came from Ridley and his associates, [17], [18] integrating both clinical and histologic changes. Ridley's construct is a six-member granulomatous spectrum, ranging from high to low resistance, TT (polar tuberculoid), BT (borderline tuberculoid), BB (borderline), BL (borderline lepromatous), LLs (subpolar lepromatous), and, finally, LLp (polar lepromatous):

$$TT \Leftarrow BT \Leftrightarrow BB \Leftrightarrow BL \Leftrightarrow LLs\ LLp$$

Conceptually, TT and LLp are clinically stable, but, between the poles, the hosts granulomatous posture may change, as indicated by the arrows, upgrading (or reversing) to a posture of higher resistance, often with devastating inflammation, or downgrading to a posture of lower resistance, usually silent but occasionally inflammatory. BT patients may upgrade to TT, thus, becoming stable, but LLs patients do not downgrade to LLp nor do LLp patients upgrade. Putatively, the host's granulomatous posture is the result of the degree of cell-mediated immunity directed against *M. leprae*.

In comparison of pre-Ridley and Ridley terminology, tuberculoid corresponds to TT and BT, borderline or dimorphic to BB and BL, and lepromatous to LLs and LLp. In virtually all TT patients, and in most BT cases, acid-fast bacilli cannot be found, whereas in BB, BL, LLs, and LLp, bacilli are demonstrable with ease. Ridley's construct is useful in classifying patients, especially for immunity. Another classification system is useful for treatment: paucibacillary, that is to say no acid-fast bacilli found, or multibacillary, that is to say one or more bacilli found.

Peripheral Nerve Changes

Four types of peripheral nerve abnormalities are common in leprosy: (1) nerve enlargement (usually perceived as asymmetry), particularly in those close to the skin, such as the great auricular, ulnar, radial cutaneous, superficial peroneal, sural and posterior tibial; (2) sensory loss in skin lesions; (3) nerve trunk palsies either with signs and symptoms of inflammation or without such overt manifestations, that is, silent neuropathy, [19] usually with both sensory and motor loss (weakness and/or atrophy) and, if long-standing, also with contracture; and (4) acral distal symmetric anesthesia, a withering away, so to speak, of the type C fibers, involving heat and cold discrimination before loss of pain or light touch, beginning in acral areas and, over time, extending centrally but sparing the palms, at least for a while. Uncommon peripheral nerve abnormalities include nerve abscesses (palisading granulomas formed about cutaneous sensory nerves) and the carpal tunnel syndrome. Anhidrosis is a common manifestation of sympathetic nerve involvement.

Dermatologic and Neural Changes

POLAR TUBERCULOID LEPROSY In TT, immunity is strong as manifested by spontaneous cure and the absence of downgrading to a posture of less host resistance. The primary skin lesion of TT is a plaque, often assuming an annular configuration secondary to peripheral propagation and central clearing (Fig. 202-1). The border of the plaque or both borders of the annulus are sharply marginated. Typically, the lesion is firmly indurated, elevated, erythematous, scaly, dry, hairless, and hypopigmented, but clinically, considerable variation is encountered.

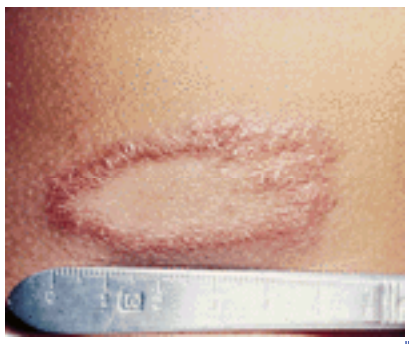

FIGURE 202-1 A solitary, anesthetic, and annular lesion of polar tuberculoid leprosy (TT), which had been present for 3 months. Its sharp margins, erythema, and scale are more evident than its elevation. The central red dots are the sequelae or “footprints” of testing for pinprick perception when it is absent. (If present, the patient withdraws, preventing overtly purpuric consequences.)

A nearby sensory nerve may or may not be enlarged, but the lesion itself is characteristically anesthetic and anhidrotic. Skin lesions are often solitary, particularly in those patients who are TT de novo, as contrasted to those who upgrade to TT from BT, where multiple lesions, usually no more than three, may be found. In both groups, immunity is sufficient to effect cure, thus, placing an upper limit of 10 cm on lesion size, but antibiotic therapy is recommended.
BORDERLINE TUBERCULOID LEPROSY In BT disease, immunologic resistance is strong enough to restrain the infection, in that the disease is limited and bacillary growth retarded, but the host response is insufficient to self-cure. These patients are somewhat unstable—resistance may increase, upgrading to TT, or decrease, downgrading to BL. The primary skin lesions of BT are plaques and papules. As in TT, an annular configuration is common and both borders are sharply marginated but annular lesions or plaques may have satellite papules (Fig. 202-2). Hypopigmentation may be conspicuous in darkly pigmented patients. In contrast to TT, typically, there is little or no scaling, less erythema, less induration, and less elevation, but lesions may become much larger, that is, well over 10 cm in diameter, a single lesion sometimes involving an entire extremity over time. Multiple, asymmetric lesions are the rule, but solitary lesions are not rare.

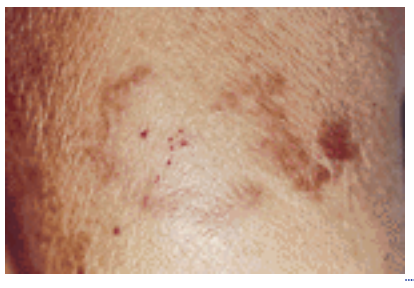

FIGURE 202-2 One of several lesions of borderline tuberculoid (BT), which had an incompletely annular configuration with satellite papules. Compared to the TT lesion in Fig. 202-1, there is less erythema, no evident scales, but sharp margination, and the footprints of absent pinprick perception are also seen.

Loss of sensation in skin lesions is the rule and nerve trunk involvement, enlargement, or palsies, usually in no more than two and asymmetric, are common. Nerve abscesses, when they occur, are most often seen in males with BT disease.
BORDERLINE LEPROSY BB is the immunologic midpoint or mid-zone of the granulomatous spectrum, being its most unstable area, with patients quickly up- or downgrading to a more stable granulomatous posture with or without a clinical reaction. Characteristic skin changes are annular lesions with sharply marginated interior and exterior margins, large plaques with islands of clinically normal skin within the plaque, giving a “Swiss cheese” appearance, or the classic dimorphic lesion. Because of instability, the BB posture is short-lived and such patients are evidently rarely seen; for example, we have yet to see a nonreactional patient meeting both clinical and histologic criteria.
BORDERLINE LEPROMATOUS LEPROSY In BL disease, resistance is too low to significantly restrain bacillary proliferation, but still sufficient to induce tissue destructive inflammation, especially in nerves. Thus, patients with BL may have the worst of both worlds. The BL category is highly variable in its clinical expression. Although seen in only a third of BL patients, the classic dimorphic lesion is the most characteristic, having an annular configuration with a poorly marginated outer border (lepromatous-like) but a sharply marginated inner one (tuberculoid-like, hence, having both morphologies or dimorphic) (Fig. 202-3). Poorly or sharply marginated plaques with “punched out” or “Swiss cheese”

sharply marginated areas of normal skin in the interior of the plaque are also characteristic, and can be viewed as a variant of the classic dimorphic lesion. Annular lesions with sharply marginated exterior and interior borders are not uncommon. When they occur, lepromatous-like, poorly defined papules and nodules may be numerous, but are usually accompanied by some sharply marginated lesions somewhere (Fig. 202-4).

FIGURE 202-3 A characteristic borderline or dimorphic lesion, which is an indurated and elevated annular plaque that has a well defined “tuberculoid” interior margin, but a poorly defined “lepromatous” exterior margin. Having both morphologies, it is termed “dimorphic.” (*From Demis DJ, editor: Clinical Dermatology, 23rd revision,* Vol. 3, unit 16–29, 1996, p 14. Courtesy of Lippincott Williams & Wilkins.)

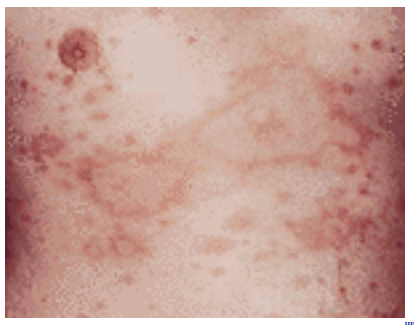

FIGURE 202-4 Multiple lesions in a patient with borderline lepromatous (BL) leprosy. The annular lesions vary in size and are asymmetrically distributed. In contrast, the poorly defined papular and nodular lesions are roughly symmetric. Loss of sensation was present in most lesions.

Lesions range in number from solitary (something happens first, the tip of an inapparent iceberg) to numerous and widespread. Generally speaking, the annular and plaque lesions, however numerous, are asymmetric, but the lepromatous-like nodules, if numerous, are symmetric. Skin lesions are often hypesthetic or anesthetic, but not necessarily so. Nerve trunk palsies have their highest prevalence in BL disease, but are variable in number, ranging from none to serious neurologic deficits, both motor and sensory, in all four extremities. Involvement of both median and ulnar nerves, not infrequently bilateral, is characteristic. When disease is extensive, BL patients may also develop acral distal symmetric anesthesia. Untreated BL patients have slowly relentless progression of skin and nerve changes. With or without treatment, this course may be altered by a reactional state, upgrading reactions being more common than erythema nodosum leprosum (ENL; see below). Also, BL patients may silently downgrade to an LLs granulomatous posture.

LEPROMATOUS LEPROSY In lepromatous leprosy (LL) disease, the lack of cell-mediated immunity toward *M. leprae* permits unrestricted bacillary replication and widely disseminated, multiorgan disease. Poorly defined, skin-colored nodules are the most characteristic lesions, usually up to 2 cm in diameter, and symmetrically distributed (Fig. 202-5). Dermatofibroma-like or histiocytoma-like lesions, usually multiple, are sharply marginated erythematous papules, sometimes confluent into plaques, and are not rare in untreated Mexican-born patients, but are also seen in Filipinos and Samoans (Fig. 202-6). Diffuse dermal infiltration is always present subclinically and may be overtly manifested by widening of the nasal root and fusiform swelling of the fingers, mimicking a rheumatic illness. With progressive bacillary proliferation, further cellular infiltration, and the consequent thickening of the dermis, the skin is thrown into folds producing the leonine faces often in conjunction with nodular lesions. Less-common presenting skin lesions include digitate, barely indurated patches of erythema (Fig. 202-7), which in light-skinned patients are sometimes followed by a mild hyperpigmentation; in dark-skinned patients, multiple hypopigmented macules may originate in such lesions, a veil of melanin concealing the erythema. A clinical clue of LLs is a sharply marginated region in a lesion, perhaps the residual of a BL lesion in a patient who has downgraded to LLs.

FIGURE 202-5 *A, B*. Multiple skin-colored papular and small nodular lesion in a patient with polar lepromatous (LLp) leprosy. The margination of the lesions is variable, some being poorly defined. The absence of clinical inflammation is evident. Some distortion of the normal helix is arising from diffuse infiltration as well as from the nodular lesions.

FIGURE 202-6 Multiple papular lesions, which are solitary and confluent, in a patient with subpolar lepromatous (LLs) leprosy. Their uniformly sharp margins and erythema are in contrast to the lesions in Fig. 202-5.

FIGURE 202-7 These multiple, barely palpable, erythematous, and asymptomatic lesions had been erupting over the previous 2 months in a LLs patient. With treatment, as lesions remitted they became mildly hyperpigmented. Here, the accentuation of the normal skin markings are in contrast to their effacement in the lesions in Fig. 202-5 and Fig. 202-6.

Hair loss, common on the eyebrows, where it progresses laterally to medially, but also on the eyelashes and extremities, may be partially reversible if treated early. Scalp involvement is rare. Loss of eccrine sweating from sympathetic nerve involvement is common but rarely so extensive as to lead to heat intolerance. Any given skin lesion may or may not be hypesthetic but generally, in each patient, some are. Nerve trunk palsies occur, but are less common than in BL. Acral distal symmetric anesthesia is to be expected and may be so severe as to lead to debilitating trophic changes of the hands or feet. Untreated LL disease is relentlessly progressive, but this course may be altered by reactional states. LLs and LLp subjects frequently develop ENL, but LLp patients do not develop reversal reactions (see below), whereas LLs patients may.

Systemic Associations

Because of motor or sensory changes in cranial nerve V, the eye may be at risk in TT and BT disease, as well as in BB, BL, and LL leprosy. In the latter group, numerous changes in the cornea and anterior chamber are possible, iritis being a common serious change, occurring de novo or in association with reactions. Corneal insensitivity is the common, treatable change. Routine ophthalmologic examination is recommended for all patients.

In all LL patients and in BL with extensive disease, wide dissemination of the infection is the rule, but, with the exception of the upper respiratory tract (tip of the nose through the vocal cords with rhinitis, septal perforation, and nasal collapse being not uncommon), eyes and testicles (atrophy, impotence, and infertility), clinically troublesome injury is unusual. With effective chemotherapy, chronic disability from ocular or upper respiratory tract involvement is less common than previously, but has not disappeared, making ophthalmologists and otolaryngologists still vital to the successful management of patients with leprosy, to evaluate and treat acute changes, and to prevent chronic changes.

Variants

PREGNANCY AND POSTPARTUM Pregnancy is a precipitating factor for leprosy in 10 to 25 percent of women patients, presumably because of altered immunity. When pregnant, LL and BL patients are predisposed to develop ENL, but in the postpartum period, they are predisposed to develop reversal reactions, putatively due to reduced immunity in the former and restored immunity in the latter. [20] Of the drugs used to treat leprosy, none have been proven to be safe for the fetus and one is clearly contraindicated. Fetal damage attributable to dapsone evidently has not been observed, hence continuation of dapsone in multibacillary patients is usually recommended. The wishes of the patient should be carefully considered. Untreated, lactating BL and LL patients have viable bacilli in their milk, but no definable risk has been identified in infants ingesting such bacilli. [21] Dapsone in mother's milk may produce hemolysis in baby.

INDETERMINATE LEPROSY Indeterminate leprosy is a term with nearly as many meanings as it has users. We prefer the definition of Khanolkar, [22] designating an early lesion, appearing before the host makes a definitive immunologic commitment to cure or to an overt granulomatous response. Clinically, the indeterminate lesion is a hypopigmented macule, with or without a sensory deficit and acid-fast bacilli, if found, are in very small numbers. Such lesions are rare in our clinic. The term is inappropriately used to describe lesions rich in bacilli but having neither typical tuberculoid or lepromatous histological responses, such patients usually being BL and occasionally LL.

ACQUIRED IMMUNODEFICIENCY SYNDROME OR HIV INFECTION In contrast to the high incidence of tuberculosis and *M. avium-intracellulare* infections in AIDS or HIV patients, leprosy does not behave as an opportunistic infection in these individuals. Also, AIDS or HIV does not appear to influence disease expression (tuberculoid versus lepromatous) or the frequency of reactional states, but may be a risk factor for recurrent reversal reactions. [23]

DISABILITY OF HANDS AND FEET Approximately one-quarter to one-third of newly diagnosed patients with leprosy will eventually have some chronic disability secondary to irreversible nerve injury, usually of the hands or feet, or from eye involvement. Weakness from loss of innervation of muscles is a self-evident cause of disability. Loss of protective sensation is less obvious, but no less real. When a sharp or hot object cannot be perceived as such, injury occurs. Because this injury is more severe than if sensation were normal, infection is more apt to occur. Because the infection can produce no painful signal, the part is not rested, allowing the infection to become extensive before help is sought. Repetitive cycles of injury and infection, permitted by loss of protective pain sensation, is the source of severe tissue destruction in leprosy. Management and prevention of the problems arising from nerve injury require the skills of

orthopedic surgeons, podiatrists, plastic surgeons, physical therapists, orthotists and occupational therapists.
RELAPSING LEPROSY “Multibacillary” patients who are noncompliant or who develop drug resistance are prone to relapse. Such individuals present in several ways, including (1) a reprise of their initial presentation, (2) florid dermatofibroma-like lesions (histoid lesions), (3) a reactional state, and (4) a clinical state of higher resistance than their initial presentation, for example, an initially LLs individual having BL or even BT disease.

Reactional States

Generically, the reactional states of leprosy are distinctive, tissue destructive, inflammatory processes, putatively immunologically driven, that greatly increase the morbidity of the disease and, because of the experience required for optimal patient care, justify leprology as a clinical subspecialty. When present, a reactional state is superimposed upon the underlying granuloma, but it usually dominates the clinical picture. Analogous to the p electron in photobiology, when the granulomas accept immunologically driven “energy,” the excited granuloma is able to injure tissues in ways that it cannot when in its ground state.

DELAYED-TYPE HYPERSENSITIVITY REACTION (JOPLING'S TYPE I REACTION) Although widely regarded as a delayed-type hypersensitivity (DTH) response, the nomenclature is not uniform. Reversal reaction, originally synonymous with “upgrading,” has come to be used as identical to type I, probably because most type I reactions are associated with reversal. Designation by mechanism as a DTH reaction is a rational and acceptable name. DTH reactions are particularly common in BL patients, but are not rare in LLs, BB, or BT. [24] Patients may upgrade to a more-resistant granulomatous posture, remain unchanged, or downgrade to a less-resistant disease state. Clinically, DTH reactions are characterized by the abrupt conversion of previously torpid plaques to tumid lesions, and new tumid lesions arising in clinically normal skin with or without an abrupt onset of neuritis. A purplish color is characteristic, and even if not obvious, the dusky erythema may have a purplish cast (Fig. 202-8). Iritis and lymphedema (elephantiasis graecorum) may be concomitant changes. Lesions are rarely solitary, as can happen in BT upgrading to TT, often multiple, and occasionally myriad, as in BL or LLs upgrading to BT. Neuritis also ranges from mild to severe, potentially disastrous, particularly if involving multiple nerves. DTH reactions may often be a mode of presentation, and DTH reactions occurring soon after presentation and the institution of treatment may well have been DTH reactions from the beginning. Most common in the first year of treatment, DTH reactions may occur up to 7 years after starting therapy, well after treatment has stopped. The diagnosis of a DTH reaction is primarily clinical, but histologic confirmation should be sought.

FIGURE 202-8 Some of the initial presenting lesions in a patient with a DTH reaction who had borderline lepromatous (BL) leprosy. The tumidity, purplish hues, and sharp margination strongly suggest a reversal reaction. The lesions were neither painful nor tender. The differences between these lesions and those shown in Fig. 202-3 and Fig. 202-4 emphasize that the DTH reaction, not the underlying BL disease, dominates the clinical picture. The patient also had an irreversible foot drop of recent onset.

ERYTHEMA NODOSUM LEPROSUM (JOPLING'S TYPE II REACTION) ENL (first described by Murata in 1912) occurs most often in LL, in up to 75 percent of cases, but is not rare in BL patients. (ENL is not erythema nodosum occurring in leprosy; it is a leprosy-specific response, which has some features in common with erythema nodosum.) It may occur before, during, or after chemotherapy. The median time of onset is close to 1 year after onset of treatment. Clinically, this reaction is characterized by crops of painful and tender, bright pink, dermal and subcutaneous nodules arising in clinically normal skin, in association with fever, anorexia, and malaise (Fig. 202-9). Of the other organs involved, arthralgias and arthritis are more common in ENL than are neuritis, adenitis, orchitis/epididymitis, or iritis, but each may rarely be the initial structure affected. Involvement of both upper and lower extremities is the rule and facial lesions occur in one-half of the patients. A neutrophilic leukocytosis is often present, occasionally leukemoid in degree. Severe episodes can be associated with an abrupt fall in hematocrit, up to 5 g/dL, easily mistaken for dapsone-induced hemolysis. The response to thalidomide is dramatic in greater than 90 percent of patients, perhaps qualifying as a diagnostic criterion. When ENL is the presenting mode of leprosy, there may be little or no stigmata of the underlying multibacillary disease. ENL may be precipitated by pregnancy or pyogenic infections.

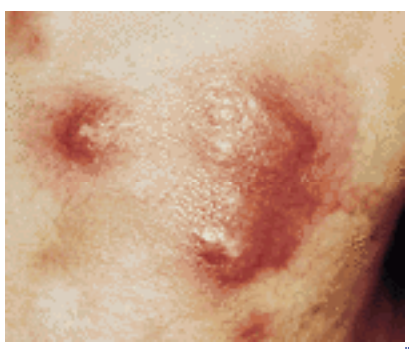

FIGURE 202-9 Lesions of erythema nodosum leprosum (ENL) in a patient with lepromatous leprosy (LL). The bright pink color is characteristic. These lesions are edematous, and pustule formation is suggested. The lesions are painful and tender.

Although episodes of ENL may be occasional or sporadic, in the more severely involved patients, episodes can be frequent to virtually unremitting. In the latter, brawny induration of the anterior thighs and preaxial portion of the arms is

characteristic, perhaps a reversible fibrosis. Other cutaneous variants are annular lesions mimicking erythema multiforme, vesicles or pseudovesicles in association with papillary edema, necrotic lesions, ulcers, frank subcutaneous abscesses, and pustular lesions mimicking pyodermas. The course of ENL, treated or untreated, ranges from sporadic and ephemeral, to frequent and persistent, lasting a matter of years. A severe, difficult to manage, form of ENL is a serious problem in Brazil and other parts of South America. The diagnosis of ENL, if considered, is usually not difficult, the clinical and histologic features being characteristic and the response to thalidomide often dramatic.

THE LUCIO REACTION Clinically, the Lucio reaction, first described by Raphael Lucio in 1853, consists of hemorrhagic infarcts. Particularly prevalent in Mexico and the Caribbean region, it is restricted to patients with Latapi's lepromatosis, described by Fernando Latapi in 1941, [25] a distinctive form of diffuse nonnodular lepromatous leprosy. When fully developed, Latipi's lepromatosis manifests a widening of the nasal root and fusiform enlargement of the fingers, both the consequence of diffuse dermal infiltration, as well as, a purplish suffusion of the hands and feet, numerous telangiectatic mats or eruptive telangiectasias, nasal septum perforation, total alopecia of eye brows and eye lashes, and a well-developed acral distal symmetric anesthesia. Firm subcutaneous nodules are palpable but not visible. Ocular sparing is the rule. The Lucio reaction occurs after Latapi's lepromatosis is well developed but before treatment is initiated. The necrotic lesions, arising in crops, have the serrated margins characteristic of septic infarcts and are painful but not tender (Fig. 202-10). Lesions usually crust and heal with scaring. Ulceration is common, especially below the knees. Lesions vary in size and extent, ranging from a few small lesions on the ankles to many large lesions, placing life in peril. With dapsone alone, lesions may worsen, but in our experiences, new lesions cease within 1 week of beginning rifampin, suggesting a strict requirement for viable bacilli. [26]

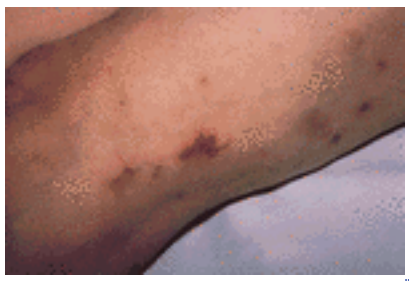

FIGURE 202-10 Lesions of the Lucio reaction, which show the characteristic hemorrhagic infarcts and serrated borders. Lesions are painful but not tender. The patient has Latapi's lepromatosis as manifested by diffuse infiltration, total alopecia of the eyelashes and brows, perforation of the nasal septum, no nodular lesions, and severe acral distal symmetric anesthesia.

LABORATORY FINDINGS

Most laboratory changes occur in LL or extensive BL disease. Hyperglobulinemia is the most common, giving an elevated sedimentation rate. A biologic false-positive serologic test for syphilis, anemia of chronic disease, and mild lymphopenia are also common. Clinically insignificant antiphospholipid antibodies are present in 50 percent of LL patients, and may give rise to a lupus anticoagulant or agglutination of sheep erythrocytes (Rubino factor). [27] If sought, the stained smear of the buffy coat shows bacilli up to 10^5/mL. Elevated serum lysozyme and angiotensin-converting enzyme values reflect the extensive accumulation and activation of macrophages synthesizing these proteases. Proteinuria, not uncommon, is associated with a focal glomerulonephritis, seen mostly in patients with ENL. As manifested by high serum follicle-stimulating hormone (FSH) and luteinizing hormone (LH) values, but low testosterone levels, LL disease involves the testicles in a majority of men with LL, but in a minority of men with BL.

PATHOLOGY

Microscopic Changes

COMMON AND UNCOMMON PATTERNS Granulomatous responses are the common tissue reactions in leprosy, with epithelioid differentiation of macrophages being characteristic of TT, BT, and BB, and undifferentiated or foamy macrophages being the hallmark of BL, LLs, and LLp. Exceptions can occur, sometimes dominating the histologic picture; exceptions include (1) chronic inflammation, particularly in BL and indeterminate disease, (2) lobular panniculitis in ENL, and (3) vasculitis in ENL and the palpable-only nodules of Latapi's lepromatosis. At the level of the low-power objective, a patchy infiltrate throughout the dermis, or a bizarre “sausage-shaped” infiltrate (following neurovascular bundles) should include consideration of leprosy in the differential diagnosis.

SPECTRAL GRANULOMATOUS PATTERNS [17], [18] In de novo TT lesions, small, well-developed epithelioid tubercles are surrounded by large lymphocytic mantles. In TT upgrading from BT, abundant Langhans-type giant cells and a brisk exocytosis into the epidermis are added to the preceding pattern, and caseation may be present. In BT tissues, lymphocytic mantles are less well developed, Langhans-type giant cells are inconstant, and, if present at all, epidermal exocytosis is focal. Acid-fast bacilli are not found in TT and are only rarely seen in BT. The presence of bacilli or plasma cells in what otherwise appears to be BT warrants consideration of a reversal reaction. In BB, lesions are lymphopenic, giant cells are absent, and bacilli are common. The classic BL tissue responses are a moderately dense lymphocytic infiltrate restricted to the space occupied by the macrophages, and lamination of the perineurium with infiltrating inflammatory cells. A chronic lymphohistiocytic infiltrate is an alternate pattern. In LLs, lymphocytes are present focally or sparsely distributed generally, and the laminated perineurium is not infiltrated. In LLp, lymphocytes are fewer than in LLs, and there is no perineural lamination. From BL to LLp, the extent of the granuloma and the numbers of globi (large secondary lysosomes packed with bacilli) are highly variable, but bacilli are always easily found, even if with great quantitative differences.

PATTERNS IN REACTIONAL STATES Reversal reactions, when compared with prereactional tissues, occasionally do not differ, but may show edema, epithelioid change, increased lymphocytes, Langhans-type and foreign-body giant cells, epidermal thickening, and, occasionally, enhanced bacteriolysis. [28] ENL lesions usually have neutrophils, a marked increase in lymphocytes, epidermal thickening, and a gradient of inflammatory cells, scant in the papillae and heavy in the deep dermis or subcutis. Lucio lesions feature ischemic necrosis in both epidermis and dermis, vessel occlusion by

thrombosis or endothelial proliferation, and heavy bacillary parasitization of endothelial cells. [26]

Immunopathology and Immunology

Investigation into the immunology of leprosy offers three promises: (1) a better understanding of the disease itself; in particular, the immunopathogenesis of the granulomatous spectrum and the reactional states; (2) eradication or control of the disease by vaccination; and (3) development of a probe of cell-mediated immunity in humans that, when understood in the model of leprosy, will illuminate other disease processes.

CELLULAR IMMUNITY The great diversity of leprosy is exemplified by comparing its two polar forms. The high-resistance tuberculoid form is characterized by few lesions, rare organisms, epithelioid cell granulomas, and a tendency to self-cure. A sharp margin on a plaque is the inscription of anti- *M. leprae* DTH on the skin; a nerve trunk palsy is its inscription on a peripheral nerve. Tuberculoid leprosy appears to be an entirely different disease than the low-resistance lepromatous form, characterized by wide dissemination, abundant organisms, foamy macrophages, and, if untreated, relentless progression. Strain variation of *M. leprae* is an unlikely explanation for the diverse host responses in leprosy. [29] The observations of a positive lepromin skin test in tuberculoid subjects and unresponsiveness in lepromatous patients was the first objective and reproducible evidence that host immunity was the mechanism of polar diversity. [3] Lymphocyte transformation tests provided an in vitro correlate of the lepromin skin and substantial evidence that mediation of polar diversity was through the cellular-immune response. On the contrary, antibody responses to *M. leprae* were found to be stronger in lepromatous patients, indicating the humoral immunity does not lead to resistance to disease. Immunophenotypic studies established an important difference between the lymphocyte subsets infiltrating skin lesions and tuberculoid subjects having a predominance of the CD4 subset (CD4:CD8 = 2:1), but lepromatous patients having a predominance of the CD8 subset (CD4:CD8 = 1:2). [30] The skewing of T cell subsets in lesions was independent of those in the peripheral blood, because all patients had a normal CD4:CD8 ratio of 2:1. Therefore, it is important to study the immune response of patients at the site of disease activity, that is, the skin lesions. By using the sequential application of reverse transcriptase and polymerase chain reaction techniques to tissue extracts, studies of mRNA cytokine profiles in polar tissues have provided a functional explanation for their immunopathogenesis. [31] Tuberculoid lesions have a type 1 (T_H1 or T_H1-like) proinflammatory profile, in particular abundant mRNA coding for interleukin (IL)-2, interferon (IFN)-?, and IL-12, but scant mRNA coding for IL-4 or IL-10. In contrast, lepromatous tissues have a type 2 (T_H2 or T_H2-like) anti-inflammatory profile, in particular, abundant IL-4 mRNA and IL-10 mRNA, but little mRNA coding for the type 1 cytokines. Furthermore, CD4+ T cells in tuberculoid lesions were shown to produce IFN-?, whereas, CD8 T cells in lepromatous lesions accounted for the production of IL-4. [32] The presence of type 1 cytokines likely results in strong T cell and macrophage activation, the result being cell-mediated immunity to localize the infection. On the other hand, the type 2 cytokines found in lepromatous lesions likely lead to the strong antibody responses, but concomitantly inhibit T cell and macrophage responses resulting in progression of the infection. The importance of this paradigm is reflected in experiments designed to augment cell-mediated immunity in lepromatous patients, where the administration of recombinant IFN-? to lepromatous patients reduced the number of bacilli infiltrating tissues. [33] The decision by the host as to which cytokine profile to make, that is, type 1 or type 2, may rest with the response of the native immune system to *M. leprae*. Cytokines produced by the native immune system may profoundly affect the adoptive response, [34] and some of the Toll-like receptors (TLR) of the native system are triggered by mycobacterial lipoproteins [35] (see Chap. 22 and Chap. 28). Reversal reactions and positive lepromin skin tests (Mitsuda reactions), long considered to be delayed-type hypersensitivity responses, [36] also have a CD4+ T cell predominance and a type 1 cytokine profile, but both differ from tuberculoid lesions by having a relative excess of *M. leprae*-reactive ?d T cells, perhaps related to these being recent lesions. [37] Host cytokine profiles are subject to change. LLs patients undergoing a reversal reaction switch from a type 2 to a type 1 profile; the mechanism of the switching is yet to be determined. [38]

ANTIBODY IMMUNITY ENL is widely regarded to be mediated by immune complexes. There are large amounts of anti-*M. leprae* antibodies in both LL and BL patients. All classes of antibodies are represented and their specificities directed against a number of substrates including specific and cross-reacting peptides, but these antibodies do not confer disease protection. Also, the blood of BL and LL patients contains abundant antigens including intact bacilli, up to 10^5/mL. Therefore, it is readily conceivable that BL and LL patients should be subject to immune complex-mediated tissue injury. The best direct support for the hypothesis that ENL is immune complex mediated is the presence of split complement products in serum, which is consistent with extravascular complement activation within tissues. [39] Inferential evidence is that of neutrophil infiltration, suggesting an Arthus phenomenon, and an excess of glomerulonephritis in ENL patients. Also, the cytokine profile in ENL is type 2, despite a preponderance of the CD4+ subset. [38] However, evidence for immune complex mediation is far from persuasive—it has not been reproduced and it is confounded by a number of observations, including human leukocyte antigen (HLA)-DR framework antigen in lesional epidermis, [40] an increase in IFN-? containing cells by hybridization studies, [41] an excess of IL-2–staining cells as compared with LL tissue, [42] and the precipitation of ENL by the administration of rIFN-?. [43] Also, other thalidomide responsive syndromes, such as rheumatoid arthritis, tuberculosis cachexia, multiple myeloma, and Behçet's syndrome, are not directly immune complex mediated. Perhaps both immune complexes and cellular immunity are important in the pathogenesis of ENL. Little is known concerning the immunopathogenesis of the Lucio reaction. Extant evidence favors immune complex mediation. The abundant acid-fast bacilli in endothelial cells could be the optimum location for presentation of antigen to antibody. Also, the cryoprecipitate from Lucio serum is more indicative of complement activation than that from ENL patients. [44]

DIAGNOSIS

A firm diagnosis of leprosy requires the satisfaction of one of two criteria: a consistent peripheral nerve abnormality or the demonstration of mycobacteria in tissues.

The diagnosis begins with a suspicion of leprosy, which should be aroused by the presence of any of several known risk factors, including (1) birth or residence in an endemic area, which is almost sine qua non for the diagnosis, (2) a blood relative with the disease, which could reflect transmission, common genetic makeup, or common environmental

exposure, and (3) armadillo (seven-banded) exposure in North American.

The possibility of leprosy also should be suggested by particular clinical constellations such as (1) simultaneous skin lesions and peripheral nerve abnormalities, (2) a differential diagnosis that includes granuloma, vasculitis, or lymphoma, (3) a peripheral neuropathy of unknown type in a patient in or from an endemic area, the so called pure neuritic leprosy, and (4) simultaneous palsies of cranial nerves V and VII, considered to be leprosy until proven otherwise.

Because *M. leprae* does not grow in cell-free media, demonstration of mycobacteria by their acid-fast property is used most commonly in diagnosis. Acid-fast bacilli in tissue sections are best shown by carbolfuchsin staining, using modifications of the Ziehl-Neelson method, collectively called Fite-Farraco stains . *M. leprae,* like *Nocardia* species, is only weakly acid-fast. In smears, either the Ziehl-Neelson method or oramine-rhodamine staining with fluorescent microscopy is satisfactory. Because of characteristic clinical and histologic changes, positive specification of *M. leprae* is rarely required.

Characteristic histologic changes are extremely helpful in suggesting or corroborating a diagnosis of leprosy, but, excepting the presence of epithelioid cell granulomas within nerves, are not absolutely diagnostic.

False Negatives

The six errors that lead to missing the diagnosis of leprosy are (1) failure to consider the diagnosis, usually from ignoring birth or residence in an endemic area; (2) failure to inform the pathologist of the suspicion of leprosy—an infiltrate may not be granulomatous, thus no acid-fast bacilli stain will be done by the pathologist if there is no known clinical suspicion; (3) an inadequate neurologic exam, in particular, the patient is not properly instructed to distinguish between dull and sharp (if the patient is not instructable, absence of a histamine-induced axon reflex flare, with a positive symmetric control, is good evidence of type C pain fiber loss); (4) presence of pinprick perception does not exclude loss of heat and cold discrimination; (5) improper staining for bacilli in biopsy specimens—in a conventional Ziehl-Neelson stain *M. leprae,* being only weakly acid-fast, may be decolorized altogether; and (6) tissue sampling error—the advancing border should be selected for biopsy not the clearing center.

False Positives

The four errors that lead to improperly diagnosing leprosy are (1) inflammatory lesions may have blunted pain perception (histamine tachyphylaxis), producing diminished sensation similar to that seen in some leprosy lesions; (2) atypical mycobacterial infection may have the abundant acid-fast bacilli characteristic of lepromatous disease; (3) environmental mycobacteria-like water, including that used to process tissue sections, as suggested by bacilli in the embedding medium, or not associated with cellular infiltrates; (4) from time-to-time, cunning artifacts are misinterpreted as acid-fast bacilli. If a patient, suspected of having leprosy, has no history of residence in a known endemic area, then one of these errors should be seriously considered.

ALTERNATIVE METHODS Alternative methods of establishing a diagnosis have been pursued but, at present, are of limited value. *M. leprae* specific antibodies are most prevalent in multibacillary cases, where there is no need for better diagnosis, and are, in endemic areas, far more prevalent than the disease, thus further restricting their utility. [10] Polymerase chain reaction (PCR) may be negative in up to one-half of paucibacillary cases, making a positive signal of value but a negative signal of no help. PCR should be most helpful in the diagnosis of patients with lesions having acid-fast bacillus, but no stigmata of leprosy, and negative cultures. [45] Lepromin skin testing, because of the high rate of positive reactions in unexposed adults, is not useful in diagnosis, but can be of value in classification of diagnosed patients; all TT and most BT (85 percent in our experience) being positive (3 mm or more of induration at 21 days) and BB through LLp being negative (less than 3 mm).

TREATMENT

Medical management is directed at the infection itself, or if present, at a reactional state. For paucibacillary disease (TT or BT) the World Health Organization (WHO) recommends the combination of unsupervised dapsone (bacteriostatic) 100 mg daily and supervised rifampin (bactericidal) 600 mg monthly for a duration of 6 months. [46] We prefer dapsone 100 mg daily for 2 to 3 years, with or without rifampin 600 mg monthly, with follow-up examination at 1 and 2 years after discontinuing treatment.

For multibacillary disease (BB, BL, and LL) the WHO recommends unsupervised dapsone 100 mg daily, supervised rifampin 600 mg monthly and clofazimine 50 mg daily, unsupervised, and 300 mg monthly supervised for a routine duration of 2 years. [46] The rationale for this regimen is that rifampin will kill all susceptible organisms, including those resistant to dapsone, and dapsone will eventually eliminate all susceptibles, including those resistant to rifampin; clofazimine is added to obviate the risk of primary dapsone resistance. This regimen is considered by the WHO to be curative and is the cornerstone of the anticipated reduction of the prevalence of leprosy to less than 1 case per 10,000 people. The report of a 20 percent relapse rate within 8 years after completion of this regimen suggests a need for alternative approaches, [47] particularly in heavily bacillary patients (biopsy index of 5 or more).

For the treatment of multibacillary disease, other regimens may be used. Because the incidence of primary dapsone resistance is low in our patient population, we often use the combination of rifampin 600 mg daily and dapsone 100 mg daily for 3 years followed by dapsone 100 mg daily indefinitely or cessation of treatment. Alternative regimens of rifampin 600 mg daily in combination with either minocycline (bactericidal) 100 mg daily or clarithromycin (bactericidal) 500 mg daily for 2 to 3 years, followed by monotherapy, has been well tolerated, except for hyperpigmentation from the minocycline. [48] Short-term therapy with three microbicidal agents (rifampin, minocycline, and ofloxacin or moxifloxacin) is currently experimental. [49]

In reversal reactions, because of the risk of permanent nerve damage, prompt institution of prednisone therapy (0.5 to 1 mg/kg per day) is recommended (but still wanting a controlled trial). The dose of prednisone is titrated against overt nerve tenderness, the patient's symptoms, and careful sensory evaluation of hands and feet, for example with graded Weinstein filaments. Once instituted, therapy should be tapered slowly and continued for a minimum of 6 months. If response of neuritis to prednisone is not prompt, then rest, enforced with splinting of effected extremities, is also recommended. In ENL, thalidomide use is dramatically effective in a majority of patients, if not interdicted by its teratogenic effects. For outpatients, we usually start with 100 to 200 mg nightly of thalidomide and, if it is only partially effective, we add prednisone in a 0.5 to 1.0 mg/kg range, tapering the prednisone over the subsequent 6 to 8 weeks. Higher doses of thalidomide are usually restricted to inpatients in whom excessive sleepiness is not a problem. If not available, corticosteroids in conjunction with clofazimine at 200 mg per day may be effective. Thalidomide is slowly tapered to 100 mg and then to 50 mg daily.

Adverse reactions to dapsone seen in the near term include the dapsone syndrome, a rare, potentially fatal infectious mononucleosis-like condition and three kinds of hemolytic anemia, almost universally from a direct membrane effect, uncommonly from a glucose-6-phosphate deficiency, and rarely from an idiosyncratic response (see also Chap. 254). In the long-term, dapsone is associated with peripheral neuropathy, usually motor with a sensory component, and, rarely, bone marrow suppression, especially agranulocytosis.

The serious problem with rifampin is hepatotoxicity. Red urine is alarming but banal. As a P450 inducer, rifampin may lessen the effect of other drugs, for example, oral contraceptives resulting in pregnancy, or reduced anti-inflammatory activity of corticosteroids. Once monthly use is rarely associated with severe hemolysis and acute renal failure.

Clofazimine produces skin darkening from the clofazimine itself in the near-term and from a ceroid-lipofuscin pigment in the long-term. [50] At usual doses of 50 to 100 mg a day, gastrointestinal intolerance, dry skin, and acquired ichthyosis are common. Prolonged administration of large doses may produce a novel enteropathy secondary to mucosal and enteric lymph node drug accumulation. Accumulation in the spleen may predispose to rupture.

Thalidomide, infamous for teratogenicity, may produce constipation and dizziness. Neuritis, a common side effect in nonleprosy patients, appears to be rare in ENL patients (see also Chap. 264).

Long-term use of minocycline may be limited by hyperpigmentation, [48] much more common in leprosy than in acne, perhaps related to the large accumulation of macrophages in leprosy. We have seen both diffuse hyperpigmentation and intense hyperpigmentation at the site of lesions, usually on the legs or feet.

Corticosteroids, in addition to their well-known side effects, may also exacerbate coexisting diseases, for example, tuberculosis, hepatitis B, and some gastrointestinal parasites.

REFERENCES

Lyme borreliosis (Lyme disease) is a vector-borne infection primarily transmitted by *Ixodes* ticks and caused by at least three different but closely related species of *Borrelia*. The disease may affect different organs, and the clinical picture and course may be highly variable. Erythema (chronicum) migrans, borrelial lymphocytoma, and acrodermatitis chronica atrophicans (ACA) are the cutaneous hallmarks.

HISTORICAL ASPECTS

Three dermatologic conditions—erythema migrans, lymphadenosis benigna cutis (LABC), and ACA—have long been well known to European dermatologists. Both the atrophic and the inflammatory forms of ACA were described by different European authors more than a century ago, but the disease was first named and further characterized by Herxheimer and Hartmann in 1902. The first report of an erythema developing after a tick bite was presented by Afzelius in Sweden in 1909, and he gave it the name *erythema migrans*. A few years later, the term *erythema chronicum migrans* was used in an Austrian case report by Lipschütz. The designation *lymphocytoma* was first used by Biberstein in 1923. Bäfverstedt coined the term *lymphadenosis benigna cutis* in his monograph on pseudolymphomas published in 1943. [1]

In 1941 and 1944, the German neurologist Bannwarth described a syndrome, later to be named after him, with focal and often severe radicular pain, lymphocytic meningitis, and cranial nerve paralysis. The association with tick bites and erythema migrans was later observed by Schaltenbrand.

In the United States, erythema migrans was not described until the 1970s. In 1977, Steere et al. reported on an epidemic form of arthritis occurring in several communities around Lyme, Connecticut, on the Connecticut River. [2] Lyme arthritis was soon linked to a preceding erythema migrans, and manifestations in the nervous system and the heart were also found. [2]

In the early 1980s, Burgdorfer et al. [3] showed that Lyme disease was caused by tick-borne spirochetes. With use of modified Kelly medium, [4] cultivation of spirochetes from *Ixodes* ticks, from erythema migrans lesions, and from blood and cerebrospinal fluid specimens from a few patients with Lyme disease was successful. These spirochetes were classified as a new species of *Borrelia* and were named *B. burgdorferi.* Later, spirochetal cultivations and serologic tests also revealed that Bannwarth's syndrome and ACA were caused by *B. burgdorferi* and that these spirochetes may also cause LABC. However, as all cases diagnosed as LABC or pseudolymphomas do not have a borrelial etiology, Weber et al. introduced the term *borrelial lymphocytoma* in 1985. [5]

EPIDEMIOLOGY

Lyme borreliosis is a disease with a wide distribution in the northern hemisphere. Cases have been reported from Canada, 46 of the United States, most European countries, the Federal Republic of China, Korea, and Japan. In the former Soviet Union, cases have been recognized from the Baltic republics to the Pacific Ocean. It is the most common vector-borne disease of bacterial origin in the United States and Europe. There have been discussions as to whether the true incidence is rising or whether the reported increase is mainly attributable to greater recognition and awareness of this infection.

ETIOLOGY

The spirochete causing Lyme borreliosis was discovered unexpectedly in conjunction with a tick survey on Long Island, New York, in 1981 and 1982. [3] Studies of the morphology, antigen profile, and DNA indicated that the spirochete named *B. burgdorferi* was a new species in the genus *Borrelia* (order Spirochaetales). Antigenic heterogeneity was soon found among different strains of *B. burgdorferi*. The three genospecies of *B. burgdorferi sensu lato,* which have been shown to be human pathogens, have been named *B. burgdorferi sensu stricto, B. garinii,* and *B. afzelii*. There are differences in the geographic distribution of these genospecies. [6] Thus, until now, only *B. burgdorferi sensu stricto* has been found in the United States. In Europe, all three species are present, although at least in the Netherlands, Germany, Austria, Scandinavia, and Russia, *B. garinii* and *B. afzelii* seem to dominate. In the Asian parts of the former Soviet Union and in Japan, Korea, and China, *B. garinii* and *B. afzelii,* but not *B. burgdorferi sensu stricto,* have been found.

The primary vectors of Lyme borreliosis are hard ticks belonging to the *Ixodes ricinus* complex, that is, *I. scapularis* (*I dammini*) and *I. pacificus* in North America , *I. ricinus* and *I. persulcatus* in Europe, and *I. persulcatus* and *I. ovatus* in Asia. They are three-host ticks, parasitizing a wide range of animals, including humans. During feeding on a spirochetemic host, the larval or nymphal tick may become infected, and it may then remain infectious throughout the rest of its life by transstadial transmission of spirochetes. The feeding activity of the different stages is often seasonal during the spring, summer, and autumn. The rate of infection in nymphs and adult ticks ranges from a few percent to greater than 50 percent. Transovarial transmission seems to be rare. Instead, the main reservoirs of *B. burgdorferi* are the hosts, mainly considered to be rodents, of the larvae and nymphs. However, birds and many other warm-blooded animals may serve as additional reservoirs. Large animals such as deer may play an important role in feeding adult ticks. In endemic areas, domestic animals are frequently seropositive for antibodies to *B. burgdorferi,* and manifestations of Lyme borreliosis have been demonstrated in such animals.

Tick vectors other than those of the genus *Ixodes* may transmit *B. burgdorferi* but are less efficient vectors. Transmission of *B. burgdorferi* by nontick vectors such as deer flies, horseflies, and mosquitoes, or by direct contact with fluids from infected animals has been reported. However, Lyme borreliosis obtained in other ways than through a tick bite is probably very rare, with many patients unaware of the preceding tick bite because the nymphal tick, which is considered to be the most important vector for transmitting *B. burgdorferi* to humans, is so small that it often escapes detection.

CLINICAL MANIFESTATIONS

Classification of Clinical Disease

By analogy with syphilis, the natural history of Lyme borreliosis can be divided into three stages based on the clinical manifestations. Because the course in the individual patient does not imply a uniform temporal sequence with development of all the stages and because the infection is sometimes not manifest until stage two or three, many clinicians believe that a staging system with numbers may be misleading. It has therefore been proposed that the terms *early localized infection, early disseminated infection,* and *late* or *chronic infection* should be used instead (Table 203-1). Besides the clinical picture, the duration of the disease is probably also important in therapeutic decisions. A definition of chronic or late infection as persistent infection lasting more than 12 months has been suggested. Because many signs and symptoms of Lyme borreliosis are nonspecific, the cutaneous borrelial manifestations may serve as helpful and important landmarks in the identification of Lyme borreliosis.

Early Lyme borreliosis
Localized infection: Erythema migrans and borrelial lymphocytoma without signs or symptoms of disseminated infection. (Regional lymphadenopathy and/or minor constitutional symptoms may be present.)
Early disseminated infection: Multiple erythema migrans–like skin lesions. Early manifestations of neuroborreliosis, arthritis, carditis, or other organ involvement.
Late Lyme borreliosis
Chronic infection: ACA. Neurologic, rheumatic, or other organ manifestations—persistent or remitting for at least 12 months.

*The classification provides a guideline for the timing of different disease manifestations.

TABLE 203-1 **Classification of Lyme Borreliosis***

Geographic Differences in the Clinical Picture

The clinical manifestations caused by the different genospecies of *B. burgdorferi sensu lato* are similar but may vary in some respects. [6] All three strains may cause erythema migrans, neuroborreliosis, and arthritis. With few exceptions, analyses of sera or spirochetes isolated from patients with ACA or borrelial lymphocytoma have indicated that these manifestations are associated with infection with *B. afzelii*. *B. burgdorferi sensu stricto* is associated with a high frequency of articular manifestations. In Europe, *B. garinii* causes neuroborreliosis more often than *B. afzelii*. These findings support the concept of a strain-dependent organotropism of *B. burgdorferi*.

The differences in the geographic distribution of the three genospecies may explain some of the different clinical pictures of Lyme borreliosis described in Europe and the United States. Multiple erythema migrans–like lesions have been found in a higher frequency among American patients (25 to 48 percent) [7] than among Europeans (8 percent or less). [8] A higher frequency of arthritis has also been reported from the United States. In contrast, only a few cases of ACA and borrelial lymphocytoma have been described in Americans.

Within the last decade the risk of concurrent infection with other tick-transmitted agents, such as *Babesia* and *Ehrlichia,* has been described, especially in the northeastern and Great Lakes regions of the United States, but also in Europe. In experimentally coinfected animals, disease appears to be more severe than in those infected by *B. burgdorferi* alone, perhaps because babesial as well as ehrlichial infection may lead to immune suppression. Recent data indicate that coinfection may modify the clinical course of human Lyme borreliosis. [9], [10] Tetracyclines and clindamycin/quinine, respectively, are the treatments of choice for ehrlichiosis and babesiosis.

CUTANEOUS MANIFESTATIONS

Erythema Migrans

CLINICAL FEATURES [7], [8], [11], [12], [13] **and** [14] Erythema migrans, the principal cutaneous hallmark of Lyme borreliosis, starts at the site of a tick bite, but it is not unusual for the bite to pass unnoticed. The incubation period may vary from a few days to 3 months but is usually 1 to 3 weeks. [7], [8], [14] The initial erythema is usually homogeneous (Fig. 203-1), and it sometimes remains so until it heals. In long-standing lesions, the center partly or totally fades, leaving an annular erythema that spreads centrifugally (Fig. 203-2). A central reddish patch, representing the site of the tick bite, may sometimes be apparent. The diameter of the erythema migrans ranges from less than 1 decimeter to several decimeters. The size of the lesion or the distance the erythema has migrated mostly corresponds to the duration of the infection. The peripheral reddish band may be more or less sharply demarcated and is mostly 1 to 2 cm wide. With time, the erythematous border often fades; it may wax and wane and is sometimes visible only after the skin has been warmed up (e.g., in a hot bath). The classic lesion is round, but elliptical or irregular forms may be seen. The duration of an untreated lesion of erythema migrans may vary from some days to about a year, but generally it disappears within weeks or months.

FIGURE 203-1 Homogeneous erythema migrans of 3 weeks' duration.

FIGURE 203-2 Annular erythema migrans of 2 months' duration.

In North America, the lesion is more often of shorter duration than in Europe, and associated with more intense inflammation and signs suggestive of spirochetal dissemination. [14] Erythema migrans may appear almost anywhere on the skin surface, but the lower extremities are most usually affected. Facial involvement is common in children. [11] The clinical spectrum of erythema migrans is wider than previously reported. Atypical appearances with blisters or hemorrhagic or scaling lesions may develop. Other variants are small, stationary erythemas or a localized swelling without any obvious erythema at the site of the tick bite. Erythema migrans may pass unnoticed, as it may be poorly visible and asymptomatic. However, many patients experience local itching or sensations of irritation or heat. [7], [8], [12] In most cases, the local symptoms are mild or moderate, but in a few cases, more intense dysesthesia/hyperesthesia may occur at or near the site of the eruption. Regional lymphadenopathy may be present. In at least half of the patients, constitutional signs or symptoms, such as headache, low-grade fever, malaise, gastrointestinal complaints, and/or myalgia/arthralgia, accompany the skin lesion, or sometimes start before the erythema. [7], [8], [12], [13] Severe fatigue or emotional disturbances, such as irritability and depression, may develop. The constitutional reactions are usually mild or moderate, of an intermittent and changing nature, and last for some days to one or a few weeks. If they are more pronounced or long-lasting, they may signal a disseminated infection with meningitis.

MULTIPLE ERYTHEMA MIGRANS–LIKE LESIONS The development of secondary erythema migrans–like lesions is the cutaneous sign of hematogenous spread of spirochetes and of disseminated infection, as evidenced by successful spirochetal cultivation from secondary lesions. The lesions may follow the initial erythema migrans lesion or sometimes appear almost simultaneously. The multiple lesions may be homogeneous or annular; they are often, but not always, smaller than a solitary erythema migrans lesion and may be nonmigrating.

PATHOLOGY The epidermis is usually unaffected and there is a generally sparse dermal lymphocytic infiltrate with an admixture of a few plasma cells. The infiltrate is mainly confined to the perivascular regions.

DIAGNOSIS The clinical picture and the characteristic evolution of the erythema are most often sufficient to make the correct diagnosis. In atypical cases, the seasonal onset, the history of exposure to an area highly endemic for Lyme borreliosis, the history of a tick bite at the site of the lesion, the nonspecific histopathologic features, and/or elevated serum antibodies to *B. burgdorferi* (see below) are helpful clues. However, seronegativity does not rule out the diagnosis, as many patients with early uncomplicated erythema migrans are seronegative. The diagnosis can be confirmed by cultivation of borreliae from a skin-biopsy specimen. If the lesion does not resolve after adequate antibiotic therapy, the diagnosis of erythema migrans ought to be reconsidered.
DIFFERENTIAL DIAGNOSIS Important differential diagnoses are granuloma annulare, erysipelas, tinea, fixed-drug eruptions, lupus erythematosus, dermatomyositis, erythema gyratum repens, and nonspecific tick or insect bite reactions. In patients with multiple lesions, erythema multiforme and Sweet's syndrome may also be considered. Histopathologic examinations are often helpful.

Borrelial Lymphocytoma

CLINICAL FEATURES [1], [5], [15] Borrelial lymphocytoma often, but not always, starts at the site of the tick bite. The incubation period may vary from a few weeks to several months. [15] Some patients have a history of a preceding erythema migrans, and others may show a concomitant erythema migrans located around or near the lymphocytoma. [1], [5], [15] That a lymphocytoma may start at a distance from the spirochetal inoculation is obvious in cases where it begins close to the periphery of a large migrating erythema migrans lesion. The classic borrelial lymphocytoma presents as a solitary bluish-red nodule, 1 to 5 cm in diameter, often accompanied by regional lymphadenopathy. Predilection sites are the earlobe (Fig. 203-3) and the nipple/areola mammae region. Other sites of predilection are the scrotum and the nose. Ear and scrotal lesions are mostly seen in children, and breast lesions are mostly seen in adults. In many cases, there are no or only slight local symptoms, such as tenderness and itching. However, constitutional symptoms such as headache, fever, and arthralgia/myalgia may occur.

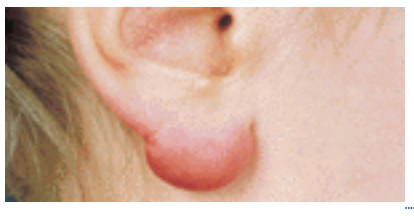

FIGURE 203-3 Borrelial lymphocytoma of 3 months' duration.

PATHOLOGY Usually the epidermis is unaffected. There is a dense dermal lymphocytic infiltrate, dominated by polyclonal B cells. The presence of germinal centers (Fig. 203-4), similar to those seen in reactive lymph nodes, is a helpful clue but not an obligatory diagnostic sign.

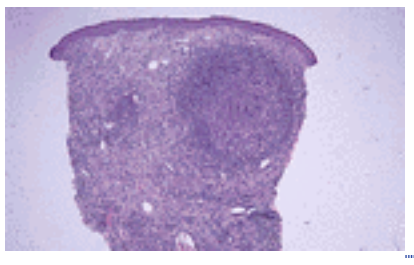

FIGURE 203-4 Borrelial lymphocytoma. Punch biopsy specimen from a scrotal lesion. In the dermis and subcutis there is a dense lymphocytic infiltrate displaying a follicular pattern with a large germinal center. (*Micrograph by Eva Brehmer-Andersson, MD.*)

DIAGNOSIS Besides the clinical picture, a history of a preceding erythema migrans lesion or a tick bite in the vicinity of the lesion supports the diagnosis. Histopathologic findings of a dense dermal lymphocytic infiltrate with germinal centers are suggestive of, but not specific for, borrelial lymphocytoma. Elevated serum antibody titers to *B. burgdorferi* have been found in more than half of the patients.
DIFFERENTIAL DIAGNOSIS Borrelial lymphocytoma of the breast is often primarily suspected of being a malignant tumor. Conventional histopathologic examinations may be decisive in distinguishing a borrelial lymphocytoma from granuloma faciale, granuloma annulare, sarcoidosis, lupus erythematosus, polymorphous light eruptions, and arthropod bite granuloma. Lesions without germinal centers may be difficult to differentiate from malignant lymphoma. In such cases, immunohistochemical characterization of the cell infiltrate is of diagnostic help.

Acrodermatitis Chronica Atrophicans

CLINICAL FEATURES [8], [11] A connection between ACA and a preceding tick bite is rarely suspected by patients. Approximately 20 percent have a history consistent with a preceding untreated erythema migrans, usually on an extremity where ACA lesions developed 6 months to 10 years later. [8], [11] Some patients also have a history of preceding neurologic and/or rheumatic complaints. Among patients with ACA there is a preponderance of females (about 70 percent), and it is generally a disease of the middle-aged or elderly. It usually starts on the extensor aspect of one extremity. The most common site is the lower leg, with initial involvement of the foot, ankle, or knee region. The dorsal aspect of the hand or the olecranon area are other common sites. The fingers, toes, and soles may become involved. With time, more widespread involvement of the extremity may occur, and the lesions usually spread from distal to proximal sites. Additional limbs may become affected, but sometimes not until after several years. More extensive involvement of the trunk or involvement of the face is uncommon. The first cutaneous sign is a bluish-red discoloration, often with edematous swelling. Sometimes the erythema may be very slight and swelling may dominate the clinical picture, suggesting venous stasis or lymphedema. A typical feature is that one of the feet or just the heel gradually increases in size. [11] ACA lesions often develop slowly and insidiously, and initially both the erythema and the swelling may wax and wane. Fibrous thickening of the skin in the form of indurated bands or nodules may develop. The most common bands are ulnar bands (Fig. 203-5A). The same area is also the most common site of single or multiple fibrotic nodules (Fig. 203-5C).

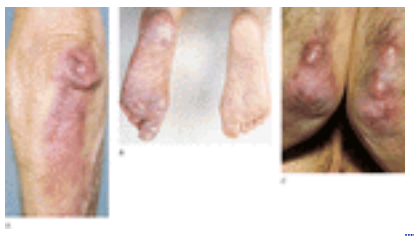

FIGURE 203-5 *A*. Ulnar band in a patient with acrodermatitis chronica atrophicans that has been present for more than 10 years. *B. burgdorferi* has been cultivated from this lesion. *B*. Acrodermatitis chronica atrophicans with bluish-red discoloration and advanced atrophy of the plantar surface of one of the feet. *C*. Acrodermatitis chronica atrophicans with fibrotic nodules on the elbows.

Sclerotic skin lesions that may be clinically and histopathologically indistinguishable from localized scleroderma or lichen sclerosus et atrophicus have been described in 5 to 10 percent of patients with ACA. The term *pseudoscleroderma* has previously been used for the sclerotic skin lesions that may occur in ACA. Inflammatory ACA lesions may persist for years or decades, with gradual conversion to atrophic skin lesions (Fig. 203-5B). Both inflammation and atrophy may occur in different regions in the same patient. In the advanced atrophic phase, the skin becomes cigarette paper–like and wrinkled, appendageal structures disappear, and the vessels become prominent (Fig. 203-6). Besides diffuse atrophy, macular atrophy, which was previously described as atrophia maculosa cutis or dermatitis atrophicans maculosa, may rarely occur.

FIGURE 203-6 Acrodermatitis chronica atrophicans. Typical end-stage cutaneous atrophy is seen on both legs with prominence of the superficial veins.

Extracutaneous Manifestations in Patients with ACA

Enlarged regional lymph nodes are common. Migrating and/or intermittent pain is fairly frequent. A rather common and characteristic feature is pain arising from impacts against bony prominences—such as the knuckles, the olecranon, or the malleoli—underlying ACA skin lesions. As diagnosed by clinical and electroneurographic examinations, more than 50 percent of patients with ACA have peripheral neuropathy, mostly mild or moderate. This neuropathy may be a sensory or motor mono- or polyneuropathy, or patchy dysesthesia, at the sites of the skin lesions. Symptoms such as hyperesthesia, muscular weakness, a feeling of heaviness, and muscle cramps are common in patients with ACA. These symptoms are mainly located in the limb(s) affected by skin lesions. Profound fatigue, emotional disturbances, and personality changes sometimes accompany ACA. However, there are usually no cerebrospinal fluid abnormalities in patients.

Subluxations/luxations of small joints of the fingers or toes and periosteal thickening of bones have been found underneath the skin lesions in patients with long-standing ACA. Periarticular manifestations such as knee or olecranon bursitis and Achilles tendinitis on the same limb as the cutaneous involvement may precede or accompany ACA. Attacks of knee–joint effusions were found to have preceded or to have occurred simultaneously with ACA in approximately one-fifth of patients studied.

PATHOLOGY [16] There are usually no epidermal changes in the early inflammatory phase of ACA, but sometimes the epidermis is thin and shows liquefaction degeneration. The most common dermal findings are telangiectases in combination with a patchy and/or interstitial, often dense lymphocytic infiltrate with a moderate to rich admixture of plasma cells (Fig. 203-7). This infiltrate may involve the whole or part of the dermis, and sometimes also the subcutaneous fat. As the disease progresses, degeneration of elastin and collagen begins. After many years, advanced dermal atrophy develops, including atrophy of hair follicles and of sebaceous glands. In the advanced atrophic phase, the inflammatory cells decrease in number or almost disappear.

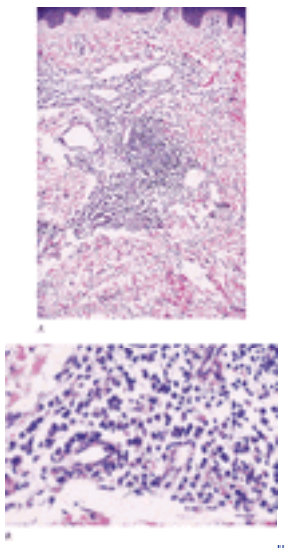

FIGURE 203-7 Acrodermatitis chronica atrophicans. Punch biopsy specimen from the dorsum of the foot. *A*. The dermis contains telangiectasias and a patchy cell infiltrate. Epidermis is not involved. *B*. High-power view of the infiltrate, which consists mainly of plasma cells. (*Micrograph by Eva Brehmer-Andersson, MD.*)

DIAGNOSIS The clinical recognition of ACA may be difficult. If a red-violaceous discoloration, with or without swelling, is observed on a foot or heel, the dorsal aspect of a hand, the olecranon area, or, in more advanced cases, on more than one extremity (especially in an elderly woman), a diagnosis of ACA should be considered. Cutaneous atrophy may not appear for several years and is not an obligatory clinical or histopathologic criterion for a diagnosis of ACA. As compared to the prepenicillin era, patients with advanced atrophy are seen less frequently nowadays. Instead, the diagnostic efforts should be concentrated on recognizing inflammatory ACA lesions. The clinical diagnosis should be further verified by the histopathologic pattern and by elevated serum titers of IgG antibodies to *B. burgdorferi*. The diagnosis may be confirmed by spirochetal cultivation, as borreliae may still be present in the skin even after more than 10 years of ACA. Thus, ACA is a cutaneous example of prolonged survival of *B. burgdorferi* in humans.
DIFFERENTIAL DIAGNOSIS ACA lesions are frequently overlooked or regarded as physiologic changes due to age. A discolored, sometimes swollen and painful leg is often misdiagnosed as circulatory insufficiency in these patients. Fibrotic nodules may be confused with rheumatic nodules.

Sclerotic and Other Skin Lesions

B. burgdorferi may cause skin lesions that are clinically and histopathologically indistinguishable from localized scleroderma and lichen sclerosus et atrophicus (see Chap. 113, Chap. 114, and Chap. 173). A high frequency of elevated serum antibody titers to *B. burgdorferi* has been found in some studies of patients with scleroderma, [17] but this finding could not be confirmed by others. [18] In patients with ACA and pseudoscleroderma, the sclerotic lesions sometimes predominate, the inflammatory ACA lesions are missed, and the patient is diagnosed as suffering from morphea or lichen sclerosus et atrophicus. [18] However, in most cases diagnosed as morphea or lichen sclerosus et atrophicus, there is no evidence of borrelial infection. [19]

As with syphilis, *B. burgdorferi* infection may sometimes mimic other conditions in its clinical and histopathologic features. Granuloma annulare (see Chap. 100), eosinophilic fasciitis (see Chap. 96 and Chap. 173) benign lymphocytic infiltration (Jessner-Kanof) (see Chap. 159), and anetoderma (see Chap. 105) have been described in connection with Lyme borreliosis.

EXTRACUTANEOUS MANIFESTATIONS

Lyme borreliosis is a complex multisystem disease that may affect the nervous system, joints, heart, and eyes in addition to the skin.

Neurologic Manifestations

Neuroborreliosis [20], [21] and [22] may involve both the peripheral and the central nervous system (CNS).

EARLY NEUROBORRELIOSIS This usually begins 4 to 10 weeks after the onset of the infection. The triad of lymphocytic meningitis, cranial neuritis, and radiculoneuritis is a typical feature of neuroborreliosis. Compared with many other bacterial meningitides, the symptoms of a borrelial meningitis may often appear mild and fluctuating. Nonspecific signs or symptoms such as fever, fatigue, malaise, vomiting, weight loss, or headache with or without neck stiffness may be the only clinical manifestations. In such cases, a history of a preceding tick bite and/or erythema migrans is helpful when considering the possibility of a diagnosis of neuroborreliosis. However, approximately one-third of patients lack these important clues. [20] The most common manifestations from the peripheral nervous system are radicular pains and facial palsy. In patients with a preceding erythema migrans, the skin lesion has often been located in the same part of the body as the subsequent radiculoneuritis or facial palsy. Untreated early neuroborreliosis generally heals within 3 to 6 months. However, if less-than-adequate therapy is given, some patients may develop manifestations from other organs or late neuroborreliosis.
LATE NEUROBORRELIOSIS (CHRONIC NEUROBORRELIOSIS) In the United States up to 5 percent of untreated patients may develop chronic neuroborreliosis, sometimes after long periods of latent infection. [22] A mild late neurologic syndrome, without inflammatory changes in the cerebrospinal fluid, called Lyme encephalopathy and manifested primarily by subtle cognitive disturbances, has been reported in North America. One form of late neuroborreliosis seen in Europe is the chronic peripheral neuropathy often associated with ACA. These patients usually lack spinal fluid abnormalities, in contrast to patients with severe CNS syndromes. Progressive encephalomyelitis with hemiparesis, para- and quadriparesis, ataxia, multiple sclerosis–like demyelinating disease, dementia-like deficiencies, mental changes, and/or incapacitating fatigue have been described, but these severe forms of late neuroborreliosis are uncommon. [21]

Rheumatic Manifestations

Reports on Lyme arthritis came first from the United States [2], [7], [23] and later from Europe. [24] Intermittent episodes of arthralgia or migrating musculoskeletal pain may occur early in the development of Lyme borreliosis. Months after the onset of the infection, a single episode or intermittent attacks of mono- or oligoarthritis may occur. In contrast to the symmetric polyarthritis seen in rheumatoid arthritis, Lyme arthritis characteristically affects only one or a few large joints, most commonly the knee joint. Often the pain is not severe, and swelling of the joint usually dominates the clinical picture. Arthritic attacks can recur for months and even years. In children, Lyme arthritis may sometimes mimic juvenile rheumatoid arthritis. Approximately 10 percent of patients in the United States with Lyme arthritis have been reported to develop chronic arthritis with erosion of cartilage and bone.

Cardiac Manifestations

The frequency of cardiac involvement in patients with Lyme borreliosis is not well established. The most common findings have been atrioventricular conduction disturbances, with the majority showing transient first-degree atrioventricular block. Occasionally, complete heart block requiring a temporary pacemaker has developed. Other abnormalities are rhythm disturbances, acute myopericarditis, pancarditis, and heart failure. [25]

Ocular Lyme Borreliosis

Early lyme borreliosis is sometimes accompanied by conjunctivitis. Ocular motor palsies and solitary cases of iritis, iridocyclitis, choroiditis, keratitis, retinal hemorrhage, optic neuritis, ischemic optic neuropathy, and papilledema have been reported. [26]

Gestational Lyme Borreliosis

Most women with documented Lyme borreliosis during pregnancy appear to give birth to normal infants. [27] Solitary cases of fetal death, malformations, and prematurity have been reported.

LABORATORY EXAMINATION

Detection of *B. burgdorferi*

CULTIVATION OF SPIROCHETES In atypical cases, spirochetal cultivation, using modified Kelly medium, [4] is the most specific and reliable way of diagnosing Lyme borreliosis. Spirochetal cultivation from human tissue or fluid has not become a routine diagnostic method as it is laborious and mostly a low-yielding process. One exception might be cultivation from skin specimens, as successful cultivation from more than 60 to 70 percent of skin-biopsy specimens from patients with erythema migrans has been reported. [6], [28]
DEMONSTRATION OF SPIROCHETES IN TISSUES Spirochetes may be demonstrated in biopsy specimens with different silver stains. Polyclonal or monoclonal antibodies to borrelial antigens have also been used to demonstrate spirochetes in tissue specimens. These techniques for visualizing spirochetes are difficult to evaluate, however, and there may be a risk of both over- and underdiagnosis.
POLYMERASE CHAIN REACTION In the analysis of skin biopsies from patients with erythema migrans and ACA, polymerase chain reaction (PCR) has achieved a diagnostic sensitivity at least comparable to that of culture. [29], [30] In the detection of *B. burgdorferi* in joint fluid, PCR testing has been reported to be superior to culture. [31]

Serology of Lyme Borreliosis

Serologic examination is at present the most important laboratory aid in diagnosing Lyme borreliosis. The serologic results must, however, be interpreted with caution, as false-negative as well as false-positive results are common with the currently used tests. In early Lyme borreliosis, particularly in patients with signs or symptoms of disseminated disease, significantly increasing IgM and/or IgG antibody titers to *B. burgdorferi* may be found in consecutive tests performed at an interval of 2 to 3 weeks. Later on, the IgG titers are often stationary, and finding serologic proof of current infection may be difficult. Because high prevalence of seropositivity has been found among asymptomatic sports enthusiasts, outdoor workers, and other control individuals in endemic areas, the diagnostic value of the serologic findings may be limited, particularly in cases where only slightly elevated titers have been found. The lack of standardization also means that there may be great variations in sensitivities and specificities among different laboratories.

The tests most widely used at present for measuring antibodies to *B. burgdorferi* are the indirect immunofluorescence assay and the enzyme-linked immunosorbent assay (ELISA).The tests are of low diagnostic value in the earliest phase of Lyme borreliosis. Only 20 to 50 percent of patients with uncomplicated erythema migrans have been found to be seropositive in IgM and/or IgG ELISA. [32], [33] Patients with multiple erythema migrans–like lesions and those with borrelial lymphocytoma are more often seropositive. In most cases where signs or symptoms of a disseminated infection have been present for several weeks, elevated serum titers to *B. burgdorferi* are found. Almost 100 percent of patients with ACA are seropositive, and they usually show very high serum IgG titers to *B. burgdorferi*. [32], [33]

With use of Western blot techniques, IgM and IgG antibodies to a number of spirochetal polypeptides have been found in sera from patients with Lyme borreliosis. Western blotting is also used as a diagnostic tool but with varying criteria for positivity in different laboratories.

False-positive serologic reactions may occur in patients with relapsing fever and syphilis. In contrast, patients with high serum titers to *B. burgdorferi,* such as those with ACA, often have cross-reactive antibodies to treponemal antigens that

are detectable in the fluorescent treponemal antibody-absorption test.

CEREBROSPINAL FLUID EXAMINATION IN NEUROBORRELIOSIS The presence of cerebrospinal fluid (CSF) abnormalities with a lymphocytic pleocytosis, in combination with the finding of intrathecally synthesized antibodies to *Borrelia,* is diagnostic for neuroborreliosis with CNS involvement. [20]

TREATMENT

Since the 1940s, European dermatologists have treated patients with erythema migrans and ACA with oral penicillin. It is not known whether the antibiotic susceptibility may differ among *B. burgdorferi* strains from different parts of the world. Attempts have been made to determine antibiotic sensitivities of *B. burgdorferi* in vitro and in experimental animals. Because the methodology for such studies is not yet standardized, the studies should be interpreted with caution. Tradition and clinical experience, variations in the clinical spectra, and the advantage of a drug effective against a possible coinfecting agent such as *Ehrlichia* have resulted in varying treatment regimens in different parts of the world. [12], [23], [34], [35] and [36]

Few large, well-controlled treatment studies have been performed on groups of well-defined patients with similar manifestations of Lyme borreliosis. As in syphilis, the difficulties of therapy seem to increase with the duration of the disease. The possibility has been considered that the spirochetal division time may be longer in the late than in the early stage of syphilis, and that a longer period of therapy will be needed for late cases. The same may be true for late Lyme borreliosis.

The recommendations for treatment may be modified in the future, when further treatment trials have been carried out. Current guidelines for treatment of adult patients with different manifestations of Lyme borreliosis are given below.

Treatment of Uncomplicated Erythema Migrans

Doxycycline (100 mg orally, bid), or amoxicillin (500 mg orally, tid) is recommended for 14 to 21 days. [14] In Europe, phenoxymethyl penicillin (1g orally, bid/tid) for 14 days is also used.

In patients with erythema migrans and concurrent manifestations from other organs, the latter may be decisive for the choice of therapy. Such manifestations are particularly common in patients with multiple erythema migrans–like lesions. Before the start of therapy in patients with erythema migrans and signs or symptoms suggestive of neuroborreliosis, a diagnostic spinal tap should be performed. Alternatively, an antibiotic regimen has to be chosen that gives therapeutic CSF concentrations.

Treatment of Borrelial Lymphocytoma

The same treatment regimens as for uncomplicated erythema migrans are proposed. In patients with a disease duration of several months, prolonged courses of antibiotics for up to 20 to 30 days may be required.

Treatment of Neuroborreliosis or Cardiac Abnormalities

In the United States a 2- to 4-week course of intravenous ceftriaxone is most commonly given. Parenteral therapy with cefotaxime or penicillin G may be a satisfactory alternative. [14]

In cases of cardiac abnormalities where only first-degree atrioventricular block is present, and in early neuroborreliosis, oral regimens with doxycycline (100 mg, bid) for 14 days are also used, especially in Europe.

Treatment of Lyme Arthritis

Doxycycline (100 mg orally, bid/tid) or amoxicillin (500 mg orally, tid) for 30 to 60 days or IV regimens with ceftriaxone for 14 to 28 days are recommended in the United States, [14] whereas in many parts of Europe, shorter treatment periods and oral regimens with doxycycline (100 mg orally, bid) have been found to be sufficient.

Treatment of ACA

Doxycycline (100 mg orally, bid) for 20 to 30 days is recommended. Both intravenous penicillin or ceftriaxone have also been used.

Jarisch-Herxheimer Reaction

Mild to moderate Herxheimer reactions may sometimes appear after the institution of antibiotic therapy. Intensification of the current cutaneous rash and of local symptoms or the appearance of new signs or symptoms such as fever have been reported to occur. [36], [37]

PREVENTION

A vaccine for Lyme disease is approved for adults and commercially available in the United States. The efficacy of this vaccine has been reported to be 76 percent after three injections, but booster injections may be needed every 1 to 3 years to maintain protection. [38] In Europe the situation may be more complicated, as three different *Borrelia* species are

involved, but vaccine tests are under investigation in different European countries.

Protection from tick bites by the use of protective clothing in risk areas and body inspection and removal of any attached ticks as soon as possible are the most important prophylactic methods. Prophylactic antibiotic therapy after a tick bite is generally not recommended in the United States or Europe because it is controversial whether the value of such treatment can balance the risk of adverse reactions to antibiotics. Results of animal tests in the United States show that it usually takes at least 24 h of attachment for an infected blood-sucking *I. scapularis* tick to transmit spirochetes to its host. [39] However, data from the former Soviet Union indicate that humans bitten by *I. persulcatus* usually are already infected during the first 24 h of attachment. [40] In this study, prophylactic treatment with doxycycline (100 mg, bid) for 3 to 5 days was an efficient method for preventing humans bitten by *Borrelia*-infected ticks from contracting Lyme borreliosis. More recently, it was shown that a single 200 mg dose of doxycycline given within 72 h after an *I. scapularis* tick bite can prevent Lyme disease, [41] but it has also been suggested that this prophylaxis should be restricted to geographic regions where the incidence of Lyme disease is high. [42]

COURSE AND PROGNOSIS

Natural Course (See Table 203-1)

On ethical grounds, the natural history of untreated Lyme borreliosis cannot be studied today, and no prospective investigations on the natural course have been carried out on large groups of unselected patients. During the preantibiotic era and the era preceding the discovery of the etiologic agent, many of the cases of early borrelial infection probably healed spontaneously. In 1977, Steere et al. reported on 12 patients in the United States with untreated erythema migrans, 6 of whom had multiple skin lesions. Of those patients, 7 developed arthritis or arthralgia. [2] This study was later expanded to 55 untreated patients. Six patients (11 percent) developed neurologic abnormalities, 2 (4 percent) developed cardiac involvement, and 28 (51 percent) developed arthritis. [23] Among 16 untreated Swedish patients with solitary erythema migrans, 2 patients developed recurrent erythema migrans lesions, 2 developed meningitis, and 1 developed ankle arthritis during the follow-up period. [12]

Posttherapeutic Course

Treatment failures have been reported with most of the different regimens. However, in the vast majority of patients, antibiotic therapy results in healing of the infection. Convalescence periods of several months, especially with persisting fatigue, are not uncommon in patients treated for Lyme borreliosis.

Reinfection in patients previously treated for erythema migrans is not unusual. [12], [13]

The resolution time for erythema migrans varies. [23], [34], [36] In most cases, the erythema begins to fade a few days after the start of therapy. In some patients the skin lesion has disappeared by the time the treatment is terminated, but in others it may persist longer. In patients with borrelial lymphocytoma, it might take more than a month after antibiotic therapy before the lesion has disappeared completely.

As a rule, the clinical improvement in ACA after antibiotic therapy occurs gradually and may continue for at least 1 year. The first sign of improvement is an abatement of the swelling. The cyanotic discoloration fades to varying degrees. Histologically there is a reduction in the number of infiltrating cells. Residual erythema, present several months after therapy, is generally caused by hyperemia resulting from remaining dilated vessels. The least satisfactory results are obtained in patients with advanced atrophy of the skin.

Serologic follow-up examination after therapy has shown that seroreversal tends to be slower in late than it is in early Lyme borreliosis. After antibiotic therapy, patients with ACA exhibit gradually decreasing antibody titers to *B. burgdorferi*. However, in only a minority of patients does the titer fall to normal values within 1 year. [32], [34] Serologic reactivity after therapy may perhaps persist indefinitely in patients with long-standing ACA, as in patients treated for late syphilis.

Some patients with chronic joint involvement do not respond to antibiotic therapy, even after repeated courses of different antibiotics. It has been speculated that *B. burgdorferi* may sometimes initiate immunologic reactions that may continue for varying lengths of time, even in the absence of live spirochetes.

Disparate opinions exist about the long-term consequences of borrelial infection. Some authors have described a post-Lyme syndrome and prolonged antibiotic therapy has been recommended. However, recent controlled trials show that antibiotic treatment for 90 days did not improve symptoms more than placebo. [43] In another study, it was shown that persisting nonspecific symptoms in patients treated for Lyme disease are similar to those among age-matched controls without Lyme disease. [44]

Kawasaki syndrome (KS) is an acute multisystem vasculitis that primarily affects infants and young children. Although KS was originally described as a benign illness of early childhood, it is now recognized that this disease is the leading cause of acquired heart disease in children in the United States and western Europe. Children with KS who do not receive appropriate treatment within the first 10 days of onset of fever have a 20 to 25 percent risk of developing coronary artery abnormalities. Early recognition and prompt treatment with the combination of intravenous immunoglobulin and aspirin reduces the prevalence of coronary artery abnormalities to less than 5 percent. Thus acute KS must be diagnosed early and treated promptly. A diagnosis of KS is based on the presence of fever plus at least four of five criteria listed in Table 204-1. [1]

Fever of 5 or more days without other explanation, and at least four of the five following criteria:

- Bilateral, painless, bulbar, nonexudative, conjunctival injection
- One of the following changes in the oropharynx: injected or fissured lips, injected pharynx, or strawberry tongue
- One of the following extremity changes: erythema of the palms or soles, edema of the hands or feet, periungal desquamation
- Polymorphous exanthem
- Acute nonsuppurative cervical lymphadenopathy (≥1.5 cm in diameter)

*A diagnosis of atypical Kawasaki syndrome can be made when less than four criteria are present and when coronary artery aneurysms are present.

TABLE 204-1 **Diagnostic Criteria for Kawasaki Syndrome**

HISTORICAL ASPECTS

KS, originally called mucocutaneous lymph node syndrome, was first recognized and described in Japan in 1967 by Dr. Tomisaku Kawasaki. [2] He reported his experience with 50 children who had been seen during the preceding 6-year period at the Tokyo Red Cross Medical Center. These children appeared to manifest a constellation of findings distinct from any previously described disease. After this description, numerous cases were reported throughout Japan. Dr. Kawasaki's first description in the English language of the disease appeared in 1974. In 1976, the syndrome was first reported in the United States by Melish, Hicks, and Larson in a group of 12 children from Honolulu seen between 1971 and 1973. Since then, KS has been recognized worldwide in children of every racial group.

EPIDEMIOLOGY

Although KS occurs worldwide in children of all racial groups, it is most prevalent in Japan and in children of Japanese ancestry (reviewed in Ref. 3). KS is primarily an illness of young children, with approximately 80 percent of patients being younger than 5 years of age. The ratio of males to females is about 1.5:1. The incidence rate is the highest for Japanese children between 6 and 12 months of age, with equal numbers in the first and second years of life. KS only rarely occurs in the same school, daycare center, or household. Thus, person-to-person transmission of the disease appears to be unlikely. In Japan, the recurrence rate of KS is reported to be 3.9 percent and the proportion of sibling cases 1.4 percent. The rate of recurrence is highest within the first 12 months following the first episode. [4] These studies suggest common exposure to an infectious agent in genetically predisposed individuals.

The incidence of KS in Japan increased from 1967 to the mid-1980s. Nationwide epidemics, with wavelike spread of cases, occurred in 1979, 1982, and in late 1985 to early 1986. Since the mid-1980s the incidence of KS in Japan has increased steadily such that the incidence rate in 1998 was over 1.5 times higher than that in 1987. [5] The endemic annual incidence of KS is approximately 111 cases per 100,000 children younger than age 5 years. Both the endemic and the epidemic form of KS in Japan occur most commonly in the late winter and spring, with another period of slightly increased incidence during late fall. KS has been increasingly recognized in other Asian countries as well.

Epidemiologic findings in the United States and Europe reveal striking similarities to those in Japan. KS has been reported in all parts of the United States and Europe, occurring sporadically or as temporally limited community-wide epidemic outbreaks. Surveillance studies suggest that approximately 3000 patients with KS are hospitalized annually in the United States. The peak age is 18 to 24 months of age. More than 80 percent of cases occur in patients younger than 5 years of age, and most cases occur in patients younger than 2 years of age. Infants younger than 12 months of age,

and particularly those younger than 6 months of age, appear to be at an increased risk of developing coronary artery abnormalities. The prevalence of KS is highest among Asians, intermediate in blacks, and lowest in whites. Regardless of the racial group affected, however, the clinical picture is similar.

ETIOLOGY AND PATHOGENESIS

Although multiple factors are likely to play a role in the pathogenesis of KS, several observations suggest that immune activation is involved in its pathogenesis (reviewed in Ref. 6). First, the acute phase of KS is characterized by increased numbers of activated helper T cells and monocyte/macrophages, as well as a marked polyclonal B cell activation. Second, there is increased production of multiple proinflammatory cytokines. Serum levels of interleukin (IL)-1, tumor necrosis factor (TNF)-a, IL-6, adrenomedullin, and vascular endothelial growth factor have been reported to correlate with the development of coronary artery abnormalities. [7], [8] Third, the histologic lesion in coronary arteries and other medium-sized arteries suggests a role for immune-mediated vascular injury (see pathology section below). Fourth, the acute phase of KS is associated with the appearance of circulating antibodies that are cytotoxic against cardiac myosin and vascular endothelial cells prestimulated with IL-1, TNF-a, or interferon (IFN)-?. [9] Finally, successful treatment of patients with intravenous immunoglobulin plus aspirin reduces the immune activation associated with this disease. [10] In contrast, KS patients treated with aspirin alone have prolonged T and B cell activation.

At present, there is no consensus regarding the etiology of KS. Nevertheless, it is widely agreed that KS is caused by an infectious agent because of the acute, self-limited nature of this disease, seasonal incidence, geographic clustering of outbreaks, and the unique susceptibility of young children. Furthermore, the fever and other clinical findings in acute KS (see Table 204-1) significantly overlap with bacterial toxin-mediated diseases such as toxic shock syndrome (TSS) or scarlet fever.

The activation of T cells and monocytes/macrophages found in acute KS is characteristic of diseases caused by bacterial toxins that act as superantigens. [11] Staphylococcal enterotoxins (SEs), TSS toxin-1 (TSST-1), and streptococcal pyrogenic exotoxins (SPEs) are prototypic superantigens that stimulate a large proportion (up to 35 percent) of T cells in a human leukocyte antigen (HLA)-DR–dependent yet unrestricted manner. These bacterial toxins bind directly to conserved amino acid residues outside of the peptide antigen binding groove on major histocompatibility complex (MHC) class II molecules and selectively stimulate T cells expressing specific T cell antigen receptor (TCR) ß chain variable gene segments. Other variable elements (Dß, Jß; Va, Ja) of the TCR contribute much less to the recognition of these superantigens. In contrast, nominal peptide antigens generally require all five variable elements for optimal T cell recognition and therefore stimulate only a low number of T cells (less than 1 in 1000).

To determine whether the immune activation during acute KS results from stimulation by superantigen(s), T lymphocytes of 19 children with KS were analyzed for TCR Vß gene usage. [12] Patients with acute KS demonstrated marked expansion of Vß2 and, to a lesser extent, Vß8-positive T cells. In contrast, cells from control subjects showed no evidence for overexpression of TCR Vßs. During the convalescence phase of KS, percentages of Vß2-positive and Vß8-positive T cells returned to normal levels. This selective expansion of circulating Vß2-positive T cells is similar to the changes observed in T cells from patients with staphylococcal TSS, an illness with many clinical similarities to acute KS.

Since the initial report there have been confirmatory and nonconfirmatory reports of Vß2 expansion in acute KS. [13], [14], [15] and [16] The ability to find Vß2-positive T cell abnormalities in the peripheral blood of patients with acute KS may depend on the timing of the blood collection, as superantigens stimulate the expression of homing receptors, thereby triggering the migration of T cells into inflamed tissues. [13] Thus, increased Vß2-positive T cells may be observed in the tissue even with normal or decreased Vß2-positive T cell values in the peripheral blood. Indeed, Yamashiro and colleagues have observed a selective expansion of Vß2-positive T cells in the small intestinal mucosa of patients with acute KS. [17] They suggested that the gastrointestinal tract may be the primary site of entry for a superantigen-secreting organism causing acute KS.

To further test the hypothesis that acute KS is triggered by a superantigen, Abe et al. [18] analyzed the sequences of random cDNA clones containing Vß2 gene segments of T cells from patients with acute KS. In patients with a two- to threefold increase in numbers of Vß2-positive T cells, a clonotypic expansion of Vß2-positive T cells might be expected to result in identical junctional sequences in up to 67 percent of the clones. However, none of the acute KS Vß2-positive T cell clones had the same junctional sequence. In view of the selective expansion of Vß2-positive T cells in acute KS, the extensive ß-chain junctional diversity suggests that these Vßs play a dominant role in recognition. This type of recognition is generally not a feature of responses to most peptide antigens. This high frequency of response and the prominent role for Vß2 is most consistent with the hypothesis that T cell activation observed in the peripheral blood of acute KS is mediated by a superantigen that induces Vß2-positive T cell expansion.

To identify potential bacterial superantigen(s) involved in the pathogenesis of KS, Leung et al. [19] analyzed cultures in a blinded manner from the groin, axilla, rectum, and pharynx of 16 patients in the acute phase of KS and 15 age-matched, febrile control patients. All group A beta-hemolytic streptococci and coagulase-positive *Staphylococcus aureus* isolates were screened for toxin production. Superantigen-producing bacteria were found in 13 of 16 patients with acute KS, but only in 1 of 15 control patients ($p < 0001$). Of 13 toxin (superantigen)-positive cultures from patients with KS, 11 were TSST-1, secreting *S. aureus,* and 2 of 13 were *streptococci,* producing streptococcal pyrogenic exotoxin B (SPEB) and streptococcal pyrogenic exotoxin C (SPEC). Importantly, TSST-1 and SPEC are known to possess Vß2 stimulatory activity, whereas SPEC has both Vß2 and Vß8 stimulatory activity.

It should be noted that 12 of 13 culture-positive patients had toxin-producing *S. aureus* isolated from the pharyngeal or rectal cultures. Only 1 of 13 patients had toxin (superantigen)-producing bacteria exclusively on the skin. This suggests that the primary site of bacterial colonization or infection in KS patients is the mucosal surface of the gastrointestinal tract, consistent with the observation by Yamashiro et al. [17] that there is a selective expansion of Vß2-positive T cells in the small intestinal mucosa of patients with acute KS. Furthermore, these data suggest that several staphylococcal or

streptococcal superantigens with TCR Vß2-stimulatory activity may cause the acute clinical features listed in Table 204-1 by inducing fever and tissue inflammation via the massive release of cytokines. Since these sentinel observations, several studies have confirmed this initial report, while others have failed to find superantigen-producing *S. aureus* or *Streptococci* associated with acute KS. [20], [21] A recent multicenter, blinded, controlled study also confirmed an association of TSST-1 producing *S. aureus* and SPEC-producing *streptococci* with acute KS but, interestingly, other superantigens were not associated with KS. [22] Furthermore, the recent description of guttate psoriasis (known to be caused by Vß2-stimulatory superantigens) in a patient following KS with associated *S. aureus* on throat culture, and a series of 10 patients who developed psoriasis during or following acute KS are consistent with a superantigenic etiology in KS. [23], [24] and [25]

CLINICAL MANIFESTATIONS

Dermatologic Features

The mucocutaneous manifestations of KS are varied and not all children exhibit each feature. The major diagnostic criteria for KS are listed in Table 204-1 and are reviewed in references 1 to 3. KS is a triphasic illness beginning with an acute phase that lasts 7 to 14 days, followed by a subacute phase of approximately 25 days and a convalescent phase that lasts nearly 70 days. The cardinal feature of the acute phase is a prolonged high fever that frequently spikes to 40°C (104°F) and is associated with a toxic appearance in virtually all patients. In the absence of anti-inflammatory therapy, the duration of fever is usually 1 to 2 weeks.

Approximately 90 percent of children with KS develop an exanthem in the first days of their acute febrile illness (Fig. 204-1). The eruption favors the trunk and proximal extremities, but can be generalized. It can be quite variable, having been described as macular, papular, morbilliform, urticarial, and even “target-like” resembling erythema multiforme. The initial rash may be indistinguishable from an acute viral exanthem or adverse drug reaction, but is rarely vesicular or bullous. Recently, plaque-type and pustular psoriatic lesions have been described in the acute phase. [25]

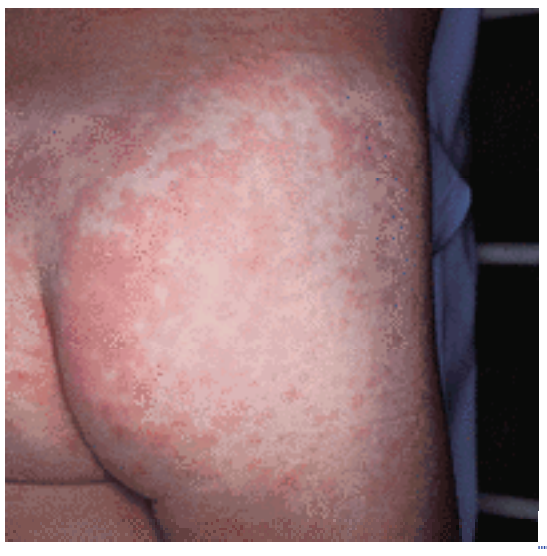

FIGURE 204-1 A generalized morbilliform eruption appearing early in the febrile course of a 5-year-old boy with Kawasaki syndrome.

One of the earliest signs of KS is a characteristic perineal eruption (Fig. 204-2). In one study of 58 children, 67 percent had the perineal eruption. [26] Onset is usually within the first 6 days of the illness and presents as diffuse macular or plaque-type blanching erythema involving part or all of the perineal skin. These involved areas can be warm and tender. Within 48 h, the erythematous areas begin to desquamate. This desquamation occurs earlier than that of the palms and soles.

FIGURE 204-2 Generalized erythema and early desquamation in the perigenital and perineal area of a 4-year-old girl with Kawasaki syndrome. This feature occurs early in the illness and involves 67 percent of affected children.

In 90 percent of patients, a nonexudative conjunctival injection begins shortly after the onset of fever and generally involves the bulbar conjunctivae more severely than the palpebral conjunctivae. Conjunctival vessels become engorged and dilated. There is no purulent discharge or crusting of the eyelashes, as is seen in bacterial conjunctivitis. Conjunctival injection is associated with anterior uveitis in approximately 83 percent of patients examined within the first weeks of illness.

Oral mucosal findings are very characteristic of KS and occur in almost all cases. The lips become “cherry” red, dry, and often cracked, producing small hemorrhagic fissures. In contrast to staphylococcal scalded skin syndrome, there is no

radial crusting of the perioral skin. There are no punctate ulcerations, as are seen in herpes gingivostomatitis or aphthae, and no diffuse erosions with confluent hemorrhagic crusts, as are seen in Stevens-Johnson syndrome. The tongue has been described as “strawberry,” with hypertrophied papillae and hyperemia, but only about half the cases seem to have this feature.

Profound edema and erythema of the distal aspects of the hands and feet with fusiform swelling of the fingers is also noted in almost all cases (Fig. 204-3). Onset is usually within a few days of the start of illness. These hyperemic areas are subject to desquamation 10 to 18 days later, during the subacute phase. The desquamation characteristically begins at the tips of the fingers and toes and may develop either fine peeling or shedding of thick “casts” of palmar and plantar skin, similar to that seen in scarlet fever (Fig. 204-4).

FIGURE 204-3 Erythema and edema of the distal fingertips are characteristic of the early phase of Kawasaki syndrome.

FIGURE 204-4 Desquamation starting at the tips of the fingers occurs 10 to 18 days after the onset of illness, as illustrated in this 3-month-old infant with Kawasaki syndrome.

Generalized fine desquamation, especially in the areas of the skin that had previously been erythematous, is also common at this time. Recurrent skin peeling, especially in those children with nasal staphylococcal colonization, may occur for several years, usually following upper respiratory tract infections. [27] Because of the severe systemic nature of the illness and the prolonged high fever, it is not surprising that some children develop telogen effluvium, with significant but transient hair loss 6 to 12 weeks following the acute phase of the illness. Similarly, Beau's lines of the nails and/or shedding of the nails have been observed weeks to months later. Transient episodes of psoriasis have been described 4 to 12 weeks after the acute phase, but none of these children have developed chronic psoriasis. [23], [25] Lymphadenopathy is the least frequent finding and is seen in less than 75 percent of patients. The adenopathy generally consists of a single enlarged, nonsuppurative cervical node measuring at least 1.5 cm.

Systemic Associations

Table 204-2 lists other associated clinical features of KS. Arthralgia and arthritis occur in approximately one-third of patients. During the acute phase, the arthritis usually involves the small joints, whereas involvement of the large weight-bearing joints usually occurs in the second and third weeks of the illness. Urethritis associated with sterile pyuria is frequently present in acute KS. Aseptic meningitis is usually associated with mild mononuclear cell pleocytosis of the cerebrospinal fluid and with normal glucose and protein. Hydrops of the gallbladder may be present with or without obstructive jaundice. Diarrhea, vomiting, abdominal pain, cranial nerve palsies, otitis media, and infarction of organs whose vascular supply is compromised by thrombosis may also be presenting symptoms. Sensorineural hearing loss has also been associated with KS.

- Cardiovascular abnormalities, including myocarditis, arterial aneurysms, pericarditis, aortic or mitral regurgitation, ventricular arrhythmias
- Arthralgia and arthritis
- Urethritis with sterile pyuria
- Aseptic meningitis
- Hydrops of the gallbladder
- Diarrhea, vomiting, or abdominal pain
- Sensorineural hearing loss
- Uveitis
- Hepatic dysfunction

TABLE 204-2 **Associated Clinical Features of Kawasaki Disease**

During the convalescent phase there is generally a paucity of physical findings. Patients who suffer cardiovascular complications from this illness may have persistent cardiac abnormalities, including chronic myocardial dysfunction, aortic or mitral regurgitation, and cardiac arrhythmias. Occasionally a patient may experience clinical exacerbation, with recurrence of fever and other acute clinical signs, such as rash and conjunctival injection, after they had appeared to resolve. This occurs most often within a few weeks of onset of illness and may be associated with an increased risk of coronary artery disease.

Cardiac Manifestations

Abnormal cardiac findings are a hallmark of KS. Myocarditis is frequently observed during the first week after onset of fever. Pericardial effusion may develop toward the latter part of the acute phase and is secondary to myopericarditis. It is rare that these patients progress to cardiac tamponade, and the pericardial effusion generally resolves spontaneously. Congestive heart failure may occur as a result of myocarditis in the acute phase. During the subacute stage, congestive heart failure is usually caused by myocardial dysfunction secondary to ischemia or infarction.

Coronary artery ectasia or aneurysms occur in nearly 25 percent of patients with KS who are not treated with intravenous immunoglobulin. Dilatation of the coronary arteries may be detected by echocardiography beginning 7 days after the onset of fever, usually peaking 3 or 4 weeks into the illness. A minority of patients (approximately 5 percent) may suffer from aortic or mitral regurgitation due to valvulitis, transient papillary muscle dysfunction, or as a complication of myocardial infarction.

On cardiac examination, patients with acute KS often present with tachycardia and gallop rhythms, both in excess of the fever and anemia associated with the illness. In a minority of patients, a pericardial friction rub, dysrhythmias, aortic and mitral regurgitation, the findings of congestive heart failure, and the appearance of peripheral arterial aneurysms appear during the latter part of the acute phase or during the subacute phase.

LABORATORY FINDINGS

During the acute phase of KS, patients develop a leukocytosis with a predominance of neutrophils and an increase in band count. A normocytic, normochromic anemia without evidence of hemolysis or reticulocytosis presents during the first week of illness and persists until the inflammatory process subsides. Increased platelet turnover occurs together with marked hypercoagulability in the acute phase. Thrombocytosis peaks typically in the third to fourth week after onset of fever. Elevation of liver transaminases, usually two- to threefold, is common in the acute phase, usually with a cholestatic profile of elevated bilirubin and alkaline phosphatase. Sterile pyuria caused by urethritis is observed in up to 75 percent of patients during the first week of illness. Early in the disease, acute-phase reactants such as C-reactive protein and serum a $_1$-antitrypsin, are increased with the onset of fever and persist for 6 to 10 weeks. Similarly, erythrocyte sedimentation rates are uniformly elevated in patients with acute KS. Elevation of the latter typically persists after resolution of fever, a feature that may help to distinguish KS from common viral illness. Although patients with KS have a polyclonal B cell activation, their sera do not contain the usual autoantibodies associated with collagen-vascular disease (i.e., no rheumatoid factor or antinuclear or anti-DNA antibodies). Low serum albumin levels are reported to be a risk factor for the development of coronary artery aneurysms and poor clinical outcome. [28]

Electrocardiographic changes may be present in over half of patients with acute KS. These abnormalities can include prolonged PR interval, left ventricular hypertrophy, abnormal Q waves, ventricular dysrhythmias, and nonspecific ST-T wave changes. Two-dimensional echocardiography has been used extensively for the assessment of ventricular function, the anatomy of the proximal coronary arteries, and the presence of a pericardial effusion. In general, it is preferable to obtain a baseline two-dimensional echocardiogram before the seventh day of illness (prior to onset of coronary dilation) and a repeat echocardiogram 3 to 5 weeks after illness onset (when coronary artery abnormalities are likely to be detected). Coronary arteriography is generally reserved for the patient with persistent abnormalities on echocardiograms or any patient with symptoms of myocardial ischemia. It is especially useful for visualization of coronary artery stenoses or distal coronary artery lesions that are difficult to define by two-dimensional echocardiography.

PATHOLOGY

Extensive gross and microscopic studies have been carried out at autopsy of KS patients who have died in different phases of their illness. The case-fatality rate for KS is approximately 0.4 percent, with most deaths occurring secondary to the cardiovascular complications of this disease. Fujiwara and Hamashima classified the pathology of this syndrome into four stages, according to the duration of illness at death. [29] Stage 1 (0 to 9 days after onset) is characterized by acute vasculitis and perivasculitis of small blood vessels. Microscopically, the acute vascular lesion in KS is associated with evidence for endothelial activation and endothelial cell damage. [29], [30] The lesion is also associated with the infiltration of both neutrophils and mononuclear cells. The mononuclear cells consist of activated T cells and monocyte/macrophages. [31] MHC II antigens are expressed on the coronary arterial endothelium in acute KS but not in normal controls. IFN-? is a potent in vivo inducer of class II MHC antigens, and IL-1, as well as TNF-a, plays an important role in the induction of leukocyte adhesion molecules. The induction of class II MHC antigens on endothelial cells, as well as the observation of leukocyte adhesion to endothelial cells in the vascular lesion of KS, suggests that cytokine-induced endothelial antigens play an important role in the pathogenesis of this disease. In the larger arteries, the initial inflammation involves the intima and the vasa vasorum without inflammation of the media. Pericarditis, myocarditis, inflammation of the atrioventricular conduction system, and endocarditis with valvulitis are also present.

Stage 2 (12 to 25 days after onset) is characterized by a marked infiltration of inflammatory cells into the media of the coronary arteries as well as other medium-sized arteries, and aneurysms with thrombosis begin to form. At this stage, it is presumed that the formation of aneurysms is occurring as the result of destruction of the blood vessel walls that follows release of proteolytic enzymes and inflammatory mediators into the media. In stage 3 (28 to 31 days), the acute inflammatory process regresses, and granulation of the coronary arteries is noted. In stage 4 (40 days to 4 years), scar formation, organization of thrombi, intimal proliferation and neoantiogenesis continue to occur for several years after onset of the disease. [32] This process can result in severe stenosis of the coronary arteries as well as other medium-sized arteries.

The peak time of death is 3 to 4 weeks after onset of the acute illness. Death can occur as early as during the first week of illness and as late as more than 10 years after the acute illness. During stage 1 of KS, patients usually die of acute

myocarditis or cardiac arrhythmia caused by inflammation of the atrioventricular conduction system. In stage 2 of the disease, death can result from rupture of the coronary arteries or myocarditis, including lesions of the atrioventricular conduction system, or myocardial insufficiency caused by thrombosis of the coronary arteries. Sudden death late in the illness (stage 3), or years after recovery from acute KS (stage 4), may occur as the result of myocardial infarction in children with residual coronary artery aneurysms and stenoses.

It is worth emphasizing that although coronary arteries are invariably involved in this disease, almost any other medium- or large-sized blood vessel may be involved when examined at autopsy. Aneurysm formation has been reported in the femoral, iliac, renal, axillary, and brachial arteries. KS is a systemic vasculitis that can affect most small- and medium-sized blood vessels. Cutaneous vasculitis, however, is not a prominent feature of KS.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

According to the guidelines set forth by the American Heart Association, [1] the patient with KS should have fever lasting 5 or more days without other reasonable explanation and satisfy at least four of the five following criteria (Table 204-1): (1) bilateral nonexudative conjunctival injection; (2) at least one of the following mucous membrane changes: injected or fissured lips, diffuse injection of the oral and pharyngeal mucosa, or “strawberry tongue”; (3) at least one of the following peripheral extremity changes: erythema of the palms or soles, edema of the hands or feet during the acute phase, or periungual desquamation during the convalescent phase; (4) polymorphous exanthem; and (5) acute nonsuppurative cervical lymphadenopathy (>1.5 cm in diameter). In atypical cases, patients with fever and fewer than four of the principal symptoms can be diagnosed as having KS when coronary artery disease is detected by two-dimensional echocardiography or coronary angiography. Males younger than 6 months of age are at particularly high risk for atypical KS. The diagnosis of atypical KS should be considered in any infant with prolonged fever (>2 weeks). Findings that should trigger the search for another diagnosis include discrete intraoral ulcerations, exudative conjunctivitis and generalized lymphadenopathy which is rarely seen in acute KS.

KS has clinical features compatible with infection, hypersensitivity reactions, or exposure to environmental toxins. The differential diagnosis includes staphylococcal or streptococcal scarlet fever or toxic shock syndrome; staphylococcal scalded skin syndrome; viral exanthem, particularly measles; Rocky Mountain spotted fever; leptospirosis; infantile polyarteritis nodosa; mercury toxicity (acrodynia); Stevens-Johnson syndrome; erythema multiforme; adverse drug reaction; and juvenile rheumatoid arthritis. KS has a variety of mucocutaneous manifestations, some of which are characteristic, but many of which are shared with these other infectious and reactive disorders. The correct diagnosis of KS hinges on recognizing the cumulative combination of mucocutaneous, systemic, and laboratory findings. Considerations that help in eliminating certain viruses such as measles and influenza from the differential diagnosis include local epidemiology, vaccination history, and culture results.

Because KS is based on diagnostic criteria that use clinical characteristics that overlap with other illnesses, diagnostic dilemmas can arise, particularly in atypical cases that do not completely fulfill the diagnostic criteria, but which are associated with the development of coronary artery abnormalities. Instances of atypical KS are most common in infants, the age group that is at greatest risk of coronary artery abnormalities. The decision to initiate therapy in children who do not satisfy the American Heart Association criteria can be supported by laboratory results showing acute phase reactants (elevated white blood cell count, elevated sedimentation rate), an ultrasound showing a pericardial effusion or a slit lamp exam showing anterior uveitis.

TREATMENT AND PROGNOSIS

Current management is aimed at reducing inflammation in the myocardium and coronary artery wall, and at preventing coronary thrombosis. Aspirin in combination with high-dose intravenous immunoglobulin is the cornerstone of therapy for acute KS. Aspirin is administered in doses of 80 to 100 mg/kg of body weight per day in four divided doses to achieve a serum salicylate level of 20 to 25 mg/dL during the acute phase of the illness. At therapeutic doses, aspirin reduces fever, toxicity, and joint symptoms within 48 h. [33] After defervescence, usually around the fourteenth day of illness, the aspirin dose is reduced to 3 to 5 mg/kg of body weight per day to continue inhibiting platelet activity. Aspirin is discontinued if no coronary abnormalities have been detected by 6 to 8 weeks after onset of the illness and the platelet count and sedimentation rate have normalized. Aspirin therapy is continued indefinitely if coronary artery aneurysms develop and persist. Digitalis and diuretics are used as needed in the patient with congestive heart failure. In patients at risk for cardiovascular complications, some physicians add dipyridamole, 1 mg/kg body weight per day, to further inhibit platelet aggregation. Therapy of the mucocutaneous manifestations of the disease is entirely symptomatic and includes emollients for desquamating skin and antihistamines for pruritus.

No definitive prospective study has demonstrated that high-dose aspirin therapy prevents coronary artery abnormalities. In contrast, several randomized multicenter studies have demonstrated that high-dose (greater than 1 g/kg) IV immunoglobulin in combination with aspirin therapy is safe and effective in reducing the prevalence of coronary artery abnormalities. [34], [35], [36] and [37] IV immunoglobulin both reduces the overall prevalence of coronary artery abnormalities and prevents the formation of giant aneurysms, the most serious form of coronary abnormality caused by KS. Abnormalities of left ventricular systolic function and contractility also improves more rapidly in children treated in the acute phase with high-dose IV immunoglobulin together with aspirin than in those children treated with aspirin alone. [38]

At present, the treatment of choice for acute KS is a single high dose of IV immunoglobulin (2 g/kg) administered over 10 to 12 h with aspirin (80 to 100 mg/kg per day). When compared with multiple-dose regimens of approximately equivalent total dose, this single high dose of IV immunoglobulin has a lower incidence of coronary abnormalities, more rapid resolution of fever and laboratory indices of acute inflammation, and reduction in the duration of hospitalization, as well as higher peak serum IgG levels. [36] Of interest, peak-adjusted serum IgG levels are lower among patients who subsequently develop coronary artery abnormalities and the levels are inversely related to fever duration and laboratory

indices of acute inflammation.

A minority of patients who receive IV immunoglobulin have persistent fever 48 h after completion of the infusion. A subset of patients might also demonstrate initial defervescence but then have recurrence of their fever after being afebrile for 24 h or more. In both situations, a repeat dose of IV immunoglobulin may be indicated. [39]

At present, the use of systemic steroids in the treatment of KS is controversial. Several studies from Japan report that patients treated with steroids alone or in combination with aspirin have a higher frequency of coronary aneurysms and of subsequent myocardial infarction and death. [40] A more recent study of four patients with KS resistant to IV immunoglobulin suggested a response to high-dose pulse methylprednisolone (30 mg/kg per day for 1 to 3 days) therapy. [41] In 1999, Shinohara et al. reviewed the experience with prednisolone in children with KS. [42] The authors concluded that prednisolone resulted in a shorter duration of fever and a lower prevalence of coronary artery aneurysms. However, this study was a retrospective review of patients who received different doses and different schedules of IV immunoglobulin than what is currently used in the United States. Case reports of either oral or intravenous corticosteroid use in patients with unresponsive disease despite at least two adequate doses of IV immunoglobulin suggest a possible role for steroids in the reduction in the acute inflammatory phase, as well as control of the vasculitis. [43], [44] However, controlled studies are needed to determine whether systemic corticosteroids should be used in patients who fail to respond to IV immunoglobulin therapy.

Patients who develop coronary artery aneurysms must be monitored closely for the long-term cardiac sequelae of KS. [45] Stress echocardiography and coronary angiography may be indicated in patients with evidence of myocardial ischemia. For the KS patients with obstructive changes in one or more coronary arteries, anticoagulant therapy may be required. For more severe cardiovascular symptoms, the options include the use of intravenous streptokinase or urokinase when a thrombus is present, balloon angioplasty, and/or coronary artery bypass grafting. [46], [47]

PROGNOSIS

The major long-term morbidity in KS is related to cardiovascular complications from this disease. The majority of children (50 to 67 percent) with arterial aneurysms will show angiographic regression within 6 months to 2 years after onset of their disease. [48] The likelihood of resolution of the aneurysms appears to be determined by the initial size of the aneurysm, with smaller aneurysms having a greater likelihood of regression. Some studies, however, indicate that there is evidence of persisting abnormal vascular wall morphology and vascular dysfunction at the site of regressed coronary aneurysms in patients with previous KS. [49] Patients with giant aneurysms, that is, those with a maximum diameter greater than 8 mm, have the worst prognosis. The majority of patients with giant aneurysms progress to stenosis or obstruction. Nearly all late deaths from KS occur in this subgroup of patients.

Children without known cardiac sequelae during the first month of KS appear to return to their previous state of health without cardiac impairment. A study of patients many years after resolution of acute KS, however, using high-resolution ultrasound to study endothelium-dependent vascular responses, showed evidence of persistent endothelial dysfunction, even in patients without detectable early coronary artery involvement. [50] Increased blood pressure, adiposity and higher fasting triglyceride levels have also been reported in patients with previous KS. Thus, it is generally recommended that children with KS be followed over the long-term by a cardiologist to rule out the development of myocardial dysfunction, late-onset valvular regurgitation, or premature coronary artery disease.

MYCOLOGY

The dermatophytes are a group of taxonomically related fungi whose ability to form molecular attachments to keratin and use it as a source of nutrients allows them to colonize keratinized tissues, including the stratum corneum of the epidermis, hair, nails, and the horny tissues of animals. [1] Superficial infection caused by a dermatophyte is termed *dermatophytosis,* whereas *dermatomycosis* refers to systemic or deep fungal infections.

Historical Aspects

Systematic study of superficial fungal infection began more than 150 years ago when Remak described the mycelial nature of the clinical disease favus. In 1841, Gruby isolated the organism of favus in culture and experimentally reproduced the disease with inoculation in normal skin. However, it was not until 1910 that Raymond Saboraud published his seminal treatise, *Les Tiegnes,* classifying the dermatophytes into four genera based on their microscopic and clinical characteristics. In 1934, Emmons' critical review of dermatophyte taxonomy resulted in the three genera known today: *Epidermophyton, Microsporum,* and *Trichophyton*.

Laboratory Procedures

The success of laboratory confirmation of clinically diagnosed superficial fungal infection relies on the proper collection of specimens for microscopic examination and culture.

MICROSCOPIC EXAMINATION

Hair Examination of lesions involving the scalp or beard with a Wood lamp may reveal the fluorescent pteridine of certain pathogens (Table 205-1). Hairs must be plucked, not cut, for examination by low-power microscopy, which may reveal three possible patterns of infection:

Ectothrix	Endothrix
Yellow-green fluorescence	Dull gray-green fluorescence
M. audouinii	*T. schoenleinii*
M. canis	
M. ferrugineum	
No fluorescence	No fluorescence
M. fulvum	*T. gourvilii*
M. gypseum	*T. soudanense*
T. megninii	*T. tonsurans*
T. mentagrophytes	*T. violaceum*
T. rubrum	*T. yaoundei*
T. verrucosum	

TABLE 205-1 **Laboratory Characteristics of Dermatophytes that Cause Tinea Capitis**

1. Ectothrix—small or large arthroconidia forming a sheath around the hair shaft (Fig. 205-1);

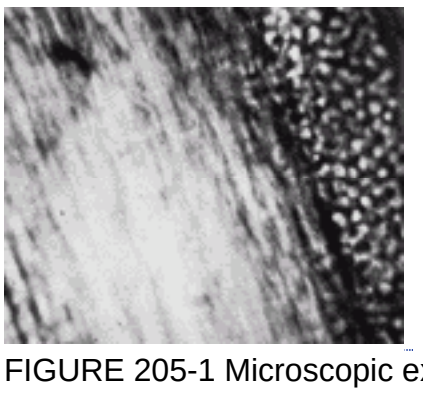

FIGURE 205-1 Microscopic examination of ectothrix hair involvement.

2. Endothrix—arthroconidia within the hair shaft (Fig. 205-2);

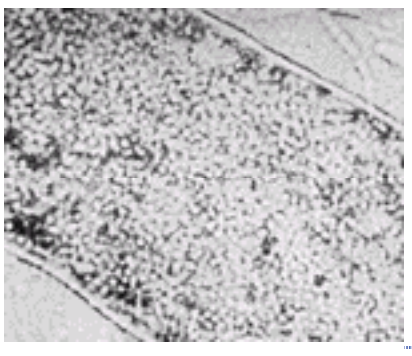

FIGURE 205-2 Microscopic examination of endothrix hair involvement.

3. Favic—hyphae arranged in parallel within and around the hair shaft (Fig. 205-3).

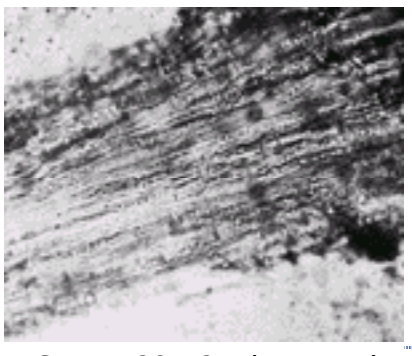

FIGURE 205-3 Microscopic examination of favic hair involvement seen with *T. schoenleinii*.

Skin and nails Skin samples should be taken by scraping with the dull edge of a scalpel outward from the advancing margins of a lesion. Nail specimens must include clippings of the entire thickness of dystrophic areas of nail, as proximal from the distal edge as possible. In a potassium hydroxide (KOH) preparation, fungal hyphae will appear as septate and branching structures (Fig. 205-4); however, culture is required for speciation.

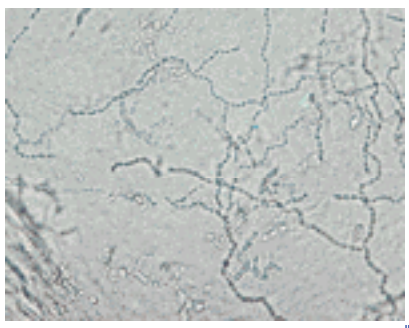

FIGURE 205-4 Microscopic examination of skin scrapings (scales) revealing septate, branching hyphae.

CULTURE PROCEDURES Speciation of superficial fungi is based on the macroscopic, microscopic, and metabolic characteristics of the organism. Sabouraud's dextrose agar (SDA) [dextrose 40 g; agar 20 g; peptone 10 g; distilled water (adjusted to pH 5.5) to 1000 mL] is the most commonly used isolation medium and serves as the basis for most morphologic descriptions. However, contaminant saprobes (organisms that feed on dead or decaying matter) grow rapidly on this medium, masking true pathogens. This necessitates the addition of cycloheximide (0.5 g/L) and chloramphenicol (0.05 g/L) to inhibit saprobes and bacteria, making the medium highly selective for the isolation of dermatophytes. Commercial versions of this agar are Mycosel and Mycobiotic. Dermatophyte test medium (DTM) contains the pH indicator phenol red; it remains yellow with the growth of most saprophytes, but turns red when dermatophyte proteolytic activity increases the pH to 8 or above. Identification of isolated fungi is facilitated by the use of potato dextrose agar (PDA), which stimulates the production of conidia and pigment. Finally, species of *Trichophyton* are often differentiated by their nutritional requirements, revealed on *Trichophyton* agar Numbers 1 through 7. These are a

casein basal medium (T1) with the addition of inositol (T2), thiamine and inositol (T3), thiamine (T4), and nicotinic acid (T5), as well as an ammonium nitrate basal medium (T6) supplemented with histidine (T7). It is essential that each laboratory use standardized media, of which several commercial variants are available. Cultures are incubated at room temperature (26°C/78.8°F) for up to 4 weeks before being discarded as no growth. With more than 40 known dermatophytes, proper identification requires a suitable reference source. [2] Figure 205-5 lists the characteristics of the most common pathogens.

Epidemiology

Classifying superficial fungi by their usual habitat (Table 205-2) is useful for understanding their various clinical presentations and patterns of transmission.

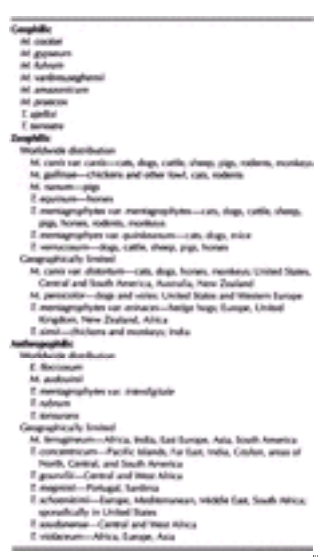

TABLE 205-2 **Usual Habitat of Dermatophytes Known to Cause Human Disease**

Geophilic organisms grow in the soil and only sporadically infect humans; when they do, the result is usually inflammatory. Strains of *M. gypseum,* the most common geophilic pathogen, cultured from humans are more virulent than those from the soil, accounting for occasional epidemic spread under appropriate conditions. [3]

Zoophilic species are found on animals, but are also transmitted to humans sporadically. Domestic animals and pets are becoming an increasing source of these infections in urban areas (e.g., *M. canis* in cats and dogs). Transmission may occur through direct contact with a specific animal species or indirectly by infected animal hair carried on clothing or present in contaminated buildings or feed. Exposed areas such as the scalp, beard, face, and arms are favored sites of infection. Although human infection with zoophiles is often suppurative, animal infection may be clinically silent, demonstrating the unique adaptation of fungi to their animal hosts. [4]

Anthropophilic species have adapted to humans as hosts. Unlike the sporadic geophilic and zoophilic infections, anthropophilic infections are often epidemic in nature. They are transmitted from person to person via direct contact or fomites. Markedly inflammatory reactions can occur because of variability in virulence as well as host susceptibility. Kerion formation, suppuration, or other manifestations of inflammatory tinea facilitate early diagnosis. Noninflammatory disease, in contrast, results in a clinically silent “carrier” state that serves to delay diagnosis and propagate the infection.

Host variability also affects presentation. Immunocompromised individuals are more susceptible to severe or refractory dermatophytoses, and advances in chemotherapy and transplant medicine have led to an increase in opportunistic infections by previously nonpathogenic dermatophytes. [5] Interestingly, only the severity of dermatophytosis is increased with HIV disease, not the prevalence. [6] Age, sex, and race are additional important epidemiologic factors, as dermatophyte infections are five times more prevalent in males than females. [7] However, *T. tonsurans* tinea capitis is more common in female adults than male adults, and most common in African-American children.

T. tonsurans also illustrates how patterns of human travel may rapidly influence the distribution of endemic fungi. Within

the past quarter century, it has replaced *M. audouinii* as the predominant cause of tinea capitis in the United States, correlating well with the immigration of Mexican and Caribbean populations. The relative resistance of *T. tonsurans* to griseofulvin has also contributed to its predominance. [4] Finally, local customs influence rates of dermatophytoses. For example, the use of macerating occlusive footwear has made tinea pedis and onychomycosis much more common in industrialized nations. [6]

Pathogenesis

Superficial fungi must overcome several obstacles in order to colonize keratinized tissue. They must resist the effects of UV light, variation in temperature and moisture, competition from normal flora, and fungistatic fatty acids and sphingosines produced by keratinocytes. After adherence, spores must germinate and penetrate the stratum corneum at a rate faster than desquamation. This penetration is accomplished by the secretion of proteinases, lipases, and mucinolytic enzymes, which also provide nutrients. Trauma and maceration also facilitate penetration. New defenses emerge once the deeper layers of epidermis are reached, including competition for iron by unsaturated transferrin and possibly inhibition of fungal growth by progesterone. From this point, the degree of inflammation is highly dependent on immune system activation.

Immune detection and chemotaxis of inflammatory cells may occur through several mechanisms. Some fungi produce low-molecular-weight chemotactic factors much like those produced by bacteria. Others activate complement, creating complement-derived chemotactic factors. Keratinocytes may also induce chemotaxis by releasing IL-8 in response to antigens such as trichophytin. Accumulating neutrophils produce zinc-binding calprotectin, in addition to numerous oxidants and enzymes. Accumulating macrophages inhibit fungal growth via the free radical nitric oxide. Fungal mannans appear to counteract this response by inhibiting inflammation and phagocytosis. [7]

Type IV, or delayed-type hypersensitivity (DTH), plays a pivotal role in clearing dermatophytoses. This arm of cellular immunity is maintained by interferon-gamma secretion from type 1 T-helper lymphocytes (T_H1 cells). In patients without previous exposure to a dermatophyte, primary infection causes minimal inflammation, and a trichophytin skin test is negative. [8] The infection produces mild erythema and scale, the result of increased keratinocyte turnover. It is hypothesized that dermatophyte antigen is then processed by epidermal Langerhans cells and presented in local lymph nodes to T lymphocytes. The T lymphocytes undergo clonal proliferation and migrate to the dermis and epidermis to attack the fungus. [7] At this time, the lesion becomes abruptly inflammatory, and the epidermal barrier becomes permeable to transferrin and migrating cells. Soon the fungus is cleared and the lesion spontaneously resolves. The trichophytin skin test is now positive, and clearing of a second infection will be more rapid. Patients who display an IgE-mediated, immediate hypersensitivity (IH) reaction to the trichophytin skin test, instead of a DTH response, are prone to chronic dermatophytoses, usually with *T. rubrum*.

Atopic individuals are notoriously susceptible to chronic dermatophytosis. A likely explanation is that atopy, in which overactive type 2 T-helper lymphocytes (T_H2 cells) induce IH responses to antigen, inhibits or overpowers the ability of T_H1 cells to maintain a DTH response. [8]

Dermatophytid reactions, which occur in 4 to 5 percent of patients, are inflammatory reactions of the skin at a site distant from the primary fungal infection. [9] Unlike the primary lesion, these are KOH examination and culture negative. They may take the form of follicular papules, erythema nodosum, vesicular id of the hands and feet, erysipelas-like, erythema annulare centrifugum, or urticaria. [10], [11], [12], [13], [14] and [15] They typically occur at or slightly after the height of infection, or just after initiation of systemic antifungals, [16] and disappear with resolution of the primary lesion. Occasionally an id reaction is widespread or inflammatory enough to warrant concomitant topical or systemic corticosteroids. Although the precise mechanism is unknown, these reactions are associated with a DTH response to the trichophytin test and may involve a local DTH response to systemically absorbed fungal antigen. [9], [10]

Genetics

In households afflicted with *T. concentricum* and *T. rubrum,* relatives are more likely to be infected than conjugal partners, even with equal exposure to the fungus. Also, pedigrees from families with chronic dermatophytoses suggest an autosomal dominant pattern of susceptibility. Potential explanations for this phenomenon include genetic predisposition toward the development of IH responses and autosomal dominant differences in keratins that affect the ability of a fungus to attach to and digest the proteins. [1], [8]

DERMATOPHYTOSES

Tinea Capitis

Tinea capitis is a dermatophytosis of the scalp and associated hair. It may be caused by any pathogenic dermatophyte except *E. floccosum* and *T. concentricum*. The most common cause worldwide is *M. canis,* whereas in the United States it is *T. tonsurans*. [17]

EPIDEMIOLOGY Although the incidence of tinea capitis remains unknown, it is most commonly found in children ages 3 to 14 years; it is uncommon in adults. Transmission is increased with decreased personal hygiene, overcrowding, and low socioeconomic status. Organisms responsible for tinea capitis have been cultured from fomites such as combs, caps, pillowcases, and theater seats, to name a few. Even after shedding, hairs may harbor infectious organisms for over a year. [18] Asymptomatic carriers are common, making tinea capitis difficult to eradicate. [19]
PATHOGENESIS Ectothrix dermatophytes (Table 205-1) typically establish infection in the perifollicular stratum corneum, spreading around and into the hair shaft of mid- to late-anagen hairs before descending into the follicle to penetrate the cortex of the hair. Intrapilary hyphae then descend to the border of the keratogenous zone, where they

grow in equilibrium with the keratinization process, never entering the nucleated zone. The terminal tuft of hyphae at this border zone is termed *Adamson's fringe,* and from here the hyphae proliferate and divide into arthroconidia that reach the cortex of the hair and are transported upward on its surface. Plucked hairs will break just above the fringe, where the hair is now weakest. Microscopically, only the ectothrix arthroconidia may be visualized on plucked hairs, although intrapilary hyphae are present as well. The pathogenesis of endothrix infections is the same except that arthroconidia remain within the hair shaft, replacing the intrapilary keratin and leaving the cortex intact. As a result, the hair is very fragile and breaks at the surface of the scalp where support from the follicular wall is lost, leaving behind a tiny black dot. Thus, “black dot” tinea capitis is observed. Endothrix infections are also more chronic because of their ability to persist past the anagen phase into the telogen phase. [3], [20]

CLINICAL MANIFESTATIONS The clinical appearance of tinea capitis depends on its etiology (Table 205-3).

Inflammatory	Noninflammatory	Black Dot	Favus
M. audouinii	*M. audouinii*	*T. tonsurans*	*M. gypseum*
M. canis	*M. canis*	*T. violaceum*	*T. schoenleinii*
M. gypseum	*M. ferrugineum*		*T. violaceum*
M. nanum	*T. tonsurans*		
T. mentagrophytes			
T. schoenleinii			
T. tonsurans			
T. verrucosum			

*Note that a single organism may have more than one presentation.

TABLE 205-3 **Organisms Associated with Clinical Types of Tinea Capitis***

Noninflammatory, human, or epidemic type This pattern is seen most commonly with the anthropophilic ectothrix organisms *M. audouinii* or *M. ferrugineum*. The lesion begins as a small erythematous papule surrounding a single hair shaft and spreads centrifugally, encompassing nearby hairs. Scaling is usually present, but inflammation is minimal. Hairs in the affected area turn gray and lusterless secondary to their sheath of arthroconidia, and break off just above the level of the scalp (Fig. 205-6). These lesions frequently appear as one or more well-demarcated patches on the occiput or posterior neck. [18]

FIGURE 205-6 Tinea capitis caused by *M. audouinii*.

Inflammatory type This pattern is usually seen with zoophilic or geophilic pathogens, the most common examples being *M. canis* and *M. gypseum,* respectively. The spectrum of inflammation ranges from a pustular folliculitis to kerion (Fig. 205-7), which is a boggy mass studded with broken hairs and follicular orifices oozing with pus. [21] Such inflammation often results in scarring alopecia. Inflammatory lesions are usually pruritic, and may be associated with pain, cervical lymphadenopathy, fever, and additional lesions on glabrous skin.

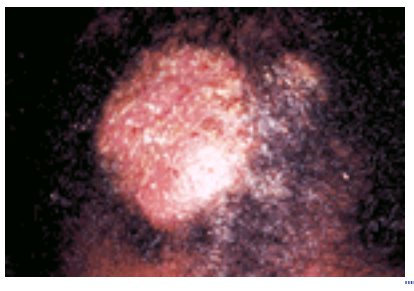

FIGURE 205-7 Kerion of the scalp.

“Black dot” tinea capitis This form of tinea capitis is caused by the anthropophilic endothrix organisms *T. tonsurans* or *T. violaceum*. Hair loss may or may not occur. When it does, hairs broken at the level of the scalp leave behind grouped black dots (Fig. 205-8). Diffuse scaling is again usually present, but inflammation varies from minimal to pustular folliculitis or furuncle-like lesions to kerion. [21] Affected areas are usually multiple or polygonal with poorly demarcated, finger-like margins. Normal hairs commonly remain within patches of alopecia.

FIGURE 205-8 “Black dot” tinea capitis caused by *T. tonsurans*.

PATHOLOGY In tinea capitis, methenamine silver and PAS stains reveal hyphae around and within the hair shaft. The dermis demonstrates a perifollicular infiltrate of mixed lymphocytes, histiocytes, plasma cells, and eosinophils. Follicular disruption leads to an adjacent foreign-body giant cell reaction. Markedly inflammatory lesions such as a kerion demonstrate a more intense infiltrate of polymorphonuclear leukocyte abscesses within the dermis and follicle. [22] Organisms are difficult to visualize, but fungal antigens are detectable with immunofluorescent techniques. [23]

DIFFERENTIAL DIAGNOSIS The differential diagnosis of minimally inflammatory, scaly tinea capitis includes seborrheic dermatitis, atopic dermatitis, and psoriasis. Pronounced alopecia invites the consideration of alopecia areata, trichotillomania, secondary syphilis, and pseudopelade. The hairs of tinea capitis do not display the exclamation point morphology typical of alopecia areata or the artifactual-appearing hairs of different lengths seen with trichotillomania. Inflammatory tinea capitis must be differentiated from the bacterial pyodermas, folliculitis decalvans, and perifolliculitis

capitis abscedens et suffodiens. The differential diagnosis of scarring alopecia also includes discoid lupus erythematosus, lichen planopilaris, pseudopelade, and radiation dermatitis.

TREATMENT Systemic antifungals are necessary for clearance of tinea capitis as they penetrate the hair follicle. Oral griseofulvin has been the gold standard of therapy for the past 40 years, but is being increasingly challenged by simpler regimens of the oral triazole and allylamine antifungals. Because of shorter track records, these alternatives are currently reserved for patients intolerant or unresponsive to griseofulvin.

Griseofulvin The usual dose of griseofulvin is 1 g/day of the microcrystalline form or 0.5 g/day of the ultramicrosize version. The pediatric dosage is 10 to 20 mg/kg per day of the ultramicrosize form taken with a fatty meal to facilitate absorption. [18] Treatment is continued until clinical and mycologic cure is documented, which usually takes 6 to 8 weeks. The dose may be increased to 20 to 25 mg/kg per day for refractory infections. The disadvantages of griseofulvin include poor compliance because of cost, length of treatment, its bitter taste in liquid form, photosensitivity, and gastrointestinal side effects. [17] It also potently induces cytochrome P450 enzymes. [24]

Fluconazole Available as both tablets and a pleasant-tasting liquid, fluconazole at doses of 6 mg/kg per day for 20 days is 89 percent effective in curing *T. tonsurans* tinea capitis. [25] Another effective treatment option appears to be once-weekly dosing of 8 mg/kg fluconazole for 8 to 16 weeks. [26] Absorption of fluconazole is not affected by meals, and gastrointestinal side effects are uncommon. Hepatitis has been reported, but occurs less frequently than with ketoconazole. [24]

Itraconazole At doses of 3 to 5 mg/kg per day, itraconazole effectively eradicates tinea capitis caused by either *Microsporum* or *Trichophyton* species in 4 to 6 weeks. [27], [28] Possible adverse effects of itraconazole include gastrointestinal upset, diarrhea with liquid itraconazole, and peripheral edema, especially when used in conjunction with calcium channel blockers. Like fluconazole, hepatotoxicity occurs at much lower rates than with ketoconazole. [24] Routine monitoring of hematologic and hepatic function is only necessary for therapy continuing beyond 4 weeks.

Terbinafine Doses of 3 to 6 mg/kg per day of terbinafine can cure *Trichophyton* tinea capitis in 2 to 4 weeks, but requires 4 to 8 weeks for treatment of *Microsporum*. [17] A recent randomized comparison of 4 weeks of terbinafine to 8 weeks of griseofulvin showed no statistically significant difference overall. However, a subgroup with *Trichophyton* infection responded better to terbinafine, while *M. audouinii* infections responded better to griseofulvin. [29] Terbinafine also produces gastrointestinal side effects and rare hepatitis. Although it has fewer cytochrome P450 effects than the other oral antifungals, tricyclic antidepressant toxicity has occurred with concomitant terbinafine use as a result of CYP2D6 inhibition. [24] Hepatic function and a complete blood count need only be monitored for therapy extending beyond 6 weeks. [17]

Adjuvant therapy With markedly inflammatory tinea capitis, oral glucocorticoids may reduce the incidence of scarring. Though there is no evidence for differences in cure rates, oral glucocorticoids are beneficial in relieving pain and swelling. The usual dose of prednisone is 1 mg/kg each morning for the first 10 to 15 days of therapy. Household transmission may be prevented through the treatment of infected family members or animals and disinfection of the environment. The use of ketoconazole 2% shampoo or selenium sulfide 2.5% by all household members three times weekly also reduces transmission by decreasing the shedding of spores. [17] Children may attend school during treatment. [30]

Tinea Favosa

Tinea favosa or favus (Latin, “honeycomb”) is a chronic dermatophyte infection of the scalp, glabrous skin, and/or nails characterized by thick yellow crusts (scutula) within the hair follicles which lead to scarring alopecia.

EPIDEMIOLOGY Favus is usually acquired before adolescence and extends into adulthood. [31] Associated with malnutrition and poor hygiene, it has become geographically limited in the past century, as it is now seen almost exclusively in Africa, the Middle East, and parts of South America. [32] Even in these regions, its incidence is dramatically declining. [33]

ETIOLOGY *T. schoenleinii* is the most common cause of human favus, with *T. violaceum* and *M. gypseum* occurring as rare isolates. [32] Although favus occurs in poultry, mice, and horses, there is only a single case report of human favus caused by an organism responsible for animal favus. [34]

CLINICAL MANIFESTATIONS Early favus (usually the first 3 weeks of infection) is characterized by patchy follicular erythema of the scalp with slight perifollicular scaling and mild matting of the hair. Progressive hyphal invasion distends the follicle, first producing a yellowish-red papule, then a yellow concave crust often centered about a single dull, dry hair (Fig. 205-9) that is less brittle than that of endothrix infections. The scutulum may reach 1 cm in diameter, engulfing surrounding hairs and coalescing with other scutula to form large adherent mats with an unpleasant cheese-like or musky odor. Over several years the lesions advance peripherally, leaving central, atrophic clearings of alopecia. [32] Atypical presentations occur in infected individuals with relatively good hygiene, and may include diffuse scaling with small or absent scutula. [35] Glabrous skin involvement may be papular, papulosquamous, or vesicular, with or without scutula. *T. schoenleinii* nail invasion is indistinguishable from other causes of onychomycosis.

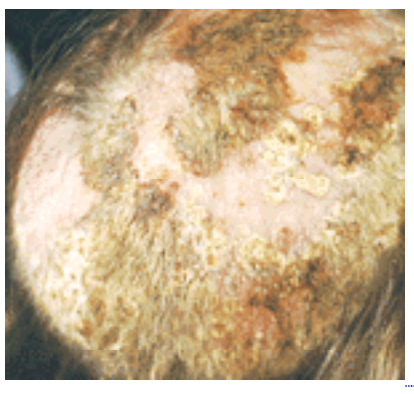

FIGURE 205-9 Favus caused by *T. schoenleinii.* Note the numerous yellow scutula.

LABORATORY FINDINGS *T. schoenleinii* exhibits subtle grayish green fluorescence along the entire hair with Wood lamp examination. Microscopy with KOH preparation reveals hyphae arranged lengthwise around and within the hair

shaft, rare arthroconidia, and vacant air spaces (Fig. 205-3). [32]
PATHOLOGY Hyphae are present in the stratum corneum, inside scutula, and inside and around hairs. The scutula also contain sebum and keratinaceous debris, and lie atop an atrophic epidermis. Acanthosis is often present near the margins of the lesion. In the dermis, particularly beneath scutula, are plasma cell or granulomatous perifollicular infiltrates. Advanced disease may exhibit fibrosis with diminished infiltrates. [36]
DIFFERENTIAL DIAGNOSIS Atypical and early favus may be difficult to distinguish from seborrheic dermatitis, psoriasis, or tinea amiantacea. With the development of cicatricial alopecia, favus must be differentiated from radiation or chemical injury, pseudopelade, folliculitis decalvans, lupus erythematosus, and lichen planopilaris.
TREATMENT Griseofulvin (1 g/day of the microcrystalline form or 0.5 g/day of the ultramicrosize version) is effective in the treatment of favus. Concomitant nail infection, however, requires 6 to 12 months of therapy. Also beneficial are local débridement of crust, improved hygiene, and simultaneous treatment of infected family members. [32] Finally, because epilated hairs may carry viable *T. schoenleinii* for years, their removal from the environment is imperative for controlling transmission. [37]

Tinea Barbae

Tinea barbae (tinea sycosis, barber's itch) is a dermatophytosis of the facial terminal hair of men. Dermatophytosis of the same area in females or prepubertal males involves glabrous skin and is termed tinea faciale.

EPIDEMIOLOGY Tinea barbae is by definition seen only in males. Largely transmitted by contaminated barbers' razors in the past, improved sanitation has reduced its incidence. As a result, tinea barbae is now often contracted by direct exposure to cattle, horses, or dogs, and is thus most commonly seen in rural settings on farmers or ranchers.
ETIOLOGY Tinea barbae is most commonly caused by the zoophilic organisms *T. mentagrophytes* and *T. verrucosum,* and, uncommonly, *M. canis*. Among the anthropophilic organisms, *T. megninii, T. schoenleinii,* and *T. violaceum* may cause tinea barbae in endemic areas, while *T. rubrum* is an infrequent cause. [32]
CLINICAL MANIFESTATIONS Tinea barbae is typically unilateral and more often involves the beard area than the moustache or upper lip. Three forms exist: (1) inflammatory or kerion-like, (2) superficial or sycosiform type, and (3) the circinate, spreading type.
Inflammatory type Usually caused by *T. mentagrophytes* and *T. verrucosum,* inflammatory tinea barbae (Fig. 205-10A) is analogous to kerion formation in tinea capitis. The lesions are nodular and boggy with a crusting seropurulent discharge. [38] Hairs in this area are lusterless, brittle, and easily epilated to demonstrate a purulent mass about the root. Perifollicular pustulation may coalesce to form sinus tracts and abscess-like collections of pus, eventuating in a scarring alopecia. [32]

FIGURE 205-10 *A*. Tinea barbae, kerion. Sharply demarcated red nodule studded with multiple yellowish pustules. The surface is edematous and weeping. *B*. Superficial tinea barbae. Diffuse erythema with scattered follicular papules and pustules.

Superficial type Caused by the less inflammatory anthropophiles, this form of tinea barbae closely resembles bacterial folliculitis, with diffuse erythema and perifollicular papules and pustules (Fig. 205-10B). Hairs that are dull and brittle make endothrix infection with *T. violaceum* a more likely etiology than *T. rubrum*.
Circinate type Much like tinea circinata of glabrous skin, circinate tinea barbae exhibits an active, spreading vesiculopustular border with central scaling and relative sparing of the hair. [38]
PATHOLOGY Histopathologic findings are similar to those seen with tinea capitis. Fungi may be demonstrated in both the hair and stratum corneum, but not in the dermis. A chronic inflammatory response is seen perifollicularly, often with a neutrophilic infiltrate within the follicle. Extremely inflammatory lesions reveal minimal to no fungi. [22]
DIFFERENTIAL DIAGNOSIS Other diagnoses to consider with tinea barbae include bacterial folliculitis (sycosis vulgaris), perioral dermatitis, candidal folliculitis, pseudofolliculitis barbae, acneiform dermatitis, contact dermatitis, halogenoderma, and herpes simplex. Bacterial folliculitis is more often bilateral, more painful, and more commonly involves the upper lip. [32] History, patch testing, Tzanck smears, or viral cultures can identify the other diagnoses.
TREATMENT Microsize griseofulvin at 1g daily until 2 to 3 weeks after clinical resolution is recommended for tinea barbae, particularly chronic cases. However, inflammatory *T. verrucosum, T. mentagrophytes,* and *M. canis* infections usually resolve without treatment in 2 to 4 weeks. [32] Adjunct measures include topical antifungals, warm compresses, shaving, and débridement of crusted discharge. Systemic glucocorticoids are helpful for symptoms of severe inflammatory lesions. [38] No data beyond case reports exist for the other systemic antifungals.

Tinea Corporis (Tinea Circinata)

Tinea corporis refers to all dermatophytoses of glabrous skin except the palms, soles, and groin.

EPIDEMIOLOGY Tinea corporis may be transmitted directly from infected humans or animals, via fomites, or via autoinoculation from reservoirs such as *T. rubrum* colonization of the feet. [1] Children are more likely to contract zoophilic pathogens, especially *M. canis* from dogs or cats. Occlusive clothing and a warm, humid climate are associated with more frequent and severe eruptions. [39] The occlusive clothing, frequent skin-to-skin contact, and minor trauma (mat burns) of competitive wrestling create an environment in which dermatophytes flourish. Numerous outbreaks of "tinea corporis gladiatorum" have resulted, mostly caused by *T. tonsurans*. [40] Preliminary evidence suggests a high prevalence of disease even in the absence of an epidemic. [41] Tinea imbricata, caused by *T. concentricum,* is largely limited to areas of the Far East, South Pacific, and South and Central America, and is more prevalent in natives than resident nonnatives. Explanations for this observation include the necessity to acquire chronic infection in early childhood [42] and genetic susceptibility (see above).

ETIOLOGY Although any dermatophyte can cause tinea corporis, the most common causes are *T. mentagrophytes, T. rubrum,* and *M. canis.* [4] *T. rubrum* and *T. verrucosum* are the most likely candidates in cases with additional follicular involvement. [38]

CLINICAL MANIFESTATIONS Table 205-4 presents the many variants of tinea corporis. The classic presentation is an annular lesion with scale across the entire erythematous border. The border is often vesicular (Fig. 205-11) and advances centrifugally. The center of the lesion is usually scaly, but may exhibit clearing. Concentric vesicular rings suggest tinea incognito caused by *T. rubrum,* whereas the concentric rings of tinea imbricata demonstrate little to no vesiculation. [1] *T. rubrum* infections may also present as large, confluent polycyclic or psoriasiform plaques (Fig. 205-12).

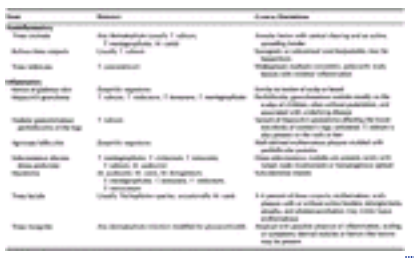

TABLE 205-4 **Variants of Tinea Corporis**

FIGURE 205-11 Tinea corporis with typical "ringworm-like" configuration.

FIGURE 205-12 Polycyclic pattern of tinea corporis.

LABORATORY FINDINGS Any erythematous, scaly eruption should be scraped for KOH examination. Obtaining scales by scraping outward from the active border maximizes sensitivity, while vesicles and bullae harbor the most organisms in their roofs. Because of the high rate of false-negative KOH preparations, fungal culture of scrapings is often necessary for diagnosis. However, in cases with dermal granulomata, culturing biopsy material produces the highest yield.

PATHOLOGY PAS stains of typical tinea circinata reveal red hyphae within the stratum corneum (Fig. 205-13). Hyphae are basophilic with hematoxylin and eosin, and stain black with methenamine silver. If organisms are absent, the histopathology is nonspecific and resembles an acute or chronic dermatitis with or without spongiotic vesiculation. The nodular perifolliculitis variant, caused by *T. rubrum,* displays a perifollicular granulomatous reaction commonly accompanied by central necrosis and suppuration. Organisms are present in the hairs and dermis, and large spores (6 µm) may be found within multinucleated giant cells. [22]

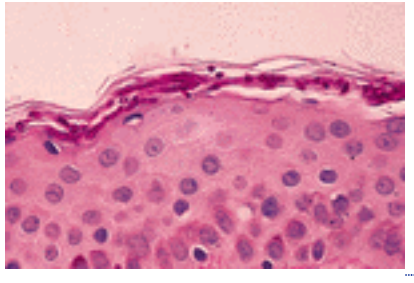

FIGURE 205-13 PAS stain of dermatophyte in stratum corneum. (*Courtesy of Sonia Toussaint, MD.*)

DIFFERENTIAL DIAGNOSIS The differential diagnosis of annular tinea corporis includes erythema annulare centrifugum, nummular eczema, and granuloma annulare. Erythema annulare centrifugum is distinguished by scale at the

trailing edge of the advancing border instead of over the entire border. Nummular eczema tends to produce more numerous and symmetric lesions than tinea corporis, and lacks central clearing. Granuloma annulare consists of intradermal papules without scale. A papulosquamous lesion of tinea corporis may resemble psoriasis, lichen planus, secondary syphilis, seborrheic dermatitis, pityriasis rosea, or pityriasis rubra pilaris. These are usually readily differentiated by their unique clinical features, otherwise a biopsy is diagnostic. Tinea faciei often lacks a distinct raised scaly border, and may mimic a photodermatosis such as lupus erythematosus or dermatomyositis. [43] However, most tinea faciei lack the follicular plugging and poikiloderma of connective tissue diseases. Other photodermatoses to consider include polymorphous light eruption, contact dermatitis, and acne rosacea. For inflammatory variants of tinea corporis, other infectious processes such as bacterial, candidal, or deep fungal infections should be considered. Verrucous and granulomatous lesions can resemble mycobacterial infections or blastomycosis.
TREATMENT For isolated lesions of tinea corporis, topical agents such as the allylamines, imidazoles, tolnaftate, butenafine, or ciclopirox are effective. Most are applied twice daily for 2 to 4 weeks. Oral antifungals are reserved for widespread or more inflammatory lesions. Comparative studies in adults show fluconazole 150 mg weekly for 4 to 6 weeks, itraconazole 100 mg daily for 15 days, and terbinafine 250 mg daily for 2 weeks to be as effective as griseofulvin 500 mg daily for 2 to 6 weeks, with no significant differences in adverse events. [44] Safe and effective regimens for children include ultramicrosize griseofulvin 10 to 20 mg/kg per day for up to 6 weeks, itraconazole 5 mg/kg per day for 1 week, [45] and terbinafine 3 to 6 mg/kg daily for 2 weeks.

Tinea Cruris

Tinea cruris is a dermatophytosis of the groin, genitalia, pubic area, perineal, and perianal skin.

EPIDEMIOLOGY Much like tinea corporis, tinea cruris spreads via direct contact or fomites, and is exacerbated by occlusion and warm, moist climates. Again, autoinfection from distant reservoirs such as tinea pedis caused by *T. rubrum* or *T. mentagrophytes* is common. [1]
ETIOLOGY Most tinea cruris is caused by *T. rubrum, T. mentagrophytes,* and *E. floccosum,* with the latter being most often responsible for epidemics. [32]
CLINICAL MANIFESTATIONS Tinea cruris usually appears as multiple erythematous papulovesicles with a well-marginated, raised border. Pruritus is common, as is pain with maceration or secondary infection. *E. floccosum* tinea cruris is more likely to display central clearing, and is most often limited to the genitocrural crease and the medial upper thigh. In contrast, *T. rubrum* infections are often coalescent with extension to the pubic, perianal, buttock and lower abdominal areas (Fig. 205-14). The genitalia are typically unaffected. [32] Common secondary changes include lichenification caused by chronic scratching or weeping, maceration, and pustulation caused by bacterial superinfection. Finally, many topical treatments may complicate the presentation by causing an allergic or irritant contact dermatitis.

FIGURE 205-14 Tinea cruris. Scaling erythematous plaque with sharp margins.

LABORATORY FINDINGS KOH examination of infected scales reveals septate hyphae. Culture on SDA with antibiotics and incubation at room temperature will reveal growth within 2 to 4 weeks.
PATHOLOGY The histologic findings are identical to those of tinea corporis.
DIFFERENTIAL DIAGNOSIS Similar-appearing diseases with crural involvement include psoriasis, seborrheic dermatitis, candidiasis, erythrasma, lichen simplex chronicus, familial benign pemphigus, and Darier-White disease. Candidiasis displays satellite pustules, peripheral to brightly erythematous plaques and it more often involves the scrotum. Erythrasma fluoresces coral red under Wood lamp, unlike tinea cruris. If KOH and fungal culture are unrevealing, biopsy may be necessary to exclude the other diagnoses.
TREATMENT Most tinea cruris is successfully treated with the topical antifungals used for tinea corporis, preferably as a powder or cream. Minimizing occlusion and moisture in the area are also helpful. As with tinea corporis, oral antifungals are reserved for refractory, widespread, or more inflammatory lesions. Safe and effective treatment for adults includes fluconazole 150 mg weekly for 4 to 6 weeks, itraconazole 100 mg daily for 15 days, terbinafine 250 mg daily for 2 weeks, and griseofulvin 500 mg daily for 2 to 6 weeks. [44] Safe and effective regimens for children include ultramicrosized griseofulvin, 10 to 20 mg/kg per day for up to 6 weeks, itraconazole, 5 mg/kg per day for 1 week, [45] and terbinafine, 3 to 6 mg/kg per day for 2 weeks.

Tinea Pedis and Tinea Mannum

Tinea pedis is a dermatophytosis of the feet, whereas tinea manuum affects the palmar and interdigital areas of the hand.

EPIDEMIOLOGY Present worldwide, tinea pedis and tinea manuum are the most common dermatophytoses. Tinea pedis has risen from obscurity prior to the twentieth century to a prevalence of approximately 10 percent today primarily as a result of modern occlusive footwear, although increased worldwide travel has also been implicated. [32] The incidence of tinea pedis is higher among those using communal baths, showers, or pools. Whether this is caused by increased maceration or increased transmission remains unclear. [46] Tinea manuum may be acquired by direct contact with an infected person or animal, the soil, or autoinoculation from a distant site. [47] However, it is nearly always associated with tinea pedis [32] and has been shown to occur most commonly following tinea pedis in the hand used to excoriate the feet. [48] Manual labor and preexisting inflammatory conditions of the hand are additional risk factors. [47] Both tinea pedis and tinea

manuum are exacerbated by hyperhidrosis, tropical climates, and any anatomic abnormality leading to closed web spaces.

ETIOLOGY Tinea pedis and tinea manuum are caused predominantly by *T. rubrum, T. mentagrophytes* var. *interdigitale,* and *E. floccosum*.

CLINICAL MANIFESTATIONS Tinea pedis may present as any of four forms, or a combination thereof.

Chronic intertriginous type The most common presentation of tinea pedis, the chronic intertriginous type, begins as scaling, erosion, and erythema of the interdigital and subdigital skin of the feet, particularly between the lateral three toes. Under appropriate conditions, the infection will spread to the adjacent sole or instep, rarely involving the dorsum. [32] This pattern is produced by fungal infection alone and has been termed *dermatophytosis simplex*. Occlusion and bacterial coinfection soon produce the interdigital maceration, pruritus, and malodor of *dermatophytosis complex* (Fig. 205-15), or “athlete's foot.” [49]

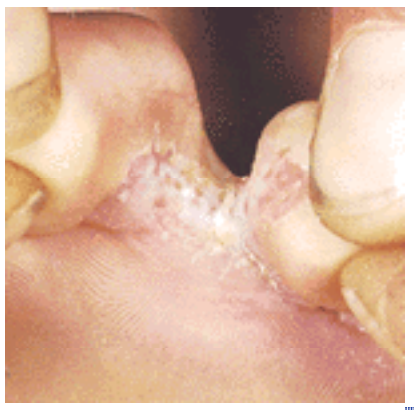

FIGURE 205-15 Tinea pedis, interdigital. The area is macerated and has opaque white scales and some erosions.

Chronic hyperkeratotic type Usually bilateral with patchy or diffuse scaling limited to the thick skin of the feet, this is also known as “moccasin-type” tinea pedis (Fig. 205-16). *T. rubrum,* the most common etiology, produces very few minute vesicles, leaving collarettes of scale less than 2 mm in diameter. Erythema is variable. [1] Unilateral tinea manuum commonly occurs in association with hyperkeratotic tinea pedis, resulting in the “two feet–one hand syndrome” (Fig. 205-17). Oral antifungals are often required for treatment due to the high incidence of concomitant onychomycosis and relapse. [50]

FIGURE 205-16 Tinea pedis. Superficial white scales in a moccasin-type distribution. Note arciform pattern of the scales, which is characteristic.

FIGURE 205-17 “One hand, two feet” presentation of *T. rubrum*.

Vesiculobullous type This form, typically caused by *T. mentagrophytes* var. *interdigitale,* features tense vesicles greater than 3 mm in diameter, vesiculopustules, or bullae on the thin skin of the sole and periplantar areas. Remissions and relapses occur with fluctuations in exposure of the feet to heat and humidity.

Acute ulcerative type Rampant bacterial coinfection, most often from gram-negatives in combination with *T. mentagrophytes* var. *interdigitale,* produces vesiculopustules and large areas of purulent ulceration on the plantar surface. Cellulitis, lymphangiitis, lymphadenopathy, and fever are frequently associated. The vesiculobullous and acute ulcerative types commonly produce a vesicular id reaction, either as a dyshydrotic-like distribution on the hands or on the lateral foot or toes. The vesicles are by definition KOH and culture negative. Tinea manuum (Fig. 205-18) predominantly presents as the hyperkeratotic type, although crescentic, exfoliating, vesicular, folliculopapular, and dorsal erythematous forms are also described. [32]

FIGURE 205-18 Tinea manus. Polycyclic pattern of an eruption composed of scaling vesicles with involvement of the thumb nail; the nail exhibits destruction of the nail plate.

LABORATORY FINDINGS KOH examination of scales reveals septate, branching hyphae. For vesiculobullous lesions, examination of the roofs yields the highest rate of positivity. Fungal cultures should be performed on SDA with cycloheximide and chloramphenicol.
PATHOLOGY Histologically, hyperkeratotic tinea pedis or tinea manuum is characterized by acanthosis, hyperkeratosis, and a sparse, chronic superficial perivascular infiltrate in the dermis. Vesiculobullous forms display spongiosis, parakeratosis, and subcorneal or spongiotic intraepithelial vesiculation. With both types, foci of neutrophils are occasionally seen in the stratum corneum, as well as fungal organisms with PAS or methenamine silver staining.
DIFFERENTIAL DIAGNOSIS If KOH examination and fungal culture are negative, other considerations for interdigital disease include psoriasis, soft corns, bacterial coinfection, candidiasis, and erythrasma. The likelihood of candidal and bacterial infection increases with the severity of maceration, denudation, and pruritus. [51] Unlike tinea pedis, erythrasma fluoresces coral red under a Wood lamp. The hyperkeratotic type must be differentiated from psoriasis, hereditary or acquired keratodermas of the palms and soles, dyshydrosis, pityriasis rubra pilaris, and Reiter's syndrome. Contact dermatitis may also be considered, although it more commonly affects the dorsal foot than tinea pedis. Children are more likely to have peridigital dermatitis or atopic dermatitis. Vesiculobullous or vesiculopustular presentations may be confused with pustular psoriasis, palmoplantar pustulosis, and bacterial pyodermas.
PREVENTION AND TREATMENT Minimizing chronic moisture is important in preventing tinea pedis. This may be achieved through talcum powder, absorbent socks, nonocclusive shoes, and, occasionally, 20 to 25% aluminum chloride hexahydrate powder. Antifungal powders such as undecylenic acid and tolnaftate are also beneficial. [38] Mild interdigital tinea pedis without bacterial involvement can be treated topically with an allylamine, azole, ciclopirox, tolnaftate, or undecenoic acid. [52] Topical terbinafine for 1 week is 66 percent effective, [53] while the other topicals generally require 4 to 6 weeks of application. The newer oral antifungals have replaced griseofulvin as the treatments of choice for severe or refractory tinea pedis. The dosing schedule of terbinafine is 250 mg daily for 2 weeks. Effective regimens of itraconazole for adults are 200 mg twice daily for 1 week, 200 mg daily for 3 weeks, or 100 mg daily for 4 weeks, [44] while children should receive 5 mg/kg per day for 2 weeks. [45] Fluconazole 150 mg weekly for 3 to 4 weeks or 50 mg daily for 30 days is also effective. [44] Associated onychomycosis is common; if present, treatment of the onychomycosis is necessary to prevent recurrence of tinea pedis. Maceration, denudation, pruritus, and malodor obligate a search for bacterial coinfection by Gram stain and culture. Antibiotics should be started once bacterial infection is documented and chosen based on sensitivity studies. Adjunctive topical therapy such as 0.25% acetic acid for *Pseudomonas* and colorless Castellani's paint are also helpful. Finally, because vesiculobullous tinea pedis is the result of a T cell–mediated immune reaction, symptomatic relief with topical or systemic corticosteroids may be warranted during the beginning of antifungal treatment. [54]

ONYCHOMYCOSIS

Onychomycosis denotes any infection of the nail caused by dermatophyte fungi, nondermatophyte fungi, or yeasts. Tinea unguium, however, refers strictly to dermatophyte infection of the nail plate. The four clinical types of onychomycosis are: (1) distal subungual onychomycosis (DSO), (2) proximal subungual onychomycosis (PSO), (3) white superficial onychomycosis (WSO), and (4) candidal onychomycosis.

Epidemiology

Onychomycosis is a common infection, with a prevalence estimated at 2 to 18 percent worldwide and up to 48 percent incidence by age 70. [55] Higher rates of onychomycosis are associated with male gender, age, smoking, and peripheral arterial disease. [56] Finally, 30 percent of patients with dermatophytoses elsewhere also have tinea unguium. The dermatophytosis commonly begins as tinea pedis before extending to the nail bed, where eradication is more difficult. This site then serves as a reservoir for recurrent distal infections, particularly in the setting of a hot and humid environment created by occlusion or tropical climates. [1]

Etiology and Pathogenesis

The dermatophytes, especially *T. rubrum, T. mentagrophytes* var. *interdigitale, T. tonsurans,* and *E. floccosum,* cause the great majority of onychomycosis. Table 205-5 categorizes the most likely causative dermatophytes according to patterns of concurrent infection in other areas. [57]

Tinea unguium + tinea pedis and/or tinea corporis
T. rubrum
T. mentagrophytes var. *interdigitale*
E. floccosum
Tinea unguium + tinea capitis or favus
T. tonsurans
T. violaceum
T. megninii
T. schoenleinii
Tinea unguium + tinea imbricata
T. concentricum

TABLE 205-5 **Causative Organisms According to Anatomic Patterns of Infection**

Yeasts are the source of approximately 5 percent of onychomycosis, the majority of which is caused by *Candida albicans* and occurs in conjunction with chronic mucocutaneous candidiasis. The nondermatophyte molds *Acremonium, Aspergillus, Fusarium, Onychocola canadensis, Scopulariopsis brevicaulis,* and *Scytalidium dimidiatum* account for approximately 4 percent of onychomycosis. [55] The nondermatophyte molds appear to have a predilection for antecedently diseased or aged nails (Fig. 205-19). [38]

FIGURE 205-19 Onychomycosis can be caused by nondermatophyte fungi such as *Aspergillus niger*.

DSO may be caused by any of the organisms listed above, beginning with invasion of the stratum corneum of the hyponychium and distal nail bed. The infection then spreads proximally up the nail bed to the ventral nail plate. Hyperproliferation of the nail bed in response to the infection creates subungual hyperkeratosis, and progressive invasion of the nail plate results in an increasingly dystrophic nail. PSO results primarily from *T. rubrum* and *T. megninii* infection of the proximal nail fold, which then spreads to the proximal ventral nail plate. [58] *T. rubrum* causes PSO almost exclusively in those infected with HIV. [6] WSO is a direct invasion of the dorsal nail plate. Seen only on toenails, it is usually caused by *T. mentagrophytes,* although nondermatophyte molds such as *Aspergillus, Scopulariopsis,* and *Fusarium* are also known etiologies. *Candida* species invade via the hyponychial epithelium to affect the entire thickness of the nail plate. [58]

Clinical Manifestations

DSO (Fig. 205-20), the most common form, begins as a whitish to brownish-yellow opacification at the distal edge of the nail or near the lateral nail fold. As the infection progresses, subungual hyperkeratosis leads to onycholysis. Increasing invasion of the ventral nail plate makes it thick, discolored, and friable. The subungual debris also provides a site for secondary infection by bacteria, other molds, and yeasts.

FIGURE 205-20 Distal subungual onychomycosis.

Early PSO (Fig. 205-21) is evident as a white to beige opacity on the proximal nail plate that may gradually enlarge to affect the entire nail. WSO (Fig. 205-22) is recognized as white to dull yellow sharply bordered patches anywhere on the surface of the toenail. The affected areas are rough and friable, and may coalesce with time. Candidal onychomycosis is rare, affecting either the fingernails or toenails of those with chronic mucocutaneous candidiasis. These lesions resemble DSO as the nail may be thickened, rough, and opaque or darkened. Nailbed thickening also occurs and may be severe enough to create “pseudoclubbing.” [58] In contrast to DSO, a paronychial inflammatory response is often present, and subungual debris does not accumulate. [32]

FIGURE 205-21 Proximal subungual onychomycosis in a patient with AIDS; Kaposi's sarcoma is also seen on the fourth toe.

FIGURE 205-22 White superficial onychomycosis.

Laboratory Findings

Because onychomycosis is responsible for only 50 percent of dystrophic nails, laboratory diagnostic confirmation is often helpful prior to treatment with an oral antifungal. KOH examination, nail biopsy, and fungal culture on SDA (with and without antimicrobials) are most useful. However, microscopy is often negative even when there is a high clinical suspicion of onychomycosis, and nails with positive microscopy often yield negative cultures. As most false-negatives are caused by sampling error, the simplest measures to maximize yield are to maximize sample size and perform repeat collections. [59]

Finally, because of the difficulty in discerning pathogens from contaminants, the following guidelines should be followed: (1) if a dermatophyte is isolated on culture, it is a pathogen; (2) if a nondermatophyte mold or yeast is cultured, it is considered significant only if hyphae, spores, or yeast cells are seen on microscopic examination; and (3) confirmation of an infection by a nondermatophyte requires repeated isolation, classically defined as at least 5 of 20 inocula without concurrent isolation of a dermatophyte. [60]

Pathology

Hyphae are seen lying between the nail laminae parallel to the surface, with a predilection for the ventral nail and nail bed stratum corneum. [61] The epidermis may show spongiosis and focal parakeratosis and there is a minimal dermal inflammatory response. In WSO, the organisms are present superficially on the dorsal nail and display unique “perforating organs” and “eroding fronds.” Candidal onychomycosis displays invasion of pseudohyphae throughout the entire nail plate, adjacent cuticle, granular layer and stratum spinosum of the nail bed, and the hyponychial stratum corneum. [58]

Differential Diagnosis

A variety of disorders may cause nail changes similar to onychomycosis, including hand eczema, pachyonychia congenita, Darier's disease, Reiter's syndrome, lichen planus, exfoliative dermatitis, and Norwegian scabies. Neither the pitting produced by psoriasis nor the typically transverse ridges seen in the dystrophic nails of hand eczema are seen with fungal nail infections. Otherwise, most of the above disorders are differentiated by related skin findings and history. WSO must be distinguished from the acquired and congenital leukonychias. All leukonychia of the fingernails not WSO.

Treatment

The only effective topical agent for tinea unguium is ciclopirox (8% lacquer) applied daily for 48 weeks. When used for mild to moderate disease, it is 34 percent effective in achieving mycologic cure alone and 7 percent effective in achieving mycologic cure and clear nails. [62] Despite its poorer efficacy when compared to the newer oral antifungals, topical ciclopirox is more cost effective because of its relatively low cost. [63]

Oral antifungals may be used for refractory, severe, or nondermatophytic onychomycosis, or when a shorter treatment regimen is desired. Selecting an antifungal should be based primarily on the causative organism, potential adverse effects, and drug interactions. As potent inhibitors of cytochrome P450 3A4, the azole antifungals are contraindicated with drugs such as astemizole, terfenadine, lovastatin, simvastatin, triazolam, and midazolam. Baseline and interval testing of liver enzymes is prudent for each agent discussed below.

Terbinafine is fungicidal against dermatophytes, *Aspergillus,* and *Scopulariopsis,* but demonstrates variable activity against *Candida* species. A course of 250 mg daily for 6 weeks is effective for most fingernail infections, while a 12-week course is required for toenail infections. Most adverse effects are gastrointestinal, and cytochrome P450 interactions are

insignificant.

Itraconazole is fungistatic against dermatophytes, nondermatophyte molds, and yeasts. Safe and effective schedules include pulse dosing at 400 mg daily for 1 week per month or a continuous dose of 200 mg daily, both of which require 2 months of treatment for fingernails and 3 months for toenails. [55] Children may receive 5 mg/kg daily. [45] Elevated liver enzymes occur in 0.3 to 5 percent of patients, returning to normal within 12 weeks of discontinuation.

Fluconazole is fungistatic against dermatophytes, some nondermatophyte molds, and *Candida*. The usual dosage is 150 to 300 mg once per week for 3 to 12 months, although 450 mg weekly may be used in refractory onychomycosis. Adverse effects include gastrointestinal disturbance and elevated liver enzymes. [55]

Griseofulvin is no longer considered standard treatment for onychomycosis because of its adverse effects, drug interactions, prolonged treatment course, and low cure rates. Final options for refractory cases include surgical avulsion or chemical removal of the nail with 40% urea compounds in combination with topical or oral antifungals. [64]

TINEA NIGRA

Tinea nigra is a rare infection, usually of the palmar stratum corneum, caused by the nondermatophyte *Phaeoannellomyces werneckii* (formerly called *Exophiala werneckii*).

Epidemiology

Tinea nigra usually occurs in tropical or subtropical areas, including Central and South America, Africa, and Asia. Of the approximately 150 cases reported in North America since 1950, the majority were associated with tropical travel. [65] However, endemic foci exist in the coastal southeastern United States. Person-to-person transmission is rare. [66]

Etiology

Nearly always caused by *Phaeoannellomyces werneckii,* other dematiaceous fungi may produce the disease. *Stenella araguata,* for example, has been isolated from clinical tinea nigra. Such dematiaceous fungi are commonly found in soil, sewage, and decaying vegetation, [66] although *P. werneckii* was also recently isolated from the surfaces of rocks in the Mediterranean and Northern Europe. [67]

Clinical Manifestations

Tinea nigra presents as an asymptomatic, mottled brown to greenish-black macule with minimal to no scale (Fig. 205-23). The macule is often darkest at the advancing border. Although usually seen on the palm or ventral surface of the fingers, plantar involvement is possible.

FIGURE 205-23 Tinea nigra palmaris. An irregular, brownish-black macule on the palm caused by *P. werneckii*. (*Courtesy of Stuart Salasche, MD.*)

Laboratory Findings

KOH examination of scrapings from the lesion reveals brown to olive-colored hyphae and oval to spindle-shaped yeast cells occurring singly or in pairs with a central transverse septum. Cultures may be performed on SDA with cycloheximide and chloramphenicol. Growth is initially yeastlike and brown to shiny black, appearing as the typical two-celled yeast forms under microscopic examination. With time, mycelial growth predominates as aerial hyphae create a fuzzy grayish-black colony. Deeply pigmented, thick, septate hyphae 7 to 10 µm in diameter are seen microscopically.

Pathology

Skin biopsy shows brown, branching hyphae in the upper stratum corneum on hematoxylin and eosin stain. Hyperkeratosis is present without dermal inflammation.

Differential Diagnosis

Mistaking tinea nigra for a melanocytic lesion such as a junctional nevus or melanoma may lead to unnecessary biopsy. Pigmentation from Addison's disease, syphilis, pinta, or chemical exposure should also be considered. Tinea nigra is easily differentiated from all of these by KOH examination. *Scytalidium* may rarely produce a lesion similar to tinea nigra, but is usually associated with interdigital scaling, palmoplantar scaling, or onychomycosis. [68]

Treatment

Tinea nigra responds easily to topical therapy with a keratolytic (Whitfield's ointment, 2% salicylic acid), tincture of iodine, azole antifungal, or terbinafine. [65], [69] Treatment should be continued for 2 to 4 weeks after clinical resolution to prevent relapse. Oral agents are unnecessary and often ineffective. [66], [69]

PIEDRA

Piedra is an asymptomatic fungal infection of the hair shaft caused by *Piedraia hortae* (black piedra) and *Trichosporon beigelii* (white piedra).

Epidemiology

Black piedra is seen commonly in humans and primates of tropical areas such as South America, the Pacific Islands, and the Far East, and less commonly in Africa and Asia. Scalp hair is most commonly affected. Infestation is encouraged for religious and esthetic reasons by some indigenous cultures. [65]

White piedra is most common in the temperate climates of South America and Asia, and occurs infrequently in the United States and Europe. It affects facial, axillary, and genital hair more commonly than the scalp. [38] Person-to-person transmission is rare, and infection has not been associated with travel to endemic areas. [70] Found commonly in soil, air, and sputum, *T. beigelii* appears to be a ubiquitous fungus capable of producing white piedra only in situations of low hygiene. [65]

Clinical Manifestations

Black piedra is characterized by firmly attached, hard, brown-black nodules on the hair shaft that vary from microscopic to a few millimeters in size, and are gritty to palpation. [65] Black piedra weakens the hair shaft, often resulting in broken hairs.

White piedra consists of softer and less adherent whitish to beige nodules that may be discrete or coalesce into sleeve-like structures. Broken hairs are less common than with black piedra.

T. beigelii may also cause onychomycosis, [70] and is responsible for more than 100 cases of disseminated infection in immunocompromised hosts. [68] Cutaneous manifestations of dissemination may include erythematous or purpuric papules or papulovesicles. In these cases, *T. beigelii* may be cultured from the lesions and visualized in biopsy material. [71]

Laboratory Findings

Nodules of black piedra examined with KOH display a periphery of aligned hyphae and a well-organized center of thick-walled cells packed closely together, sometimes termed “pseudoparenchyma.” These nodules are mostly outside of the hair shaft. *P. hortae* grows well, albeit slowly, on most laboratory media. Colonies are dark-brown to black and glabrous initially, eventually developing aerial mycelia. Microscopy demonstrates septate hyphae, chlamydospores, and irregularly shaped hyphal elements. Most media result in asexual growth. The nodules of white piedra have a less organized and more intrapilar appearance than do the nodules of black piedra, with hyphae arranged perpendicularly to the hair shaft. [65] *T. beigelii* thrives on SDA without cycloheximide. Colonies are at first yeastlike and creamy, but develop radial convolutions with age. Microscopy reveals septate hyphae that easily fragment into 3 to 7 µm arthroconidia. Arthroconidia eventually become oval and exhibit budding.

Diagnosis

Microscopy immediately differentiates piedra from nits, hair casts, developmental hair shaft defects, and trichomycosis axillaris. In addition, the nodules of trichomycosis axillaris are usually smaller and may fluoresce under a Wood lamp.

Treatment

Shaving the infected hair is often curative but may be augmented by the use of a topical azole antifungal. Because of the high rate of relapse and evidence for intrafollicular organisms in white piedra, some authors suggest employing an additional systemic antifungal in this disease. [70]

CANDIDIASIS

Candidiasis (or candidosis) indicates a diverse group of infections caused by *Candida albicans* or by other members of the genus *Candida*. These organisms typically infect the skin, nails, mucous membranes, and gastrointestinal tract, but they also may infect internal organs and cause systemic disease.

Historical Aspects

Initially classified as a *Sporotrichum* by Gruby, the organism was placed in the genus *Oidium* (*O. albicans*) by Robin in 1847. Later, it was confused with *Monilia candida,* a fungus isolated from rotting vegetation. The name *Monilia* was stubbornly defended by Castellani and accounts for the term *moniliasis* being used as a synonym for candidiasis in the literature. This term is a misnomer and actually refers to the imperfect stage of certain ascomycetes; it has no relationship to the genus *Candida*. Controversy persists over the nomenclature of *Candida* infections. In the United States, *candidiasis* is the accepted term, although *candidosis* is preferred in Canada, the United Kingdom, France, and Italy.

In 1853, Robin first described systemic candidiasis, whereas cutaneous and chronic mucocutaneous candidiasis were described in 1907 and 1909, respectively. In 1877, Grawitz described the dimorphic nature of the organism. The genus *Candida* was established in 1923, and Martin subsequently classified several species of yeast within this genus. In the antibiotic era of the 1940s, candidiasis was first reported as an opportunistic infection.

Etiology

The genus *Candida* is a heterogeneous group of approximately 150 yeast species. [1] Many species of *Candida* are opportunistic human pathogens, although the majority do not infect humans. *C. albicans* is a dimorphic yeast that is responsible for 70 to 80 percent of all candidal infections, which makes it the most common cause of superficial and systemic candidiasis. [2] All species within the genus *Candida* share the ability to produce pseudomycelia, with the exception of *C. glabrata* (Fig. 206-1). *Candida* do not possess morphologic or biochemical characteristics that would classify them in the genera of imperfect yeast, nor do they produce ascospores or telospores. Other species of *Candida* produce clinical disease under certain circumstances, such as immunosuppression, prolonged hospitalization, and previous antibiotic use. [2], [3] These infections may be systemic or localized (Table 206-1). Recent epidemiologic studies indicate that the relative prevalence of *C. albicans* in clinical isolates is declining, with other species such as *C. glabrata, C. tropicalis, C. krusei,* [2] *C. dubliniensis,* [4] and *C. parapsilosis* [5] emerging as pathogens. The different species of *Candida* can be identified in the laboratory by Delft auxanography, substrate fermentation tests, and microscopic examination of yeast morphology. In addition, polymerase chain reaction (PCR) assays and other molecular techniques for species differentiation are becoming more readily available. [6]

C. parapsilosis	Paronychia, endocarditis, otitis externa, systemic disease, vaginitis
C. tropicalis	Vaginitis; intestinal, bronchopulmonary, and systemic infections; onychomycosis; bone and joint disease; central nervous system disease
C. stellatoidea	Vaginitis, systemic disease, bone and joint disease
C. guilliermondii	Endocarditis, cutaneous candidiasis, onychomycosis, bone and joint disease
C. krusei	Vaginitis, urethritis
C. glabrata	Esophagitis, vaginitis, endocarditis
C. krusei	Endocarditis, vaginitis
C. zeylanoides	Onychomycosis
C. viswanathii	Central nervous system disease
C. lusitaniae	Systemic disease
C. dubliensis	Oral candidiasis, systemic disease, joint disease

TABLE 206-1 **Candidal Isolates Other than** *C. albicans*

Pathogenesis

C. albicans is often found as a saprophyte and colonizes the mucous membranes of warm-blooded animals. In up to 50 percent of normal individuals, the oropharynx is colonized. [3] In addition, *C. albicans* exists as a commensal organism in the vaginal mucosa of 20 to 25 percent of asymptomatic, healthy women. [7] The yeast is rarely isolated from normal human skin except occasionally from intertriginous areas. Likewise, the organism is seldom found in soil, vegetation, or air samples.

Predisposing factors to *Candida* infection include local skin conditions, nutritional status, altered physiologic states, systemic illness, and iatrogenic causes, as outlined in Table 206-2.

Mechanical factors
Trauma (burns, abrasions)
Occlusion, moisture, and/or maceration
Dentures
Occlusive dressings or garments
Obesity
Nutritional factors
Anhelmintosis
Iron deficiency (chronic mucocutaneous candidiasis)
Generalized malnutrition
Physiologic alterations
Extremes of age
Pregnancy
Menses
Systemic illnesses
Down syndrome
Acrodermatitis enteropathica
Endocrine disease
Diabetes mellitus
Cushing's disease
Hypoadrenalism
Hypothyroidism
Hypoparathyroidism
Uremia
Malignancy (especially hematologic, thymoma)
Immunodeficiency
AIDS
Severe combined immunodeficiency syndrome
Myeloperoxidase deficiency
Chediak-Higashi syndrome
Hyperimmunoglobulinemia E syndrome
Chronic granulomatous disease
DiGeorge syndrome
Nezelof syndrome
Iatrogenic causes
Indwelling catheters and intravenous lines
X-irradiation
Medications
Glucocorticoids
Other immunosuppressive agents
Antibiotics (especially broad-spectrum, extremidazole)
Tranquilizers
Oral contraceptives (especially estrogen-dominant)
Colchicine
Phenylbutazone

TABLE 206-2 **Factors Predisposing to** *Candida* Infections

As a dimorphic fungus, *Candida* has the ability to transform from a budding yeast phase to an invasive mycelial growth phase, which is necessary for tissue infection. Initiation of infection is aided by adherence of the organism to epithelial cells and subsequent invasion into the tissue. [8] Tissue invasion occurs by elaboration of keratinolytic enzymes, phospholipases, or strain-specific proteolytic enzymes. Histopathologically, a clear space is seen around the organisms, suggesting an ongoing process of epithelial tissue lysis. In recent years, investigators have identified multiple virulence genes that mediate tissue adherence and invasion of *Candida* species. [8], [9]

An experimental animal model demonstrates the ability of *Candida* to cause infections of the skin and mucous membranes. [10] Using the staphylococcal toxin epidermolysin to cleave the epidermis selectively below the granular layer, Ray et al. [11] showed that only *C. albicans* and *C. stellatoidea* inoculated into this cleft were capable of invading the stratum corneum and eliciting inflammation. Other species were incapable even under occlusive experimental conditions.

Maibach and Kligman's experiments in human cutaneous candidiasis also demonstrated differences in virulence among *Candida* species. [12] These investigators noted that the cutaneous inoculation of *C. albicans* could produce disease only if the site of inoculation was occluded. Within 36 to 72 h, typical subcorneal, erythematous pustules developed. The severity of the infection was proportional to the size of the inoculum. [13] Staining showed organisms in the stratum corneum but not in the pustules. Cutaneous lesions were produced using a sterile extract of disintegrated candidal cells and a sediment of killed ruptured cells. The authors postulated the existence of an endotoxin-like substance that mediated the pustular response. [12] These experiments provided initial evidence for the host inflammatory response to

Candida infection.

Immunology

The host response to *Candida* infection includes local skin and mucosal defenses as well as the systemic immune response. Local factors include (1) integrity of the stratum corneum, (2) competing microbial flora, (3) epidermal proliferation and skin desquamation due to inflammation, and (4) direct epithelial cell inhibition of yeast growth. [14] Normal skin, with its constant sloughing and regeneration, provides an effective barrier against *Candida*. Skin-surface lipids are partially inhibitory as well. Damage to this barrier by mechanical means or occlusion facilitates infection. The host microbial flora compete with *Candida* for nutrients and epithelial adherence sites and produce by-products toxic to the yeast. As with cutaneous dermatophyte infections, the skin increases its turnover rate significantly during the early stages of infection, which helps shed the organism. [15] Recent in vitro studies have shown that vaginal [16]) and oral [14] epithelial cells inhibit the growth of *Candida,* likely by a mechanism involving direct contact between the yeast and epithelial cell membrane proteins.

The systemic immune response to *Candida* involves both humoral and cell-mediated immunity. In addition, polymorphonuclear leukocytes (PMNs) and macrophages phagocytize and kill yeast. Cell-mediated immunity contributes more to host defense against mucosal *Candida* infection than humoral immunity. [7] In mucocutaneous candidiasis and HIV infection, a defect in cell-mediated immunity may lead to extensive superficial candidiasis despite normal humoral defenses. Serum antibody production to the principal candidal cell-wall glycoprotein antigens occurs in low titers in normal individuals due to colonization of the gastrointestinal tract early in life. [17] However, patients with B cell deficiency states, such as X-linked agammaglobulinemia or severe hypogammaglobulinemia, are not at increased risk for candidal infections. [18]

Numerous immunologic defects are associated with chronic mucocutaneous candidiasis (CMC), although 25 to 35 percent of patients with CMC have no specific immunologic defect. [19] CMC usually involves abnormalities in cell-mediated immunity (CMI), whereas humoral immunity is largely intact. Table 206-3 contains a list of some of the commonly described immunologic abnormalities in patients with CMC. In some cases, the observed immunologic defect is reversed after successful antifungal therapy. This suggests that a massive antigenic load (particularly mannan) may interfere with CMI—perhaps by the generation of specific T-suppressor cells. [20]

1. Complete anergy to common skin test antigens or selective unresponsiveness to *C. albicans* antigen. This group can be further divided based on in vitro lymphocyte transformation and lymphokine production studies to Candida.
   a. Lymphocyte transformation negative and lymphokine production positive
   b. Lymphocyte transformation positive and lymphokine production negative
   c. Both lymphocyte transformation and lymphokine production negative
2. Selective IgA deficiency
3. Plasma inhibitor to lymphocyte transformation by *C. albicans*
4. Serum inhibitor of polymorphonuclear leukocyte chemotaxis and killing of *C. albicans*
5. Abnormal monocyte chemotactic and killing responses
6. Combined abnormality of monocyte mobility and phagocytosis killing
7. Abnormal complement function
8. Abnormal macrophage function
9. Hyperimmunoglobulinemia E and impaired granulocyte chemotaxis
10. Defective suppressor T cell function
11. Defective mannan handling by monocytes
12. Impaired generation of helper T cells

TABLE 206-3 **Immunologic Abnormalities in Chronic Mucocutaneous Candidiasis**

Phagocytosis of yeast organisms is accomplished primarily by PMNs and macrophages after opsonization by the classical or alternative complement pathway. [3] Patients with neutropenia or diseases affecting PMN function (see Table 206-3) are particularly susceptible to candidal infections. In addition, histologic studies show that the PMN is the predominant early inflammatory cell in candidal infections. [17]

Ray et al. [21] demonstrated that a purified mannan cell wall polysaccharide from *C. albicans* exhibits endotoxin-like activity in vitro and is capable of activating complement via the alternative pathway. The generation of factors such as C5a induces neutrophil chemotaxis. The contribution of complement activation to host defense against *Candida* has been demonstrated in rodents that have been complement-depleted (using cobra venom factor) and in hereditary C5-deficient animals. In this setting, experimentally induced candidal infections do not elicit a neutrophil response. The organism invades more rapidly and extensively in these animals than in controls. [10], [22] Both PMNs and macrophages have C3b surface receptors, and the deposition of C3b opsonins on *Candida* organisms therefore may facilitate phagocytosis. [23], [24] Macrophages also exhibit opsonin-independent phagocytosis, perhaps mediated by the mannose receptor on their cell surfaces. [18] Ultimately, PMNs and macrophages accomplish intracellular killing by both the oxidative pathway of myeloperoxide oxidase–halide–hyperoxide and nonoxidative means. [18], [25]

Clinical Manifestations

The cutaneous and mucosal manifestations of candidiasis can be divided into several distinct clinical syndromes.

ORAL CANDIDIASIS Acute pseudomembranous candidiasis or thrush is the most common form of oral candidiasis. Predisposing factors include diabetes mellitus, systemic steroids, antibiotic use, pernicious anemia, malignancies, and cell-mediated immunodeficiency [3], [27] (see Table 206-2). Up to one-third of patients infected with HIV develop oral candidiasis, and over 90 percent of patients with AIDS develop oral candidiasis over the course of their disease. [26] Oral candidiasis appears as discrete white patches that may become confluent on the buccal mucosa, tongue, palate, and gingivae (Fig. 206-2A). This friable pseudomembrane resembles milk curds and consists of desquamated epithelial cells, fungal elements, inflammatory cells, and food debris. Scraping the patches exposes a brightly erythematous

surface underneath. Microscopic examination of this material reveals masses of tangled pseudohyphae and blastospores (see Fig. 206-1). In severe cases, the mucosal surface may ulcerate. Typical oral thrush is characteristic, but the atrophic or ulcerative forms of oral candidiasis can be confused with mucositis due to chemotherapeutic drugs, herpetic infections, erythema multiforme, pemphigus, lichen planus, discoid lupus erythematosus, pernicious anemia, histoplasmosis, leukoplakia, secondary syphilis, or aspirin burn.

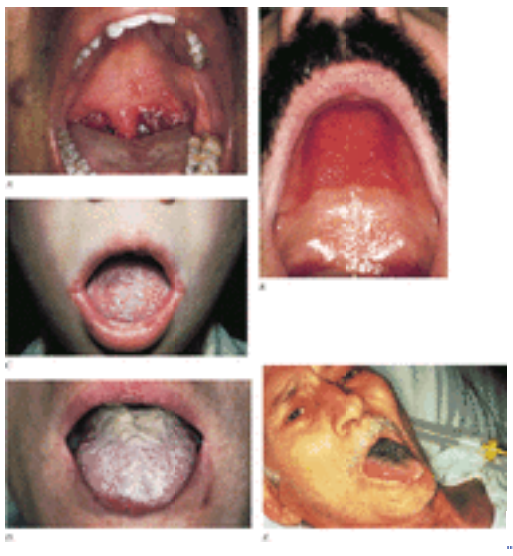

FIGURE 206-2 *A.* Pseudomembranous candidiasis or thrush. Note the characteristic white patches on the palate. *B.* Atrophic candidiasis under dentures. *C. Candida* perlèche with erythema and fissuring at the corners of the mouth. *D.* Hyperplastic candidiasis of the tongue. *E.* Black hairy tongue is characterized by pigmented hypertrophied filiform papillae of the dorsum of the tongue and is usually associated with oral antibiotic therapy.

Acute atrophic candidiasis (erythematous candidiasis) commonly occurs after sloughing of the thrush pseudomembrane. [27] This condition is associated with broad-spectrum antibiotics, glucocorticoids, and HIV. [3] The most common location is on the dorsal surface of the tongue, where there are patchy depapillated areas with minimal pseudomembrane formation. Chronic atrophic candidiasis (denture stomatitis) (see Fig. 206-2B) is a common form of oral candidiasis. Female patients are affected more commonly than males. Clinical findings of chronic erythema and edema of the palatal mucosa that contacts the dentures as well as angular cheilitis are present. Presumably, the chronic low-grade trauma and occlusion provided by dentures predispose to candidal colonization and subsequent infection. [28] Candidal cheilosis (angular cheilitis) or perlèche is characterized by erythema, fissuring, maceration, and soreness at the angles of the mouth (see Fig. 206-2C). This condition is commonly encountered in habitual lip lickers and in elderly patients with sagging skin at the oral commissures. Loss of dentition, poorly fitting dentures, malocclusion, and riboflavin deficiency may be predisposing factors. Cheilosis is often associated with chronic atrophic candidiasis due to denture wear. [27] The differential diagnosis of perlèche includes secondary syphilis, glucagonoma, or iron-deficiency states. Chronic hyperplastic candidiasis or candidal leukoplakia is characterized by adherent, firm plaques on the buccal mucosa or tongue that are translucent to white in color with surrounding erythema (see Fig. 206-2D). Conditions associated with chronic hyperplastic candidiasis include oral leukoplakia and erythroplakia, smoking, and use of dentures. This condition can be resistant to therapy. [27] Median rhomboid glossitis causes central papillary atrophy of the dorsal surface of the tongue. Lesions also may appear as exophytic, lobulated masses in the midline on the tongue. [3] Although median rhomboid glossitis once was thought to be a developmental anomaly, now *Candida* is recognized as its etiology. Black hairy tongue is associated with *C. albicans*. An alteration in normal oral flora allows overgrowth with fungi and bacteria. The filiform papillae hypertrophy, and the surface of the tongue cannot undergo normal desquamation (see Fig. 206-2E). Factors that may worsen the condition include poor oral hygiene, radiation therapy, and use of antacids. The lesion occurs at the same location as median rhomboid glossitis but also can be generalized to cover the entire dorsal surface of the tongue. Patients often complain of a tickling sensation in their mouths due to elongated papillae. Treatment consists of physical debridement and good hygiene. [29] For uncomplicated oral candidiasis, topical antifungal agents are the first line of treatment. [3] The most commonly used drugs include nystatin suspension (400,000 to 600,000 units qid) held in the mouth and then swallowed, clotrimazole troches (10 mg dissolved in the mouth five times per day), 1% to 2% gentian violet, and chlorhexidine rinse. Nystatin, while safe for long-term use, is not as effective as clotrimazole troches. If reinfection of the oral cavity occurs, systemic therapy is indicated. Fluconazole can be given as a single dose of 200 mg or as 100 mg/d for 5 to 14 days. Itraconazole (100–200 mg daily for 14 days) can be used in fluconazole-resistant patients. For denture-wearing patients with candidiasis, proper oral hygiene is an essential component of treatment. Dentures must be removed from the mouth at night and may be soaked in 0.1% hypochlorite solution to eliminate *Candida*. [3]

VAGINAL AND VULVOVAGINAL CANDIDIASIS Approximately three-quarters of all women will experience an episode of vulvovaginal candidiasis (VVC) in their lifetime. *C. albicans* causes 80 to 90 percent of VVC, and *C. glabrata* is the next most common species. [1] Risk factors for VVC include diabetes mellitus, steroid use, intrauterine devices, tight-fitting and synthetic clothing, and immunosuppression. [30] A retrospective study conducted by MacDonald et al. [31] also showed a clear relationship between the use of oral antibiotics and subsequent VVC. These factors disrupt the vaginal lactobacilli that normally inhibit overgrowth of *Candida*. [1] Patients generally present with a thick vaginal discharge associated with burning, itching, and occasional dysuria. Examination shows whitish plaques on the vaginal wall with underlying erythema and surrounding edema that can extend to the labia and perineum. Recurrent vulvovaginal candidiasis is defined as four or more episodes per year. Recurrent VVC occurs in up to 5 percent of women. [1] Changes in the hormonal environment, such as pregnancy and the luteal phase of menstruation, can induce a relapse of VVC. Use of a genital cleansing solution or douche is also associated with recurrent candidiasis. The mechanism may be an allergy or hypersensitivity response that increases susceptibility to *Candida*. Frequent sexual intercourse may predispose women to recurrent VVC. This is due to both vaginal abrasions sustained during intercourse and semen allergy. [32] Numerous vaginal and oral antifungal agents are available to treat candidal vulvovaginitis. Many surveys have demonstrated that most women prefer oral therapy. Patients with severe local symptoms may require topical or intravaginal therapy to relieve itching and burning. Some women may find increased vaginal symptoms after using a topical azole because of allergic contact dermatitis. [33] Available topical imidazoles include butaconazole, miconazole, tiaconazole, and

clotrimazole. Both creams and suppositories may be used for 3 or 7 days. [34] Terconazole 0.4% cream for 7 days, 0.8% cream for 3 days, or 80-mg suppositories for 7 days are also effective. [35] All these topical agents are safe to use during pregnancy. [33] Oral fluconazole, itraconazole, and ketoconazole offer similar efficacy to topical therapy. Ketoconazole, while effective, has the undesirable side effect of hepatotoxicity. [33] Studies have shown better compliance with fluconazole and faster recovery as compared with intravaginal clotrimazole. [36] Itraconazole is also as effective as clotrimazole. Single-dose therapies have been explored for improved convenience and compliance. Options include one 500-mg clotrimazole suppository and one 150-mg fluconazole tablet. These drugs have the ability to maintain therapeutic concentrations in the vagina for 5 days. Severe or recurrent candidal vaginitis should not be treated with single-dose therapy. Prophylactic regimens can be used to prevent recurrent VVC. A weekly application of terconazole 0.8% cream [37] or clotrimazole cream [33] has been shown to prevent recurrences. A single 150-mg dose of fluconazole each month also has been used successfully as prophylaxis [38] in women who are HIV-positive with recurrent vaginal candidiasis.

BALANITIS OR BALANOPOSTHITIS *Candida* species cause 30 to 35 percent of infectious balanitis. Factors predisposing to balanitis include candidal vaginal infection in sexual partners, diabetes mellitus, and an uncircumcised state. [39] *C. albicans* balanitis presents as small papules or fragile papulopustules on the glans or in the coronal sulcus. These break to leave superficial erythematous erosions with a collarette of whitish scale. Infection may spread to the scrotum and inguinal areas. In diabetics or immunosuppressed patients, a severe edematous, ulcerative balanitis may occur. Occasionally, patients present with a transient erythema and burning occurring shortly after intercourse. These symptoms likely represent a hypersensitivity response to candidal vaginitis in their partners. The recommended treatment for candidal balanitis is topical clotrimazole cream or a single 150-mg dose of fluconazole. [39]

CUTANEOUS CANDIDIASIS *C. albicans* has a predilection for colonizing moist, macerated folds of skin. Intertrigo is the most common clinical presentation on glabrous skin. Usual locations for intertrigo include the genitocrural, axillary, gluteal, interdigital (Fig. 206-3A), and inframammary (see Fig. 206-3B) areas and between folds of skin on the abdominal wall. Predisposing conditions include obesity, occlusive clothing, diabetes mellitus, and occupational factors. [40] Cutaneous candidiasis appears as pruritic, erythematous, macerated skin in intertriginous areas with satellite vesicopustules. These pustules break open, leaving a red, macular base with a collarette of easily detachable necrotic epidermis.

FIGURE 206-3 Candidal intertrigo. *A.* Erythematous, eroded plaques involving the scrotum and inguinal area with satellite lesions. *B.* Confluent and discrete erythematous, eroded areas with pustular and erosive satellite lesions. *C.* The infant shows red macular plaques on the vulva surrounded by a delicate collar. Outside the main lesions are a few satellite lesions. *D. Erosio interdigitalis blastomycetica.* Erythematous eroded areas between the fingers occurring in a waitress.

Cutaneous candidal infection is diagnosed by the typical appearance of skin lesions and the presence of satellite vesicopustules. The clinical diagnosis can be confirmed by KOH examination and culture of skin scrapings. Intertriginous candidiasis occasionally can be confused with tinea infections, eczema, seborrheic dermatitis, intertriginous psoriasis, erythrasma, bacterial intertrigo, familial benign pemphigus, Leiner's disease, glucagonoma, or flexural Darier's disease. Intertrigo has been treated successfully with topical antifungals. Nystatin and topical imidazole creams effectively treat cutaneous candidiasis. Nystatin and miconazole powder can dry moist intertriginous areas. Adding a topical steroid to the treatment regimen helps relieve itching, burning, and pain. [40] Several clinical variants of *Candida* intertrigo deserve special mention. Candidal diaper dermatitis is caused by yeast colonization from patients' gastrointestinal tracts. Chronic occlusion by wet diapers furthers the infection. Lesions appear first in the perianal area and spread to the perineum and inguinal creases, which show pronounced erythema [41] (see Fig. 206-3C). *Erosio interdigitalis blastomycetica* refers to interdigital candidal infection of the hands or feet and, because of anatomic considerations, usually affects the third or fourth innerspace (see Fig. 206-3D). *Candida* miliaria often affects the back in bedridden patients. Lesions start as isolated vesicopustules that contain yeast. *Candida* also can colonize and infect the skin around wounds with occlusive dressings. Broad-spectrum topical antibiotics also contribute to *Candida* wound infections. [42] Erythematous pustular folliculitis may be caused by *C. albicans*. Although the lesions are perifollicular in location, true invasion of the hair shaft is usually not observed. [43] These lesions are commonly distributed in the perioral area. A severe form of *C. albicans* folliculitis resembling pyoderma faciale has been described in the perioral area. [44], [45] Candidal paronychia is common in individuals whose hands are chronically involved in wet work (e.g., housekeepers, bakers, fishermen, bartenders). Typically there is redness, swelling, and tenderness of the paronychial area with prominent retraction of the cuticle toward the proximal nail fold (Fig. 206-4). Occasionally, pus can be expressed. Secondary nail changes include onycholysis and transverse depressions of the nail plate (Beau's lines) with a brownish or green discoloration along the lateral borders. [46], [47] Candidal paronychia should be differentiated from bacterial paronychia or paronychia associated with hypoparathyroidism, celiac disease, acrodermatitis enteropathica, Reiter's syndrome, acrokeratosis paraneoplastica, or retinoid therapy.

FIGURE 206-4 Chronic onychia and paronychia from *C. albicans*. *A.* Note the warm but not hot, slightly tender, edematous nail fold with some onycholysis. This is very often misdiagnosed as staphylococcal paronychia. *B.* This is a chronic inflammatory condition of the nail fold that also can involve the nail plate.

Chronic paronychial infections due to *C. albicans* are resistant to therapy. All wet work should be minimized. Topical agents should be applied and allowed to drain under the proximal nail fold. Occlusion using a finger cot may allow better drug penetration. A topical imidazole in solution form is the ideal treatment. [40] Also, 4% thymol in chloroform or absolute alcohol has anticandidal activity and is drying. Oral ketoconazole or surgical marsupialization of the proximal nail fold is recommended in resistant cases. [46] The rare syndrome of congenital candidiasis presents in the first 24 hours of life. Organisms spread to the uterus of pregnant women with *Candida* vaginitis and thus infect the fetus. Affected neonates have a pink maculopapular eruption that progresses to vesicles and pustules with desquamation. Lesions occur predominantly on the upper half of the body and on the palms and soles. While most neonates have a benign course, approximately 20 percent have transient respiratory distress or clinical signs of sepsis. Preterm and low-birth-weight infants are at higher risk for fatal dissemination of the disease. Although congenital cutaneous candidiasis may resolve spontaneously, topical therapy with nystatin is recommended to prevent disseminated disease. Amphotericin B at 0.5–1.0 mg/kg per day should be used to treat systemic neonatal candidiasis. [48], [49] The incidence of disseminated candidiasis is steadily rising as more patients with hematologic malignancies are treated with potent immunosuppressive drugs and other patients undergo bone marrow and organ transplants (see Table 206-2). The organisms responsible include *C. albicans, C. tropicalis, C. lusitaniae, C. krusei,* and *C. parapsilosis.* [50] These organisms may gain hematogenous access from the oropharynx or gastrointestinal tract when the function of the mucosal barrier is compromised (e.g., mucositis secondary to chemotherapy) or through contaminated intravenous catheters. Organs most commonly involved include the lungs, spleen, kidneys, liver, heart, and brain. [51] Candidal endophthalmitis occurs often and correlates well with multiple-organ involvement. [52] Skin lesions occur in some patients with disseminated infection. The recognition of such lesions may be important in early diagnosis because antemortem blood cultures are negative in a high percentage of patients with autopsy-proven systemic candidiasis. [51] The characteristic skin lesions are 0.5- to 1.0-cm erythematous papulonodules that become hemorrhagic. The eruption is located on the trunk and extremities and has a varying number of lesions. Associated findings include fever and myalgias. [53], [54] Necrotic cutaneous lesions also have been described that resemble ecthyma gangrenosum. [55], [56] In intravenous heroin abusers, macronodular and folliculitis-like skin lesions occur in the scalp and other terminal hair-bearing areas when candidal organisms infiltrate the hair follicles. [57] The differential diagnosis of papules in systemic candidiasis includes *Pityrosporum* folliculitis, [58] bacterial sepsis (e.g., gonococcal, meningococcal, pseudomonal, staphylococcal), and other disseminated fungal infections (e.g., aspergillosis). Necrotic cutaneous lesions due to *Candida* may appear identical to *Pseudomonas* ecthyma or deep fungal infections (e.g., cryptococcosis, torulopsosis, or sporotrichosis). The management of disseminated candidiasis includes the early use of amphotericin B. Newer lipid-based formulations may reduce nephrotoxicity. Some studies support the empirical use of amphotericin B in febrile neutropenic patients with antibiotic-resistant infections. Another option in the treatment of disseminated candidiasis is 5-flucytosine (150 mg/kg). Amphotericin B and 5-flucytosine may be combined in the treatment of *Candida* meningitis or hepatosplenic candidiasis. [51]

CHRONIC MUCOCUTANEOUS CANDIDIASIS Chronic mucocutaneous candidiasis (CMC) consists of several clinical syndromes characterized by chronic, treatment-resistant, superficial candidal infections of the skin, nails, and oropharynx. There is virtually no propensity for disseminated visceral candidiasis. In many cases there are specific abnormalities in CMI; in others, the defects are more global. The clinical findings and immunologic defects have been reviewed extensively. [59]

Clinical syndromes Table 206-4 categorizes CMC syndromes and summarizes their distinguishing features. [59], [60], [61] and [62]) In general, the various syndromes may be familial or sporadic. When presenting in childhood, lesions are detected before the age of 3 years. Oral lesions or diaper dermatitis appear first, followed by angular cheilitis (perlèche), lip fissures, nail and paronychial involvement, vulvovaginitis, and cutaneous involvement. In chronic localized mucocutaneous candidiasis, markedly hyperkeratotic, hornlike, or granulomatous lesions may appear (candidal granuloma) on the face, eyelids, scalp, lips, or acral areas (Fig. 206-5). On the scalp they may resemble the lesions of favus and can lead to alopecia. In chronic diffuse candidiasis, lesions may appear with an erythematous, serpiginous border or areas of brownish desquamation on a background of mild erythema (see Fig. 206-5). Concomitant dermatophyte infection of the skin may occur and confuse the clinical presentation. [59] The lesions of CMC may resemble those of tinea (e.g., favus), bacterial pyoderma, acrodermatitis enteropathica, and halogenoderma.

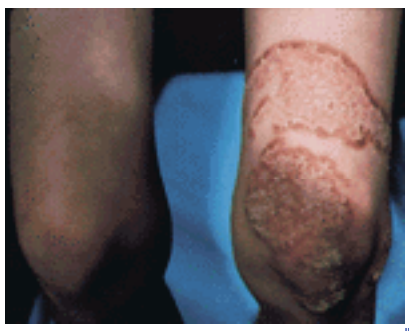

FIGURE 206-5 Mucocutaneous candidiasis. Well-demarcated serpiginous border.

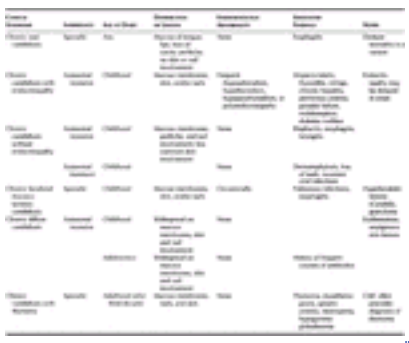

TABLE 206-4 **Classification of Chronic Mucocutaneous Candidiasis**

Nail involvement is characterized by markedly thickened and dystrophic nail plates whose entire thickness is invaded by *Candida.* The paronychial areas are red and edematous, and the fingertips are often bulbous in appearance [46] (see Fig. 206-4). Conditions that have been associated with CMC include candidal esophagitis or laryngitis, endocrinopathies (usually hypoparathyroidism, hypoadrenalism, hypothyroidism), circulating antinuclear antibodies, diabetes mellitus, vitiligo, iron deficiency, chronic active hepatitis, pernicious anemia, malabsorption, alopecia totalis, dental enamel dysplasia, keratoconjunctivitis, pulmonary fibrosis, and keratitis, ichthyosis, and deafness (KID) syndrome. Recurrent pyogenic, viral, or other fungal infections also may occur. When CMC first appears in adulthood, it is often associated with a thymoma and the other conditions listed in Table 206-4. [63] In the past, chronic mucocutaneous candidiasis has been notoriously difficult to treat. The best results are seen with a combination of antifungal drugs and immune deficiency correction. [63] The most important consideration in the treatment of CMC is the specific immune deficiency. Although antifungal treatment will clear the lesions quickly, the infection recurs within a few weeks of stopping the drug unless the underlying immune defect is corrected. Patients with CMC have used oral azoles with good efficacy for years. [59] Several different methods of immune regulation have been used. A patient with DiGeorge syndrome received thymic tissue transplantation and had spontaneous clearing of CMC. The infection of a patient with severe combined immunodeficiency and extensive CMC also cleared after transplantation of cultured fetal thymus donor leukocytes. Infusion with *Candida*-specific transfer factor proteins from donor T lymphocytes also has produced remission of CMC. [63]

Laboratory Findings

Direct microscopic examination of specimens for the presence of yeast and isolation of yeast in culture are needed to diagnose infection definitively. In superficial candidal infections, the diagnosis can be made by examining skin scrapings and observing typical budding yeasts with hyphae or pseudohyphae. *C. albicans* grows readily on bacterial media, but Sabouraud's agar with added antibiotics is usually recommended for isolation. Whitish mucoid colonies grow within 2 to 5 days. Of all superficial infections, chronic paronychiae may have the lowest yield of positive cultures.

In systemic candidiasis with skin lesions, the diagnosis usually can be made from histopathologic examination and culture of appropriate skin biopsy specimens. Blood cultures often are negative in this setting. [51] Serologic studies using immunodiffusion, counterimmunoelectrophoresis, and latex agglutination methods may be somewhat helpful in the diagnosis of systemic candidiasis. However, false-negative and false-positive reactions are common. More promising are techniques to detect circulating candidal antigens (e.g., mannan) or metabolic products (e.g., arabinitol). [64]

MICROSCOPIC STUDIES Since *Candida* species may infect virtually any organ system, specimens for laboratory examination will vary from body fluids to surgical biopsies. Direct microscopic examination for the presence of yeast provides rapid evidence to support the clinical diagnosis. Body fluids such as urine and cerebrospinal fluid should be centrifuged and the sediment examined directly to increase the probability of finding yeast. Sputum, surgical biopsies, and tissue scrapings must be treated with a clearing agent such as 10% potassium hydroxide (KOH) and ink before the material is examined. *Candida* appears as oval budding cells, elongated filamentous cells connected end to end (pseudohyphae), or septate hyphae (see Fig. 206-1). However, this method does not permit species identification.
CULTURE METHODS Sediment from centrifuged body fluids, tissue from biopsies, and skin scrapings should be inoculated promptly onto Sabouraud's dextrose agar containing antibacterial antibiotics. Cultures are incubated at room temperature [25–to 27°C (77–80.6°F)] and examined periodically for growth of yeast. Negative cultures are discarded after 4 weeks. All yeast colonies must be subcultured and tested further for identifying morphologic and biochemical characteristics before they can be speciated.
PATHOLOGY Superficial candidiasis is characterized by subcorneal pustules. Organisms are seldom seen within the pustule but can be visualized in the stratum corneum with the aid of a periodic acid–Schiff (PAS) stain. The histology of a candidal granuloma shows marked papillomatosis and hyperkeratosis and a dense dermal infiltrate consisting of lymphocytes, granulocytes, plasma cells, and multinucleated giant cells. In systemic candidal infections with skin involvement, biopsies show focal areas of yeast in the dermis and within blood vessels. Organisms can be identified using PAS or methenamine silver stains. There may be a surrounding mononuclear cell infiltrate, [65] leukocytoclastic vasculitis, or microabscess formation.

“ *PITYROSPORUM* INFECTIONS” OF THE SKIN: PAPULOSQUAMOUS TINEA VERSICOLOR, “ *PITYROSPORUM*” FOLLICULITIS, AND INVERSE TINEA VERSICOLOR

The genus *Malassezia* includes seven species of lipophilic basidiomycetous yeast: *Malassezia furfur, M. pachydermatis, M. sympodialis, M. globosa, M. restricta, M. slooffiae,* and *M. obtusa*. [66] Previously, *M. furfur, M. pachydermatis,* and *M. sympodialis* were the only members of the genus. In 1996, Gueho et al. [67] proposed a new taxonomic classification based on morphology, ultrastructure, and molecular biology that added four new species. These yeasts cause a wide spectrum of superficial cutaneous disease, including tinea versicolor, folliculitis, and seborrheic dermatitis. [68]

History

Eichstedt first recognized tinea versicolor as a cutaneous fungal infection in 1846. For several years the disease was considered to be dermatophyte in origin, but Baillon, impressed by the yeastlike nature of the organism, coined the name *Malassezia* in 1889 to distinguish this organism from the *Microsporum* species of dermatophytes. [69] In 1951, Gordon isolated and characterized the organism *M. furfur* and renamed it *Pityrosporum orbiculare*. [70] It is now recognized and accepted that *M. furfur* is the correct name and that *P. orbiculare, P. ovale,* and *M. ovalis* are synonyms.

Etiology and Pathogenesis

M. furfur can be cultured from diseased and normal skin and is considered part of the normal flora, particularly in sebum-rich areas of the skin. [71] *M. furfur* is a dimorphic, lipophilic organism that grows in vitro only with the addition of C_{12} to C_{14} fatty acids such as olive oil and lanolin. Under appropriate conditions, it converts from the saprophytic yeast to the predominantly parasitic mycelial morphology associated with clinical disease. Factors responsible for mycelial transition include a warm, humid environment, heredity, Cushing's disease, immunosuppression, and a malnourished state. [71]

The species of *Malassezia* can be differentiated by their nutritional requirements, morphology, and molecular biology. [67], [72] *M. pachydermatis* is the one member of the genus *Malassezia* without an absolute requirement of exogenous lipids for growth. Although previously recognized as a zoophilic organism, it has been identified only recently as a human pathogen. In one study, *M. pachydermatis* caused a series of infections in a neonatal care nursery, where it was presumably spread to patients from health care workers whose pet dogs were colonized with the fungus. [73] Other members of the genus, including *M. sympodialis* and *M. sloofiae,* are part of the normal skin flora. [74] A recent study also linked *M. sympodialis* with neonatal cephalic pustulosis, a skin disorder also known as *neonatal acne.* [75]

M. furfur has long been identified as the fungus causing tinea versicolor. However, recent studies indicate that *M. globosa* may be involved in the pathogenesis of this disease. Crespo Erchiga et al. [74], [76] cultured the lesions of tinea versicolor in 96 patients, and *M. globosa* was found in 97 percent.

Tinea versicolor is an opportunistic infection of the skin. Experimental inoculation of *Malassezia* under occlusion can cause infection. [71] The resulting increase in humidity, temperature, and CO_2 tension appear to be important factors that make the skin susceptible to infection. [70] When the occlusion is terminated, healing occurs, although the organism is not eradicated from the skin and can be cultured from clinically uninvolved areas. [77] It also may colonize follicular structures, and a high recurrence rate is expected.

Immunology

No specific deficiencies in antibodies or complement components have been found in patients with tinea versicolor. Similar titers of specific IgG antibody are seen in healthy controls and tinea versicolor patients. [78] Furthermore, Sohnle and Collins-Lech [79] have shown that *M. furfur* induces IgA, IgG, and IgM antibodies and that it also activates complement through the alternative and classical pathways. The precise role that CMI and other immunologic factors play in the disease process is unknown.

The immune response seen in *Malassezia* folliculitis is likewise poorly understood. Patients with *Malassezia* folliculitis have higher titers of IgG antibodies than those with tinea versicolor or controls. [80] Both nonspecific inflammatory responses and specific cellular immunity are also observed. Faergemann et al. [78] have shown that patients with seborrheic dermatitis and *Malessezia* folliculitis have an increased number of NK1+ and CD16+ cells and complement activation consistent with irritant stimulation of the immune system. In addition, biopsies of involved skin lesions showed an increase in inflammatory cytokines. [78]

Clinical Features

Cutaneous infections with *Malassezia* may take three forms: (1) papulosquamous, (2) folliculitis, and (3) inverse tinea versicolor. The most common presentation is scaly hypo- or hyperpigmented macules observed in characteristic areas of the body, including the chest, back, abdomen, and proximal extremities (Fig. 206-6). Less common areas of involvement include the face, scalp, and genitalia. The characteristic scale is described as dustlike or furfuraceous. This characteristic feature of the disease can be produced by lightly scraping a scalpel blade over the involved skin. [71] The color of the lesions varies from almost white to reddish brown or fawn-colored. The presenting complaint is usually a cosmetic one because lesions often fail to tan with sun exposure. Pruritus is mild or absent.

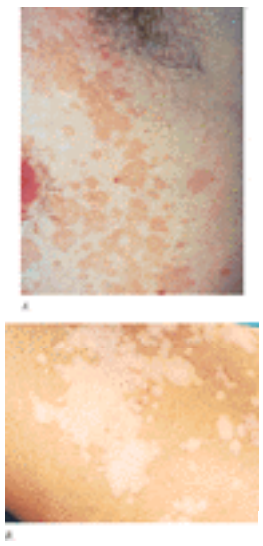

FIGURE 206-6 *A.* Pityriasis versicolor. These lesions are darker because of hyperemia secondary to inflammatory response and increased melanin. *B.* Tinea versicolor. There are sharply marginated, uniformly hypopigmented macules with a fine, sometimes barely perceptible scale, but they are easily scraped off with a glass slide. When the lesions are very large, as on the left, they can be confused with vitiligo.

The yeast may filter the rays of the sun and interfere with normal tanning. [71] Furthermore, the metabolites of *M. furfur* such as azaleic acid, a dicarboxylic acid, can cause depigmentation by inhibiting tyrosinase and injuring melanocytes. [71], [77] This long-standing damage to melanocytes may explain why most hypopigmented lesions persist for months and some persist for years. [71]

In *Malassezia* (*Pityrosporum*) folliculitis, lesions typically appear on the back, chest, and sometimes the extremities (Fig. 206-7A). Pruritus is more common than with typical tinea versicolor. The primary lesion is a perifollicular, erythematous, 2- to 3-mm papule or pustule. Only appropriate culture and KOH examination can distinguish this infection from a bacterial folliculitis. Frequently, biopsy with special stains for fungus is necessary (see Fig. 206-7B). Diabetes mellitus [70] or prior glucocorticoid or antibiotic therapy [77]) can predispose to this disorder.

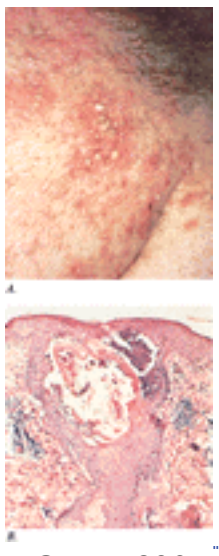

FIGURE 206-7 *A, B. Pityrosporum* folliculitis on the anterior chest. Note the organisms in the follicular ostia on staining with hematoxylin and eosin.

The lesions of inverse tinea versicolor are encountered predominantly in flexural areas. [81] Because of its location, inverse tinea versicolor can be confused with seborrheic dermatitis, psoriasis, erythrasma, candidiasis, and dermatophyte infections.

Rarely, *M. furfur* can infect organs other than the skin. A premature infant on total parenteral nutrition with intravenous lipid supplementation has been reported who showed no skin lesions but had an extensive vasculitis of small pulmonary arteries as well as pneumonia. *M. furfur* was seen microscopically in areas of lipid deposition. The organism has been cultured from peritoneal dialysate and blood and, with increasing frequency, from patients receiving parenteral intravenous lipid supplementation. Presumably, this provides an appropriate growth medium for *M. furfur*. [70]

Each of the cutaneous variants has an equal sex distribution and tends to flare during the summer months, presumably due to increased heat and humidity. These infections are also more common in tropical climates. Although the disease can occur at any age, late adolescents and early adults are predominantly affected. [71]

Laboratory Findings

To identify the *Malassezia* yeast forms, scale from involved skin should be scraped onto a glass slide and treated with 10% KOH. Alternatively, cellophane tape can be used to pick up skin scales from the lesion. The tape is mounted on a glass slide with methylene blue, and the organism is selectively stained. [80]

Sabouraud's dextrose agar overlaid on the surface with sterile olive oil or lanolin readily supports the growth of this

lipophilic yeast. To reduce the growth of contaminating organisms, antibiotics such as penicillin, streptomycin, and cycloheximide are incorporated into this medium. In general, cultures are not required for diagnosis because organisms can be demonstrated with 10% KOH.

Pathology

In tinea versicolor, the organisms inhabit the stratum corneum. There is usually no dermal infiltrate. Yeast may be observed with hematoxylin and eosin (H&E) stain alone. PAS staining is confirmatory. Microscopic examination reveals clusters of oval budding yeast cells 3.5 × 4.5 µm long with short, septate, and occasionally branching hyphae (Fig. 206-8). The microscopic appearance of the yeast is classically described as “spaghetti and meatballs.” In *Malassezia* folliculitis, organisms are noted in widened follicular ostia mixed with keratinous material (see Fig. 206-7B). Rupture of the follicular wall can occur with a resulting mixed inflammatory and foreign-body giant cell response.

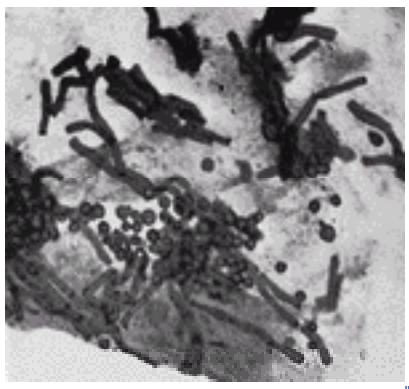

FIGURE 206-8 “Spaghetti and meatballs” appearance of tinea versicolor in a KOH preparation.

Diagnosis

The clinical appearance of tinea versicolor is usually characteristic, and KOH examination is confirmatory. A Wood's lamp examination may show yellowish fluorescence of involved skin. The differential diagnosis includes pityriasis alba, confluent and reticulated papillomatosis of Gougerot and Carteaud, pityriasis rosea, seborrheic dermatitis, vitiligo, or secondary syphilis.

For the folliculitis variant, both bacterial and candidal folliculitis should be considered in the differential diagnosis. The skin lesions of disseminated candidiasis also can be confused with *Malassezia* folliculitis. [83]

Treatment and Prognosis

There are multiple topical products that are useful in treating tinea versicolor. The most widely used has been 2.5% selenium sulfide shampoo. This should be applied liberally over and beyond the affected areas, left on for at least 10 min, and then washed off. The cycle is repeated every day for 2 weeks. Subsequently, we recommend applying the drug once or twice per month to prevent recurrence. All the topical azole antifungals have been effective in the treatment of tinea versicolor. Ketoconazole 2% shampoo may be lathered on affected areas and left for 5 min; this is repeated for 3 consecutive days. [84] Recent studies have shown that topical terbinafine, 1% solution applied twice daily to lesions for 7 days, has cure rates of greater than 80 percent. [85], [86]

While topical therapy is ideal for this condition, systemic treatment may be necessary for patients with extensive disease, frequent recurrences, or failure of topical agents. [87] In addition, patients often prefer the convenience of oral therapy. Cure rates range from 90 to 100 percent with ketoconazole (200 mg daily for 7 days) or itraconazole (200–400 mg daily for 3–7 days). Fluconazole is also effective and can be given as a single dose of 400 mg. [86], [88] Oral terbinafine is not an effective treatment, likely because therapeutic drug levels are not achieved in the stratum corneum. [71] In addition, griseofulvin is not effective in the treatment of tinea versicolor. Whether systemic or oral medications are used, clinical improvement is not seen until 3 to 4 weeks after treatment because the involved epidermis must slough. [86]

Malassezia folliculitis also can be treated successfully with both topical and systemic therapy. As with most types of folliculitis, systemic therapy is more effective. Although there are few controlled trials, oral ketoconazole (200 mg daily for 4 weeks), fluconazole (150 mg weekly for 2–4 weeks), and itraconazole (200 mg daily for 2 weeks) are useful systemic agents in the treatment of this papulopustular folliculitis. [80]

Tinea versicolor is often a chronic, recurrent condition. Prophylactic measures, as discussed earlier, and fastidious cleanliness may lessen the risk of recurrence.

Deep Fungal Infections

SUBCUTANEOUS MYCOSES
Sporotrichosis
Mycetoma (Maduromycosis, Madura Foot)
Chromoblastomycosis (Chromomycosis)
Pheohyphomycosis (Phaeomycotic Cyst, Cystic Chromomycosis)
Lobomycosis (Keloidal Blastomycosis, Lobo's Disease)
Subcutaneous Zygomycosis [Basidiobolomycosis, Subcutaneous Phycomycosis and Conidiobolomycosis, (Rhino)-Entomophthoromycosis]
Rhinosporidiosis
SYSTEMIC MYCOSES
Histoplasmosis
Blastomycosis (North American Blastomycosis, Gilchrist Disease)
Coccidioidomycosis (Coccidioidal Granuloma, Valley Fever, San Joaquin Valley Fever, Desert Rheumatism)
Paracoccidioidomycosis (South American Blastomycosis, Paracoccidioidal Granuloma)
Infections due to Penicillium marneffei (Penicilliosis, Penicilliosis Marneffei)
Cryptococcosis (Torulosis, European Blastomycosis)
Cutaneous Aspects of Systemic Opportunistic Mycoses
Systemic Candidiasis
Zygomycosis (Mucormycosis, Phycomycosis)
Other Opportunistic Mycoses
Actinomycosis
Nocardiosis

REFERENCES

Deep fungal infections comprise two distinct groups of conditions, the subcutaneous and systemic mycoses. Neither are common, and the subcutaneous mycoses, with some exceptions, are largely confined to the tropics and subtropics. In recent years, the systemic mycoses have become important opportunistic infectious complications in immunocompromised patients, including those with AIDS and patients receiving treatment for malignancies. They also include a group of primary respiratory infections such as histoplasmosis and coccidioidomycosis, which may affect otherwise healthy individuals and those with underlying illness. The fungi that cause these respiratory infections are usually dimorphic or exist in a different morphologic phase, e.g., yeast or mold, at different stages of their life cycle.

Patients with subcutaneous fungal infections often present to a physician with signs of skin involvement. By contrast, patients with systemic mycoses only occasionally have skin lesions, either following direct involvement of the skin as a portal of entry or after dissemination from a deep focus of infection. There are a number of excellent texts about fungi and the diseases they cause. [1], [2], [3] and [4]

SUBCUTANEOUS MYCOSES

The subcutaneous mycoses, or mycoses of implantation, are infections caused by fungi that have been introduced directly into the dermis or subcutaneous tissue through a penetrating injury, such as a thorn prick. Although many are tropical infections, some, such as sporotrichosis, are also prevalent in temperate climates; any of these infections may present as an imported disease in a patient who has originated from an endemic area, sometimes after a lapse of many years. The most common subcutaneous mycoses are sporotrichosis, mycetoma, and chromoblastomycosis. Rarer infections include lobomycosis and subcutaneous zygomycosis.

Sporotrichosis

Sporotrichosis is a subcutaneous or systemic fungal infection caused by the dimorphic fungus *Sporothrix schenckii*. [5], [6] The fungus occurs in the natural environment, presumably in mold form, but develops as a yeast in infections. The most frequent site of this infection is the dermis or subcutis. There is also a systemic form of sporotrichosis whose clinical features range from pulmonary infection to arthritis or meningitis. One important characteristic of the diagnosis of cutaneous lesions is the scarcity of organisms in tissue, making confirmation of the diagnosis potentially difficult. [6] Sometimes in tissue, fungal cells are surrounded by an eosinophilic refractile fringe, the asteroid body, that is a characteristic of the organism, although a similar phenomenon may occur with other infections.

HISTORICAL ASPECTS The first published case in Western literature was in 1898 by Schenck from the Johns Hopkins Hospital. Subsequently, a series of reports appeared in France from 1903 onward that described the disease and its treatment with potassium iodide. One important feature of the infection is the development of clusters of cases in defined geographic areas. For instance, there was a major outbreak of sporotrichosis in the South African gold mines from 1941 to 1944.
EPIDEMIOLOGY Infections occur in both temperate and tropical countries. They are seen in North, South, and Central America, including the southern United States and Mexico, as well as in Africa, Egypt, Japan, and Australia. [6] The countries where the highest rates of infection occur are Mexico, Brazil, and South Africa. However, sometimes hyperendemic areas are found where large numbers of cases occur. [7] In the United States, infections are most common

in the midwestern river valleys. Infections are now rare in much of Europe. In nature, the fungus grows on decaying vegetable matter such as plant debris, leaves, and wood. Although it is usually a cause of sporadic infection, *S. schenckii* also may affect groups of workers exposed to the organism, such as those using straw as a packing material, gardeners, and forestry workers and those whose recreational activities bring them into contact with plant debris. The organism is thought to be introduced into the skin through a local injury.

CLINICAL MANIFESTATIONS The two clinical varieties of sporotrichosis are the subcutaneous and systemic forms of disease. [5], [8], [9] Subcutaneous sporotrichosis is by far the more common and includes two main forms: lymphangitic and fixed infections. The lymphangitic form is the more common and usually develops on exposed skin sites such as hands or feet. The first sign of infection is the appearance of a dermal nodule that breaks down into a small ulcer. Draining lymphatics become inflamed and swollen, and a chain of secondary nodules develops along the course of the lymphatic (Fig. 207-1); these also may break down and ulcerate. In the fixed variety, which accounts for about 15 percent of cases, the infection remains localized to one site, such as the face, and a granuloma develops that subsequently may ulcerate. Satellite nodules may form around the rim of the primary lesion. Other clinical variants of subcutaneous sporotrichosis may mimic mycetoma, lupus vulgaris, and chronic venous ulceration. In some cases, deep extension of the infection may affect joints or tendon sheaths. Patients with AIDS who develop sporotrichosis often have multiple cutaneous lesions [9] without prominent lymphatic involvement, but deep infections such as arthritis are also reported (see below).

FIGURE 207-1 Sporotrichosis. An ulcerated nodule is seen on the thumb with proximal lymphangitic spread represented by subcutaneous nodules. (*Courtesy of Takeji Nishikawa, MD.*)

In the much rarer systemic form of sporotrichosis, lesions can develop almost anywhere, although chronic lung nodules, with cavitation, arthritis, and meningitis have been described most frequently. These may coexist with cutaneous lesions of sporotrichosis.

DIFFERENTIAL DIAGNOSIS Conditions commonly confused with sporotrichosis are mycobacterial infections and leishmaniasis. The nontuberculous mycobacterial infection due to *Mycobacterium marinum* (fish-tank granuloma), in particular, closely resembles lymphangitic sporotrichosis.

LABORATORY DIAGNOSIS The best sources of diagnostic material are smears, exudates, and biopsies. *S. schenckii* is seen very rarely in direct microscopic examination because yeasts are usually present only in small numbers; the organism can be isolated readily on Sabouraud's agar. In primary culture, the fungus grows as a mold, with compact, white colonies that darken with age. Microscopically, the hyphae produce small oval or triangular conidia either on specialized hyphae or elsewhere on the mycelium. Ideally, the organism should be converted to yeast phase on enriched media such as brain-heart infusion (BHI) agar at 37°C in order to complete the identification. Pathologically, sporotrichosis causes a mixed granulomatous reaction with neutrophil microabscesses. The fungus, if present, is usually in the form of small (3 to 5 µm) cigar-shaped or oval yeasts that may, on occasion, be surrounded by a thick, radiating eosinophilic fringe forming the distinctive asteroid body. Organisms are usually sparsely distributed in lesions, and it may be necessary to scan several sections in order to identify one yeast. A sporotrichin skin test is available in some Latin American countries and may have a role to play in allowing the physician to identify the most appropriate laboratory investigations to instigate.

TREATMENT While spontaneous remissions may occur, most patients are treated with antifungal chemotherapy. Potassium iodide (saturated solution), 4 to 6 mL tid, is effective in the cutaneous types of sporotrichosis and should be continued for 3 to 4 weeks after clinical cure. The daily dose is built up slowly from 1 mL tid over 2 to 3 weeks to avoid side effects such as hypersalivation and nausea. This is an inexpensive form of therapy, but it is unpalatable. Alternative treatments include itraconazole, 200 mg daily, and terbinafine, 250 mg daily, which are better tolerated, and intravenous amphotericin B for deep infection. In all cases, treatment is continued for at least 1 week after clinical resolution.

Mycetoma (Maduromycosis, Madura Foot)

Mycetoma is a chronic localized infection caused by different species of fungi or actinomycetes. It is characterized by the formation of aggregates of the causative organisms, known as *grains,* that are found within abscesses. These either drain via sinuses onto the skin surface or involve adjacent bone, causing a form of osteomyelitis. Grains are discharged onto the skin surface via these sinuses. The disease advances by direct spread, and distant metastatic sites of infection are very rare. Mycetomas caused by species of fungi are known as *eumycetomas,* and those caused by aerobic actinomycetes or filamentous bacteria are known as *actinomycetomas*. The organisms are usually soil or plant saprophytes [11] that are only incidental human pathogens.

HISTORICAL ASPECTS Although this is a disease of great antiquity, the original description of the disease in the Western literature was in 1694 by Engelbert Kaempfer, a German physician in southern India. Over a century elapsed before the disease was redescribed by an English army surgeon, called Gill, working in southern India in 1842. Subsequent cases from India, Africa, and South America confirmed the presence of the disease in a wide variety of tropical countries.

EPIDEMIOLOGY Mycetomas are mainly, but not exclusively, found in the dry tropics where there is low annual rainfall. [11], [12] They are sporadic infections that are seldom common, even in endemic areas. [13] Occasionally, nonimported cases are reported from temperate climates, although in these cases the most common organism is *Scedosporium apiospermum*. Actinomycetomas due to *Nocardia* species are most common in Central America and Mexico (Table 207-1). In other parts of the world, the most common organism is a fungus, *Madurella mycetomatis*. The actinomycete *Streptomyces somaliensis* is isolated most often from patients originating from Sudan and the Middle East. The causative organisms of mycetoma have been isolated from either soil or plant material, including Acacia thorns, in endemic areas.

Organisms	H&E Section Appearances
Eumycetoma	
Dark grains	
Madurella mycetomatis	Cement present, vesicles sometimes prominent
M. grisea	Cement absent, compact outer layer
Leptosphaeria senegalensis	Cement in outer zone, dark periphery with vesicular center
Exophiala jeanselmei	Cement absent, often hollow
Pyrenochaeta romeroi	Cement lacking, compact outer layer
Pale grains	
Fusarium spp., *Acremonium*, *Scedosporium apiospermum*, *Aspergillus nidulans*, *Neotestudina rosati*	Compact, pigment lacking, interwoven fungal filaments (*S. apiospermum* may have prominent vesicles)
Actinomycetoma	
Pale (white to yellow) grains	
Actinomadura madura	Basophilic-stained fringe in layers
Nocardia brasiliensis	Small, pale blue, eosinophilic fringe
Yellow to brown grains	
Streptomyces somaliensis	Grains fractured, basophilic or pink
Red to pink grains	
A. pelletieri	Small, basophilic layers

Note: H&E, hematoxylin and eosin stain.

TABLE 207-1 **Macroscopic and Histopathologic Features of Mycetoma Grains**

The organisms are implanted subcutaneously, usually after a penetrating injury. It is unusual to find any underlying predisposition in patients with mycetoma, and the persistence of the organism after the initial inoculation appears to be related to its ability to evade host defenses through a variety of adaptations such as cell wall thickening and melanin deposition. [14]

CLINICAL MANIFESTATIONS The clinical features of both fungal and actinomycete mycetomas are very similar. [12] They are most common on the foot, lower leg, or hand, although head or back involvement also may occur. Infection of the chest wall is most characteristic of *Nocardia* infections. The earliest stage of infection is a firm, painless nodule that spreads slowly with the development of papules and draining sinus tracts over the surface (Fig. 207-2). Local tissue swelling, chronic sinus formation, and later bone involvement distort and deform the original site of infection (Fig. 207-3 and Fig. 207-4). Lesions are seldom painful except in the late stages and where sinus tracts are about to emerge onto the skin surface. Dissemination from the initial site is exceptionally rare, although local lymphadenopathy may occur.

FIGURE 207-2 Mycetoma. Brawny edema and crusted papules on the plantar surface.

FIGURE 207-3 Eumycetoma caused by *Scedosporium*.

FIGURE 207-4 Mycetoma. Chronic fibrotic involvement of the foot with lymphatic spread to the popliteal fossa.

X-ray changes include periosteal erosion and proliferation, as well as the development of lytic lesions in the bone. Bone scans or magnetic resonance imaging (MRI) may identify bone lesions at an earlier stage.

DIFFERENTIAL DIAGNOSIS Chronic bacterial or tuberculous osteomyelitis may resemble mycetoma. Actinomycosis (see below) is also similar but usually develops close to certain sites, such as the mouth or the cecum, where the causative organisms are sometimes commensal.

LABORATORY DIAGNOSIS Finding the mycetoma grains is the key to establishing the diagnosis, and these are generally discharged from the openings of sinus tracts. However, they also may be obtained by removing the surface crust from a pustule or sinus tract with a sterile needle and gently squeezing the edges. Grains are 250- to 1000-µm white, black, or red particles that can be picked out with the naked eye. Direct microscopy of grains is important because it will show whether the grain is composed of the small actinomycete or broader fungal filaments. In general, it is not possible to distinguish the fine actinomycete filaments in KOH mounts or, for that matter, in hematoxylin and eosin–stained material. In addition, black grains are always caused by fungi; red grains, by actinomycetes (see Table

207-1). Final identification requires isolation of the causal agent in culture. In view of the number of possible species, a series of different culture media and conditions of incubation should be employed. Morphologic and physiologic characteristics are used to distinguish between the genera and species. Serology is only diagnostically helpful in some cases, e.g., *S. somaliensis,* and even then it is more appropriate as a guide to therapeutic response. Histologically, there is a chronic inflammatory reaction with neutrophil abscesses and scattered giant cells and fibrosis. [11] Grains (50 to 250 µm) are found in the center of the inflammation. Their size and shape may help in the identification, although with nonpigmented fungal causes of mycetoma, this is seldom sufficient (Fig. 207-5).

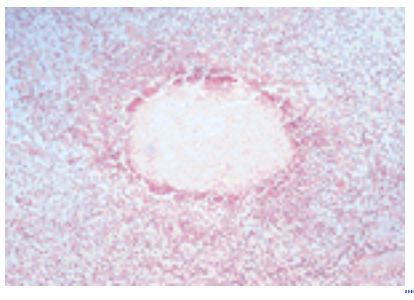

FIGURE 207-5 Pale eumycetoma grain (H&E stain).

TREATMENT Actinomycetomas generally respond to antibiotics such as a combination of dapsone with streptomycin or sulfamethoxazole-trimethoprim plus rifampin or streptomycin. Amikacin also may be used in recalcitrant *Nocardia* infections. The responses in all but a few cases are good. [15] Of the fungal causes of mycetoma, *M. mycetomatis* may respond to ketoconazole, 200 mg daily over several months. For the others, a trial of therapy with griseofulvin, terbinafine, or itraconazole is worth attempting. However, responses to chemotherapy are unpredictable, although antifungals may slow the course of infection. Surgery, usually amputation, is the definitive procedure and may have to be used in advanced cases. However, the value of major surgery in a disfiguring but non-life-threatening infection has to be weighed against the availability of appropriate prosthetic limbs.

Chromoblastomycosis (Chromomycosis)

Chromoblastomycosis is a chronic fungal infection of the skin and subcutaneous tissues caused by pigmented or dematiaceous fungi that are implanted into the dermis from the environment. In the ensuing inflammation, they form thick-walled single cells or cell clusters (sclerotic or muriform bodies), and these may elicit a marked form of pseudoepitheliomatous hyperplasia often accompanied by transepidermal elimination of organisms. The infection can be caused by a number of different pigmented fungi, the most common being *Phialophora verrucosa, Fonsecaea pedrosoi, F. compactum, Wangiella dermatitidis,* and *Cladophialophora carrionii*. [16]

HISTORICAL ASPECTS The first confirmed case was in a patient from New England described by Lane and Medlar in 1915, although subsequently most of the early reports came from Brazil. There is considerable confusion over the correct designation of the first reported isolates because their names have changed considerably over time. This problem of identification is discussed below.

EPIDEMIOLOGY The fungi that cause chromoblastomycosis can be isolated in the environment from wood, plant debris, or soil. [17] The vast majority of infections are caused by *F. pedrosoi* and *P. carrionii*. As with other subcutaneous mycoses, infection follows implantation through a tissue injury. The infection is found as a sporadic condition in Central and South America, although rarely in North America. It occurs in the Caribbean region, Africa (particularly Madagascar), Australia, and Japan. It also may occur as an imported infection outside the usual endemic areas. The disease is most frequent in male rural workers.

CLINICAL MANIFESTATIONS The initial site of the infection is usually on the feet, legs, arms, or upper trunk. The clinical features vary. [17] The initial lesion is often a warty papule that expands slowly over months or years (Fig. 207-6 and Fig. 207-7). Alternatively, lesions may be flatter and plaquelike with an atrophic center. The more common verrucous form spreads slowly and locally. Individual lesions may be very thick and often develop secondary bacterial infection. Satellite lesions around the initial site of infection are local extensions of the infection and usually are produced by scratching. Complications of chromoblastomycosis include local lymphedema leading to elephantiasis and squamous carcinomas in some chronic lesions.

FIGURE 207-6 Chromoblastomycosis. A solitary, large verrucous plaque surrounded by a halo of erythema is seen on the calf. (*Courtesy of Ted Rosen, MD, and Howard Rubin, MD.*)

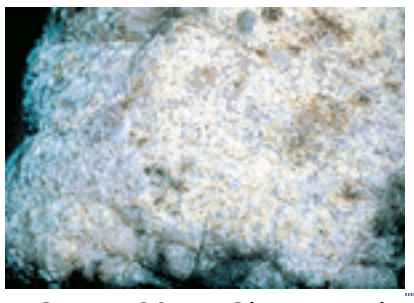

FIGURE 207-7 Close-up view of chromoblastomycosis.

DIFFERENTIAL DIAGNOSIS The disease must be differentiated from chronic tropical lymphedema with hyperplasia (mossy foot). Other chronic verrucous lesions such as tuberculosis and blastomycosis are often more extensive. The identification of organisms in the lesions of chromoblastomycosis is essential.

LABORATORY DIAGNOSIS The typical sclerotic or muriform fungal cells can be seen in skin scrapings taken from the surface of lesions, particularly areas where there is a small dark spot on the skin surface, using KOH mounts. The lesions also should be biopsied because the pathologic changes and presence of muriform cells are typical. The histology shows a mixed granulomatous response, with small neutrophil abscesses and often exuberant epidermal hyperplasia. [18] The organisms, which are often seen either in giant cells or in neutrophil abscesses, appear singly or in small groups of brown pigmented cells, often with a single or double septum and thick cell wall. In culture, these fungi are very similar in gross macroscopic appearance, producing black colonies with a downy surface. Their cultural identification depends on demonstrating the presence of different but specific types of sporulation, and either single or multiple sporulation mechanisms may be seen in each organism. Accurate differentiation between the different fungi may be difficult. At this stage, the choice of treatment does not depend critically on correct identification of the organisms, although there may be differences in the speed of response to azole drugs (see below).

TREATMENT The main treatments for chromoblastomycosis are itraconazole, 200 mg daily, with or without flucytosine, 30 mg/kg qid (in a patient with normal renal function) [19]; terbinafine, 250 mg daily [20]; and in extensive cases, intravenous amphotericin B (up to 1 mg/kg daily). Thiabendazole is a further alternative, although nausea and vomiting may limit the use of the drug. Lesions can be spread by surgery, which should be used only as an adjunctive therapy after drug treatment. The local application of heat may be helpful in some instances. The responses of these fungi to different antifungal agents do not appear to differ significantly, although there is some evidence that *C. carrionii* responds more rapidly to itraconazole. In any event, treatment is continued until there is clinical resolution of lesions, which usually takes several months. Extensive lesions often respond poorly to treatment.

Pheohyphomycosis (Phaeomycotic Cyst, Cystic Chromomycosis)

Pheohyphomycosis is a rare infection characterized by the formation of subcutaneous inflammatory cysts. It is caused by dematiaceous fungi, the most common of which are *Exophiala jeanselmei* and *Wangiella dermatitidis,* but some 103 species have been described as causal agents. [21] However, unlike in chromoblastomycosis, these organisms form short, irregular, pigmented hyphae in tissue. The infection may occur in any climatic area, although it is more common in the tropics. It also may appear in immunosuppressed patients, particularly those receiving long-term glucocorticoid therapy. The lesions present as cysts and may be mistaken for other similar structures such as Baker's cysts. The diagnosis is usually made after surgical excision. Histologically the cyst wall consists of palisades of macrophages and other inflammatory cells surrounded by a fibrous capsule, and the fungal hyphae are found in the macrophage zone. Although the fungi in tissue lesions are usually pigmented, this is not always the case; if special melanin stains such as Masson-Fontana are used, the organisms will stain, showing that they can produce melanin in small quantities. The treatment is surgical excision, although relapse can occur, particularly in immunocompromised patients.

Lobomycosis (Keloidal Blastomycosis, Lobo's Disease)

This is an uncommon infection seen in Central and South America, often in remote rural areas. The source of the organism is unknown, although similar lesions have been found on freshwater dolphins. Lobomycosis is characterized by the appearance of keloid-like skin lesions on exposed sites. [22] Although it cannot be cultured in vitro, it is caused by a fungus that forms chains of rounded cells in tissue, each joined by a small tubule. Lesions may occur anywhere on the body but usually are found on exposed parts such as the legs, arms, and face. They can spread from site to site by autoinoculation. Antifungal drugs are not effective, and surgical removal is the main treatment.

Subcutaneous Zygomycosis [Basidiobolomycosis, Subcutaneous Phycomycosis and Conidiobolomycosis, (Rhino)-Entomophthoromycosis]

This is a rare tropical subcutaneous mycosis characterized by the development and spread of a chronic, firm swelling involving subcutaneous tissue. There are two main varieties, caused by different organisms. [23] The first, most often caused by *Basidiobolus ranarum* (*B. haptosporus*), is more common in children. It occurs in a wide variety of countries and environments from South America to Africa and Indonesia. The organism can be found in plant debris and in the intestinal tracts of reptiles and amphibians. Lesions usually develop around limb girdle sites and present with a firm, slowly spreading, woody cellulitis. The second form, caused by *Conidiobolus coronatus,* is seen in adults. The organism can be isolated from soil, plant debris, and some insects. The early infection starts in the region of the inferior turbinates of the nose. Spread involves the central part of the face, and once again, the swelling is hard and painless. It may cause very severe deformity of the nose, lips, and cheeks.

Histopathologically, a chronic granulomatous response with large numbers of eosinophils can be seen. The fungi are present as large, straplike hyphae without cross-walls or septa. They are also often surrounded by refractile eosinophilic material (Splendore-Hoeppli phenomenon). The organisms can be cultured readily on Sabouraud's agar. Lesions usually respond to oral treatment with potassium iodide, given in similar doses to those used in sporotrichosis (see above). Ketoconazole (400 mg daily) and itraconazole (100–200 mg daily) also may be useful in this condition, although

experience to date is limited to a few cases.

Rhinosporidiosis

Rhinosporidiosis is a chronic infection caused by the organism *Rhinosporidium seeberi,* which causes the development of polyps affecting the mucous membranes. The organism has never been cultured, and it is now thought to be a member of the Protista. Rhinosporidiosis is seen most often in southern India and Sri Lanka. Cases also have been described in South America, the Caribbean, and South Africa. Exposure to water (lakes, pools) has been associated with the infection. The main site affected is the nasal mucosa, but the conjunctival mucosa also may be affected. [24] The infection causes the development of large polyps that are studded with white flecks; these are small cysts or sporangia containing small spores. These are best seen in histopathologic sections, where the large sporangia or spore sacs in different phases of development are readily seen. The only treatment is surgical excision.

SYSTEMIC MYCOSES

The systemic mycoses are fungal infections whose initial portal of entry into the body is usually a deep site such as the lung, gastrointestinal tract, or paranasal sinuses. They have the capacity to spread via the bloodstream to produce a generalized infection. In practice, there are two main varieties of systemic mycosis: the opportunistic mycoses and the endemic respiratory mycoses.

The chief opportunistic systemic mycoses seen in humans are systemic or deep candidiasis, aspergillosis, and systemic zygomycosis. These affect patients with severe underlying disease states, such as AIDS, or with neutropenia associated with malignancy, solid-organ transplants, or extensive surgery. Where combination antiretroviral therapy is used, the incidence of systemic mycoses in HIV-infected patients has dropped considerably. In the neutropenic patient in particular, other fungi also may cause infection occasionally. Different underlying conditions predispose to different mycoses, and a scheme for this is shown in Table 207-2. Generally, skin involvement is not common with these opportunistic infections, which can occur in any climate and environment. The clinical manifestations of the opportunistic mycoses are also variable because they depend on the site of entry of organism and the underlying disease.

Predisposition	Infection
Neutropenia (whatever cause) functional neutrophil defects	Aspergillosis, oropharyngeal and/or systemic candidiasis, zygomycosis, infections due to rare organisms
CD4 lymphopenia (e.g., AIDS)	Oropharyngeal candidiasis, cryptococcosis and endemic respiratory mycoses such as histoplasmosis, nocardiosis
Diabetes mellitus	Zygomycosis
Heart valve surgery	Various but mainly *C. albicans* and non-albicans *Candida* spp.
Abdominal surgery	Candidiasis

TABLE 207-2 **Underlying Predisposition and Opportunistic Systemic Mycoses**

The endemic respiratory mycoses are histoplasmosis (classic and African types), blastomycosis, coccidioidomycosis, paracoccidioidomycosis, and infections due to *Penicillium marneffei*. The clinical manifestations of these infections are affected by the underlying state of the patient, and many develop in the presence of particular immunodeficiency states, notably AIDS. However, they follow similar clinical patterns in all infections. These infections also may affect otherwise healthy individuals. They have well-defined endemic areas determined by factors that favor the survival of the causative organisms in the environment, such as climate. The usual route of infection is via the lung.

In practice, because of the tendency for both groups of infections to develop in predisposed patients, the distinction between opportunistic and endemic mycoses is blurred. This is particularly the case with the deep infection cryptococcosis, which shares clinical and pathologic features of the two main types of systemic mycosis but is mainly seen now in AIDS patients.

Histoplasmosis

Fungi of the dimorphic genus *Histoplasma* cause a number of different infections in animals and humans. These range from equine farcy, or equine histoplasmosis, a disseminated infection of horses caused by *H. farciminosum,* to two human infections known as *classic* or *small-form histoplasmosis* and *African histoplasmosis*. These are caused, respectively, by two variants of *H. capsulatum: H. capsulatum* var. *capsulatum* and *H. capsulatum* var. *duboisii*. They can be distinguished because their respective yeast phases differ in size, the *capsulatum* variety producing cells from 2 to 5 µm in diameter and the *duboisii* form producing cells of 10 to 15 µm in diameter. The other important differences are in their epidemiology and clinical manifestations. They also show minor antigenic differences that are apparent in serodiagnosis, but their mycelial phases are identical. The two types of human infections will be referred to as *histoplasmosis* and *African histoplasmosis* because this nomenclature is used most widely.

HISTOPLASMOSIS (SMALL-FORM OR CLASSIC HISTOPLASMOSIS OR HISTOPLASMOSIS CAPSULATI)
Histoplasmosis results from infection with the dimorphic fungus *H. capsulatum* var. *capsulatum*. A sexual state of this fungus *Ajellomyces capsulatus* also has been described. The infection starts as a pulmonary infection that, in most individuals, is asymptomatic and heals spontaneously, the only evidence of exposure being the development of a positive intradermal skin test reaction to a fungal antigenic extract, histoplasmin. [25] However, in addition, there is a symptomatic disease that includes respiratory infections and acute or chronic pulmonary histoplasmosis, as well as a disseminated infection that may spread to affect the skin or mucous membrances. Direct inoculation into the skin may occur as a result of a laboratory accident.
Historical aspects Histoplasmosis was first recognized in Panama by Darling in 1905 as the cause of death in a patient from Martinique. The proof that this was caused by a fungus rather than a protozoan came in 1929 when de Monbreun, at

Vanderbilt University, grew the organism in culture. Even so, its importance as a cause of a wider spectrum of infections, including lung disease, was not recognized until the 1940s.

Epidemiology Histoplasmosis occurs in many countries from the Americas to Africa, India, and the Far East. In the United States, it is endemic in the Mississippi and Ohio River valleys, where often more than 80 percent of the population may have acquired the infection asymptomatically. Exposure rates are usually lower in all other endemic areas, although high rates are also found in northern South America and some Caribbean islands. Histoplasmosis is not found in Europe. *H. capsulatum* is an environmental saprophyte that can be isolated from soil, particularly when it is contaminated with bird or bat excreta. The disease is acquired by inhalation of spores, and epidemics of respiratory infection may occur in persons exposed to a spore-laden environment when exploring caves or cleaning sites heavily contaminated with bird droppings, such as bird roosts or barns. Although any person can acquire histoplasmosis through inhalation, it causes a distinctive disseminated infection in patients with disease affecting cellular immune capacity, such as AIDS or lymphoma. [26], [27]

Clinical manifestations The spectrum of histoplasmosis includes asymptomatic as well as benign symptomatic infections and a progressive disseminated variety with bloodstream spread to multiple organs. [25] Skin lesions may develop as a result of immune-complex formation in the primary infection (erythema multiforme) or from direct spread after dissemination from the lungs; rarely, infections may develop at a point of inoculation into the skin. Asymptomatic forms of histoplasmosis are, by definition, without signs or symptoms, but those exposed usually have a positive histoplasmin skin test. The percentage of skin test reactors in the community indicates the chances of exposure, and in endemic areas, this may range from 5 to 90 percent. Occasionally, asymptomatic pulmonary nodules removed at surgical exploration or autopsy are found to contain *Histoplasma*.

ACUTE PULMONARY HISTOPLASMOSIS In this form, patients are often exposed to large quantities of spores such as may be encountered in a cave or after cleaning a bird-infested area. Patients present with cough, chest pain, and fever, often with accompanying joint pains and rash—toxic erythema, erythema multiforme, or erythema nodosum. These skin rashes are not common, occuring in fewer than 15 percent of patients, but they may be precipitated by treatment of the acute infection. On chest x-ray, there is often diffuse mottling, which may calcify with time.

CHRONIC PULMONARY HISTOPLASMOSIS This usually occurs in adults and presents with pulmonary consolidation and cavitation, closely resembling tuberculosis. Skin involvement is not seen.

ACUTE DISSEMINATED HISTOPLASMOSIS In these patients there is widespread dissemination to other organs such as the liver and spleen, lymphoreticular system, and bone marrow. Patients present with progressive weight loss and fever. This form is the type that is most likely to occur in untreated AIDS patients, who often develop skin lesions as a manifestation of disseminated infection [27] (Fig. 207-8). There are papules, small nodules, or small molluscum-like lesions that subsequently may develop into shallow ulcers. Diffuse micronodular pulmonary infiltrates also may develop. Patients have progressive and severe weight loss, fever, anemia, and hepatosplenomegaly.

FIGURE 207-8 Histoplasmosis, disseminated. Multiple erythematous keratotic papules and small plaques resembling guttate pattern psoriasis are seen on the chest and arm of a male with advanced HIV disease. (*Courtesy of JD Fallon, MD.*)

The distinction between acute and chronic dissemination in histoplasmosis is somewhat artificial because these merely represent extremes of behavior, with progression occurring over a few months, on the one hand, and over several years, on the other. Intermediate forms occur, and other organs such as the meninges and heart may be affected.

CHRONIC DISSEMINATED HISTOPLASMOSIS This may appear months or years after a patient has left an endemic area. The most common clinical presenting features are oral or pharyngeal ulceration or adrenal insufficiency (Addison's disease) due to adrenal infiltration. The mouth ulcers are often large, irregular, and persistent and affect the tongue as well as the buccal mucosa. The patients otherwise may appear well, but it is important to investigate them for evidence of infection elsewhere, e.g., by abdominal CT scan. Adrenal infection in particular should be excluded.

PRIMARY CUTANEOUS HISTOPLASMOSIS This form is rare and follows inoculation of the organism into the skin, for instance, after accidental laboratory- or postmortem room–acquired infection. The primary lesion is a nodule or indurated ulcer, and there is often local lymphadenopathy.

Differential diagnosis The organism is the same size as a number of others causing deep mycoses such as *P. marneffei* and small forms of *Blastomyces* and *Cryptococcus* (see below). It is also similar in size to *Leishmania* species, and in the tropics, kala-azar is an important part of the differential diagnosis. These observations emphasize the importance of carrying out appropriate laboratory tests to confirm the diagnosis.

Laboratory diagnosis The diagnosis of histoplasmosis is established by identifying the small intracellular yeast-like cells of *Histoplasma* in sputum, peripheral blood, bone marrow, or biopsy specimens. *Histoplasma* must be separated from *P. marneffei* because the two organisms are of a similar size, although the latter shows characteristic septa formation. The identity of the organism should be confirmed by culture; it grows as a mold at room temperature. The white, cottony colonies develop at room temperature on Sabouraud's glucose agar to produce two types of spores, the larger (8–15 µm), rounded, tuberculate macroconidia being typical; the smaller microconidia are infectious. Confirmation of the identity should be obtained by demonstrating the production of diffusing exoantigen by an immunodiffusion assay (exoantigen test). Mycelial-phase cultures of *H. capsulatum* are very infectious, and laboratories receiving specimens should be warned about the suspected diagnosis. The intradermal histoplasmin skin test is an epidemiologic tool that is

of no help in diagnosis. In patients with disseminated histoplasmosis, it is often negative. By contrast, serology is often useful in diagnosis. A rising complement-fixation titer indicates dissemination. Precipitins detected by immunodiffusion are also valuable because the presence of antibodies to specific H and M antigens correlates well with active or recent infection. [28] A new development, particularly helpful in AIDS patients, has been serologic tests for the detection of circulating *Histoplasma* antigens. [29] In histopathologic sections, *H. capsulatum* is an intracellular parasite often seen in macrophages. The cells are small (2–4 µm in diameter) and oval in shape with small buds (Fig. 207-9). Mycelial forms are seen rarely in tissue.

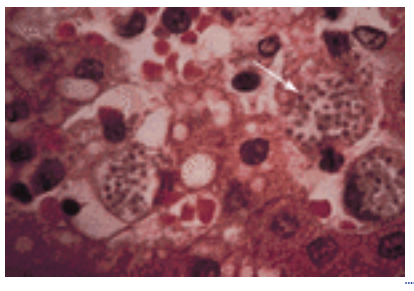

FIGURE 207-9 Histoplasmosis, disseminated. Lesional biopsy specimen shows dermal macrophages packed with dozens of tiny yeast forms of *H. capsulatum*.

AFRICAN HISTOPLASMOSIS (LARGE-FORM HISTOPLASMOSIS OR HISTOPLASMOSIS DUBOISII) This infection is sporadic and uncommon. [30] It is seen in patients from areas south of the Sahara and north of the Zambezi River in Africa. Infections seen outside Africa are all imported. The most common clinically involved sites are the skin and bone, although lymph nodes and other organs, including the lungs, may be affected. Skin lesions range from small papules resembling molluscum contagiosum to cold abscesses, draining sinuses, or ulcers. It is not clear if there is an asymptomatic form of African histoplasmosis as in classic histoplasmosis. The diagnosis is confirmed by culture and microscopy (direct microscopy or histopathology). The organisms of *H. capsulatum* var. *duboisii* are different from the smaller *capsulatum* forms. They are usually 10 to 15 µm in diameter, slightly pear-shaped, and clustered in giant cells. *Histoplasma* serology, using conventional tests, is often negative in African histoplasmosis.

TREATMENT The choice of therapy for histoplasmosis depends on the severity of the illness. For patients with some disseminated or localized forms of the disease, oral itraconazole (200–400 mg daily) is highly effective. It also has been used for long-term suppressive treatment of the disease in AIDS patients after primary therapy either with itraconazole or amphotericin B. [31] However, there is now evidence that provided CD4 counts do not fall in patients on HAART therapy, suppressive treatment can be discontinued. Intravenous amphotericin B (up to 1 mg/kg daily) is given to patients with widespread and severe infections and is the main alternative used. Ketoconazole and fluconazole are also effective in many cases. In African histoplasmosis, itraconazole is also the treatment of choice, but once again, in severe cases amphotericin B may be used. [30]

Blastomycosis (North American Blastomycosis, Gilchrist Disease)

Blastomycosis is a chronic mycosis caused by the dimorphic pathogen *Blastomyces dermatitidis*. [32] Its chief sites of involvement are the lungs, but disseminated forms of the infection may affect skin, bones, CNS, and other sites.

HISTORICAL ASPECTS The infection was first described by Gilchrist in 1894. Many of the early cases were described from the Chicago area, and originally this disease was called *North American blastomycosis* until, in 1952, the first case was described from North Africa. It is now recognized that this infection has a wider distribution, although it is not common anywhere.

EPIDEMIOLOGY The infection is found in North America and Canada. [33] Most cases, though, come from the Great Lakes Region and southern states of the United States. It also occurs sporadically in Africa, with the largest numbers of cases coming from Zimbabwe, [34] and cases also have been reported from the Middle East and India. It is thought that the natural habitat of *Blastomyces* is in some way related to wood debris and is close to rivers or lakes or in areas subjected to periodic flooding. However, it is difficult to isolate *Blastomyces* from the natural environment. [35] Blastomycosis also may affect domestic animals such as dogs.

CLINICAL MANIFESTATIONS As with histoplasmosis, there is a subclinical form of the infection; its prevalence has not been defined in detail because of lack of a commercial *Blastomyces* skin test antigen and the extent of antigenic cross-reactivity with fungi such as *Histoplasma*. Primary cutaneous blastomycosis is also very rare and follows trauma to the skin and the subsequent introduction of fungus, for instance, in laboratory workers or pathologists. [36] After inoculation, an erythematous, indurated area with a chancre appears in 1 to 2 weeks with associated lymphangitis and lymphadenopathy. Pulmonary blastomycosis is very similar in clinical presentation to pulmonary tuberculosis. [33], [36], [37] There may be no symptoms, or there may be low-grade fever, chest pain, cough, and hemoptysis, and unlike histoplasmosis, it often coexists with disseminated disease. Skin lesions are a common presenting feature of disseminated blastomycosis. [36], [38] They are often symmetric and usually affect the face and extremities. The early lesion is a papule or nodule, which may ulcerate and discharge pus. With time, this enlarges to form a hyperkeratotic lesion, often with central scarring or ulceration (Fig. 207-10, Fig. 207-11 and Fig. 207-12). Oral lesions are less common. Multiple skin lesions are often found in disseminated infection. Other patients may present with nodules and abscesses, and in many patients lesions of different morphologies are present. African patients with blastomycosis have a higher frequency of skin and bone involvement. [34] Although blastomycosis can affect almost any organ, other common sites for dissemination include the bone, the epididymis, and the adrenal gland. Less commonly, there is widespread rapid dissemination with multiple organ involvement, and *B. dermatitidis* can produce a form of adult respiratory distress syndrome (ARDS). Skin lesions in widespread disseminated disease are usually papules, abscesses, or small ulcers. Widespread blastomycosis has been described in AIDS patients, but it is not common. [39]

FIGURE 207-10 Blastomycosis. Older lesion, appearing as a verrucous plaque.

FIGURE 207-11 Blastomycosis. Inflammatory plaque with ulceration resembling pyoderma gangrenosum on the calf. (*Courtesy of Elizabeth M. Spiers, MD.*)

FIGURE 207-12 Blastomycosis. Chronic verrucous plaque on the cheek.

DIFFERENTIAL DIAGNOSIS The chronic skin granulomas must be differentiated from those due to tuberculosis, other deep mycoses, nonmelanoma skin cancers, pyoderma gangrenosum, and drug reactions due to bromides and iodides.
LABORATORY IDENTIFICATION The fungus can be found in KOH mounts of pus, skin scrapings, or sputum as thick-walled, rounded refractile spherical cells with broad-based buds (Fig. 207-13). In culture, the fungus grows as a mycelial fungus at room temperature. It produces small, rounded or pear-shaped conidia. At higher temperature (37°C) and on enriched media, it produces yeast forms with the characteristic buds. In tissue sections, the typical organisms with broad buds may be found, although it may be necessary to search several fields to find the characteristic cells.

FIGURE 207-13 Direct preparation (KOH) of *Blastomyces.*

These are often found in giant cells or surrounded by neutrophils (Fig. 207-14). Precipitating antibodies to *B. dermatitidis* are often present in the sera of infected patients, and a characteristic precipitin line, the E band, has been described in a high proportion of proven cases; there is also an enzyme-linked immunosorbent assay for blastomycosis. However, one of the problems with serodiagnosis in blastomycosis is the presence of a high number of false-positive reactions in uninfected persons and cross-reactivity with other fungi.

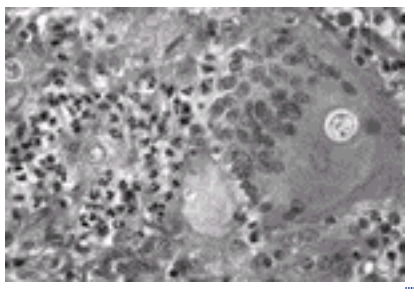

FIGURE 207-14 Blastomycosis. Lesional biopsy specimen shows many thick-walled budding yeast forms.

TREATMENT Treatment is similar to that used for histoplasmosis, itraconazole (200–400 mg daily) is used in the less severe forms of the infection or where there is only localized spread. Treatment is usually given for at least 6 months. Follow-up surveillance is necessary because relapse can occur, particularly where there are deep sites of infection or the patient is immunosuppressed. Amphotericin B (up to 1 mg/kg daily) is generally used for the treatment of widespread

disseminated forms of blastomycosis. Ketoconazole is an alternative therapy.

Coccidioidomycosis (Coccidioidal Granuloma, Valley Fever, San Joaquin Valley Fever, Desert Rheumatism)

Coccidioidomycosis is the infection caused by the fungus *Coccidioides immitis*. It shows an unusual form of dimorphism, with a mold form at room temperature and the development of large, spore-containing structures, spherules, in infected tissue. As with other endemic mycoses, there are asymptomatic, acute and chronic pulmonary, and disseminated forms. The disease can affect otherwise healthy individuals or predisposed patients, including those with AIDS.

HISTORICAL ASPECTS Coccidioidomycosis was first described as a disseminated infection in Argentina by Posadas in 1892. Later, this was connected with a benign self-resolving form, valley fever, in California, and in 1938, studies with an antigen from the organism, coccidioidin, confirmed that there was widespread exposure in endemic areas of the United States.

EPIDEMIOLOGY *C. immitis* is endemic in some semidesert areas of the southwestern states of the United States (e.g., California, Arizona, New Mexico, and Texas) and in parts of Mexico and Central and South America. The climate of the endemic areas is marked by very high summer temperatures and low annual rainfall, demonstrated by a characteristic vegetation with cacti and mesquite bushes. Skin tests with coccidioidin show that the incidence of exposure in endemic areas may be as high as 95 percent. The fungus is found in soil and can affect other animals as well as humans. Exposure may result from a brief visit to an endemic area, and local weather can determine exposure rates. [40], [41] For instance, dust storms may cause infection in large numbers of individuals. The usual route of infection is respiratory, although direct implantation into the skin can occur rarely.

CLINICAL MANIFESTATIONS As with other systemic mycoses, there is an asymptomatic or subclinical form that is common in endemic areas, judging by the percentages of skin test reactors to coccidioidin in the healthy population. The primary pulmonary form, which is the most common clinical type, presents as a chest infection with fever, cough, and chest pain. Complications such as pleural effusion may occur. Erythema multiforme or erythema nodosum, [41] often accompanied by arthralgia or anterior uveitis, occurs from the third to the seventh week in about 10 to 15 percent of patients and is more common in females. Sometimes an early, generalized, macular and erythematous rash is seen in some patients. The chronic pulmonary form of the disease presents with chronic cough and resembles tuberculosis. Skin lesions normally do not occur in this phase. In the rare primary skin infection, following inoculation, there is an indurated nodule that develops 1 to 3 weeks after local trauma. This is followed by regional lymphadenopathy. Disseminated coccidioidomycosis develops in fewer than 0.5 percent of infected individuals. It is mainly seen in patients from certain ethnic backgrounds (American blacks, Filipinos, or Mexicans), in pregnant women, and in immunosuppressed patients, including those with AIDS. [42], [43] In disseminated disease, lesions may develop in the skin, subcutaneous tissues, bones, joints, and all organs. The skin lesions (Fig. 207-15) are abscesses, granulomas, ulcers or discharging sinuses in which there is underlying bone or joint disease. Some lesions appear as flat plaques with central atrophy. Meningitis is an important complication of dissemination and is usually not associated with signs of infection in other sites. In AIDS patients, persistent pneumonia, skin lesions, and widespread dissemination can all occur.

FIGURE 207-15 Coccidioidomycosis, disseminated. Intact and ulcerated papules and nodules are seen on the cheek and nose of this comatose patient with coccidioidomycotic meningitis. (*Courtesy of Francis Renna, MD.*)

DIFFERENTIAL DIAGNOSIS Physicians in endemic areas should be aware of the connection between erythema nodosum and coccidioidomycosis. It also may occur in visitors to endemic areas after only a short stay.

LABORATORY DIAGNOSIS A characteristic of the laboratory findings is the ability of *C. immitis* to form spore-containing spherules. These are large (up to 250 µm) and can be seen in KOH mounts of sputum, cerebrospinal fluid (CSF), or pus. In culture, colonies of *C. immitis* are mycelial, fast-growing, white, and cottony. On microscopy, there are chains of arthrospores at intervals on the older mycelium. *C. immitis* in the mold phase is highly infectious, and cultures should be handled carefully. Serologic tests are of value in the diagnosis and prognosis of coccidioidomycosis. [44] Precipitins develop in about 90 percent of infected individuals within 2 to 6 weeks but are short-lived; complement-fixing antibodies are characteristic of more severe infections and, in active infection, increase to a maximum after 6 months. Skin tests with coccidioidin are of little value in diagnosing infections. Spherulin is an antigen obtained from spherules of *C. immitis* and may be better than coccidioidin for detecting sensitization. However, in severe infections, cutaneous anergy to both is common. Spherules containing large endospores can be seen in tissue sections, although there are a variety of less distinct intermediate stages in spherule formation that also can be seen. Before endospores form, the cytoplasm of the immature spherule is basophilic and subsequently breaks up into spores. Mycelium is seen rarely in histopathologic sections.

TREATMENT No specific therapy apart from rest is necessary in the primary pulmonary infection, and there is little evidence that the symptoms are either improved or shortened by giving an oral azole drug, even though it is widespread practice. For disseminated disease, treatment is still unsatisfactory, but amphotericin B (1 mg/kg daily), itraconazole (200–400 mg daily), or fluconazole (200–600 mg daily) can all be given. [45] Experience with the newer antifungal agents such as voriconazole and posaconazole is limited at present. It is important to follow patients carefully, given the frequency of relapse. Meningitis, arthritis, and progressive disseminated infection involving multiple sites are all particularly refractory to therapy. Generally, soft tissue coccidioidomycosis (skin and joint) has a better prognosis, and the mortality in patients who present with soft tissue lesions is low.

Paracoccidioidomycosis (South American Blastomycosis, Paracoccidioidal Granuloma)

Paracoccidioides brasiliensis is a dimorphic fungus that causes a respiratory infection with a tendency to disseminate to the mucous membranes and lymph nodes. It is confined to Central and South America. [46]

HISTORICAL ASPECTS Paracoccidioidomycosis was first described in Brazil by Lutz in 1908. Although initially thought to be related to coccidioidomycosis, described a few years earlier in Argentina, the organism was isolated in 1912 and shown to be different.
EPIDEMIOLOGY Paracoccidioidomycosis has been reported from most Latin American countries, but the infection is found most commonly in parts of Brazil, Colombia, and Argentina. The infection does not occur in the United States, although it has been reported from Mexico. Exposure rates can be estimated by skin test reactivity and appear to be equal in both males and females, although the prevalence of positive reactors in endemic areas seldom exceeds 25 percent. In contrast, the active infection is seen predominantly in males. The mechanism is thought to be connected to the presence of a cytoplasmic estrogen receptor on the fungus, and in vitro, estradiol suppresses the conversion of mycelium to yeast. [47] The ecologic niche of the organisms is unknown, but the condition is much more frequent in rural areas; exposure has been associated with proximity to water or areas of high atmospheric humidity. [48]
CLINICAL MANIFESTATIONS There are a number of different clinical patterns of infection that depend on the predominant site of clinical involvement. These include the lung (pulmonary form), the mucous membranes (mucocutaneous form), and the lymph nodes (lymphatic form). Many patients have a mixed type of infection with involvement of different organ groups. [46] Patients rarely present with an acute form of pulmonary infection; rather, it tends to be chronic and slowly progressive with weight loss and chronic cough. The lesions may be bilateral and nodular on chest x-ray, and there is often extensive fibrosis. Other sites of involvement include mucocutaneous areas. Oral or circumoral lesions are common in the mucocutaneous forms of paracoccidioidomycosis; lesions also occur in the nose, conjunctivae, or around the anus. These lesions may be small granulomas or ulcers. They heal with scarring, which may cause considerable deformity. The cervical lymph nodes are sometimes enlarged, tender, and tethered to the overlying skin; they rarely suppurate. Other systemic sites of involvement include the spleen, intestines, lungs, and liver. Paracoccidioidomycosis is uncommon in AIDS patients, although there is a widespread variety that is a more rapidly progressive form of disseminated infection occurring in young adults or older children without recognizable predisposition. [49]
DIFFERENTIAL DIAGNOSIS This includes tuberculosis, leishmaniasis, and other deep mycoses.
LABORATORY DIAGNOSIS Sputum, exudates, and scrapings can be screened using KOH. They show numbers of round yeasts with a characteristic form of multiple budding in which a parent cell is surrounded by large numbers of smaller buds. The organism is dimorphic and produces a cottony mycelial-phase growth on primary isolation at room temperature. Once again, the characteristic yeast phase can be induced on enriched media such as BHI agar at 37°C. Serology is very helpful in confirming the diagnosis, the main tests being the immunodiffusion assay and a complement-fixation test. Recently, antibodies to a 43-kDa antigen have been found to be highly specific for this infection in immunoblotting. There is also an antigen-detection test useful in monitoring patients with disseminated disease. Histopathologically, there is a mixed granulomatous response with fibrosis. The organisms can be seen with special fungal stains such as methenamine silver (Grocott modification). In tissue, the characteristic budding pattern can be seen, although it may be necessary to search several fields to find the most typical structures (Fig. 207-16). In widespread infections, masses of small yeast forms may be mistaken for *Histoplasma*.

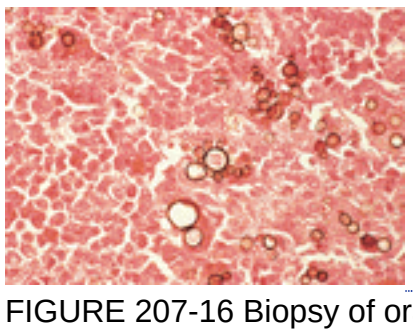

FIGURE 207-16 Biopsy of oral mucosal lesion showing multiple budding *Paracoccidioides brasiliensis.*

TREATMENT The treatment of choice in most cases is itraconazole, which can produce remissions in 3 to 6 months. [50] Ketoconazole is an alternative. Relapses can occur, and where possible, patients should be reviewed periodically after primary therapy. In very extensive infections and in severely ill patients, such as those with the progressive disseminated type of infection, intravenous amphotericin B may be necessary. Severe pulmonary or intraoral fibrosis may remain after treatment.

Infections due to *Penicillium marneffei* (Penicilliosis, Penicilliosis Marneffei)

This infection is a more recently recognized disease found in Southeast Asia. *P. marneffei* is a member of the common genus *Penicillium*. It shows an unusual pattern of dimorphism in that it develops yeast-like cells that reproduce with septal formation, dividing the cells into two. It is inhaled via the lungs, and it is not known whether there is a primary cutaneous form of the infection.

HISTORICAL ASPECTS This disease was first recognized in 1959 by Segretain in a specimen from Vietnam. [51] Subsequent cases in U.S. veterans from Vietnam and then cases from Thailand and China have confirmed the wide geographic extent of this infection.
EPIDEMIOLOGY The natural source of *P. marneffei* is unknown. Infections are confined to Southeast Asia, particularly Thailand, South China, and Vietnam. However, there are reports in other Asian countries, including northeast India, and imported cases are seen in Europe and the United States. Natural infections are known to occur in bamboo rats, which are large burrowing rodents. The infection affects otherwise healthy individuals as well as those with immune defects and is most common after the rainy season. [52] Patients with AIDS appear to be particularly susceptible to this infection.
CLINICAL MANIFESTATIONS There has been no work to demonstrate that there is a subclinical form of *Penicillium*

infection, even though this is likely. Patients usually present with localized pulmonary or disseminated disease. The chest signs are those of chronic pulmonary disease. [53], [54] Over 50 percent of AIDS patients with this infection have multiple skin lesions, which are umbilicated papules that may enlarge and ulcerate. They are usually widely scattered on the face and trunk. Other organs including the liver, gastrointestinal tract, spleen, and bone marrow may be affected.

DIFFERENTIAL DIAGNOSIS The main differential diagnosis is with other disseminated mycoses such as histoplasmosis and cryptococcosis, which also can be found in the endemic area in AIDS patients. Biopsy and, where necessary, culture will distinguish between the different causes.

LABORATORY DIAGNOSIS *P. marneffei* forms characteristic yeastlike cells that are divided by a septum in tissue and are best seen in histopathologic sections stained with methenamine silver. These cells are small (2–4 µm) and difficult to see in blood films or skin or bone marrow smears, but they may be highlighted with stains such as leishmanin. In culture, *P. marneffei* is a green or grayish mold that produces typical *Penicillium* conidiophores and a diffusible red pigment. There is no commercial serologic test as yet.

TREATMENT In severe cases, amphotericin B is necessary. In many cases, however, there is a good response to itraconazole (200–400 mg daily). In AIDS patients, this is continued after initial therapy to prevent relapse. [54]

Cryptococcosis (Torulosis, European Blastomycosis)

Cryptococcosis is the infection caused by the encapsulated yeast *Cryptococcus neoformans*. Although the main portal of entry is through inhalation into the lungs, the disease usually presents with signs of extrapulmonary dissemination such as meningitis. Cutaneous lesions can develop as a result of dissemination or, rarely, through inoculation.

HISTORICAL ASPECTS *C. neoformans* was first demonstrated by Busse and Buschke in a patient with a bone infection in 1894. The capsule was originally misidentified as the result of histolytic action in vivo. In its time, this organism has been assigned to a variety of different fungal genera from *Torula* to *Saccharomyces*. Subsequently, other cases showed that *Cryptococcus* could cause a variety of different clinical forms of disease, notably meningitis. The advent of the AIDS epidemic has affected the epidemiology of this infection considerably, and in areas such as northern Thailand, cryptococcosis is one of the main secondary complications of HIV infection. [55]

EPIDEMIOLOGY Cryptococcosis has a worldwide distribution, although exposure rates probably differ markedly in different countries. *C. neoformans* has two variants: *C. neoformans* var. *neoformans* and *C. neoformans* var. *gattii*. These correspond to two clusters of serotypes: (1) A, D, or AD and (2) B or C. [56] The *neoformans* variety can be isolated from pigeon excreta and is more common in AIDS patients; the *gattii* form is found in the debris of certain eucalyptus trees in the tropics and California, but it is less often isolated from AIDS patients. Two sexual varieties called *Filobasidiella neoformans* and *F. bacillispora* correspond to the *neoformans* and *gattii* varieties, respectively. Patients with certain immunodeficiency states caused by AIDS, malignant lymphomas, sarcoidosis, collagen disease, and carcinoma and those receiving systemic glucocorticoid therapy are particularly susceptible. The incidence of cryptococcosis in patients with established AIDS varies in different countries from 3 to 6 percent in the United States, to 3 percent in the United Kingdom, to over 12 percent in parts of Africa, e.g., Zaire. Strains of serotype D are more likely to be found in skin lesions, which occur in 10 to 15 percent of cases of disseminated cryptococcosis.

CLINICAL MANIFESTATIONS There is probably a subclinical form of cryptococcosis because unaffected individuals may have positive skin tests. However, the most common clinical manifestation of disease is meningoencephalitis. This presents with classic signs of meningismus, changes in consciousness, mental changes, and nerve palsies. In AIDS patients, these signs may be only weakly expressed. Pulmonary infection can be found in about 10 percent of those with meningitis. Chest signs include the appearance of nodular shadows, cavitation, and pleural effusion. Patients with AIDS often present with fever and mild headache and few other features of infection. [55] Cutaneous lesions may develop in about 10 percent of cases but are seldom pathognomonic. [57], [58], [59] and [60] Acneiform papules or pustules progressing to warty or vegetating, crusted plaques, ulcers, and hard infiltrated plaques or nodules are characteristic of widespread systemic infection (Fig. 207-17). Cold abscesses, cellulitis, and nodular lesions also occur. In otherwise healthy patients or those with sarcoidosis, lesions may be solitary, and in such patients they may be the only clinical manifestation of infection.

FIGURE 207-17 Cryptococcosis, disseminated. Multiple, discrete, skin-colored papules and nodules resembling molluscum contagiosum are seen on the face of a male with advanced HIV disease. (*Courtesy of Loïs Vaillant, MD.*)

In primary cutaneous cryptococcosis with direct inoculation of organisms into the skin, the skin lesions are usually solitary nodules that break down and ulcerate. Local lymphadenopathy also develops. The term *primary cutaneous cryptococcosis* is also used loosely to describe solitary lesions of cryptococcosis, but in many such cases there is also evidence of dissemination to other internal organs. It is important to investigate all patients who present with cutaneous lesions for evidence of dissemination to other sites. [58]

DIFFERENTIAL DIAGNOSIS Cryptococcal skin lesions may mimic a range of other conditions, particularly other systemic mycoses in AIDS patients. It is important to biopsy and culture suspicious lesions in immunocompromised patients.

LABORATORY DIAGNOSIS Cryptococci are large (5–15 µm), budding cells with capsules that are best observed by direct microscopy of India ink or Nigrosin mounts (Fig. 207-18). The organism is not difficult to grow in culture. Various biochemical features such as the production of urease and the ability to pigment on Guizotia seed medium are characteristic. Serologic tests are rapid and specific. The main test is an antigen-detection assay using latex agglutination or ELISA, and this is simple and very rapid to perform on blood or CSF. Very high titers are found in AIDS patients in serum and CSF. Non-AIDS patients with single, localized skin lesions are often antigen-negative.

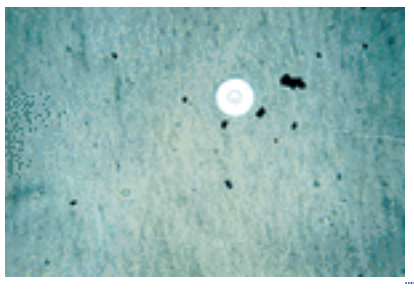

FIGURE 207-18 Cryptococcosis. India ink preparation of cerebrospinal fluid.

In tissue sections, the large pleomorphic yeasts stimulate either a granulomatous reaction or very little inflammation. The capsules of the cells can be stained using the mucicarmine or alcian blue stains.
TREATMENT The most frequently used drug regimen in the non-AIDS patient is intravenous amphotericin B combined with flucytosine. In patients with single skin lesions and no other signs of infection, alternatives such as fluconazole or itraconazole can be used. In AIDS patients, there is a very high relapse rate, and the usual policy is to give a 10- to 14-day course of amphotericin B with or without flucytosine, followed by long-term fluconazole. [61] However, it may be possible to stop suppressive therapy in patients receiving HAART. Fluconazole given on its own is an alternative approach.

Cutaneous Aspects of Systemic Opportunistic Mycoses

Skin lesions are not common with the opportunistic fungal infections, but they can occur in some, particularly in certain predisposed groups. When they occur, their presence may be very helpful because it is possible to biopsy easily accessible lesions in order to establish the diagnosis.

Systemic Candidiasis (See Chapter 206)

This follows dissemination of *Candida* species from the gastrointestinal tract or via the bloodstream. Skin lesions may occur particularly in two situations: (1) In neutropenic patients, there is often a severe disseminated disease with widespread skin nodules and associated muscle pains, [62] and (2) in intravenous drug abusers, candidiasis may present with a follicular, pustular rash in the beard area and scalp. Other lesions include retinal deposits and abscesses around the costochondral junctions. [63]

Systemic candidiasis is usually treated with intravenous amphotericin B (conventional or lipid-associated) or fluconazole. Resistance to some azole drugs, such as fluconazole and ketoconazole, is more common with certain non- *albicans Candida* species, and these antifungal agents should be avoided in infections caused by these species.

Zygomycosis (Mucormycosis, Phycomycosis)

Zygomycosis is a rare disease caused by zygomycete fungi such as *Rhizomucor, Absidia,* and *Rhizopus. Cunninghamella bertholletiae* and *Saksenaea vasiformis* are less common causes. Zygomycetes cause disease in patients with poorly controlled diabetes, neutropenia, or renal disease. They can invade necrotic burned areas or involve the facial skin secondary to invasive infection of the paranasal sinuses (Fig. 207-19). Zygomycete infections also have been associated with close apposition of the skin with contaminated dressing materials in the case of *R. rhizopodiformis* [64] or with wooden tongue depressors in the case of *R. microsporus*. [65] The zygomycete fungi have a tendency to invade blood vessels, causing widespread infarction. Infections may respond to intravenous amphotericin, and recent results with lipid-associated amphotericin B formulations have been encouraging.

FIGURE 207-19 Mucormycosis. *A.* The face of this young woman with diabetes mellitus shows proptosis, unilateral facial edema, and a right-sided facial palsy associated with infection beginning in the right maxillary sinus. *B.* Ulcer. *C.* Hyphae in tissue.

Other Opportunistic Mycoses

Other fungi causing systemic infections also may produce skin lesions in the process of bloodstream dissemination. The best known of these organisms are *Aspergillus, Scedosporium, Trichosporon,* and *Fusarium*. Skin infection is seen mainly in severely immunocompromised patients such as those with neutropenia.

Aspergillus may produce large necrotic lesions such as ecthyma gangrenosum, but smaller papules and cold abscesses also can occur. [66] *Fusarium* infections may produce widely distributed target-like lesions that may undergo central necrosis and, in some cases, digital cellulitis and superficial white onychomycosis. [67] Treatment for all these infections is usually amphotericin B.

LABORATORY DIAGNOSIS OF OPPORTUNISTIC MYCOSES Laboratory confirmation of the diagnosis is fraught with difficulties chiefly because many of the organisms are also commensals in human sites; since they occur in severely ill patients, the capacity to produce diagnostic antibody titers is compromised. The interpretation of laboratory data is consequently difficult and has to be related to the clinical state of the patient. Ideally, a histologic diagnosis should be made, although biopsy may be impossible because of the risk of bleeding. In many cases, the diagnosis of a systemic mycosis is presumptive, and treatment therefore is given empirically.

Actinomycosis

Actinomycosis is an infection caused by filamentous bacteria that form large granules (sulfur granules) in abscess cavities. Draining sinuses communicate from the center of the abscess to the skin or mucosal surface.

HISTORICAL ASPECTS The first human case was described by Israel in 1878, 1 year after the disease had been recognized in cattle. In 1910, it was first recognized that the organism, *Actinomyces israelii,* was carried in the oral cavity and tonsils. Early literature is full of reports of this infection, which fortunately is seen much less frequently nowadays.
EPIDEMIOLOGY The main causative organism, *A. israelii,* an anaerobic actinomycete, is a normal inhabitant of the human mouth. Actinomycosis is therefore an endogenous infection. *A. bovis, A. naeslundii, Arachnia propionica,* and *Bifidobacterium eriksonii,* all inhabitants of the mouth, are rarer causes of human disease. The incidence of the infection is affected by the availability of good dental care, since poor dental hygiene and delayed treatment of intraoral infections lead to a greater risk of actinomycosis. The disease has a worldwide distribution but is not common. Other sites of carriage include the vaginal mucosa, and this also may affect the development of infection. In most cases of actinomycosis, the formation of granules is thought to require cooperation with other bacteria.
CLINICAL MANIFESTATIONS There are five main types of actinomycosis, depending on the primary site of infection. [68], [69] Actinomycosis usually remains localized. The infections are cervicofacial, thoracic, abdominal, pelvic, and primary cutaneous. Cervicofacial actinomycosis is the most common form of this infection (Fig. 207-20). It usually presents with an indurated nodule or plaque on the cheek or submaxillary region. In the later stages, multiple sinuses develop on the surface; these discharge pus and sulfur granules. The initial site of infection is probably a dental abscess, and it is likely that many cases are now treated before the typical features develop. Sulfur granules are sometimes found in tonsillar crypts after elective tonsillectomy, and in this case, they do not appear to be causing symptomatic illness.

FIGURE 207-20 Actinomycosis, cervicofacial form. *A.* Localized lesion with sinus margin. *B.* Chronic cervicofacial, actinomycosis. (*Courtesy of R. Arenas, MD.*)

Thoracic actinomycosis only presents with skin changes if the underlying lung infection, which mimics pulmonary tuberculosis, involves the outer chest wall. Once again, multiple sinuses communicate with the underlying lung infection. Abdominal actinomycosis usually begins with an abscess in the appendix or cecum. Skin involvement, which is now rare, follows extension of the infection to the anterior abdominal wall with the formation of sinuses. Pelvic actinomycosis is a distinct form of actinomycosis associated with the use of intrauterine contraceptive devices. However, the skin is not affected, and the infection presents as an intrapelvic mass associated with signs of chronic pelvic inflammation. Primary cutaneous actinomycosis is very rare. [70] It occurs on exposed skin and clinically mimics mycetoma; the infection is thought to follow implantation of organisms.
DIFFERENTIAL DIAGNOSIS Actinomycosis has a typical appearance, with draining sinuses related to potential sites of infection. Tuberculosis and mycetoma are the main differentials to be excluded.
LABORATORY DIAGNOSIS The presence of sulfur granules is typical. These are yellow granules up to 1 to 2 mm in diameter that on Gram staining contain a mixture of thin bacterial filaments. Cultures of *A. israelii* are incubated under anaerobic conditions at 37°C. Histopathologically, there is a suppurative inflammatory process, and small abscesses contain the granular colonies of the organism surrounded by neutrophils. With hematoxylin and eosin staining, the outer zone of the granule contains a layer of eosinophilic, refractile, clublike structures.
TREATMENT *A. israelii* is sensitive to sulfonamides, streptomycin, penicillin, chloramphenicol, chlortetracycline,

oxytetracycline, tetracycline, rifampicin, and erythromycin. [71] High doses of intravenous or intramuscular penicillin are the usual treatment given for this infection. The course has to be continued for several weeks. Alternative medications include erythromycin, tetracyclines, and imipenem.

Nocardiosis

Nocardiosis is an acute or chronic infection caused by filamentous bacteria of the genus *Nocardia*. These cause localized skin or subcutaneous infections, including abscesses and actinomycetoma, as well as a systemic infection that may disseminate to involve the skin.

HISTORICAL ASPECTS As with actinomycosis, nocardial infection was first described in cattle in 1888 by Nocard. The first human patient had a disseminated infection with involvement of the lungs and brain. Nocardiosis has become more common because it is associated with immunosuppression.
EPIDEMIOLOGY The main pathogenic species of *Nocardia* are *N. asteroides, N. brasiliensis,* and *N. otitidis-caviarum*. These are soil organisms, but generally, *N. asteroides* is environmentally dominant in northern climates, whereas *N. brasiliensis* is more common in the south. *Nocardia* can gain entry through a superficial wound to cause a localized dermal or subcutaneous infection; it also can be inhaled via the lungs to cause a pulmonary infection. In causing systemic disease, *Nocardia* usually behaves as an opportunistic pathogen, causing disease in patients with an underlying predisposition such as AIDS, solid-organ transplant, Cushing syndrome, diabetes, and following the use of corticosteroids in the treatment of various diseases. Occasionally, there are outbreaks of nocardiosis in hospitals, associated with contamination of ventilation systems. [72]
CLINICAL MANIFESTATIONS Rarely, *Nocardia* can cause a subcutaneous abscess or a lymphangitic form (see "Sporotrichosis" above), in which multiple suppurative nodules develop along a lymphatic chain. [73], [74] and [75] Actinomycetoma due to *Nocardia* species has been described earlier. In systemic nocardiosis, the main sites for infection are the lung or the brain. Lung lesions resemble pulmonary tuberculosis, whereas brain lesions present as intracranial space-occupying lesions and with fever. In about 30 percent of cases of systemic infection there are metastatic cutaneous abscesses, which are often multiple [76]; this is a particular feature of infection in patients with AIDS. [77]
LABORATORY DIAGNOSIS Although *Nocardia* species form grains in mycetomas, in other infections they are present as fine-branching filaments. These can be seen in pus from skin lesions or sputum after staining by Gram stain, methenamine silver, and modified acid-fast techniques because *Nocardia* are only partially acid-fast. The organisms can be cultured on Sabouraud's agar. Serology can be useful in the diagnosis of systemic nocardiosis.
TREATMENT The most widely used treatment is co-trimoxazole. Alternatives include ampicillin, minocycline, amikacin, and more recently, imipenem. Unfortunately, the results of in vitro testing for antibiotic sensitivity may not accurately reflect the subsequent clinical responses.

Viral Diseases: General Considerations

DEFINITION
CLASSIFICATION
VIRAL REPLICATION
CELLULAR CONSEQUENCES OF VIRAL INFECTION
PATHOGENESIS OF VIRAL INFECTIONS IN THE SKIN
HOST RESPONSE
DIAGNOSIS OF VIRAL INFECTIONS
THERAPY AND PREVENTION

REFERENCES

Skin lesions are a prominent feature of many viral diseases. In some instances, cutaneous lesions suggest a specific viral illness whose diagnosis can be quickly established by appropriate procedures. At other times, the differential diagnosis includes several viral and nonviral conditions. This situation may require costly, specialized, time-consuming, and possibly nondefinitive diagnostic procedures. However, the application of new techniques for laboratory diagnosis can shorten the time for diagnosis. To complement advances in diagnosis, there are several effective antiviral agents for treating at least some viral diseases with cutaneous manifestations, and other potential antiviral agents are in clinical trials. Consequently, making the correct diagnosis in viral infection may have important implications for therapy as well as for prognosis. It may also contribute to the surveillance and control of infectious disease within the community. Preventive vaccines have reduced or eliminated several viral infections, and the development of new vaccines against other viruses could have a similar impact on the diseases they induce.

DEFINITION

Viruses form a diverse group of infectious agents that share a distinctive composition and a unique mode of replication. [1], [2], [3] and [4] Viruses are not cellular organisms. Although certain viruses encode a small number of enzymes, viruses do not possess functional ribosomes or other cellular organelles. These agents therefore lack much of the machinery required for their own multiplication. They multiply only inside cells, where they make use of the cellular synthetic apparatus to produce their components. It is because their replication depends on the host cell that viruses are often referred to as “obligate intracellular parasites.”

The most important element of a virus is its genetic information (the viral *genome*), which may be either deoxyribonucleic acid (DNA) or ribonucleic acid (RNA), depending on the type of virus. [5], [6] The life cycle of a virus may be divided into two parts. In one part, the virus exists as an extracellular particle (also called a *virion*), where the viral genetic information is surrounded by a highly organized protein coat that can be seen by electron microscopy. The virion serves to transmit the viral genetic information, functionally intact, to a susceptible host. The second part of the viral life cycle is that period when the viral genetic information is present inside a cell, where it is usually found in a nonparticulate form. Certain pathogenetic aspects of virus infection occur during the nonparticulate portion of the virus life cycle. The duration of this intracellular phase is extremely variable, from a few hours in acute infections, to years when a virus establishes latency.

CLASSIFICATION

All organisms, from bacteria to humans, are susceptible to infection by a range of viruses, but no single virus is capable of infecting all classes of cells. Each virus is broadly classified as a bacterial, plant, or animal virus based on the type of cell it can infect. The animal viruses are divided into several large families according to the size, shape, and structure of the virion and the type of viral nucleic acid within it, as shown in Table 208-1. In the virion, the viral genome consists of only a single type of nucleic acid—either DNA or RNA. Viruses of a given family can be identified by physical methods, such as the size and shape of their virions by electron microscopy, by antigenic cross-reactivity, or by nucleic acid homology. Although viruses are grouped principally according to their virion morphology and nucleic acid composition, a given family of viruses usually shares functional, genetic, biochemical, and immunologic features.

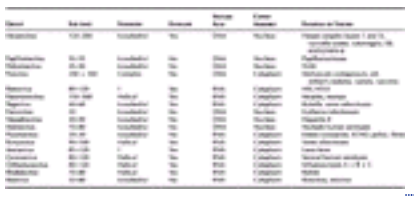

TABLE 208-1 **Selected Animal Virus Groups**

The virion is composed of the viral genetic core surrounded by a protective protein coat called the *capsid*. In certain virus families (such as herpesviruses and retroviruses), the capsids are located inside a virion envelope (composed of lipid, protein, and carbohydrate), which is required for infectivity (Table 208-1). The viral envelope is sensitive to drying, so that infectivity is lost on dry surfaces. The virions of other viruses (such as papillomaviruses) do not possess an envelope, so their capsids are called “naked.” Because the capsid proteins are usually stable in dry environments,

viruses whose virions lack an envelope typically remain infectious for long periods after drying.

In most viruses, the capsid is arranged in one of two patterns: helical symmetry or icosahedral (cubic) symmetry (Table 208-1). Poxviruses have a more complicated structure, which is classified as “complex.” In viruses with helical symmetry, the protein subunits that form the capsid are assembled in an elongated, helical form. The subunits in viruses with icosahedral symmetry are assembled into an icosahedral structure, which is a symmetric polyhedron with 20 equilateral triangular faces. Viruses within a given family may be further classified according to their relatedness at the nucleic acid level, their antigenic cross-reactivity, and the host cells that they infect.

Figure 208-1 shows examples of virions from the three main families of viruses (papillomaviruses, herpesviruses, and poxviruses) that multiply in the epidermis. The viral genomes of these three families are composed of DNA. As noted above, papillomaviruses possess naked (nonenveloped) capsids, and herpesviruses have enveloped virions. Poxvirus virions are large, have a very complex structure, and are enveloped, but their envelope is not required for their virions to be infectious. Hence, poxviruses can remain infectious after drying.

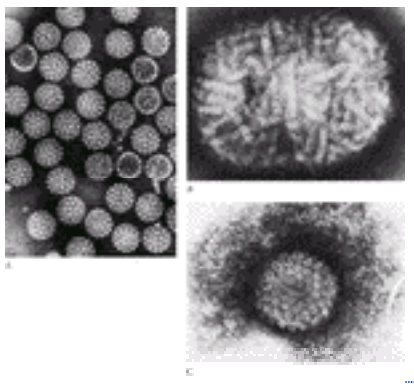

FIGURE 208-1 Electron micrographs of negatively stained virions (×200,000). *A.* Papillomavirus: multiple nonenveloped human papillomavirus (wart) virions showing capsid subunits (capsomeres). *B.* Poxvirus: single molluscum contagiosum virus virion, showing complex tubular structures. *C.* Herpesvirus: single varicella-zoster virus virion showing capsid inside envelope. VIRAL REPLICATION

Viruses replicate inside cells by synthesizing their various structural components separately and then assembling them into multiple virions. [6] This contrasts with cells, which multiply by binary fission (the production of two progeny cells from a single parental cell). Viruses use the host-cell machinery to synthesize and assemble new virions, because these agents do not contain the apparatus required for their own replication.

Viral genomes encode two main classes of proteins. Some virus-encoded proteins are used to form the virions; these proteins are called *structural proteins* or *virion proteins*. Viral genomes also encode *nonstructural proteins*; as their name implies, these proteins do not participate in forming the structural components of the virion. The nonstructural viral proteins often play key roles in the replication of the virus, although they are not usually incorporated into the virion. Acyclovir inhibits herpesvirus replication because the drug is activated inside herpesvirus-infected cells by virus-encoded nonstructural proteins. [7]

Nonstructural proteins of certain viruses may redirect the cell to synthesize the proteins required by the virus at the expense of those required for normal function of the cell. Many tumor viruses, including papillomaviruses, encode nonvirion proteins that increase cell growth and lead to inappropriate control of cell division (see Chap. 37). The intracellular pathogenicity of a virus may be partly due to effects of nonvirion proteins. [8]

The viral replication cycle, which has been studied in detail in tissue culture, involves several more or less sequential steps: attachment (adsorption), penetration, uncoating, biosynthesis, virion assembly, and release. Attachment of virions to cells involves a specific interaction between the viral capsid or envelope (for those viruses that possess enveloped virions) and receptors on the cell surface. For example, HIV enters cells via an interaction between viral envelope protein and two classes of receptors: cellular CD4 receptors and chemokine receptors. [9] Consequently, cells that lack the appropriate cell surface receptors for a particular virus will not be infected by that virus. Although most people are quite susceptible to HIV infection, rare individuals who lack the appropriate chemokine receptors, or who have modified versions of them, may be relatively resistant to HIV infection or the development of AIDS. [10], [11]

Following penetration of the virion into the cell, cellular enzymes degrade the envelope and capsid (uncoating), which begins the nonparticulate phase of the virus life cycle. During biosynthesis, the viral genome instructs the infected cell to produce the proteins encoded by the viral genes. Viruses vary in their size and complexity. The genome of poliovirus, which is a small virus with a simple virion structure, encodes a single precursor protein, which is cleaved to give rise to the structural and nonstructural viral proteins. By contrast, poxviruses, whose virions are more than 10 times larger than poliovirus virions and are much more complex, encode dozens of structural and nonstructural proteins.

The virions of most viruses, including papillomaviruses, herpesviruses, and poxviruses, are assembled inside the cell and released following cell death and lysis. However, enveloped viruses whose virions are assembled at the cell surface (such as retroviruses and paramyxoviruses) are released by budding from intact cells; with these viruses, productive infection and release of virions may or may not be accompanied by toxic effects on the infected cell. Each virus has its characteristic site of replication within the cell. Papillomaviruses and herpesviruses are assembled in the nucleus (Fig. 208-2 and Fig. 208-3). Poxviruses, which are the only DNA viruses that replicate in the cytoplasm, synthesize their

virions in organized cytoplasmic “viral factories” (Fig. 208-4).

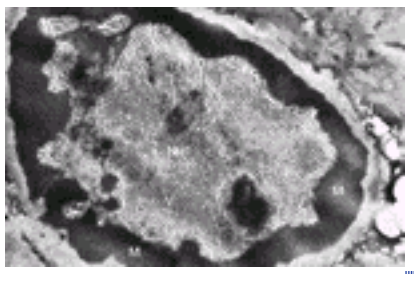

FIGURE 208-2 Papillomavirus-infected cell. Electron micrograph (×20,000). Nucleus (Nuc) of a stratum corneum cell, filled with papillomavirus virions (V); chromatin is marginated (M). Mature keratin can be seen in an adjacent cell (S).

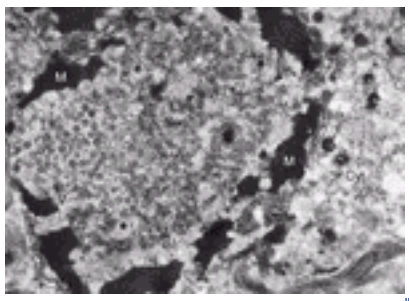

FIGURE 208-3 Varicella-zoster virus (a herpesvirus)-infected cell. Electron micrograph (×24,000). Portion of cell of the stratum spinosum. The nucleus (Nuc) contains varicella-zoster virions (V). Chromatin is marginated at (M). Virions (V) and tonofilaments (T) are shown in the cytoplasm (Cyt).

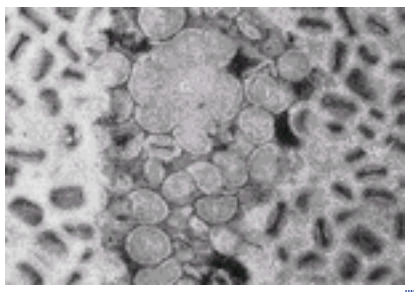

FIGURE 208-4 Molluscum contagiosum (a poxvirus)-infected cell. Electron micrograph (×45,000). Cytoplasm of a spinosum cell filled with mature molluscum contagiosum virions (V), immature virus forms (i), and viroplasm in a gyrate pattern (G).

Typically, hundreds or thousands of new virions are produced from each infected cell, and they, in turn, infect previously uninfected cells. One cycle of virus replication may last from 3 to 36 h, depending on the virus and cell involved. Interruption of any step will prevent the development of new infectious virions.

Each virus can infect and replicate in only a limited number of cell types. The spectrum of susceptible cells depends on the virus. Human papillomaviruses can infect a very narrow range of cells, namely certain differentiating human epidermal cells. Other viruses can infect a much broader range of cells; herpes simplex viruses can replicate in many different human and nonhuman cell types.

Even within a given tissue, a virus may be infectious only for cells with a specific degree of differentiation. The important role of the differentiated state of the cell in determining whether or not a virus will undergo replication is seen in the skin lesions of molluscum contagiosum. Because molluscum contagiosum virus (MCV) particles are sometimes found in cells of the upper dermis, the virus must be capable of attachment and penetration in these cells. MCV does not, however, replicate in dermal cells, indicating that an intracellular block to MCV synthesis exists in the dermal cells. MCV particles are also found in the basal layer of epidermal cells, but synthesis of new viral components does not begin until the cells reach the suprabasal layers. This observation implies that MCV replication can take place only in partially differentiated epidermal cells.

CELLULAR CONSEQUENCES OF VIRAL INFECTION

Typically, infected cells develop gross and often characteristic cytopathic changes and eventually die. Infections of this type are termed *cytocidal* or *lytic*. However, some viruses can replicate without causing irreversible damage to the host cell. Noncytocidal infection of this type may occur in tissue culture with measles virus and many other enveloped RNA viruses, leading to a chronically infected culture. While many retroviruses replicate without killing cells, cell lysis plays an important role in the pathogenesis of HIV infection. [9]

Two other types of noncytocidal infection are neoplastic transformation [12], [13] and viral latency. [14], [15] Tumor viruses, when they transform cells, alter the normal control of cellular proliferation. In general, tumor viruses (such as the polyomavirus SV40) do not synthesize new virions in neoplastically transformed cells, although such transformation requires the continued expression of a portion of the viral genome. It is interesting to note that SV40 is exclusively cytocidal for some cell types (permissive infection), induces transformation exclusively in other cells (nonpermissive infection), and induces both types of infection in still other cell types (semipermissive infection), again underlining the importance of the host cell in affecting the outcome of infection. Epidermal cells are semipermissive for papillomavirus infection. Virus-induced

neoplasia is discussed in greater detail in Chap. 37.

Viral latency, which is a mechanism for evading the host immune response, commonly occurs with herpesviruses and papillomaviruses. Latently infected cells either produce very small numbers of new virions so that spread to uninfected cells is minimal or they synthesize no virions but retain an intact and potentially activatable viral genome.

PATHOGENESIS OF VIRAL INFECTIONS IN THE SKIN

There are several general patterns of viral infection. [15] The most typical is that of acute infection followed by viral clearance, usually by immune mechanisms. This pattern occurs frequently with viruses that produce exanthems, such as measles. Another pattern is that of acute infection followed by latent infection, which may then be followed by viral reactivation. In viruses with cutaneous manifestations, this pattern occurs often with herpes simplex virus, varicella-zoster virus, and papillomavirus. A third pattern is that of chronic infection, as occurs frequently with HIV infection. Often, active infection with some viruses, such as papillomaviruses and MCV, may persist for months or years, even in immunocompetent hosts.

Virus infections may affect the skin by three different routes: direct inoculation, systemic infection, or local spread from an internal focus. In warts, herpes simplex, chickenpox, herpes zoster, molluscum contagiosum, and smallpox, virus shedding from human skin lesions represents an important source in the transmission of virus to other people. Skin lesions may be produced by the direct effect of virus replication on infected cells, the host response to the virus, or the interaction of replication and host response.

The viruses of warts, molluscum contagiosum, vaccinia, orf, milker's nodules, and (primary) herpes simplex, all of which infect the skin by direct inoculation, replicate in the epidermis. Their viral cytopathic effects account for the appearance of early lesions. The immune system presumably contributes to the evolution of those lesions that subsequently develop an inflammatory response. The incubation period is generally short because the lesions develop at the site of inoculation. The incubation period for warts is longer, presumably because the virus replicates slowly or cell-to-cell spread of virus occurs to only a limited extent.

In systemic infections, the skin is infected during viremia, so that the dermis is generally infected earlier than the epidermis. It is not known how the distribution of viral exanthems is determined. In chickenpox and smallpox, the damage from cytocidal infection of the skin is a prime cause of the lesions. On the other hand, there is suggestive evidence from patients with impaired cellular immunity that the lesions of rubella and measles result in part from a cell-mediated immune response to the virus. The basis of most exanthems associated with enteroviral infections remains to be established; there is significant cytocidal viral replication in the skin in hand-foot-and-mouth disease.

Recurrent herpes simplex and herpes zoster represent the local spread of virus to the skin following reactivation of the latent virus present in peripheral nerves. Cytocidal infection clearly plays an important role in these lesions, although lesions may contain less virus than during primary infection, presumably because of immunity.

HOST RESPONSE

The severity of illness induced by a particular virus varies considerably from person to person. While the size of the viral inoculum and the portal of entry play some role, it is believed that host factors usually account for most of this variation. Both immunologic and nonimmunologic responses appear to be important. [8], [15], [16], [17] and [18] Conversely, viral infection may have significant direct and indirect effects on the immune system, especially those viruses that infect lymphoid cells, such as Epstein-Barr virus and HIV. [9]

Antibody responses to viral infection represent the major host defense against reinfection by the same virus; [19] the prophylactic administration of type-specific antibodies can prevent or modify some primary viral infections even in patients with impaired cellular immunity. However, humoral immunity is thought not to contribute to the recovery from most primary viral infections, as viral infection of patients with isolated deficiencies of humoral immunity usually follows a normal course. There are several mechanisms by which antibodies may inhibit the spread of virus. These include neutralization of virus through prevention of viral attachment to target cells (which may be increased by complement); enhancement of viral uptake by phagocytic cells, which then inactivate the virus; and (complement-mediated) immune lysis of infected cells.

Specific cell-mediated immunity (CMI) is also elicited during viral infections and influences the course of many viral infections. CMI is usually protective, although it may sometimes increase the degree of cellular pathology (as in the eruption of measles). Patients with impaired CMI often have difficulty handling primary or recurrent viral infection. Such patients are at risk of developing severe primary virus infections, persistent warts, chronic herpes simplex virus infections, disseminated herpes zoster, and AIDS. The protective antiviral mechanisms have not yet been fully established. Sensitized T cells are known to be capable of lysing infected cells and of liberating lymphokines, which attract phagocytic cells. Natural killer cells, virus-specific cytotoxic lymphocytes, and antibody-dependent cell-mediated cytotoxicity can inhibit infection under experimental conditions.

Inflammatory cells may produce some of their antiviral effects via the production of interferons, a unique family of closely related cytokines that are active against viruses. [20] Interferon, which can be induced by foreign RNA or DNA (including viral nucleic acids), is secreted into the extracellular fluid. Resistance to virus infection is induced in those cells that come in contact with the interferon. Virtually all viruses are capable of inducing interferon and are susceptible to its action, but viruses differ greatly in their degree of interferon induction and in their sensitivity to its action. Interferon is responsible for recovery in several types of virus infection in mice, and the presence of interferon correlates with the recovery phase of several human viral infections. Genetic factors may also play a role in determining the outcome of viral infections. In animal models, cellular genes can determine the susceptibility to viral infection at several levels, including virion

attachment to cells, viral replication, and viral-induced immune responses. [21]

DIAGNOSIS OF VIRAL INFECTIONS

Four major approaches are used in the laboratory to diagnose viral infection: virus isolation, microscopy, detection of viral nucleic acids or viral antigens, and serology. [22], [23] and [24] As with all laboratory tests, the results must be interpreted in the context of the clinical setting. Fortuitous infection with a virus unrelated to the illness should always be considered. For many viruses, considerable progress has been made in the development of relatively rapid assays that are sensitive and specific. [22], [23], [25] Most of these newer assays depend upon the ability to detect small amounts of viral nucleic acids and/or viral antigens.

Cultivation of the virus has represented the traditional “gold standard” for viral diagnosis. Virus isolation is most useful if the suspected pathogen can be readily propagated and positive results can be obtained in a short time. If necessary, more precise identification of the cultured virus can be carried out with specific tests for viral nucleic acid or viral antigen. Culture techniques for herpes simplex virus are quite sensitive, with diagnostic changes in cells often appearing within 1 to 2 days of inoculation. The closely related varicella-zoster virus is much more difficult to grow in culture, leading to frequent false-negative results.

When virus isolation is attempted, specimens should be obtained as early in the disease as possible. In vesicular conditions, fluid from an early vesicle is often a good source of virus. Lesional specimens are less likely to be positive with nonvesicular exanthems. Specimens should also be obtained from additional sites as indicated. Specimens are often collected in a sterile tube with 2 to 5 mL of a buffered isotonic balanced salt solution containing penicillin and streptomycin. Preferably, they should be transported on ice immediately to the laboratory. If this is not practical, specimens should be frozen [at –70°C (–94°F), if possible]. The suspected pathogen(s) should be indicated, because it may determine the type of cell culture or test animal to be inoculated.

The direct identification of a virus in clinical specimens can theoretically be accomplished more quickly than tests that rely on culturing the virus. This approach may be especially useful for detecting those viruses difficult to propagate in culture and those, such as papillomaviruses, for which no reproducible culture system is available. Direct analysis may identify characteristic cells, as with Tzanck smears for herpesviruses (this test will not distinguish between herpes simplex and varicella-zoster viruses) or the histologic appearance of MCV-containing lesions.

The direct identification of virus from clinical material is limited by the sensitivity and specificity of the assay. The use of assays based on detecting viral nucleic acid is having a progressively larger impact on direct identification, initially through molecular hybridization, and more recently through application of the polymerase chain reaction (PCR). [22], [23], [25] This latter technique, which can specifically amplify minute quantities of viral nucleic acid, has revolutionized diagnostic virology. Assays based on PCR and related techniques are extremely sensitive, often being able to detect as few as 1 infected cell in 10,000, and highly specific. The main pitfall of PCR is that its great sensitivity makes it very susceptible to yielding false-positive results via cross-contamination with minute quantities of viral nucleic acid. However, meticulous attention to detail and appropriate controls can usually overcome this potential liability.

More traditional techniques are also available. For those lesions that contain large numbers of viral particles, electron microscopy of a lesion or its extract may provide morphologic identification of the virus. [24] The positive identification of specific viral antigen in clinical material through use of immunologic techniques permits a more specific diagnosis than direct microscopy. For example, immunologic techniques can distinguish between herpes simplex virus and varicella-zoster virus. Radioimmunoassay, enzyme-linked immunosorbent assay, immunoelectron microscopy, fluorescent antibody, or immunoperoxidase techniques identify viral antigen by the use of viral-specific antibody.

Serologic studies to detect viral antibodies may be important for epidemiologic purposes, for identifying infection with viruses such as HIV and hepatitis B, and for those situations where acute sera contain diagnostic antibodies, as with heterophile antibodies in infectious mononucleosis. In most acute viral illness, serologic analysis requires acute and convalescent sera, which limits its use in that setting to making a retrospective diagnosis. Paired sera are required because a positive serology during the acute phase may merely mean the individual was infected previously with a member of that virus family, but it does not have implications for the etiology of the current illness. The acute specimen should be taken as early in the illness as possible and the convalescent specimen 2 to 4 weeks later. Serum should be separated immediately from the coagulated blood and refrigerated or preferably frozen at –20°C (–4°F) until antibody tests can be run simultaneously on both specimens. A fourfold or greater rise in antibody titer between the first and second specimen generally indicates recent infection. A variety of assays are used to measure antibody levels, each detecting a certain type of antigen-antibody reaction. The antibody titer of a given serum is defined as the reciprocal of the highest dilution that gives a positive reaction.

THERAPY AND PREVENTION

Prophylaxis of viral infection has thus far proved more successful than the specific treatment of established infection. Vaccines have been extremely useful in the prevention of a variety of viral illnesses. [19], [26], [27] Recombinant DNA techniques are making it possible to develop effective subunit vaccines composed only of viral protein, rather than traditional vaccines, which represent either an attenuated strain of the pathogen or an inactivated preparation of the entire virus. [28], [29] In addition to vaccines that induce active immunity, the passive administration of type-specific antibody soon after exposure can prevent chickenpox in compromised hosts. Sensitive procedures for the detection of hepatitis B and HIV infection in potential blood donors has drastically reduced the incidence of transmission of these agents by transfusion.

Because viruses are adapted to the cells they infect and because they make use of the cellular machinery, many chemotherapeutic agents that have been considered as potential antiviral agents affect cells to about the same extent as

they affect viruses. However, this difficulty has already been overcome in several instances, and additional antiviral agents are under development (see Chap. 260). [7], [30], [31] Most antivirals seek to exploit a specific property of a particular virus. Azidothymidine (AZT) and several protease inhibitors, which are approved for use in the treatment of HIV infection, interfere with HIV replication by preferentially inhibiting synthesis of the viral genome and the processing of viral proteins, respectively. [9], [32], [33] Acyclovir, an antimetabolite that is approved for use in selected herpesvirus infections, is preferentially activated by herpesvirus-infected cells through its affinity for two herpesvirus enzymes involved in DNA synthesis. Interferon is a potentially potent antiviral agent that inhibits most viruses and at low dosages is relatively nontoxic to cells. Interferon has been approved for use in treatment of certain genital papillomavirus infections and has also been helpful in the management of some children with papillomas of the larynx.

Rubella (German Measles)

EPIDEMIOLOGY
CLINICAL MANIFESTATIONS (Table 209-1)
COMPLICATIONS
LABORATORY FINDINGS
CONGENITAL RUBELLA (Table 209-2)
Diagnosis
IMMUNITY AND IMMUNIZATION
REFERENCES

Rubella (German measles) is a common communicable infection of children and young adults characterized by a short prodromal period; enlargement of cervical, suboccipital, and postauricular glands; and a rash of approximately 2 to 3 days' duration. The disease has rare sequelae and, were it not for its devastating effect on the fetus, would be of relatively little significance in terms of morbidity or complications.

EPIDEMIOLOGY

Prior to immunization programs, epidemics of rubella were noted at 5- to 7-year intervals. The disease is worldwide in its distribution and tends to occur most frequently during the spring months in North America. During the past decade, fewer than 200 cases were reported in most years in the United States. [1] It is rare in young infants and is most common in school-age children, adolescents, and young adults. Recent outbreaks in North America have occurred in young men in Latino communities who have come from countries without immunization programs. [2] Through these outbreaks, viruses that are common abroad have been introduced into the United States. [1] It is spread via the respiratory route, and the period of infectivity extends from the end of the incubation period to the disappearance of the rash. A single attack confers lifelong immunity in most individuals, although subclinical reinfections can be demonstrated by laboratory tests in some “immune” individuals who are subsequently exposed to the wild virus. Two attacks of rubella with rash are most unlikely to be encountered; in such instances, one of the episodes is usually not rubella but is caused by another viral infection.

The virus of rubella may be recovered from the pharynx as early as 7 days before and up to 14 days after the onset of the rash. Viremia is rarely demonstrated after the onset of the rash. [3]

CLINICAL MANIFESTATIONS (Table 209-1)

TABLE 209-1 **Some Distinctive Features of the Rashes of Rubella, Measles, and Scarlet Fever**

The incubation period ranges between 14 and 21 days and is usually 16 to 18 days. Prodromal signs and symptoms are rare in young children, and the rash usually appears without prior complaint. In older children, adolescents, and adults, low-grade fever, headache, conjunctivitis, sore throat, rhinitis, cough, and lymphadenopathy may precede the rash by 1 to 4 days and disappear rapidly after the rash appears. In some adults, however, these symptoms and signs may persist longer and be more severe, and the infection under such circumstances may be difficult to distinguish from rubeola (measles) unless Koplik's spots, characteristic of measles, are observed. The rash of rubella is first noted on the face (Fig. 209-1) and rapidly spreads to the neck, arms, trunk, and legs. It consists of pink-red macules and papules that are discrete and remain so on the extremities, coalescing on the trunk to give a uniform red blush.

FIGURE 209-1 Rubella. Erythematous macules and papules appearing initially on the face and spreading usually within 24 h.

The rash, which usually disappears by the end of 2 or 3 days, clearing first from the face, may occasionally be followed by fine desquamation. This rapid disappearance is in contrast to measles (rubeola), in which the rash persists for longer periods. An enanthem is often seen at the end of the prodromal period or beginning of the rash, consisting of red spots, pinhead in size, scattered over the soft palate. The lymphadenopathy of rubella is striking; it involves all lymph nodes, but enlargement and tenderness are most common in the suboccipital, postauricular, and anterior and posterior cervical nodes. In older children and adults, lymphadenopathy may be noted several days before the rash; but in both children and adults, the enlargement and tenderness are most striking on the first day of the rash. Enlargement of glands may persist for days to weeks, but tenderness rapidly subsides. Splenomegaly may occasionally be detected. The fever of rubella is usually of low grade and seldom lasts beyond the first day or two of the eruption except in individuals who have joint involvement, in whom fever may persist. Arthritis caused by rubella occurs much more frequently in adults than in children, and is usually first noted as the rash fades. Small and large joints may become painful, with or without swelling, possibly simulating rheumatic fever or rheumatoid arthritis. In one epidemic, joint involvement was seen in 25 percent of children younger than 11 of years age and in 52 percent of patients 11 years of age or older. [4] Striking effusions into joints have been reported. The arthritis of rubella usually lasts 1 to 2 weeks but occasionally may persist for longer periods or may be recurrent.

COMPLICATIONS

Rubella is essentially a benign disease. Rarely, it may produce an encephalitis, which tends to be mild and is usually followed by complete recovery and no effect on intellectual function. Thrombocytopenic purpura, which may result from rubella, may be accompanied by epistaxis, petechiae, ecchymoses, intestinal hemorrhage, and hematuria. These manifestations frequently clear within a month of onset but may occasionally persist for longer periods. Rarely, a peripheral neuritis may follow rubella.

LABORATORY FINDINGS

The white blood cell count is usually low but may be normal. Increased numbers of atypical lymphocytes may be noted, and in some cases, increased numbers of plasma cells have been reported. Among patients with meningoencephalitis, varying numbers of lymphocytes may be found in the cerebrospinal fluid (CSF).

TABLE 209-2 **Some Manifestations of the Congenital Rubella Syndrome**

Gregg, in 1941, [5] was the first to record the devastating effects of rubella infection in the fetus and to describe the congenital rubella syndrome. Approximately 50 percent of infants who acquire rubella during the first trimester of intrauterine life will show clinical signs of damage from the virus. The earlier the infection, the more severe the fetal damage. In such infants, multiple congenital defects include low birth weight, microcephaly with mental retardation, cataracts, nerve deafness, and congenital heart disease (usually patent ductus arteriosus or ventricular septal defect).

Following completion of organ development in the fetus, infection with rubella may produce a variable clinical picture, which may include hepatitis, splenomegaly, pneumonitis, myocarditis, encephalitis, and osteomyelitis. When the bone marrow is affected, the infant may be born with thrombocytopenia and bleeding into the skin, producing a striking picture of petechiae and ecchymoses given the colorful term “blueberry muffin baby.” In congenital rubella, a retinopathy consisting of a diffuse deposit of black pigmentation is commonly found.

Diagnosis

Infants with congenital rubella may be chronically infected for many months. Virus can be cultured from the nasopharynx, urine, CSF, and even the lens of infants with congenital cataract. As time passes, the amount of virus shed in the nasopharynx and urine gradually declines and disappears. Approximately 85 percent of infants infected in utero will excrete virus in the first month of life; 1 to 3 percent continue to excrete virus in the second year of life. The large amounts of virus from congenitally infected infants are very hazardous to pregnant women working with such infants who may be susceptible to infection. The infant with congenital infection will usually have elevation of IgM as a result of antibody produced by the infant itself, together with elevated IgG caused by passive transfer of antibodies in the maternal blood. IgG traverses the placenta, in contrast to IgM, which does not. The IgG antibodies disappear over the first few months of life. Passively acquired IgG by the fetus from an immune mother may explain the rarity of acquired rubella in early infancy. The antibodies against rubella consist of neutralizing, complement-fixing, and hemagglutination-inhibition antibodies. Neutralizing and hemagglutination-inhibition antibodies usually persist for life. The hemagglutination-inhibition antibodies are easily and quickly measured and serve to determine whether a recent infection can be attributed to rubella by an increase in titer in the convalescent period over the titer in the acute stage. A fourfold increase or more is considered diagnostic of the infection. Testing for these antibodies also enables the physician to determine whether a woman of childbearing age is immune or susceptible to German measles.

More sensitive tests—latex agglutination, fluorescence immunoassay, passive hemagglutination, hemolysis in gel, and enzyme immunoassay—are now available.

IMMUNITY AND IMMUNIZATION

Lifelong immunity usually follows an attack of rubella. Reinfection can occur but is usually not accompanied by clinical signs and symptoms. A rise in antibody level can occur; viremia from subclinical reinfection is very rare. Thus, congenital rubella is very unlikely in an infant whose mother has had an attack of rubella in the past and acquires a reinfection during pregnancy. In these instances, evaluation of fetal blood obtained by cordocentesis for specific rubella IgM antibodies or for evaluation by newer techniques using polymerase chain reaction (PCR) may help to confirm a diagnosis of fetal infection. [6], [7] The availability of rubella vaccine [8], [9] and its widespread use has markedly reduced the frequency of congenital infection.

In the United States, rubella vaccine is usually given together with mumps and measles vaccines in a single injection [mumps, measles, rubella (MMR)] at the age of 12 to 15 months and again at school entry (4 to 6 years of age).

Recommendations have been that rubella vaccine should not be given to a pregnant woman. Recent studies indicate that no cases of congenital rubella syndrome were seen among infants born to women who had been inadvertently vaccinated against rubella within 3 months of or early in pregnancy. Based upon this evidence the recommendation now is that pregnancy should be avoided for 28 days rather than 3 months following immunization. [10] Asymptomatic infections have occurred, but as noted, no cases of congenital defects have been documented. Interruption of pregnancy is not indicated.

The child or adult to whom rubella vaccine is administered does not shed sufficient virus to infect susceptible individuals in close contact. As a result, it is safe to immunize children in a family in which the mother is pregnant. [11]

REFERENCES

Measles is a universal, highly contagious, acute viral disease of childhood. It is characterized by high fever, cough, coryza, conjunctivitis, and Koplik's spots, which precede the appearance of a florid, generalized macular and papular rash.

HISTORICAL ASPECTS

The term *measles* is thought to come from the Latin *misellus* or *misella,* a diminutive of the Latin *miser,* eaning "miserable," which described the inmate of a medieval leper house. *Morbilli,* the diminutive of *morbus,* was introduced to distinguish minor rash disease from bubonic plague, *morbus,* the major disease. *Morbilliform* is a synonym for *measles-like;* it is still in common use.

No accurate information is available on the early history of measles. The tenth-century Arabian physician Rhazes generally has been credited with distinguishing measles from smallpox, although he cited El Yehudi, a Hebrew physician from the first century, as first describing the disease. However, it was probably not until the severe epidemics of measles during the seventeenth century that these diseases were clearly separated; e.g., the astute clinical and epidemiologic observations of Thomas Sydenham were completed at this time. [1]

In more recent times, transmission of measles to monkeys was first reported by Josias, [2] and other investigators [3], [4] demonstrated that monkeys could be infected with blood or nasopharyngeal secretions obtained from patients.

The isolation of measles virus in tissue culture by Enders and Peebles [5] provided the essential techniques for definitive characterization of virus excretion and antibody response in this disease and for its ultimate control. In 1960, Enders and coworkers successfully attenuated measles virus, [6] and after extensive field trials, a live measles virus vaccine was licensed for general use in the United States in 1963. Since that time, the administration of over 300 million doses of vaccine has almost eliminated indigenous measles within the United States.

EPIDEMIOLOGY

Measles is a universal illness, worldwide in distribution, that occurs primarily in children. However, the age incidence varies according to the environmental setting. In congested urban areas, the highest attack rate occurs in infancy and early childhood. In rural and less crowded areas, the attack rate is highest in the early school years, at ages 5 to 10 years. When measles has been introduced into isolated communities, the attack rate has approached 100 percent among the susceptible population of all ages. Very young infants, under 4 months of age, are usually protected by the persistence of transplacentally acquired maternal measles antibody.

Neither race nor sex affects the attack rate of measles, but the general state of health and nutrition clearly affects morbidity and mortality rates. Measles is primarily a disease of winter and spring in temperate climates, with the peak incidence of infection usually occurring in March or April.

The epidemiology of measles has changed dramatically because of the impact of massive immunization programs for eradication of the disease. The Measles Elimination Program, aided by a policy of school exclusion for those without proof of measles immunization, reduced the total number of reported cases in the United States to approximately 100 in both 2000 and 2001 (CDC/NIP/ESD personal communication to author, July 2, 2002). Almost half these cases can be attributed to importation from other countries. However, this success leaves no room for complacency. Low immunization rates among urban poor infants and young children allowed tragic epidemics of measles during the 3-year period 1989 to 1991, when 18,000, 28,000, and almost 10,000 cases, respectively, were reported nationally. Black and Latino infants and preschool children bore the brunt of the epidemic. Hospitalization and death rates were remarkably high (see "Complications" below). As a consequence of increased efforts targeted at high-risk groups and the requirement that a second dose of measles vaccine be given before school entry, by 1995, the number of confirmed cases of measles in the United States declined to 301. In 1996, the number increased slightly to 508 cases, but the striking finding was that 34 percent of the patients were above 19 years of age. This older group missed the introduction of the second dose of

vaccine. [7] Further local efforts, the impact of the second dose of measles vaccine, and expanded efforts in other countries of the western hemisphere have contributed to the current situation in the United States and, in fact, to only approximately 2000 cases in Central and South America. Isolated, serious outbreaks still occur even in countries with generally high immunization rates. Nearly 3300 cases were reported in the Netherlands in 2000 among a community with religious objections to immunization. Japan still has an estimated 100,000 to 200,000 cases anually, associated with 50 to 100 deaths. In Africa and Asia, approximately 30 million cases of measles still contribute to almost 900,000 fatalities annually. Public and private resources are currently being marshalled to ensure that immunization becomes available in these areas.

ETIOLOGY AND PATHOGENESIS

Measles virus has been classified as a paramyxovirus. Its structure and many of its biologic properties are similar to those of the larger members of the myxovirus group, i.e., mumps, Newcastle disease virus (NDV), and parainfluenza viruses. It is a heat-labile virus with an RNA core and an outer envelope of protein and lipoprotein. The virus is stable at low temperatures (especially in the presence of protein) but is inactivated rapidly by ultraviolet radiation, ether, trypsin, acetone, and beta-propiolactone. Complement fixation, hemagglutination, and hemolysis are properties of the virus that have been used for laboratory diagnosis (see " Diagnosis" below). The virus has been adapted by serial passage to grow well in numerous continuous cell lines.

At the time of the initial isolation of measles virus in tissue culture, certain characteristic cytopathic effects were noted that were strikingly similar to previously well-recognized pathologic changes occurring during natural infection in humans. These included formation of syncytia and multinucleated giant cells with intranuclear and intracytoplasmic eosinophilic inclusions.

Measles virus is antigenically stable and distinct from mumps virus and the other larger myxoviruses. There is some degree of cross-reactivity with the agents of canine distemper and bovine rinderpest, but these cause no difficulty in serodiagnosis in humans.

The natural route of infection is by droplet spread of infectious secretions from an infected patient to the respiratory tract of a person who is susceptible. It is suspected that after local multiplication at this site of entry, there may be an early viremia, but this has not been documented. During the prodromal period, virus can be detected in nasopharyngeal secretions, lymphatic tissue, blood, and urine, [8] and virus may persist in the urine for 4 days after onset of the rash. [9] However, viremia and pharyngeal shedding of virus cease by the second day of rash, a time when measles antibody reaches detectable levels in the serum.

The mechanism of the rash has not been established; rash may be a direct effect of viral invasion on epithelial and vascular endothelial cells, or it may result from the damaging effects of a virus-antibody complex. In support of the latter theory is the temporal relationship between onset of rash and appearance of antibody (the same is true in rubella, another exanthem) and the absence of rash in the few rare children, usually those with leukemia, who have developed chronic measles infection without rash or antibody production but with fatal giant cell pneumonia. [10] The experience of these children is in sharp contrast to that of children with classic (Bruton-type) agammaglobulinemia, who respond to measles infection in a normal fashion. [11] Delayed allergy (tuberculin-type skin sensitivity) is intact in these children, and they may make small quantities of humoral antibody as well. Similarly, two complications of measles, encephalitis and thrombocytopenic purpura, are suspected of having an allergic basis, but direct evidence is not available to clarify these points.

CLINICAL MANIFESTATIONS

The course of measles may be divided into three distinct phases: (1) an essentially asymptomatic incubation period of 10 or 11 days following exposure, (2) a prodromal phase characterized by fever, malaise, and increasingly severe coryza, conjunctivitis, and cough that persists for 3 or 4 days, followed by (3) onset of the rash, which usually reaches its maximum within several days and rarely persists longer than 5 to 6 days. The pathognomonic Koplik's spots usually appear in the mouth 24 to 48 h before onset of the rash and may remain discrete for 2 or 3 days. A typical clinical course is illustrated in Fig. 210-1.

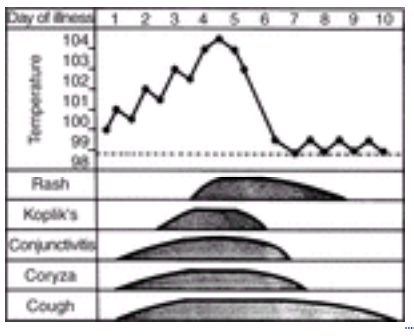

FIGURE 210-1 Schematic diagram illustrating the clinical course of typical measles. (*From Krugman S, Ward R: Infectious Diseases of Children, 3d ed. St. Louis, Mosby, 1964, with permission.*)

Prodromal Symptoms

The coryza, conjunctivitis, cough, and fever that characterize the measles prodrome increase in severity until the rash has reached its peak. The coryza is similar to that in a severe common cold. The conjunctivitis is most strikingly palpebral, extending to the lid margin, so that the eyes appear to be red-rimmed. Lacrimation, lid edema, and

photophobia accompany the conjunctivitis. A brassy or barking cough, due to diffuse involvement of the tracheobronchial tree, may be quite severe even in the absence of a complicating pneumonia and may persist for a week after the coryza. The temperature frequently reaches 40 to 40.5°C (104 to 104.9°F) at the peak of the rash but falls promptly to normal in the absence of complications. Generalized adenopathy is common in measles.

Rash

After a prodromal period of 1 to 7 days, an erythematous, discrete, macular and papular rash (Fig. 210-2B, Fig. 210-2C) appears behind the ears and over the forehead. It spreads down over the neck and trunk and then distally over the upper and lower extremities. The hands and feet are involved. This progression is usually complete, and the rash most intense, within 3 days, which coincides with the peak of the other major clinical signs of fever, cough, and conjunctivitis. Those areas in which the rash appears first tend to be most heavily involved, and confluence of lesions on the face and upper neck is common. Lesions on the legs usually remain discrete and macular and papular. The exanthem begins to fade in the order of its appearance; sometimes clearing of the face begins on the third day while the eruption is still discrete and fresh on the legs. Although the early erythematous rash blanches on pressure, the fading rash consists of brown staining (inflammatory melanosis with old hemorrhage) that does not blanch. [12] Variable degrees of fine, branny desquamation may be present as the rash clears. In the United States, the desquamation is never as extensive as that which may occur in severe scarlet fever, but desquamation has been described as quite marked in other areas of the world, such as Nigeria. [13]

FIGURE 210-2 Measles (rubeola; morbilli) has a characteristic prodrome of 3 to 4 days that consists of coryza, a striking palpebral conjunctivitis with photophobia, and a “barking” cough. The first lesions appear on the soft palate as blotchy erythema, but the most pathognomonic lesions of the prodrome, if present, are Koplik's spots (*A*), which appear as tiny white lesions surrounded by an erythematous ring (“grains of sand”). Koplik's spots precede the onset of the generalized rash by 1 to 2 days, remain for 2 to 3 days, and usually are heavily clustered on the buccal mucosa opposite the second molars. The purplish-red rash on the body appears first behind the ears and over the forehead and then spreads slowly to involve the entire body by the third day: the eruption extends downward over the neck, shoulders, and trunk and then distally over the upper and lower extremities; the spread of this rash over the central parts of the trunk (*B*) first is in contrast with that of German measles, which spreads rapidly to involve the entire body in 1 day. The measles rash remains in its original site while it spreads to the extremities, in contrast with the rash in rubella, which disappears from each site as it spreads. The erythematous macular and popular lesions, which were discrete (*C*), become confluent on the face and upper part of the neck, whereas they may remain discrete on the legs. As the rash disappears, it becomes brownish-yellow owing to capillary hemorrhages.

The severe hemorrhagic measles (“black measles”) associated with extreme toxicity, respiratory tract and gastrointestinal bleeding, hyperpyrexia, and a significant mortality rate is now rare and should not be confused with the purpuric lesions that may be seen in fair-skinned children during the course of ordinary measles.

Oral Lesions

The earliest oral lesions, according to Weinstein, [12] are a series of pinpoint elevations connected by a network of minute vessels on the soft palate. These red dots then coalesce as the entire pharynx becomes reddened. Herrman spots, bluish-gray or white areas on the tonsils, also may be present. Neither of these lesions is pathognomonic of measles. The pathognomonic lesions of measles described by Henry Koplik, [14] a New York pediatrician, begin as small, irregular, bright-red spots that usually precede onset of the rash by 24 to 48 h. In the center of each red spot is a minute bluish-white speck. These Koplik's spots are clustered most heavily on the buccal mucosa opposite the second molars (see Fig. 210-2A), but occasionally they are seen on the conjunctivae at the inner canthus and, at autopsy, in the large intestine. [15] During the first day of rash, Koplik's spots are usually easy to see as a cluster of fine grains of sand on a red background. They normally become less distinct as the rash progresses.

COMPLICATIONS

The complications of measles fall into two categories: those which are due to the measles infection alone and/or the patient's response to the infection and those due to superinfection with pathogenic bacteria. Encephalitis, which occurs in approximately 1 of every 800 cases, is the most dreaded and unpredictable complication of measles. Although most children recover completely, death or permanent brain damage occurs in a significant minority of children who develop measles encephalitis. Purpura, usually associated with thrombocytopenia, may be severe. These complications may be due to a direct effect of measles virus on the target tissues, or there may be an immunologic component. Common bacterial complications are otitis media and pneumonia caused by the pneumococcus, group A hemolytic *Streptococcus, Hemophilus influenzae,* or occasionally, *Staphylococcus aureus*. The onset of these complications is frequently accompanied by a secondary fever spike or prolongation of fever at a time when defervescence ordinarily would be expected.

Complication rates have always been higher among the very young, the malnourished, and those with other underlying diseases. The last serious outbreaks in the United States (1989–1991) were focused in just such inner-city populations.

Approximately one-third of cases were in children under 4 years of age.

Hospitalization rates of 15 to 20 percent, usually attributed to dehydration and/or respiratory distress, were associated with measles itself or bacterial superinfection. Although most of the deaths occurred in young children, almost one-third of the 97 deaths in 1990 were in adults. Some of the deaths in adults were in individuals known to be immunocompromised (e.g., HIV-infected). Death rates reached almost 4 per 1000 cases, far higher than the less than 1 per 1000 experienced in the United States in the prevaccination era but still tenfold lower than the rate seen among malnourished children in developing nations.

Measles may aggravate or exacerbate tuberculosis. The reasons for this and for the transient anergy it produces are unknown. Both measles and measles vaccine may depress the tuberculin skin test reaction for 2 or 3 weeks.

A complication, new since the vaccine era, has been described in children who received killed measles virus vaccine and subsequently were exposed to and infected with natural measles. [16] Some of these children have developed atypical infection characterized by urticarial, vesicular, and petechial rashes, swollen hands and feet, severe pneumonia, high fever, and extreme prostration. Although children may be quite sick with this syndrome, the illness appears to be self-limited. Similarly, administration of the live attenuated measles virus vaccine after prior immunization with the killed vaccine may produce erythema, edema, and even vesiculation at the injection site, with or without fever for several days.

Another late-developing complication of measles is subacute sclerosing panencephalitis (SSPE). Patients with this progressive and usually fatal disease recover uneventfully after acute measles. Months or years later, mental and motor deterioration, often with myoclonic seizures, are associated with a characteristic spike-and-wave pattern of the electroencephalogram, remarkably elevated serum and cerebrospinal fluid (CSF) measles antibody titers, and elevated total CSF IgG. In brain tissue, measles virus antigen has been demonstrated by immunofluorescence, measles-like nucleocapsids have been seen on electron microscopy, and infectious virus with the characteristics of measles has been isolated in tissue culture by meticulous techniques of cocultivation and serial passage. Fortunately, this rare complication (estimated at 5 to 10 cases per million cases of measles) appears to be even less common among children protected by attenuated measles vaccines (1 case per million doses of vaccine).

LABORATORY FINDINGS

In uncomplicated measles, routine laboratory tests are unremarkable and not particularly helpful. There is a mild leukopenia, and the chest roentgenogram frequently reveals an increase in bronchovascular markings. Cytologic examination of nasal secretion and sputum may demonstrate characteristic multinucleated giant cells.

Isolation of measles virus from blood, urine, or pharyngeal secretions during the prodromal and early rash period (see “ Etiology and Pathogenesis” above) requires virus laboratory facilities, which are available in only a limited number of research and reference institutions.

Serologic tests for measles include measurements of neutralizing, complement-fixing (CF), and hemagglutination-inhibiting (HI) antibodies. Paired sera taken shortly after onset of rash and 2 to 3 weeks later will show diagnostic (fourfold or greater) rises in measles antibody measured by each of these tests. Neutralizing and HI antibodies persist at detectable levels for many years after natural infection (probably for life in most instances), but CF antibody persistence is not so predictable. [17] The most sensitive and convenient of these serologic tests are the HI technique [18] and the enzyme-linked immunosorbent assay (ELISA). [19] These tests, which are specific for measles, can be most helpful in clarifying the cause of the unusual case of atypical measles. Bacterial superinfections and measles encephalitis usually are associated with a polymorphonuclear leukocytosis.

PATHOLOGY

The measles exanthem begins with hyaline necrosis of epidermal cells, followed by exudation of serum around the superficial vessels in the dermis and by proliferation of endothelial cells. [20] The epithelial cells become necrotic. Intranuclear inclusions may be seen. In the later stages, there is leukocytic infiltration of the dermis and lymphocytic cuffing of vessels. In uncomplicated measles, the invariable presence of multinucleated giant cells in the respiratory tract and lymphoid tissues (Warthin-Finkeldey cells) throughout the body has been accepted as evidence of measles virus invasion of these tissues (see “ Etiology and Pathogenesis” above). Tracheobronchitis is as much a part of measles as the exanthem. Rarely, a fatal penumonia, characterized by the presence of giant cells in the lungs, occurs in children with underlying disease such as leukemia. The histopathologic characteristics of measles encephalitis are similar to those observed in other postviral encephalitides. Early lesions include lymphocytic infiltration of the walls of small veins in gray and white matter, measured cellular infiltration, degeneration of ganglion cells, and microglial proliferation. Perivascular demyelinization follows these initial changes. Adams et al. [21] described intranuclear and intracytoplasmic inclusions and small giant cells in brain tissue obtained from fatal cases of measles encephalitis. Confirmation of these observations by others would add indirect support to the concept that direct invasion of the CNS by measles virus is of pathogenic significance in measles encephalitis.

DIAGNOSIS

The clinical course of full-blown measles is so characteristic that diagnosis should represent no problem. The 3- to 4-day prodrome of cough, conjunctivitis, and coryza, with appearance of Koplik's spots, followed by a macular and papular rash, is unambiguous. Laboratory confirmation is usually not necessary. However, when measles has been modified by prophylactic administration of human immunoglobulin at the time of exposure (see “ Treatment” below), the disease may be significantly attenuated; it may consist of various combinations of brief fever, cough, and rash, or it may be subclinical.

The unusual clinical picture seen in patients who develop measles despite prior immunization with inactivated (killed)

measles vaccine may be diagnosed on the basis of a prior history of such immunization and recent measles exposure (see " Complications" above).

TREATMENT

As in other systemic viral infections, there is no specific therapy for measles. Supportive therapy consisting of rest, diet, hydration, aspirin, a vaporizer, and mild antitussive agents appropriate for the febrile child with tracheobronchitis is frequently helpful in management of the self-limited disease. The prophylactic administration of antibiotics is unwarranted because it does not prevent bacterial complications and, in fact, may predispose the patient to superinfection with a treatment-resistant organism. [22] Antibiotic therapy should be instituted promptly, however, if bacterial complications develop (see " Complications" above). Therapy for measles encephalitis is also supportive.

PREVENTION [23], [24], and [25]

Measles is preventable. Guidelines for using the highly effective and safe live attenuated measles vaccine (licensed in 1963) have continued to evolve in response to the vaccine-induced changing epidemiology of the disease. A single dose of vaccine produces detectable levels of measles antibody in approximately 95 percent of recipients. Immunity from vaccine is protective against this disease, presumably for life, in most or all of those who seroconvert. However, it has become clear in recent years that the 5 percent of children who fail to respond to an initial dose of measles vaccine have provided a reservoir for continued outbreaks of disease, especially in settings where large numbers of adolescents and young adults congregate (e.g., college and high school campuses).

In 1989, because of the morbidity and costs associated with the outbreaks among young people, public health authorities in the United States adopted a two-dose measles immunization schedule (a practice already in place in 10 European countries). In the United States, the first dose of vaccine is usually given at age 15 months to avoid an interfering effect from maternal measles antibody. The second dose is given prior to school entry or early in elementary school.

The major epidemics of measles experienced in 1990 and 1991 were not due to vaccine failure (i.e., the 5 percent who fail to respond to the first dose of vaccine). The failure has been in distributing vaccine to poor children. Measles vaccination rates for inner-city children 2 years of age dropped to less than 50 percent, setting the stage for epidemics with a lower age distribution and higher complication and death rates than experienced previously in the United States. For control of epidemic measles, the timing and number of subsequent doses of vaccine are now adjusted by local health officials. The first dose may be given as early as 6 months of age. An extra dose after age 15 months but before school entry may be required in certain communities. It is likely that recommendations concerning the timing, number of doses, and perhaps even route of administration of measles vaccine will continue to evolve.

Significant controversy has been generated by unconfirmed but widely publicized reports that measles vaccine (as measles-mumps-rubella vaccine, or MMR) is a cause of autism spectrum disorder. Extensive reviews by respected panels of the Medical Research Council (United Kingdom), the American Academy of Pediatrics, and the Institute of Medicine (IOM) of the National Academy of Sciences have concluded that current scientific evidence favors rejection of a causal association between autism and MMR vaccine (IOM Report, May 2001). Nevertheless, immunization rates have fallen as low as 65 percent in parts of the United Kingdom, and serious concern exists of a resurgence of measles in that country.

Immune serum globulin (ISG) may be used to modify or prevent measles if given within 6 days of exposure. The recommended dose is 0.25 mL/kg of body weight, given intramuscularly. ISG is especially valuable for infants too young for active immunization. For children and adults who are immunosuppressed, the dose is 0.5 mL/kg. The maximum dose is 15 mL. In contrast to other congenital or acquired causes of immunosuppression, HIV infection is not a contraindication for measles vaccination, but when exposed, such children should still receive ISG.

COURSE AND PROGNOSIS

Uncomplicated measles runs a self-limited course, lasting about 10 days, with no sequelae. However, the prognosis varies greatly with the age of the patient, his or her nutritional and general health status, and perhaps access to early and appropriate supportive care. Prior to widespread immunization, approximately 500 deaths were attributed to measles each year in the United States. In the early 1980s, when measles cases dropped to an average of only 3000 yearly, deaths were few. In 1990, with almost 100 deaths, the rate of almost 4 per 1000 greatly exceeded the death rate of 3 per 10,000 that characterized the preimmunization era rate for infants in the United States. Morbidity and mortality in developing nations, where poverty prevents access to care, continue to reflect the general health status of children in these areas, with measles a major contributor to infant mortality. This experience offers ample justification for the World Health Organization's Expanded Program for Immunization.

Hand-Foot-and-Mouth Disease

HISTORICAL
EPIDEMIOLOGY
PATHOGENESIS
CLINICAL MANIFESTATIONS
HISTOPATHOLOGY
DIAGNOSIS
DIFFERENTIAL DIAGNOSIS
TREATMENT
COURSE AND PROGNOSIS

REFERENCES

Hand-foot-and-mouth disease (HFMD) is an illness characterized by a distinctive vesicular eruption in the mouth and on the extremities. The causative agents are enteroviruses, most commonly coxsackievirus A16, less commonly A5, A7, A9, A10, B2, and B5, and enterovirus 71, which has been responsible for the largest reported outbreaks. [1] Infection with adenovirus 21 also has been associated with this disease. [2] HFMD caused by coxsackieviruses is usually a benign, self-limited illness, but that caused by enterovirus 71 has been associated with significant morbidity and with fatalities. [3]

HISTORICAL

Robinson et al. [4] first described an outbreak in Canada in 1957, characterized by fever, pharyngeal lesions, and a vesicular exanthem on the extremities, associated with coxsackievirus A16. Alsop et al. [5] reported a similar outbreak in the United Kingdom in 1959 and coined the term *hand-foot-and-mouth disease.* Enterovirus 71 infection was first recognized in 1969 and has been associated with individual cases or outbreaks of HFMD since that time. [5], [6]

EPIDEMIOLOGY

HFMD is worldwide in distribution and occurs in both sporadic cases and in outbreaks. [7], [8] and [9] Extraordinarily large examples of the latter have been reported in association with enterovirus 71 infection, including two recent outbreaks in Taiwan that were estimated to involve more than 100,000 cases. [10] As is the case with enteroviral infections in general, HFMD occurs most commonly during the warmer times of the year, from summer through late fall in temperate climates and throughout the year in tropical areas. Children younger than age 10 are affected most frequently, and intrafamilial spread of infection to other siblings is common. [1], [11] Household members who are adults also may be infected but usually without clinical manifestations.

Most enteroviral infections are transmitted by fecal-oral spread, and it has been assumed that this is also the case with HFMD. However, the rapidity of spread seen in the large enterovirus 71 outbreaks suggests that respiratory or droplet spread might occur, as is the case with respiratory illness caused by coxsackievirus A21. [1], [10]

PATHOGENESIS

The pathogenesis of enteroviral infections has been established largely through studies of polioviruses. [12] It has been assumed that the pathogenesis of nonpoliovirus enteroviruses, such as those which cause HFMD, is similar, and available evidence generally supports this. Infection begins by ingestion of fecal (or possibly respiratory) material that contains virus, which then infects the oropharynx or gastrointestinal tract. The cellular site of initial virus replication is not established but may involve M cells in the gastrointestinal tract. [13] Within 1 to 3 days, virus replication can be detected in regional lymphoid tissue, from which a “minor” viremia ensues. This is not manifested clinically but results in spread of virus to reticuloendothelial tissues such as bone marrow, spleen, liver, and deep lymph nodes. In most cases of enteroviral infection, virus replication is contained at this point by host defenses, and clinical manifestations are not noted. In a minority of infections, virus replication continues in reticuloendothelial tissues or in deep lymph nodes, and a “major” viremia results. This viremia probably accounts for the “nonspecific” or prodromal febrile illness component of many enterovirus-associated illnesses. [14] The major viremia results in dissemination of virus to end organs that are involved with disease, such as the skin and oral mucosa in HFMD, the central nervous system, or the heart. The incubation period of HFMD is believed to be short, lasting 3 to 6 days.

CLINICAL MANIFESTATIONS

HFMD commonly begins with a nonspecific prodromal illness consisting of low-grade fever (38° to 39°C) that lasts 1 to 2 days and is accompanied by malaise and occasionally by upper respiratory tract symptoms or abdominal pain. The presenting complaints are most frequently sore mouth or sore throat, and young children so afflicted may refuse to eat. The characteristic features of the disease are painful oral lesions that are present in virtually all cases (Fig. 211-1). These are generally few in number, usually between 5 and 10, most frequently are found on the tongue, buccal mucosa, or hard palate but can be present anywhere in the oropharynx. [11], [15] The lesions begin as erythematous macules and papules, 2 to 8 mm in diameter, that progress rapidly to vesicles on an erythematous base. The vesicles quickly erode and form yellow to gray shallow ulcerations surrounded by an erythematous halo. Several vesicles may coalesce to form larger lesions that resemble bullae. While vesicular lesions are the hallmark of HFMD, the duration of the vesicles is

sufficiently short that the oral lesions usually have ulcerated by the time patients present to the physician.

FIGURE 211-1 *A.* Shallow ulcerations on the tongue that are part of the oral lesions of hand-foot-and-mouth disease caused by coxsackievirus A16 infection. *B.* Vesicular and popular lesions on the fingers and feet in hand-foot-and-mouth-disease. (From Haley JC, Flood AF: Hand-foot-and-mouth disease, in *Dermatology in General Medicine,* 5 th ed, edited by IM Freedberg, AZ Eisen, K Wolff, KF Austen, LA Goldsmith, SI Katz, and TB Fitzpatrick. New York, McGraw Hill, 1999, p 2405)

Cutaneous peripheral lesions are present in approximately 75 percent of patients and appear either simultaneously with the oral lesions or shortly thereafter. [1], [11] The lesions typically occur on the distal extremities and are more common on the hands than on the feet (Fig. 211-1 and Fig. 211-2). The extensor surfaces and sides of the finger, hands, toes, and feet are involved most frequently, but lesions may be present on the palms and soles as well. Less frequently, lesions occur more proximally on the extremities, as well as on the buttocks or genitalia. Lesions are usually painful and tender but on occasion can be asymptomatic. The number of lesions on the periphery is highly variable and can range from several to more than 100. [16]

FIGURE 211-2 *A, B.* Vesicles and bullae on an erythematous base on the hands and feet in hand-foot-and-mouth-disease. These are usually painful and are associated with a vesicular enanthem. (From Haley JC, Flood AF: Hand-foot-and-mouth disease, in *Dermatology and General Medicine,* 5 th ed, edited by IM Freedberg, AZ Eisen, K Wolff, KF Austen, LA Goldsmith, SI Katz, and TB Fitzpatrick. New York, McGraw Hill, 1999, p 2404)

The evolution of the cutaneous lesions is similar to that described for the oral lesions. Initially, a small (2–10 mm in diameter) erythematous macule or papule is seen that evolves into a clear vesicle surrounded by an erythematous halo. The vesicles collapse and form crusts that resolve gradually in 7 to 10 days without sequelae. A cutaneously disseminated form of HFMD described in an infant with eczema has been called *eczema coxsackium.* [17]

HISTOPATHOLOGY

Cutaneous lesions of HFMD consist of intraepidermal vesicles that are infiltrated with polymorphonuclear leukocytes and mononuclear cells and contain fluid and eosinophilic, proteinaceous material (Fig. 211-3). The epidermis of the blister wall has dyskeratotic and acantholytic cells. [18] As the basal cell layer is lost, vesicles can expand to form subepidermal bullae. Eosinophilic intranuclear inclusions and intracytoplasmic crystalline arrays of picornavirus particles (by electron microscope) have been seen in cells surrounding dermal vessels. [19] The dermis adjacent to vesicles also has a mixed polymorphonuclear and mononuclear cell infiltrate, along with edema fluid.

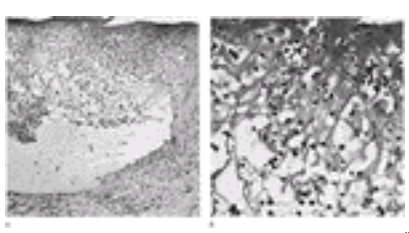

FIGURE 211-3 *A.* Intraepidermal bulla with focal loss of epidermis at base. The cavity is filled with polymorphonuclear leukocytes and mononuclear cells (H&E Stain). *B.* Higher magnification of roof of bulla with dyskeratotic epidermal cells and exocytosis of mononuclear cells (H&E stain). (From Haley JC, Flood AF: Hand-foot-and-mouth disease, in *Dermatology in General Medicine,* 5 th ed, edited by IM Freedberg, AZ Eisen, K Wolff, KF Austen, LA Goldsmith, and TB

Fitzpatrick. New York, McGraw Hill, 1999, p 2405)

DIAGNOSIS

The diagnosis of HFMD is usually based on the characteristic clinical picture of an oral enanthem and a vesicular exanthem on the extremities, usually in association with a low-grade febrile illness. Laboratory diagnosis is rarely required, except in the case of unusual or severe manifestations (see below). Definitive diagnosis is established by isolation of virus from lesions in tissue culture. Isolation of virus from throat or stool provides only presumptive etiologic evidence because enteroviruses may be shed for weeks in the oropharynx and even longer in the stool, and thus the presence of virus may reflect an unrelated, intercurrent infection. The ability to cultivate virus in vitro is highly variable among enterovirus groups and serotypes and may take several days to weeks. [1] The use of polymerase chain reaction (PCR) provides a rapid, sensitive, and specific method to detect enteroviruses in clinical specimens. PCR primers employ a highly conserved portion of the 5' nontranslated portion of the enterovirus genome that can detect most enteroviruses, except for echovirus 22 and 23. [20], [21] The likelihood of a positive culture or PCR detection increases with the number of sites or lesions that are sampled.

Serologic tests are of limited utility in diagnosis of enteroviral infections. There are 67 distinct serotypes of enteroviruses, so type-specific neutralization tests are performed infrequently, unless a specific serotype is being sought (e.g., coxsackievirus A16). Type and group immunoassays employing ELISA or other methodologies appear to be less sensitive and specific than neutralization tests but have been used to detect IgM antibody responses against group B coxsackieviruses in support of the diagnosis of acute infection. [22]

DIFFERENTIAL DIAGNOSIS

The presence of oral lesions and vesicles on the hands and feet forms a characteristic pattern for HFMD that is unlikely to be caused by other illnesses. If only oral lesions are present, they may be confused with herpetic gingivostomatitis, herpangina, or aphthous ulcers. Herpetic gingivostomatitis is usually more extensive than HFMD and frequently is accompanied by higher fever, cervical lymphadenopathy, and more systemic symptoms. Herpangina, caused by any of several enteroviruses, usually involves the posterior orpharynx, fauces, and soft palate. Aphthae may appear anywhere on the oral mucosa or tongue but are not accompanied by fever or systemic symptoms. Chickenpox can include oral lesions, but the cutaneous lesions are usually central and much more extensive than those in HFMD. Patients with erythema muliforme usually have more extensive oral or cutaneous involvement, along with a variety of different lesions, such as target lesions. Drug eruptions also tend to be more extensive than lesions seen in HFMD and frequently are pruritic rather than painful.

TREATMENT

HFMD is usually a benign, self-limited illness that resolves within 7 to 10 days. Treatment usually is not necessary, although analgesics and particularly topical anesthetics may provide relief from painful oral lesions. A single report of benefit in the treatment of HFMD with the use of acyclovir, which does not inhibit RNA viruses, is unconvincing. [23]

COURSE AND PROGNOSIS

As noted earlier, the vast majority of cases of HFMD resolve spontaneously within a week to 10 days without sequelae. Occasionally, cases associated with more prolonged fever, systemic symptoms, diarrhea, and joint pains have been reported. [24] CNS involvement as defined by headache, nuchal rigidity, myoclonus, tremor, and cerebrospinal fluid (CSF) pleocytosis has been reported to be as frequent as 8 to 24 percent of patients in some outbreaks of HFMD caused by enterovirus 71. [25] Encephalitis and flaccid paralysis also have been reported but appear to be considerably less frequent. [25], [26] Rare life-threatening and fatal complications also have been reported, chiefly in cases in the largest outbreaks of enterovirus 71 associated with HFMD (0.083 cases per 1000 children younger than 15 years of age), most of whom had pulmonary edema or hemorrhage as a cause of death. [10] In outbreaks involving both viruses, serious complications were less frequent in cases associated with coxsackievirus A16 than with enterovirus 71. [10], [27] Whether the occurrence of recently reported large outbreaks of HFMD caused by enterovirus 71 that are associated with uncommon but serious complications are recently emerged or merely recently recognized phenomena is unclear at present. Herpangina

EPIDEMIOLOGY
ETIOLOGY/PATHOGENESIS
CLINICAL MANIFESTATION
DIFFERENTIAL DIAGNOSIS
TREATMENT
NATURAL HISTORY AND PROGNOSIS

REFERENCES

Herpangina is an acute viral infection of the oropharynx that presents as multiple, acute ulcerations or gray-white papulovesicular lesions with associated marginal erythema. [1], [2] and [3] The infection usually occurs during warm months, with the highest incidence from June to October. It frequently occurs in epidemics affecting children ages 3 through 10 years. Herpangina is one of three oropharyngeal infections caused by group A coxsackieviruses, the others being hand-foot-and-mouth disease and acute lymphonodular pharyngitis. [4], [5] Of the 24 known types of group A coxsackieviruses, type A4 causes the majority of cases of herpangina. Types A1 to A10 and A16 to A22 have also been implicated, however, as have group B coxsackieviruses (strains 1 to 4), echoviruses, adenoviruses, and other enteroviruses. [6], [7], [8], [9] and [10]

EPIDEMIOLOGY

Herpangina can occur in any age group, but as noted above, it most commonly affects children ages 3 to 10 years. [6], [7] There may be outbreaks of herpangina among groups of children in close contact, such as classmates in school or siblings at home. The incubation period is approximately 4 days. The virus may cause subclinical infection manifest as febrile illness without the characteristic oropharyngeal lesions. During the summertime in a temperate climate, it may be possible to isolate the virus from as many as 1.5 to 7.5 percent of asymptomatic persons. Although it spreads primarily through inhalation of aerosolized drops of saliva (e.g., from sneezing and coughing), group A coxsackieviruses can be recovered not only from saliva, but also from nasal and oropharyngeal washing, and from stool. The disease is worldwide in distribution. There is no sex difference and no known difference by race or national origin in the prevalence of the disease.

ETIOLOGY/PATHOGENESIS

Coxsackieviruses are RNA enteroviruses named for the town in upper New York State where they were first discovered. Coxsackieviruses have been separated into two groups, A (24 known types) and B (6 known types), [2], [3] based upon the lesional pathology produced in laboratory suckling mice. This distinction has limited practical value, however, because virus speciation is rarely necessary in the clinical setting.

Although most often coxsackievirus infection is self-limited, fever, chills, oropharyngeal ulcerations, sore throat, and dysphagia are characteristic. These viruses can also cause hepatitis, meningitis, myocarditis, pericarditis, and acute respiratory disease. Following infection, permanent immunity to the specific infecting strain develops, but because of the many antigenic strains, the illness may appear more than once in the same individual.

CLINICAL MANIFESTATION

The typical presentation of herpangina is a sudden onset of fever, chills, sore throat, headache, and body aches. Most patients experience fever ranging from 38°C to 41°C (100. 4°F to 105.8°F) and mild leukocytosis (10,000 to 15,000/mL ^{3}). Examination of the oral cavity reveals multiple shallow papulovesicular lesions affecting, in order of frequency, the anterior pillars of the tonsillar fauces, soft palate, uvula, and tonsils; the lesions quickly progress to shallow ulcers with brisk marginal erythema (Fig. 212-1). For patients with this clinical presentation and lesions affecting the hands and feet, hand-foot-and-mouth disease is the most likely diagnosis (see Chap. 211 and Fig. 211-1 and Fig. 211-2).

FIGURE 212-1 Typical appearance of the oropharyngeal lesions of herpangina. Acute, multiple papulovesicular lesions quickly progress to form shallow ulcerations with brisk marginal erythema.

DIFFERENTIAL DIAGNOSIS

No reliable, practical definitive laboratory diagnostic test is available or necessary for the diagnosis of herpangina: the diagnosis is based on the clinical presentation. [3], [11], [12] Several disorders can be confused with herpangina, for example, coxsackievirus infection resulting in hand-foot-and-mouth disease or lymphonodular pharyngitis, and primary herpetic gingivostomatitis. Less commonly confusion may arise in regard to oral candidiasis, deficiency diseases and hematologic disorders, infectious mononucleosis, and the enanthems of measles, varicella, scarlatina, and diphtheria. Serologic, microbiologic, hematologic, and histologic examination will differentiate among these disorders when the clinical presentation alone is insufficient to make the diagnosis with confidence. Table 212-1 summarizes the distinguishing features among the disorders commonly confused with herpangina.

TABLE 212-1 **Comparative Features of Disorders that May Be Confused with Herpangina**

TREATMENT

Herpangina resolves with supportive care in 4 to 7 days; no specific treatment is available or necessary. Supportive care includes maintaining proper hydration and administering acetaminophen to control fever. The use of antihistamine mouth rinses can provide symptomatic relief from painful oral lesions. Rapid resolution of oral lesions has been reported with the use of allopurinol mouthwashes. [13]

NATURAL HISTORY AND PROGNOSIS

The fever associated with herpangina rarely lasts more than 4 days; the oral lesions rarely last more than a week. With the exception of the occasional child who suffers a febrile convulsion, the prognosis is good and the course benign. Immunity to one strain does not protect an individual from future infection by a different antigenic strain of the virus.

Because other more virulent and potentially fatal enteroviruses can mimic the presentation of herpangina, signs and symptoms that progress significantly or continue beyond 7 days warrant aggressive exploration. [6], [8], [9] and [10]

Erythema infectiosum (fifth disease) is primarily a childhood illness that is characterized by a “slapped cheek” appearance of the face and an erythematous, lacy eruption on the trunk and extremities. Parvovirus B19, the etiologic agent, may also cause arthropathy, aplastic crisis in patients with increased red blood cell turnover, chronic anemia in immunocompromised persons, and fetal hydrops.

HISTORICAL ASPECTS

The first known clinical picture of a patient with erythema infectiosum is drawn in Robert Willan's book *On Cutaneous Diseases* (1808). Throughout the 1800s, the disease was thought to be a mild form of rubella or measles. Tschamer described a distinct illness compatible with erythema infectiosum in 1889, although he thought it was abortive rubella. [1] It was designated fifth disease in the early 1900s when infectious exanthems were numbered first through sixth. [2]

The first clue to the etiologic agent came in 1975 in England. During routine screening of serum from healthy blood donors for hepatitis B surface antigen, nine samples of blood had false-positive results by counterimmunoelectrophoresis (CIE), but were negative by the more sensitive techniques of hemagglutination and radioimmunoassay (RIA). Electron microscopy of these serum samples demonstrated viral particles that were designated B19 after a specimen label from one of the blood donors. [3] The authors postulated that this was an infectious agent because 30 percent of adults had IgG antibody to the viral antigen. It was later confirmed that B19 was a parvovirus. [4] Parvoviruses had previously been thought to infect only animals. In this manner, the virus was discovered, but association with a clinical illness awaited.

Parvovirus was identified as the etiologic agent of an acute febrile illness in two British soldiers in 1980, and was found in the serum of patients with sickle cell anemia and hypoplastic crisis in 1981. The virus was suggested as a cause of aplastic crisis in sickle cell disease. In 1983, there was an outbreak of fifth disease among London schoolchildren. [5] Serum samples from 31 schoolchildren and 6 exposed adults, all with clinical signs of the disease, contained parvovirus-specific IgM antibody. There was no IgM detected in exposed asymptomatic individuals. These findings suggested parvovirus B19 as the cause of erythema infectiosum.

EPIDEMIOLOGY

Fifth disease is worldwide in distribution, can occur throughout the year, and can affect all ages. It tends to occur in epidemics, especially associated with school outbreaks in the late winter and early spring. Serologic studies show increasing prevalence with age. Various studies indicate that from 15 to 60 percent of children 5 to 19 years old and 30 to 60 percent of adults are seropositive. [6] Seroprevalence increases to greater than 90 percent in the elderly. [6] Previous infection with B19 seems to confer lifelong immunity.

The incubation period for erythema infectiosum is from 4 to 14 days. [7] After intranasal inoculation of parvovirus-infected serum to healthy volunteers, low-grade fever and nonspecific complaints occurred at the time of viremia, 6 to 14 days after inoculation, and the rash appeared at day 17 or 18. [8]

Parvovirus B19 is thought to be transmitted primarily by the respiratory route via droplet aerosol during the viremic phase, and B19 DNA has been found in respiratory secretions of viremic patients. [8] After the rash of erythema infectiosum appears, B19 is not found in respiratory secretions and is usually not present in the serum. This suggests that persons with erythema infectiosum are infectious only prior to the onset of the rash.

The virus seems to be effectively spread after close contact. The secondary attack rate among susceptible household contacts is approximately 50 percent. Transmission may occur via blood transfusion, from blood products, and vertically from mother to fetus. [9] The transmission of B19 through blood transfusion is particularly problematic because the

nonenveloped virus is not killed by the solvent detergents or heat that are used to inactivate HIV and hepatitis viruses. [10]

ETIOLOGY AND PATHOGENESIS

The B19 virus belongs to the family *Parvoviridae* and the genus Parvovirus. [11] Two other genera in this family, the Dependoviruses and the Densoviruses, infect other vertebrates and insects. [12] B19 lacks an envelope and contains single-stranded DNA. It is the smallest single-stranded DNA-containing virus known to infect humans, measuring 18 to 26 µm in diameter. Parvoviruses are widespread in veterinary medicine, but animal parvoviruses are not thought to be transmissible to humans. [10]

The pathogenesis of erythema infectiosum is unknown, but the mechanism may involve immune complexes. The more serious manifestations of parvovirus infection relate to the fact that the virus infects and lyses erythroid progenitor cells. Recent evidence suggests that the blood group P antigen (globoside) is a receptor of parvovirus. Because some individuals lack P antigen, they are not susceptible to infection with B19. [13] In patients with increased red blood cell destruction or loss who depend on compensatory increase in red cell production to maintain stable red cell indices, B19 infection may lead to transient aplastic crisis. Such patients include those with anemia associated with acute or chronic blood loss. When parvovirus infects the erythroblasts in a developing fetus with decreased red cell survival, the result may be hemolysis and anemia. [14] Anemia may trigger congestive heart failure, edema (fetal hydrops), and possibly fetal death.

PREVENTION

There is currently no vaccine to prevent parvovirus B19 infection. Candidate vaccines are in clinical trials. [15] It is not known whether immunoglobulin given around the time of exposure will prevent infection or alter the course of the disease.

Because patients with erythema infectiosum are no longer infectious by the time they develop the illness, control measures directed toward these individuals are not likely to be effective. If these persons are hospitalized, no special precautions need to be taken. Because the virus is transmitted before the rash appears, the disease is easily spread in situations of close prolonged contact such as schools, day care centers, workplaces, and homes.

Patients with aplastic crisis or immunosuppression with chronic B19 anemia may have high titer viremia and are particularly infectious. These individuals should be placed in respiratory and contact isolation if hospitalized, and pregnant health care providers should not care for them directly. Hospital workers are at risk of contracting nosocomial infections from these patients [16] and could spread the virus to patients if adequate precautions are not taken.

CLINICAL MANIFESTATIONS

Parvovirus B19 in Children

Most infections caused by B19 are asymptomatic and unrecognized. Fifth disease, the most common clinical picture associated with the virus, usually begins with nonspecific symptoms such as headache, coryza, and low-grade fever about 2 days prior to the onset of the rash. [17] Patients may have headache, pharyngitis, fever, malaise, myalgias, coryza, diarrhea, nausea, cough, and conjunctivitis coinciding with the rash. Approximately 10 percent of children with erythema infectiosum develop arthralgias or arthritis. Large joints are affected more often than small joints. [17] Occasionally, children may present with chronic joint complaints suggestive of juvenile rheumatoid arthritis. [18]

The characteristic rash begins with confluent, erythematous, edematous plaques on the malar eminences, the “slapped cheeks” (Fig. 213-1). As the facial rash fades over 1 to 4 days, pink to erythematous macules or papules appear on the trunk, neck, and extensor surfaces of the extremities. These lesions have some central fading, giving them a lacy or reticulated appearance [17] (Fig. 213-2). The rash can be morbilliform, confluent, circinate, or annular, and there have been reports of palmar and plantar involvement. [7] The eruption typically lasts 5 to 9 days, but can recur for weeks or months with triggers such as sunlight, exercise, temperature change, bathing, and emotional stress. In some outbreaks, pruritus is a major feature of the rash in children. [7]

FIGURE 213-1 Child with the characteristic “slapped cheeks”.

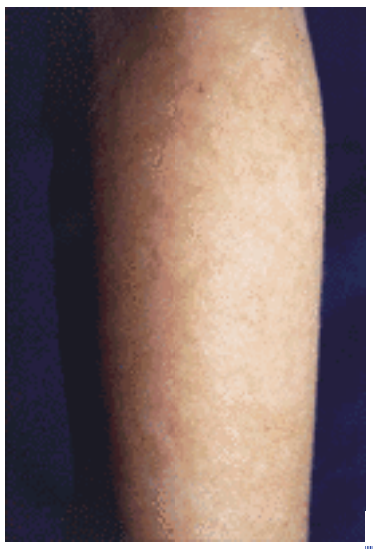

FIGURE 213-2 Reticulate erythematous macules on the extremity.

There have been occasional reports of parvovirus B19 associated with vascular purpura, including Henoch-Schönlein purpura. [19] An enanthem consisting of erythema of the tongue and pharynx and red macules on the buccal mucosa and palate can occur.

Parvovirus B19 in Adults

Acute arthropathy is the primary manifestation of B19 viral infection in adults. [20] It occurs mainly in women and affects the small joints of the hands, the knees, wrists, ankles, and feet. Occasionally, other joints such as the spine and costochondral joints are involved. This symmetric polyarthritis is usually of sudden onset and is self-limited but can be persistent or recurrent for months. It may mimic Lyme arthritis or rheumatoid arthritis.

The constitutional symptoms are usually more severe in adults than in children. [21] Fever, adenopathy, and a mild arthritis without a rash is the usual course. Women are more likely than men to have joint complaints and rash, while men often present with only a flulike illness. [20] Some adults may have fatigue, malaise, and depression for weeks after the infection. Asymptomatic infection can certainly occur in adults as well as in children. In one outbreak, 26 percent of adults were reported to be asymptomatic. [20] Parvovirus B19 can cause numbness and tingling of the fingers with or without other features of fifth disease. [22] Pruritus that is sometimes severe can occur with or without a rash. It has been suggested that if pruritus is a complaint in a patient with acute-onset arthritis, parvovirus should be considered as a possible cause.

The rash in adults, if present at all, is usually macular and blotchy or lacy, often on the extremities, and rarely demonstrates the characteristic slapped-cheek appearance. [20] Other cutaneous manifestations associated with B19 infection in adults include purpura, vesicles and pustules, palmoplantar desquamation, a morbilliform exanthem with Koplik spots, and livedo reticularis.

Papular Purpuric Gloves-and-Socks Syndrome

In 1990, Harms et al. [23] described a unique syndrome of pruritic erythema and edema of the hands and feet with petechiae, fever and oral erosions. This rare exanthem, now known as papular, purpuric gloves-and-socks syndrome (PPGSS), seems to affect teenagers and adults. However, it can affect children also. [24] Patients usually have mild prodromal symptoms of fatigue and low-grade fever, myalgias, and arthralgias. Subsequently, itchy, painful, symmetrical edema and erythema of the distal hands and feet occurs. [25] Purpuric papules appear on the hands and feet with abrupt demarcation at the wrists and ankles. The enanthem, if present, arises on the lips, soft palate, and buccal mucosa. The syndrome resolves spontaneously within 2 weeks. Although many viruses have been implicated as causative agents for PPGSS, B19 is the virus proven to cause the syndrome. [26]

COMPLICATIONS

As more attention is focused on parvovirus B19, an increasing number of complications are recognized. Subclinical infection is quite common. However, this virus can be responsible for a variety of hematologic, rheumatologic, and neurologic abnormalities.

Transient Aplastic Crisis

Parvovirus B19 is the most common cause of transient aplastic crisis in patients with chronic hemolytic anemias. [27] This has been demonstrated in sickle cell anemia, hereditary spherocytosis, heterozygous ß-thalassemia, pyruvate kinase deficiency, and autoimmune hemolytic anemia, as well as in other conditions of decreased red cell production or increased red cell destruction. The aplastic crisis may be the initial manifestation of the underlying hematologic disease. [28]

Patients typically have fever and constitutional complaints, followed 1 week later by fatigue, pallor, and worsening anemia. [29] Rarely is a rash reported with aplastic crisis. There is an absence of reticulocytes, and the hemoglobin may fall below 4 µg/dL. Bone marrow examination shows hypoplasia or aplasia of the erythroid series. Red blood cell transfusion may be necessary, and most patients recover in 1 week, although the problem can be fatal if untreated.

Transient red cell aplasia can occur in healthy persons without underlying hematologic abnormalities. [30] It is likely that the aplasia is missed in individuals without disorders of shortened erythrocyte survival because the hemoglobin does not drop low enough to cause symptoms.

Chronic B19 Infection

In immunocompromised patients, B19 infection can cause a serious, prolonged anemia from persistent lysis of red blood cell precursors. [30] Parvovirus-related chronic anemia has been reported in HIV-infected patients, as well as in transplant recipients and those with congenital immunodeficiencies, acute leukemias, lupus erythematosus, and during the first year of life without immunodeficiency. These patients respond dramatically to intravenous gamma globulin, suggesting that antibody is the main defense to human parvovirus infection. [31]

Fetal B19 Infection

Fetal infection with B19 may result in a normal fetus, spontaneous abortion (especially in the first half of pregnancy), hydrops fetalis in the second half of pregnancy, congenital anemia, and even late fetal death. [32] Nonimmune fetal hydrops is the most common complication of intrauterine infection with B19. Because B19 virus can infect erythroid precursors, extensive hemolysis can occur in the fetus, leading to severe anemia, tissue anoxia, high-output heart failure, and generalized edema. The fetus may show ultrasonographic evidence of subcutaneous edema, ascites, pleural effusion, pericardial effusion, placental edema, and polyhydramnios. The overall risk of fetal death is not clearly known, but recent studies suggest that this risk is about 6.5 percent with maternal infection. [32] The risk of fetal death for a woman with unknown serologic status is estimated to be less than 2.5 percent after a household exposure and less than 1.5 percent after a significant work exposure. It seems that in B19-infected pregnant women, most fetuses are not infected; if they are infected, usually there is not an adverse outcome. [33] Furthermore, about half of women of childbearing age are immune to parvovirus infection because of prior infection.

Because parvoviruses are known teratogens in animals, there has been much concern about whether they cause birth defects in humans. In sera collected from 253 infants with a wide range of congenital abnormalities, there was no parvovirus-specific IgM detected to suggest recent infection. [34] There has been one report of a B19-infected abortus with eye abnormalities, [35] and another of an infected abortus with cleft lip, cleft palate, and micrognathia. [36] Rare reports describe cardiac abnormalities, [37] neurologic problems, [38] and “blueberry muffin” nodules. [39] It has been concluded from these few studies that parvovirus B19 is not a common cause of birth defects.

Other Complications

There are reports of B19 infection causing encephalitis, meningitis, brachial neuritis, a myasthenia-like syndrome, and motor weakness. Parvovirus infection has been blamed for a Wegener's granulomatosis-like illness, [40] polyarteritis nodosa, [41] Kawasaki disease, [42] and a systemic lupus erythematous-like picture. [43] In addition, there are reports of other hematologic complications including idiopathic thrombocytopenic purpura, transient neutropenia, myocarditis, a hemophagocytic syndrome, and the Diamond-Blackfan syndrome.

LABORATORY FINDINGS

In patients with erythema infectiosum, laboratory results are usually normal, including reticulocyte count, hematocrit, and tests of liver and renal function. Patients with aplastic crisis have reticulocytopenia and anemia, the severity of which depends on the degree of the underlying anemia. Reticulocytopenia, anemia, lymphopenia, neutropenia, and thrombocytopenia can occur in healthy individuals with B19 infections, although these are usually not significant enough to cause clinical symptoms. The erythrocyte sedimentation rate is rarely elevated, and rheumatoid factor has been positive in some cases of parvovirus-associated arthritis.

PATHOLOGY

Histologic examination of various tissues demonstrates homogeneous, intranuclear inclusions with peripheral condensation of chromatin in erythroid precursor cells. [44] Electron microscopy of these inclusions reveals parvovirus-like particles. [44] In fetal tissues, a leukoerythroblastic reaction may also be seen. The histopathologic changes in the skin of patients with erythema infectiosum include a sparse superficial perivascular lymphocytic infiltrate that is not considered diagnostic.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of erythema infectiosum is usually based on the clinical features. The differential diagnosis includes rubella, measles, scarlet fever, roseola, enteroviral infection, erysipelas on the cheek, and drug hypersensitivity. These other disorders may have more significant systemic illness and lack the progression from the slapped cheeks to the lacy extremities that is so characteristic of fifth disease. Because no animal model or easy tissue culture system exists for the B19 virus, laboratory testing for the antibody or the virus is performed only in a limited number of research laboratories. The Centers for Disease Control and Prevention will currently test the serum of patients with aplastic crisis, immunodeficiency, and chronic anemia; pregnant women with B19 exposure; and fetal hydrops cases in which B19 infection is suspected. The testing is not done on a routine basis and is arranged through state health departments.

Detection of recent infection is usually performed with assays for IgM antibody. RIA or enzyme-linked immunosorbent assay (ELISA) techniques can detect IgM within a few days after onset of illness. IgM can be measured for up to 6 months in many cases, although there is a decline in titer in the second month after onset. IgG can be identified with the

same techniques by the seventh day of illness and lasts for years and is therefore best for documenting past infection. Parvovirus antibody is often not detectable in immunodeficient persons. B19 virus can be detected in serum during viremia by a variety of techniques including RIA, CIE, and ELISA. The most specific tests are dot-blot hybridization [45] and the polymerase chain reaction, [46] which may allow identification of B19 DNA in serum, urine, respiratory secretions, cerebrospinal fluid, and bone marrow. B19 DNA can be detected with PCR for up to 4 months after the onset of illness. [47]

TREATMENT AND PROGNOSIS

There is no specific treatment available for parvovirus B19 infection. Erythema infectiosum is a benign condition, and usually no treatment is necessary. Supportive therapy for relief of fatigue, malaise, pruritus, and arthralgia may be needed. The chronic anemia of persistent B19 infection may be treated successfully with commercially available intravenous immunoglobulin, which contains neutralizing anti-B19 antibodies. Transient aplastic crisis, which can be life-threatening, may require oxygen therapy and blood transfusion.

Serologic testing for B19 IgG and IgM should be offered to pregnant women who are exposed to parvovirus B19. Infected pregnant women are followed by frequent ultrasonograms. Evidence of hydrops fetalis warrants umbilical cordocentesis to check for anemia, viral DNA, IgG, and IgM. The management of infected fetuses is controversial. Some physicians advocate observation because spontaneous resolution is common. Fetuses with severe anemia and compromise are usually managed with intrauterine exchange transfusion, but this procedure does carry risk.

Parvovirus B19 infection in healthy individuals is self-limited. The rash of erythema infectiosum and the parvovirus arthropathy usually resolve in 1 to 2 weeks, but can recur or persist for months. If untreated, transient aplastic crisis can be fatal, but most patients recover in 1 week. Chronic anemia from B19 usually resolves if treated with gamma globulin. Fetal hydrops can lead to fetal death if not treated.

Herpes simplex virus (HSV) infections are very common and are caused by two closely related types of HSV. Their main clinical manifestations are mucocutaneous infections, with HSV type 1 (HSV-1) being mostly associated with orofacial disease, while HSV type 2 (HSV-2) is usually associated with perigenital infection. Studies in past years have brought insights into the molecular biology of HSV, the epidemiology and presentation of its infections, and an expanded menu of options for their treatment and prevention. Treatments that ameliorate the signs and symptoms of herpes have been developed, but a viable general strategy to prevent HSV infections remains elusive.

HISTORICAL ASPECTS

The earliest reference to herpetic infections was made approximately 2,000 years ago by the Roman physician Herodotus who described them as “the herpetic eruptions that appeared about the mouth at the crisis of simple fevers.” John Astruc, a French physician, described genital herpes in 1736, in the “ *De morbis venereis.*” [1] Person-to-person transmission of herpes was recognized in 1893. At the beginning of the twentieth century, histopathologic studies described the multinucleated giant cells associated with herpesviruses infections. The infectious nature of the disease was shown by Lowestein in 1919, who demonstrated that virus from herpetic lesions caused lesions on the rabbit cornea. [2] In 1968, HSV-1 and HSV-2 were first distinguished on the basis of antigenic and other biological features. [3]

EPIDEMIOLOGY

The incidence of primary infection with HSV-1, which is responsible for the vast majority of recurring labial herpes, is greatest during childhood, when 30 to 60 percent of children are exposed to the virus. Rates of infection with HSV-1 increase with age, with 90 percent of adults older than 50 years of age being seropositive for HSV-1. [4] From 20 to 40 percent of the population have had episodes of herpes labialis. [5] The frequency of recurrent episodes is extremely variable, and in some studies averages about once per year, [6] but there is evidence that the frequency and severity of recurrent HSV-1 disease decrease over time.

Acquisition of HSV-2 correlates with sexual behavior and the prevalence of the infection in the pool of one's potential sexual partners. Antibodies to HSV-2 are rare in people before the onset of intimate sexual activity, and rises steadily thereafter. HSV-2 seroprevalence in the United States is 22 percent in persons 12 years of age or older. [7]

Although most patients infected with HSV-1 or HSV-2 are asymptomatic, they still can transmit the virus. Studies using DNA polymerase chain reaction (PCR) assays show that rates of detecting HSV-2 DNA in genital secretions of people who have never recognized herpes outbreaks (asymptomatic persons) are similar to the rates of shedding viral DNA in persons who have experienced symptomatic genital herpes but who are not symptomatic at the moment of testing (subclinical shedding). [8] It is estimated that more than 70 percent of transmission of HSV-2 is associated with asymptomatic and subclinical reactivation and shedding. [9] The average risk of transmission for couples discordant for genital herpes (i.e., one partner has genital herpes and the other does not) is about 10 percent per year, when the couples simply refrain from intercourse during outbreaks. [9] In another study, the overall rate of HSV-2 infection averaged 5.1 cases per 100 person-years in sexually active persons. As with other sexually transmitted infections, the rate of acquisition of HSV-2 infection is higher for women than for men (6.8 versus 4.4 cases per 100 person-years; relative risk, 1.55). Asymptomatic HSV-2 infection is more common among men and persons who are also seropositive for HSV-1, suggesting that prior infection with HSV-1 reduces one's likelihood of experiencing symptomatic HSV-2 infection. [10]

ETIOLOGY AND PATHOGENESIS

The Virus

HSV-1 and HSV-2 are members of the Herpesviridae family, a group of lipid-enveloped double-stranded DNA viruses responsible for a wide variety of common human infections. Both serotypes of HSV and the closely related varicella-zoster virus (VZV) are members of the Alpha-herpesviridae virus subfamily. Alpha herpes viruses infect multiple cell types in culture, grow rapidly, and efficiently destroy the host cells. Infection in the natural host is characterized by lesions in the epidermis, often involving mucosal surfaces, with spread of virus to the nervous system and establishment of latent infections in neurons, from which virus periodically reactivates.

The complete 152-kbp genomic DNA sequence of HSV-1 was published in 1988, [11] and the complete HSV-2 genome was reported a decade later. [12] Both genomes are linear and consist of two regions of unique sequence, each of which is bounded by a pair of inverted repeat elements. There is a high degree of genetic and antigenic homology between HSV-1 and HSV-2, but they are distinct; an analysis of herpesvirus phylogeny estimated that the two HSV types diverged from an ancestral protoherpesvirus approximately 8 million years ago. [13]

Herpesvirus replication is a carefully regulated, multistep process. Shortly after infection, five “immediate-early” genes are transcribed. The proteins encoded by these genes stimulate the synthesis of about a dozen “early” proteins that are required for genome replication. Most current antiviral drugs interact with two of these proteins, the thymidine kinase and the viral DNA polymerase enzyme. After DNA replication, the remaining set of more than 60 “late” HSV-2 genes is expressed. They encode virion structural components and proteins needed for their proper assembly.

In vivo, HSV infections can be divided into three stages: acute infection, establishment and maintenance of the latency, and reactivation of virus. During acute infection, virus replicates at the site of inoculation on mucocutaneous surfaces, resulting in primary lesions from which virus rapidly spreads to infect sensory nerve terminals, where it travels by retrograde axonal transport to neuronal nuclei in regional sensory ganglia. In a subset of infected neurons, a latent infection is established in which viral DNA is maintained as an episome and HSV gene expression is severely restricted: of all of the viral genes, only one is abundantly transcribed during latency. In the last stage, replication reactivates with concomitant anterograde axonal transport of newly assembled virus to a peripheral site, at or near the original portal of entry.

Differences in the ability of HSV strains to use different cell surface receptors may account for serotype and strain differences in tissue tropism and pathogenicity. Initial attachment of HSV to cells is mediated primarily by binding of one or more viral envelope glycoproteins (primarily HSV glycoprotein B and glycoprotein C) to heparan sulfate proteoglycans on the surface of susceptible cells. These interactions facilitate attachment of HSV glycoprotein D to one of a family of specific cellular coreceptors. One such receptor is the herpesvirus entry mediator A (HveA), a member of the tumor necrosis factor receptor super-family. Two other cell surface coreceptors named HveB and HveC are members of the immunoglobulin superfamily and are closely related to the poliovirus receptor. HveB mediates the entry of HSV-2 strains, but fails to mediate the entry of wild-type HSV-1. HveC mediates the entry of HSV-1 and HSV-2, and has been implicated as in spread of HSV-1 and HSV-2 from mucosal surfaces to the nervous system.

The molecular mechanisms underlying the latency and reactivation of HSV are not well understood. In latently infected ganglia, the viral DNA persists as an episome, and within the genome, only parts of the long repeat elements are expressed, yielding the so-called latency-associated transcripts (LATs). LATs are not essential for productive infection or establishment and maintenance of latency, but may modulate reactivation. HSV mutants that are deleted for their ability to express LATs can establish latent infections in mice, guinea pigs, and rabbits as efficiently as their wild-type parental virus, but reactivate less frequently.

HSV-1 reactivates most efficiently and frequently from trigeminal ganglia, while HSV-2 reactivates primarily from sacral ganglia. The rate of reactivation of HSV appears to be influenced more by the quantity of latent viral DNA in the ganglia than by the accumulation of LATs. [14] In addition to the quantity of latent virus being a determinant of the relative rate of HSV reactivation, there are type-specific sequences within the viral LAT-encoding region of the HSV genome that appear to influence recurrence rates in particular anatomic sites. [15] In addition to viral genes, host factors strongly influence HSV reactivation. Reactivation is induced in experimentally infected animals by exposure to UV irradiation, by hyperthermia, by local trauma, and by other physiological stressors. These model systems emulate well what occurs in similarly stressed humans.

Immune Response

Host immunity to HSV clearly influences the risk of acquiring the infection, the severity of disease, and the frequency of recurrences. Through studies in animal models and observations of immune-deficient people, the host genetic background, multiple immune cell types (including macrophages, natural killer cells, and different T cell subpopulations), antibodies that mediate neutralization and/or antibody-dependent cell-mediated cytotoxicity, and cytokine responses have all been implicated as important host defenses against HSV infections.

The humoral immune response is important in reducing virus titers at the site of inoculation and in regional neural tissues during primary infection. Animals are effectively protected from disseminated and neurologic disease by passive transfer of polyclonal or monoclonal antibodies, and by antibody responses elicited actively through vaccination. Moreover, the transfer of HSV-specific antibodies from the mother to the child is a key factor in protecting against neonatal herpes. But, in other human HSV infections, humoral immune responses play less important roles than the cellular immune responses, as disease in patients with deficits in humoral immunity is no more severe that that in normals, while those with defects in cellular immunity can experience severe and recurring infections. Most patients mount antibody responses

to HSV infection within 4 to 6 weeks after infection. Some of these responses are type-specific, while other cross-react with proteins of the other virus type.

The risk of severe HSV disease and the rate of recurrence correlates with the level of cellular immune competence of the host. Patients with mild decreases in cellular immunity may experience only an increased number of recurrences and a slower resolution of lesions, while severely compromised patients are more likely to develop disseminated, chronic, or drug-resistant infections.

Studies of humans and mice have implicated a role for both CD8+ and CD4+ T lymphocyte subsets, for natural killer (NK) cells, and for inflammatory cytokines like interferon-? in mediating protection against HSV. However, the contribution of each cell subset and cytokine in the control of HSV infection has not been clearly defined.

The roles of immunity in sustaining latency and in limiting reactivation of HSV are less clear. There is some evidence that constant immune surveillance and engagement are required to maintain latency. Other findings implicate immunity only in defining whether virus once reactivated would spread and become clinically evident.

PREVENTION

Strategies to prevent HSV infection have proven inadequate to address the growing epidemic of genital herpes. HSV infection can be prevented by total abstinence, as indicated by very low seroprevalence rates in cloistered nuns. Barrier contraceptives reduce rates of transmission if used routinely. [16] Other than these public health approaches, most efforts involve antiviral therapy and vaccines directed at genital herpes.

Antiviral Therapy

As discussed more fully below, antiviral therapy decreases both symptomatic and subclinical shedding of HSV-2. In a double-blinded, placebo-controlled, crossover clinical trial of acyclovir 400 mg twice a day, subclinical shedding decreased from 6.9 percent of the days in the placebo group to 0.3 percent of the days in the treatment group. [17] Studies using PCR show that daily administration of oral acyclovir reduces the frequency of HSV DNA detection by a median of 80 percent. [18] Famciclovir decreases asymptomatic shedding in men from 1.09 to 0.08 percent of the days analyzed. Because of its ability to reduce both symptomatic and subclinical shedding of HSV-2, a mathematical model predicted that antiviral therapy would affect the spread of genital herpes through the populace. [19] The results imply that high rates of treatment would significantly reduce the prevalence of HSV-2, but would also increase the incidence of drug-resistant HSV-2 infection. However, even in the worst-case scenario in this model, the use of acyclovir would prevent at least five new infections for every case that develops resistance to the drug. Based on these findings, chronic suppressive therapy was predicted to be more beneficial than episodic treatment in reducing the transmission of infection and widespread treatment was recommended. A mathematical model for use of topical penciclovir in recurrent herpes labialis, however, did not predict a decrease in the prevalence of HSV-1 infection. [20]

Vaccines

The best public health strategy to reduce infection and morbidity associated with HSV infection is development of effective vaccines. Unfortunately, no vaccine has proven to protect adequately against acquisition of HSV or to reduce the number of recurrent episodes, although there are hopeful developments in these directions. Recombinant glycoprotein vaccines containing immunogenic HSV proteins have been developed and tested by multiple pharmaceutical and biotechnological companies. In a preliminary study, a recombinant HSV-2 glycoprotein D vaccine with alum adjuvant decreased the frequency of symptomatic outbreaks in patients with genital herpes. A modified form of the vaccine (with added glycoprotein B and a lipid emulsion adjuvant known as MF59) was not found, in larger studies, to decrease the number of recurrences in patients with genital herpes, but it was able to decrease the duration and severity of a subsequent study outbreak of genital herpes. [21] Two phase III studies of the effect of this vaccine (one in monogamous seronegative partners of individuals with genital herpes, and the other in seronegative persons attending clinics for sexually transmitted diseases) failed to prevent acquisition of genital herpes infection or disease. A recombinant gD2 vaccine that uses monophosphoryl lipid-A (MPL) as adjuvant has a modest effect in preventing genital herpes in HSV-1 and -2 seronegative women, but not in males or HSV-1 seropositive females. [22]

A major theoretical limitation of recombinant HSV vaccines is their inability to induce broad and protective cellular immune responses. To better do so, investigators have turned their attention to DNA-based and genetically engineered live vaccines. The use of replication-defective HSV mutants has been tested with success as a candidate vaccine in animal models. These viruses are capable of only a single round of replication, and therefore have no pathogenic potential while potentially inducing the full spectrum of immune responses. lso, these mutant constructs open the possibility of engineering agents with additional genes that encode antigens from other infectious agents, envisioning a vaccine that can protect against multiple infections. Also underway, with initial promising results in animal models, are studies of DNA vaccines for HSV. The first phases of human trials of DNA and replication-defective vaccines have begun.

CLINICAL MANIFESTATIONS

The clinical manifestations of HSV infection depend on the site of infection and, as indicated above, the immune status of the host. Primary infections with HSV, namely those that develop in persons without preexisting immunity to either HSV-1 or HSV-2, are usually more severe, frequently with systemic signs and symptoms, and they have a higher rate of complications, than recurrent episodes.

Orofacial Infections

Herpetic gingivostomatitis (Fig. 214-1) and pharyngitis are mostly commonly associated with a primary HSV-1 infection. The symptoms of primary oral herpes may resemble those of aphthous stomatitis and include ulcerative lesions involving the hard and soft palate, tongue, and buccal mucosa, as well as neighboring facial areas. Patients with pharyngitis exhibit ulcerative and exudative lesions of the posterior pharynx that can be difficult to differentiate from streptococcal pharyngitis. Other common symptoms are fever, malaise, myalgias, pain on swallowing, irritability, and cervical adenopathy.

FIGURE 214-1 Primary herpetic gingivostomatitis in a child. (*Courtesy of Clyde S. Crumpacker, MD.*)

Reactivation of virus from these primary infections involves the perioral facial area, mainly the lips, with the outer third of the lower lip being the most commonly affected (Fig. 214-2). Other facial locations include the nose, chin, and cheek, and account for less than 10 percent of the cases. Two-thirds of labial lesions involve the vermilion border, while the rest occur at the junction of the border with the skin. In patients with frequent recurrences, lesions may differ slightly in location with each episode. Immunocompetent patients tend not to experience recurrent intraoral lesions, but can present with clusters of tiny vesicles and ulcers on the gingivae and anterior hard palate that are mildly symptomatic. Prodromal symptoms precede herpes labialis in 45 to 60 percent of episodes. [4] Patients experience pain, burning, or itching at the site of the subsequent eruption. Even in the immunocompetent patient, the severity of recurrent herpes labialis is extremely variable, and may vary from that of prodromal symptoms alone without the subsequent development of lesions (aborted episodes), to extensive disease induced by severe local sunburn.

FIGURE 214-2 Recurrent facial herpes simplex with grouped vesicles and crusting. (*Courtesy of Clyde S. Crumpacker, MD.*)

The progression of the classical herpes lesions has been divided according to the following stages based on their features: prodromal, erythema, and papule (the developmental stages); vesicle, ulcer, and hard crust (disease stages); followed by dry flaking and residual swelling (resolution stages). The lesions usually resolve within 5 to 15 days.

Trigger factors for oral herpes recurrences include emotional stress, illness, exposure to sun, trauma, fatigue, menses, chapped lips, and the season of the year. [23] Other well-documented triggers include exposure to UV irradiation, trigeminal nerve surgery, oral trauma, epidural administration of morphine, and abrasive, laser, and chemical facial cosmetic procedures. The exact mechanism by which these diverse factors triggers HSV reactivation is unknown.

HSV-2 causes a primary orofacial infection that is indistinguishable from that associated with HSV-1 except that it is usually in adolescents and young adults and following genital–oral contact. Moreover, HSV-2 orolabial infections are 120 times less likely to reactivate than is orolabial HSV-1 disease. [6]

Genital Infection

Genital herpes is the major clinical presentation of HSV-2 infection, but it may also result from HSV-1 in 10 to 40 percent of the cases, primarily ones following oral–genital contact. Because of their epidemiology, acquisition of HSV-1 in a person with prior HSV-2 infection is unusual, but HSV-2 acquisition in the presence of previous HSV-1 infection is common, and infection of the genital tract with both HSV-1 and HSV-2 has been described. Patients with previously known HSV-1 genital infection who develop frequent genital herpes recurrences should be tested for HSV-2 infection. [24]

The clinical courses of acute first-episode genital herpes among patients with HSV-1 and HSV-2 infections are similar. These infections are associated with extensive genital lesions in different stages of evolution, including vesicles, pustules, and erythematous ulcers that may require 2 to 3 weeks to resolve (Fig. 214-3). In males, lesions commonly occur on the glans penis or the penile shaft; in females, lesions may involve the vulva, perineum, buttocks, vagina, or cervix. There is accompanying pain, itching, dysuria, vaginal and urethral discharge, and tender inguinal lymphadenopathy. Systemic signs and symptoms are common and include fever, headache, malaise, and myalgias.

Herpetic sacral radiculomyelitis, with urinary retention, neuralgias, and constipation, can occur. HSV cervicitis occurs in more than 80 percent of women with primary infection. It can present as purulent or bloody vaginal discharge, and examination reveal areas of diffuse or focal friability and redness, extensive ulcerative lesions of the exocervix, or, rarely, necrotic cervicitis. Cervical discharge is usually mucoid, but it is occasionally mucopurulent.

FIGURE 214-3 *A*. Primary genital herpes with vesicles. *B*. Primary herpetic vulvitis. (*Courtesy of Clyde S. Crumpacker, MD.*)

The rates of recurrence for genital HSV-2 infections vary greatly among individuals and over time within the same individual. Infections caused by HSV-2 reactivate approximately 16 times more frequently than HSV-1 genital infections, and average 3 to 4 times per year, but may appear virtually weekly. [6] Recurrences tend to be more frequent in the first months to years after first infection. [6] The classical clinical manifestations of recurrent HSV-2 infection include multiple small but grouped vesicular lesions in the genital area. They may ulcerate promptly in women, some days later in men. The recurrence of genital lesions is usually heralded by a prodrome of tenderness, itching, burning, or tingling. Without treatment, the lesions usually heal in 6 to 10 days. Herpetic cervicitis is less common in recurrent disease, occurring in 12 percent of the patients. It may present without external lesions. Signs and symptoms that are less classical for genital HSV infection and which may divert one from the correct diagnosis include small erythematous lesions, fissures, pruritus, and urinary symptoms. HSV can cause urethritis, usually manifested only as a clear mucoid discharge, dysuria, and frequency. Occasionally, HSV can be associated with endometritis, salpingitis, or prostatitis. Symptomatic or asymptomatic rectal and perianal infections are common. Herpetic proctitis presents with anorectal pain, anorectal discharge, tenesmus, and constipation, with ulcerative lesions of the distal rectal mucosa.

FIGURE 214-4 Herpetic whitlow of the middle finger with associated erythema multiforme in a nurse's aide. (*Courtesy of Clyde S. Crumpacker, MD.*)

Other Cutaneous Infections

HSV can infect any skin site. The common theme among virtually all of these cutaneous presentations is the requirement that virus has penetrated otherwise normal and well-keratinized tissues. Herpetic whitlow (Fig. 214-4) is the infection of the fingers by HSV acquired by direct inoculation or by direct spread from mucosal sites at the time of primary infection. Thus, a typical presentation of whitlow would be in children who suck their fingers during a primary gingivostomatitis outbreak. It is also a well-documented occupational hazard for medical personnel. It is usually caused by HSV-1, but HSV-2 whitlow may develop as a manifestation of primary inoculation following manual–genital contact with an infected partner. The infected region becomes erythematous and edematous. Lesions are usually present at the fingertip and can be pustular and very painful. Fever and local lymphadenopathy are common. Whitlow is often misdiagnosed as a bacterial paronychial infection, but the surgical drainage, often needed for a bacterial infection, is unnecessary and potentially harmful, while antiviral therapy speeds healing. Whitlow may recur.

Cutaneous herpes can be transmitted between athletes involved in contact sports, such as wrestling (herpes gladiatorum) and rugby (herpes rugbiaforum or scrum pox), and may do so as outbreaks or small epidemics among team members. In these instances, multiple herpetic lesions may appear across the thorax, ears, face, arms, and hands, caused by facilitation of infection by trauma to the normally keratinized skin sustained during the practice of the sport. Concomitant ocular herpes can occur.

Eczema herpeticum (Kaposi's varicelliform eruption) (Fig. 214-5) results from a widespread infection following inoculation of virus to skin damaged by eczema. It is usually a manifestation of primary HSV-1 infection in a child with atopic dermatitis, but other skin conditions also can be complicated by cutaneous dissemination of HSV. Some of the known predisposing conditions include mycosis fungoides, Sézary syndrome, Darier's disease, various bullous diseases of the skin (particularly if patients are receiving immunosuppressive therapy), and burns of second or third degree. The severity of these infections ranges from mild to fatal, with mortality rates of up to 10 percent being reported before antiviral therapy was available. Mortality was usually primarily caused by bacterial superinfection and bacteremia.

Common pathogens include *Staphylococcus aureus, Streptococcus,* and *Pseudomonas*.

FIGURE 214-5 Eczema herpeticum in areas of atopic dermatitis. (*Courtesy of Clyde S. Crumpacker, MD.*)

In a typical severe primary attack, several days after exposure vesicles develop in large numbers over the areas of active or recently healed atopic dermatitis, particularly the face, and continue to appear in crops for several days more. The vesicles become pustular and markedly umbilicated. Patients commonly have high fever and adenopathy. Viremia with infection of internal organs can be fatal. Recurrences are usually far milder than these first infections. Arriving at the correct diagnosis can be delayed because of secondary impetiginization of the lesions, but it always should be considered in children with infected eczema, particularly if the child is more ill systemically than one might anticipate with impetigo. Eczema herpeticum of the young infant is a medical emergency and early treatment with acyclovir can prove lifesaving.

Recurrent HSV infection is the most common precipitating event in cases of recurrent erythema multiforme (EM) (Fig. 214-5) (see Chap. 58). HSV–associated EM (HSVAEM) is usually an acute, self-limited, recurrent disease. The duration of the disease is usually about 3 weeks. The lesions are usually disseminated and symmetric, occurring on acral extremities and face, and there is grouping of the lesions over the elbow and knees, as well as nail fold involvement; photodistribution and isomorphic phenomenon can occur. Mucosal involvement is usually mild and restricted to the mouth. Constitutional symptoms are rare and the skin lesions heal without scarring.

Ocular Infections

HSV is a leading cause of recurrent keratoconjunctivitis and its associated corneal opacification and visual loss. It is usually caused by HSV-1, except in neonates in whom HSV-2 is more prevalent. The majority of HSV eye disease is caused by reactivation of the virus in the trigeminal ganglia, but primary infections of the eye can also occur. Usually, the initial manifestation of herpetic eye disease is a superficial infection of the eyelids and conjunctiva (blepharoconjunctivitis), or corneal surface (dendritic or geographic epithelial ulcer). Deeper involvement of the cornea (stromal keratitis) or anterior uvea (iritis) represent more serious forms of the disease and can cause permanent visual loss. Acute retinal necrosis is a rare but rapidly progressive disease characterized by retinal arteriolar sheathing, uveitis, and peripheral retinal opacification, with variable pain and visual loss. Bilateral involvement may occur, and retinal detachments are common. It is usually associated with HSV-1 infection, but HSV-2 retinitis has been described and VZV causes a similar process. [25]

Neurologic Disorders

All HSV infections involve the nervous system, as neurons are the sole proven site of virus latency. Neurologic manifestations of HSV infections, however, are not universal, but highly variable in their presentation and severity. HSV meningitis is manifested by headache, fever, and mild photophobia, with lymphocytic pleocytosis in the cerebrospinal fluid (CSF). Most cases result from HSV-2 infection. It resolves spontaneously in 2 to 7 days. It is usually seen in association with primary genital HSV-2 infection. Recurrent lymphocytic meningitis (Mollaret's meningitis) is associated with recurrent HSV-2 infection, often without symptomatic genital disease. Involvement of the sacral nerves with autonomic nervous system dysfunction, numbness, pelvic pain, tingling, urinary retention, constipation, and CSF pleocytosis has been reported in association with HSV infection. Symptoms usually resolve in a few days, but in some cases, the neurologic residua take weeks to months to disappear, occasionally becoming permanent. Rare cases of transverse myelitis and Guillain-Barré syndrome after HSV infection have been reported.

Bell's palsy is an acute, peripheral facial paresis of unknown cause, and is thought to result from inflammation and subsequent mechanical compression of the facial nerve in the temporal bone. Reactivation of HSV and VZV are implicated in the pathogenesis of the disease. [26], [27]

HSV encephalitis is the most commonly identified acute, sporadic viral encephalitis in the United States, accounting for 10 to 20 percent of all cases. Nearly all of the cases arising after the neonatal period (see below) are caused by HSV-1. HSV encephalitis usually presents with acute onset of focal neurologic symptoms and fever. Involvement of the temporal lobe is a characteristic feature of this disease, but overall, it is difficult to differentiate HSV encephalitis clinically from other viral encephalitides. PCR of the CSF for HSV DNA is the most sensitive noninvasive technique to help in the diagnosis. Brain biopsies had been the gold standard method to establish the diagnosis until the advent of PCR. However, even with therapy, neurologic sequelae are frequent, especially in persons older than 35 years of age. Patients with presumed HSV encephalitis should be treated empirically with intravenous acyclovir until the diagnosis is confirmed

or an alternative diagnosis is made.

Immunocompromised Host

All manifestations of HSV infection seen in the immunocompetent host can also be seen in immunocompromised patients, but they are usually more severe, more extensive and difficult to treat, and, for many of them, recurrences are more frequent as well. Patients with defects of T cell immunity are at particular risk for progressive mucocutaneous or visceral infections, but as indicated above, the degree of dissemination depends on the level of immunodeficiency of the host. Recurrent and persistent ulcerative HSV lesions are among the most common and defining opportunistic infections in patients with AIDS. Genital herpes is very common in patients with HIV and can be persistent and severe. Oropharyngeal HSV in immunocompromised patients can present with widespread involvement of the mucosa and extremely painful, friable, hemorrhagic, and necrotic lesions, similar to the mucositis caused by cytotoxic agents or other infectious agents. The lesions can spread locally to involve the esophagus. Esophagitis presents with odynophagia, dysphagia, substernal pain, and multiple ulcerative lesions. Esophagitis can also arise directly by reactivation of HSV and its spread to the esophagus via the vagus nerve. Tracheobronchitis and pneumonitis can also occur by spreading of the virus from oropharyngeal HSV.

HSV can reactivate from visceral ganglia of the autonomic nervous system or disseminate hematogenously to other visceral organs, causing pneumonitis, hepatitis, pancreatitis, other portions of the gastrointestinal tract, as well as adrenal necrosis. Most of these severe infections are caused by HSV-1, but HSV-2 can do so as well. Few are ever diagnosed except at autopsy.

Neonatal Herpes

The neonate is a special category of immune-deficient host. The incidence of neonatal herpes is approximately 1 in 3500 live births. Seventy percent of neonatal HSV cases are caused by HSV-2 inoculated directly by infectious genital secretions at the time of delivery. The category of maternal infection plays a significant role in defining the risk of neonatal herpes. Primary genital herpes is associated with a risk of neonatal infection of 33 to 50 percent for vaginally delivered babies. Risk of transmission to a neonate is highest in women who develop primary herpes in the third trimester. This is because primary infections are usually associated with prolonged excretion of high titers of virus, and there will have been no time for the mother to mount an immune response against the virus and transfer protective antibodies to the child. In contrast, recurrent maternal infection is associated with a risk of transmission of less than 3 percent. [28]

Neonatal herpes infections manifest in one of three forms: skin, eye, and mouth (SEM) involvement; encephalitis; or disseminated disease. The latter two forms account for more than 50 percent of cases of neonatal herpes. Without therapy, the overall mortality of neonatal herpes is 65 percent, and fewer than 10 percent of untreated neonates with central nervous system (CNS) infection will develop normally. With current therapeutic modalities, most babies with SEM disease survive, but approximately 5 percent of these children remain at risk for long-term neurologic sequelae. For treated babies with encephalitis, mortality is 14 percent, with 50 percent developing normally after 1 year. For babies with disseminated disease, mortality is 55 percent, with 85 percent of the survivors apparently developing normally after 1 year. [29]

LABORATORY FINDINGS

The method of choice for diagnosis of HSV infection depends on the clinical presentation. In many instances, the history and clinical findings may be sufficient, but the social, emotional, and therapeutic implications of a diagnosis dictate that it be confirmed by laboratory testing when possible. For patients with lesions, virus isolation by cell culture is the method of choice. In culture, HSV causes typical cytopathic effects and most specimens will prove positive within 48 to 96 h after inoculation. The sensitivity of the culture depends on the quantity of the virus in the specimen. Even in the most experienced centers, only approximately 60 to 70 percent of fresh genital lesions are culture-positive. Isolation of the virus is most successful when lesions are cultured during their vesicular stage, and when specimens are taken from immunocompromised patients or from patients suffering from a primary infection.

Direct fluorescent antibody staining of lesion scrapings and antigen detection assays can also be used, but sensitivity is somewhat lower than that of viral culture. [30] The Tzanck smear can be helpful in the rapid diagnosis of herpesviruses infections, but it is less sensitive than culture and staining with fluorescent antibody, with positive results in fewer than 40 percent of culture-proven cases. It is performed by scraping the base of a freshly ruptured vesicle and staining the slides with Giemsa or Wright stain (the Papanicolaou staining method can also be used), followed by examination for the multinucleated giant cells that are diagnostic of herpetic infection. Both HSV and VZV will cause these changes. PCR is more sensitive than viral isolation, and has been extensively used for the diagnosis of CNS infections, but it is still not available for routine practice settings. It may also be useful for the detection of HSV in late stage ulcerative lesions. Both viral culture and PCR assays enable typing of the isolate as HSV-1 or HSV-2. This information helps to predict the frequency of reactivation after a first-episode of HSV infection. In the skin biopsy specimens, the epithelial cells are enlarged, swollen, and often separated. Multinucleated cells with intranuclear eosinophilic inclusion bodies (Cowdry type A inclusions) can be seen.

Serologic detection of antibodies to HSV can be helpful in certain settings but the results are often misinterpreted. Its main function is in differentiating a primary episode from a recurrent infection (Table 214-1). A positive serologic test result can be useful in patients with recurrent, genital lesions that are not present at times of examination and, therefore, a positive culture cannot be obtained. Serologic testing can also be helpful for counseling patients with initial episodes of disease and their partners, especially during pregnancy, and in counseling partners of patients with genital herpes about their risk of acquiring HSV.

Classification	Virus isolated	Serologic results		Serologic	Comments
		HSV-1	HSV-2	HSV-1	HSV-2
Primary HSV-1	HSV-1	+	+	+	+
Primary HSV-2	HSV-2	+	+	+	+
Primary HSV-1 plus previous HSV-2 infection*	HSV-1	+	+	+	+
Primary HSV-2 plus previous HSV-1 infection	HSV-2	+	+	+	+
Recurrent HSV-1	HSV-1	+	+ or +	+	+ or +
Recurrent HSV-2	HSV-2	+ or +	+	+ or +	+

*Note.

TABLE 214-1 **Classification of Herpes Simplex Infections According to Viral Isolation and Paired Serologic Test Results**

The traditional serologic testing techniques for HSV are seriously deficient because they reflect the substantial cross-reactivity between HSV-1 and HSV-2 antigens. The Western blot assay, in identifying responses to non–cross-reacting herpes glycoproteins can differentiate between HSV-1 and HSV-2 infection, but it is expensive and only available in a few research laboratories. Recently, simple kits for type-specific serologic assays, based on antigenic differences between HSV-1 and HSV-2 glycoprotein G have been tested and have entered the market. [31] It is anticipated that in time they will be in high demand. Guidelines for their use in general clinical practice are not yet available. However, it seems obvious that they should be used only by practitioners who are prepared to counsel patients about the meaning of the test results in terms of the natural history of the disease, available treatment regimens, disease transmission, and the emotional and social implications of the diagnosis.

MANAGEMENT

All sexually active persons should be educated regarding the nature and risks of acquiring and transmitting sexually transmitted infections, including HSV. Studies show that about half of the patients with asymptomatic HSV-2 infection have mild unrecognized disease and can be taught to recognize their symptoms and signs of genital herpes. Also, patients should be counseled regarding safer sex practices. It must be emphasized that the majority of transmission occurs in asymptomatic phases and from people who have no classical lesions. Patients with genital herpes should be counseled to refrain from sexual intercourse during outbreaks and for 1 to 2 days after, and to use condoms between outbreaks. Suppressive therapy may also be an option (see below), but it has not yet proven to decrease transmission.

Pregnant women who are known to have genital herpes should be reassured that the risk of transmitting herpes to the baby during childbirth is extremely low. Recommendations for the management of pregnant women with recurrent genital herpes have been made, but there has been no controlled trial of the overall approach. [32] The recommendations include clinical evaluation at delivery, with delivery by cesarean section indicated if there are signs and symptoms of active infection (including prodrome). Women with primary HSV infection during pregnancy, particularly during the second and third trimesters, should be treated with antiviral therapy. For women at or beyond 36 weeks of gestation who are at risk for recurrent HSV infection, suppressive antiviral therapy also may be considered. Cesarean section delivery may not reliably prevent neonatal HSV infection when membranes are ruptured for long periods of time (=24 h). The role of culturing the mother and/or the baby for HSV is controversial. Current recommendations include culturing for HSV at the time of delivery in women with a history of genital herpes. Women with active genital lesions at delivery and their babies should be cultured serially. Cultures should be taken from eye, oronasopharynx, and suspected sites every 2 to 3 days during the first 4 weeks of life. [33]

Women who are known by history and serologic tests not to have genital herpes should be counseled about signs and symptoms of HSV and how to avoid acquiring the infection during pregnancy. Serology is helpful in counseling a couple in which the male partner has recurrent genital herpes and the pregnant wife is susceptible.

Antiviral Therapy

Many HSV infections require no specific treatment at all. Keeping the lesions clean and dry while they heal by themselves may be all that is required. Treatment is warranted for infections that are likely to prove protracted, highly symptomatic, or complicated. Acyclovir, an acyclic guanosine analogue, was the first compound shown to prevent replication of a virus at concentrations far below those that affect cellular nucleic acid synthesis. This finding was a key factor in establishing antiviral chemotherapy as a major medical intervention. Acyclovir inhibits HSV-1 and HSV-2 replication by 50 percent at a concentration of 0.1 and 0.3 µg/mL (range, 0.01 to 9.9 µg/mL), respectively, but is toxic at concentrations of >30 µg/mL. Any strain that requires more than 3 µg/mL of acyclovir to be inhibited is said to be relatively drug-resistant. Acyclovir must be phosphorylated to be active, and it requires the viral thymidine kinase for efficient monophosphorylation. After this key initial step, the monophosphate is converted to acyclovir triphosphate by cellular kinases. The fully active acyclovir triphosphate competes with the natural substrate, deoxyguanosine triphosphate, and it is more efficiently incorporated into viral DNA by the viral polymerase compared to the cellular polymerase. The incorporated acyclovir triphosphate prevents chain elongation and terminates viral DNA synthesis. Therefore, acyclovir has a highly favorable therapeutic index because of its preferential activation in infected cells and preferential inhibition of the viral DNA polymerase. Acyclovir was approved for the treatment of HSV in 1982. In recent years, various derivative compounds have been developed, each of which offers some modest advantages over acyclovir.

Valaciclovir, the L-valyl ester of acyclovir, is an oral prodrug of acyclovir, designed to overcome the poor gastrointestinal (GI) absorption of acyclovir itself. The bioavailability of acyclovir from oral valaciclovir is three- to fivefold greater than that achieved after oral acyclovir administration, and it can be used in a more convenient dosage regimen. Valaciclovir is usually well tolerated, but in a study of very high-dose valaciclovir (8 g/day) for cytomegalovirus prophylaxis in HIV patients, there was a trend toward earlier deaths in the valaciclovir arm with a possible association with thrombotic microangiopathy. [34] This association was not been observed in other studies of high-dose valaciclovir.

Famciclovir is the well-absorbed oral form of the related guanosine analogue penciclovir. Similar to acyclovir, famciclovir is converted by phosphorylation to its active metabolite penciclovir-triphosphate. The efficacy and adverse effect profile

of famciclovir is comparable to that of acyclovir. Penciclovir 1% cream is approved by the Food and Drug Administration (FDA) for the treatment of herpes simplex labialis.

Docosanol 10% cream is approved by the FDA for over-the-counter treatment of recurrent herpes labialis. Docosanol is a long-chain saturated alcohol that inhibits entry of lipid-enveloped virus into the cell. It decreased the healing time by 18 h when compared with placebo. [35]

The current recommendations for antiviral treatment depend on the clinical disease, on host immune status, and whether one is treating a primary or recurrent episode or considering suppressive therapy. Table 214-2 describes the dosages and regimens for these different scenarios. For disseminated or severe herpes infections, the treatment of choice remains intravenous acyclovir 5 to 10 mg/kg every 8 h. Some experts use acyclovir 15 mg/kg IV every 8 h for life-threatening HSV infection, including encephalitis. The dose of intravenous acyclovir for disseminated or CNS neonatal herpes is 20 mg/kg per dose given every 8 h.

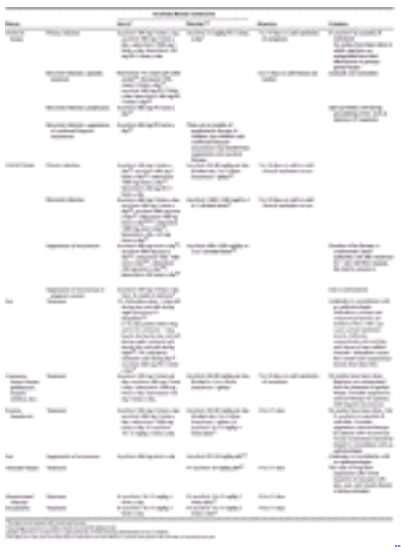

TABLE 214-2 **Recommended Regimens for the Treatment of Herpes Simplex Infections**

For first episodes of genital HSV-2 infections oral acyclovir, famciclovir, and valaciclovir all speed the healing, resolution of symptoms, and decrease viral shedding. When compared with placebo, acyclovir decreases time to healing from 16 to 12 days, the duration of pain from 7 to 5 days, and the duration of constitutional symptoms from 6 to 3 days. [36] Valaciclovir was compared with acyclovir in the treatment of primary episodes, and shown to be equivalent. [37] But antiviral treatment of initial herpes episodes does not decrease subsequent recurrences. The reason for this is that HSV establishes latent infection within hours after inoculation and days before symptoms evolve. While carefully conducted animal studies showed that very early therapy with antivirals (before lesions have appeared) can decrease the amount of latent virus and hence reduce the rate of subsequent reactivation, this is not a practical or appropriate strategy for humans, except perhaps in the setting of a clear laboratory contamination with an infectious inoculum of HSV.

Treatment of recurrent episodes of genital herpes with famciclovir, acyclovir, or valaciclovir has been shown to reduce the time of healing from about 7 to 5 days, time of cessation of viral shedding from 4 to 2 days, and duration of symptoms from 4 to 3 days when compared with placebo. Valaciclovir and acyclovir are equivalent, [38], [39] and it is likely that famciclovir, if tested, would be as well.

For persons with frequent or complicated genital recurrences, long-term suppressive therapy with acyclovir or its analogues is the most effective management strategy. [40], [41] Because genital herpes is not progressive in the normal host, and because the rate of recurrences varies over time and may decrease after some years, it is wise to recommend a “holiday” from treatment every year or so to reassess the person's continuing need for treatment.

The use of antiviral suppressive therapy during the late phase of pregnancy to avoid neonatal herpes has also been advocated, but a formal study of the approach would require a very large number of participants because of the rare incidence of neonatal herpes. A more achievable goal is to decrease the need for cesarean deliveries caused by herpes recurrences during labor. Cost–benefit analyses have been favorable for the use of acyclovir in pregnancy. [42] Pregnant women who had at least one episode of genital herpes during pregnancy were randomized to receive acyclovir 200 mg or placebo four times a day starting at 36 weeks. Acyclovir decreased the rate of cesarean sections from 16.5 to 8.4 percent. Pregnant women who did not have a genital herpes recurrence during pregnancy and who did not receive prophylaxis had a cesarean rate of 9.9 percent. There were no cases of neonatal herpes during the study period and there were no complications as a result of the antiviral treatment administered during pregnancy. [43] Larger studies to define the risks and benefits of antiviral suppressive therapy in pregnancy are needed.

Orolabial HSV infections warrant antiviral treatment less often than do the genital infections. Primary HSV gingivostomatitis should be treated with oral acyclovir. The pediatric dose is 15 mg/kg of acyclovir suspension PO five times a day for 7 days. When it is started within 3 days of onset of the disease, this regimen decreases the duration of oral and extraoral lesions, fever, and eating and drinking difficulties. Valaciclovir and famciclovir may be equally effective, but they have not been studied in this setting and are not currently approved for use in children. Severely ill children may need to be hospitalized for hydration, and intravenous acyclovir may be necessary.

Treatment of recurrent herpes labialis with antiviral drugs in immunocompetent hosts has shown only modest benefits so far. The infections are inherently briefer and less symptomatic than genital herpes. Treatment is only effective if used very early in the disease, especially in the prodromal or erythema lesion stages. Patients who wish treatment should

have the medication available and be vigilant for the earliest signs and symptoms of a recurrence. When treatment is felt to be required, the therapy of choice is penciclovir 1% cream every 2 h while awake for 4 days. [44] Treatment should be initiated as early as possible. When initiated within 1 h of first symptom of recurrence, penciclovir sped the healing of lesions (4.8 days versus 5.5 days) and decreased the duration of pain (3.5 days versus 4.1 days). This regimen is approved by the FDA. Docosanol 10% cream is approved by the FDA for over-the-counter treatment of herpes simplex labialis. It is to be applied five times a day, at the first sign of recurrence of herpes simplex labialis. There has been no direct comparison with topical penciclovir.

Oral acyclovir 400 mg five times a day for 5 days affords marginal benefit if begun in the earliest hour or two of the outbreak. Famciclovir 500 mg three times a day for 5 days, when started within 48 h after experimental ultraviolet radiation, decreased the median time to healing from 6 to 4 days, [45] but is not useful for the more usual sporadic cases of herpes labialis. Valaciclovir should be comparable to acyclovir and famciclovir, but it has not been studied in this setting. Creams and ointments containing 5% and 10% acyclovir are not beneficial in recurrent herpes labialis.

The use of suppressive acyclovir for herpes labialis is controversial. In one small study, oral acyclovir, 400 mg twice a day, was effective in decreasing recurrences of herpes labialis. [46] In studies with skiers (and therefore significant and anticipated sun exposures), acyclovir 400 mg twice a day was shown to reduce recurrences in one study, [47] while acyclovir 800 mg bid failed to prevent recurrences in another study. [48]

Herpetic eye disease should always be treated in consultation with an ophthalmologist. Options usually involve topical antivirals. These include idoxuridine, vidarabine, and trifluridine. Topical antivirals are effective in shortening the duration of dendritic and geographic keratitis, and are used to prevent corneal epithelial disease in patients with blepharitis and conjunctivitis, as well as patients on topical steroid therapy for corneal stromal inflammation and iridocyclitis. Oral acyclovir is also effective for dendritic and geographical epithelial keratitis. Suppressive acyclovir therapy reduces the rates of all types of recurrent ocular HSV disease, and it is most important for patients with a history of HSV stromal keratitis, because it can prevent additional episodes and potential loss of vision.

Antiviral Resistance

The specter of drug resistance hangs over the family of antiherpes drugs as it does over all other classes of antimicrobials. However, virtually all clinically relevant drug resistance has been seen in immunocompromised patients. The primary mechanism of acyclovir resistance is selection of viral mutants defective or deficient in thymidine kinase (TK) expression. Most mutants that are TK deficient are somewhat attenuated in virulence in vivo. In animal models, totally TK-deficient mutants have been severely impaired, most notably failing to reactivate from latency.

The treatment of resistant HSV infection is complicated. First, one must make the diagnosis. Very few people who claim to be “resistant” to one of the antiviral drugs actually harbor resistant virus. There is a common misconception that treatment prevents all recurrences, now and forever. One should suspect resistance only in people who continue to have culture-proven outbreaks of unaltered frequency and severity, especially if the lesions do not heal by themselves. When resistance is suspected, virus should be recovered and tested specifically for sensitivity to acyclovir. These tests are expensive but now widely available through commercial reference laboratories. Second, the options for patients with true resistance are few and far from ideal due to the lack of alternatives that are safe and easy to administer. Foscarnet, an organic analogue of inorganic pyrophosphate, inhibits replication of all known herpesviruses in vitro and does not require activation by TK or other kinases, and therefore can be effective in the treatment of acyclovir-resistant HSV. Foscarnet requires intravenous therapy and can cause numerous adverse reactions including nephrotoxicity, electrolytes disturbances, anemia, and seizures. Also, foscarnet-resistant herpesvirus strains have been described.

Cidofovir is an acyclic nucleoside phosphonate with broad-spectrum activity against a wide variety of DNA viruses including herpesviruses. Being a nucleotide (rather than nucleoside) analogue, it does not require the viral TK for its intracellular phosphorylation to the active form. Cidofovir has been tested in cases of acyclovir-resistant HSV and topical cidofovir has been used with success to treat progressive herpetic lesions. [49] Intravenous cidofovir is associated with considerable nephrotoxicity and requires the coadministration of saline hydration and probenecid.

Varicella (chickenpox) and herpes zoster (shingles, zoster) are distinct clinical entities caused by a single member of the herpesvirus family, the varicella-zoster virus (VZV). The different clinical manifestations of these two diseases are a result of differences in the host and in the circumstances of infection, not to differences in their etiologic agent. [1], [2]

Varicella, an acute, highly contagious exanthem that occurs most often in childhood, is the result of primary infection of a susceptible individual. In normal children, systemic symptoms are usually mild and serious complications are extremely rare. In adults and in immunologically compromised persons, varicella is more likely to be associated with life-threatening complications.

Herpes zoster is a localized disease characterized by unilateral radicular pain and a vesicular eruption that is generally limited to the dermatome innervated by a single spinal or cranial sensory ganglion. It occurs most often in elderly people. Herpes zoster is the result of the reactivation of endogenous virus that had persisted in latent form within sensory ganglia following an earlier attack of varicella. The incidence of complications increases with immune-impairing conditions. [3]

EPIDEMIOLOGY

Epidemiology of Varicella

Varicella is distributed worldwide, but its age-specific incidence differs in temperate versus tropical climates and in those populations who have received the varicella vaccine. In temperate climates in the absence of vaccination, varicella is endemic, with a regularly recurring seasonal prevalence in winter and spring, and periodic epidemics that depend upon the accumulation of susceptible persons. In Europe and North America, 90 percent of cases occur in children younger than 10 years of age and fewer than 5 percent of cases occur in individuals older than the age of 15. [3] National Health Interview Survey (NHIS) data indicated an incidence of 15 cases per 1000 population per year, with the highest annual incidence (90 per 1000 population per year) among children 5 to 9 years of age. [4] More recent studies report the highest annual incidence among children 1 to 4 years of age (e.g., 154 per 1000 population in Olmstead County, Minnesota). [5] The trend toward younger age of infection may be related to increased attendance at preschools and day care centers. From 1988 to 1995, there were approximately 11,000 hospitalizations and 100 deaths caused by varicella each year in the United States. [6] The risk of hospitalization and death was much higher in infants and adults than in children, and most varicella-related deaths occurred in previously healthy people. [7]

In tropical and semitropical countries, the mean age of varicella is higher and the susceptibility of adults to primary VZV infection is significantly greater than in temperate climates. High levels of susceptibility to varicella among adults emigrating from tropical climates is well documented in the U.S. military, where up to 40 percent of recruits from Puerto Rico and the Philippines have been VZV seronegative.

Varicella is highly contagious. Attack rates of 87 percent among susceptible siblings in households and nearly 70 percent

among susceptible patients on hospital wards have been reported. More than 95 percent of cases of varicella are clinically apparent, although occasionally the exanthem may be so sparse and transient as to pass unnoticed. A typical patient is infectious for 1 to 2 days (rarely, 3 to 4 days) before the exanthem appears, and for 4 or 5 days thereafter, that is, until the last crop of vesicles has crusted. The immunocompromised patient, who may experience many successive crops of lesions for a week or more, is infectious for a longer period of time. The mean incubation period of varicella is 14 or 15 days, with a range of 10 to 23 days. It is often prolonged in patients who develop varicella after passive immunization with varicella-zoster immune globulin (VZIG) or zoster immune plasma (ZIP), or active immunization with the live attenuated Oka strain varicella vaccine. [8]

The major route by which varicella is acquired and transmitted is thought to be the respiratory tract, but infection may also be spread by direct contact. Varicella crusts are not infectious, and the duration of infectivity of droplets containing virus is probably quite limited. Although the infectiousness of patients with varicella is thought to depend largely upon virus shed from the mucous membranes of the upper respiratory tract, VZV has only rarely been cultured from pharyngeal secretions; however, it can be detected in the oropharynx of the majority of patients using polymerase chain reaction (PCR)-based assays. [9]

One attack of varicella generally confers lasting immunity to the disease. Reexposure to the virus boosts humoral and cell-mediated immune responses but rarely leads to clinical illness. Most reported second attacks of varicella involve incorrect diagnoses; others may represent cutaneous dissemination in patients with herpes zoster (see below). With severe immunocompromise, reinfections manifested as varicella have been observed. In addition, persons who develop modified varicella (e.g., because they are infected early in infancy in the presence of maternal antibody or have been immunized with live attenuated varicella vaccine) may respond to exogenous exposure by developing a second, usually mild, episode of “breakthrough” varicella.

Epidemiology of Herpes Zoster

Herpes zoster occurs sporadically throughout the year without seasonal prevalence. The occurrence of herpes zoster is independent of the prevalence of varicella, and there is no convincing evidence that herpes zoster can be acquired by contact with other persons with varicella or herpes zoster. Rather, the incidence of herpes zoster is determined by factors that influence the host-virus relationship.

One strong risk factor is older age (Fig. 215-1A). [3] Experts calculate the lifetime incidence of herpes zoster to be 10 to 20 percent in the general population and an annual incidence of 600,000 to 850,000 cases of herpes zoster in the United States. [10]

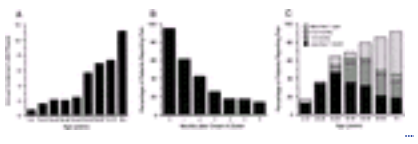

FIGURE 215-1 *A*. The epidemiology of herpes zoster and postherpetic neuralgia. The annual incidence of herpes zoster per 1000 persons in a general medical practice. *B*. The percentage of patients with pain persisting after the onset of the herpes zoster rash. These data are from the placebo recipients in one large, double-blind treatment study. *C.* The proportion of patients with postherpetic neuralgia according to age. (*From Kost and Straus,* [17] *with permission.*)

Another major risk factor is cellular immune dysfunction. Immunosuppressed patients have a 20 to 100 times greater risk of herpes zoster than immunocompetent individuals. Herpes zoster is frequently an early manifestation of HIV infection, and thus high-risk individuals who develop herpes zoster should be evaluated for coincident HIV infection.

Second episodes of herpes zoster are uncommon in immunocompetent persons, and third attacks are not unheard of but many of these occur in immunocompromised individuals. [11] Immunocompetent patients suffering multiple episodes of herpes zoster–like disease are far more likely to be suffering from recurrent zosteriform herpes simplex virus infections. [12]

Patients with herpes zoster are less contagious than patients with varicella. The rate at which susceptible household contacts develop varicella after exposure to herpes zoster appears to be one-third that of cases following exposure to varicella. [11] Virus can be isolated from vesicles of uncomplicated herpes zoster for up to 7 days after the appearance of the rash and for much longer periods in some immunocompromised individuals. Patients with uncomplicated dermatomal zoster appear to spread the infection by means of direct contact with their lesions. Patients with disseminated herpes zoster may, in addition, transmit the infection in aerosols, so that airborne and contact isolation is required for such patients.

ETIOLOGY

VZV is a member of the herpesvirus family. [1], [2] Other members pathogenic for humans include herpes simplex viruses type 1 (HSV-1) and type 2 (HSV-2); cytomegalovirus (CMV); Epstein-Barr virus (EBV); human herpesvirus-6 (HHV-6) and human herpesvirus-7 (HHV-7), which cause roseola; and Kaposi's sarcoma–associated herpesvirus, also called human herpesvirus type 8. All herpesviruses are morphologically indistinguishable and share a number of properties, including a propensity for establishing latent infections that persist for life.

The VZV genome encodes about 70 genes, most of which have DNA sequence and functional homology to genes of the other herpesviruses. Immediate early (IE) gene products regulate VZV replication. Early gene products, such as the

virus-specific thymidine kinase and the viral DNA polymerase, support viral replication. Late genes encode virus structural proteins that serve as targets of antibody and cellular immune responses.

There is only one VZV serotype; however, viruses isolated from individual cases of varicella or herpes zoster worldwide are basically similar, but minor variations in their nucleotide sequences allow one to distinguish cases associated with wild-type or vaccine virus strains.

PATHOGENESIS

Pathogenesis of Varicella

Entry of VZV is through the mucosa of the upper respiratory tract and oropharynx. Initial multiplication at this portal of entry results in dissemination of small amounts of virus via the blood and lymphatics (the primary viremia). This virus is cleared by cells of the reticuloendothelial system, the major site of virus replication during the remainder of the incubation period.

The incubating infection is partially contained by innate host defenses [e.g., interferon, natural killer (NK) cells] and by developing immune responses. In most individuals, virus replication eventually overwhelms these still undeveloped defenses, so that about 2 weeks after infection, a much larger (secondary) viremia and associated symptoms and lesions occur. Skin lesions appear in successive crops, reflecting a cyclic viremia, which in the normal host is terminated after about 3 days by VZV-specific humoral and cellular immune responses. Virus circulates in mononuclear leukocytes, primarily lymphocytes. The frequent observations of elevated serum levels of hepatocellular enzymes in the acute stage of uncomplicated varicella suggest the routine, subclinical involvement of many organs; it is merely the ease with which skin involvement in varicella is recognized that makes it so noteworthy.

Effective host immune responses terminate viremia and limit the progression of varicella lesions in the skin and other organs. Humoral immunity to VZV protects against varicella. People with detectable serum antibody do not usually become ill after exogenous exposure. [13] Cell-mediated immunity to VZV also develops during the course of varicella, persists for many years, and protects one from severe infections. [14]

Pathogenesis of Herpes Zoster

During the course of varicella, VZV passes from lesions in the skin and mucosal surfaces into the contiguous endings of sensory nerves and is transported centripetally up the sensory fibers to the sensory ganglia. In the ganglia, the virus establishes a latent infection that persists for life. Herpes zoster occurs most often in dermatomes in which the rash of varicella achieves the highest density—those innervated by the first (ophthalmic) division of the trigeminal nerve and by spinal sensory ganglia from T1 to L2.

Although the latent virus in the ganglia retains its potential for full infectivity, reactivation is sporadic, infrequent, and associated with immunosuppression; irradiation of the spinal column; tumor involvement of the cord, dorsal root ganglion, or adjacent structures; local trauma; surgical manipulation of the spine; and frontal sinusitis as a precipitant of ophthalmic zoster. Most important, though, is the senescence of the cellular immune response to VZV with increasing age. [11], [15]

VZV may also reactivate without producing overt disease. Although asymptomatic reactivation of VZV has not been proven definitively, the small quantity of viral antigen released during such contained reactivations would be expected to stimulate and sustain host immunity to VZV. [16]

When host resistance falls below a critical level, reactivated virus can no longer be contained. [11] Virus multiplies and spreads within the ganglion, causing neuronal necrosis and intense inflammation, a process that is often accompanied by severe neuralgia. Infectious VZV then spreads antidromically down the sensory nerve, risking intense neuritis, and is released around the sensory nerve endings in the skin, where it produces the characteristic cluster of zoster vesicles. Spread of the ganglionic infection proximally along the posterior nerve root to the meninges and cord results in local leptomeningitis, cerebrospinal fluid pleocytosis, and segmental myelitis. Infection of motor neurons in the anterior horn and inflammation of the anterior nerve root account for the local palsies that may accompany the cutaneous eruption, and extension of infection within the central nervous system may result in rare complications of herpes zoster (e.g., meningoencephalitis, transverse myelitis).

Pathogenesis of Pain in Herpes Zoster and Postherpetic Neuralgia

Pain is a major symptom of herpes zoster. It often precedes and generally accompanies the rash, and it frequently persists after the rash has healed—a complication known as postherpetic neuralgia (PHN). A number of different but overlapping mechanisms appear to be involved in the pathogenesis of pain in herpes zoster and PHN (Fig. 215-2). [17], [18]

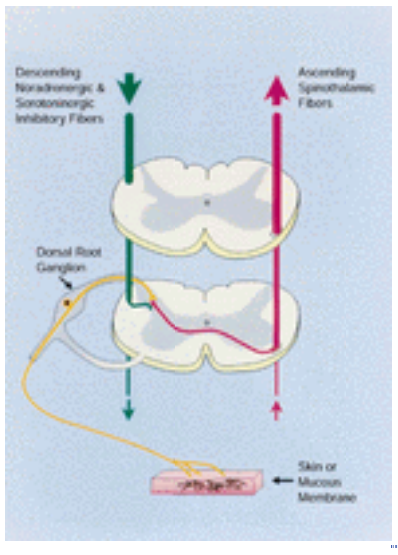

FIGURE 215-2 Pathway of normal pain perception. Noxious stimuli activate free nerve endings in the skin to generate signals that are conveyed through unmyelinated C fibers (*red*) and small Ad fibers to the neuronal bodies in the segmental dorsal root ganglia, then proximally to the dorsal horn of the spinal cord, where they form synapses with second-order neurons. Spinal cord neurons are subject to powerful descending inhibitory signals from the brain (*green*), mediated by the biogenic amines serotonin and norepinephrine. Drugs that potentiate the central effects of biogenic amines, such as tricyclic antidepressant drugs, may act by enhancing these descending pathways. Endogenous opiates also contribute to descending inhibitory input. The net result of peripheral afferent input and descending inhibitory input is projected cephalad, joining other ascending fibers in the contralateral spinothalamic tract (*orange*). Information from the spinothalamic tract is integrated with input from brainstem and cortical areas for the perception of specific aspects of pain as well as more general affective components of pain perception.

Injury to the peripheral nerve and to neurons in the ganglion triggers afferent pain signals. Inflammation in the skin triggers nociceptive signals that further amplify cutaneous pain. The abundant release of excitatory amino acids and neuropeptides induced by the sustained barrage of afferent impulses during the prodrome and acute phase of herpes zoster may cause excitotoxic injury and the loss of inhibitory interneurons in the spinal dorsal horn. Damage to neurons in the spinal cord and ganglion, and to the peripheral nerve, is important in the pathogenesis of PHN. Damaged primary afferent nerves may become spontaneously active and hypersensitive to peripheral stimuli and also to sympathetic stimulation. In turn, excessive nociceptor activity and ectopic impulse generation may sensitize central nervous system neurons, producing prolonged and augmented central responses to innocuous as well as noxious stimuli. Clinically, these mechanisms result in allodynia (pain and/or unpleasant sensations elicited by stimuli that are normally not painful, e.g., light touch) with little or no sensory loss, and explain relief of pain by local lidocaine infiltration.

The anatomic and functional changes responsible for PHN appear to be established early in the course of herpes zoster. Consistent with this is the correlation of initial pain severity and the presence of prodromal pain with the subsequent development of PHN and the failure of antiviral therapy to fully prevent PHN (see below).

CLINICAL MANIFESTATIONS

Clinical Manifestations of Varicella

PRODROME OF VARICELLA In young children, prodromal symptoms are uncommon. In older children and adults, the rash is often preceded by 2 to 3 days of fever, chills, malaise, headache, anorexia, severe backache, and, in some patients, sore throat and dry cough.
RASH OF VARICELLA In unvaccinated persons, the rash begins on the face and scalp and spreads rapidly to the trunk, with relative sparing of the extremities (Fig. 215-3). New lesions appear in successive crops, but their distribution remains central. The rash tends to be denser in the small of the back and between the shoulder blades than on the scapulae and buttocks and more profuse on the medial than on the lateral aspects of the limbs.

FIGURE 215-3 Varicella. *A.* A full spectrum of lesions—that is, erythematous papules, vesicles (“dewdrops on rose petals”), crusts, and erosions at sites of excoriation—is seen in a child with a typical case of varicella. *B.* A wider range of lesions, including many large pustules, is seen in a 21-year-old female who was febrile as well as “toxic” and had varicella pneumonitis.

A striking feature of varicella lesions is their rapid progression from rose-colored macules to papules, vesicles, pustules, and crusts (Fig. 215-3A). The typical vesicle of varicella is 2 to 3 mm in diameter and elliptical, with its long axis parallel to the folds of the skin. The early vesicle is surrounded by an irregular area of erythema, which gives the lesions the

appearance of a “dewdrop on a rose petal.” The vesicular fluid soon becomes cloudy with the influx of inflammatory cells, which convert the vesicle to a pustule (Fig. 215-3B). The lesion then dries, beginning in the center, first producing an umbilicated pustule and then a crust. Crusts fall off spontaneously in 1 to 3 weeks, leaving shallow pink depressions that gradually disappear. Scarring is rare unless the lesions were picked at by the patient or superinfected with bacteria. Healing lesions may leave hypopigmented spots that persist for weeks to months. Vesicles also develop in the mucous membranes of the mouth, nose, pharynx, larynx, trachea, gastrointestinal tract, urinary tract, and vagina. These mucosal vesicles rupture so rapidly that the vesicular stage may be missed. Instead, one sees shallow ulcers 2 to 3 mm in diameter. A distinctive feature of varicella is the simultaneous presence, in any one area of the skin, of lesions in all stages of development. Careful prospective studies have shown that the average number of lesions in healthy children ranges from 250 to 500; secondary cases resulting from household exposure are more severe than primary cases resulting from exposure at school, presumably because more intense and prolonged exposure at home results in a higher virus inoculum. Fever usually persists as long as new lesions continue to appear, and its height is generally proportional to the severity of the rash. It may be absent in mild cases or rise to 40.5°C (105°F) in severe cases with extensive rash. Prolonged fever or recurrence of fever after defervescence may signify a secondary bacterial infection or another complication. The most distressing symptom is pruritus, which is usually present throughout the vesicular stage. The varicella vaccine alters the natural history of the rash. A small percentage of vaccinees develop “breakthrough” varicella after exposure to people with active VZV infections. The usual breakthrough rash is predominately maculopapular with fewer lesions (i.e., less than 60) and fewer vesicles than the rash of natural varicella. The incidence and severity of fever is also less than that in natural varicella. [19]

COMPLICATIONS OF VARICELLA In the normal child, varicella is rarely complicated. The most common complication is the secondary bacterial infection of skin lesions, usually by staphylococci or streptococci, which may produce impetigo, furuncles, cellulitis, erysipelas, and, rarely, gangrene. [20] These local infections often lead to scarring and, rarely, to septicemia with metastatic infection of other organs. Bullous lesions may develop when vesicles are superinfected by staphylococci that produce exfoliative toxins. Invasive group A streptococcal infections are particularly virulent. Up to one-third of invasive group A streptococcal infections are associated with varicella, usually occurring within 2 weeks of the onset of the rash. [21] Secondary bacterial pneumonia, otitis media, and suppurative meningitis are rare complications and typically respond to appropriate antibiotic therapy. Bacterial superinfection is common and potentially life-threatening, however, in leukopenic patients. Other complications reflect a basic defect in the capacity of the host to limit VZV dissemination. [22] In adults, fever and constitutional symptoms are more prominent and prolonged, the rash of varicella is more profuse, and complications are more frequent. [22] Primary varicella pneumonia is the major complication of adult varicella. [23] Some patients are virtually asymptomatic, but others develop severe respiratory embarrassment, with cough, dyspnea, tachypnea, high fever, pleuritic chest pain, cyanosis, and hemoptysis 1 to 6 days after onset of the rash. The severity of the symptoms usually exceeds the physical findings, but the roentgenogram typically reveals diffuse, peribronchial nodular densities throughout both lung fields with a tendency to concentrate in the perihilar regions and at the bases. The mortality in adults with frank varicella pneumonia has been estimated to be between 10 and 30 percent, but it is less than 10 percent if immunocompromised patients are excluded. Varicella during pregnancy is a threat to both mother and fetus. [24] The fetus may die as a consequence of premature labor or maternal death in severe varicella pneumonia, but varicella during pregnancy does not, otherwise, substantially increase fetal morbidity or mortality. Nevertheless, even in uncomplicated varicella, maternal viremia can result in intrauterine (congenital) VZV infection. [25] Perinatal varicella (i.e., varicella occurring within 10 days of birth) is more serious than varicella in infants infected even a few weeks later. The morbidity and mortality of varicella are also markedly increased in immunocompromised patients. In these patients, continued virus replication and dissemination result in a prolonged high-level viremia, a more extensive rash, and a longer period of new vesicle formation. Immunosuppressed and glucocorticoid-treated patients may develop pneumonia, hepatitis, encephalitis, and hemorrhagic complications of varicella, which range in severity from mild febrile purpura to severe and often fatal purpura fulminans and “malignant” varicella. [26], [27] Central nervous system (CNS) complications of varicella occur in fewer than 1 in 1000 cases; they include several distinct syndromes. Varicella-associated Reye's syndrome (acute encephalopathy with fatty degeneration of the liver) typically occurs 2 to 7 days after the appearance of the rash. In the past, from 15 to 40 percent of all cases of Reye's syndrome occurred in association with varicella, particularly when aspirin was administered for fever, with mortality as high as 40 percent. [28] Acute cerebellar ataxia is more common than the other neurologic complications of varicella, occurring in 1 in 4000 cases, and more benign. [29] Encephalitis is much less common, occurring in 1 in 33,000 cases, but causes death or permanent neurologic sequelae. The pathogenesis of cerebellar ataxia and encephalitis remains obscure, but in many cases it is possible to detect VZV antigens, VZV antibodies, and VZV DNA in the cerebrospinal fluid of patients, suggesting direct infection of the CNS. [30] Although elevated aminotransferase levels are common, clinical hepatitis is rare except as a complication of progressive varicella. Other rare complications of varicella include myocarditis, glomerulonephritis, orchitis, pancreatitis, gastritis and ulcerative lesions of the bowel, arthritis, Henoch-Schönlein vasculitis, optic neuritis, keratitis, and iritis. The pathogenesis of many of these complications has not been delineated, but direct parenchymal or endovascular infection, or vasculitis induced by VZV antigen-antibody complexes appear to be responsible in most cases.

Clinical Manifestations of Herpes Zoster

PRODROME OF HERPES ZOSTER Pain and paresthesia in the involved dermatome often precede the eruption by several days and vary from superficial itching, tingling, or burning to severe, deep, boring, or lancinating pain. It may be constant or intermittent and is often accompanied by tenderness and hyperesthesia of the skin in the involved dermatome. The preeruptive pain of herpes zoster may simulate pleurisy, myocardial infarction, duodenal ulcer, cholecystitis, biliary or renal colic, appendicitis, prolapsed intervertebral disk, or early glaucoma, and leads to serious misdiagnosis and misdirected interventions. A few patients experience acute segmental neuralgia without ever developing a cutaneous eruption—a condition known as zoster sine herpete.

RASH OF HERPES ZOSTER The most distinctive feature of herpes zoster is the localization and distribution of the rash, which is nearly always unilateral, does not cross the midline, and is generally limited to the area of skin innervated by a single sensory ganglion (Fig. 215-4A). The area supplied by the trigeminal nerve, particularly the ophthalmic division, and the trunk from T3 to L2 are most frequently affected; the thoracic region alone accounts for more than half of all reported cases, and lesions rarely occur distal to the elbows or knees. [10], [11]

FIGURE 215-4 Herpes zoster. *A.* Early involvement of a thoracic dermatome with erythema within the dermatome and areas of grouped vesicle formation. *B.* Later involvement with crusted sites on the back, where the eruption first appeared, and many confluent hemorrhagic vesicles and bullae on the lateral chest wall, where the eruption appeared more recently; some vesicles are also seen outside the involved dermatome, representing hematogenous dissemination, a not uncommon occurrence. *C.* Ophthalmic zoster. Note the involvement of the tip of the nose, which frequently signals involvement of the eye.

Although the individual lesions of herpes zoster and varicella are indistinguishable, those of herpes zoster tend to evolve more slowly and usually consist of closely grouped vesicles on an erythematous base, rather than the more discrete, randomly distributed vesicles of varicella. This difference reflects intraneural spread of virus to the skin in herpes zoster, as opposed to viremic spread in varicella. [31] Herpes zoster lesions begin as erythematous macules and papules that often first appear where superficial branches of the affected sensory nerve are given off, for example, the posterior primary division and the lateral and anterior branches of the anterior primary division of spinal nerves. Vesicles form within 12 to 24 h and evolve into pustules by the third day. These dry and crust in 7 to 10 days. The crusts generally persist for 2 to 3 weeks (Fig. 215-4B). In normal individuals, new lesions continue to appear for 1 to 4 days (occasionally for as long as 7 days). The rash is most severe and lasts longest in older people, and is least severe and of shortest duration in children. Between 10 and 15 percent of reported cases of herpes zoster involve the ophthalmic division of the trigeminal nerve (Fig. 215-4C). [32] The rash of ophthalmic zoster may extend from the level of the eye to the vertex of the skull, but it terminates sharply at the midline of the forehead. When only the supratrochlear and supraorbital branches are involved, the eye is usually spared. Involvement of the nasociliary branch, which innervates the eye as well as the tip and side of the nose, occurs in 30 to 40 percent of patients with ophthalmic zoster. Thus, when ophthalmic zoster involves the tip and the side of the nose, careful attention must be given to the condition of the eye. Herpes zoster affecting the second and third divisions of the trigeminal nerve (Fig. 215-5) and other cranial nerves may produce symptoms and lesions in the mouth, ears, pharynx, or larynx. The so-called Ramsay-Hunt syndrome (facial palsy in combination with herpes zoster of the external ear or tympanic membrane, with or without tinnitus, vertigo, and deafness), results from involvement of the facial and auditory nerves.

FIGURE 215-5 Cephalic herpes zoster with facial palsy (Hunt syndrome). A 60-year-old female with right-sided facial palsy and vesicles on her (*A*) *tongue and* (*B*) *soft palate.*

COMPLICATIONS OF HERPES ZOSTER (Table 215-1)

Cutaneous	Visceral	Neurologic
Bacterial superinfection	Pneumonitis	Postherpetic neuralgia
Scarring	Hepatitis	Meningoencephalitis
Zoster gangrenosum	Esophagitis	Transverse myelitis
Cutaneous dissemination	Gastritis	Peripheral nerve palsies
	Pericarditis	Motor
	Cystitis	Autonomic
	Arthritis	Cranial nerve palsies
		Sensory loss
		Deafness
		Ocular complications
		Granulomatous angiitis (causing contralateral hemiparesis)

TABLE 215-1 **Complications of Herpes Zoster**

The sequelae of herpes zoster include cutaneous, ocular, neurologic, and visceral complications. Most complications of herpes zoster are associated with the spread of VZV from the initially involved sensory ganglion, nerve, or skin, either via the bloodstream or by direct neural extension. The rash may disseminate after the initial dermatomal eruption has become apparent. When immunologically competent patients are carefully examined, 17 to 35 percent of them are found to have at least a few vesicles in areas distant from the involved and immediately adjacent dermatomes. The disseminated lesions usually appear within a week of onset of the segmental eruption and, if few in number, are easily overlooked. More extensive dissemination (with 25 to 50 lesions or more), producing a varicella-like eruption (generalized herpes zoster; Fig. 215-6), occurs in 2 to 10 percent of unselected patients with localized zoster, most of whom have immunologic defects as a result of acquired immunodeficiency, as seen with HIV infection, underlying malignancy (particularly lymphomas), or immunosuppressive therapy. If the rash spreads widely from a small, painless area of herpes zoster, the initial dermatomal presentation may go unnoticed, and the ensuing disseminated eruption may be mistaken for varicella.

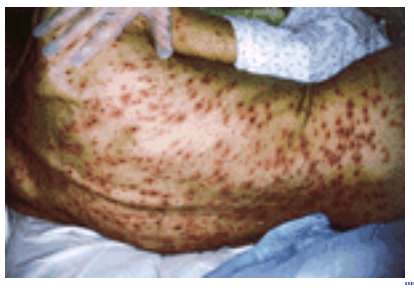

FIGURE 215-6 The back of a patient with chronic lymphocytic leukemia and disseminated herpes zoster. (*From Straus et al.,* [85] *with permission.*)

When the dermatomal rash is particularly extensive, as it often is in severely immunocompromised patients, there may be superficial gangrene with delayed healing and subsequent scarring (Fig. 215-7). Secondary bacterial infection may also delay healing and cause scarring.

FIGURE 215-7 *A.* Acute, necrotic herpes zoster involving the first and second distributions of the fifth cranial nerve in a woman with lymphoma receiving cytotoxic chemotherapy. *B.* Dense scar formation and temporal muscle wasting several weeks later. (*From Straus et al.,* [85] *with permission.*)

The eye is involved in 20 to 70 percent of patients with ophthalmic zoster, with a wide range of possible complications. [32] VZV is also the principal cause of acute retinal necrosis (ARN), a fulminant sight-threatening disease observed primarily in otherwise healthy individuals. [33] Herpes zoster may be attended by a variety of neurologic complications (Table 215-1), of which PHN is the most common and important. [34] PHN has been defined as pain after the rash has healed or pain 1 month or 3 months after rash onset. In clinic and community studies using the first two definitions, the overall incidence of PHN is 8 to 15 percent (Fig. 215-1B). [17], [35], [36] Age is the most significant risk factor for PHN (Fig. 215-1C). In a recent study, patients aged 50 years or older had a 14.7-fold higher prevalence (95 percent CI, 6.8 to 32.0) of pain 30 days after rash onset than patients younger than 50 years of age. [36] Other risk factors for PHN include the presence of prodromal pain, severe pain during the acute phase of herpes zoster, greater rash severity, more extensive sensory abnormalities in the affected dermatome and, possibly, ophthalmic (as opposed to thoracic or abdominal) herpes zoster. [37] PHN usually remits spontaneously over several months; the risk of long-lasting PHN also increases with increasing age. The patient with PHN may suffer from constant pain (described as “burning, aching, throbbing”), intermittent pain (“stabbing, shooting”), and/or stimulus-evoked pain, including allodynia (“tender, burning, stabbing”). Allodynia, the experience of pain elicited by stimuli that are normally not painful, is a particularly disabling component of the disease. Patients with allodynia suffer from severe pain after the lightest touch of the affected skin by things as trivial as a cold wind or a piece of clothing. These subtypes of pain may produce disordered sleep, depression, anorexia, weight loss, chronic fatigue, and social isolation and interfere with dressing, bathing, general activity, traveling, shopping, cooking, and housework.

HERPES ZOSTER IN THE IMMUNOCOMPROMISED HOST Except for PHN, most serious complications of herpes zoster occur in immunocompromised persons. [38] These complications include necrosis of skin and scarring (Fig. 215-7) and cutaneous dissemination with an incidence as high as 25 to 50 percent. Approximately 10 percent of patients with cutaneous dissemination manifest widespread, often fatal, visceral dissemination as well, particularly to the lungs, liver, and brain. [38] HIV-infected patients are fairly unique in their tendency to suffer multiple recurrences of herpes zoster as their disease progresses; herpes zoster may recur in the same or different dermatomes or in several contiguous or noncontiguous dermatomes. Herpes zoster in patients with AIDS may be severe, with cutaneous and visceral dissemination. Patients with AIDS may also develop chronic verrucous, hyperkeratotic, or ecthymatous cutaneous lesions caused by acyclovir-resistant VZV (Fig. 215-8).

FIGURE 215-8 Chronic verrucous lesions of herpes zoster despite long-term acyclovir treatment in a patient with advanced AIDS. (*Courtesy of David Paar, MD.*)

The incidence and severity of herpes zoster are also markedly increased in hematologic malignancies and in recipients of solid organ and bone marrow transplants (BMT). [39] Disseminated infection is common and often occurs without a recognizable cutaneous focus of localized herpes zoster.

PATHOLOGY

Cytopathology

The cutaneous lesions of varicella and herpes zoster are histologically indistinguishable (Fig. 215-9) and similar to those produced by HSV. The characteristic changes include “ballooning degeneration” with the formation of intranuclear inclusion bodies, and multinucleated giant cells. The nuclei exhibit margination of chromatin and contain inclusion bodies (Fig. 215-9B). Early in infection, these inclusion bodies may be homogeneous and moderately basophilic; however, they rapidly evolve into classical Cowdry type A inclusion bodies [sharply demarcated acidophilic (eosinophilic) inclusions that are separated from the deeply basophilic ring of marginated chromatin at the nuclear membrane by a clear zone or halo]. VZV glycoproteins induce pairs and groups of adjacent VZV-infected cells to fuse to form multinucleated giant cells.

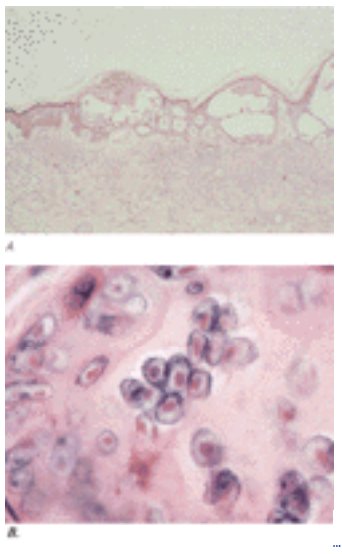

FIGURE 215-9 Herpes zoster, histopathology. *A.* Intraepidermal vesicle, acantholysis, reticular degeneration; underlying dermis shows edema and vasculitis. *B.* Multinucleated giant cells with characteristic nuclear changes.

Pathology of Varicella

The initial event in the formation of cutaneous lesions of varicella is probably infection of capillary endothelial cells in the papillary dermis, with subsequent spread of virus to epithelial cells in the epidermis, hair follicles, and sebaceous glands. [40] In early papular lesions, the epithelium is slightly elevated as a result of swelling of the infected epithelial cells and to edema and vascular congestion of the underlying dermis. In the superficial dermis, capillary endothelial cells are swollen, and their nuclei often contain typical intranuclear inclusion bodies. In the epidermis, the cells initially involved are those of the germinal layer and the deeper portion of the stratum spinosum. These cells show ballooning degeneration with loss of intercellular bridges (acantholysis) and are soon separated by intercellular edema.

The papular lesions rapidly evolve into intraepidermal vesicles as a result of the infection and degeneration of increasing numbers of epithelial cells, the fusion of adjacent areas of microscopic degeneration, and the continuing influx of edema fluid, which elevates the uninvolved stratum corneum to form a delicate clear vesicle. At this stage, the vesicle fluid contains fibrin, degenerating and “ballooned” epithelial cells, and abundant cell-free infectious VZV. As the lesions progress, polymorphonuclear leukocytes and a small number of macrophages invade from the underlying dermis, and the vesicle fluid becomes cloudy; this transforms the vesicle into a pustule. The fluid is then absorbed, with the formation of a flat, adherent crust that is eventually detached by the regrowth of subjacent epithelial cells. The evolution from papule to early crusting normally occurs over a period of 24 to 48 h.

In fatal varicella, focal lesions and viral antigens are found in virtually every organ, the lungs and liver being the most common sites of severe involvement. [41] There is widespread vascular damage, with characteristic acidophilic intranuclear inclusion bodies in endothelial cells lining small blood vessels and lymphatics; capillaries within individual lesions are often destroyed, resulting in thrombosis and hemorrhage.

Pathology of Herpes Zoster

Although the histopathology of the skin lesions of herpes zoster and varicella is the same (Fig. 215-9), herpes zoster is accompanied by acute inflammation of the corresponding sensory nerve and ganglion. The ganglion shows intense lymphocyte infiltration, necrosis of nerve cells and fibers, endothelial cell proliferation and lymphocytic cuffing of small vessels, focal hemorrhage, and inflammation of the ganglion sheath. [42] Satellite cells and neurons contain characteristic acidophilic intranuclear inclusion bodies, virus particles visible by electron microscopy, and VZV antigens demonstrable by immunofluorescence.

The peripheral nerve shows diffuse lymphocytic infiltration and focal hemorrhage, with axonal degeneration and demyelination of sensory fibers. Virus particles and VZV antigens are present in Schwann and perineural cells. The inflammatory reaction in the ganglion also extends proximally to the posterior nerve root and into adjacent regions of the cord or brainstem, producing a segmental myelitis. A mild lymphocytic leptomeningitis is generally present and is most intense over the involved segments and nerve roots.

CLINICAL AND LABORATORY DIAGNOSES

Clinical Diagnosis of Varicella

Varicella can usually be diagnosed readily on the basis of the appearance and evolution of its characteristic rash (see Fig. 215-3), particularly when there is a history of exposure within the preceding 2 to 3 weeks.

Disseminated HSV infections may resemble varicella; however, there is often an obvious concentration of lesions at and surrounding the site of the primary or recurrent infection (e.g., the mouth or external genitalia) and there may be marked toxicity and encephalitis.

The remaining differential diagnosis of varicelliform rashes include impetigo, the vesicular exanthems of coxsackievirus and echovirus infections (e.g., hand-foot-and-mouth disease syndrome), rickettsialpox, insect bites, papular urticaria, scabies, contact dermatitis, dermatitis herpetiformis, drug eruptions, secondary syphilis, and erythema multiforme. The character, distribution, and evolution of the lesions, together with a careful epidemiologic history, usually differentiate these diseases from varicella. The rashes associated with classical measles, rubella, roseola (herpesvirus types 6 and 7 infections), and erythema infectiosum (parvovirus B19 infection) are not vesicular and should not be mistaken for varicella. When any doubt exists, the clinical impression should receive laboratory confirmation.

Clinical Diagnosis of Herpes Zoster

In patients with prodromal pain, herpes zoster is often confused with other causes of localized pain. Once the eruption appears, the diagnosis is usually obvious (Fig. 215-4 and Fig. 215-5).

Disseminated herpes zoster may be mistaken for varicella when there is widespread dissemination of VZV from a small, painless area of herpes zoster or from the affected sensory ganglion in the absence of an obvious dermatomal eruption. This is not infrequent in profoundly immunosuppressed, seropositive persons (Fig. 215-6).

A cluster of vesicles, particularly near the mouth or genitals, may represent herpes zoster, but it may also be a recurrent HSV infection. [12] Zosteriform herpes simplex is often impossible to distinguish from herpes zoster on clinical grounds. A history of multiple recurrences at the same site is common in herpes simplex but does not occur in herpes zoster in the absence of profound and clinically obvious immune deficiency.

Laboratory Diagnosis

The lesions of varicella and herpes zoster are indistinguishable by histopathology (Fig. 215-9). The presence of multinucleated giant cells and epithelial cells containing acidophilic intranuclear inclusion bodies (Fig. 215-9B) distinguishes the cutaneous lesions produced by VZV from all other vesicular eruptions, except those produced by HSV. These cells can be demonstrated in Tzanck smears prepared at the bedside; material is scraped from the base of an early vesicle and stained with hematoxylin-eosin, Giemsa, Papanicolaou, or Paragon multiple stain.

Punch biopsies provide more reliable material for histologic examination than Tzanck smears and facilitate diagnosis in the prevesicular stage and in atypical lesions such as the chronic verrucous lesions produced by acyclovir-resistant VZV in patients with AIDS (Fig. 215-8).

The definitive diagnosis of VZV infection, as well as the differentiation of VZV from HSV, is accomplished by the isolation of virus in cell cultures inoculated with vesicle fluid, blood, cerebrospinal fluid, or infected tissue, or by the direct identification of VZV antigens or nucleic acids in these specimens. [29], [43] Virus isolation is the only technique that yields infectious VZV for further analysis, such as determination of its sensitivity to antiviral drugs; however, VZV is extremely labile, and only 30 to 60 percent of cultures from proven cases are positive. To maximize virus recovery, specimens should be inoculated into cell culture immediately. It is important to select new vesicles containing clear fluid for aspiration, because the probability of isolating VZV diminishes rapidly as lesions become pustular. VZV is almost never isolated from crusts.

VZV can be isolated and propagated in vitro in monolayer cultures of a variety of human (and certain simian) cells. [44] The cytopathic effects induced by the replicating virus in such cell cultures are characterized by the formation of acidophilic intranuclear inclusion bodies and multinucleated giant cells similar to those seen in the cutaneous lesions of the disease. These changes are indistinguishable from those produced by HSV, but whereas HSV rapidly spreads to infect the remaining cells in the culture, the cytopathic effect of VZV remains focal. Cytopathic effects of VZV are generally not apparent until several days after specimen inoculation. Modifications of the cell culture assay in which vesicle fluid or lesion scrapings are centrifuged onto cells growing on coverslips at the bottom of thin glass-walled “shell” vials followed by staining of the cells with fluorescein- or enzyme-labeled monoclonal antibodies to VZV proteins can confirm the presence of VZV in 24 to 72 h, well before cytopathic effects are evident in conventional cell cultures. [44]

Immunofluorescent or immunoperoxidase staining of cellular material from fresh vesicles or prevesicular lesions has become the diagnostic method of choice in many centers; it can detect VZV significantly more often and faster than virus culture, even relatively late in the disease when cultures are no longer positive. [44] Enzyme immunoassays provide another rapid and sensitive method for antigen detection.

Detection of nucleic acids in clinical specimens by nucleic acid hybridization or following amplifications by PCR provides the greatest assay sensitivity and is revolutionizing the diagnosis of VZV infections. [30], [44]

Serologic tests provide a retrospective diagnosis of varicella and herpes zoster reliably when acute and convalescent sera are available for comparison. [13], [44] They can also identify susceptible individuals who may be candidates for

isolation or prophylaxis. The technique most commonly used is a solid-phase enzyme-linked immunosorbent assay (ELISA). This assay, however, often lacks sensitivity and specificity and fails to detect antibody in people who are immune, and sometimes yield false-positive results in susceptible individuals. [44] Several more sensitive techniques have been developed to measure humoral responses to VZV. These include an immunofluorescence assay for antibody to VZV-induced membrane antigens [fluorescent antibody to membrane antigen (FAMA)] that reliably distinguishes immune from susceptible adults and a latex agglutination test that is comparable in sensitivity and specificity to FAMA assays, but is much simpler to perform. [45]

TREATMENT

Antiviral Agents

The nucleoside analogues acyclovir, famciclovir, valaciclovir, and vidarabine; the pyrophosphate analog foscarnet (Fig. 215-10); and human alpha interferons show efficacy in treating VZV infections. [46] Acyclovir is a guanosine analogue that is selectively phosphorylated by VZV thymidine kinases (it is a poor substrate for cellular thymidine kinase) and is thus concentrated in infected cells. Cellular enzymes then convert acyclovir monophosphate to acyclovir triphosphate, which interferes with viral DNA synthesis by inhibiting viral DNA polymerase.

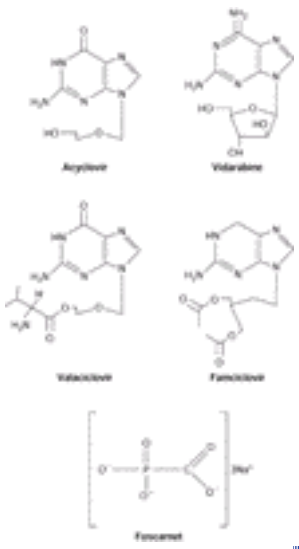

FIGURE 215-10 The chemical structures of five antiviral drugs proven effective in the treatment of varicella-zoster virus infections.

Two prodrugs, valaciclovir and famciclovir, produce higher antiviral blood levels and permit less frequent dosing than acyclovir. [47], [48] Valaciclovir is a valine ester of acyclovir that is converted enzymatically to acyclovir after absorption. Famciclovir is a prodrug of penciclovir, a nucleoside analogue similar to acyclovir in mechanism of action and antiviral activity against VZV and HSV. Famciclovir is converted enzymatically to penciclovir after absorption.

Foscarnet is an analogue of inorganic pyrophosphate that inhibits the replication of all known herpesviruses in vitro. It exerts its antiviral activity by selective inhibition at the pyrophosphate binding site of virus-specific DNA polymerases and reverse transcriptases at concentrations that do not affect cellular DNA polymerases. Foscarnet does not require phosphorylation by thymidine kinase to be activated and is therefore active against acyclovir-resistant VZV mutants that lack thymidine kinase activity.

Vidarabine, which is not a very selective inhibitor of virus replication, is potentially cytotoxic. It must be administered in large volumes of fluid. It is rarely used today.

Although the interferons are active, their cost, toxicity, and inconvenience have virtually eliminated their clinical use in varicella and herpes zoster. [49]

Acyclovir-resistant varicella and herpes zoster have been documented in patients with advanced AIDS (Fig. 215-8). Because of the mechanism of acyclovir resistance by VZV (mutations in the viral thymidine kinase gene), these infections are cross-resistant to ganciclovir, valaciclovir, famciclovir, and penciclovir. They usually respond to foscarnet, 40 mg IV every 8 h; however, the infections commonly recur once treatment has ended.

Treatment of Varicella

TOPICAL In normal children, varicella is generally benign and self-limited. Cool compresses or calamine lotion locally, oral antihistamines, and tepid baths with baking soda or colloidal oatmeal (3 cups per tub of water) may relieve itching. Creams and lotions containing glucocorticoids and occlusive ointments should not be used. Antipyretics may be needed, but salicylates must be avoided because of their association with Reye's syndrome. [28] Minor bacterial infections are treated with warm soaks. Bacterial cellulitis requires systemic antimicrobial therapy that is effective against *Staphylococcus aureus* and group A beta-hemolytic streptococcus.

ANTIVIRAL THERAPY

Normal children (Table 215-2) A large randomized, controlled trial of acyclovir treatment of healthy children 2 to 12 years of age found that early treatment (within 24 h of the appearance of rash) with oral acyclovir (20 mg/kg four times a day for 5 days) modestly reduced the maximum number of lesions, the time to cessation of new lesion formation, and the duration of the rash, fever, and constitutional symptoms when compared to placebo. [50] Because varicella is a relatively benign infection in children and the clinical benefits of treatment are modest, it does not require routine acyclovir

treatment; however, many have favored its use where cost is not a concern, where it can be begun in time to benefit the patient (within 24 h of rash), and where there is a perceived need to speed resolution of the infection so that parents can comfortably return to work. Because secondary cases among susceptible children in the household are generally more severe than the index cases, and because early initiation of treatment is more readily accomplished in secondary cases, treatment with acyclovir seems reasonable.

Patient Group	Regimen
Normal	
• Neonate	• Acyclovir 500 mg/m² q8h × 10 days
• Child	• Symptomatic treatment alone, or acyclovir 20 mg/kg per dose × 5 days
• Adolescent, adult, or glucocorticoids used	• Acyclovir 800 mg per 5 × /day × 7 days
• Pneumonia, pregnancy	• Acyclovir 800 mg per 5 × /day × 7 days, or acyclovir 10 mg/kg IV q8h × 7 days
Immunocompromised	
• MILD varicella or mild compromise	• Acyclovir 800 mg per 5 × /day × 7–10 days
• Severe varicella or severe compromise	• Acyclovir 10 mg/kg IV q8h × 7 days or longer
• Acyclovir-resistant (advanced AIDS)	• Foscarnet 40 mg/kg IV q8h until healed

TABLE 215-2 **Treatment of Varicella in the Normal and Immunocompromised Patient**

Normal adolescents and adults A randomized, controlled trial of acyclovir treatment of healthy adolescents 13 to 18 years of age found that early treatment with oral acyclovir (800 mg five times a day for 5 days) reduced the maximum number of lesions and time to cessation of new lesion formation compared to placebo. [51] A randomized, placebo-controlled trial of oral acyclovir in healthy adults with varicella showed that early treatment (within 24 h of onset of cutaneous lesions) with oral acyclovir (800 mg five times a day for 7 days) significantly reduced the time to crusting of lesions, the extent of disease, and duration of symptoms and fever. [23] Thus, routine treatment of varicella in adults seems reasonable. Although not tested, it is likely that valaciclovir 1000 mg PO q8h or famciclovir 500 mg q8h would be convenient and appropriate substitutes for acyclovir in normal adolescents and adults. Many physicians do not prescribe oral acyclovir in uncomplicated varicella during pregnancy because the risk to the fetus of treatment is unknown. Other physicians recommend oral acyclovir for infections in the third trimester when organogenesis is complete, when there may be a heightened risk of varicella pneumonia, and when infection can be spread to the newborn. Intravenous acyclovir is often considered for pregnant women with varicella who have extensive cutaneous and/or systemic disease.
Complications of varicella in normal persons Uncontrolled studies of immunocompetent adults with varicella pneumonia suggest that early treatment (within 36 h of hospitalization) with IV acyclovir (10 mg/kg q8h) may be useful in reducing fever and tachypnea and improved oxygenation. [52] Other serious complications of varicella in the immunocompetent host, such as encephalitis, meningoencephalitis, myelitis, and ocular complications, should be treated with IV acyclovir.
Immunocompromised patients Controlled clinical trials of IV acyclovir demonstrated a decrease in the incidence of life-threatening visceral complications when administered within 72 h of onset to immunosuppressed patients with varicella. [26] Immune compromise, however, is a continuum ranging from minimal to severe. Intravenous acyclovir has been the standard of care for management of varicella in patients with substantial immunodeficiency. While such oral therapy with valaciclovir or famciclovir might suffice for patients with mild degrees of immune impairment, there are no controlled clinical trials to guide the decision.

Treatment of Herpes Zoster

TOPICAL During the acute phase of herpes zoster, the application of cool compresses, calamine lotion, cornstarch, or baking soda may help to alleviate local symptoms and hasten the drying of vesicular lesions. Occlusive ointments should be avoided, and creams and lotions containing glucocorticoids should not be used. Bacterial superinfection of local lesions is uncommon and should be treated with warm soaks; bacterial cellulitis requires systemic antibiotic therapy. Topical treatment of the herpes zoster rash with antiviral agents is not effective.
ANTIVIRAL THERAPY The major goals of therapy in patients with herpes zoster are to (1) limit the extent, duration, and severity of pain and rash in the primary dermatome; (2) prevent disease elsewhere; and (3) prevent PHN.
Normal patients Table 215-3 lists the current recommendations for treatment of herpes zoster. Oral acyclovir significantly reduced the time to rash healing and the duration of viral shedding and acute pain in randomized controlled trials in patients older than 50 years of age who were treated within 72 h of rash onset. [17], [47] Clinical trials of acyclovir demonstrated conflicting results, however, regarding the efficacy of preventing PHN. Meta-analyses of the individual acyclovir trials indicated a reduction in the duration of chronic pain. [53] Randomized controlled trials comparing acyclovir to famciclovir and valaciclovir to famciclovir demonstrated equivalent results in rash healing, acute pain, and the duration of chronic pain. [48], [54] All three drugs are acceptable agents for older adults, with cost and dosing schedule determining the choice of agent. Because of the lower risk of PHN, antiviral therapy is less valuable or necessary for treatment of uncomplicated herpes zoster in healthy people younger than 50 years of age. The utility of antiviral agents is questionable if more than 72 h have elapsed since the onset of rash, except perhaps for patients who have ophthalmic zoster or who continue to have new vesicle formation.

Patient Group	Regimen
Normal	
• Age < 50 years	• Symptomatic treatment only, or acyclovir 800 mg/dose 5 × /day × 7 days
• Age ≥ 50 years, or with ophthalmic involvement	• Acyclovir 800 mg per 5 × /day × 7 days, or valaciclovir 1 g per q8h × 7 days, or famciclovir 500 mg per q8h × 7 days
Immunocompromised	
• MILD compromise, or HIV	• Acyclovir 800 mg per 5 × /day × 7–10 days or valaciclovir or famciclovir
• Severe compromise	• Acyclovir 10 mg/kg IV q8h × 7–10 days
• Acyclovir-resistant (advanced AIDS)	• Foscarnet 40 mg/kg IV q8h until healed

TABLE 215-3 **Treatment of Herpes Zoster in the Normal and Immunocompromised Patient**

Ophthalmic zoster represents a special therapeutic challenge because of the risk of ocular complications. Examination by an ophthalmologist should be sought in all cases. Oral acyclovir was effective for the prevention of ocular complications of ophthalmic zoster in a randomized, controlled trial. [55] Famciclovir and valaciclovir appear to have comparable efficacy to acyclovir in the treatment of ophthalmic zoster. [56], [57]
Immunocompromised patients A randomized, double-blind, placebo-controlled trial in immunocompromised patients with herpes zoster showed that acyclovir (500 mg/m ^{2} IV q8h for 7 days) halted progression of herpes zoster, both in patients with localized disease and in patients with cutaneous dissemination before treatment. [58] Acyclovir accelerated the rate of clearance of virus from vesicles and markedly reduced the incidence of visceral and progressive cutaneous dissemination. Pain subsided faster in acyclovir recipients, and fewer reported HN, but these differences were not statistically significant. Clinical trials comparing IV acyclovir therapy with vidarabine therapy for the treatment of herpes zoster in immunocompromised patients showed that acyclovir was significantly more effective and less toxic. [38], [58] In

patients with mild immunocompromise and localized herpes zoster, oral acyclovir, valaciclovir, or famciclovir will usually suffice. [59], [60] A randomized, controlled trial of oral famciclovir versus oral acyclovir in localized herpes zoster in immunocompromised patients following bone marrow or organ transplantation or oncology treatment found that the two treatments were equivalent in rash healing and loss of acute pain and that both were well tolerated. [60]

ANTIINFLAMMATORY THERAPY The possibility that PHN may be caused by inflammation of the sensory ganglion and contiguous neural structures has provided the rationale for the use of glucocorticoids during the acute phase of herpes zoster in an attempt to further reduce acute pain and prevent PHN. Randomized controlled trials, however, showed that the addition of glucocorticoids to acyclovir did not change the incidence of chronic pain. [61], [62] The common adverse effects of glucocorticoids argue against their routine use in older patients with herpes zoster; however, glucocorticoids did reduce acute pain in most trials, and in one trial of acyclovir and prednisone, the time to uninterrupted sleep, return to daily activity, and cessation of analgesic therapy was reduced in patients who received glucocorticoids. [62] Consequently, some experts advocate oral glucocorticoids for otherwise healthy older adults whose rash is complicated by moderate to severe pain and who have no contraindications to glucocorticoids. Others, including one of the authors (MO), do not recommend the use of glucocorticoids in this setting.

ANALGESICS Greater acute pain severity is a risk factor for PHN, and ongoing acute pain may contribute to central sensitization and the genesis of chronic pain. Therefore, aggressive pain control is both reasonable and humane. The severity of acute herpes zoster pain should be determined with simple standardized pain scales. Clinicians should prescribe scheduled nonopiate or opiate analgesics with the goal of limiting the severity of pain to below 3 or 4 on a 0-to-10 scale and to a level that does not interfere with sleep. The choice, dosage, and schedule of drugs is governed by the patient's pain severity, underlying conditions, and response to specific drugs. If pain control remains inadequate, then regional or local anesthetic nerve blocks should be considered. The effectiveness of carefully managed opiates, regional anesthetic nerve blocks, anticonvulsants, and tricyclic antidepressants during the acute phase of herpes zoster in reducing the incidence, duration, or severity of PHN is not known and needs to be tested in rigorous clinical trials.

Treatment of Postherpetic Neuralgia

PHN, once established, is difficult to treat. [17] Fortunately, it resolves spontaneously in most patients (Fig. 215-1B). Clinicians have advocated a wide range of treatments, including many oral and topical medications, epidural injection of local anesthetic and glucocorticoids, acupuncture, biofeedback, subcutaneous injections of triamcinolone, *trans*-epidermal electric nerve stimulation (TENS) units, spinal cord stimulators, and systemic administration of a variety of compounds, but most have not been validated by controlled trials.

TOPICAL THERAPY The topical lidocaine patch and EMLA (eutectic mixture of local anesthetics) cream produced significant pain relief in patients with PHN in controlled clinical trials; they are easy to use and are not associated with systemic lidocaine toxicity. [63] The 10 × 14-cm lidocaine patch contains 5% lidocaine base and other ingredients on a polyester backing. One or more patches are applied over the affected area for 12 h a day. EMLA is applied over the affected area under an occlusive dressing once a day. The disadvantages of the patch are application site reactions such as skin redness or rash, and substantial cost. Capsaicin (*trans*-8-methyl- *N*-vanillyl-6-nonenamide), an extract of hot chili peppers, is a chemical known to deplete substance P, an important endogenous neuropeptide that acts as a chemomediator of nociceptive impulses from the periphery to the CNS. A small clinical trial of topical capsaicin for 4 weeks in patients with PHN demonstrated significant effects of this therapy on pain, with 75 percent of patients experiencing substantial pain relief. [64] Unfortunately, the ointment burns too much to be tolerated by approximately one-third of subjects. In the authors' experience, capsaicin is rarely effective in patients with PHN.

ORAL AND ANESTHETIC AGENTS Gabapentin significantly reduced average daily pain scores in patients with PHN in a randomized, placebo-controlled trial. [65] The adverse effects of gabapentin included somnolence (27 percent), dizziness (24 percent), and ataxia (7 percent). Some experts have begun to prescribe gabapentin to patients with severe pain early in the course of herpes zoster, although the efficacy of this approach is unproven. Tricyclic antidepressants produced moderate to good pain relief in 44 to 67 percent of elderly patients with PHN in several randomized, controlled trials. [66], [67] Nortriptyline and desipramine are preferred alternatives to amitriptyline because they cause less sedation, cognitive impairment, orthostatic hypotension, and constipation in the elderly. Scheduled opioid therapy may also reduce PHN. In a randomized, placebo-controlled crossover trial of sustained-release oxycodone in patients with PHN, treated patients reported significant pain relief when compared to placebo. [68] Multiple anecdotal reports have advocated the use of peripheral, sympathetic, epidural, and ganglion blocks with local anesthetics and/or corticosteroids in PHN, but well-designed controlled trials are unavailable to support the efficacy of these treatments. [69] Recently, in patients with intractable PHN for more than a year who had failed oral and topical treatments, Kotani et al. reported good or excellent pain relief for up to 2 years in 90 percent of patients treated with intrathecal methylprednisolone plus lidocaine, compared to 6 percent in patients treated with intrathecal lidocaine alone. [70] These are remarkable results, but the safety and the feasibility of this intervention needs to be confirmed.

PREVENTION AND CONTROL

Prevention and Control of Varicella

VARICELLA VACCINE Several studies conducted in Europe, Japan, and the United States from the 1970s through early 1990s demonstrated that the live attenuated VZV (Oka strain) vaccine was immunogenic, that it was efficacious in protecting against varicella, that breakthrough cases were relatively mild, and that it was well tolerated in children. [71] Similar results were obtained in adults when two doses were given 4 to 8 weeks apart. Vaccinated children and adults developed breakthrough varicella from wild-type virus at a rate of 1 to 3 percent per year, as compared to the attack rate of natural varicella in unvaccinated children of 8 to 13 percent per year. On the basis of these data, the FDA licensed the Oka/Merck vaccine in the United States in 1995. The Advisory Committee on Immunization Practices (ACIP) and American Academy of Pediatrics recommend the varicella vaccine for (1) routine childhood immunization, one dose at 12 to 18 months of age; (2) susceptible, immunocompetent older children, adolescents and adults, using two doses, 4 to 8 weeks apart for persons older than 13 years of age; (3) individuals at high risk for exposure or transmission, including susceptible health care workers, family of immunosuppressed individuals, teachers of children, day care workers,

residents and staff in institutional settings, nonpregnant women of childbearing age, and college students; (4) postexposure prevention and outbreak control; and (5) day care and school entry. [72] The duration of vaccine-induced immunity over the life span is not yet known, but a high percentage of children followed long-term have remained seropositive; [73] however, it is likely that the immunity induced by the vaccine is not as solid as that induced by wild-type VZV infection. In adults, approximately 20 percent of vaccinees lose antibodies to VZV over time but continue to be partially protected—breakthrough varicella is characterized by mild disease and not severe varicella. [71] From the Vaccine Adverse Event Reporting System, the Food and Drug Administration and the Centers for Disease Control and Prevention (CDC) described 6574 case reports of adverse events per 9.7 million doses sold from March 1995 to July 1998. [74] The most common events were rashes (*n* = 3640) and injection site reactions (*n* =575). Of the case reports, 285 (4 percent) were serious, including seizures, neuropathy, encephalitis, ataxia, and thrombocytopenia at a rate of 2.9/100,000 doses. Whether these serious events were causally related to the vaccine was unclear. This rate is much lower than the rate for serious events following natural varicella. Herpes zoster was reported in vaccinees, but it occurred at lower frequency than herpes zoster caused by wild-type virus. Cases of laboratory-confirmed herpes zoster in vaccinees from several studies included some cases caused by reactivation of the vaccine virus and others caused by reactivation of wild-type virus that had been acquired but gone unrecognized. The effectiveness of the vaccine demonstrated in clinical trials has been confirmed in routine clinical practice, and the epidemiology of varicella in the United States is changing. [75], [76] and [77] Active surveillance showed that vaccination rates increased from less than 10 percent of children aged 12 to 23 months in 1995 to approximately 70 percent in 1999. Concomitantly, in 1999 and 2000, varicella incidence declined by approximately 80 percent, with the greatest decline among children 1 to 4 years of age. There was also a marked reduction in varicella-related hospitalizations and an attenuation of varicella seasonality. Many states now mandate the vaccine for school entry. [77] Carefully selected immunosuppressed children may also benefit from the varicella vaccine. When children with acute lymphoblastic leukemia (ALL) in remission and off chemotherapy are vaccinated, fewer than 10 percent develop a papular or papulovesicular rash, and most develop antibody and cell-mediated immunity to VZV. [78] Although not licensed for this indication, vaccine is available from the manufacturer to any physician through a research protocol for use in patients who have ALL and who meet certain eligibility criteria. In addition, the ACIP recommends that the vaccine be considered for asymptomatic or mildly symptomatic HIV-infected children in CDC class N1 or A1 with age-specific CD4+ T lymphocyte percentages greater than or equal to 25 percent. [72]

POSTEXPOSURE PROPHYLAXIS AND INFECTION CONTROL Patients with varicella and herpes zoster may transmit varicella to susceptible individuals. No preventive measures are recommended for a normal child who has been exposed to varicella or herpes zoster. On the other hand, it is desirable to prevent or modify varicella in high-risk immunocompromised individuals. Passive immunization with zoster immune globulin (ZIG) prepared from the plasma of donors recovering from herpes zoster and containing a high titer of antibody to VZV, zoster immune plasma (ZIP) obtained from otherwise healthy individuals during convalescence from varicella or herpes zoster, and varicella-zoster immune globulin (VZIG) harvested from outdated blood from blood banks, all protect immunosuppressed children from severe varicella when administered within 3 to 5 days of exposure. [79] Standard preparations of pooled human immunoglobulins for IV administration (IVIG) are probably also acceptable. Table 215-4 lists recommended criteria for the use of VZIG and related products.

TABLE 215-4 **Criteria for the Use of Varicella-Zoster Immune Globulin (VZIG) for the Prophylaxis of Varicella***

Active immunization with the live attenuated varicella vaccine is also effective in preventing illness or modifying varicella severity in children if used within 3 days of exposure. [80] Whereas protection afforded by VZIG is transient, varicella vaccine induces long-lasting immunity to VZV and protection against subsequent exposures. Chemoprophylaxis with acyclovir also has been studied in susceptible children following household exposure to varicella. Children who received postexposure treatment with acyclovir experienced fewer and lesssevere cases of varicella than children in the control group; [81] however, the appropriate timing is critical, immunity to varicella may not be achieved, and there are always fears that resistant strains will be selected by promiscuous applications of this approach. Hence, it is not recommended for routine use in children. Infection control practices for VZV increase in importance with the age and compromised immune status of the exposed, susceptible individual. There is no need to prevent exposure of susceptible normal children to VZV, but careful isolation procedures should be enforced to prevent infection of susceptible immunocompromised patients, newborn infants, and adults, particularly women of childbearing age. Exposure of susceptible immunocompromised patients to VZV warrants reduction in the dosage of glucocorticoids and immunosuppressive drugs and administration of VZIG. Hospital and long-term care facility personnel without a clear history of varicella or herpes zoster should be tested for antibody to VZV so that appropriate leave from work can be instituted following VZV exposure. In hospitals, airborne and contact precautions are recommended until all lesions are crusted for patients with varicella, immunocompromised patients with localized herpes zoster, and any patient with disseminated herpes zoster. [83] Contact precautions are recommended for immunocompetent patients with localized herpes zoster.

Prevention and Control of Herpes Zoster

Until universal vaccination greatly reduces the number of people harboring large amounts of latent VZV, prevention of herpes zoster must be aimed at preventing reactivation and spread of the virus. Long-term suppressive acyclovir treatment is only practical in immunocompromised patients at proven risk of developing herpes zoster within a defined time period, that is, in the year following bone marrow or solid organ transplantation. For the more general population, other strategies must be devised.

One approach to the prevention of herpes zoster is the stimulation of immunity to VZV, which wanes in elderly and other high-risk individuals. [15] Studies of healthy adults older than 55 years of age with a history of varicella demonstrate an increase in VZV-specific T lymphocytes and humoral immunity after vaccination with live attenuated VZV vaccine that is

similar to the increased immunity to VZV observed after an episode of herpes zoster. [84] These findings suggest that vaccination of this subset of patients may be useful in preventing herpes zoster and its complications. [15] A randomized, double-blind, placebo-controlled Veterans Affairs Cooperative Studies Program trial, involving more than 38,000 healthy adults aged 60 years and older, is currently being carried out in the United States in collaboration with the National Institute of Allergy and Infectious Diseases and Merck & Co., Inc., to determine whether immunization with a more potent formulation of the licensed varicella vaccine can reduce the frequency and severity of herpes zoster and its complications, particularly PHN.

REFERENCES

Cytomegaloviruses are widely disseminated in nature and species-specific members of this genera affect many animals, including rodents, domestic animals and primates. Human cytomegalovirus (HCMV) belongs to the Herpesviridae family, subfamily Betaherpesvirinae, and its formal designation is human herpesvirus 5.

HCMV shares many characteristics with other herpesviruses, including the general architecture of the virion, the genome structure and properties, including enzyme and viral DNA synthesis, the assembly of capsids in the nucleus, the irreversible destruction of the infected cells during the productive cycle, and the ability to remain latent in natural hosts after a primary infection, producing overt disease subsequently.

HCMV also has distinguished characteristics, such as salivary gland tropism, species-specificity, and slow growth in cultured cells that undergo typical cytopathic changes. It shows typical herpesvirus morphology with a core containing a linear double-stranded DNA surrounded by a capsid with 162 capsomeres, a tegument region of amorphous material that bridges the nucleocapsid to the envelope, and an envelope mostly derived from altered cell membranes of the host.

The only cell known to be fully permissive for HCMV replication in vitro is the human fibroblast. In these cells, HCMV grows slowly requiring 48 to 72 h to yield detectable levels of progeny virus. In vivo, however, cells infected with HCMV may be found in tissues of epithelial origin (liver, lung, salivary glands, kidneys, bile ducts, gut), in mesenchymal cells (endothelial cells, fibrocytes), in peripheral blood mononuclear cells and, occasionally, in inflammatory cells such as macrophages.

HISTORICAL ASPECTS

Weller coined the term HCMV, in 1957, because of the cytopathic cellular changes the virus produces in cell culture and in the so-called “congenitally acquired cytomegalic inclusion disease (CID).” In tissues, such changes include cell enlargement with the characteristic “owl's eye” intranuclear inclusions that had been described long before the virus was isolated, in the salivary glands of infants dying with CID. For a long time, the inclusions were considered the result of a protozoan infection, until Cole and Kuttner, in 1926, described a filtrable agent present in the submaxillary glands of guinea pigs. [1] Because the histopathologic features observed in the salivary glands of animals were similar to those in humans, the agent became initially known as “salivary gland virus.” Finally, in 1956, three laboratories independently described an identical cytopathic effect and isolated the virus. The virus was found to replicate in human fibroblastic tissue with the appearance of large refractile cells containing intranuclear inclusions identical to those observed earlier in CID patients with salivary gland infections. [2], [3] and [4]

EPIDEMIOLOGY

Worldwide 70 to 90 percent of people are infected with HCMV. HCMV may be considered one of the most successful examples of a human infectious agent, displaying an array of strategies for perpetuating and propagating itself in its natural host. It infects humans both vertically and horizontally, and many of its genetically unique strains continue to

circulate in the general population throughout the world.

HCMV is transmitted to approximately 70 percent of individuals living in good hygienic surroundings and to 90 to 100 percent of people of poor socioeconomic conditions. Transmission occurs during primary infection, reinfection, or reactivation, but the peculiar symbiotic relationship of HCMV with the host usually is manifest by subclinical infections. The infected persons may become reservoirs from which the virus spreads to other susceptible persons. As a consequence, the majority of adults show serologic evidence of HCMV infection.

Because of its lability, close or intimate contact is required for the horizontal dissemination of HCMV. The virus is present in oropharyngeal, cervical and vaginal secretions, urine, semen, breast milk, tears, feces, and blood. [5], [6] and [7] Because of its persistence in a life-long latent state after the primary infection, it is released for years in an occasional or continuous manner. The former occurs mostly during reactivation when infectious virions are shed in the saliva or other body fluids in a significant fraction of seropositive young adults. Reactivation may also lead to vertical (intrauterine) transmission. [7]

NATURAL HISTORY

The natural history of HCMV infection includes a primary infection, the latent infection, and possible reinfections and reactivations. The primary infection may be prenatal (via transplacental [8] or intrauterine transmission [7]), perinatal (via cervical secretion) or postnatal (via infected urine, saliva, breast milk, [8] blood transfusions, or organ transplantation [9]). Because infection occurs more readily in unhygienic environments, the vast majority of children of poor socioeconomic background are primarily infected by the onset of puberty.

After primary infection, HCMV remains in a latent state in specific cells of the host. In these cells, the genome takes the form of a closed circular molecule and expresses only a small fraction of viral genes. Peripheral blood mononuclear cells and other myeloid progenitors have been suggested as the reservoir of latent virus, but salivary glands and kidney cells also may play such a role. [10], [11]

Occasionally, however, the virus reactivates, and infectious virions appear in the saliva and/or urine. Such temporary reactivations are asymptomatic, but allow the virus to spread horizontally and even vertically if the reactivation happens during pregnancy. Reactivation is induced by an alteration of the host–parasite relationship caused by physiologic conditions, such as pregnancy and natural decay of defenses, to concurrent debilitating diseases, immunosuppressive drugs, and operative procedures. Cellular and humoral immune mechanisms are considered important in this regard. During immunosuppression, the rate of HCMV isolation increases presumably as a result of reactivation, although procedures such as allografting or blood transfusion implemented at the same time may provide additional opportunities for reinfection.

Reinfection is caused by a virus of a different antigenic type. Although it may be epidemiologically important to distinguish between reinfection and reactivation, both are clinically similar. The term *recurrent infection,* therefore, is often used to mean both possibilities.

Congenital Infection

Thirty to 40 percent of primary HCMV infections during pregnancy result in congenital infection of the newborn. As in rubella, the fetus is probably infected through maternal viremia and subsequent infection of the placenta, but infection of the myometrium via cervix or infected spermatozoa is also possible. Whether a cell-free virus or a leukocyte-associated virus is required for placental infection and why intrauterine transmission occurs only in one-third of pregnant women with primary infection are still open questions. In the course of a maternal infection, however, intrauterine transmission may also result from reactivation or reinfection with another HCMV strain.

Many factors play a role in this mode of transmission. Women who transmit the virus to their fetus, for example, have a more intense and prolonged HCMV-specific antibody response than those who do not transmit it. [12] In fact, if the antibody response is regarded as an indirect marker of viral replication, women who transmit the virus are those who replicate it more efficiently, supplying, therefore, the placenta with larger amounts of HCMV. Also, the host cell–mediated immune response and the hypothetical barrier function of the placenta are likely to be important.

Perinatal Infection

Eight to 56 percent of infants become infected and excrete HCMV into the urine during the first 6 months of life. Because intrauterine transmission accounts only for 0.4 to 2.5 percent of cases, the wide increase that occurs within the first months of life should be considered, in the absence of blood transfusion, as the result of mother-to-infant transmission. This occurs predominantly via infected genital secretions or breast milk, especially colostrum. [8] After breast milk ingestion, HCMV probably replicates within children's salivary glands.

Postnatal Infection

Forty to 80 percent of children are infected before puberty. HCMV primary infection in a normal host is usually asymptomatic and finding the routes of transmission is difficult. Probably saliva represents one of the most efficient sources of virus. An 80 percent rate of HCMV acquisition has been demonstrated in a group of children attending day care centers where HCMV-containing saliva can be recovered from toys.

Excretion of large quantities of virus is common in infants with congenital infection and may persist for years following birth, regardless of the severity of the infection. This provides an important source of virus and the spread of infection to

other infants and their caretakers. [13] Also, children with subclinical infection may spread the virus and pregnant women are at high risk, with oral and respiratory routes being the probable modalities of transmission. [14]

In normal adults, HCMV infection may be regarded also as a sexually transmissible disease, being more prevalent among women with past or current gonococcal infection. [15] HCMV is shed from the female genital tract, as cultures of cervical secretions show, in 3 to 35 percent of subjects. [16] An extremely high seroprevalence has been observed in sexually active homosexual men. [17] How relevant this route of transmission may be is uncertain, because sexual genital contacts are usually preceded by oral-to-oral contacts and HCMV excretion rate in semen is unknown. [5] By analogy with Epstein-Barr virus (EBV) infection, HCMV infection may represent in young adults a “kissing disease” rather than a classically venereal disease.

Other routes of transmission, though less frequent, are also important. Multiple transfusions or the transfusion of large quantities of blood are a particular problem. Leukocytes are the blood product mainly responsible; in fact, procedures that limit their quantity in transfused blood have reduced the incidence of this type of infection. [18] Screening blood donors has also contributed to a reduction in the incidence of infections. Blood-transfusion transmission is an uncommon event, because only 2.4 percent of blood units taken from HCMV seropositive donors actually lead to infection of seronegative recipients. [19]

HCMV is an important posttransplant pathogen in allograft recipients. Because HCMV is known to replicate actively in the distal convoluted tubules of infected kidneys and in mononuclear inflammatory cells in their interstitial spaces, approximately 50 percent of seronegative renal transplant recipients develop primary HCMV infection. Overall, however, 60 to 100 percent of allograft recipients of solid organs [20] become infected. HCMV reinfection (because of immunosuppression caused by operative procedures, therapies, and most probably HCMV reactivation) occurs in more than 85 percent of patients who are seropositive at the time of transplantation. [21]

Generally, the infection rate is indirectly related to the degree of the recipient immunosuppression. Obviously, the seronegative transplant recipients of organs donated by seropositive subjects are those who run the highest risk (33 to 83 percent infected in the case of kidney transplant). In addition, they usually develop a more severe disease than seropositive recipients. The risk for a seronegative patient who receives a graft from a seronegative donor is lower, but not nil (0 to 30 percent infected). [21]

Usually, not only does a more severe disease develop in transplant recipients who undergo a primary infection as compared to those with reactivation or reinfection, but HCMV infection also seems to have a negative influence on long-term graft function and patient survival. In cardiac allograft recipients, for example, coronary restenosis is caused by accelerated graft arteriosclerosis, while in kidney and hepatic transplantation, the mechanism of the damage is unclear. [22]

HCMV infection is a frequent cause of morbidity and mortality. After allogeneic bone marrow transplantation (BMT), for example, approximately 50 percent of all recipients develop HCMV infection. [9] Many remain asymptomatic, but some develop gastroenteritis, fever, leukopenia and wasting, hepatitis, or retinitis. The average incidence of HCMV pneumonia is 15 percent with 80 to 90 percent mortality.

With regard to HCMV infection, BMT differs from solid organ transplants. For example, the infection rate in seronegative recipients from seropositive marrow donors is lower than in seropositive recipients. In addition, BMT recipients receive less blood product than those patients transplanted with solid organs. All these considerations suggest that the donor marrow has only minor importance as a fomite and that the cause of infection is reactivation of latent virus.

The relevance of HCMV infection in inducing graft-versus-host disease in the posttransplant period is still debated.

Infection in the HIV-Infected Host

In HIV-positive patients, HCMV may influence the natural history of the HIV infection, independently of its role as an opportunistic pathogen, and it may be a possible cofactor in the progression to AIDS. In fact, an in vitro HCMV-HIV interaction has been shown, either directly through transactivation of the HIV genome or indirectly through the production of cytokines.

Although the in vivo evidence of this concept is at present debated, [23], [24] HCMV remains one of the most important opportunistic and life-threatening infections in AIDS patients. The longer survival of HIV patients emphasizes the importance of their HCMV infection by providing more opportunities for primary and recurrent infections to develop when cellular immunity is impaired or absent. In fact, the risk of developing opportunistic infections seems, at least partly, to be correlated with the level of the CD4+ lymphocyte count. In the case of HCMV infection, however, other mechanisms may be involved, such as a functional deficiency of the residual CD4+ cells or infection of other organs. [25]

IMMUNOLOGY

Immune surveillance mechanisms are important in HCMV infection. Probably, all components of the immune system act in concert to control the acute infection and to maintain the latent state, but T cells and the class I major histocompatibility complex (MHC)-restricted CD8+ cytotoxic T lymphocytes, natural killer (NK) cells, and antibody-dependent cellular cytotoxicity all play a central role. [11] This is shown by patients with deficiencies in this arm of the immune system who are at greater risk, and by the observation that a prompt cellular immune response is correlated with a good prognosis. [11] The specific immunity is mediated by CD8+ cytotoxic T lymphocytes that have their major target antigens [26] in the HCMV matrix protein pp65. In fact, patients with acute infection show increased levels of CD8+ T cells and a reversed CD4/CD8 ratio. Expansion of CD8+ T cells, comprising a CD8+ T cell subset that coexpresses the CD57 antigen, persists for

several months. Although the role of the CD8/CD57+ cells is still unclear, they probably mediate contact-dependent suppression and produce an inhibitory soluble factor. [27]

As for CD4 T cell functions, the acute infection is accompanied by a decrease of their antiviral action, but their role is uncertain. Lymphoproliferative responses to mitogens and viral antigens and the reactivity to skin tests are, in fact, diminished and a selective impairment of T cell activation via the T cell receptor/CD3 complex, which can be corrected by addition of exogenous interleukin (IL)-2, has been shown. [28] CD4+ T cells probably intervene by producing cytotoxicity-mediating cytokines and their role in controlling viral replication in salivary glands is influenced by the level of interferon (IFN)-?. [29]

The inhibition of the cell-mediated immunity is a part of the HCMV vast array of immune escape strategies. First of all, HCMV inhibits the cell-surface expression of the MHC class I within the infected cells by a variety of HCMV gene products. In addition, it impairs IFN-?–induced MHC class II-dependent antigen presentation by macrophages and protects infected cells interfering also with IFN-a–stimulated antiviral and immunoregulatory activity. [30] It also encodes proteins that can interfere with the presentation of viral peptide antigens to T cells and interacts with NK cells through a virally encoded MHC class I homologue. This is the UL18 gene product, which binds the host ß $_2$-microglobulin. The UL18 protein acts as a surrogate ligand that engages the NK-cell receptors, preventing recognition and lysis of HCMV-infected cells and may be used by the virus both as mechanism of infection and to evade the host immune response. [31], [32]

Additional mechanisms for the virus to evade the host immune response and facilitate human transmission probably include the possibility of HCMV-infected cells remaining protected from CD8+ cytotoxicity. This is the result of the alteration of MHC class I antigen surface expression [31], [32] and binding of the host ß $_2$-microglobulin. Human cytomegalovirus can survive in body fluids as ß $_2$-microglobulin–coated particles associated with its envelope, masking the antigenic sites necessary for neutralization. [33]

The biologic significance of other mechanisms of viral protection remains unclear. For example, HCMV is able to induce the expression of receptors with high affinity for the Fc portion of human IgG in the cytoplasm and membrane of the infected cells, and to immunoactivate polyclonal B cells, accounting for the increased plasma levels of IgG and the overproduction of autoantibodies.

The host-protective role of the humoral immune response is still controversial. Antibodies of IgG class are produced promptly at the time of primary infection and persist lifelong. IgM class antibodies are produced in primary, but not in the recurrent infections of immunocompetent individuals and they persist for 3 to 4 months. On the contrary, immunosuppressed patients may fail to mount an IgM response during primary infection and only one-third of them have IgM detectable in recurrent infections. During intrauterine infection, IgM antibodies are produced by the fetus together with IgG antibodies that remain detectable when the passively transferred maternal antibodies are cleared. Nonetheless, HCMV can be transmitted in the presence of passively acquired antibodies, though the severity of disease may be reduced if it occurs. Consequently, pooled human gamma globulins can be used in selected allogeneic BMT and renal transplant recipients. [34]

The nature and limits of the protective responses are, however, still largely undefined. Although HCMV-specific immune responses in a normal host may contribute to the limited growth of the virus in the involved tissue and to the fact that rarely do normal hosts exhibit clinical evidence of infection, immunity cannot prevent reinfection. On the other hand, the cell-mediated response may be a cause of disease. There is evidence that HCMV pneumonia can occur in allograft patients and, perhaps, some skin eruptions may be autoimmune conditions. [11] It is unclear what types of cells harbor the virus and support a productive infection, and if leukocytes act as specific carriers of the virus during acute infection. It is also unclear what represents the reservoir of replicating virus and the site of its latency. The cellular receptor for HCMV entry has not been identified, though the salivary glands, kidney, and mononuclear cells are considered the major sites of proliferation in primary infection. Finally, although we know that the most potent reactivators are immunosuppressive therapy, HIV infection, and organ transplants, the mechanism of reactivation remains unknown.

CLINICAL PRESENTATION

The main types of clinical presentation are congenital infection, postnatal infection, infection in the normal host, the postperfusion syndrome, and infection of the immunocompromised host.

Congenital Infection

CID occurs in 0.5 to 2 percent of newborns, often as a result of transplacental transmission of the virus. [8] Clinical manifestations are more severe in the offspring of mothers primarily infected in pregnancy than in those who undergo reactivation, and the earlier the gestational infection the more severe the disease. [8] Disease may develop in fewer than 10 percent of affected newborns and its manifestations may be so diverse as to include hepatomegaly with or without jaundice and splenomegaly, cardiovascular abnormalities (paraventricular calcifications), and gastrointestinal (GI) disorders (esophageal or biliary atresia, ileal or colonic stenosis, pyloric malformation). Neurologic abnormalities (deafness, encephalitis, psychomotor retardation, and paralysis) may be severe. [8] Sequelae, ranging from unilateral hearing loss to multiple central nervous system (CNS) abnormalities, intracranial calcifications, and impaired intellectual performance, develop in 10 to 20 percent of congenitally infected newborns, even if they were asymptomatic at birth. [8], [35] Manifestations may occur alone or in combination and are associated with a high risk of mortality.

Perinatal and Postnatal Infection

Postnatal infection is the most common clinical outcome of primary congenital infection and usually is asymptomatic.

Only occasionally does it present with a symptom complex, which resembles EBV mononucleosis syndrome.

Infection in the Normal Host

HCMV infection in immunocompetent patients often passes unnoticed, most individuals being unaware of their seroconversion. The clinical disease consists of a mononucleosis-like syndrome with a long-term unexplained febrile illness or pharyngitis, tonsillitis, lymphadenopathy, and/or arthralgias. [36] Numerous systemic manifestations are reported affecting one or more organ systems and tissues. Lymphadenopathy is less frequent than in EBV-induced infectious mononucleosis, and the Paul-Bunnell test is invariably negative. An elevated serum transaminase level is the most common evidence of liver involvement, but icteric hepatitis and fatal massive hepatic necrosis have also been observed. Laundry-Guillain-Barré syndrome and involvement of the CNS with encephalitis and meningitis have also been reported. The GI tract is another major site of HCMV involvement, exhibiting ulcerations from the esophagus to the colon. Retinitis and conjunctivitis, myocarditis, pericarditis, pneumonia, and hematologic abnormalities have also been described. [36]

Laboratory findings include atypical lymphocytosis, elevated hepatic transaminases, and a negative heterophile antibody response. Atypical lymphocytes have been shown to be mainly CD8+ T cells, while there is a decrease in CD4+ T cells, resulting in low CD4/CD8 ratios.

Postperfusion Syndrome

The postperfusion syndrome, [37] which occurs after a blood transfusion, is a mononucleosis syndrome in which the liver involvement is usually prominent. Transfused immunocompetent recipients rarely develop HCMV disease and, when it occurs either as primary infection or reactivation–reinfection, most of them are symptomless. Even if they become symptomatic, prognosis remains good without sequelae. In immunocompromised patients, the likelihood of developing a postperfusion syndrome is mostly related to the underlying condition of the recipient. Patients with AIDS and those who require massive transfusion support run a high risk of acquiring infection and developing severe disease.

Infection in the Immunocompromised Host

Organ transplant recipients and those with HIV infection may respond to primary or recurrent HCMV infections by remaining completely asymptomatic, but, more frequently, they develop viremia with bouts of fever and variable liver, lung, GI, and retinal involvement. The mortality rate is very high (80 to 90 percent).

Reactivation of latent intracellular virus is the major cause of HCMV infection in HIV-infected individuals in whom, most often, a disseminated and chronic disease develops with a high frequency of relapses and plurivisceral localization. Human cytomegalovirus retinitis is the most common visceral complication and presents with visual defects or decreased visual acuity. Gastrointestinal disorders caused by HCMV are also frequent in AIDS patients, and may involve all levels of GI tract, from esophagus to rectum. Colitis is a prominent manifestation with diarrhea, abdominal pain, weight loss, and bleeding.

Lungs, adrenal glands, and the CNS with encephalitis may also be involved. [38] Most patients have multiple sites of involvement and most often HCMV infection coexists with other opportunistic infections. Death as a result of HCMV-induced organ failure is possible, but the main cause of demise in AIDS patients remains *Pneumocystis carinii* pneumonia. [38]

Also in immunosuppressed transplanted patients, HCMV reactivation is the major cause of severe infections. Several risk factors predict the outcome: the degree of the immunosuppression, the need to supply blood products, the occurrence of graft-versus-host-disease, and the serologic status of the donor and the patient. [9], [37]

Symptoms occur from 1 to 4 months after transplantation. Gastrointestinal involvement is a major cause of mortality and develops later. Although there is limited evidence that the colon is involved in kidney transplant recipients and the upper GI tract in heart transplant recipients, the entire GI tract may be affected. Symptoms include esophagitis, abdominal pain, diarrhea, and bleeding, or massive hemorrhage in the case of GI perforation. [38] In renal transplant patients HCMV may cause interstitial glomerulonephritis that leads to poor graft function.

In HCMV-seropositive recipients who undergo allogeneic BMT, the risk of developing HCMV disease is great. It has been suggested that allogeneic reactivity triggers HCMV reactivation, but autologous-BMT recipients are at the same risk, and, when the disease develops, it is often as severe as after allogeneic BMT. [9] HCMV interstitial pneumonia is the most serious manifestation, leading to death more frequently than any other infectious agent. [37]

Skin Lesions

During HCMV infection, the skin is involved, especially in immunocompromised patients (Fig. 216-1), with both nonspecific and specific lesions. [39] The specific lesions are those ascribable to HCMV in the affected tissues or to the typical histopathologic features. The nonspecific lesions are mostly a consequence of immunologic abnormalities that follow viral infection or of hypersensitivity manifestations especially arising after antibiotic therapy. [11] The lesions include generalized macular and papular rashes, and urticarial and scarlatiniform eruptions. [36], [40] A widespread eruption, usually pruritic and morbilliform, appears in patients who receive ampicillin and its incidence increases in proportion to the duration of ampicillin treatment, as it occurs in EBV mononucleosis. The mechanism by which ampicillin triggers the development of rashes in patients with HCMV or EBV infection is unknown. High levels of infection-induced cytokines, HCMV-encoded proteins homologous to MHC class I, impaired CD4 T cells, control and expression of HCMV-enhanced adhesion molecules, all are hypothesized mechanisms that might induce the expansion of MHC class I–restricted

ampicillin-specific T cells. [11]

FIGURE 216-1 Papules and nodules on the back of a patient with Hodgkin's disease and disseminated HCMV. (*From Sugiura H et al: Successful treatment of disseminated cutaneous cytomegalic inclusion disease associated with Hodgkin's disease. J Am Acad Dermatol* **24**:346; 1991, *with permission.*)

CID cutaneous manifestations fall into this group. They consist of petechiae, purpura, jaundice, and blueberry muffin lesions [8], [41] (Fig. 216-2). The latter are violaceous or dark blue-red infiltrative papules and nodules that are characterized histologically by dermal erythropoiesis.

FIGURE 216-2 Infant with congenital HCMV infection: “blueberry muffin baby.” (*From Groark SP, Jampel RM: Violaceous papules and macules in a newborn. Dermal erythropoiesis associated with congenital cytomegalovirus infection. Arch Dermatol* **114**:116, 1989, *with permission.*)

The specific lesions differ according to the patient's immunocompetence. In the immunocompromised host, there are localized lesions and widespread eruptions (Fig. 216-3). Histologically, there is evidence of HCMV in the endothelial cells of the dermal vessels. [40] In fact, HCMV has been found in antemortem skin biopsies of hyperpigmented and indurated areas of the thighs, [42] granulating areas of burned patients, [43] a cutaneous ulceration on the chest, [44] a verrucous plaque on the heel, [45] crusted papules on the face, and ulcerations on the oral mucosa. [46] An ulcerative vulvovaginitis in a woman with AIDS has also been attributed to HCMV infection. [47] HCMV and herpes simplex virus have been simultaneously observed in the same skin ulcer of the lower lip and in necrotic papules of the legs in two AIDS patients. [48] HCMV has also been found in biopsies of erythematous and purpuric morbilliform eruptions, [44] scattered verrucous lesions, [45] and in a widespread eruption of perifollicular papulopustules. [49] Generalized urticaria during disseminated HCMV infection and a vesiculobullous eruption with histologic evidence of intraepidermal multinucleate giant cells, consistent with the cytopathic damage usually produced by the herpes group viruses, has also been reported. [40], [50]

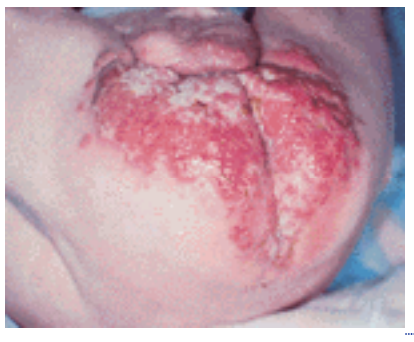

FIGURE 216-3 Infant with AIDS and diaper dermatitis–like disseminated HCMV. (*From Thiboutot DM et al: Cytomegalovirus diaper dermatitis. Arch Dermatol* **127**:396, 1991, *with permission.*)

Although most of the literature of the last 20 years reports cases of patients with ulcerations of the genital area who have been diagnosed later or even at autopsy, [40], [51] the skin is often the initial site of HCMV involvement and may provide the first clue to systemic infection.

Immunocompetent individuals very rarely present with cutaneous HCMV involvement. Only in two cases have specific dermatologic manifestations been reported. They consisted of erythematous, edematous, purpuric papules, and plaques in a livedo pattern on the lower extremities of a 7-year-old girl [52] and a purpuric rash with bullae on the legs in an adult woman. [53] The case of a patient with an acute papular and purpuric dermatosis in a characteristic “gloves-and-socks” distribution is also worth mentioning. [54] Usually, the papular-purpuric gloves-and-socks syndrome is considered a manifestation of parvovirus B19 infection, but in this particular patient, the specific anti-HCMV IgM antibodies detection suggested an active HCMV infection. In addition, HCMV has been found in ulcerated nodules of patients with systemic lupus erythematosus [55] and in skin lesions of 11 of 29 patients with vitiligo. [56] HCMV antibodies have been observed in patients with systemic sclerosis, [57] while, in psoriasis, a symptomless HCMV antigenemia was found associated with anti-HCMV IgG, but not IgM. This cleared with conventional antipsoriatic topical treatment. It may be related to a systemic overexpression of tumor necrosis factor (TNF)-a promoting HCMV activation. Alternatively, HCMV activation might exacerbate psoriasis via proinflammatory cytokines in infected cells. A recent study, however, found no evidence of HCMV-DNA in plaque psoriasis, indicating that cutaneous infection is not strictly necessary in the pathogenesis of the disease. [58]

DIAGNOSIS

Demonstrating HCMV pathogenicity is possible by different techniques and at least two strategies, namely the direct detection of virus and the specific immune response, are needed. However, the concordant results of several methods are necessary to establish a pathogenic relationship. It is quite important, therefore, to have a correct idea of the methods currently employed and of their own diagnostic significance (Fig. 216-4).

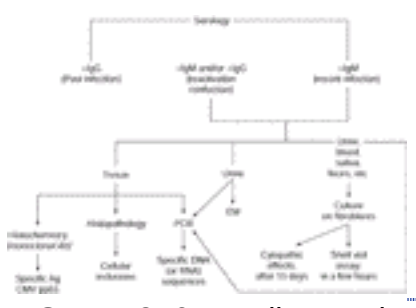

FIGURE 216-4 A diagnostic algorithm.

Culture Methods

Specimens may be collected from saliva, blood, urine, feces, semen, cervical secretions, bronchoalveolar lavage, fluid, and tissue biopsies obtained from target organs like skin, lung, liver, and kidney. [42] Diagnosis of congenital or perinatal infection needs urine or saliva samples and only rarely lumbar puncture or liver biopsy. In adults, urine, and heparinized blood are the best specimens. Culture of HCMV from oral lesions is not considered to be very specific because the virus can be excreted from other sites of the upper GI tract. [46]

Immunocompromised patients should be investigated by repeated cultures of saliva, urine, and blood. In saliva and urine of allograft recipients, HCMV excretion is very common, but it might be a mere coincidence. Viremia is more rare, but more specific and supports the diagnosis of HCMV, mononucleosis, or hepatitis. It is also indicative of a poor prognosis. Detecting HCMV in peripheral blood mononuclear cells does not prove that the virus has caused the disease because it might be in a latent state. By contrast, the detection of HCMV free in the plasma is considered a marker of active viral replication and strongly supports its involvement in the pathogenesis. [39]

HCMV grows only in human fibroblast cell culture. All cultures should be observed at least twice weekly to detect the focal cytopathic effect because the virus grows slowly, in contrast to herpes simplex and varicella-zoster viruses in epithelial cell cultures. [51] Modifications of this assay include the centrifugation enhancement of the specimen and the detection of intracellular HCMV proteins by immunofluorescence (shell vial assay). With the shell vial assay, the nuclear staining that results from immediate early gene expression can be seen within 10 to 15 h after inoculation. The shell vial assay has higher sensitivity (70 to 95 percent when compared to virus isolation) and specificity (100 percent by using monoclonal antibodies) and thus permits chemotherapy to be started earlier.

Light Microscopic Examination

The most commonly available method for diagnosing HCMV infection is histologic examination that, though specific, is less sensitive than cultures. Hematoxylin and eosin–stained sections may show enlarged, irregularly shaped, endothelial cells containing intracytoplasmic and intranuclear inclusions. [40] These Cowdry type A intranuclear inclusions are surrounded by a halo and may be found also in other tissues including liver, lung, gut, kidney, and brain. Cytomegalic changes without the characteristic inclusions have also been reported. These cells may be either present around or within the blood vessels. [49] Some intraluminal cytomegalic cells may have phagocytosis capacity. [40]

Electron Microscopy Examination

Although electron microscopy may show the characteristic viral particles of the Herpesviridae family, it cannot distinguish HCMV from other herpesviruses. The pseudoreplica method, [59] instead, identifies HCMV rapidly in the urine from infected infants in whom it is excreted at high titer. In immunocompetent children, viruria is considered specific because it is very unusual for any other herpesvirus to be found at so high a titer in infantile urine. This is not the case for immunosuppressed patients in whom the rate of virus excretion is usually lower and other herpesviruses are frequently found.

Immunohistochemistry

Indirect immunofluorescence is a rapid and sensitive method to identify numerous cellular antigens in some tissues, especially by using specific monoclonal antibodies against nuclear and cytoplasmic HCMV antigens. The detection of antibody-reactive polypeptides of UL83 (pp65) in circulating leukocytes (HCMV pp65 antigenemia assay) offers a method of estimating the viral burden. The high specificity provided by the use of monoclonal antibodies together with the very short processing time make the HCMV-antigen assay of great value in predicting invasive infection in allograft recipients and in HIV-positive patients, and in monitoring the efficacy of the treatment. A new approach to this method is the application of direct quantification of pp65 using flow cytometry. [60] Immunoperoxidase staining detects HCMV by using monoclonal antibody directed against the virus in paraffin-embedded tissues. [42]

In Situ Hybridization

DNA hybridization technology is based on the detection of particular nucleic acid sequences in biologic material, even in formalin-fixed, paraffin-embedded tissues. A labeled single strand of DNA with sequences complementary to the target nucleic acid (DNA probe) is used to seek and hybridize the viral genome in the test specimen. This test localizes specifically HCMV genomes in a particular cell type, but it is not a first-line test.

Polymerase Chain Reaction

HCMV DNA can be easily detected by polymerase chain reaction (PCR). In contrast to in situ hybridization, PCR does not give evidence about the specific cellular localization of the virus. In addition, detecting a viral genome in a cell or a tissue does not permit one to conclude about its etiopathogenetic role. PCR cannot distinguish between latent and productive infection or between latently infected cells and active replication. Only quantitative PCR gives data on the viral burden and its possible replicative state. It has been used to prove that patients with HCMV disease have more HCMV DNA in plasma (and even more in leukocytes) than those without disease. The viral load in leukocytes has been detected in immunocompromised patients often before the onset of symptoms and has been found to decrease during ganciclovir treatment. In blood and plasma samples, HCMV DNA levels seem to be suitable for screening patients at risk and monitoring the efficacy of antiviral therapy. [61]

Serologic Tests

The evaluation of the antibody titer is obtained by enzyme-linked immunosorbent assay or by complement fixation. Detecting IgG antibodies against HCMV suggests a past infection, while their rising level is often used as a marker of acute infection. Although detecting IgM antibody in acutely ill patients is highly significant for HCMV primary or recurrent infection, attention should be paid to both false-positive and false-negative results. A patient with disseminated HCMV infection has been reported not to show a change in antibody titer during a several month period. In addition, infectious mononucleosis or a positive rheumatoid factor can raise the HCMV IgM titer. [42] In contrast, immunocompromised patients with primary or recurrent infections may fail to produce specific IgM antibodies, leading to a poor prognosis. In transplant patients, the production of IgM antibodies following a recurrent infection is even more unpredictable.

Histopathologic Findings

Cutaneous HCMV is difficult to diagnose both clinically and histopathologically. Often, only a few cells exhibit cytolytic changes in a specimen even if, in severe disseminated disease, evidence of HCMV involvement can be found in virtually all organ systems. In fact, HCMV can be cultured from tissues easier than typical lesions can be seen. Generally, under light microscopy and with routine histologic staining, the typically infected cells appear exceedingly large with limited cytoplasm and prominent central nucleus. The latter often contains marginated chromatin and evident intranuclear inclusions surrounded by a clear halo (“owl's eye” inclusions) [40] (Fig. 216-5). In the skin, the typically affected cells are the endothelial cells, less frequently affected are fibrocytes and inflammatory cells. Only rarely have the epithelial cells (keratinocytes, eccrine ductal cells) been described.

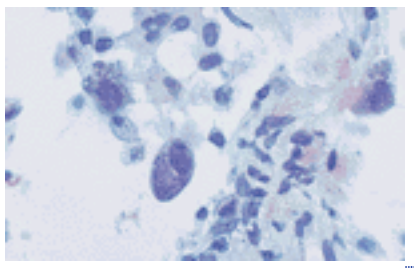

FIGURE 216-5 Intracellular inclusions in a cell infected by HCMV. (*From Konstadt JW et al: Disseminated cytomegalovirus infection with cutaneous involvement in a heart trasplant patient. Clin Cases Dermatol* **2**:2, 1990, *with permission.*)

The cell initially rounds, mainly by progressive swelling of the nucleus that appears basophilic, and it may display a prominent nucleolus and a reticulated pattern of nucleoplasm. Next, the cell continues to enlarge, particularly the nucleus that appears pale and convoluted. The nucleoplasm is marginated and vacuolated, while the cytoplasm is smudged and peripherally darker. Fully developed changes reveal that many, but not all, enlarged nuclei contain a purplish or basophilic inclusion body usually with a halo. Cytoplasm may contain granular, poorly defined, eosinophilic inclusions. The entire cell, however, stains basophil, except for the inclusions. [62]

Various authors differ markedly in their description of the nuclear inclusions, describing them as purplish, eosinophilic, basophilic, or amphophilic. These color variations may be a result of the different stages of nuclear changes in which the cells have been observed.

TREATMENT

Different antiviral agents can be used to treat HCMV infection and their combination (ganciclovir + foscarnet or foscarnet + cidofovir) or association with interferon is recommended because of their potentially decreased toxicity, higher efficacy, and delayed onset of drug resistance.

High-dose acyclovir has been used for prophylaxis in allogeneic BMT recipients and in renal allograft recipients with conflicting results, [63] but now it has been mostly replaced by new drugs.

Ganciclovir is a nucleoside analogue of acyclovir that does not require viral thymidine kinase for phosphorylation and activation. In vitro, it displays potent activity against HCMV and it is administered IV at 10 mg/kg per day for induction therapy and orally at 3000 mg/day for maintenance and prevention. An intraocular implant of 4.5 mg is used in HCMV retinitis. Ganciclovir toxicity includes leukopenia and thrombocytopenia, with abnormalities in spermatogenesis, leading to sterility, also described in experimental animals. The usual course of treatment is 14 days, but retreatment may be needed for some patients who relapse. After solid-organ transplantation, prophylaxis with ganciclovir reduces significantly the rate of both infection and disease, whereas acyclovir affects only the latter. [64]

Valganciclovir is a prodrug of ganciclovir that has been developed for the treatment of HCMV retinitis in AIDS patients. Oral valganciclovir is rapidly hydrolyzed to ganciclovir, providing a daily dose comparable to that of IV ganciclovir and equally effective. High ganciclovir blood levels can be achieved without the complications associated with the long-term access. [65]

Foscarnet interacts directly with the pyrophosphate binding site of the viral DNA polymerase. It is administered IV at 180 mg/kg per day (60 mg/kg every 8 h) for induction therapy and at 120 mg/kg per day for maintenance of HCMV retinitis and of acyclovir-resistant mucocutaneous infections. Dose adjustments for changes in renal function are necessary. Foscarnet has the same efficacy as ganciclovir, but it allows AIDS patients to survive longer, perhaps because of its antiretroviral activity. In fact, after 14 days of foscarnet induction therapy, the p24 HIV antigen levels decrease below the baseline.

Cidofovir is a nucleotide analogue with broad antiviral activity, that is effective in HCMV retinitis of AIDS patients refractory to other antiviral agents. It is administered IV at 5 mg/kg per week with sufficient hydration and under cover of probenecid to prevent nephrotoxicity. It can also be administered topically as 1% gel. [66] Despite such a route of administration, its pharmacokinetic properties allow a once-a-week dosing. Side effects include nephrotoxicity, bone marrow suppression, and ophthalmologic toxicity.

As a result of long-term maintenance therapy or of a subdose regimen, resistance to ganciclovir and foscarnet has been reported. For ganciclovir, the overall resistance rate ranges from 7.6 to 22 percent. For foscarnet, it is 26 percent after a 6-month therapy, rising to 37 percent after 9 months, while the overall resistance rate of cidofovir is 29 percent after 3 months. [67]

Novel agents under clinical development are maribavir and fomivirsen. Maribavir inhibits viral DNA synthesis by blocking terminal DNA processing, while fomivirsen is an antisense oligonucleotide with a sequence complementary to the coding region of the major immediate early HCMV gene of which it blocks the expression. It was recently approved for the local treatment of HCMV retinitis by intravitreal injection.

HCMV retinitis in AIDS patients profited from the advent of the highly active antiretroviral therapy (HAART). Allowing immunocompetency to be restored, HAART may eliminate the need for ongoing antiviral therapy, [68] leading to a dramatic reduction in the rate of HCMV infection and disease. Because AIDS patients were mostly at risk of developing HCMV drug resistance, the rate of the latter has also declined.

Efforts to develop vaccines able to confer immunity against HCMV have been made in recent years, but attenuated laboratory strains of HCMV induced only limited and temporary immunity. The use of replicating viral vaccine for preventing HCMV infection has met with some resistance because of the lack of knowledge of the determinants of HCMV virulence. The risk of vaccinating women of childbearing age with a replicating and possibly teratogenic virus and the oncogenic potential of such a vaccine raised other concerns. More recent interest has focused on the production of HCMV proteins from a recombinant expression system like the major envelope glycoprotein and the pp65 matrix protein, the last being considered an important target of HLA-restricted cytotoxic T cells after natural infection.

TREATMENT

REFERENCES

Epstein-Barr virus (EBV) is the etiologic agent of infectious mononucleosis and is associated with oral hairy leukoplakia and B cell lymphoma in patients with AIDS or acquired immunodeficiencies. EBV is also associated with malignancies including Burkitt's lymphoma, nasopharyngeal carcinoma, Hodgkin's disease, and certain T cell lymphomas.

In 1964 Epstein, Barr, and Achong described the presence of herpesvirus-like particles in Burkitt's lymphoma tissue. [1] In 1968, the Henles reported that EBV was the causative agent of infectious mononucleosis. [2] EBV DNA was demonstrated in biopsy tissues from patients with Burkitt's lymphoma and nasopharyngeal carcinoma in 1970, [3] in AIDS patients with B cell lymphomas in 1982, [4] and in Reed-Sternberg cells from patients with certain subtypes of Hodgkin's disease in 1989. [5]

EPIDEMIOLOGY

Infection with EBV is usually asymptomatic or presents with nonspecific symptoms in infants and young children. In contrast, infection of adolescents and young adults often results in infectious mononucleosis. While most individuals, especially those in developing countries, are infected at a young age and have few symptoms, persons from higher socioeconomic classes are less likely to have been infected during childhood and therefore are more likely to manifest primary EBV infection as infectious mononucleosis. [6] Most adults in the United States are seropositive for EBV by age 25 and are no longer susceptible to infection.

EBV is usually spread by contact with salivary secretions from asymptomatic persons shedding the virus. The incubation period of infectious mononucleosis is estimated to be 30 to 50 days. Transmission has been documented from blood transfusion and bone marrow transplantation. EBV can be isolated from saliva of asymptomatic seropositive individuals in 15 to 20 percent of attempts. Higher rates of shedding are seen in immunocompromised patients, [7] and in patients with infectious mononucleosis.

ETIOLOGY AND PATHOGENESIS

EBV is a member of the herpesvirus family. [8] The receptor for EBV (CD21) is present on B cells and epithelial cells. Infection of epithelial cells results in replication of the virus with lysis of the cell and release of infectious virus. Infection of B cells in vitro results in transformation and immortalization of the cells. These infected B cells are latently infected and usually do not produce infectious virus.

Humans become infected with EBV from oral secretions. The virus infects epithelial cells in the oropharynx, and B lymphocytes become infected either by direct contact with EBV-containing oral secretions or by contact with infected epithelial cells. The infected B cells proliferate and are controlled by an expansion of reactive T cells resulting in enlargement of lymphoid tissues and the symptoms of infectious mononucleosis. Following acute infection, EBV persists for life as a latent infection of B cells. These EBV-infected B cells remain low in number because of continued T cell surveillance. In the setting of cellular immune deficiency disorders, the EBV-infected B cells proliferate and may become clinically significant.

CLINICAL MANIFESTATIONS

Infectious Mononucleosis

Infectious mononucleosis is associated with the triad of fever, sore throat, and lymphadenopathy. [8] Erythema of the pharynx occurs in 85 percent of cases, and 20 percent of patients have a grayish-white pharyngeal exudate. Pharyngitis may be accompanied by tonsillar enlargement and may be associated with streptococcal infection. Other frequent signs and symptoms include malaise, headache, anorexia, myalgias, chills, and hepatosplenomegaly; less-common findings are nausea, abdominal pain, jaundice, and rash. Infectious mononucleosis is usually self-limited and symptomatic for 2 to 4 weeks; malaise and fatigue, however, can persist for months. Infrequent complications of infectious mononucleosis include autoimmune hemolytic anemia, thrombocytopenia, upper airway obstruction caused by hypertrophy of lymphoid tissue, hepatitis, meningitis, encephalitis, and rupture of the spleen.

A morbilliform or papular rash, usually on the arms or trunk, is present in 5 to 15 percent of cases of infectious

mononucleosis. The rash is more common in young children, is usually present during the first week of the illness, and may persist until the second week. The rash can have atypical features including a vesicular or scarlatiniform eruption, urticaria, or petechiae.

The vast majority of patients with infectious mononucleosis treated with ampicillin develop a maculopapular rash (Fig. 217-1 and Fig. 217-2). Rash has also been reported with amoxicillin, but is less frequent in patients treated with other beta-lactam antibiotics, including penicillin and cloxacillin. The eruption usually begins as erythematous or copper-colored lesions 5 to 10 days after beginning the antibiotic and starts on the trunk and spreads to the face and extremities as it becomes generalized. It may be associated with pruritus and usually resolves within 1 week. The rash associated with ampicillin usually appears later, is more severe and longer in duration, and more often involves the palms and soles than the rash in patients not treated with the antibiotic. It can be associated with other features of hypersensitivity reactions such as arthralgia, edema of the face and extremities, and diarrhea. The eruption is not predictive of future positive skin tests or adverse reactions to ampicillin or penicillin.

The etiology of the rash is thought to be caused by formation of antibodies associated with the polyclonal B cell proliferation that occurs with EBV infection and subsequent immune complex formation with activation of complement. Circulating immune complexes composed of immunoglobulins, complement components (C3, C4, and C5), EBV capsid antibody, and viral particles were associated with urticaria in one patient and became undetectable during recovery. [9] Skin reactions (consisting of a wheal =3 mm) to ampicillin were detected in two-thirds of patients with infectious mononucleosis, independent of prior ampicillin therapy. [10] Increased levels of serum antibodies reacting to ampicillin were detected in the serum of patients with infectious mononucleosis whether or not they had been treated with the antibiotic. The presence of these antibodies may be important in immune complex formation resulting in an Arthus reaction in the walls of small arterioles.

Urticaria has been reported in 5 percent of patients during the acute stage of infectious mononucleosis in the absence of antibiotic therapy or prior history of allergy. [11], [12] Cold-induced urticaria associated with cryoglobulinemia has also been seen during infectious mononucleosis in the absence of ampicillin therapy. [13], [14] Cold-induced acrocyanosis and cryoglobulinemia with vasculitis of the small vessels of the skin have each been noted in patients with infectious

mononucleosis.

Other skin lesions, including isolated palmar papules, erythema nodosum, and erythema multiforme, have also been reported in patients with infectious mononucleosis. Painful, bluish-black genital ulcerations have been reported in patients with acute EBV infection, and in one case, EBV was isolated from the ulcers. [15]

Periorbital edema is present in 2 to 35 percent of patients with infectious mononucleosis, and palatal enanthem is present in 3 to 13 percent of cases. The enanthem consists of multiple 0.5 to 1 mm erythematous petechiae, located between the hard and soft palate, which can coalesce to form larger lesions.

Laboratory findings in infectious mononucleosis include lymphocytosis that peaks during the second or third week of illness and >10 percent atypical lymphocytes. The atypical lymphocytes are vacuolated with a large cytoplasm. They may have indentations in the cytoplasmic membrane and are predominantly EBV-specific reactive T cells. Neutropenia, thrombocytopenia, and elevated transaminases and alkaline phosphatase are frequent findings during the first month of illness.

Infection with cytomegalovirus, toxoplasmosis, HIV-1, or hepatitis viruses can also produce the symptoms of infectious mononucleosis.

Oral Hairy Leukoplakia

Oral hairy leukoplakia is a benign hyperplasia of epithelial cells caused by active replication of EBV (Fig. 217-3). Lesions are usually present on the lateral surface of the tongue, but occasionally involve the dorsal and ventral surfaces of the tongue, buccal mucosa, soft palate, floor of the mouth, or pharynx. [16], [17] Patients present with slightly raised white lesions that are not well demarcated and have a corrugated or hairy appearance. The lesions may wax and wane, are not painful, and do not scrape off. Oral hairy leukoplakia is seen predominantly in patients with HIV, but has also been found in other immunosuppressed persons including transplant recipients as well as in persons with no known immunodeficiency. Histologically the lesions show parakeratosis, acanthosis, intranuclear inclusions, ballooning of the cytoplasm or an eosinophilic “ground glass” appearance, and little inflammation in the subepithelial layer. [18] Dysplasia is usually not seen and lesions do not progress to malignancy.

The lesions contain virus in the upper layers of the epithelium, but not in the basal layers. Biopsies from oral hairy leukoplakia contain EBV antigens, viral linear DNA (indicative of replicating virus), and large numbers of herpesvirus particles on electron microscopy. EBV viral capsid and early antigens are present, consistent with virus replication.

The differential diagnosis includes candidiasis, lichen planus, idiopathic or tobacco-associated leukoplakia, carcinoma, and geographic tongue. A presumptive diagnosis is usually made by the typical clinical appearance in an HIV-infected individual. Biopsy may be appropriate in atypical cases, such as patients not infected with HIV. The presence of EBV DNA in tissue or lesion scrapings by in situ hybridization is more specific than cytopathologic changes for the diagnosis of oral hairy leukoplakia. [19]

Cutaneous Malignancies

EBV has been detected in skin lesions from patients with cutaneous T/natural killer (NK) cell lymphomas. Most of these lymphomas are termed *angiocentric T cell lymphomas*. They present with ulcers, vesicles, nodules, or violaceous papules, and usually involve the nose, but may also present with lesions on the cheeks, lips, extremities, or trunk. [20] EBV is more likely to be present in patients with secondary cutaneous angiocentric lymphomas than in those with primary disease. [21] Some patients with NK cell lymphomas have severe hypersensitivity reactions to mosquito bites. Patients with hydroa vacciniforme–like lesions often progress to T cell lymphoma. [22] These patients present with fever and vesiculopapular lesions on the face and dorsum of the hands, and their lesions contain T cells with EBV DNA. A case of cutaneous T cell lymphoma associated with EBV was reported in a patient with AIDS. [23] Many patients with EBV-associated cutaneous T/NK cell lymphomas have a poor response to chemotherapy and progress to a hemophagocytic syndrome with pancytopenia and coagulopathy.

Subcutaneous panniculitic T lymphomas associated with hemophagocytosis and EBV present with indurated plaques, fever, hepatosplenomegaly, and pancytopenia. [24] Biopsies show cytophagic histiocytic panniculitis with lymphocytic infiltration into fat lobules and phagocytic or “beanbag” cells (Fig. 217-4). [25]

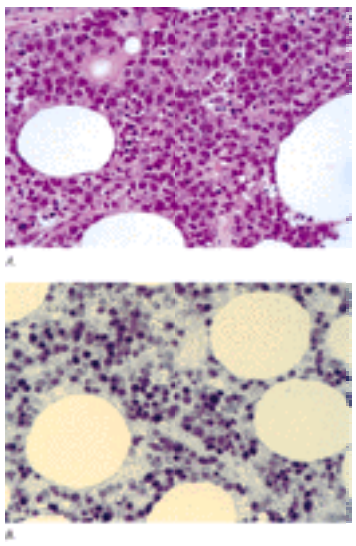

FIGURE 217-4 *A.* Bean-bag cells containing multiple nuclei in a patient with EBV-associated subcutaneous lymphoma, ×400. *B*. In situ hybridization for EBV-encoded RNA of the same subcutaneous lymphoma shows numerous cells expressing EBV RNA stained black, ×400. (*Courtesy of Keiji Iwatsuki, MD, Okayama University, Okayama, Japan.*)

EBV is also associated with B cell lymphomas that occur after transplantation or in persons with AIDS. While most of these patients have lesions in lymph nodes or viscera, some present with ulcerated cutaneous nodules containing EBV DNA. [26], [27] A patient with Hodgkin's disease who presented with skin nodules containing EBV RNA has been reported. [28] EBV–associated cutaneous B cell lymphoma has been reported in patients with rheumatoid arthritis or dermatomyositis who were receiving methotrexate, and many of these tumors resolved when the drug was discontinued. [29] EBV has also been detected in subcutaneous nodules of patients with lymphomatoid granulomatosis, [30] and in the epidermis in a patient with chronic lymphocytic leukemia and a papular rash. [31]

Other Skin Findings

Infantile papular acrodermatitis, or the Gianotti-Crosti syndrome, is associated with EBV and presents with symmetric erythematous lichenoid papules on the face, extremities, and buttocks, usually sparing the trunk (Fig. 217-5). [32] The rash is not pruritic and may be accompanied by splenomegaly, hepatitis, and lymphadenopathy. The rash often occurs in young children after an upper respiratory tract illness, but can occur in adults. The lesions show dermal edema, exocytosis of lymphocytes, and apoptotic keratinocytes. [33] An epidemic of Gianotti-Crosti syndrome caused by EBV was reported in Italy. [34]

FIGURE 217-5 Papules in a patient with Gianotti-Crosti syndrome associated with Epstein-Barr virus infection. (*Courtesy of Thomas Ruzicka, MD, Heinrich Heine University, Dusseldorf, Germany.*)

Kawasaki-like disease [35] and granuloma annulare–like eruption [36] have also been reported in patients with EBV infection. EBV has also been detected in lesions from patients with Kikuchi's histiocytic necrotizing lymphadenitis. [37] This benign condition occurs more often in females and presents with fever, chills, sore throat, cervical adenopathy, erythematous papules, nodules, and ulcers.

DIAGNOSIS

Acute infection with EBV is usually diagnosed by a positive heterophile test (e.g., monospot test). Heterophile antibodies agglutinate sheep or horse erythrocytes and do not recognize EBV antigens. More than 90 percent of patients with signs and symptoms of infectious mononucleosis, atypical lymphocytes, and a heterophile antibody titer of >1:40 have acute EBV infection. Heterophile antibodies may not become elevated until the third week of the illness, and usually persist for only 3 months. Heterophile antibodies are less common in persons who do not present with infectious mononucleosis.

EBV–specific antibody tests are useful for diagnosis of patients with negative heterophile antibodies or those with atypical symptoms. IgM antibody to the viral capsid antigen (VCA) is particularly helpful in the diagnosis of acute infection because it is elevated only during acute infection. Unfortunately, some commercial assays are nonspecific and report elevated levels of IgM anti-VCA antibodies in other settings as well. Antibody to early antigens (EA) is less useful

because it is elevated in 70 percent or fewer of patients with infectious mononucleosis. Seroconversion to IgG VCA or EBNA (EBV nuclear antigen) antibody positivity is useful for diagnosis of acute EBV infection; IgG VCA and EBNA antibodies usually persist for life. EBV DNA, RNA, and proteins can be detected in tissues from patients with oral hairy leukoplakia, lymphoproliferative disease, or EBV-associated malignancies (Fig. 217-4). Isolating EBV from oral secretions is of little value, because the virus is shed in a large percentage of healthy persons.

TREATMENT

Infectious mononucleosis is usually self-limited and therapy for symptoms includes rest and antipyretics. Although acyclovir inhibits virus replication in vitro and limits shedding of the virus, acyclovir is ineffective for reducing the symptoms of infectious mononucleosis. [38] Glucocorticoids are not indicated for patients with uncomplicated illness and may predispose to bacterial superinfection. [39] The combination of acyclovir and glucocorticoids has no significant effect on the duration of symptoms of infectious mononucleosis. [40] Glucocorticoids (1 mg/kg per day of prednisone for 2 to 3 days and tapered off over 1 to 2 weeks) may be useful in some patients with airway obstruction, severe hemolytic anemia, thrombocytopenia, or in very selected cases of encephalitis, myocarditis, pericarditis, or debilitating malaise and fever.

Patients with exudative pharyngitis that is accompanied by beta-hemolytic streptococci should be treated with penicillin or erythromycin. Ampicillin or amoxicillin should not be given during the acute phase of infectious mononucleosis.

Treatment of oral hairy leukoplakia is usually unnecessary. The lesions resolve during treatment with oral acyclovir (400 to 800 mg five times daily); however, they usually recur 2 weeks to 2 months after the drug is stopped. [17] Oral hairy leukoplakia has been reported to resolve with antiretroviral therapy, presumably as a result of better control of the underlying HIV infection. Surgical excision is associated with long-term remissions, but the disease can recur elsewhere on the tongue. [41] Topical tretinoin, [42] podophyllum resin, [43] trichloroacetic acid, and glycolic acid have all been used to remove lesions, but the disease recurs after treatment is discontinued.

REFERENCES

Human herpesvirus 6 (HHV-6) and human herpesvirus 7 (HHV-7) are two newly recognized viruses that share close genetic, biologic, and immunologic features. They differ from all other known human herpesviruses in their primary T cell tropism and their inability to directly induce cellular transformation in vitro. They are present in the normal population in a latent phase and have been implicated as etiologic agents in various conditions, including exanthem subitum.

HISTORICAL ASPECTS

Salahuddin and colleagues first isolated HHV-6 in 1986 after herpes-like particles were identified in the peripheral mononuclear blood cells (PMBCs) of patients with various forms of lymphoproliferative disorders, some of whom were also infected with HIV-1. [1] At the time, only five human herpesviruses were known: herpes simplex virus (HSV or HHV-1 and HHV-2), varicella zoster virus (VZV or HHV-3), Epstein-Barr virus (EBV or HHV-4), and human cytomegalovirus (CMV or HHV-5). As the virus was initially isolated from B lymphoreticular disorders, it was named human B lymphotrophic virus (HBLV). Shortly thereafter, Lusso and associates characterized it as the first preferentially T-lymphotrophic human herpesvirus. [2] Subsequently, HHV-6 has been found to also infect natural killer cells, monocytes, glial cells, and fibroblasts. [3]

Four years later, using similar culture conditions, Frenkel and colleagues isolated HHV-7, a second human herpesvirus with a predominant T-lymphocyte tropism. [4] The role of these organisms as etiologic agents in exanthem subitum has been well established. [5], [6] Recent observations and in vitro studies have provided a greater insight into other disease states in which they may play a causal role, including pityriasis rosea and neoplastic disorders.

EPIDEMIOLOGY

HHV-6 and HHV-7 are ubiquitous in the population. At birth, most children have IgG antibodies to HHV-6 and HHV-7 because of their exposure to maternal immunoglobulin. Primary infection is thought to be acquired largely through oropharyngeal secretions, as suggested by the frequent detection of the virus in salivary secretions. Dahl and associates found peripheral blood HHV-6 DNA by polymerase chain reaction (PCR) assays in 41 to 44 percent of pregnant women, 25 percent of women at delivery, and 24 percent of age-matched controls. HHV-6 to DNA occurred in only 1 percent of cord blood samples. Thus, fetal transfer of HHV-6 is probably rare, and there is currently no indication that congenital infection with HHV-6 is harmful to the fetus. [7] Viral particles have also been recovered from vaginal and cervical secretions.

HHV-6 antibody levels reach a nadir at 4 to 7 months of age, then increase throughout infancy so that by 12 months two-thirds of children have been infected, with peak antibody levels being reached at 2 to 3 years. HHV-7 antibody levels reach a nadir at 6 months, with antibody levels peaking at 3 to 4 years. Adult seroprevalence rates of HHV-6 and HHV-7 show some waning of antibody levels with increased age. Clinical data suggest that HHV-6 and HHV-7 may persist as an active viremia, however, or remain latent in asymptomatic adults.

HUMAN HERPESVIRUS 6 AND 7

HHV-6 and HHV-7 are members of the ß-herpesvirus family. HHV-6 is a double-stranded DNA virus with an enveloped virion and an icosahedral capsid 170 to 200 nm in diameter that encloses the viral genome. The capsid is composed of 162 subunits (capsomeres) that resemble tubular structures. An amorphous integument acquired from the nuclear membrane encapsulates the genome and capsid (nucleocapsid). HHV-6 replicates by a rolling circle mechanism, with the formation of head-to-tail concatamers in infected nuclei. Fusion events with the nuclear membrane result in the release of

the capsids into the cytoplasm of infected cells. They undergo envelopment in cytoplasmic vacuoles, yielding mature virions. Further fusion with the cell membrane releases completed particles into the extracellular space.

More than 30 polypeptides have been identified in virions and infected cells, including 7 glycoproteins. In addition to structural components of the virion, certain enzymes essential for viral replication, including virus-specific DNA-polymerase, are synthesized in infected cells. Thymidine kinase, uracil-DNA-glycosidase, and deoxyuridine triphosphate nucleotidohydrolase, as well as other herpesvirus-specific enzymes, are not synthesized. [8] Ganciclovir kinase, similar to that produced by CMV, is detected.

The HHV-6 genome is 160 to 170 kilobase pairs (kbp) in length. A central segment containing a unique sequence that is rich in A+T and approximately 140 kbp in length has been identified. It is flanked by two identical direct repeat segments, rich in G+C, of approximately 8000 base pairs each. These direct repeats contain essential elements for viral DNA packaging and replication, and possibly for the maintenance of latency. [9] They also contain a tandem repetitive sequence (GGGTTA) that is also present in the genome of the Marek's disease virus. The overall content of G+C is 43 percent, one of the lowest among the Herpesviridae. The genome shares the highest degree of nucleotide sequence homology with HHV-7, while both HHV-6 and HHV-7 are more distantly related to CMV, [10] with approximately 65 percent homology. HHV-6 also possesses a gene with striking homology to the rep gene of adeno-associated virus type-2 (AAV-2), [11] a defective parvovirus dependent on adenovirus for replication. The AAV-2 rep protein inhibits cellular transformation by papillomaviruses. The HHV-6 replike gene product is functional and has been shown to block H- *ras* cellular transformation, to mediate AAV-2 DNA replication, and to alter HIV-1 transcription via the long terminal repeat. [12]

There are two major viral subgroups (A and B) for HHV-6. [13] The overall genetic divergence between the two variants is approximately 5 percent. The prototype of HHV-6A is strain GS. [1] The prevalence and time of primary infection with HHV-6A are still undefined, as type A is detected less frequently than type B. HHV-6A has been frequently detected in the plasma of patients after bone marrow transplantation, [14] serum of patients with multiple sclerosis, [15] and blood of immunocompromised patients such as those with AIDS. Although the detection of virus in these patients suggests a role for the virus in the etiology of these disorders, to date no human disease has been definitely linked to this subgroup. The prototype of HHV-6B is strain Z29. [16] It is responsible for most cases of primary infection of early childhood and has been associated with exanthem subitum. Its prevelance in Western countries is universal.

Characterization of HHV-7 is not yet complete. The HHV-7 genome is approximately 145 kbp. The genome encodes more than 70 proteins, including 2 major capsid proteins, and shares the greatest nucleotide homology with HHV-6A.

PATHOGENESIS

It is believed that HHV-6 and HHV-7 establish latent infections, as observed with other herpesviruses, thereby persisting indefinitely in the infected host. Although no in vitro models of latency exist, infection persists in cultured monocytes. [17] It is postulated that salivary and bronchial gland epithelial cells and circulating monocytes act as reservoirs for these viruses.

Human Herpesvirus 6

HHV-6 is a cytopathic virus. Unlike EBV, HHV-6 does not cause direct immortalization of its target cells. Both EBV and HHV-6 preferentially infect CD4+ T cells, [2] although HHV-6A is also able to infect cytotoxic effector cells, including CD8+ T cells, natural killer cells, and ?d T cells. HHV-6 can also infect, yet ineffectively lyse, nonimmune cells such as fibroblasts, neural cells, muscular cells, and epithelial cells. The receptor for HHV-6 is not known. HHV-6 has been shown to downregulate the expression of CD3 and aß heterodimers on T-cells, [18] thus having a potential immunosuppressive effect. HHV-6 can also transcriptionally activate the expression of CD4 in cells that physiologically do not express it. [19] It is also a powerful inducer of cytokines, including TNF-a and IL-1ß.

Human Herpesvirus 7

The major receptor for HHV-7 is the CD4 glycoprotein, [20] which also serves as the major receptor for HIV. HHV-7 and HIV-1 compete for CD4 occupancy and reciprocally interfere both in CD4+ T cells and in mononuclear phagocytes. HHV-7 downregulates CD4 expression. The use of its envelope in anti-HIV therapy has been proposed.

CLINICAL MANIFESTATIONS

Cutaneous Manifestations

EXANTHEM SUBITUM Zahorsky, in 1913, described exanthem subitum as *roseola infantum* (Latin, “pink rash of infants”). Veeder and Hemplemann introduced the name *exanthem subitum* (Greek, “sudden rash”) in 1921 to describe the most characteristic clinical finding, that of the sudden appearance of a rash on the fourth or fifth day of illness. Exanthem subitum originates in a mild, self-limited illness of short duration that is commonly mistaken for other illnesses that cause fever and rash in children. Exanthem subitum is a nonreportable infection, occurring equally in boys and girls. Although most studies of large groups of affected children showed no characteristic seasonal or monthly incidence, Juretic, in a review of 243 cases, noted a peak occurrence in May. [21] The typical age range is between 6 months and 2 years, with occasional cases described in older children and adults. Maternal antibodies play a role in the prevention of clinical infection prior to 6 months of age. The estimated incubation period is 5 to 15 days. Many viruses have been postulated to be the causative agent of exanthem subitum, including echovirus 16, coxsackieviruses, adenoviruses, and parainfluenzavirus type 1. To date, there is no conclusive evidence to support these hypotheses. In 1988, Yamanishi and colleagues provided evidence that HHV-6 was a causal agent of exanthem subitum. [22] HHV-7 has subsequently been

shown to play a similar causal role. The virus is present in high concentrations within mononuclear blood cells during the febrile stage of the illness. Subsequently, HHV-6 and HHV-7 antibodies develop. The onset of the disease is abrupt. In spite of a high fever, ranging from 38.9°C to 40.6°C (102°F to 105°F), the child is generally in no distress. A bulging anterior fontanelle, tonsillar and pharyngeal inflammation, tympanic injection, and nodal enlargement have been observed. There are generally no other systemic symptoms. The fever drops precipitously on the fourth day, coinciding with the rapid onset of a rash. The exanthem consists of nonpruritic, rose-pink macules and papules, 2 to 3 mm in diameter that blanch on pressure and are surrounded by a white halo (Fig. 218-1). The rash characteristically appears first on the trunk and may spread to the neck, upper extremities, and lower extremities. Fully evolved within 12 hours, it lasts 1 to 2 days. In some cases, the rash appears suddenly and disappears within a few hours. Resolution occurs without desquamation or hyperpigmentation. Palpebral edema (Berliner's sign, “heavy eyelids”) and periorbital edema are quite common.

FIGURE 218-1 Exanthem subitum. Multiple, blanchable macules and papules on the back of a febrile child, which appeared as the temperature fell. (*Courtesy of Karen Wiss, MD.*)

The differential diagnosis of high fever with sudden defervescence and an evanescent exanthematous eruption is quite narrow, but should include rubella, measles, scarlet fever, erythema infectiosum, other viral infections with exanthems (i.e., enterovirus, adenovirus, echovirus, coxsackievirus, rotovirus), and adverse cutaneous drug reactions. The characteristic clinical findings form the basis for diagnosis. Laboratory tests may reveal a transient leukopenia with a relative lymphoctyosis and occasional atypical lymphocytes. The course of exanthem subitum is mild, and there are generally no sequelae. The most common complication is the development of seizures. It is unclear whether the seizures are secondary to fever or to infection. Meningoencephalitis and fulminant hepatitis, confirmed by isolation of either HHV-6 or HHV-7 viral DNA from cerebrospinal fluid in the febrile phase, have been reported as complications of exanthem subitum. Thrombocytopenia has also been observed. Intussusception has been reported in three Japanese children with HHV-6 infection. [23] No treatment is generally required, given the self-limited nature of this disease. Primary infection with HHV-6 and HHV-7 confers lasting immunity.
PITYRIASIS ROSEA (See Chap. 46) Drago and colleagues have postulated that HHV-7 may play a role in patients with pityriasis rosea. [24] For 12 patients with pityriasis rosea, HHV-7 was isolated from sera, PMBCs, and skin biopsies using PCR techniques. Weak PCR signals were detected in PMBCs from 11 of 25 control patients. No HHV-7 was detected in control patient sera or skin biopsies. Further studies are needed to establish causality.

Neurologic Manifestations

HHV-6 may be a potential trigger for multiple selerosis. High levels of the virus have occurred in infected oligodendrocytes near plaque formations in the brains of patients with multiple sclerosis. [26] As well, IgM titers to an early HHV-6 antigen have been elevated during relapses. HHV-6 may act as a cofactor, activating a retrovirus responsible for multiple sclerosis. Active viremia and seroconversion in these children, as well as meningitis and meningoencephalitis, have implicated both HHV-6, and HHV-7 as causal agents of infant febrile seizures. [26], [27] These seizures are thought to be due to direct invasion of the central nervous system (CNS) by the virus.

Sugaya and colleagues recently reported that some cases of influenza encephalopathy were associated with HHV-6 and HHV-7 infection. [28] Of eight patients with encephalopathy, HHV-6 and HHV-7 DNA was detectable in the cerebrospinal fluid of two and three patients, respectively. No influenza virus was found in the cerebrospinal fluid.

Human Herpesvirus 6 and Human Immunodeficiency Virus

HHV-6 is thought to play an important role in the activation and propagation of HIV infection. Given its preferential tropism for CD4+ T cells and its ability to upregulate CD4 expression, HHV-6 may function as a cofactor for infection of these T cells with HIV. In addition, HHV-6 is a potent transactivator of HIV (long terminal repeat), and the HIV Tat transactivator enhances HHV-6 replication, each providing a favorable environment for replication. Active HHV-6 has been detected in multiple organs of patients with terminal AIDS at the time of autopsy. [29] In particular, HHV-6 localized to the white matter in areas of demyelinization in AIDS patients, [30] sparing areas without pathologic changes. It is postulated that HHV-6 may play a direct role in the development of AIDS-associated central nervous system disease. Clinically, HHV-6 has appeared in the cerebrospinal fluid of children with AIDS encephalitis.

Neoplastic Disorders

It has been suggested that HHV-6 may be an etiologic factor in neoplastic disorders such as Hodgkin's disease (via IgG serology and PCR), [31] non-Hodgkin's lymphoma (via Southern blot and PCR), [32] Langerhans cell histiocytosis (via PCR), [33] Kaposi's sarcoma (via PCR), [34] cervical cancer, [35] and angioimmunoblastic lymphadenopathy with dysproteinemia (via

PCR). [36] Unfortunately, no controlled studies have been conducted on these hypothesis. The tumorigenic potential of HHV-6 has nonetheless been well documented in vitro. [37]

Bone Marrow Transplantation

An important cause of idiopathic marrow suppression after bone marrow transplantation is HHV-6, as indicated by the presence of active viremia at the time of suppression. [38] This marrow-suppressive effect is thought to be partially mediated by cytokine- or virus-produced soluble factors. HHV-6A produces a more virulent aplastic anemia than does HHV-6B. The presence of HHV-6 DNA in the plasma, but not PMBCs, of bone marrow transplantation patients suggests reservoirs of HHV-6 other than peripheral blood cells. [14] Interstitial pneumonitis, [39] retinitis, [40] and bone marrow graft failure have also occurred in patients with active HHV-6 infections.

Miscellaneous

Both HHV-6 and HHV-7 have a putative role in the development of chronic fatigue syndrome. A major impediment to a confirmation of this role is the lack of a precise definition for chronic fatigue syndrome. Studies have demonstrated higher antibody titers to HHV-6 and HHV-7, as well as EBV, in patients with chronic fatigue syndrome than in control patients. Confirmation of active viral infection will allow for more supportive data.

Razonable and associates found selective reactivation of HHV-6A in critically ill immunocompetent hosts. [41] However, the incidence and degree of reactivation of the virus was not associated with any specific parameter, nor was it related to disease severity and outcome. Anti–HHV-6 IgM antibodies were also detected in patients who exhibited a drug reaction with eosinophilia and systemic symptoms (DRESS). [42] Neither anti-CMV nor anti-EBV antibodies were detected, suggesting a selective reactivation of HHV-6. Seroconversion occurred in two patients, suggesting a specific immunologic reaction induced by exogenous drugs. Interestingly, HHV-6 DNA was not detectable in the serum of any patient by PCR.

LABORATORY TESTS

The most accurate method of detection of HHV-6 and HHV-7 is the PCR evaluation of serum or plasma. [43] IgM antibody reactivity correlates well with active infection. Immunoglobulin antibody titers do not correlate with actual viral replication. Other methods employed include immunohistochemisty and RNA in situ hybridization, both of which offer the additional advantage of exact lineage identification.

SUSCEPTIBILITY TO ANTIVIRAL AGENTS

The antiviral susceptibilities of HHV-6 and HHV-7 resemble those of CMV. [44] All three viruses lack a thymidine kinase and encode for ganciclovir kinase. HHV-6 and HHV-7 are susceptible to ganciclovir and foscarnet and show minimal susceptibility to acyclovir. At present, these agents are not routinely used in the treatment of HHV-6 or HHV-7. The optimal approach to the prophylactic treatment of transplantation patients has yet to be defined. Ganciclovir should be avoided in patients with marrow suppression, and foscarnet avoided in patients with renal disease. Other drugs with in vitro activity against these viruses include ampligen and kutapressin.

SMALLPOX (VARIOLA)

Smallpox is an acute exanthematous disease caused by infection with poxvirus variolae. The significant clinical features include a 3-day prodromal illness and a generalized centrifugal rash with rapidly successive papules, vesicles, pustules, umbilication, and crusting within 14 days. Although the worldwide eradication of smallpox was officially announced in 1979, it is too soon to give up discussion of this disease in medical texts, and it is treated here as though it still existed. Recent concern about the use of smallpox as an agent of bioterrorism reinforces the thought that the disease cannot be ignored. In addition, many nations are preparing for large-scale vaccinations, furthering the need to enhance professional knowledge of the disease and the vaccine.

Historical Aspects

The first clinical description of smallpox was by Rhazes, an Arabian physician, in the tenth century A.D. Many curious beliefs concerning the cause and pathogenesis of the disease are recorded in the writings of the early physicians. Frequently smallpox was confused with chickenpox, syphilis, and measles. It is of interest that smallpox was known in China 11 centuries before the birth of Christ, and that inoculation to prevent the disease was described in the sixth century B.C., using dried crusts introduced into the nose. It is likely that smallpox was introduced into the Western world in the early centuries after Christ by the migrations of invading armies. Subsequent spread of the disease in Europe and England is intertwined with the history of these areas. As one reads the various accounts of epidemics of this disease in the fifteenth and sixteenth centuries, and later in the United States, it becomes apparent that smallpox represented a major force in life, often affecting dynasties, determining the outcome of military conflicts, as well as influencing daily life. Until the advent of Jennerian vaccination, its widespread application, and the ultimate eradication of smallpox, this disease continued to be a major threat, with widespread attack rates, persistent infection within a community, and a high mortality rate.

Epidemiology

In the past 25 years, a remarkable event occurred in public health. The efforts of many countries, coordinated by the World Health Organization (WHO), resulted in intensive case finding and application of smallpox vaccination across large populations. This resulted in the eradication of smallpox, and there have been no cases anywhere in the world since October 1977. Monkeypox, mainly in central Africa, affects human with lesions resembling variola, has a case fatality rate less than 1 percent, and has not taken over smallpox' ecologic niche.

After the eradication of the disease, smallpox virus (variola) was supposed to be limited to two laboratories (USSR and US) by the WHO. It now appears that several countries possess the virus, including some with potential terrorist relationships.

Etiology and Pathogenesis

Smallpox is caused by infection with poxvirus variola. The entire DNA genome of the virus has been analyzed, and many of the viral proteins have been sequenced. Many of these share identity with the major gene products of the vaccinia virus. It is believed that infection occurs strictly following contact with another infected human being. Evidence suggests

respiratory transmission, and the epidemiologic pattern supports this concept. Skin inoculation and fomite spread may also play a role in some instances.

Following contact, there is an asymptomatic period of 12 to 13 days. Despite the lack of symptoms, viral replication is massive. The pathogenic events that occur in the human being are suggested by analogy with Jenner's experimental mousepox infection. The virus, following introduction via the respiratory tract, undergoes local multiplication in the respiratory mucosa and regional lymphoid tissue. Primary viremia, which spreads the virus widely throughout the reticuloendothelial system, occurs where a massive multiplication occurs. A secondary viremia heralds the onset of the prodromal illness, resulting in spread to many organs and tissues, with primary manifestations in the skin. It has been postulated that serum antibody is not the significant factor in recovery from initial episodes of smallpox, and it appears likely that both delayed hypersensitivity and interferon production play some role in such recovery. Hemorrhagic forms of the disease are of interest in that a profound coagulation disorder is associated with a decrease in the number of serum platelets. Evidence indicates that depression of platelet formation occurs routinely in smallpox infection and that the hemorrhagic forms of the disease bear some similarity to disseminated intravascular coagulation, which results in reduction in coagulation factors, extensive hemorrhage, and death.

Clinical Manifestations

HISTORY An influenzal illness occurring shortly after contact has been described ("illness of contact"). Prior vaccination history and interval to symptoms are important, as the disease pattern may be altered. Prior to the onset of the typical cutaneous lesions, a prodromal period of 3 days' duration occurs, characterized by apprehension, sudden prostrating fever, severe headache, back pain, and vomiting. A prodromal rash is not uncommon; it is macular and papular or petechial, and when it occurs in the characteristic "swimming-trunk" distribution, it is felt to be pathognomonic. The patient is not infectious during the prodrome until an enanthem appears.
CUTANEOUS LESIONS The disease may take various courses. In the nonvaccinated person, a discrete pox eruption is the most frequent form of illness. Severe forms of the disease are associated with confluent eruptions and/or cutaneous hemorrhage. Infrequently, variola may occur without eruption, or with just a few pocks. A flat erythematous macular rash may precede the appearance of tense, deep-seated papules that rapidly vesiculate. These lesions are firm and more deep-seated than those of chickenpox. The rash may be very sparse, or individual vesicles may become confluent to form large patches. As the lesions mature, the classic "pustule" occurs (Fig. 219-1). These lesions do not contain bacteria, and the cloudiness represents accumulated white blood cells, debris, and protein. Central umbilication is characteristic (Fig. 219-1 and Fig. 219-2), and eventually the lesion crusts over and heals, with scar formation. Although this is the classic evolution of smallpox, many variants are encountered, especially in individuals previously vaccinated. Lesions may present a flat disklike appearance, or may undergo resolution without passing through the vesiculopustular stage.

FIGURE 219-1 *A.* Pustular smallpox: tense, clouded vesicles which maintain a firm feel. *B* and *C.* Note tendency to confluence and beginning central umbilication in some lesions.

FIGURE 219-2 Confluent smallpox. Note massive numbers of lesions, all in same stage of development, and confluency of many.

There are two recognized hemorrhagic forms of the disease: one in which hemorrhage occurs in association with prodromal symptoms but death supervenes before any of the characteristic skin lesions can occur; and a second, characterized by hemorrhage into preexisting skin lesions. Both have almost universally fatal outcomes, the first within a week and the second after 8 to 12 days. Bacterial infection of smallpox lesions occurs, and localized abscesses, cellulitis, and the like may result.
OTHER PHYSICAL FINDINGS Secondary viremia with spread to many organs may result in clinically apparent illness. Particularly common are ulceration of the cornea, laryngeal lesions with symptoms of obstruction in the upper part of the airway, central nervous system involvement with encephalitis or acute psychotic behavior, and, less commonly, osteomyelitis, pneumonia, and orchitis.
LABORATORY FINDINGS Usual diagnostic laboratory measurements are of little value in smallpox. The white blood cell

count may be elevated early in the disease, but this is not of diagnostic significance. Virus is present in the blood of patients during the prodrome and occasionally thereafter. Virus is uniformly found in the skin lesions; the early papules and vesicles provide the richest source. In hemorrhagic forms of the disease, severe thrombocytopenia occurs; in addition, marked decrease in the level of accelerator globulin (factor V), moderate decreases in the amount of prothrombin and proconvertin, and a circulating antithrombin are noted in early hemorrhagic smallpox. The late hemorrhagic form of the disease is associated with a decrease in platelets without other coagulation disturbances.

Pathology

In the papular stage of the eruption, capillary dilatation and edema of the papillary layer of the dermis are observed. Perivascular inflammatory changes occur, with lymphocytic and histiocytic infiltration. Thickening and vacuolization in the epithelium result in vesicle formation. The vesicle is deep and, because of the destruction of cells, becomes separate. Leukocyte infiltration results in the “pustule formation” which resolves by epithelial migration and crusting. Typical cytoplasmic eosinophilic inclusion bodies have been described (Guarnieri's bodies). Histopathologic changes in the mucosa are similar, with added ulceration.

Diagnosis and Differential Diagnosis

Typical smallpox in endemic areas could usually be diagnosed clinically, and ancillary virologic laboratory aids were usually unnecessary. However, now that smallpox has been eradicated worldwide, if a case arose, it would probably be confused with severe chickenpox or not suspected at all. For this reason virologic diagnosis would be essential, with confirmation of variola having global public health implications. Rapid means of laboratory diagnosis include (1) polymerase chain reaction (PCR) detection of antigen in clinical specimens, (2) electron microscopic identification of virus in vesicular fluid or scrapings from the base of a papule or early vesicle, and (3) fluorescent antibody staining of the virus from the same material. All these tests yield rapid, presumptive results in the hands of experienced workers, but definite diagnosis can be achieved only by isolation of the virus in appropriate tissue culture systems and specific identification of the virus by neutralization with variola antiserum. Retrospective diagnosis can be afforded by evaluation of serum antibody rises in a 2- to 3-week interval, using paired sera collected during the acute and convalescent phases of the illness.

In summary, the diagnosis of smallpox is primarily clinical and based upon obtaining an adequate history of exposure, the observation of an approximately 2-week incubation period followed by a severe 3-day prodrome, ultimately terminating in a typical rash with centrifugal distribution and all lesions in the same stage of development. One cannot rely on the presence of Guarnieri's bodies to establish the diagnosis, although they may be suggestive.

In the preeruptive phase of smallpox, distinction must be made from dengue, enterovirus infections, and other febrile illnesses. The prodromal rash may be confused with that of measles. History of contact and the appropriate incubation interval should serve to make one suspect smallpox.

Hemorrhagic smallpox may be confused with meningococcal septicemia, coagulation disorders, typhus, and other acute hemorrhagic exanthems. Eruptive smallpox is most frequently mistaken for chickenpox. The lack of prodromal symptoms, the successive appearance of crops of superficial vesicles, the centripetal distribution, and the varying stages of development of chickenpox lesions all serve to distinguish this disease from variola.

Treatment

This disease has been prevented by Jennerian vaccination, but no effective specific treatment is known. Thiosemicarbazone and antivariola or antivaccinia serum and immune globulin failed in the therapy of established smallpox. Cidofovir has shown promise in early in vitro and animal studies.

Good nursing care with attention to the prevention of secondary bacterial infection is critical in treatment. Appropriate antimicrobial therapy for bacterial complications should be employed, and attention should be paid to the nutritional, fluid, and electrolyte needs of patients.

Course and Prognosis

The overall mortality rate of smallpox approximates 30 percent, with confluent disease representing a greater risk than discrete eruptions. Fulminant smallpox is universally fatal, as are the hemorrhagic forms of the illness.

Bioterrorism with Smallpox

Smallpox has been used as a biologic weapon at least since the time of the French and Indian Wars (1754–1767), when blankets of smallpox victims were distributed to the American Indians. The high case fatality rate, the high frequency of secondary spread, and the absence of routine vaccinations for smallpox since 1972 all contribute to the concern about this agent in bioterrorism. In 1998, 42 percent of the US population, 114 million people, had not been vaccinated. It was possible to vaccinate more than 6 million people in New York City in 1947. The last vaccine in the United States was manufactured in the 1970s and has been stored at the Centers for Disease Control and Prevention and at Aventis laboratories in France. Recent studies have shown (1) potency is maintained; (2) a 1/5 dilution is effective, and (3) a new diluent is needed and is being manufactured. Tissue culture vaccine is currently being manufactured and tested.

COMPLICATIONS OF SMALLPOX VACCINATION (VACCINIA)*

Definition and Classification

Vaccination against smallpox consists of the introduction of vaccinia virus into the outer layers of the intact skin. Local multiplication of virus occurs, and in some instances, regional lymphadenopathy and systemic symptoms ensue. The infection is a localized one that heals by scarring and is limited by host response. A complicated vaccination is one in which any of the above components is altered. Complications may be classified as indicated in Table 219-1.

Major Categories	Specific Syndromes	Comment
Noninfectious rashes	Erythema multiforme	Differentiate from generalized
	Macular—toxic eruption	
	Macular and papular	
	Vesicular	
	Urticarial	
Bacterial superinfection	Streptococcal	Often hyperkeratotic
	Staphylococcal	
	Mixed	
Accidental inoculation (may occur in vaccinated individual)	Normal skin	
	Abnormal skin	
	Burns	
	Pyoderma	
	Exanthem	Examples: varicella, herpes
	Eczema	
	Other dermatides:	
	Mucosal	Usually oral or conjunctival
	Corneal	Vaccinal keratitis
Congenital vaccinia		
Generalized vaccinia	Benign	
Progressive vaccinia (vaccinia gangrenosa, vaccinia necrosum)	In immunologically normal persons	
	In hypogammaglobulinemia:	
	Congenital sex-linked	
	thymic alymphoplasia	
	In dysgammaglobulinemia	
	With malignancies:	
	Chronic lymphatic leukemia	
	Hodgkin's disease	
	Lymphoma	
Encephalitis	Postvaccinal	
Miscellaneous	Hemolytic anemia	Unproven
	Arthritis	
	Osteomyelitis	
	Laboratory infections	
	Pericarditis and myocarditis	

TABLE 219-1 **Classification of Complications of Vaccination**

The vaccinia virus is now being used as a vector to express other genes in mammalian cells, including potential vaccines against other diseases.

Historical Aspects

With the eradication of smallpox in the world, the routine application of infant vaccination has been greatly diminished. As a result, complications of vaccinations are seen infrequently in most countries, and not at all in many countries. However, recent concerns with bioterrorism have brought many of these questions back into the concerns of medical decision makers.

Epidemiology

Most complications could occur at any age, but they were usually seen among young infants and children. Primovaccination was most often administered to this age group, and almost all the significant complications occurred most frequently, if not exclusively, after first vaccination. In addition, the infectious complications tended to occur in the immunologically deficient child, which also contributed to the clustering in early childhood. Bacterial superinfection in some instances was related to warm weather, with the opportunity for maceration of skin and with increased exposure of the vaccination site.

Complications were reported more commonly in the Western world, despite the prevalence of vaccination in the east. This undoubtedly represented reporting differences, not a true geographic or racial relationship. The incidence of postvaccinal encephalitis appeared to be higher in the Netherlands. Whether this represented a true racial difference or simply reflected the fact of primovaccination in the adults was not clear.

Etiology and Pathogenesis

The basic mechanisms of the complications of vaccination can be divided into three categories: (1) bacterial superinfection, (2) abnormal viral replication, and (3) altered reactivity, or “allergy,” to some viral component.

Bacteria can invade the vaccination site; indeed, not all vaccine is bacteriologically sterile. That superinfection is not more common is remarkable. Apparently more than contamination is necessary; those factors of greatest importance are concurrent streptococcal infection elsewhere and excessive trauma, maceration, and manipulation of the vaccination site.

Usually the virus remains localized at the site of implantation, but occasionally infection may be transposed to healthy or unhealthy skin elsewhere on the body, or even to another person. Etiologic factors include excessive manipulation, abnormal skin (burns, atopic dermatitis, etc.), inflammatory lesions (blepharitis, herpes), and abnormal immune mechanisms. Any of these may contribute to spread of the virus away from the intended localized vaccination site.

Among the host factors responsible for limitation of viral spread and recovery from vaccination are development of serum antibody, delayed hypersensitivity, and interferon production. Serum antibody and delayed hypersensitivity are specific and are induced soon after infection; antibody appears to be less important in recovery than delayed hypersensitivity. Interferon is nonspecific and has been found in the skin of animals recovering from vaccinia infection who have been rendered deficient in antibodies and in delayed hypersensitivity. It has also been found in human vaccination crusts. Individuals who lack antibody-synthesizing capacity may develop progressive and widespread vaccinal lesions. However, even these patients, if they retain delayed-hypersensitivity responsiveness, may undergo perfectly normal vaccinations. In addition, patients with normal antibody levels, but with absent delayed-hypersensitivity responsiveness, are susceptible to the progressive form of the disease. As indicated, interferon is also important and may account for recovery of animals in the absence of the other two functions. However, data for human beings are lacking, and the

importance of this mechanism of resistance is not known.

Allergy, or presumed altered reactivity, to viral components appears to be responsible for the erythema multiforme type of skin rash observed in some individuals after primovaccination. This mechanism has also been implicated in the pathogenesis of postvaccinal encephalitis; it is assumed the virus or a virus–central nervous system complex invokes an immune response directed against brain antigens, which then results in an antigen–antibody inflammatory reaction and the clinical picture of encephalitis.

Clinical Manifestations

ERYTHEMA MULTIFORME–LIKE ERUPTIONS An intensely erythematous macular rash may follow smallpox vaccination. This rash has the characteristics of erythema multiforme in that iris or bull's-eye lesions appear and tend to coalesce. The rash is often symmetric and florid, involving a large portion of the body. This is a totally benign manifestation representing an allergic reaction.
BACTERIAL SUPERINFECTION Purulent complications of smallpox vaccination involve principally impetiginous infection with *Staphylococcus aureus* or group A beta-hemolytic streptococci. When poultices were employed, tetanus could be introduced by the soil or dung elements incorporated in such primitive techniques.
ACCIDENTAL INOCULATION Vaccinia virus can be implanted from the site of vaccination onto the skin or mucous membrane anywhere on the individual's body. The virus can also be transferred to another individual. Each of the lesions is characteristic of a primary smallpox vaccination except they do not tend to scar. Certain implantations may be more hazardous than the occasional single-site inoculation. These include implantation onto large areas of abnormal skin (burns or other dermatoses), into the eye (vaccinal keratitis may result), extensive mucosal lesions, and implantation around various body orifices which may impede certain bodily functions (Fig. 219-3). A recombinant vaccine caused severe but limited vaccinial lesions in a pregnant woman who had epidermolytic hyperkeratosis.

FIGURE 219-3 Eczema vaccinatum. Lesions are in areas of active eczema. Note typical vaccinal character of individual lesions.

CONGENITAL VACCINIA Vaccination of the pregnant woman, especially in the third trimester, may result in disseminated disease fatal to the fetus. Congenital vaccinia may also occur. The infant may be stillborn or may develop lesions shortly after birth.
GENERALIZED VACCINIA Generalized vaccinia as used in this classification refers to a benign generalized eruption, each lesion of which is identical to its primary smallpox vaccination. Although little is known of the immunology surrounding such a defect, it is clear that some children with isolated IgM deficiency are liable to this complication. Lesions tend to heal rapidly. Occasionally, there may be recurrent crops of lesions.
PROGRESSIVE VACCINIA (VACCINIA GANGRENOSA, VACCINIA NECROSUM) If a smallpox vaccination shows no evidence of normal resolution within 2 weeks of inoculation, a presumptive diagnosis of progressive vaccinia should be made. In this disease, the normal immunologic response to vaccination is impaired. This may occur in an otherwise normal individual or in persons with generalized defects in immunologic capacities. In its complete form, the site of vaccination fails to heal and continues to enlarge, often for months. Usually, no systemic signs of illness are present and, in the absence of some other disease, physical findings are limited to the vaccination. These lesions differ from normal ones in that little inflammatory response is observed. The vaccination initially has a soft, rubbery appearance with little scabbing (Fig. 219-4). As the lesion progresses in size, considerable central necrosis becomes evident, and thick, dark eschars form (hence the synonym *vaccinia necrosum*). The initial lesion may become huge, with the entire upper arm and shoulder involved. In many cases, secondary lesions are evident; in some cases, satellite vaccinations occur close to the primary one, and, in addition, viremic lesions may appear at distant sites. Each of the secondary lesions progresses in the same fashion as the primary one (Fig. 219-5). Variations are observed in that the primary lesion may become ulcerative or may have a piled-up appearance, but the progression is characteristic.

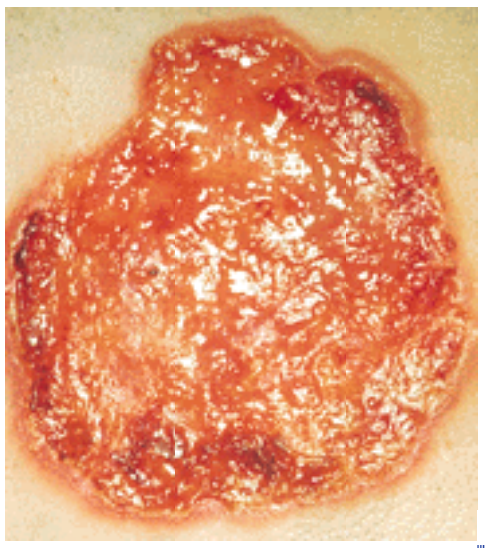

FIGURE 219-4 Progressive vaccinia: large, nonhealing vaccination site with “soft, rubbery” border, high virus content, and lack of surrounding inflammatory response; present 4 months in 10-month-old male with variant of thymic alymphoplasia.

FIGURE 219-5 Secondary viremic lesions in progressive vaccinia. Two lesions on arm, which demonstrate variability, both positive for vaccinia virus, occurred in an elderly female with chronic lymphatic leukemia; complete clearing with thiosemicarbazone therapy.

Untreated disease or illness failing to respond to treatment may be of long duration, during which extensive tissue destruction, secondary bacterial infection and septicemia, mucosal lesions, pneumonia, and other complications may occur. The course is progressively downhill, although the patient may not manifest correspondingly severe constitutional symptoms until relatively late in the disease.
ENCEPHALITIS A meningoencephalitis syndrome occurs rarely as a complication of smallpox vaccination. The sudden onset of headache and vomiting in the second week after vaccination may herald this illness. Convulsions, lethargy, coma, paralysis, signs of cerebral edema, increased intracranial pressure, and focal neurologic findings may occur. In other instances, the disease may resemble aseptic meningitis or myelitis.

Laboratory Findings

VIROLOGIC Specimens from suspected vaccinal lesions can be inoculated into a variety of tissue culture systems. Identification is by typical pock formation or by classic cytopathogenic effect with subsequent neutralization by antisera. Additionally, specific vaccinia antigen can be detected by a variety of methods from specimens obtained from lesions.
IMMUNOLOGIC AND HEMATOLOGIC Response to vaccinia virus may be critical in determining host susceptibility. Vaccinia-neutralizing antibody can be measured, as can a delayed-hypersensitivity reaction. In certain clinical states, total immunologic capacity may need to be surveyed, as the vaccinal infection is simply an indicator of a more comprehensive immunologic defect. Assays for immunoglobulin antibody capacity and for cell-mediated immune function may need to be employed.

Treatment

Complications of vaccination can be reduced by recognizing those predisposing conditions that lead to each of the separate types of complication. Thus, individuals who have eczema or other skin lesions should not be vaccinated or exposed to an individual who is vaccinated. Individuals with immunologic deficiency, receiving immunosuppressive therapy, or suffering from diseases such as lymphatic malignancies that heighten susceptibility should avoid contact with vaccinia virus and should not be vaccinated. If such individuals are exposed, use of either vaccinia immune globulin by injection or methisazone (isatin thiosemicarbazone) reduces the risk.

In the past, administration of vaccinia immune globulin (VIG) for complications of vaccination has been utilized. Some VIG for intramuscular use is stored at the CDC. New lots of VIG, compatible with intravenous or intramuscular administration, are being produced. Children with erythema multiforme or simple autoinoculation disease and vaccinal encephalitis should not receive this preparation as it is of no benefit. On the other hand, those with extensive intradermal involvement such as eczema vaccinatum or burns should be treated with VIG. VIG should be used in conjunction with immunologic therapy in those severe complications such as progressive vaccinia. Early in vitro and animal studies with cidofovir show promise in treating vaccinia infections.

In vaccinia keratis, topical antivirals are the preferred method of treatment. VIG should be avoided because of the potential of increased scarring.

Course and Prognosis

As indicated in the separate sections, prognosis is variable. Most complications are self-limited or respond to simple measures; a few require extraordinary forms of therapy, and even with such treatment a small group remains who are unresponsive.

TREATMENT

REFERENCES

Orf is a self-limited exanthematic dermatitis caused by a viral infection that is typically seen on the hands of people handling infected animals. The word “orf” is derived from the Anglo-Saxon name for cattle. [1] In 1937, George Peterkin reported the occurrence of orf in humans from contagious pustular dermatitis in sheep. [2] References to the disease date back to the 1520s. The clergy knew of orf as Pope Leo X referred to Martin Luther, founder of the reformation, as a “scabby sheep” infecting “the flock.”. [1]

The agent that causes this contagious pustular dermatitis is a worldwide, zoonotic, epitheliotropic, double-stranded DNA poxvirus of the genus parapoxvirus (PPV). Parapoxvirus ovis (PPOV) causes orf, which is also referred to as ecthyma contagiosum, scabby mouth, sore mouth, contagious pustular dermatitis, or infectious pustular dermatitis. In animals, it is typically located around the commissures of the lips and nostrils of infected sheep and goats, [3] and on the teats of ewes suckling young. [4] The cutaneous and pathologic features of human and ovine orf virus lesions are similar, and in both hosts, infection is confined to the epidermis, with no evidence of systemic spread. [5] Primary lesions generally resolve in 6 weeks. [6]

EPIDEMIOLOGY AND ETIOLOGY

Orf is prevalent worldwide wherever sheep and goats are raised; consequently, it is not uncommon in farming communities. Age and race are not factors for human infection. The disease is most common in kids and lambs 3 to 6 months of age and is seen during the spring, when newborn lambs that lack immunity fall prey to the disease. [7], [8] Infection of older susceptible animals has proven that orf virus can be carried by adult animals either in subclinical lesions or as true persistent infections, which can be exacerbated by the stress of handling and transportation. [9] Susceptible lambs become infected from contact with virus-containing objects such as saliva, lesions and crusts of afflicted animals or fomites (i.e., barn doors, wire fencing, feeding troughs, shears, and bottles). [8], [10] Notably, the virus remains infective on fomites for years at room temperature. It is able to survive heating and drying and is resistant to lipid solvents such as ether and chloroform. [11] The disease is associated with a high morbidity but low mortality rate. Orf is also found in goats, camels, bighorn sheep, reindeer, mountain goats, gazelles, wild sheep, and rams. [9], [12] Transmission to humans occurs via a bite or contact with virus-containing objects into traumatized skin; overt clinical signs of orf virus infection are not a requirement for the spread of virus to man. [9] It can also be transmitted by accidental inoculation with orf vaccines and from infected carcasses. [13] As a zoonosis, orf is a recognized occupational hazard for abattoir workers, farmers, veterinary surgeons and farmers who bottle-feed sheep. [6], [9], [13] Only three cases of human-to-human spread have been reported worldwide. [14]

The true incidence of human orf is unknown. The farming community is so familiar with the disease that it tends not to seek medical attention. This may be a result of the spontaneous healing of the lesion, a lack of effective treatment, or that most attacks occur during the spring, which is the busiest time of the farming year. [13], [15]

Live unattenuated virus from scab material and attenuated orf virus strains have been used for vaccination. In one study, scarification of sheep with the D1701 attenuated orf virus strain caused only mild skin lesions while it induced immunity against orf virus infection that lasted 4 to 6 months. [16] This vaccination is successful in reducing the severity of disease but the lesions induced add to the environmental load of disease-causing virus. [17] It is unlikely that any orf vaccine will be able to stimulate full immunity to reinfection, as wild-type strains of orf virus contain virulence genes [6] (discussed below). In prevention of human infection it may be more prudent to focus on usage of personal protective equipment, such as protective gloves when feeding sheep, and isolating infected animals.

IMMUNE AND INFLAMMATORY RESPONSE

In sheep, primary lesions of orf can be severe and proliferative, taking 4 to 6 weeks to resolve. Reinfection lesions, seen in annual outbreaks of infected flocks, are less severe and resolve faster, usually within 2 weeks. This indicates that viral replication, and therefore lesion development, is influenced by the host immune response. The immune and inflammatory response to orf virus infection has been experimentally studied in sheep. The cell phenotype and cytokine response in ovine local lymph is vigorous and typical of an antiviral response, involving CD4+ helper and CD8+ cytotoxic T cells, interferons, and antibodies. [6] There is evidence in the literature that the immune response to orf virus infection in humans is similar to that reported in sheep. [18] An unusual feature is the accumulation of major histocompatibility complex (MHC) class II dendritic cells in the skin lesions of sheep. [19] Histologically, human orf lesions are similar to those in sheep,

involving epidermal proliferation with areas of swelling, vacuolation, and angiogenesis. A study has not been performed to determine whether dendritic cells accumulate adjacent to the infected cells in humans as they do in sheep. [19] Host-acquired immunity involving CD4+ T cells and antibody is effective in controlling the extent of viral replication in the skin of infected sheep, but it does not prevent reinfection. [3] The CD45R–T cell subset is the principal cellular source of lymphokines [interleukin (IL)-2, interferon (IFN)-?, and granulocyte-macrophage colony-stimulating factor (GM-CSF)] during reinfection in sheep. [20] In humans, however, despite evidence to the contrary from surveys and experimental inoculation, immunity to orf has been reported to be life-long after a single infection. [15], [18]

A number of immunogenic proteins have been visualized in convalescent sera from infected sheep. [21] Murine monoclonal antibodies recognize the identified structural proteins that include the 39- and 42-kDa envelope proteins, and the 10-kDa putative fusion protein. Uncharacterized 22- and 65-kDa antigens have also been described. These proteins can be used to discriminate between the different parapoxviruses. [21], [22] In spite of a high titer of antibody in the sera of orf virus infected sheep, passive transfer of antibody in colostrum or serum of orf-naÏve lambs does not confer protection to infection. [8]

Viral virulence proteins that aid in evading host immunity include homologues of the gene encoding the cytokine IL-10, the mammalian vascular endothelial growth factor (VEGF) gene, granulocyte-macrophage colony-stimulating factor inhibitor, and the orf virus interferon resistance gene.

MOLECULAR ANATOMY OF ORF VIRUS

Members of the genus Parapoxvirus of the family Poxviridae are grouped into PPV bovis 1 [bovine pustular stomatitis (BPS)], PPV bovis 2 [milker's nodule (MN) or pseudo-cowpox virus] and PPV ovis [orf virus (OV)]. More recently, PPV of red deer in New Zealand has been suggested as a fourth species of the genus. [23], [24] OV is the prototype species of the genetically heterogeneous parapoxvirus genus. [16] PPV can be distinguished from other poxviruses by its distinct virion shape; it is an ovoid particle about 250 nm × 160 nm. [11] The surface tubules of parapoxvirus appear as a twinelike structure, 10 to 20 nm wide, forming a long crisscross design that extends for up to 1 µm in length. [11] Electron microscopic demonstration of orf virus in the scabs effectively confirms the presence of disease [25] and helps to distinguish them from orthopoxviruses. [11] Monoclonal antibodies that recognized the 40- to 43-kDa protein of orf virus were found to react against 45- to 48-kDa proteins present in pseudo-cowpox virus and bovine popular stomatitis virus, two other parapoxviruses. [21]

VIRULENCE PROTEINS

An orf virus virulence protein with immunomodulatory function is the orf virus homologue of the ovine gene encoding the cytokine IL-10 that is suggested to have been captured from its host sheep during the evolution of orf virus. [26] IL-10 is a cytokine that exhibits immunosuppressive activity by inhibiting proinflammatory cytokines [IL-1ß, IL-6, tumor necrosis factor (TNF)-a] and chemokine (IL-8) synthesis in macrophages. These cytokines are responsible for the stimulation, recruitment, and activation of neutrophils, monocytes and lymphocytes at the site of inflammation. [27] IL-10 also inhibits antigen-specific T cell proliferation by downregulating MHC class II molecules on antigen-presenting cells. [27]

A homologue of the mammalian VEGF gene was the first of the orf virus virulence genes to be described. [28] Construction of a recombinant orf virus in which viral VEGF was inactivated proved that viral VEGF is responsible for mitogenesis of vascular endothelial cells, induction of vascular permeability, and activations of VEGF receptor 2. [5] Absence of viral VEGF did not affect virus growth in tissue culture, but resulted in substantially reduced clinical indications of infection in the lesions. However, viral replication in the early stage of infection was not impaired. [5] Data supporting VEGF-like factor promoting angiogenesis also support the view that the VEGF receptor VEGFR-2 is predominantly responsible for the signaling of vascular endothelial cell mitogenesis as well as for the induction of dermal vascularization and epidermal hyperplasia. [5]

A soluble protein inhibitor of ovine granulocyte-macrophage colony-stimulating factor (ovGM-CSF) and ovine interleukin-2 (ovIL-2) are also effective in evading host immunity. IL-2 and IFN-? are implicated in protective immunity to orf virus reinfection. [3] IL-2 is also known to be a T cell growth factor produced by T cells that can activate cytotoxic T cells and natural killer (NK) cells. [27] The role of GM-CSF in orf virus infection is less clear; it is known that GM-CSF stimulates hematopoietic progenitor cells to develop into neutrophils, macrophages, eosinophils, and basophils. In nonhematopoietic tissues, GM-CSF recruits these cells to sites of inflammation and activates them. [6] GM-CSF also regulates antigen presentation by dendritic cells. [29]

The presence of an orf virus interferon resistance gene (OVIFNR) may protect the virus from the antiviral effect of IFNs for long enough to allow at least some viral replication, which suggests the importance of interferons in host resistance to orf virus infection.

CLINICAL MANIFESTATIONS

The cutaneous lesions of orf are usually 2 to 3 cm in diameter and present after an incubation period of 5 to 6 days. [13] Characteristically, lesions evolve through six stages lasting approximately 6 days each. The sequential stages include the clinical progression of a slightly elevated, erythematous papule into a target lesion that presents as a nodule with a white middle ring containing a red center and periphery (Fig. 220-1). The acute weeping stage describes the rapidly growing, elevated phase (Fig. 220-2). The regenerative, dry stage is accompanied by the appearance of black dots over the surface of the nodule. Small papillomas develop over the nodule during this papillomatous stage. During the regressive stage the formation of a dry crust and scab develop with resolution and no resultant scar formation (Table

220-1).

FIGURE 220-1 The target phase shows a white circle with central and peripheral erythema.

FIGURE 220-2 In the acute phase, there is weeping of the surface overlying an elevated tumor.

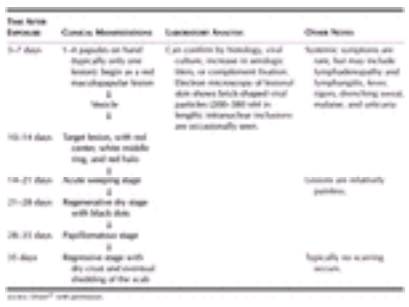

TABLE 220-1 **Clinical Manifestation of Orf**

Accompanying signs that can occur include localized swelling, secondary bacterial infection, lymphangitis, regional lymphadenopathy, and short-lived fever. Other reported complications include 22 cases of secondary erythema multiforme [30] and vesicular eruptions, [31] secondary spread of infection to face and hands associated with active atopic dermatitis, [31] and 5 reported cases of bullous pemphigoid occurring approximately 3 weeks after the lesion. [32]

PATHOLOGY

The first stage, or papular stage, of orf virus infection begins with erythema shortly after infection and coincides with the accumulation of dermal fluid. [5] In the target stage, intranuclear and intracytoplasmic inclusions are present in superficial, vacuolated epidermal cells in areas corresponding to the white ring (Fig. 220-3). There is an accumulation of neutrophils, basophils, dendritic dells, and lymphocytes, including both B and T cells. [33] The acute weeping stage is distinguished by loss of epidermis over the central part of the lesion. Peripherally, there is reticular degeneration and microvesicles are present. There is distention and loss of the epidermal cells of hair follicles followed by regeneration of the epidermis. The black dots observed clinically correspond to an accumulation of cellular breakdown products within the follicles. Many papillary elevations and finger-like downward projections of the epidermis are seen in the papillomatous stage (Fig. 220-4). In the regressive stage, the papillomas are reduced in size, and histiocytes, macrophages, lymphocytes, and plasma cells decrease in number. [10], [11]

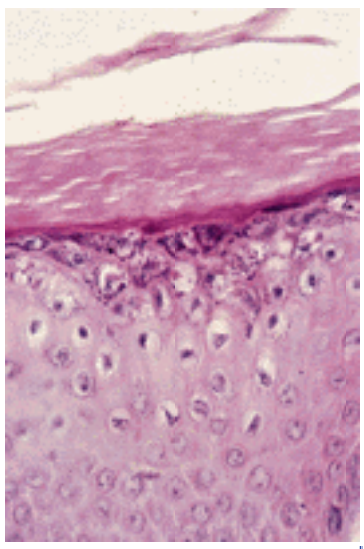

FIGURE 220-3 In the target phase there are superficial vaculated epidermal cells with inclusion bodies.

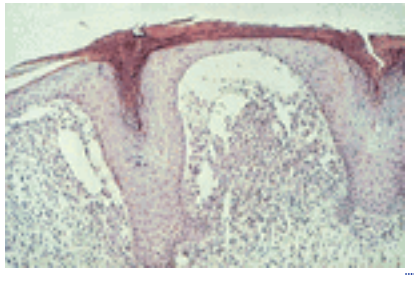

FIGURE 220-4 Later in the target stage there are finger-like projections of the epidermis and a dense inflammatory infiltrate accompanied by massive edema in the papillary body.

The papillomatosis, acanthosis, and the dermal infiltrate are responsible for the size of the growing lesion. These manifestations are consistent with the finding that the VEGF homologue is encoded as an early gene product and is responsible for promoting angiogenesis, and that the receptor VEGFR-2 is predominantly responsible for the signaling of vascular endothelial cell mitogenesis, as well as the induction of both dermal vascularization and epidermal hyperplasia. [5]

Regional lymph node studies in sheep have shown that in the afferent lymph draining infected skin, polymorphonuclear cells, dendritic cells, and lymphocytes and lymphoblasts that are predominantly CD4+ T cells, rather than CD8 T cells or B cells, [20], [34] accumulate. There is also an increase in the production of IFN-a, IFN-?, GM-CSF, IL-1ß, IL-2, and IL-8. [6], [19]

DIAGNOSIS

The self-limited course of the usually solitary lesion can be diagnosed by a careful history and follow-up. A typical evolving skin lesion in a person with a history of contact with sheep or goats is usually sufficient for diagnosis. Orf infection can resemble a pyogenic granuloma, erythema multiforme, cutaneous anthrax, basal or squamous cell carcinomas, or malignant melanoma (Table 220-2). Facial orf lesions particularly may mimic skin tumors. A biopsy can be done if the diagnosis is in question. Laboratory diagnosis can also be made by passage of the virus to cultured sheep cells, fluorescent antibody tests, and electron microscopy, [11] but these are rarely required.

Milker's nodules:	Clinically identical; source of infection is cattle.
Cowpox:	Early lesions of cowpox are similar.
Anthrax:	More hemorrhagic and lesions progresses more rapidly to an eschar.
Tularemia:	Typically, tularemia has systemic symptoms, with high fever, headache, malaise, and myalgias. The skin ulcer is more chancre-like.
Tuberculosis (Primary inoculated):	Most lesions occur in children. A painless shallow ulcer develops and heals poorly.
Mycobacteria infection (atypical):	Lesions often last 1 to 2 years before healing.
Syphilitic chancre:	Lesions typically occur on the genitalia rather than the hand.
Sporotrichosis:	Begins as a single necrotic nodule, but multiple nodules arise in a linear fashion along the lymphatics.
Pyogenic granuloma:	Juicy, red papule that bleeds easily often with an epidermal collarette at the base.
Keratoacanthoma:	Appears as a dome-shaped papule or plaque with a central crater filled with keratin.
Giant molluscum contagiosum:	Lesions do not weep or became necrotic and often appear in clusters.

TABLE 220-2 **Differential Diagnosis of Orf**

TREATMENT

There is no effective treatment for orf. Management is focused on waiting for spontaneous resolution, which typically occurs within 6 weeks with no scarring. Compresses, culture and sensitivity testing, and antibiotics are appropriate measures if secondary bacterial infection occurs. Care must be taken to avoid overtreatment in the form of parenteral antibiotics, primary excision, and cautery, or even repair with a skin graft or flap. The prognosis is excellent.

Molluscum Contagiosum

EPIDEMIOLOGY
ETIOLOGY AND PATHOGENESIS
CLINICAL MANIFESTATIONS
PATHOLOGY
DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS
TREATMENT

REFERENCES

Molluscum contagiosum is a common, benign, viral infection of the skin and mucous membranes that generally affects children. In adults, the condition may be transmitted sexually. The fully developed lesion is an umbilicated papule, and most patients have multiple lesions. Molluscum can be extensive in patients with AIDS or other disorders associated with immunologic dysfunction.

EPIDEMIOLOGY

Infections with the molluscum contagiosum virus (MCV) occur throughout the world, but their frequency varies considerably. The disease commonly affects children, sexually active adults, and immunocompromised individuals. On some Pacific islands, 5 percent of children under 10 years of age may be affected. The prevalence in the United States is much lower. Although the infection may develop at any age, the fact that the majority of cases are found in children suggests that adults are resistant to infection.

MCV is transmitted by person-to-person spread and possibly by fomites, as poxviruses are resistant to desiccation. Outbreaks have been reported among children attending swimming pools, and genital lesions in adults are probably transmitted sexually. [1] The incidence of subclinical infection is unknown. The role of humoral immunity is unclear, although many patients possess IgG antibodies against viral antigens. [2], [3] Individuals with impaired cellular immune function may have widespread lesions. Patients with AIDS are at particular risk of MCV infection, with prevalence rates of 5 to 18 percent; [4], [5] the frequency and severity of infection vary inversely with the CD4+ count. Lesions in AIDS patients are often refractory to treatment.

ETIOLOGY AND PATHOGENESIS

MCV is a poxvirus that is distinct morphologically, serologically, and pathologically from other poxviruses. [6], [7] It is a large 200 by 300 nm DNA virus that replicates in the cytoplasm of infected cells and induces hyperplasia, as do other poxviruses. The complete sequence of the MCV DNA genome has been determined. [8] About two-thirds of the viral genes are similar to those of the orthopoxviruses, such as vaccinia virus and variola virus, while about one-third appear to be novel immune defense molecules. [8], [9]

Unlike most other poxviruses, MCV has not been reproducibly propagated in tissue culture. There has been some experimental success in reproducing the lesions and inducing MCV replication using cell-free lesional extracts to infect human foreskin grafts in nude mice. [10], [11] However, serial transmission has not yet been achieved. Experimental transmission to humans with an incubation period of 2 to 7 weeks has been observed. Attempts to transmit the disease to other species have been unsuccessful. Three different MCV strains (I, II, and III) have been identified based on restriction endonuclease digestion patterns. MCVI is more prevalent than MCVII, with MCVIII being extremely uncommon. [12], [13] No clinical differences have been evident among the strains.

Viral growth is confined to the epidermis; virus particles are synthesized in cytoplasmic foci of cells in the malpighian and granular layers. The rate of cell division in the basal layer of lesional skin is twice that of normal skin. It remains unclear how the MCV infection causes this hyperproliferation. The higher rate may be due to the inhibition of the normal keratinocyte apoptotic differentiation program by specific MCV encoded proteins. [14], [15] and [16]

The novel genes of the MCV genome that may interfere with immune recognition and host defense mechanisms include (1) a major histocompatibility complex class I heavy chain homologue that may inhibit presentation of MCV-specific peptides, (2) a chemokine homologue that may inhibit inflammation, and (3) a glutathione peroxidase homologue that may protect the virus and infected cells from oxidative damage by peroxides, which may form in response to infection. [8], [9], [11] These features of the virus may explain the paucity of inflammatory and immune response seen even in lesions of immunocompetent patients. They may also account, at least in part, for the difficulties encountered in treating infection in immunocompromised individuals.

CLINICAL MANIFESTATIONS

Lesions begin as minute papules that usually enlarge to 3 to 6 mm and, rarely, may become as large as 3 cm in diameter. The individual lesions are discrete, smooth, pearly to flesh-colored, dome-shaped papules, often with central umbilication in which lies a white, curdlike core, which may be easily expressed. Lesions may appear on any area of the skin or mucous membranes. They are often grouped in one or two areas (Fig. 221-1), but may be widely disseminated. Most

patients have fewer than 20 lesions, although some may have several hundred. In temperate climates, the virus involves the head, eyelids, trunk, and genitalia most often. In the tropics, lesions occur most commonly on the extremities. Lesions in adults frequently appear on the genitalia (Fig. 221-2). Lesions may resolve spontaneously with or without inflammation.

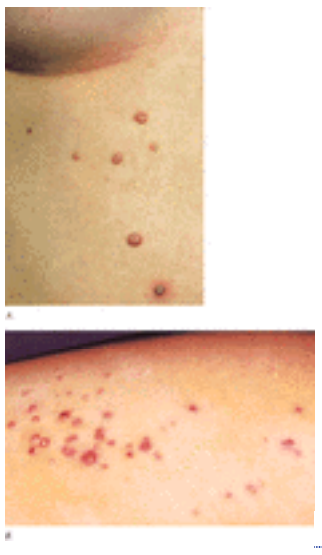

FIGURE 221-1 Molluscum contagiosum. *A*. Discrete, solid, skin-colored papules, 1 to 2 mm in diameter with central umbilication. *B*. Multiple, scattered, and discrete lesions, some of which are inflamed.

FIGURE 221-2 Molluscum contagiosum. Multiple umbilicated papules are seen on the abdomen, thigh, and penis of this 33-year-old HIV-infected male.

Immunocompetent cells are absent from the infected epidermis, even when they are present in the underlying dermis. [17] In adults with AIDS, molluscum often occur exclusively at extragenital sites, although they may be confined to the genitalia. In AIDS patients, lesions may attain a very large size and mimic cutaneous tumors. Although the lesions are usually asymptomatic, pruritus may be present, and an eczematous reaction may develop around some lesions. Conjunctivitis and keratitis may complicate lesions around the eyelid. Patients with atopic dermatitis or other conditions with impaired immune function may develop widespread lesions, and secondary bacterial infection also occurs.

PATHOLOGY

The histologic appearance of the hypertrophied and hyperplastic epidermis is characteristic (Fig. 221-3). [18] Above the normal-appearing basal layer are lobules of enlarged epidermal cells that contain multiple Feulgen-positive intracytoplasmic inclusion bodies (molluscum bodies or Henderson-Paterson bodies). These inclusion bodies, which contain the viral particles, increase in size as the infected cell moves toward the surface. In the horny layer, the molluscum bodies are enmeshed in a fibrous network that dissolves in the center of the lesions, forming the central core, which is composed primarily of molluscum bodies.

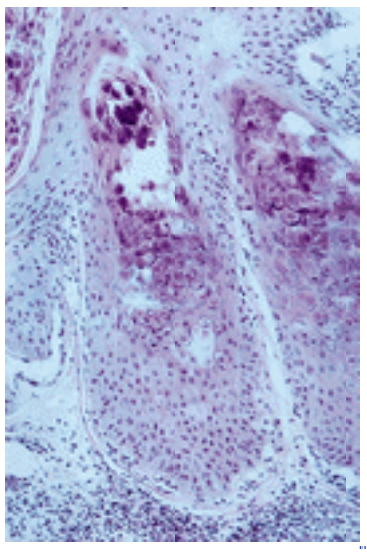

FIGURE 221-3 Molluscum contagiosum. Downgrowth of infected epidermal cells bearing large eosinophilic cytoplasmic inclusion bodies.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The distinctive clinical appearance of the lesions, stained smears of the expressed core, and biopsy usually lead to the diagnosis. It is necessary to differentiate molluscum contagiosum from warts, varicella, pyoderma, papillomas, epitheliomas, basal cell carcinoma, and lichen planus. In the immunity-impaired host, bacterial and fungal infections should be considered.

TREATMENT

Because the condition is usually self-limited and lesions heal without scarring in the absence of a secondary bacterial infection, treatment is not always mandatory. Individual lesions may last 2 to 4 months, but the development of new lesions by autoinoculation is common. Most cases resolve spontaneously in 6 to 9 months, but some may persist for years, especially in immunosuppressed individuals.

Removal of lesions with a sharp curette or cryotherapy with liquid nitrogen are simple, relatively painless, and effective treatments. More than one treatment session may be necessary, however, either because of recurrence or because of the development of new lesions. Other destructive or inflammatory agents, such as potassium hydroxide [19] and silver nitrate, [20] have been used to treat molluscum lesions. A double-blinded study showed self-administered topical podophyllotoxin cream to be superior to placebo. [21] Historically, canthardin and tretinoin have been used. More recently, topical imiquimod [22], [23], [24], [25] and [26] and cidofir [27], [28] have been reported to be effective in uncontrolled studies. A small clinical trial found topical acidified nitrate led to the resolution of molluscum in children. [29] Treatment with oral cimetidine is controversial, as a controlled regimen has not been reported. [30], [31] and [32]

Cure may be especially difficult in patients with impaired immune function. In HIV-infected patients, treatment of the underlying HIV infection may promote the recovery of immune function and amelioration of the molluscum lesions. [33] Anectodotal studies suggest the topical use of imiquimod and cidofir may be effective for recalcitrant molluscum in HIV-1 immunocompromised patients.

Chapter 222

Douglas Lowy

Milker's Nodules

ETIOLOGY
EPIDEMIOLOGY
CLINICAL MANIFESTATIONS
PATHOLOGY
DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS
COURSE, PROGNOSIS, TREATMENT, AND PREVENTION

REFERENCES

Milker's nodule is a benign viral skin disease which generally consists of one or a few nodules on the hand or forearm. The virus is usually transmitted to cattle handlers from infected cows.

ETIOLOGY

The etiologic agent is called pseudocowpox virus (PCPV), paravaccinia virus, or milker's node virus. It is a poxvirus from the parapoxvirus subgroup, which also includes orf virus and bovine papular stomatitis virus. [1] PCPV is endemic in cattle. Lesions in cows, which may be chronic and recurrent, appear mainly on the teats, although other areas may be affected. In cows, the condition is called *pseudocowpox.* There is no cross-immunity with the cowpox, vaccinia, or variola orthopox group of poxviruses. Bovine papular stomatitis virus infection of cattle is characterized by lesions around the mouth; [2] it induces lesions in humans that are identical to milker's nodules, and some investigators believe that the two viruses may be identical. [3]

PCPV can be propagated in bovine or human cells in tissue culture. [4], [5] It resembles the virus of orf (ecthyma contagiosum) morphologically and serologically, [6], [7] and [8] but the two viruses can be distinguished by viral DNA hybridization or polymerase chain reaction. [9] As is true of other poxviruses, paravaccinia is a large (150 × 300 nm) brick-shaped DNA virus that contains many enzymes and replicates in foci in the cytoplasm of infected cells. [10] Infection often induces a mild degree of hyperplasia and increased dermal vascularity. The disease has been transmitted experimentally from human to human and from human to cow. [11]

EPIDEMIOLOGY

Milker's nodule has a worldwide distribution, occurring where cattle are found. Most cases are sporadic, but small epidemics have been reported. Because the disease is usually transmitted to humans by direct contact with infected cattle, milkers are most at risk. Cases also occur among stockyard and slaughterhouse workers. Most cases arise in individuals who recently became milkers, and infection in humans usually induces lasting immunity. Indirect transmission from virus-contaminated material to patients with burned skin has been reported. [12] The incidence of subclinical infection is not known. Although infectious virus is found in human lesions, person-to-person transmission under natural conditions has not been documented.

CLINICAL MANIFESTATIONS

The typical case consists of a single asymptomatic or slightly painful 1 cm erythematous nodule on a finger (Fig. 222-1). [13], [14] There are usually no more than four lesions, and they are generally confined to the hand and forearm. Rarely, other areas of the skin may be involved, or numerous lesions may be present. Lymphadenopathy is uncommon.

FIGURE 222-1 Milker's nodule. *A*. Firm, purple, eroded nodule occurred following milking a cow. *B*. Multiple, purple papules and nodules occurred in a second-degree scalding burn sustained in a milking barn.

The incubation period is usually 4 to 7 days, but may be as long as 2 weeks. In the absence of secondary bacterial infection, each lesion usually heals spontaneously in 4 to 6 weeks without scar formation. Leavell and Phillips [14] have described six clinical stages, each lasting about a week. Initially, the lesion begins as an erythematous macule, which soon becomes papular. The target stage is next: the lesion, which is papulovesicular, has a red center, surrounded by a white ring and a red halo. This stage is followed by a period of weeping and erosion. The lesion then becomes a firm, crusted nodule. Next, small papillomatous elevations develop on the nodule. Finally, during the regressive stage, the lesion darkens and sloughs.

PATHOLOGY

Pathologic changes are present in both epidermis and dermis; the precise histologic appearance depends on the clinical stage. [14], [15] The manifestations are similar to those of orf. Epidermal changes include hyperkeratosis, parakeratosis, acanthosis, and striking elongation of the rete ridges. These alterations increase progressively as the lesion develops. In early lesions, the upper portion of the malpighian layer may contain balloon cells and cells with many intracytoplasmic and some intranuclear inclusions. Later, reticular degeneration, multilocular vesicles, spongiosis, and intracellular edema may be the prominent findings. The dermis contains a marked increase in the number of capillaries and a nonspecific inflammatory infiltrate that is most intense during the acute weeping stage. Electron micrographic examination of the superficial portion of a lesion usually reveals the characteristic cytoplasmic viral particles. The hypervascularity in the dermis may be secondary to the production and secretion of a virally encoded homologue of vascular endothelial growth factor (VEGF), a potent stimulator of vascular proliferation. A VEGF homologue in the orf virus contributes to its pathogenicity in sheep, [16] and the close similarity between orf virus and PCPV makes it likely that PCPV also contains an analogous gene.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis is generally based on the history, clinical appearance, and biopsy. It can be established more definitively by the electron microscopic demonstration of viral particles, by propagation of the virus in tissue culture, or by polymerase chain reaction. Orf and bovine papular stomatitis are usually excluded by history.

Milker's nodule must also be differentiated from a large number of other conditions, including true cowpox, herpetic whitlow, pyoderma, anthrax, tularemia, primary inoculation tuberculosis, atypical mycobacterial infection, syphilitic chancre, sporotrichosis, and pyogenic granuloma.

COURSE, PROGNOSIS, TREATMENT, AND PREVENTION

Because the disease is self-limited, only symptomatic therapy is generally indicated. Parapoxviruses are inhibited by cidofovir, and the nonregressing orf lesion in an immunocompromised patient responded to topical treatment. [17] Prevention is limited to the isolation of infected animals.

Warts, or verrucae, are benign proliferations of the skin and mucosa that result from infection with papillomaviruses. These viruses do not produce acute signs or symptoms, but induce slow-growing lesions that can remain subclinical for long periods of time. A subset of human papillomaviruses (HPVs) has been associated with the development of epithelial malignancies.

HISTORICAL ASPECTS

Cutaneous warts were known to the ancient Greeks and Romans, and until the nineteenth century genital warts were believed to be a form of syphilis or gonorrhea. The viral etiology of warts was implied from the observation that inoculation of wart filtrates from which cellular and bacterial products were removed could induce papillomas at the site of injection. All warts were considered to be derived from a single virus, because isolates from cutaneous, genital, or laryngeal warts could induce papillomas at other sites. However, advances in recombinant DNA technology have now identified more than 100 different HPV genotypes. [1]

ETIOLOGIC AGENT

The papillomaviruses comprise a large family of double-stranded DNA viruses found in humans and many other species. [2] They are distantly related to the polyomaviruses, which include simian virus 40, polyomavirus, BK virus, and JC virus. All papillomaviruses are highly host-specific, which means that those from one species do not induce papillomas in heterologous species. HPVs infect only humans. Rabbits, cows, and dogs are the natural host for some papillomaviruses, but for unknown reasons these viruses are not found in common strains of mice. These limitations place significant restrictions on investigating the mechanism and biologic consequences of papillomavirus infection in a laboratory animal model. Although it is now possible to cultivate HPVs in normal epithelial cell culture (see below), the process results in only minute amounts of virus, and in vitro culture of HPV is not a simple, routine test in any laboratory.

Recombinant DNA technology has enabled the molecular cloning of the complete viral DNA or genome from clinical lesions. The entire nucleotide sequence for the genomes of many human and animal papillomaviruses is now known. Comparison of these papillomavirus DNAs reveals that they share a similar genetic organization (Fig. 223-1) and are predicted to encode related protein products. [3] The papillomavirus genome is present within the viral particle as a single, supercoiled, covalently closed circle of double-stranded DNA. Each genome is composed of approximately 8000 nucleotide base pairs, which is approximately one-twentieth the size of a herpesvirus genome. The papillomavirus genome encodes only eight to nine proteins, which are historically separated into two groups, E (early) and L (late). The E proteins, most of which participate in viral DNA replication, are expressed before the L proteins and are not incorporated into the infectious virus particle. Because the E genes do not encode a DNA polymerase or thymidine kinase, papillomaviruses are not susceptible to inhibition by acyclovir. The L1 and L2 genes encode the structural proteins that form the outer protein shell, called the capsid of the viral particle, which is called the virion. The spherical virion measures 55 nm in diameter and surrounds the viral DNA.

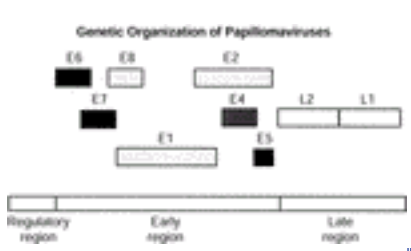

FIGURE 223-1 All papillomavirus genomes are composed of approximately 8000 nucleotide base pairs, represented as a linear sequence but actually a closed circle of double-stranded DNA. The boxes depict the viral genes, each of which encodes a protein. The regulatory region is a DNA segment that does not encode proteins, but participates in the expression of the viral genes and the replication of the viral DNA. In general, E6, E7, and E5 represent transforming genes; E1 and E2 coordinate replication and expression of the viral genome; and the L1 and L2 proteins form the viral capsid. E4 encodes a protein that may be involved in the release of the virus from the cell's keratin framework.

Until recently, clinical lesions have been the only source of infectious papillomavirus particles, except for a limited number of papillomaviruses that have successfully propagated in human keratinocytes grown under the renal capsule of athymic nude mice. [4] The use of the so-called raft culture system, which forms a stratified squamous epithelium, has now produced limited amounts of infectious HPV. [5] In standard tissue culture cells, the application of genetic engineering technology has led to the production of infectious bovine papillomavirus. [6] These and related advances make it likely that the number of infectious HPV types produced in the laboratory, as well as the amount of virus, will increase considerably in the near future.

HUMAN PAPILLOMAVIRUS TYPES

Although more than 80 HPV types have been completely or partially sequenced, [1] the actual number of types may range between 100 and 150. Currently, the relatedness of their DNA sequence distinguishes between HPV types. Until recently, molecular hybridization techniques were used to determine the HPV type of a particular isolate. The ease with which the polymerase chain reaction (PCR), which has both high sensitivity and specificity, can be used to amplify and sequence any viral DNA isolate has now led to HPV types being defined by DNA sequence homology. Fresh tissue is not required, and PCR has been successfully applied to detect and type HPV DNA in paraffin-embedded tissue blocks that are decades old. [7] Two HPV isolates are assumed to be of the same type if the sequences of their L1 genes are at least 90 percent identical. [1] It is likely a new HPV type if, after the viral genome has been molecularly cloned and its L1 gene sequenced, the sequence is less than 90 percent homologous to the closest known HPV type. Using this approach, it has also been possible to study the evolutionary relationships between different HPV genotypes even within the same HPV type. [8]

Often associated with distinct regional predilection, histopathology, and biology, HPV types are separated into three categories: cutaneous (nongenital) types such as HPV-1, -2, -3, and -4; genital-mucosal types such as HPV-6, -11, -16, and -18; and those usually isolated from epidermodysplasia verruciformis (EV) such as HPV-5 and -8 (Table 223-1). A hypothetical evolutionary tree depicting the relationship among the HPV genotypes shows that those closely related by DNA sequence tend to induce similar lesions. [8] Examples include highly related types such as 3 and 10, which induce flat warts; types 6 and 11, which induce genital-mucosal warts (condylomata acuminata); and types 5 and 8, which induce scaly lesions in EV.

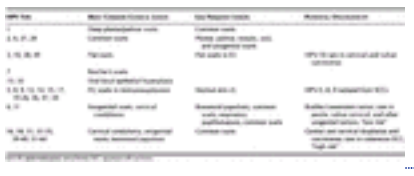

TABLE 223-1 **Clinical Associations of Human Papillomavirus (HPV) Types**

Another important distinction is that some HPV genotypes appear to have malignant potential. This was first noted in association with EV. [9] For example, almost all cutaneous squamous cell carcinomas that arise in EV warts contain specific HPV types such as 5 and 8, while benign lesions, even in the same patient, may harbor many other HPV types. Similarly, the majority of cervical carcinomas contain HPV-16, -18, or other so-called high-risk types, while the low-risk HPV-6 and -11, which are found in benign cervical disease, are rarely identified in cervical malignancies. [10]

Many other viruses are typed by the ability of antisera to distinguish their capsid antigens, and antisera made by immunization with intact papillomavirus virions can generate type-specific antibodies. [11] However, serologic typing requires the generation of antisera specific to each HPV type, which is more cumbersome and less sensitive than DNA sequence analysis and may be subject to greater interlaboratory variation. The study of HPV serotyping has been less extensive, because until recently, it was usually necessary to obtain virus from lesions. It has now been determined that the expression of L1 protein molecules of any papillomavirus in cultured cells leads to their self-assembly into virus-like particles (Fig. 223-2) that exhibit the same type-specific epitopes as the authentic virus. [8] Serologic analyses using antisera obtained by immunization with L1 virus-like particles have shown an excellent correlation between the serologic results and DNA typing, with little serologic cross-reactivity between different HPV types and considerable cross-reactivity among isolates of the same HPV type. [12]

FIGURE 223-2 Transmission electron micrograph of HPV-16 virus-like particles composed of the viral L1 and L2 capsid proteins. The L1 and L2 proteins have been expressed in cultured cells, and have self-assembled into 55-nm particles that are similar morphologically to infectious virus, except that they do not contain the viral DNA. The particles in the electron micrograph have been purified from the cells. (*Micrograph courtesy of Heather Greenstone.*)

Detergent-disrupted papillomavirus particles expose common structural antigens shared by all papillomaviruses, but not by other viruses. [11] Antibodies to such shared antigens can be used to detect structural capsid proteins in clinical materials, including formalin-fixed tissue (Fig. 223-3). However, antibodies to structural viral proteins cannot be used to confirm the presence of HPV in cells that do not synthesize large numbers of virions as in genital warts, bowenoid papulosis, dysplasias, and HPV-associated malignancies.

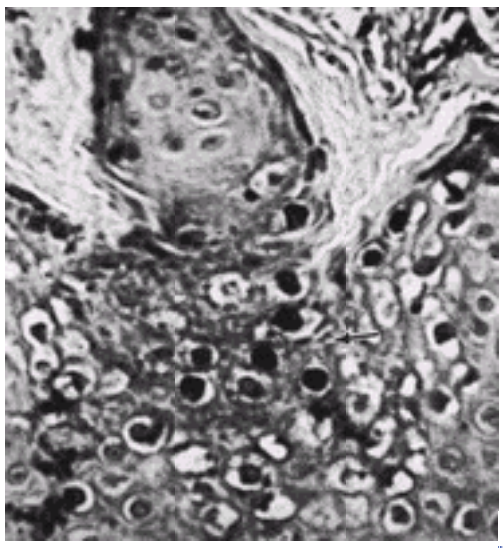

FIGURE 223-3 Immunoperoxidase assay of a verruca in which the darkly stained nuclei (*arrow*) represent cells that contain papillomavirus virion structural antigens. The positive nuclei are found in some, but are not limited to, koilocytotic cells.

EPIDEMIOLOGY

Contagion of HPV probably depends on several factors, including the location of lesions, the quantity of infectious virus present, the degree and nature of the contact, and the general and HPV-specific immunologic status of the exposed individual. Patients with impaired cell-mediated immunity are particularly susceptible to HPV infection, and warts occur in the majority of renal transplant patients on immunosuppressive therapy. [13], [14]

The source or reservoir for HPV is believed to be individuals with clinical or subclinical infection, as well as the environment. Using sensitive PCR detection methods, it is becoming increasingly evident that normal skin in immunocompetent individuals can harbor HPVs, including novel types and those found in EV. [15], [16] Therefore, when these sensitive techniques are used to find HPV DNA in a lesion not usually thought to be caused by HPV, additional evidence should be sought to determine whether the virus has contributed to the development of the lesion.

Nongenital warts occur most frequently in children and young adults, in whom the incidence may approach 10 percent. [17] The age-specific incidence of nongenital warts differs from that of anogenital warts, which are uncommon in children. Anogenital warts behave as a sexually transmitted condition, and partners can transmit the virus with high efficiency. [18] Penile lesions occur frequently in the sexual contacts of women with cervical intraepithelial neoplasia. [19]

Although genital warts in children may be a consequence of sexual abuse, such warts in infants and children commonly result from virus inoculation at birth or from incidental spread from cutaneous warts. In contrast to anogenital lesions in adults, a significant proportion of genital warts in children contain HPV types that are usually isolated from nongenital warts. [20], [21] The majority of respiratory (laryngeal) papillomas, which contain the same HPV types as are found in anogenital papillomas, [22] occur in infants and young children. In this age group, the condition is believed to have been transmitted from mothers with genital HPV infection when the infant aspirates infectious virus during birth. [22] The incidence of respiratory papillomas is much lower than that of genital HPV lesions. Maternal factors that predispose to the development of clinical respiratory lesions in children include first pregnancy and young age. [23]

In addition to causing lesions on the external genitalia, genital-mucosal HPV types also infect the uterine cervix. This sexually transmitted infection, which may involve low- or high-risk HPV types, is especially common in sexually active women younger than 25 years of age, in whom the prevalence of infection may exceed 25 percent. [24] The majority of HPV DNA–positive cervical infections are transient and remain histologically normal. [25] Persistence of HPV DNA strongly correlates with an increased risk for progression to cervical dysplasia and invasive cancer. HPV DNA has also been detected in some clinically normal penile skin. [26] Thus, even normal-appearing genital skin or mucosa may represent a reservoir for contagion.

The most common antibody response to HPV infection is directed against conformational type-specific epitopes present in the L1 protein of the viral particle. [27], [28] and [29] These epitopes are efficiently presented by virus-like particles, which can be produced in large quantity in cultured cells. The availability of virus-like particles has facilitated the development of HPV type-restricted assays to monitor the seroepidemiology of HPV infection. The most extensive use of these assays has focused on the seroprevalence of HPV-16 infection, because this is the HPV type that occurs most frequently in cervical cancer. Most, but not all, infected patients develop low serum antibody titers. The likelihood of becoming antibody-positive increases with the duration of the infection. Once an individual becomes antibody-positive, the antibodies seem to persist for many years, even if the individual becomes viral DNA–negative. Thus, the antibodies detect both past and present infection, and the seroprevalence of HPV-16 antibodies in a given population reflects the

relative prevalence of the virus within that population.

PATHOGENESIS

HPV infection occurs through inoculation of virus into the viable epidermis through defects in the epithelium. [2] Maceration of the skin is probably an important predisposing factor, as suggested by the increased incidence of plantar warts in swimmers who frequent public pools. [29] Although the receptor(s) by which cells take up HPV infection has not been identified, cell surface heparan sulfate, which is encoded by proteoglycans and binds papillomavirus particles with high affinity, is required for HPV infection. [30] To establish the chronic infection characteristic of a wart, it is probably necessary to infect an epidermal stem cell. It is believed that a single copy or at most a few copies of the viral genome are maintained as an extrachromosomal plasmid within the infected epithelial basal cells. When these basal cells divide, the viral genome is also replicated and transported within the daughter cells as they migrate upward to form the differentiating epithelium.

After experimental papillomavirus inoculation, it usually requires 2 to 9 months for a verruca to become clinically apparent. This observation implies a relatively long period of subclinical infection. This state of inapparent infection represents a potential source of infectious virus. Although the epidermis in a wart is acanthotic, hyperplasia of the proliferative basal cell population is not dramatic, in concordance with the observation that warts develop slowly.

Once an infection has taken place, new warts may develop in sites of inoculation over a period of weeks to months. Each new lesion probably results either from the initial exposure or spread from other warts. There is no convincing evidence for blood-borne dissemination. Autoinoculation of virus into apposed skin is commonly seen on adjacent digits (Fig. 223-4) and in the anogenital region.

FIGURE 223-4 *A.* Common wart, periungual. Multiple, confluent kerototic papules are apparent around the proximal periphery of the fingernails. *B.* Common wart, verruca plantaris. *C.* Common wart, mosaic plantar. A large hyperkeratotic plaque is seen on the heel, made up of multiple small coalescing warts.

HPV DNA has been detected in normal-appearing mucosa of the larynx of patients with respiratory papillomatosis who were in clinical remission [31] and in normal-appearing skin and hair adjacent to treatment sites of recurrent genital warts. [16] Whether these represent subclinical states rather than true “latency” (i.e., nonreplicating and transcriptionally inactive virus) is unknown. There is also increasing evidence that HPV DNA can be resident in clinically normal skin. [15], [16], [28] Whether HPV DNA persists in the epithelium after successful treatment of immunocompetent individuals remains an unresolved question.

Viral RNA expression (transcription) remains low until the upper malpighian layer, just before the granular layer, where viral DNA replication may result in hundreds of copies of viral DNA per cell. The viral capsid proteins (L1 and L2; see Fig. 223-1 and Fig. 223-2) are synthesized and assembled into virions in the nuclei of the cells at this level (see Fig. 223-3). The newly synthesized viral DNA is also incorporated into the virions in the nuclei of these differentiated malpighian cells. A viral protein called E1-E4 (the product of a spliced RNA from the E1 and E4 genes) may induce collapse of the cytoplasmic keratin filament network. This is postulated to facilitate release of the virions from the cross-linked cytoskeleton so that they can be inoculated into another site or desquamated into the environment.

Papillomaviruses are not enveloped, because they do not bud from the nuclear or plasma membrane, as do many viruses such as herpes simplex virus or HIV. It is their membrane-derived lipoprotein envelope that causes the rapid inactivation of these latter viruses by environmental conditions, such as freezing or desiccation, or chemicals, such as ethanol. In contrast, papillomavirus virions are resistant to desiccation [32] and to the detergent nonoxynol-9, although exposure of virions to formalin, detergents such as sodium dodecyl sulfate, [33] or high temperature can reduce their infectivity. They can remain infectious for years when warts are stored in glycerol at room temperature. Indeed, L1 and L2 form a tightly packed protein structure that is highly resistant to proteases.

The relative abundance of these stable virus particles in a verruca varies with the clinical setting and the HPV type. Newer lesions tend to contain more virions than do older verrucae. Plantar warts containing HPV-1 have a high number of virions; anogenital verrucae typically have small quantities of mature virus particles; and common warts usually have intermediate numbers. Not only does the quantity of viral DNA present differ among these lesions, but also the proportion that is enclosed within the infectious virions may vary among these verrucae. [34]

Because virions do not appear in the lower epithelial levels in warts, it is believed that the state of differentiation of the infected epithelial cell coordinate viral transcription, DNA replication, and late protein production. The recent propagation of limited amounts of HPVs in cultured cells is a consequence of the ability to reproduce the milieu required for physiologic differentiation. [5], [35] Further support for the belief that the production of virus particles and virion antigens depends on the state of epithelial differentiation is the fact that as benign papillomas progress toward dysplasia, virion production decreases. Capsid proteins are almost never observed in frank malignancies, although HPV DNA is present. It is also possible to cultivate some HPVs by exposing epithelial cells to infectious virions and placing them under the renal capsule of an immunodeficient (nude) mouse for prolonged periods. In this system, the epithelial cells differentiate,

stratify, and resemble a verruca histologically, and the full virus replication cycle occurs, producing infectious virions. [4]

Experimental evidence from cell culture systems has shown that papillomavirus genes can alter cell proliferation, a characteristic common to many tumor viruses. [36], [37] Several different transformation assays have been developed to examine the biologic effects of papillomavirus genes in vitro. For example, cells may lose contact inhibition and continue to divide, exhibit increased DNA synthesis and replication rates, lose growth factor dependence, or become immortal instead of exhibiting a finite life span in vitro. Three different viral genes have been shown to possess some of these properties: E5, E6, and E7 (see Fig. 223-1). They alter cell growth by nonoverlapping, but cooperative, mechanisms.

These experimental systems have been used to examine and compare the in vitro activities of genital-mucosal HPVs. Their relative activity varies with the HPV type. In one assay, keratinocytes or cervical cells were grown as a stratified epithelium on a raft that provided an air-media interface. The introduction of high-risk HPV-16 or -18 DNA induced a disorganized pattern of differentiation with suprabasal mitotic figures resembling squamous cell carcinoma in situ, while the cells retained a normal pattern of stratification with the use of low-risk HPV-6 or -11 DNA. [38] In other in vitro models, the introduction of HPV-16 or -18 DNA into cultured human epithelial cells increased the cells growth rate, resistance to differentiation, and ability to be continuously passaged; HPV-6 and -11 DNA were much less active. Thus, for the genital-mucosal HPVs, there is an excellent correlation between their ability to induce cell transformation in vitro and their association with malignancy.

In cutaneous or cervical epithelial cells, transformation is best achieved with both E6 and E7 from HPV-16 or -18. These two HPV genes are preferentially retained and expressed in cervical cancers, implying that these assays measure a property that is closely related to the oncogenic potential of these viruses in cervical infection. [39], [40] One mechanism by which the E6 and E7 proteins exert their effects is by each binding to a different cellular protein that inhibits normal epithelial cell growth. Apparently, binding to E6 and E7, respectively, inactivates two cellular proteins, p53 and the retinoblastoma susceptibility protein (Rb), and thereby relieves infected cells from the normal growth inhibitory activities of these two cellular proteins. However, the E6 proteins from some HPV types, including those associated with malignancies in EV and immunosuppression, do not interact with p53, although they may prolong the life span of infected cells by an alternate mechanism, such as inactivation of the pro-apoptotic protein Bak. [41], [42] Several studies demonstrate that E6 and E7 must have multiple targets in the cell. [39], [40], [43], [44] The viral E5 genes encode proteins that appear to activate growth factor receptors. In the bovine (cow) papillomavirus, which induces fibropapillomas, E5 appears to preferentially activate the receptors for platelet-derived growth factor, and HPV-16 E5 may stimulate the epidermal growth factor receptor. [45], [46]

The roles of immunity and genetic susceptibility to papillomavirus infection are incompletely understood. [47] The decrease in the frequency of warts with age implies that resistance to infection develops over time, and much of this resistance may be immunologic. In experimental papillomavirus infection in animals, resistance to virus challenge correlates with the presence of neutralizing anticapsid antibodies, and serum or IgG from resistant animals can provide protection through passive transference. [48], [49] It is therefore likely that neutralizing antibodies account for at least some of the resistance to reinfection. Serum antibodies to viral capsids are detectable in some patients with current warts or a past history of warts. In patients with warts, these antibodies, as well as other host factors, may help to limit the spread of warts to new sites.

Although humoral immunity may contribute to resistance to infection, most evidence suggests that cellular immune reactivity plays a significant role in wart regression. Individuals with defective cell-mediated immunity are particularly susceptible to papillomavirus infection, and their infections are notoriously resistant to treatment. In cows, the induction of high levels of neutralizing antibodies, although protective against challenge with a papillomavirus that causes oral papillomas, do not alter established oral papillomas induced by the same virus. [50] Flat warts in patients may regress spontaneously in association with a mononuclear cell infiltrate. There are also instances in which treatment of one or a few warts may lead to resolution of many or all warts in nonimmunosuppressed patients, although this outcome is the exception rather than the rule. In uncontrolled patient studies, vaccination with wart extracts has been reported to be effective in prevention of condylomata acuminata recurrence. [51]

CLINICAL MANIFESTATIONS

Cutaneous Infections

Warts are usually classified by their clinical location or morphology. As shown in Figure 223-5, Figure 223-6, Figure 223-7, Figure 223-8 and Figure 223-9, the cutaneous manifestations of warts are varied. *Common warts* (verruca vulgaris) are scaly, rough, spiny papules or nodules that can be found on any skin surface (see Table 223-1). They occur often as single or grouped papules on the hands and fingers. *Flat warts,* (verruca plana), are 2 to 4 mm, slightly elevated, flat-topped papules that have minimal scale. These are most frequent on the face, hands, and lower legs. Verrucae may also be *filiform* or appear as cutaneous horns. *Plantar and palmar warts* are thick, endophytic, and hyperkeratotic lesions, which may be painful with pressure. Punctate black dots (“seeds”), which become evident after shaving away of the outer keratinous surface, represent thrombosed capillaries in the papilloma. *Mosaic warts* result from the coalescence of plantar or palmar warts into large plaques. Some individuals with an apparently normal immunologic state develop exuberant warts of the palms or soles that are refractory to treatment. *Butcher's warts* are verrucous papules, usually multiple, on the dorsal, palmar, or periungual hands and fingers of meat cutters.

FIGURE 223-5 Common wart. A large hyperkeratotic nodule is seen on the ear.

FIGURE 223-6 *A.* Common wart with koebnerization. A linear arrangement of warts is seen on the elbow, arising at the site of an abrasive injury. *B.* Common wart. A giant wart is seen on the dorsum of the hand in a renal transplant recipient; the lesions were resistant to treatment, but resolved spontaneously when immunosuppressive therapy was discontinued.

FIGURE 223-7 The large, scaly, and horny warts contain HPV-2. The smaller, flatter, less scaly papules are warts that contain HPV-3.

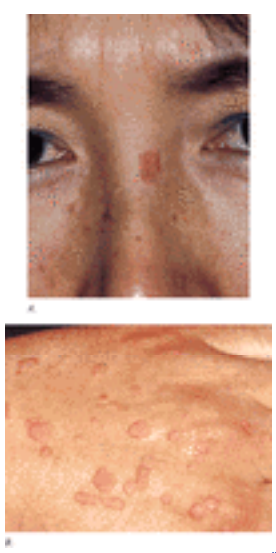

FIGURE 223-8 Common wart, verruca plana. *A.* A single pink, flat-topped lesion is evident on the nose. *B.* Many flat-topped papules occur in a linear configuration as a result of autoinoculation.

FIGURE 223-9 Mucosal wart. *A.* Multiple condyloma acuminata on the shaft of the penis. *B.* Multiple confluent condylomata on the labia minora. *C.* Multiple condylomata on the perineum of a 20-month-old boy. He was infected during vaginal delivery; his mother was not aware of her infection, but examination revealed several small condylomata.

Anogenital warts (also known as condylomata acuminata, genital warts, or venereal warts) consist of epidermal and dermal papules or nodules on the perineum, genitalia, crural folds, and anus. They vary in size and can form large, exophytic (cauliflower-like) masses, especially in the moist environment of the perineum. Discrete 1- to 3-mm sessile warts may occur on the penile shaft.

Lesions that resemble common warts also occur in this region, but are unusual. Warts may extend internally into the vagina, urethra, and perirectal epithelium.

Bowenoid papulosis is a clinicopathologic entity in which HPVs have been identified. [52] Papules, often multiple, appear as 2- to 3-mm lesions on the external male and female genitalia. Histologically, there is cellular atypia resembling Bowen's disease or squamous cell carcinoma in situ. These lesions are usually infected with HPV-16, which suggests that bowenoid papulosis may represent a precursor of penile and vulvar cancer. However, the rate of transition to frank malignancy is much lower for the external genitalia than for the cervix. These small papules should be treated, because they may represent a reservoir for the transmission of potentially oncogenic HPVs. [53] As in all genital warts, virions are difficult to detect in these lesions.

EPIDERMODYSPLASIA VERRUCIFORMIS Representing a unique susceptibility to cutaneous HPV infection, [54] EV usually manifests itself in childhood with widespread warts. The individual lesions typically have either the appearance of flat warts or flat scaly red-brown macules, which resemble lesions of pityriasis rosea or tinea versicolor (Fig. 223-10). The first type of lesion is usually caused by the same HPV types as those found in flat warts in the general population (e.g., HPV-3 and -10), while the second is usually caused by EV HPV types (e.g., HPV-5 and -8). Many EV patients are infected with multiple HPV types. The involvement of large areas of the body with warts or the failure to clear lesions despite adequate treatment is the typical indication to consider with this diagnosis. About 50 percent of EV cases are inherited, usually with an autosomal recessive pattern. At least two different genes can give rise to autosomally inherited EV, because the condition has been mapped to two distinct loci. [55] An X-linked inheritance has also been reported. [56] Viral studies to identify the HPV genotype in the lesions may be suggestive, although such analyses are still limited to research laboratories. EV HPV types may commensually reside in normal skin at very low levels, [15] and it is not clear that they normally cause disease in this setting, although their association with malignant skin tumors is well substantiated in immunosuppressed individuals. [18], [19], [20] and [21] Warts in EV are usually widespread, although there are some patients with only a few classic lesions limited to one extremity. Mucosal warts of the cervix and oropharynx are rare, but can occur. Despite treatment, warts in EV always recur, suggesting failure to mount an effective immune response to the infection. Classically, individuals with EV do not suffer from frequent bacterial or other viral infections. EV patients may have defects of cellular immunity. [54] Immunocompromised individuals, such as those with HIV infection, may have multiple warts that contain EV types and are difficult to eradicate, but this condition is acquired. [57]

FIGURE 223-10 Plane wartlike lesions on the dorsa of the hands and forearms, associated with HPV-5 and -8. The lesions are numerous, flat, reddish, and partly confluent.

Some EV patients are at high risk of developing cutaneous squamous cell carcinomas. [54] These tumors usually arise in pityriasis-like lesions on sun-exposed areas (Fig. 223-11). Most of the malignant tumors remain local, but regional and distant metastases may occur. Although pityriasis-like lesions caused by any EV type may be at increased risk of becoming malignant, the risk appears to be greatest for those caused by HPV-5 and -8. Because the malignant tumors develop on exposed areas, it is believed that UV light acts as an important cofactor in the development of the tumors. The lesions of individuals with EV who have only flat warts caused by non-EV HPV types do not seem to be at increased risk of becoming malignant.

FIGURE 223-11 Invasive cancer in an EV patient infected with numerous HPV types including HPV-5, -8, -9, -14, and others. In the tumor cells, DNA HPV-5 was detected in a high copy number. This large squamous cell carcinoma did not metastasize and did not recur after surgery. There are numerous actinic keratoses on the forehead.

Extracutaneous (Mucosal) Infections

Oral warts are small, slightly elevated, soft, often pink or white papules that may be found on the buccal, gingival, or labial mucosa or on the tongue or hard palate. [58] Verrucous, horny papillomas may occur on the palate. Mucosal lesions of the oropharynx, termed focal epithelial hyperplasia, also contain HPVs. In oral florid papillomatosis, which is thought also to be caused by a papillomavirus, multiple large verrucae appear within the oral cavity. Progression to verrucous carcinoma may occur. Oral condylomata acuminata can result from orogenital contact. Warts may also occur in the urethra, usually when meatal warts are present. [59] They may spread to the urinary bladder.

In respiratory (laryngeal) papillomatosis, patients have multiple benign, noninvasive warts that usually involve the larynx, but may extend to the oropharynx and bronchopulmonary epithelia. [22] Presenting symptoms commonly include hoarseness and stridor. Most cases occur in infants (where the lesions may block the airway), but the condition may develop at any age. These HPV-associated papillomas may spontaneously remit, especially at puberty, but recurrences are frequent, perhaps because of the persistence of viral DNA despite clinical remission. [31] The HPVs isolated from these lesions are the same types as those of cervical warts, and respiratory papillomatosis is thought to result from seeding of the larynx during parturition by virus present in maternal condylomata acuminata or cervical papillomas. [31], [60] Several studies have demonstrated the epidemiologic correlation of condylomata in mothers of infants with this disease. Nonetheless, cervical and external genitalia warts are common in the childbearing age bracket, while respiratory papillomatosis of infants is rare. It is controversial whether mothers with condylomata should undergo cesarean section, because this procedure itself has attendant risk.

As noted earlier, the uterine cervix is an important site of HPV infection. Often termed cervical warts or atypical condylomata, lesions are usually flat or slightly elevated. Their visualization may require colposcopy and enhancement following acetic acid application, which makes them appear as white patches (Fig. 223-12). Atypical condylomata may mimic cervical dysplasia or carcinoma in situ histologically, with nuclear atypia and disorganized differentiation. Cells with a central nucleus and a surrounding clear halo (koilocytotic cells) may be evident histologically in these lesions, as well as in common verrucae, and represent a hallmark of HPV infection as visualized in a Papanicolaou smear.

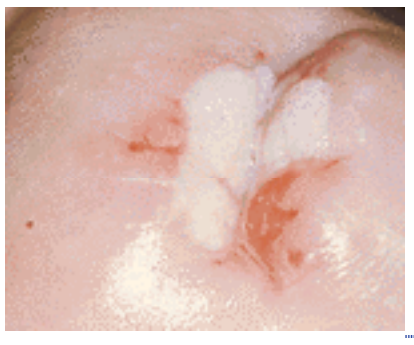

FIGURE 223-12 Colposcopic view of cervical condylomata after treatment with acetic acid for visualization as white, elevated patch.

RELATION OF PAPILLOMAVIRUSES AND MALIGNANCY

Although most papillomaviruses are associated with and limited to biologically benign lesions, epidemiologic and experimental studies indicate that certain papillomavirus genotypes have oncogenic potential. [24], [61] In animals, the benign warts induced in rabbits by the (Shope) cottontail rabbit papillomavirus can spontaneously convert to invasive squamous cell carcinoma. [62] Small doses of chemical carcinogens induce a high rate of malignant conversion in these lesions. In cattle, esophageal papillomas induced by bovine papillomavirus type 4 become malignant if the infected animals graze on bracken fern, which contains a potential carcinogen. [63] These observations and the long latency to malignant progression suggest that papillomaviruses do not induce malignant tumors directly; it is more likely that potentially oncogenic papillomaviruses act by predisposing the infected cell to become malignant. Similar conclusions seem relevant to human malignancies associated with HPVs.

In humans, the link to infection by specific HPV types was first noted in patients with EV. [54] As noted earlier, squamous cell carcinoma frequently develops in sun-exposed warts in EV lesions and is common in those warts containing HPV-5 or -8. Metastatic tumors in EV contain the viral DNA, implying that its presence is not from skin contamination and that retention of the HPV genome is necessary for maintaining the malignant phenotype. Progression of the verrucae in respiratory papillomatosis to invasive squamous cell carcinoma can occur subsequent to X-irradiation.

There is now compelling evidence that cervical infection with high-risk HPVs is the main cause of cervical cancer. [24] Even with high-risk HPVs, however, cervical infection usually has a benign outcome. [25] Patients with impaired cellular immune function, such as renal transplant recipients or those with HIV infection and AIDS, are at much greater risk of having persistent HPV infection that progresses to severe dysplasia and thus to cancer. [64], [65] These observations lead to the conclusion that HPVs usually induce benign lesions, but specific HPV types can induce the development of malignant epithelial tumors. Although HPV infection with these high-risk types may be necessary, it is not sufficient and most likely requires other cofactors to alter the cell to a malignant phenotype.

Epidemiologic and molecular evidence has also linked some penile, vulvar, anal, and oral carcinomas with HPV infection. [61], [66], [67] As with cervical cancer, these tumors are associated primarily with high-risk HPV types, which is consistent with these HPVs as a cause of the malignancies. High-risk HPVs, especially HPV-16, have been identified in some periungual cutaneous tumors. [68]

The giant condyloma acuminatum, also called the Buschke-Lowenstein tumor, is a low-grade, locally invasive squamous cell carcinoma. Low-risk HPVs, such as types 6 and 11, are usually found in these tumors. [69] Verrucous carcinoma of the penis, however, is not usually associated with HPV infection. Epithelioma cuniculatum, another rare type of verrucous carcinoma, is found on the sole and is thought to arise from a plantar wart.

There is also evidence, arising from the use of very sensitive PCR techniques, that HPVs may be found in a high proportion of nonmelanoma cutaneous tumors in patients without obvious immune impairment, as well as in immunosuppressed renal allograft recipients. [13], [14] These provocative findings require careful follow-up to determine the precise relationship between the HPVs and the cutaneous tumors, because the same PCR techniques have also identified small amounts of HPV DNA in normal skin or in dermatologic conditions in which the normal barrier function of the epithelium is impaired. [15], [16]

HISTOPATHOLOGY

Verrucae consist of an acanthotic epidermis with papillomatosis, hyperkeratosis, and parakeratosis (Fig. 223-13); some correlations can be made with HPV type. [70] The elongated rete ridges often point toward the center of the wart. The dermal capillary vessels are prominent and may be thrombosed. Mononuclear cells may be present. Large keratinocytes with an eccentric, pyknotic nucleus surrounded by a perinuclear halo (koilocytotic cells or koilocytes) are characteristic of HPV-associated papillomas. Koilocytes do not usually contain keratohyaline granules, although they occur in the malpighian layer. Papillomavirus-infected cells may have small, eosinophilic granules and dense clumps of basophilic keratohyaline granules. These granules may be composed of or associated with the papillomavirus E4 (E1-E4) protein [71] and do not represent conglomerates of virus particles. Flat warts have less acanthosis and hyperkeratosis and do not have parakeratosis or papillomatosis. Koilocytotic cells are usually abundant, indicating the viral origin of the lesion. Anogenital warts may have from slight to extensive acanthosis and parakeratosis: they lack a granular layer as they are within or adjacent to a mucosal surface. The rete ridges often form thick bands extending extensively into the underlying, highly vascular dermis. Koilocytes are often observed in these viral papillomas.

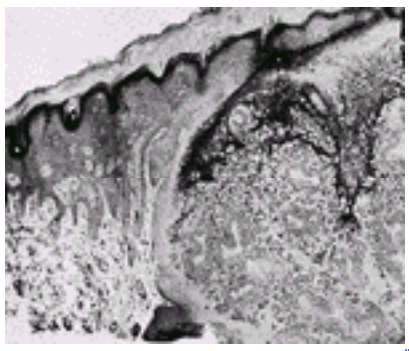

FIGURE 223-13 Verruca vulgaris. The process is one of extensive hyperplasia, and the hyperplastic cells contain both intranuclear and intracytoplasmic inclusion bodies. (*Micrograph by Wallace H. Clark, Jr., MD.*)

Plane warts, which usually contain HPV-3 or -10, have a similar appearance histologically whether in the general population or in patients with EV (Fig. 223-14). The granular and upper spinous layers contain many cells with perinuclear vacuolization. In EV, many cells from lesions containing HPV-5 or -8 have a characteristic basket-weave–like hyperkeratosis with many large clear cells in the granular and spinous layers (Fig. 223-15).

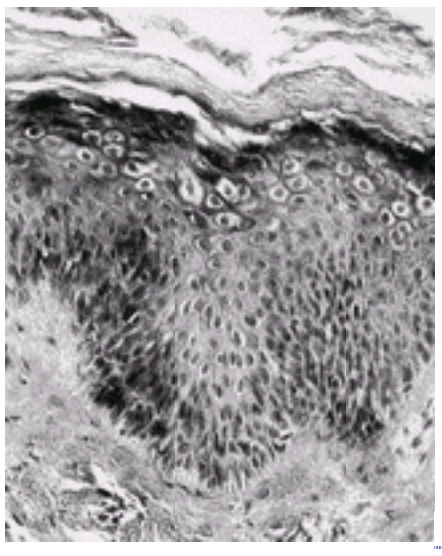

FIGURE 223-14 HPV-3–associated plane wartlike lesion in patient with EV. The histologic pattern is characteristic of a plane wart with numerous cells showing perinuclear vacuolization in the granular and upper spinous layers. H&E.

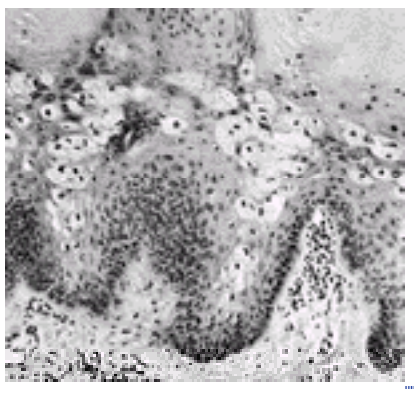

FIGURE 223-15 Characteristic cytopathic effect of EV-specific HPV in a patient found to be infected with HPV-5, -8, and -9. Very abundant clear large cells with small pyknotic nuclei replace almost the entire epidermis. H&E.

DIAGNOSIS

The clinical appearance usually leads to the diagnosis of viral wart, but histologic examination may also suggest the diagnosis. Application of 3 to 5 percent acetic acid to genital warts enhances detection of these lesions, particularly with colposcopic magnification, although diagnosis should not rest only on the presence of white lesions since there may be false-positive results. Immunohistochemical detection of papillomavirus structural proteins may confirm the presence of virus in a lesion. PCR techniques to detect cutaneous HPVs, which are currently limited to research laboratories, may vary in their sensitivity. [72] Diagnostic hybridization tests to identify genital-mucosal HPV type are now commercially available for the common genital HPV types. [73]

Cutaneous warts are common in children and young adults, but also occur in patients over 40 years of age. Multiple warts that do not spontaneously resolve, always recur after treatment, persist for years, or have an unusual morphology (especially if familial) suggest EV. HPV typing may be of benefit in confirming the diagnosis of EV and will also disclose whether the patient is infected with a type that is associated with malignancy. Immunocompromised patients, such as those with AIDS, lymphoproliferative disorders, or on chemotherapeutic drugs, may have multiple warts.

DIFFERENTIAL DIAGNOSIS

Common lesions such as seborrheic and solar keratoses, nevi, irritated achrocordons, clavi, and squamous cell carcinomas may look like verrucae. Papules of lichen planus may resemble flat warts; they may be differentiated by the presence of Wickham's striae and buccal involvement. Acrokeratosis verruciformis and epidermolytic hyperkeratosis are characterized by verrucous papules on the extremities. Syphilitic condylomata must be differentiated from venereal warts.

TREATMENT AND PROPHYLAXIS

The proper approach to the management of warts depends on the age of the patient, the extent and duration of lesions, the patient's immunologic status, and the patient's desire for therapy. [74], [75] Children with common warts may not require therapy. Studies of spontaneous regression of warts in children suggest that two-thirds will remit within 2 years, with remaining verrucae continuing to resolve at this rate. [76] However, new warts may appear while others are regressing.

Many treatments for verrucae involve physical destruction of the infected cells. The existence of multiple treatment modalities reflects the fact that none is uniformly effective or directly antiviral. The choice of treatment depends on the location, size, number and type of wart, as well as on the age and cooperation of the patient. Pain, inconvenience, risk of scarring, and experience of the physician are considerations to evaluate prior to treatment. In patients with anogenital warts (including bowenoid papulosis), sexual partners should be examined and treated if necessary. In females, the condition of the uterine cervix should be evaluated; male contacts of women with cervical disease should also be examined.

Cryotherapy using liquid nitrogen applied with a cotton tip or a spray canister to achieve a halo of ice around the lesion is a common and effective treatment for most warts. [77], [78] Caution must be used near the nail matrix when treating periungual warts. Aggressive cryotherapy with a spray canister can injure underlying structures, such as nerves.

Therefore, its use on the lateral surfaces of the digits and genitalia mandates caution. Warts on the elbows and knees of children may be particularly susceptible to scarring with cryotherapy; although effective, this modality should be used in moderation in these patients.

Warts may be curetted or surgically excised, particularly large anogenital warts unresponsive to topical treatments. Electrodesiccation of condylomata acuminata requires local anesthesia, but may be effective. Laser treatment in several different energy formats, including photodynamic therapies, can be useful for destroying warts that are treatment-resistant or those that require careful control of width and depth, such as large periungual warts. Use of a surgical mask should be routine because infectious papillomavirus has been identified in the vapor plume with laser or with electrocoagulation of warts. [79] Microscopically controlled (Mohs) surgery has been useful in the treatment of verrucous carcinoma. X-irradiation of verrucae is contraindicated because of its association with the development of malignancy in respiratory papillomatosis and EV. Avoidance of and protection from sun exposure is also important in EV. The nucleotide analogue cidofovir has been effective in the treatment of genital warts; however, pain and ulceration were common side effects. [80], [81]

Clinicians have used a variety of chemotherapeutic agents. Topical podophyllin resin is a common treatment, particularly for anogenital warts, as it is more effective on mucosal surfaces. However, podophyllin is contraindicated during pregnancy, and the potency of podophyllin preparations may be variable. Purified podophyllotoxin (Condylox) has activity that is uniform from batch to batch, and it is approved for treatment of genital and perianal warts. [82], [83] Intralesional bleomycin may eradicate verrucae, but should be used cautiously because of the possibility of extensive tissue necrosis. [84]

Caustics and acids such as salicylic acid, lactic acid, and trichloroacetic acid destroy and peel off infected skin. Home use of salicylic acid preparations can be particularly efficacious in young children who cannot tolerate other modalities. Retinoic acid has been used topically for flat warts and probably has a similar mechanism of action. Cantharidin is an extract of the green blister beetle that leads to blistering and focal destruction of epidermis.

Immunotherapies have been attempted in various forms. Induction of allergic contact dermatitis with dinitrochlorobenzene (DNCB), squaric acid dibutylester (SADBE), [85] or diphenylcyclopropenone (DPC) [86] allows localization of inflammation to warts on which the allergen is painted; it has been speculated that this treatment stimulates local immunity. DNCB is positive in the Ames bacterial test of mutagenicity, and its use remains controversial. Cimetidine has been associated with the resolution of cutaneous warts, particularly in children. Although this regimen has its supporters, a double-blind controlled study showed no beneficial effect. [87] Interferon has been effective in short-term studies, reducing warts in laryngeal papillomatosis and EV, but lesions return when therapy is stopped. [31], [88], [89] Recombinant interferon-a was approved for intralesional injection of refractory genital warts in 1989, and other forms of interferon have shown utility. [90] It is not clear that interferon acts through stimulation of immune response. Cytokines were successfully used in the treatment of warts in a patient with cyclic neutropenia. [91] Imiquimod (Aldara), a potent stimulator of the release of several proinflammatory cytokines, has been approved for treatment of genital warts. [92] Uncontrolled reports suggest it may have utility in treatment of cutaneous, plantar, and flat warts.

A variety of prophylactic and therapeutic HPV vaccine trials is contemplated or in progress. [93] Most of these focus on genital HPV infection. For animal papillomaviruses, vaccination of rabbits, dogs, and cows with virus-like particles derived from papillomaviruses that can cause lesions in the respective host have shown good protection against subsequent experimental challenge with the authentic virus. [50], [94] Early phase clinical trials in normal volunteers indicate that HPV virus-like particles are well tolerated and highly immunogenic. [95]

Viruses have attracted attention as pathogens in malignant and autoimmune diseases in animals ever since Peyton Rous discovered that a virus could cause solid tumors in fowls at the beginning of the twentieth century. The Rous sarcoma virus, named after its discoverer, turned out to contain an RNA genome, but appeared to exist as a DNA provirus in infected cells. [1], [2] This paradox was resolved when Baltimore and Temin and Mizutani independently discovered a polymerase that was able to use RNA as a template to produce DNA—the reverse transcriptase (RT). Viruses, which contain an RNA genome and an RNA-dependent DNA polymerase, belong to the family of Retroviridae. [1]

Although the history of animal retroviruses dates back to the beginning of the century, the first pathogenic human retrovirus was discovered only in 1980. At that time Poiesz and coworkers isolated a retrovirus from lymphocytes of a patient with cutaneous T cell lymphoma [3] and subsequently from a patient with leukemia classified as Sézary syndrome. [4] Independently of this work, Miyoshi and coworkers later isolated the same retrovirus from a Japanese leukemia patient. [5] The American and Japanese isolates were shown in the following years to be indistinguishable by nucleic acid comparison and the name human T cell leukemia virus type I (HTLV-1) was proposed [6] for all isolates previously called adult T cell leukemia virus (ATLV) in Japan and HTLV in the United States.

In 1982, a second human retrovirus, related to but distinct from HTLV-1, was isolated from a cell line derived from a patient with hairy cell leukemia and was named HTLV-2. [7] Although isolated from a leukemic patient, a clear association with a distinct disease has not yet been accomplished for HTLV-2.

VIROLOGY

HTLV-1 and 2 are related but distinct human retroviruses, which, together with bovine leukemia virus, form their own genus within the retroviridae. [1] Many strains of HTLV-1 have been isolated in different areas of the world, including the United States, the Caribbean islands, Africa, and Japan. [8] From sequencing data it appears that the overall nucleic acid sequence variation among different HTLV-1 strains does not exceed 7 percent. [9] Although the genomic organization of HTLV-1 and -2 is quite similar, the nucleotide sequence conservation between these two viruses is only about 55 percent. [10] Like other enveloped retroviruses, the HTLV-1 genome consists of a dimer of identical RNA subunits. [1] After infection of host cells, the RNA genome is transcribed into DNA by the viral RT and the viral DNA is integrated into the host cell genome (provirus). Like all retroviruses it contains dual long-terminal repeats (LTR) at the 3'and 5'ends and *gag, pol,* and *env* genes, which encode integral components of the virions. In addition to these genes, both the HTLV-1 and -2 genomes contain an extra sequence of approximately 1.6 kb between the *env* and the 3' LTR, which was originally called “pX.” [2] While *gag* and *pol* proteins are translated from the full-length genomic RNA, and the *env* proteins are translated from singly spliced mRNAs, the “pX” genes are expressed from RNAs produced mostly by double-splicing mechanisms. The functions of two of these at least six genes, that is, the transregulatory proteins Tax (transactivator in the region x) and Rex (regulator in the region x) have been elucidated. The 40-kDa HTLV-1 Tax interacts with cellular transcription factors and transactivates the viral LTR thereby increasing viral RNA synthesis. [2] The 27-kDa Rex protein promotes the export of the viral genomic and envelope mRNAs to the cytoplasm where they can be translated. [2] The function of the other proteins of the pX region—p21Rex, p12 [I], p13 [II], p30 [II]—still awaits full elucidation. [2]

Infection of human, monkey, and rabbit T lymphocytes by HTLV-1 in vitro leads to their continuous growth in tissue culture and the development of cell lines with growth characteristics of transformed cells. [11] In infected patients, HTLV-1 is mainly present in CD4+ T cells, [12] but it has also been found in dendritic cells of blood [13] and cells from the synovial lining of arthritic joints. [14]

The steps leading from virus infection to the development of the different HTLV-1–associated diseases are still only partly understood. Only a small percentage of patients infected with HTLV-1 ultimately develop adult T cell leukemia (ATL) and the time from infection to leukemia usually lasts several decades. [15] Unlike acute or chronic leukemia viruses, the HTLV-1 genome neither contains an oncogene nor does it transduce cellular oncogenes by insertion at critical sites within the host cell genome. [2], [11], [15] However, the HTLV-1 regulatory gene *Tax,* which is necessary for in vitro

transformation, is able to transactivate both the viral promoter and certain cellular genes. [2], [15] Transformation of human T cells in vitro is a multistep event, which involves selection of infected T cell clones. At first, T cells proliferate in response to exogenous interleukin (IL)-2 (immortalization) and, in time, lose growth factor requirement for growth (transformation). Tax, the viral transactivator, is necessary but not sufficient to induce T cell transformation inasmuch as it interferes with at least two inhibitors of cell-cycle progression as the tumor suppressor protein p16 ^{ink} and p53. [2], [15] In the transformed state, HTLV-1–infected T cells proliferate in the absence of exogenous growth factors; this event correlates with both the constitutive activation of the Jak/STAT signaling pathway [2] and the constitutive activation of the cyclin E/CDK2 complex. The in vitro model of T cell transformation appears to mirror the event that leads to leukemogenesis. In most cases of ATL, genetic mutation/deletion of p53 or p16 ^{ink} occur [2] and the leukemic cells of 70 percent of patients display constitutive activation of the Jak3 and STAT proteins. [2]

Although HTLV-2 has been less well studied than HTLV-1, most of the properties described for the latter, including the transformation of T cells in vitro and the presence and importance of transregulatory genes, are true also for the former. [15] To date, however, no disease has been associated with HTLV-2 infection.

HTLV-1 TRANSMISSION AND EPIDEMIOLOGY

The mode of transmission of HTLV-1 appears to be quite analogous to that of the human immunodeficiency virus type 1 (HIV-1). However, HTLV-1, which is mainly infectious by cell-to-cell contact, is less infectious than HIV-1, which can readily be transmitted cell free. Based on longitudinal studies, it has become well established that sexual transmission of HTLV-1 from male to female, female to male, and male to male occurs. [15], [16] Although the mechanisms of vertical transmission of HTLV-1 are not completely clarified, transmission from mother to child via breast-feeding appears to play a more important role than perinatal or intrauterine transmission. [15], [16]

In parenteral transmission, approximately one-half of patients received transfusions of an HTLV-1–infected donor seroconvert, [17], [18] whereas cell-free fresh-frozen plasma appears not to be infectious. [18] Transfusion-mediated HTLV-1 infection in Japan has been virtually terminated by mass screening of donated blood. In the United States, a screening program for blood units was initiated in 1989. Parenteral transmission via needle sharing very likely accounts for clusters of HTLV-1/-2 seropositivity in intravenous drug users in certain areas of the United States and Europe. [19] There is no indication that arthropod-borne transmission of HTLV-1 occurs.

The geographic distribution of HTLV-1 and -2 has been studied mainly by serological methods, which cannot distinguish between the two viruses. Therefore seroprevalence data usually refer to both HTLV-1 and HTLV-2. More recently, molecular methods that allow the reliable distinction between HTLV-1 and -2 infection have led to extensive molecular typing of the viruses. [8], [15]

An estimated 10 to 20 million individuals are infected by HTLV-1 worldwide. [8], [15], [16] Extensive seroepidemiologic and molecular surveys confirmed an endemic pattern in southern Japan. In Kyushu, Shikoku, and the Ryuku islands, including Okinawa, seroprevalence ranges from 1 to 36 percent, depending on the location and the age group investigated. [15], [16], [20] Similar patterns can be found in the Caribbean islands, particularly Jamaica, Trinidad, Tobago, Martinique, Haiti, Guadeloupe, and Barbados, and in countries of equatorial Africa such as Gabun, Zaire, and the Ivory Coast. [15], [16], [20] Small clusters of HTLV-1/-2 seropositive populations have been reported from restricted areas in South America, among Australian aborigines, and in the Middle East. [15], [16], [20] In the United States, Europe, and Canada, the incidence of HTLV-1 infection is low, and clusters are found predominately among immigrants from endemic areas, especially from the West Indies and Africa. [15], [16], [21] A seroepidemiologic survey among 39,898 U.S. blood donors in 8 geographically diverse areas showed a seroprevalence for HTLV-1/-2 of 0.025 percent. [16] In the United Kingdom, HTLV-1 infection among blood donors is similarly low, with a seroprevalence of approximately 0.05 percent. [22]

THE NATURAL COURSE OF HTLV-1 INFECTION AND CLINICAL DISEASE SPECTRUM

Adult T Cell Leukemia/Lymphoma

Uchiyama and coworkers first described ATL in 1977 as a distinct malignancy of mature T cells occurring primarily in patients born in southwestern Japan. [23] At the beginning of the 1980s, HTLV-1 was linked to ATL by virus isolation from leukemic cells, by the demonstration of oligoclonal or monoclonal integrated HTLV-1 provirus in leukemic cells and by extensive seroepidemiologic studies. [2], [15], [24] Besides Japan, the West Indies are a major region where HTLV-1 infection and ATL are endemic. [2], [15], [16], [24]

Although HTLV-1 is a prerequisite for ATL development, infection with this virus does not necessarily lead to development of leukemia. More than 90 percent of infected individuals remain asymptomatic carriers. [15], [16] Based on Japanese epidemiologic studies, it appears that the annual incidence rate of ATL among HTLV-1 carriers older than 40 years of age is approximately 0.6 to 1.7/1000. [25] The cumulative incidence rate of ATL in HTLV-1 carriers approximates 2 to 5 percent. The latent period from infection to outbreak of leukemia is 20 years or more, as concluded from studies in migrants. [26] Interestingly, the average age of onset of ATL differs in patients from Japan (56 years) and the Caribbean (43 years). [27]

Acute, prototypic ATL is a fatal malignancy of adult onset with a clinical presentation that appears to be identical in all endemic areas. [23], [24], [28], [29] It is characterized by the variable combination of multiorgan involvement, including hepatosplenomegaly, systemic lymphadenopathy, central nervous system (CNS) involvement, and skin lesions, with the presence of multilobated leukemic cells in the peripheral blood (Fig. 224-1A). Leukemic infiltrates of different organs may determine the clinical presentation and the morbidity. CNS involvement may alter the mental status of the patient; [28],

[29] lymphoma within the liver may lead to abnormalities in liver function tests and jaundice; and lung involvement may lead to tachypnea, cyanosis, and dyspnea. [24], [28], [29]

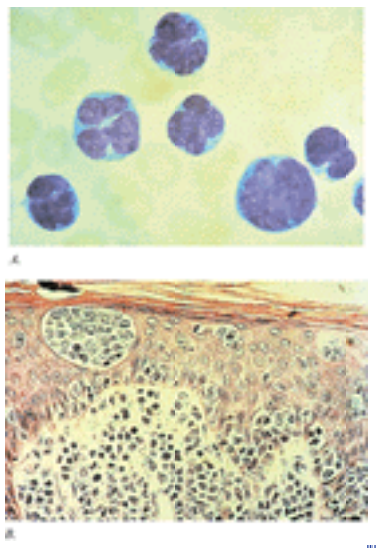

FIGURE 224-1 *A.* Abnormal lymphocyte with multilobated nucleus ("flower cell") from a patient with ATL. (*Courtesy of K Takatsuki, MD, Kumamoto University, Japan.*) *B*. ATL tumor cells are infiltrating the epidermis. (*Courtesy of B Hanchard, MD, University of the West Indies, Jamaica.*)

A striking feature in a high percentage of patients with acute ATL is refractory hypercalcemia, which may represent the first sign of the disease and indicates an aggressive course. [24], [29], [30] Patients may present with weakness, lethargy, polyuria, and polydipsia. Lytic bone lesions resembling those of multiple myeloma are often present at the time of diagnosis and levels of alkaline phosphatase may be elevated. [24], [28], [31] Parathyroid hormone levels and 1,25-dihydroxyvitamin D levels are normal in ATL patients with hypercalcemia; it had been postulated that factors produced by leukemic cells are involved in osteoclast activation, which lead to the clinical symptoms. A variety of cytokines produced by HTLV-1 infected cells and cells derived from ATL patients have been suggested to account for hypercalcemia and bone resorption in ATL patients. [24]

Based on the clinical course and laboratory parameters ATL is classified into four subtypes: (1) smoldering, (2) chronic, (3) lymphoma type, and (4) acute or prototypic ATL, for which diagnostic criteria were recently formulated (Table 224-1). [32], [33]

Smoldering ATL
5% or more abnormal lymphocytes of T cell nature in peripheral blood (PB); normal lymphocyte level (<4 ×10⁹/L; no hypercalcemia; LDH value of up to 1.5 × the normal upper limit; no lymphadenopathy; no involvement of liver, spleen, CNS, bone, and gastrointestinal tract; no ascites or pleural effusion. Skin and pulmonary lesion(s) may be present. In cases where there is less than 5%, abnormal T lymphocytes in PB, at least one histologically proven skin lesion and/or pulmonary lesions should be present.
Chronic ATL
Absolute lymphocytosis (≥4 ×10⁹/L) with T lymphocytosis > 3.5 × 10⁹/L; LDH value up to twice the normal upper limit; no hypercalcemia; no involvement of CNS, bone, and gastrointestinal tract; no ascites or pleural effusion. Lymphadenopathy and involvement of liver, spleen, skin, and lung may be present, and 5% or more abnormal T lymphocytes are seen in PB in most cases.
Lymphoma Type ATL
No lymphocytosis; ≤1% abnormal T lymphocytes; and histologically proven lymphadenopathy with or without extranodal lesions.
Acute ATL
Remaining ATL patients who usually have leukemic manifestations and tumour lesions but are not classified as any of the three other types.

TABLE 224-1 **Distinguishing Features of ATL Subtypes**

In a large series of 818 patients, 57 percent were classified as the acute type, 19 percent as the lymphoma type, 19 percent as chronic, and 5 percent as smoldering-type ATL. [32] Smoldering and chronic ATL may convert into acute ATL, which has led some authors to speak of crisis-type ATL. [28], [32]

The skin involvement in ATL varies considerably among patients but is present to a variable degree in all forms of ATL. [29], [34], [35] and [36] Skin lesions may appear as uncharacteristic erythematous patches, as papular and nodular tumors (Fig. 224-2), and as erythroderma. Nonspecific skin lesions may precede the onset of acute ATL for up to two decades. [37] Specific skin infiltrates may occur as first manifestations of ATL, and show monoclonality of skin infiltrating cells by the criteria both of T cell receptor rearrangement and integration of HTLV-1 DNA. This occurs at a time when circulating T cells of these patients still appear unaffected. [34] For this latter situation, the term *cutaneous type ATL* has been proposed. [34] It is, however, questionable whether this form represents an independent course of ATL or should be included in the smoldering form. Alternatively, it may reflect very early diagnosis of prototypic or chronic ATL, a result of improved diagnostic measures.

Diagnosis and Differential Diagnosis of ATL

Besides the characteristic clinical course of prototypic ATL, examination of the leukemic cells yields a characteristic picture: numerous multilobated cells called ATL cells or flower cells (Fig. 224-1A) are present in peripheral blood, and can usually be readily distinguished from cells of other T cell leukemias by light microscopy, although sometimes occasional cells indistinguishable from Sézary cells may be present. [24], [28], [29] In smoldering-type ATL and chronic-type ATL, multilobated cells are less frequent, and in lymphoma-type ATL they may comprise less than 1 percent of lymphocytes (Table 224-1). Monoclonal or oligoclonal integration of HTLV-1 DNA [2], [24], [34] has been demonstrated in leukemic cells, as well as in affected organs. By immunophenotyping, leukemic cells display predominantly a mature CD2+/CD3+/CD4+/CD8–/CD25+ phenotype. [24] Although most of these T cell markers can be found on other T cell malignancies, the strong expression of the IL-2 receptor alpha chain (CD25) can be regarded as distinguishing marker between ATL and Sézary syndrome. [38]

The histopathologic features seen in affected organs and lymph nodes are more variable than the picture encountered in peripheral blood, and ATL is associated with lymphomas of several histologic subtypes. Distinction of ATL from other peripheral T cell lymphomas, especially HTLV-1 positive and negative cases on morphologic grounds, cannot be accomplished. No specific pathologic finding distinguishes ATL from other forms of non-Hodgkin's lymphoma. Difficulties can also be encountered in differentiating skin involvement of ATL from mycosis fungoides (MF)/Sézary syndrome because focal epidermal infiltration by T cells or Pautrier's microabscesses (Fig. 224-1B) can be present in skin lesions of ATL. [35], [37], [39] Indeed, the diseases of patients from whom the original U.S. HTLV-1 isolates were obtained were classified as Sézary syndrome [4] and cutaneous T cell lymphoma, [3] respectively. To unequivocally establish the diagnosis of HTLV-1–associated ATL, four diagnostic criteria have been put forward: [28], [32], [33] (1) a histologically or cytologically proven lymphoid malignancy with T cell surface antigens; (2) abnormal T lymphocytes in peripheral blood except in the lymphoma type; (3) anti-HTLV-1 serum antibodies; and (4) the demonstration of clonality of HTLV-1 proviral DNA.

Prognosis and Therapy of ATL

The prognosis of ATL is largely dependent on the subtype. In the most extensive study on the course of ATL to date, 818 newly diagnosed Japanese patients were studied for a median follow-up time of 13.3 months. [27] Median survival time was 6.2 months for the acute type, 10.2 months for the lymphoma type, and 24.3 months for the chronic type. Projected 2- and 4-year survival rates were 16.7 and 5.0 percent for acute type, 21.3 and 5.7 percent for lymphoma type, 52.4 and 26.9 percent for chronic type, and 77.7 and 62.8 percent for smoldering type, respectively. The presence of hypercalcemia, high lactic acid dehydrogenase (LDH) levels, and an excessively high white blood cell count are prognostic factors [27], [32], [33], [38] associated with poor survival. Treatment of prototypic ATL is disappointing and controlled randomized studies comparing different therapeutic protocols have not been performed. Combination cytotoxic therapy used for treatments of non-Hodgkin's lymphoma has little effect on prototypic ATL and ATL lymphoma. [40] Although complete remission can be achieved in up to 40 percent of patients with different combinations of conventional chemotherapy, most of the patients relapse within weeks or months and the 4-year overall survival is below 10 percent. [40] Recently, maintenance chemotherapy with vincristine or methotrexate, prednisolone, etoposide, and cyclophosphamide (OPEC/MPEC), or with daily oral etoposide and prednisolone, was shown to improve both survival and quality of life of ATL patients. [41] Frequent complications of chemotherapy include septicemia and opportunistic infections, which are a consequence of the additive effects on the immune suppression already present in ATL patients. [24], [29], [30] Besides conventional chemotherapy the combination of alpha-interferon and zidovudine, a nucleoside analogue used in anti–HIV-1 therapy, is effective in the treatment of acute and lymphoma-type ATL. [42], [43] Allogeneic bone marrow transplantation, which has been reported in few cases of ATL, [44] as well as the combination of chemotherapy with hemopoietic growth factors, [45] might represent therapeutic options for the future. Cutaneous lesions have been treated successfully with PUVA in one patient. [46]

The course of smoldering and chronic ATL is less dramatic and involvement of inner organs and hypercalcemia are observed less frequently than in ATL lymphoma and acute ATL, [24], [27], [47] and patients have a better prognosis. [24], [27], [40], [47] Because chemotherapy-associated immunosuppression increases immunosuppression caused by the disease, early chemotherapy may be more harmful than beneficial for the patients. Consequently, patients with smoldering and chronic ATL should not be treated by chemotherapy unless they enter a more aggressive phase of their disease.

The Role of HTLV-1–Related Retroviruses in Cutaneous T Cell Lymphoma

The smoldering and the chronic subtypes of ATL can clinically and histologically mimic cutaneous T cell lymphoma (CTCL) and the first HTLV-1 isolates were obtained from patients diagnosed as MF and Sézary syndrome. [3], [4] This, together with earlier reports about the presence of retroviral particles in skin and lymph nodes of patients with these diseases, [48], [49] has incited an intensive search of HTLV-1 in CTCL. Whereas early serologic surveys for HTLV-1 in CTCL patients had revealed HTLV-1 seropositivity rates of less than 1 percent, [50] several reports recently claimed that HTLV-1 DNA sequences are detectable in tumor tissue and in cell lines derived from MF patients and in peripheral blood mononuclear cells (PBMCs) from relatives of MF patients. [51], [52] In contrast to these findings, an overwhelming majority of investigators, studying patients from the same geographic regions with comparable methods, were unable to find HTLV-1 DNA in CTCL samples, [53], [54], [55], [56], [57], [58], [59] and [60] and it is now well accepted by most that HTLV-1 is not involved in the pathogenesis of CTCL.

Neurologic Disease

HTLV-1 infection is associated with chronic progressive myelopathies, which is referred to as tropical spastic paraparesis (TSP) in the Caribbean and HTLV-1–associated myelopathy (HAM) in Japan. [61] Patients suffering from TSP/HAM are generally younger than ATL patients and the latency from infection to development of clinical neurologic symptoms has been described to be very short in individual cases. [62] The lifetime risk to develop HAM/TSP has been estimated at 1 percent. [63] In contrast to ATL, which is associated with HTLV-1 infection very early in life, TSP/HAM patients frequently become infected only in adolescence. In particular, the acquisition of HTLV-1 by blood transfusion has been reported to play an important role for TSP/HAM development. [64]

Infective Dermatitis

Infective dermatitis (Fig. 224-3) is a severe, chronic, relapsing eczema in Jamaican children [65] associated with infection by *Staphylococcus aureus* and beta-hemolytic streptococcus. [66] The association of infective dermatitis with HTLV-1 infection was recently reported. [67] Bacterial infection in infective dermatitis is difficult to control and although it responds to antibiotic treatment, prolonged therapy is necessary and relapses are common after discontinuation. [67] The characteristic clinical picture, the recalcitrant course, and HTLV-1 seropositivity sets infective dermatitis apart from other forms of recurrent eczema, including from atopic eczema. [68] Immunosuppression observed by other investigators in HTLV-1 carriers, as well as in ATL patients, [29], [69], [70] may play a role in the pathogenesis of infective dermatitis. Whereas HTLV-1–infected individuals are overrepresented among patients hospitalized for infectious diseases in Japan, [70] infective dermatitis has been rarely reported from regions outside the Caribbean. [71] Regional, cultural, or genetic factors may play an additive role in the occurrence of infective dermatitis. Evidence that infective dermatitis in childhood might be associated with subsequent development of ATL [72] comes from a recent report on a patient who developed ATL 17 years after having been diagnosed as infective dermatitis in Jamaica. [73]

Other Disorders

Besides the above diseases, certain types of uveitis, [74] polymyositis, [75] chronic inflammatory arthropathy, [76] and peripheral neuropathy [77] have been suggested to be associated with HTLV-1 infection. However, future epidemiologic and virologic studies will be necessary to establish the causative role of the virus in the pathogenesis of these diseases.

REFERENCES

Cutaneous disorders occur nearly universally during the course of human immunodeficiency virus (HIV) disease as a result of the acquired immunodeficiency or are related to treatment. Dermatologic manifestations of HIV disease are a very broad and diverse spectrum. [1] Individuals who have access to highly active antiretroviral therapy (HAART), in most cases those living in North America, western Europe, and Australia, have a markedly altered course of HIV disease if immune restoration is achieved. [2] In most cases, there is a marked reduction in the incidence of opportunistic infections (OIs) and neoplasms (ONs). Globally, however, more than 95 percent of HIV-infected individuals have no access to any medical interventions, and subsequently, many of the cutaneous manifestations associated with HIV disease become chronic and progressive. An estimated 60 million individuals had become infected by the year 2000.

EPIDEMIOLOGY

HIV is a lymphotropic human retrovirus. HIV-1 is the cause of nearly all HIV infection in the United States and Europe; HIV-2 infection has been detected mainly in West Africa. HIV is a blood-borne pathogen, transmitted by sexual contact with an infected person, significant exposures to infected blood or blood products, including needles shared among injecting drug users (IDUs), and perinatally from an infected mother to her child. Both types cause similar clinical HIV disease. HIV-1 has at least 10 subtypes, designated A through J. Subtype B is prevalent in the United States and western Europe and is found mainly among men who have sex with men (MSM) and IDUs. Subtype E—unlike subtype B—is spread very efficiently through heterosexual intercourse.

PATHOGENESIS

Four mechanisms are critical for the establishment and propagation of HIV infection over time and for the progression of HIV disease. HIV is not eliminated after primary infection. Persistent virus replication occurs in lymphoid organs throughout the course of HIV infection. Chronic stimulation of the immune system causes inappropriate immune activation and progressive exhaustion of the immune response. Destruction of lymphoid tissue results in severe impairment of the ability to maintain an effective ongoing HIV-specific immune response and to generate immune responses against new pathogens. Epidermal Langerhans cells (LCs) may become infected by HIV; decreased LC function could account for some of the cutaneous manifestations of HIV disease. [3]

NATURAL HISTORY

HIV disease is a continuum that progresses from primary infection to death, with a sequence of OIs and ONs marking the gradual destruction of the immune system (Table 225-1). Medically, the acquired immune-deficiency syndrome (AIDS) is defined by precise clinical and laboratory parameters. In an individual whose HIV status is unknown or inconclusive and who has no other cause for immunodeficiency, the following mucocutaneous findings are AIDS-defining: *candidiasis* of the esophagus, trachea, bronchi, or lungs (however, not oropharangeal candidiasis alone); *cryptococcosis* with hematogeneous dissemination to skin; *herpes simplex virus mucocutaneous ulcer* that persists longer than 1 month; and *Kaposi's sarcoma* in a patient younger than 60 years of age. In an individual who is HIV-seropositive, the following are AIDS-defining: *coccidioidomycosis* or *histoplasmosis* with hematogenous dissemination to skin and *Kaposi's sarcoma* at any age.

TABLE 225-1 **Stages of HIV Disease**

ACUTE RETROVIRAL SYNDROME (ARS)/PRIMARY HIV INFECTION

The incubation period (from presumed exposure to development of acute febrile illness) ranges from 3 to 6 weeks, varying with the route of infection and the size of the viral inoculum. Commonly reported clinical manifestations include fever (>80–90 percent), fatigue (>70–90 percent), rash (morbilliform, papulosquamous, vesicular on the upper trunk, palms, and soles) (50–60 percent) (Fig. 225-1), myalgia/arthralgia (50–70 percent), pharyngitis (50–70 percent), night sweats (50 percent), and/or nausea, vomiting, and diarrhea (30–60 percent). Less commonly reported manifestations include decreased white blood cell count/platelet count (40–45 percent), weight loss (25 percent), aseptic meningitis (24 percent), anorexia (21 percent), abnormal liver function tests (20 percent), oral ulcers (10–20 percent), and/or genital ulcers (5–15 percent). [4] The laboratory diagnosis of HIV-1 infection is made by four methods: detection of viral antigens, detection of viral nucleic acids, identification of antibodies to viral proteins, and isolation of HIV by viral culture. A delay of 3 to 4 weeks exists between newly acquired HIV-1 infection and development of antibodies, the “window period.” The core structural protein p24 antigen can be detected a week before antibodies can be measured.

FIGURE 225-1 Acute retroviral syndrome: exanthem. Discrete, erythematous macules and papules on the trunk and arm; associated findings were fever, scrotal ulcers, erythematous macules on palate, and lymphadenopathy.

COURSE AFTER ARS

Following the initial burst of viral replication and the peak of viremia, the plasma RNA level decreases and then stabilizes to a level called the *viral set point*. The maximum or peak viral load, the duration of the viral burst, the viral replicative half-life, and the host immune response all influence the viral set point. Antiretroviral intervention has several possible effects on the kinetics of the acute phase of infection. The peak viral load may be reduced without affecting the viral set point, or the peak load may not be affected, but the duration of the viral burst may be shortened with reduction in the viral set point. Cytotoxic T lymphocytes, particularly those specific for Env, help control viral replication and are associated with slower declines in CD4+ cell counts. [5] Approximately 6 months after transmission of HIV, the plasma HIV RNA level reaches a relatively stable set point that dictates the subsequent course. Patients with high viral concentrations (viral load), such as 100,000 or more copies per microliter, will have a relatively rapid course, and those with relatively low concentrations, such as 10,000 copies per microliter, will have relatively slow progression. Undetectable viral load levels may correspond with nonprogression of HIV disease. The average annual decrease in CD4+ cell count is 50 cells per microliter. Early treatment with antiretroviral drugs may reduce the viral set point and alter the prognosis of HIV infection.

Multiple variables are known to influence the rate of progression of HIV disease, contributing to induction of HIV expression, and potentially modify and accelerate the course of HIV disease: size of HIV inoculum, the site of infection,

immune status of the host, variable virulence of certain HIV strains, and reactivation of latent herpesvirus infection. In a cohort of HIV-infected homosexual males from San Francisco studied prior to effective antiretroviral drug therapy, approximately 50 percent developed AIDS within 11 years of becoming infected. Similar data have been reported in other risk groups in the United States. In a cohort of HIV-infected persons from North America, Europe, and Australia whose date of seroconversion was known, the incubation time to the development of an AIDS-defining event varied with the various risk groups, possibly because of different exposures to potential opportunistic pathogens. [6] The rate of disease progression is more rapid in developing nations that cannot afford any medical therapies than in industrialized countries.

ANTIRETROVIRAL DRUG THERAPY (ART) AND HIGHLY ACTIVE ANTIRETROVIRAL THERAPY (HAART)

The three main groups of antiretroviral drugs are nucleoside analogue reverse transcriptase (RT) inhibitors (NRTIs), nonnucleoside RT inhibitors (NNRTIs), and proteinase inhibitors (PIs). Nucleoside analogues that inhibit HIV RT slow or prevent formation of DNA copies of HIV in infected cells. Like the nucleoside analogues, NNRTIs inhibit RT, but by a different mechanism; their toxicity and resistance patterns do not overlap with the nucleosides. PIs prevent cleavage of protein precursors essential for HIV maturation, infection of new cells, and replication. Therapy with PIs in individuals with advanced HIV disease has led to marked clinical improvement and prolonged survival. All PIs can cause hyperglycemia and worsening of diabetes mellitus. NRTIs include zidovudine (ZVD, AZT), didanosine (ddI), zalcitabine (ddC), stavudine (d4T), lamivudine (3TC]), and abacavir. NNRTIs include nevirapine, delavirdine, and efavirenz. PIs include saquinavir, ritonovir, indinavir, nelfinavir, amprenavir, and lopinavir.

MUCOCUTANEOUS FINDINGS

OIs, ONs, dermatoses, adverse cutaneous drug reactions, and pruritus involving skin and/or mucosa occur more commonly as immune function deteriorates, being problematic in more than 90 percent of HIV-infected individuals. Correlated with low CD4 cell counts, cutaneous lesions may become quite atypical. Certain cutaneous disorders correlate with low CD4 cell counts (200–300 cell/µL), including Kaposi's sarcoma, oral hairy leukoplakia, multiple facial molluscum contagiosum, xerosis, and oropharyngeal candidiasis. Mucocutaneous disorders (see Table 225-2) are commonly the indication for initial HIV testing.

Highly indicative of HIV infection (correlated with risk factors for HIV infection)
• Exanthem of acute retroviral syndrome
• Proximal subungual onychomycosis
• Chronic herpetic ulcers
• Oral hairy leukoplakia
• Kaposi's sarcoma
• Eosinophilic folliculitis
• Molluscum contagiosum, multiple facial in adult
Strongly associated with HIV infection (correlated with risk factors for HIV infection)
• Any sexually transmitted disease (indicative of "unsafe" sexual practice)
• Herpes zoster
• Signs of injecting drug use
• Candidiasis: oropharyngeal or recurrent vulvovaginal
May be associated with HIV infection (correlated with risk factors for HIV infection)
• Generalized lymphadenopathy
• Seborrheic dermatitis (extensive, refractory to therapy)
• Aphthous ulcers (recurrent, refractory to therapy)

TABLE 225-2 **Mucocutaneous Disorders as Indications for HIV Serotesting**

Immune restoration syndrome is defined by manifestations of HIV disease, which may worsen despite an adequate response to HAART, as measured by an increase in CD4 cell counts and a decrease/disappearance of serum HIV RNA. With progressive HIV disease, T_H2 immune responses dominate, facilitating development of many dermatologic disorders. With HAART, T_H1 responses are restored, and some skin disorders regress; however, some conditions may worsen, such as VZV infections, HSV infections, eosinophilic folliculitis (EF), HPV infections, and mycobacterial infections. [8] These seemingly paradoxical responses may occur as the host's immune responses recognize silent or latent infections. [9]

CUTANEOUS DISORDERS OCCURRING IN HIV DISEASE

Pruritus and Pruritic Eruptions of HIV Disease

Pruritus, a common complaint in patients with late symptomatic and advanced HIV disease, is a surrogate cutaneous marker for disease progression, occurring commonly in patients with CD4 counts of less than 50 cells per microliter compared with those with counts greater than 250 cells per microliter. In most cases, primary or secondary dermatoses rather than metabolic disorders are the cause of pruritus. [10] The differential diagnosis of primary pruritic skin disorders includes EF, adverse cutaneous drug eruptions, atopic dermatitis, xerosis, dermatographism, allergic contact dermatitis, scabies, and insect bites. [11] Much less commonly, systemic and metabolic disorders such as lymphoma, renal failure, viral hepatitis (hepatitis B or C), and obstructive liver disease are associated with pruritus in the absence of cutaneous findings, i.e., “metabolic” pruritus.

An atopic diathesis may become manifest in individuals with advanced HIV disease and pruritus. Changes secondary to chronic rubbing and scratching include excoriations, atopic dermatitis, lichen simplex chronicus, and prurigo nodularis. Secondary *Staphylococcus aureus* infection (impetiginization, furunculosis, or cellulitis) is very common in any of these traumatized lesions. Ichthyosis vulgaris and xerosis are common in advanced HIV disease and may be associated with mild pruritus. PIs (especially indinavir) frequently cause xerosis with or without eczematous dermatitis, which may be associated with mild or moderate pruritus (see “ Adverse Cutaneous Drug Reactions” below). These changes occur relatively soon after initiation of therapy, presenting xerosis (dry skin) with or without eczematous dermatitis or nummular

eczema.

Eosinophilic Folliculitis

EF is a chronic pruritic dermatosis occurring in persons with advanced HIV disease. It may occur in the immune restoration syndrome. The etiology and pathogenesis are unknown but may be associated with a T_H2 immune response to an unknown antigen. [12] Clinically, small pink to red, edematous, folliculocentric papules (and much less commonly pustules) occur symmetrically above the nipple line on the chest (Fig. 225-2), proximal arms, head, and neck. Secondary changes include excoriations, excoriated papules, lichen simplex chronicus, and prurigo nodularis, as well as secondary *S. aureus* infections. In individuals with darker skin, postinflammatory hyperpigmentation often produces significant cosmetic disfigurement. Once significant immune restoration has been achieved, EF resolves. Histologic findings are specific for EF; peripheral eosinophilia is common, in some cases up to 35 percent.

FIGURE 225-2 Eosinophilic folliculitis. Multiple erythematous pruritic papules and a few pustules on the upper back in an individual with a CD4 cell count of 50/µL.

The most effective therapy for EF is prednisone. Beginning with an initial dose of 70 mg PO, prednisone is tapered by 10 or 5 mg over 7 or 14 days; established lesions resolve, new lesions do not occur, and pruritus resolves. In the majority of persons with successfully treated EF, lesions and pruritus recur within a few weeks after prednisone has been discontinued. In those with severe symptoms, prednisone can be given on alternate days or weekly. Oral isotretinoin is effective and safe in treatment of EF, usually 40 mg bid until lesions and symptoms resolve, then tapered to 40 mg daily for several weeks, and then to 20 mg daily or 40 mg qod. [13] Isotretinoin can raise serum triglyceride levels, which are often high in HIV-infected persons; serum lipids should be monitored regularly. Phototherapy with ultraviolet radiation (UVR), using ultraviolet A (UVA) or UVB with or without topical or systemic psoralen, is considered to be a safe topical treatment modality in HIV-infected persons. [14] UVR does not appear to have a significant deleterious effect on HIV viral load. [15] High-potency topical corticosteroid preparations may reduce the formation of new EF lesions as well as treat eczematous dermatitis, thus providing symptomatic relief; cutaneous atrophy is of concern with chronic application. Topical tacrolimus or pimecrolimus may be effective. Sedating antihistamines such as doxepin are most effective for symptomatic control of nocturnal pruritus; nonsedating antihistamines are ineffective in controlling pruritus.

Psoriasis Vulgaris (See Chap. 42)

The prevalence of psoriasis vulgaris and psoriatic arthritis is increased in HIV disease. The onset of psoriatic lesions may be prior to or following HIV infection. Onset of psoriasis in an individual at risk for HIV disease may be an indication for HIV serotesting. Psoriasis with onset following HIV infection has been observed to improve more with HAART than that with onset prior to HIV infection. For management of psoriasis vulgaris, see Chap. 42. Short-term administration of retinoids such as isotretinoin or acetretin is usually safe. Potential hyperlipidemia is more likely in HAART-treated individuals. Etanercept has been effective for psoriasis/psoriatic arthritis in HIV disease but is associated with infections. [16]

Erythroderma (See Chap. 44)

Erythroderma in HIV disease may be related to drug hypersensitivity, atopic dermatitis, psoriasis vulgaris, photosensitivity dermatitis, the hypereosinophilic syndrome, coexisting human T-cell lymphotrophic virus-I (HTLV-I) infection, or cutaneous T cell lymphoma. [17]

Pigmentary Disorders

Postinflammatory hyper- and hypopigmentation are the most common disorders affecting HIV-infected individuals. With the exception of light-skinned individuals of northern European heritage, significant lightening or darkening of skin occurs following any type of inflammatory dermatosis or infection. In addition to pigmentary alterations, significant atrophic or hypertrophic scarring can follow herpes zoster. This alteration in normal skin color results in significant cosmetic disfigurement, especially when it occurs on highly visible sites such as the face, neck, and upper extremities. If the dermatosis is chronic, the pigmentary change can become persistent and progressive. If the dermatosis resolves, the pigmentary disorder can take months to years to fade gradually to uniform pigmentation. The primary goal in management of these pigmentary disorders is to treat the primary skin disorder. Topical preparations containing 4% hydroquinone may be helpful in treating postinflammatory hyperpigmentation.

Photosensitivity (See Chap. 135 and Chap. 136)

Idiopathic photosensitivity is an uncommon phenomenon in HIV disease but may be the presenting complaint of advanced disease [18] (Fig. 225-3). The most common types of photosensitivity in HIV disease are related to drug therapy.

FIGURE 225-3 Chronic actinic dermatitis. Eczematous dermatitis and hyperpigmentation in the sun-exposed sites of the face, neck, and dorsum of the hands of a 50-year-old black male; no exogenous photosensitizing agents could be identified.

CUTANEOUS MANIFESTATIONS OF SYSTEMIC DISORDERS OCCURRING IN HIV DISEASE

Porphyria cutanea tarda (PCT) in HIV disease is most often associated with an underlying hepatopathy, i.e., hepatitis C virus (HCV) infection, alcoholism, or hepatitis B virus infection. Pseudoporphyria occurs in the absence of abnormalities of porphyrin metabolism and usually is drug-induced.

Cutaneous and systemic vasculitis of many etiologies has been reported to occur in HIV disease, including adverse cutaneous drug reaction, cytomegalovirus infection, polyarteritis nodosa, lymphomatoid granulomatosis, Kawasaki syndrome, and possibly HIV infection itself. [19], [20] Causative drugs should be discontinued if possible. Most other causes are not specifically treatable. Systemic immunosuppressive therapy may be indicated in some cases.

DISORDERS OF THE OROPHARYNX

Nearly all HIV-infected individuals experience disorders of the oropharynx during the course of the disease. [21] Oropharyngeal disorders have been reported to be the first sign of HIV disease in 10 percent of cases, and their detection may be an indication for HIV serotesting. In a study of oropharyngeal disorders (103 consecutive patients with late symptomatic and advanced HIV disease), candidiasis was the most common finding, diagnosed in more than 90 percent. [22] Other disorders of the lips and oropharynx included herpetic ulcers (10 percent), xerostomia (10 percent), exfoliative cheilitis (9 percent), oral hairy leukoplakia (7 percent), Kaposi's sarcoma (4 percent), patchy depapillation of the tongue (6 percent), and ulcers of uncertain cause (3 percent).

Oropharyngeal Candidiasis

(See “ Candidiasis” below)

Oral Hairy Leukoplakia (OHL)

OHL, a lesion specific to HIV disease caused by Epstein-Barr virus, has been reported in up to 28 percent of HIV-infected patients and is a marker for disease progression. [24] In a study of HIV-associated mucocutaneous disorders in 456 patients (1982–1992), [24] OHL was diagnosed in 16 percent of cases when the median CD4 cell count was 235 cells per microliter. Median survival time after OHL diagnosis was 20 months. In patients with a CD4 cell count of 300 or more cells per microliter, the detection of OHL was associated with shorter median survival time of 25 months compared with 52 months in those without the finding. OHL presents as a hyperplastic, whitish epithelial plaque(s) on the lateral tongue with corrugations accentuating the normal tongue ridges, usually bilateral but not symmetric (Fig. 225-4). The differential diagnosis includes hyperplastic oral candidiasis, HPV-induced neoplasia [condyloma acuminatum, squamous intraepithelial lesion (SIL) squamous cell carcinoma in situ (SCCIS), or invasive SCC], geographic tongue, lichen planus, tobacco-associated leukoplakia, mucous patch of secondary syphilis, and occlusive trauma. The diagnosis of OHL is usually made on clinical findings; however, if the diagnosis is uncertain, confirmatory lesional biopsy is advised. For the most part, OHL is asymptomatic, but its presence may be associated with some degree of anxiety. With HAART, OHL usually either does not occur or resolves without additional interventions.

FIGURE 225-4 Oral hairy leukoplakia. White plaques with vertical corrugations on the inferolateral aspect of the tongue. The lesions are fixed, as compared with those of thrush, which can be brushed off with a gauze pad.

Aphthous Ulcers

(See Chap. 112)

Neoplasms

Kaposi's sarcoma (KS) commonly occurs on the palate, gingiva, and tongue. Untreated, KS can evolve into large nodular lesions and ulcerate. Oral presentations of non-Hodgkin's lymphoma usually occur on the palate, gingiva, or consular area. HPV-induced SCC, both in situ and invasive, arises on the buccal mucosa, tongue, and palate.

OPPORTUNISTIC NEOPLASMS (ONs)

The prevalence of the ONs including KS, [25] HPV-induced neoplasia [squamous intraepithelial lesion (SIL), squamous cell carcinoma in situ (SCCIS), and invasive SCC of the cervix, external anogenitalia, and perineum], undifferentiated non-Hodgkin's B cell lymphoma (NHL), and primary CNS lymphoma, is increased in HIV disease. [26] The incidence of nonmelanoma skin cancer, Hodgkin's lymphoma, T cell lymphomas, and seminoma also may be increased. Many of these ONs (NHL, KS, and anogenital in situ and invasive SCC) are associated with oncogenic human viruses (Epstein-Barr virus, HHV-8, HPV) and diminished immune-mediated tumor surveillance.

Nonmelanoma Skin Cancer

The prevalence of UVR-induced SCC appears to be increased in HIV disease, as it is in immunosuppressed renal transplant recipients; as with transplant recipients, UVR-induced SCC in HIV disease may be more aggressive than in the immunocompetent host. [27], [28] Risk factors for the development of SCC and basal cell carcinoma (BCC) were fair skin and excessive sun exposure (>6 h per day during the previous 10 years). SCCs were diagnosed more commonly in individuals with advanced HIV disease than were BCCs. HPV was not an oncogenic factor in the development of these cutaneous tumors; however, p53 overexpression was hypothesized to play an etiologic role. As in immune-suppressed transplant recipients, the incidence of Merkel cell carcinoma may be increased in HIV-infected individuals. [29]

HIV-Associated KS

(See Chap. 104) [30]

HPV-Induced Dysplasias and Cancers

(See " Human Papillomavirus Infection" below)

ADVERSE CUTANEOUS DRUG ERUPTIONS (See Chap. 138)

The incidence of adverse cutaneous drug eruptions (ACDEs) to a variety of drugs is high in HIV disease (100 times more common than in the general population) and increases with advancing immunodeficiency. [31] Drug hypersensitivity complicated 3 to 20 percent of all prescriptions in one large series. In a report of 974 HIV-infected individuals followed for 46 months, 283 ACDEs occurred in 201 patients. [32] ACDEs were noted more commonly in white than in black individuals. The onset of a majority of ACDEs was within 6 to 14 days of initiation therapy. Trimethoprim-sulfamethoxazole (TMP-SMZ), other sulfonamide drugs, and penicillins were the causative agents in 75 percent of cases of ACDE. Exanthematous/morbilliform eruptions were by far the most common ACDEs, occurring in 95 percent of cases; other ACDEs observed were urticaria (4 cases), erythema multiforme (EM, 8 cases; EM major, 2 cases; EM minor, 6 cases), lichenoid eruption (1 case), and fixed drug eruption (2 cases). Systemic symptoms were reported in 20 percent of cases, including fever, headache, myalgia, and arthralgia. In most cases, the implicated or suspected drug should be discontinued. In some, such as with morbilliform eruptions, the offending drug can be continued, and the eruption may resolve. In cases of urticaria/angioedema or early Stevens-Jones Syndrome (SJS)/toxic epidermal necrosis (TEN), the ACDR can be life-threatening, and the drug should be discontinued.

Between 50 and 60 percent of HIV-infected individuals treated with intravenous TMP-SMZ develop an exanthematous eruption (often associated with fever) (Fig. 225-5) 1 to 2 weeks after starting therapy, an incidence 10 times greater than that in the general population. Successful desensitization has been accomplished in patients with prior exanthematous/morbilliform or urticarial reactions to TMP-SMZ, sulfadiazine, and dapsone. [33] Desensitization in patients with prior SJS also has been reported. [34] Coadministration of corticosteroids with TMP-SMX reduced the incidence of adverse cutaneous reactions from 47 to 13 percent. [35] The occurrence of ACDRs to TMP-SMZ also has been noted to be associated with more rapid decline in CD4 cell counts. Severe bullous eruptions appear to be more common in HIV disease. In a report of 6 cases of EM major and 6 of TEN, all adverse reactions were to sulfonamides: sulfadiazine (6 cases), TMP-SMZ (2 cases), and sulfadoxine-pyrimethamine (Fansidar) (2 cases). [36] Of 14 cases of TEN over a 6-year period (1984–1989), sulfa drugs were the most common causative agents. [36] The number of cases of TEN was 375 times that expected. TEN occurred in patients with advanced HIV disease and had a 21 percent mortality rate.

FIGURE 225-5 Adverse cutaneous drug eruption: trimethoprim-sulfamethoxazole. A typical exanthematous eruption occurred on the trunk on the tenth day after initiation of therapy with the drug.

Oral corticosteroid therapy in HIV-infected individuals raises concerns regarding increased immunosuppression with exacerbations of opportunistic infections and neoplasms such as Kaposi's sarcoma or HSV infections. A cohort of 44 asymptomatic HIV-infected individuals (200–799 CD4 cells/µL) was treated with oral prednisolone (0.5 mg/kg for 6 months; 0.3 mg/kg therafter). After 1 year of prednisolone therapy, no major side effects or HIV disease–related events had occurred. Serum p24 antigen and HIV RNA load levels remained stable; CD4 cell counts increased significantly at all time points (median increase at 1 year 119 cell/µL). A more recent study concluded that short-term prednisone was well-tolerated and reasonably safe. [37] Short-term oral corticosteroid therapy appears to be safe in most HIV-infected individuals.

Antiretroviral Agents

Antiretroviral therapy (ART) has a significant incidence of ACDRs, including hypersensitivity reactions, the lipodystrophy syndrome, and drug interactions. [38] Drug hypersensitivity commonly occurs with the nonnucleoside reverse-transcriptase inhibitors (NNRTIs) nevirapine, delavirdine, and efavirenz; the NRTI abacavir; and the PI amprenavir. [31] Approximately half the cases of antiretroviral hypersensitivity resolve despite continuation of therapy. Drug therapy should be discontinued if the following occur: mucosal involvement, blistering, exfoliation, clinically significant hepatic dysfunction, fever greater than 39°C (102.2°F), or intolerable fever or pruritus.

NRTIs currently available include zidovudine, didanosine, lamivudine, zalcitabine, and stavudine. Zidovudine (ZVD)–treated individuals (more commonly blacks than Latinos or whites) experience longitudinal melanonychia with brown-black longitudinal streaks in the nail plate (up to 40 percent of those treated). The pigmentary changes are usually noted in the finger- and/or toenails within 4 to 8 weeks after initiation of ZVD therapy but may occur as late as 1 year later. ZVD pigmented macules of mucous membranes is also common, occurring more commonly in more heavily melanized individuals. Diffuse hyperpigmentation mimicking primary adrenal insufficiency has been reported. Melanonychia and mucocutaneous pigmentation also have been reported with hydroxyurea in HIV disease. [39] Other ZVD ACDRs include hypertrichosis, hypersensitivity, leukocytoclastic vasculitis, and paronychia. Didanosine has few reported ACDRs, which include vasculitis and SJS, systemic adverse effects include pancreatitis and peripheral neuropathy. ACDRs to lamivudine are also uncommon. Zalcitabine may cause aphthous-like ulcers of the oropharynx and esophagus and drug hypersensitivity (2 percent). Rechallenge with abacavir has been associated with several deaths. [40]

NNRTIs currently in use include nevirapine, delavirdine, and loviride. Nearly 20 percent of nevirapine-treated patients experience rash, most commonly an exanthematous eruption and rarely SJS. Nevirapine causes rash in 9 to 32 percent of treated individuals in the first 4 to 6 weeks of therapy; SJS occurs in 1 percent of treated individuals. [41] Drug hypersensitivity syndrome also has been reported. [42] In addition, 18 to 50 percent of delavirdine-treated patients experience rash.

PIs, including indinavir, saquinavir, nelfinavir, and amprenavir, are commonly associated with ACDRs, including lipodystrophy, hypersensitivity reaction, and acute generalized exanthematous pustulosis. Indinavir, which has a retinoid-like effect, caused cheilitis (57 percent); diffuse dryness and pruritus (41 percent); asteatotic dermatitis on the trunk, arms, and thighs (12 percent); and defluvium of the scalp (12 percent) and other sites. Paronychia and pyogenic granuloma, single or multiple, also were reported. Symptoms resolved when indinavir was discontinued. Peripheral lipodystrophy syndrome occurred in 14 percent of subjects. Other ACDRs include acute porphyria, hypersensitivity syndrome, SJS, “frozen shoulder,” and venous thrombosis. [38] Nelfinavir causes a morbilliform eruption in 3 to 28 percent of treated individuals and, less commonly, urticaria. [43]

Lipodystrophy Syndrome

During the past few years, lipodystrophy syndrome (LDS) has been associated with PI therapy. [38], [44], [45] and [46] The HIV-related LDS is characterized by abnormal fat distribution: lipohypertrophy with central obesity, cushingoid habitus (“buffalo hump”), increased neck girth (Fig. 225-6), increased abdominal girth associated with increase intraabdominal fat (protease paunch, “crix belly”), and breast enlargement. Lipoatrophy of subcutaneous fat produces a pseudoathletic appearance, manifested on the face (Fig. 225-7) and extremities as a prominent venous pattern and musculature. Additional findings include insulin resistance, hyperglycemia, and hypertriglyceridemia. [47] Of note, not all components are present in all patients, such that there is significant variability and heterogeneity in presentation. In a study of 581 patients (61 percent were treated with PIs), the overall prevalence of lipodystrophy was 38 percent, of fat wasting 16

percent, of peripheral fat accumulation 12 percent, and of mixed syndromes 10 percent. [48] The prevalence of metabolic abnormalities was 49 percent for lipid disorders and 20 percent for glucose disorders. The pathogenesis of LDS is not known; it is hypothesized that the phenomenon occurs as a result of immune restoration or a metabolic adverse effect of the PI. Discontinuation or replacement of PI therapy does not result in reversal of dysmorphic changes in most persons. [49] Liposuction has been used to treat the buffalo hump, but the result is most often unsatisfactory. Facial lipoatrophy has been treated with fat transfer from the abdominal panniculus and injection or insertion of various inert agents, again with limited cosmetic success.

FIGURE 225-6 Lipohypertrophy. The subcutaneous fatty tissue of the cervicothoracic region as well as the preauricular cheeks and neck are strikingly enlarged in an otherwise thin male. Liposuction improved his appearance to some degree.

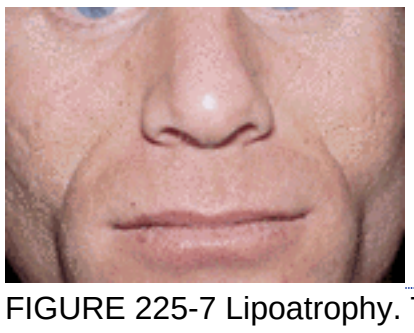

FIGURE 225-7 Lipoatrophy. The cheeks are hollowed, secondary to loss of subcutaneous fat, causing a significant cosmetic concern for the patient. The lipoatrophy remained in spite of a 20-lb weight gain.

OPPORTUNISTIC INFECTIONS

Opportunistic infections (OIs) of the skin and mucosa occurring in HIV disease for the most part represent overgrowth of resident flora (*Candida albicans*), extension beyond sites of colonization (dermatophytosis), reactivation of latent infection (human herpesviruses), or transformation of subclinical to clinical infection (HPV, MCV). The natural history of OIs has changed during the past 5 years, related to HAART and more effective therapies of infections. In individuals responding to HAART, the incidence of all OIs, with the exception of HPV infections, is markedly reduced. [50] OIs continue to be frequent, occurring in more advanced and/or untreated HIV disease.

BACTERIAL INFECTIONS

Staphylococcus aureus is the most common bacterial pathogen causing cutaneous and systemic infections in HIV disease. An increased prevalence of *S. aureus* carriage in the nares and perineum has been noted in asymptomatic and symptomatic HIV-infected individuals (up to 50 percent). Prophylaxis with agents such as TMP-SMX and clarithromycin is associated with a decreased nasal carrier rate as well as a reduced rate of infections. Primary cutaneous infections or secondarily infected dermatoses or breaks in the epidermal integrity usually occur in chronic *S. aureus* carriers. No unique staphylococcal infections occur in HIV disease. Rather, a wide range of *S. aureus* pyodermas and soft tissue infections do occur, the incidence increasing with the degree of immune deficiency. Primary staphylococcal infections include impetigo, bullous impetigo, and ecthyma; folliculitis; furuncles, and carbuncles; cellulitis; botryomycosis; and pyomyositis. Secondary infection of underlying dermatoses and superinfections occur commonly in persons with chronic atopic (eczematous) dermatitis that may be associated with elevated IgE levels, excoriations, herpetic ulcers, Kaposi's sarcoma, molluscum contagiosum (MCV), scabies, injection sites in injecting drug users, and intertrigo. Staphylococcal bacteremia may complicate either primary or secondary cutaneous infections (psoriasis or scabies); however, the most common site for hematogenous dissemination is the intravenous catheter, the source of 73 percent of cases of bacteremia. As with the majority of infections in HIV disease, staphylococcal infections tend to be recurrent. Management (see Chap. 194) should be directed at the acute infection, eradication of any underlying dermatoses, eradication of nasal carriage of *S. aureus* with mupirocin (pseudomonic acid) ointment, and chronic oral prophylaxis for recurrent infections.

Helicobacter cinaedi causes a syndrome characterized by fever, bacteremia, and recurrent and/or chronic cellulitis (resembling erythema nodosum) in compromised patients. [51] The organism is carried as bowel flora in 10 percent of homosexual men (no carriage in other groups). Diagnosis is made by considering it in immunocompromised individuals, demonstrating cellulitis on lesional biopsy (excluding panniculitis), and failure to isolate other pathogens. Bacteremia is intermittent; the organism is difficult to isolate, requiring hydrogen in the culture vial.

Pseudomonas aeruginosa causes primary infections such as cellulitis (i.e., ecthyma gangrenosum), infection at catheter sites, and secondary infection of underlying disorders such as Kaposi's sarcoma in advanced HIV disease. Cutaneous *P. aeruginosa* infection occurs by local invasion, gaining entry through breaks in the skin or by primary infection of skin appendages in the anogenital or axillary regions, or by hematogenous dissemination to the skin. Cutaneous pseudomonal infection may extend into the bloodstream, with resulting bacteremia and seeding of many organ systems.

Tuberculosis is the most common opportunistic infection in HIV disease in developing countries; cutaneous tuberculosis, however, is relatively uncommon. In non-HIV-infected persons with tuberculosis, the incidence of extrapulmonary tuberculosis is 15 percent; in HIV disease, 20 to 40 percent. In advanced HIV disease, the incidence of extrapulmonary disease increases to 70 percent. *Mycobacterium* spp. other than tuberculosis (MOTT) (a.k.a. environmental mycobacteria: *M. chelonae, M. fortuitum, M. kansasii, M. malmoense, M. gordonae, M. marinum,* and *M. hemophilum*) have been reported to cause cutaneous lesions in HIV disease. The most common MOTT agent in advanced HIV disease is *M. avium-intracellulare* complex (MAC); however, this rarely presents with cutaneous infection. The incidence of MAC infections has fallen with primary prophylaxis with azithromycin and, more recently, with HAART.

Bacillary angiomatosis (BA) and bacillary peliosis (BAP), caused by *Bartonella henselae* and *B. quintana,* occur most commonly in the setting of advanced HIV-induced immunodeficiency, characterized by angioproliferative lesions resembling cherry hemangiomas, pyogenic granulomas, or Kaposi's sarcoma. [52] Currently, the prevalence of BA in North America and western Europe is very low due to improved immune function with HAART and to prophylaxis given for infections such as MAC. Clinically, the cutaneous lesions of BA are red to violaceous, dome-shaped papules, nodules, or plaques resembling Kaposi's sarcoma and ranging in size from a few millimeters up to 2 to 3 cm in diameter (dermal vascular lesions with thinned or eroded epidermis) (Fig. 225-8). Less commonly, domed subcutaneous masses occur without the characteristic red color of more superficial vascular lesions. [53] Lesions are soft to firm and may be tender to palpation. The number of lesions ranges from solitary lesions to more than a 100 and, rarely, greater than 1000. Nearly any cutaneous site may be involved, but the palms, soles, and oral cavity are usually spared. Following hematogenous or lymphatic dissemination, the spectrum of internal disease caused by *B. henselae* and *B. quintana* includes soft tissue masses, bone marrow, lymphadenopathy, splenomegaly, and hepatomegaly; internal involvement can occur with or without cutaneous lesions. The course of BA is variable. In some patients, lesions regress spontaneously. BA infection may spread hematogenously or via lymphatics to involve bone marrow, bone, spleen, and liver. As with other OIs in HIV disease, BA can recur. The antibiotics of choice are erythromycin (250–500 mg PO qid) or doxycycline (100 mg bid), continued until the lesions resolve, usually 3 to 4 weeks. Secondary prophylaxis is indicated in patients with recurrent BA.

FIGURE 225-8 Bacillary angiomatosis. A vascular nodule of the shin was associated with disseminated small red papules and subcutaneous nodules in the inguinal areas bilaterally. The lesions appeared suddenly during a one-week period.

FUNGAL INFECTIONS

Cutaneous fungal infections in HIV disease occur as superficial infections (dermatomycoses), invasive cutaneous infections, or systemic fungal infection with hematogenous dissemination to the skin. HAART has markedly diminished the incidence of these infections. [54], [55]

Dermatophytoses

Trichophyton rubrum causes proximal subungual onychomycosis (PSO), an infection of the undersurface of the proximal nail plate. [56] PSO occurs most often in HIV-infected individuals; the diagnosis is an indication for HIV testing. Epidermal dermatophytosis can be extensive in HIV disease. Unless immunocompromise is restored, dermatophyte infections are chronic and recurrent.

Mucocutaneous Candidiasis

Cutaneous *Candida* infections such as intertrigo are relatively uncommon in adults with HIV disease: concomitant diabetes mellitus associated with HAART may increase the prevalence. Candidiasis of moist, keratinized cutaneous sites such as the anogenital region occurs with some frequency. Candidal angular cheilitis occurs at the corners of the mouth as an intertrigo, unilaterally or bilaterally; it may occur in conjunction with oropharyngeal or esophageal disease or as the only manifestation of candidal infection. Children with HIV infection commonly experience candidiasis in the diaper area and intertrigo in the axillae and neck fold. Fingernail chronic *Candida* paronychia with secondary nail dystrophy (onychia) also is common in HIV-infected children. [57]

Candida colonization of the oropharynx is common in HIV-infected individuals, up to 60 percent in the absence of any clinical findings. *C. albicans* was the most prevalent colonizing species, but multiple species may be present. Isolation of non- *albicans* species alone correlates with advanced HIV disease and very low CD4 cell counts. Oropharyngeal

candidiasis (OPC) is a marker of HIV disease progression. In a study of the onset of OPC following documented dates of HIV seroconversion, candidiasis was noted in 4 percent at 1 year after seroconversion, 8 percent at 2 years, 15 percent at 3 years, 18 percent at 4 years, and 26 percent at 5 years; the median CD4 cell count was 392 cells per microliter when OPC was first detected. [58] OPC and esophageal candidiasis (EC) have been reported to occur as a manifestation of primary HIV infection. EC, an AIDS-defining condition, occurs only with advanced CD4 count reduction (<100 cells/µL). OPC presents in four different patterns: pseudomembranous (thrush), atrophic (erythematous), hyperplastic, and as an angular cheilitis. Despite a high prevalence of candidiasis in HIV-infected individuals, disseminated candidiasis is distinctly uncommon, probably because of B cell activation and the presence of anticandidal protective antibody.

HIV-infected women with CD4 counts of 200 to 500 cells per microliter had a 33 percent incidence of vaginal candidiasis and 44 percent if the CD4 count was less than 200 cells per microliter. In a study of 117 HIV-infected women, recurrent candidal vaginitis was the most common initial clinical manifestation of HIV disease (43 of 117 women). [59] Other studies have failed to confirm an increased incidence of candidal vaginitis in HIV-infected women.

INVASIVE FUNGAL INFECTIONS

Invasive fungal infections arise by local invasion of the skin or mucosa, often followed by lymphatic or hematogenous dissemination to viscera or skin or, more commonly, activation of a latent pulmonary focus of infection. Latent pulmonary fungal infections such as cryptococcosis, histoplasmosis, coccidioidomycosis, sporotrichosis, or penicillinosis can reactivate and disseminate to various organs, including meninges and skin, in persons with advanced HIV disease. The cutaneous findings most commonly resemble multiple molluscum contagiosum–like lesions that occur most often on the face and upper trunk. Disseminated deep mycoses are much less common with HAART (see " Cryptococcosis," " Coccidioidomycosis," and " Histoplasmosis" below).

Cryptococcosis

Disseminated cryptococcosis is by far the most common life-threatening fungal infection occurring in advanced HIV disease; cutaneous cryptococcosis occurs in 5 to 10 percent of cases. [60] Skin lesions may be present for weeks or many months before presentation, occurring most commonly on the head and neck (78 percent, but they may be widespread. The most common morphology of cutaneous cryptococcosis is of molluscum contagiosum–like lesions, i.e, umbilicated skin-colored or pink papules or nodules (54 percent) (Fig. 225-9). Other types of cutaneous lesions include pustules, cellulitis, ulceration, panniculitis, palpable purpura, subcutaneous abscesses, vegetating plaques, and pyoderma gangrenosum–like lesions. [61], [62]

FIGURE 225-9 Disseminated cryptococcosis. Multiple skin-colored papules and nodules on the face. At first glance, the lesions mimic molluscum contagiosum, which is very common in advanced HIV disease.

Coccidioidomycosis

Cutaneous lesions of disseminated coccidioidomycosis are usually asymptomatic, beginning as papules and evolving to pustules, plaques, or nodules with minimal surrounding erythema; lesions often resemble molluscum contagiosum. In time, lesions may enlarge and become confluent with the formation of abscesses, multiple draining sinus tracts, ulcers, subcutaneous cellulitis, verrucous plaques, granulomatous nodules, and healing scars.

Histoplasmosis

Disseminated cutaneous histoplasmosis presents with erythematous macules; necrotic or keratin-plugged, molluscum contagiosum–like papules and nodules; pustules, folliculitis, acneform lesions, a rosacea–like eruption, or a guttate psoriasis–like eruption; ulcers; vegetative plaques; or panniculitis. [63] Several different morphologic lesions may occur on a patient. Lesions occur most commonly on the face, followed by the extremities and trunk. Oral mucosal lesions include nodules and vegetations; ulceration occurs on the soft palate, oropharynx, epiglottis, and nasal vestibule. A subtle, widespread exanthematous or psoriasiform eruption occasionally may develop in HIV-infected patients already on systemic antifungal therapy, in whom systemic symptoms are completely lacking. Hepatosplenomegaly and/or lymphadenopathy occur commonly in patients with disseminated histoplasmosis.

Sporotrichosis

In HIV disease, dissemination of local infection to other organs occurs from lung or skin foci. Hematogenously disseminated cutaneous lesions present as papules to nodules that may become eroded, ulcerated, crusted, or hyperkeratotic, usually sparing the palms, soles, and oral mucosa. Ocular involvement results in hypopyon, scleral perforation, and prolapse of the uvea. Other organs involved in disseminated sporotrichosis in HIV disease include joints, [64] lung, liver, spleen, intestine, and meninges.

Aspergillosis

Invasive aspergillosis is rare in HIV diseases, presenting as primary cutaneous infection, occurring under adhesive tape near central venous catheters, [65] or occurring as disseminated infection. Risk factors for invasive aspergillosis in HIV disease include leukopenia and therapy with glucocorticoids, broad-spectrum antibiotics, and antineoplastic agents. Skin lesions appear as skin-colored to pink umbilicated papules resembling molluscum contagiosum. The majority of patients with invasive disseminated aspergillosis die despite treatment with amphotericin B.

Penicillinosis

The dimorphic fungus *Penicillium marneffei* is the third most common opportunistic infection in HIV-infected residents of countries of Southeast Asia and the southern part of China. [66] In a report of 92 patients, [67] the clinical presentation included fever, weight loss, cough, anemia, and disseminated papular skin lesions (71 percent). The most common skin lesions were umbilicated papules, occurring most frequently on the face, pinnae, upper trunk, and arms. Genital ulcers also were reported, ranging in size from less than 1 to 3 cm in diameter. Oral lesions included papules and ulcers.

VIRAL INFECTIONS

Viruses are major pathogens causing OIs in HIV disease, many of which are manifested at mucocutaneous sites, ranging from cosmetically disfiguring facial MCV to extensive common or genital warts to life-threatening/invasive HPV–induced SCC. In the majority of cases, viral OIs represent activation of subclinical infection (HPV, MCV) or of reactivation of latent infection [human herpesviruses: herpes simplex virus 1 (HSV-1), HSV-2, varicella-zoster virus (VZV), cytomegalovirus (CMV), Epstein-Barr virus (EBV), and HHV-8 (Kaposi's sarcoma–associated virus)]. In HIV-infected individuals treated with HAART, the incidence of opportunistic viral infections has diminished markedly, with the exception of those caused by HPV; the incidence of benign and dysplastic HPV-induced lesions is stable or has increased despite immune restoration with HAART.

Herpes Simplex Virus 1 and 2 Infections (See Chap. 214)

With more advanced compromise, lesions tend to be subacute or chronic, indolent, and atypical, responding less promptly to oral antiviral therapy. Chronic herpetic ulcers of greater than 1 month's duration are an AIDS-defining condition. With increasing immunocompromise, recurrent HSV infection may become persistent and progressive. Erosions occurring at the typical sites [perioral (Fig. 225-10), anogenital, and digital] enlarge and deepen into painful ulcers. In addition to ulceration, chronic HSV infections also can present as proliferative lesions of the epidermis with or without scale. Foscarnet and cidofovir are administered intravenously for infections caused by acyclovir-resistant HSV. [68] Cidofovir gel has been effective as a topical therapy of acyclovir-resistant HSV infections. [69] Imiquimod 5% cream is also an effective topical treatment for cutaneous herpetic infections, including those caused by acyclovir-resistant HSV strains. Imiquimod 5% cream is applied to the lesion(s) hs daily or qod if irritation occurs. [70]

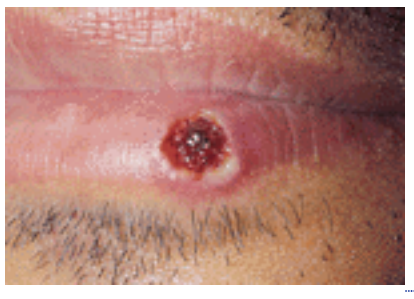

FIGURE 225-10 Herpes simplex virus infection: chronic herpetic ulcer of lip. A crusted ulceration has been present on the lip for 2 months, making it an AIDS-defining condition. The lesion resolved promptly with oral acyclovir.

Varicella-Zoster Virus (VZV) Infections

Primary VZV infection manifests as varicella (chickenpox); reactivation of VZV from a dorsal root ganglion or cranial nerve ganglion manifests as herpes zoster (HZ). [71] In the compromised host, VZV infection can present as severe varicella, persistent varicella, dermatomal HZ, disseminated HZ (sometimes without dermatomal HZ), and chronic [72] (Fig. 225-11) or recurrent HZ. Disseminated HZ is defined as cutaneous involvement by greater than three contiguous dermatomes, more than 20 lesions scattered outside the initial dermatome, or systemic infection (hepatitis, pneumonitis, encephalitis). Disseminated VZV infection in an individual harboring latent VZV can present with a clinical pattern of scattered vesicles in the absence of dermatomal HZ. Acyclovir-resistant VZV is rare. [73]

FIGURE 225-11 Varicella-zoster virus infection: ecthymatous lesions. Two ulcerated, crusted, painful ulcerations on the hip and lateral thigh had been present for 9 months. The lesions resolved with oral acyclovir therapy.

Molluscum Contagiosum Virus (MCV)

MCV commonly infects keratinized skin subclinically and can cause lesions at sites of minor trauma and in the infundibular portion of the hair follicle. [74] The clinical course of MCV infection in HIV disease differs significantly from that in the normal host and is an excellent clinical marker of the degree of immunodeficiency. Large and confluent lesions cause significant morbidity and disfigurement (Fig. 225-12). Prior to HAART, MCV infections were detected in 10 percent of individuals with HIV disease and in 30 percent of those with CD4 cell counts of less than 100 cells per microliter, the number of lesions being inversely related to the CD4 cell count. [25] In HIV-infected individuals, MCV infection tends to be progressive and recurrent after the usual therapies. With response to HAART, MCV infections regress, resolve completely, or do not occur, associated with increased CD4 cell counts and reduced viral load level. [76] For cases resistant to standard therapies, imiquimod 5% cream may be effective in both children and adults. [77] Cidofovir, a nucleotide analogue with activity against several DNA viruses, given either intraveneously or topically as a cream, may be an effective therapy. [78], [79]

FIGURE 225-12 Molluscum contagiosum virus infection: Prior to HAART, multiple facial mollusca would enlarge to cause significant cosmetic disfigurement.

Human Papillomavirus Infections

Human papillomavirus (HPV) infections occur commonly during the course of HIV disease. Of interest, the incidence of HPV infections does not decrease with HAART and immune restoration but actually may be increased. [80]

COMMON WARTS With advancing HIV disease, verrucae can enlarge, become confluent, and become unresponsive to therapy. [81] HPV-5 can cause an unusual pattern of extensive verruca plana and pityriasis (tinea) versicolor–like warts, similar to the pattern seen in epidermodysplasia verruciformis. [82] With moderate or advanced immunodeficiency, warts may become much more numerous, confluent, and refractory to usual treatment modalities. Precancerous lesions identical to mucosal lesions (SIL and SCCIS) can occur periungually and on the nail bed epidermis (usually fingers). In some cases, invasive SCC can arise at one or multiple sites on the fingers and/or nail bed. These tumors are aggressive and invade to the underlying periosteum and bone relatively early due the proximity of the underlying bony structures. Despite immune restitution with HAART, HPV infections often persist and progress unlike other opportunistic viral infections.

GENITAL WARTS HPV-6 and HPV-11 infect non- or minimally-keratinized epithelium such as anogenital sites and oropharynx and cause genital warts; HPV-16 and HPV-18 cause precancerous lesions, low-grade SIL (LSIL), high-grade SIL (HSIL), and invasive SCC. [83], [84]

ORAL WARTS Oropharyngeal HPV-induced lesions resemble anogenital condyloma, pink or white in color. Extensive intraoral condyloma acuminatum (oral florid papillomatosis) presents as multiple large plaques that can transform to verrucous carcinoma.

HPV-INDUCED DYSPLASIA: LSIL, HSIL, INVASIVE SCC The natural history of external anogenital HPV-induced dysplasia is not known. Prolonged, severe immunodeficiency provides the necessary milieu for the emergence of HPV-induced anogenital neoplasia. [85] The incidence of transformation of SCCIS to invasive SCC appears to be low. The relative risk for HPV-related anal invasive SCC is much higher in HIV-infected than in non-HIV-infected homosexual men and is more likely in advanced HIV disease. The most common sites for HPV-induced SIL, SCCIS, and invasive SCC are cervix, anus, perineum, vulva, penis, oropharynx/tongue, conjunctivae, and nail apparatus. [86] Anogenital dysplasias are likely to become more common manifestations of HIV disease because patients with profound immunodeficiency, who previously would have succumbed to OIs, are now surviving for extended periods because of HAART. [87] HAART/immune

restoration may not cause regression of these dysplasias. [88], [89] Cervical, anal, and external anogenital LSIL, HSIL, and invasive SCC have become more common in long-term survivors of HIV disease. Invasive SCC arising on external anogenital sites is usually detected earlier and is less aggressive than that arising on the cervix or anal canal. Management of external anogenital HPV infection in HIV-infected individuals is directed at identifying HSIL before progression to invasive SCC has occurred. All HIV-infected individuals should be examined annually for evidence of HPV infection, especially those with prior HPV infections. Since HPV-induced neoplasia may extend to the cervix and/or anus, direct examination by speculum and anoscope also should be performed; samples for cytology should be obtained using a cervical brush and cytofix solution during the examination. High-resolution anoscopy and biopsy are done on individuals with HSIL. [90] Individuals with documented external anogenital SIL should be followed by periodic follow-up examinations (every 4 to 6 months), noting the appearance of new lesions at these sites or an enlarging nodule or ulcerated site; biopsy of these sites is recommended. For minimally invasive SCC arising on the anal verge (nonkeratinized to keratinized epithelium) or on external anogenital sites (penis, vulva, perineum), surgical excision is recommended with adequate borders around the lesion. Invasive SCC of the anus (transformation zone) is treated by radiation therapy and chemotherapy. Prognosis for invasive anal SCC is better in those with higher CD4 cell counts at time of diagnosis.

SEXUALLY TRANSMITTED DISEASES

The great majority of HIV infections are transmitted during sexual intercourse. Individuals presenting with any sexually transmitted disease (STD) should be screened for HIV infection, syphilis, *Chlamydia,* gonorrhea, and *Trichomonas.* Possible interrelationships of STDs and HIV disease include the potential for STDs to increase the rate of both primary HIV acquisition and transmission, the potential for STDs to accelerate the natural progression of HIV infection, and the potential for HIV coinfection to alter critical clinical and/or serologic parameters used to diagnose and treat STDs. Genital ulcerative diseases (GUDs) such as syphilis, herpes genitalis, and chancroid increase the risk of acquisition of HIV. Gonorrhea and trichomoniasis also increase the risk of HIV transmission.

SCABIES (See Chap. 238)

Scabies is included in the differential diagnosis of pruritus in HIV disease. In individuals with advanced immunocompromise, scabies can occur with minimal or no pruritus but an extensive papulosquamous eruption, i.e, hyperkeratotic, crusted scabies, or Norwegian scabies. Secondary *S. aureus* infection can occur, rarely complicated by bacteremia. Oral ivermectin (200 µg/kg weekly) is the most effective therapy.

Prions and the Skin

PRIONS AS INFECTIOUS AGENTS
MANIFESTATIONS OF PRION DISEASES
TRANSMISSION OF PRION DISEASES
THE SKIN IN PRION DISEASES

REFERENCES

Prion diseases are transmissible neurodegenerative disorders [1], [2] that are characterized by cerebral accumulation of amyloid composed of an altered form of the cellular prion protein (PrP^{c}), designated scrapie prion protein (PrP^{Sc}). These diseases include kuru, Creutzfeldt-Jakob disease (CJD) and Gerstmann-Sträussler-Scheinker disease (GSS) in humans, and scrapie and bovine spongiform encephalopathy (BSE) in animals. Recently, a new human-transmissible encephalopathy, variant Creutzfeldt-Jakob disease (vCJD), was identified, which is presumably transmitted from cattle with BSE to humans. To date, vCJD has been diagnosed in more than 100 patients, preferentially in Great Britain, and has attracted considerable attention. [3] Whether these patients represent the tip of an iceberg and the harbinger of a new pandemic, or whether the number of patients with this dreadful disease will be limited to a few hundred as recently suggested, [4] the next few years will tell.

PRIONS AS INFECTIOUS AGENTS

The infectious agents of transmissible spongiform encephalopathies (TSEs) are called prions, which stands for proteinaceous infectious particles. [1], [2] Prions lack nucleic acids and consist mainly, if not entirely, of PrP^{Sc}. [1] Their contact with PrP^{c} is thought to induce conformational changes of the latter, resulting in the PrP^{Sc} isoform, which is resistant to protease digestion. PrP^{Sc} accumulates in brain cells and cerebral interstitium leading to the characteristic pathology of TSEs. [1], [2] Consequently, expression of PrP^{c} in brain cells is the prerequisite for the manifestation of prion diseases. [5] Although some researchers contest this “protein-only” hypothesis, [6] it is accepted by most researchers and it is widely used to explain the pathogenesis of TSE. In addition to brain cells, PrP^{c} is expressed by cells of different lineages, [7], [8] including skin and mucosal keratinocytes. [9], [10]

MANIFESTATIONS OF PRION DISEASES

Clinical manifestations vary slightly between different prion diseases and comprise mental deterioration with dementia and motor disturbances in CJD, cerebellar degeneration with ataxia and tremor in kuru, and early sensory and psychiatric disturbances rather than dementia and motor abnormalities in vCJD. [1], [11] In animals, restlessness, trembling, and pruritus characterize scrapie and altered behavior, including fear or aggressive responses and ataxia, characterize BSE. [12], [13] Neuropathologically, these ultimately fatal diseases are characterized by vacuolar (spongiform) degeneration of the brain, reactive astrocytosis and variable amounts of amyloid composed of PrP^{Sc} depositions. Whereas CJD, kuru, scrapie, and BSE show abundant vacuolization and little or no amyloid plaques, in GSS syndrome, amyloid deposits are abundant with variable vacuolization. Variant CJD exhibits both intense vacuolization and plaque formation. [14]

TRANSMISSION OF PRION DISEASES

Prion diseases may be inherited, they may occur sporadically, and in the laboratory setting, they are mostly transmitted by direct inoculation of infected tissue. [1], [2] In contrast, the routes of transmission in the field have not yet been determined. Although scrapie is among the longest recognized TSEs, its transmission route remains enigmatic. Direct contact with infected animals seems not to be necessary because sheep can acquire the disease even by grazing on pastures that previously have been populated by infected animals. [15] Ingestion of contaminated food has been suggested for kuru [16] and BSE. [13], [17] Supporting evidence for ingestion as route of transmission also comes from the recent demonstration that in primates fed with BSE-infected brain, PrP^{Sc} can be localized in epithelia lining the digestive tract, as well as in nerve tissue. [18], [19]

THE SKIN IN PRION DISEASES

A direct involvement of the skin in TSE has only been reported for scrapie. [12], [15] Naturally infected sheep develop a severe, itching skin disease leading to hair loss and skin ulcers (Fig. 226-1). The pathogenic cause of this skin affection is unknown and prions have not been demonstrated within these lesions. In humans, PrP^{Sc} has not been detected in samples of regular skin of two patients suffering from vCJD. [20] This finding argues against a continuous prion replication in skin of infected individuals. However, it does not preclude that skin plays a role in the transmission of prions. There is at least some suggestive evidence for this assumption. Kuru is thought to have occurred by ingestion of contaminated human organs in the course of ritual funeral ceremonies. Interestingly, a higher proportion of women as compared to men were affected. Because mainly women were involved in the preparation of the ritual meals, which involved treating the contaminated tissue, including the brain, with their bare hands, infection by inoculation was proposed as an alternative route of transmission to explain this epidemiologic finding. Other authors explain excess of kuru in women by the different

partition of body parts at the funeral ceremonies. [15], [16] The recent demonstration that prion diseases could experimentally be transmitted via inoculation into the skin of mice makes transmission via skin a realistic option. [21] In this context, it is important that the target structure of PrP^{c} is expressed in keratinocytes (KC) of normal epidermis and is strongly upregulated in inflammatory skin diseases [9], [10] and in KC in tissue culture; [9] epithelial cells have been shown to sustain prion replication. [22] In addition, infiltrating inflammatory cells strongly express PrP^{c}. [9] Therefore all elements necessary to establish prion infection and to allow it to spread within the organism are present within the skin. Although it is highly improbable that prions are able to cross an intact stratum corneum, there are many instances when this outer barrier is defective, either as a consequence of microtrauma or in the course of inflammatory skin diseases. Such defects would allow macromolecules to enter into deeper layers of the skin.

FIGURE 226-1 Ulcerations and hemorrhagic crusting on the upper hind quarter of a sheep suffering from natural scrapie.

Another potential port of entry relates to the use of in vitro reconstructed skin for transplantation on burn wounds or chronic ulcers. Constituents of bovine origin are frequently added to the tissue culture medium used to grow keratinocytes. Because in vitro cultivated keratinocytes express high amounts of PrP^{c}, [9] it is theoretically possible that prions could contaminate such cultures and be transmitted to patients. At the moment, there is no evidence that the skin represents a target organ for prion disease in humans, but potentially it may serve as a target organ for prion entry. For the dermatologist, this consideration is also important in light of the fact that prions cannot be inactivated by conventional disinfection procedures. [23] It should encourage the preferential use of disposable instruments in dermatosurgical procedures.

REFERENCES

Rickettsial infections are arthropod-borne diseases belonging to the genus *Rickettsia*. The rickettsioses and ehrlichioses should be considered when a patient is evaluated for fever and a rash. In many endemic areas of the world, rickettsial infections are emerging and reemerging pathogens. [1] New pathogenic species continue to be identified, and it is likely that some “nonpathogenic” species will eventually cause human disease.

HISTORICAL ASPECTS

The rickettsioses have had profound effects upon civilization, particularly during times of war or famine. Hans Zinsser, who recognized Brill's disease as a recrudescent form of epidemic typhus, wrote: “Typhus is not dead. It will live on for centuries, and it will continue to break into the open whenever human stupidity and brutality give it a chance, as most likely they occasionally will.” The first contemporary account of rickettsial disease appeared during the civil wars of Granada in 1489 to 1490, where a typhus-like disease killed 17,000 Spanish soldiers. The eighteenth century physician James Lind astutely recognized that the vector of epidemic typhus was carried on the bodies of men and clothes. In 1909, Charles Nicolle identified the body louse as the vector for epidemic typhus. Howard Tyler Ricketts, who ultimately died from typhus, is credited with first demonstrating the organism in typhus patients and infected lice. During World War I and the Russian Revolution, epidemic typhus caused 3 million deaths.

The earliest serologic test for rickettsiae was based upon the work of Weil and Felix, in 1915, who demonstrated that the serum of patients with typhus agglutinated certain strains of *Proteus vulgaris*.

Rocky Mountain spotted fever was first described in the late 1800s after infection occurred in pioneers in the western states of Idaho and Montana. Ricketts was able to confirm the hypothesis regarding the wood tick as the vector, and S. Burt Wolback at Harvard University Medical School identified the organism within the endothelial cells of vasculitic lesions. [2]

ETIOLOGY AND PATHOGENESIS

The rickettsioses are caused by infection with obligate, intracellular, Gram-negative bacteria. They are pleomorphic and may appear as cocci or bacilli ranging in size from 0.3 µm to 1 µm. Their genome is composed of DNA and RNA and reproduction is achieved through binary fission. *Rickettsia* are propagated by arthropod vectors that use mammals (and sometimes the arthropods themselves) as reservoirs. *Rickettsia* are separated into the typhus group and the spotted fever group on the basis of common genetics, immunologic patterns, and intracellular growth characteristics. [3], [4] The typhus group lives entirely within the cell cytoplasm, while the spotted fever group can reside within the cytoplasm or nucleus. *Rickettsia* spp. and their geographic strains can be differentiated by unique antigenic structures on cell surface proteins. Certain rickettsial cell wall lipopolysaccharides are highly immunogenic and are shared by the gram-negative bacteria *Proteus* and *Legionella*. T lymphocytes, interferon-?, and tumor necrosis factor-a are involved in immune-mediated bacterial killing. [3], [4]

Infection occurs in human beings through arthropod-induced breaks in the skin. Humans can assist this process by, for example, scratching a flea bite and enabling inoculation of *R. typhi* from the flea's feces. The organisms travel via the hematogenous and lymphatic systems until they attach to endothelial cell membranes and are phagocytosed. The clinical manifestations of most rickettsial infections are caused by a proliferation of bacteria within endothelial cells of capillaries, arterioles, and venules, resulting in a multifocal, systemic vasculitis. [4] Pathogenicity is most likely a consequence of direct cell injury.

THE SPOTTED FEVER GROUP

Rocky Mountain Spotted Fever

Rocky Mountain spotted fever (RMSF) is caused by the tick-borne *Rickettsia rickettsii.* It is the most frequently reported rickettsial infection in the United States, and without treatment, it carries a fatality case ratio of approximately 28 percent.

EPIDEMIOLOGY The vector largely responsible for RMSF in the eastern two-thirds of the U.S. is the American dog tick, *Dermacentor variabilis,* while the Rocky Mountain wood tick, *Dermacentor andersoni,* is most prevalent in the western U.S. *Amblyomma cajennense,* in Central and South America, and *Rhipicephalus sanguineus,* in Mexico, also serve as tick vectors. *R. rickettsii* is transmitted by the tick through the salivary glands after at least a 6-h feeding period. Infection can also be acquired in persons exposed to hemolymph during tick removal. [4], [5] The average annual incidence of RMSF in the U.S. from 1993 to 1996 was 2.2 cases per 1 million persons. Children aged 5 to 9 years have the highest age-specific incidence of RMSF. [6] Infection rates in a given locale and time period may be influenced by human recreational activities, use of insecticides, climatic variability, type of serologic tests used, and type of antibiotic therapy. [4] In addition, ticks infected with *Rickettsia* of unknown pathogenicity (e.g., *R. montana*) can compete with *R. rickettsii,* and affect prevalence rates. The south Atlantic region of the U.S. experiences the highest prevalence of RMSF. In the western U.S., men are more often affected than women, and children are disproportionately represented in the southern U.S. Most cases are diagnosed between April and September. [7]
PREVENTION The most effective method for preventing RMSF, as well as other tick- and mite-borne diseases, is to avoid exposure. Wearing protective clothing, using repellants, performing tick checks, and proper tick extractions are important for lowering risk of infection.
CLINICAL MANIFESTATIONS After an incubation period of 2 to 14 days (median, 7 days), RMSF presents with fever, chills, myalgia, fatigue, anorexia, and/or headache. The fever typically reaches 38.9°C (102°F) or higher, and gastrointestinal complaints frequently precede the rash. The components of the classic triad (fever, headache, and rash) are each common at presentation, but only approximately 60 percent of patients present with the complete triad. [7]
Dermatologic The rash of RMSF typically appears 3 to 5 days after the onset of illness, and occurs in 50 percent of patients by the third day. The rash usually appears first at the wrists and ankles, and over the next 6 to 18 h spreads centripetally. However, truncal or diffuse initial presentations occur in up to 10 percent of cases. Palm and sole involvement frequently occurs. [4] Individual lesions are blanchable, red macules that within a few days become papular and display evidence of petechiae or purpura (Fig. 227-1). Showers of petechiae can appear on limbs after sphygmomanometer use (Rumple-Leede test). Necrosis from overwhelming vasculitis is rare (4 percent), and preferentially occurs in peripheral locations such as the digits, penis, and scrotum (Fig. 227-1). [4] Small scars can develop from focal necrosis. “Spotless” fever, which does not imply milder disease, may occur in approximately 10 percent of cases, and is more common in the elderly and darker-complected individuals. [4] Infrequently, eschars and erythema migrans-like eruptions are reported at the site of the tick bite. Postinflammatory hyperpigmentation follows the acute eruption.

FIGURE 227-1 Rocky Mountain spotted fever. *A, B*. Early macular blanchable macules and papules on the palm, soles, and ankles; no truncal lesions were present at this time. *C, D*. Later lesions on the ankles and palm are hemorrhagic and no longer blanch with pressure; truncal lesions were present at this time. *E*. Truncal and facial hemorrhagic macules and papules 7 days after the onset of the rash. *F*. Infarction of fingers in patient whose course was complicated by disseminated intravascular coagulation. (*C, D, and F, courtesy of Charles W. Stratton, MD.*)

Systemic associations Multisystem involvement is the rule in RMSF. Vascular leakage from vasculitis results in hypotension, hypovolemia, and peripheral edema. An inappropriately high tachycardia can occur. Nausea, vomiting, and abdominal pain are common early symptoms, with more severe cases resulting in gastrointestinal bleeding and perforation. Hepatomegaly is seen in up to 25 percent of cases and is found more often in fatal cases. Jaundice is seen in up to 8 percent of cases. A severe headache is often reported and may be accompanied by a vast array of less-common neurologic manifestations (e.g., confusion, delirium, stupor, meningismus, coma, motor deficits, cranial nerve palsy, deafness, photophobia, hallucinations, seizures, Guillain-Barré syndrome). [8] Acute renal failure can result from, in part, a profound prerenal state and/or direct renal vascular injury. [9] Ocular involvement is common with up to 30 percent of cases having conjunctivitis. Periorbital edema may be seen, especially in children. Myocarditis, cardiac arrhythmias, and adult respiratory distress syndrome are infrequent, but potentially fatal complications. In patients with severe RMSF, long-term sequelae are usually the result of neurologic deficits or acral amputation/necrosis. [10]
LABORATORY FINDINGS Laboratory findings that support a diagnosis of RMSF include thrombocytopenia (32 to 52 percent of patients), anemia (5 to 24 percent), and hyponatremia (50 percent). [5] A normal leukocyte count with increased immature cells is more common than leukopenia or leukocytosis. Elevations in transaminases, lactate dehydrogenase, creatine kinase, serum bilirubin, alkaline phosphatase, blood urea nitrogen, and creatinine are variably found. [4]

Coagulopathy with increased prothrombin time and decreased fibrinogen levels, and disseminated intravascular coagulopathy are rare. The cerebrospinal fluid can exhibit increased leukocytes and increased protein concentration, and the glucose is typically normal.

PATHOLOGY Histopathologic examination shows a septic vasculitis (Fig. 227-2). Early lesions show a predominantly perivascular, lymphohistiocytic infiltrate accompanied by extravasated erythrocytes, and dermal edema. A lymphohistiocytic vasculitis can progress to a leukocytoclastic vasculitis. Less often, basal cell vacuolization, lymphocytic exocytosis, fibrin thrombi, and capillary wall necrosis is appreciated. [11] Immunohistology reveals positive staining for *R. rickettsii* in endothelial cells that are involved in the vasculitis.

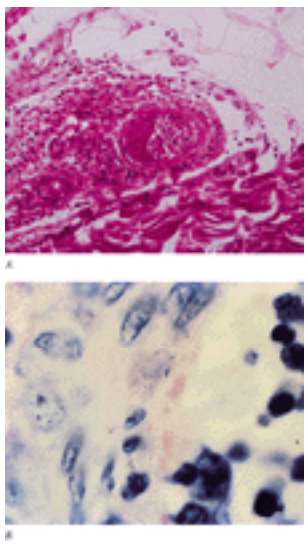

FIGURE 227-2 *A*. The vascular lesion of Rocky Mountain spotted fever as seen in an arteriole in the skin. An early thrombus is present. *B*. *Rickettsiae* are seen in endothelial cells in a skin biopsy.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS Serologic examination is the most used confirmatory test. This test detects convalescent antibodies, but is seldom diagnostic before the seventh day. This stresses the necessity for empiric treatment when RMSF is a consideration in the differential diagnosis. Indirect immunofluorescence assay (IFA), latex agglutination, and enzyme-linked immunosorbent assay are available. Of these, IFA is the most widely used, being highly sensitive (94 percent) and specific (up to 100 percent). [5] Positive values include acute titers of 1:64 or greater, or a fourfold rise in titers between acute and convalescent titers. The Weil-Felix test and complement fixation tests are no longer used because of poor sensitivity. Direct immunofluorescent or immunoperoxidase staining and polymerase chain reaction (PCR) tests of skin biopsies can be accurate and more expeditious than serology, but are not widely available. False-negative direct immunofluorescent tests can occur in patients receiving antirickettsial therapy for more than 24 h. Isolation of the organisms is difficult and hazardous, consequently it is performed by few laboratories. The differential diagnosis for RMSF when the patient initially presents without a rash is broad. Viral respiratory infections, intestinal infections, otitis media, encephalitis, and psychiatric conditions have all been confused with early RMSF. During the first few days of illness, other rickettsial infections, tularemia, and leptospirosis should be considered. Measles can mimic RMSF, but is distinguished by presence of coryza, Koplik spots, and cough. In addition, individual lesions fail to become petechial. Atypical measles, seen in patients born in the late 1950s to the mid-1960s, is more difficult to distinguish because of its centripetal location and presence of petechiae. Meningococcemia can look identical to RMSF, especially when gangrene develops in the latter. Helpful clues to support a diagnosis of meningococcemia include a more rapid onset of rash and leukocytosis. [5] Other diseases to consider are rubella, enteroviral infection, secondary syphilis, toxoplasmosis, ehrlichiosis, infectious mononucleosis, erythema multiforme, drug eruption, typhoid fever, toxic shock syndrome, preeclampsia with liver involvement and thrombocytopenia, thrombotic thrombocytopenic purpura, and idiopathic thrombocytopenic purpura.

TREATMENT AND PROGNOSIS Empiric therapy for RMSF is often necessary because of the potential mortality associated with delays in confirming the diagnosis. Treatment recommendations for RMSF are tetracycline (500 mg q6h or 25 to 50 mg/kg per day q6h, maximum daily dose 2 g), doxycycline (100 mg q12h or 1 mg/lb q12h, maximum daily dose 200 mg), or chloramphenicol (50 to 75 mg/kg per day q6h, maximum daily dose 4 g). Antibiotic therapy should be continued for 7 days and continued for 2 days after the patient remains afebrile. [4] In general, the tetracyclines are the preferred drugs for RMSF. Doxycycline is preferable to tetracycline in patients with renal failure. In children, the tetracyclines can stain teeth, but this is dose and duration dependent, and doxycycline is advocated as the treatment of choice. [12] Chloramphenicol is the treatment of choice during pregnancy, [4], [13] but doxycycline could be considered in near-term gravidas. [13] Aggressive supportive care, with particular attention paid to electrolyte and fluid replacement, is necessary in more severe disease. Without antibiotic treatment, classic RMSF results in a mortality rate that approaches 28 percent. Death occurs 8 to 15 days after the onset of symptoms. [4] Fulminant RMSF leads to a more rapid decompensation and has characteristically been reported in black males with glucose-6-phosphate dehydrogenase deficiency (G6PD). [4] G6PD patients may also have a higher risk of cutaneous necrosis. Groups with a worse prognosis include males and older adults. More severe disease is also seen with neurologic manifestations, thrombocytopenia, hepatitis, jaundice, and acute renal failure. Prompt administration of appropriate antibiotic therapy is the most important factor in determining prognosis. Since the beginning of the antibiotic era, the case fatality rate for RMSF has decreased to 2 to 5 percent. Underestimation of actual fatality rates may be a result of reliance on serologic assays with lower sensitivity.

Other Spotted Fevers

TICK-BITE ASSOCIATED

Mediterranean fever There are seven other tick-bite associated spotted fever group species pathogenic to humans (*R. conorii, R. sibirica, R. japonica, R. australis, R. honei, R. africae,* and *R. slovaca*). The prototype of this class of disease is Mediterranean fever (aka Boutonneuse fever, Marseilles fever, Israeli spotted fever) caused by *R. conorii.*

EPIDEMIOLOGY *R. conorii* is endemic in southern Europe, Middle East, southwest Asia, India, and Africa. It is transmitted primarily by the brown dog tick, *Rhipicephalus sanguineus*. Contact with dogs is reported in up to 90 percent of cases of Mediterranean fever. [14] There is a seasonal variation in case reports, with temperate regions having peaks

during the summer months.

CLINICAL MANIFESTATIONS The constitutional symptoms of the tick-bite–associated spotted fevers, including Mediterranean fever, are similar to those of RMSF. The classic cutaneous hallmark of this group is the tache noir, an erythematous, indurated papule with a central necrotic ulcer and eschar that represents locally aggressive endothelial invasion by rickettsiae and occurs in up to 72 percent of cases with *R. conorii* infection. [15] Multiple eschars can be seen in one-half of patients with African tick-bite fever (*R. africae*). The rash of this group of spotted fevers displays similar temporal and morphologic patterns as that of RMSF. However, the eruption may be more diffuse and is less frequently petechial or purpuric. Pox-like vesicular lesions and isolated lymphadenopathy are associated with *R. conorii. R. africae* infection is frequently spotless, although when rash is apparent, it has been described as vesicular. Lymphadenopathy and lymphangitis are common features of African tick-bite fever. [16] Systemic complications of Mediterranean fever are attributed to the multiorgan vasculitis and include meningoencephalitis, hepatitis, and vascular collapse. Coagulation abnormalities have been described resulting in cases of deep vein thrombosis. [4] In murine models, infection with *R. conorii* induced a procoagulant state with decreased tissue plasminogen activator and increased plasminogen activator inhibitor levels. Other laboratory abnormalities resemble those of RMSF.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS Serologic tests employing IFA technology are the mainstay of diagnosis for the spotted fevers. More rapid results for detecting *R. conorii* are obtained through direct immunofluorescence of skin biopsies, PCR amplification of skin biopsies, monoclonal antibody-coated separation immunomagnetic beads detecting circulating endothelial cells, and blood and skin cultures using centrifugation-shell vial inoculation. [4], [14] Newer serologic assays and PCR amplification of tissue have also been used for diagnosis of *R. japonica, R. slovaca,* and *R. africae.* The rash of Mediterranean fever generates a similar differential diagnosis as that of RMSF. When the tache noir is appreciated, consideration should be given to brown recluse spider bite, cutaneous anthrax, scrub typhus, rickettsialpox, aspergillosis, and mucormycosis.

TREATMENT AND PROGNOSIS Overall, the other tick-bite–associated spotted fevers run a less-aggressive course than RMSF. However, hospitalized patients with Mediterranean fever have death rates ranging from 1.4 to 5.6 percent. Even higher death rates (33 percent) have been reported when delays in diagnosis and in therapy occur. [14] Milder disease is seen in children. Groups at risk for a more fulminant course include alcoholics, the elderly, and those with diabetes mellitus, heart disease, or G6PD deficiency. [4] Treatment is similar to that of RMSF, with tetracyclines or chloramphenicol. Additionally, ciprofloxacin, azithromycin, and clarithromycin have been efficacious. [17] The newer macrolides offer a safety profile advantageous in the pediatric age group.

MITE-BITE ASSOCIATED

Rickettsialpox Rickettsialpox is an acute, self-limited, febrile disease so named because of its clinical resemblance to varicella (chickenpox) and its etiologic agent *R. akari*. The house mouse (*Mus musculus*) is the reservoir and the vector is the rodent mite, *Liponyssoides sanguineus* (*Allodermanyssus sanguineus*). [18] This rodent mite inflicts a painless bite, and is too small to be readily recognized by the victim.

EPIDEMIOLOGY First recognized in 1946 in a housing development in Queens, New York City, rickettsialpox continues to be found in urban locales infested with mice. Serologic evidence of *R. akari* infection has been demonstrated in New York City dogs, but it is not known whether dogs serve as sentinels for human disease. [19] Cases have been reported from the United States (mostly eastern seaboard), South Africa, Korea, and parts of Russia. Intravenous drug users may be at higher risk, but it is unclear if this is solely attributed to inner-city exposures (e.g., mice).

CLINICAL MANIFESTATIONS A primary lesion occurs at the site of the mite bite as early as 1 to 2 days after transmission. It consists of a frequently painless, erythematous, indurated papule ranging in size from 0.5 to 3.0 cm. Vesicle formation is followed by desiccation and a subsequent eschar (Fig. 227-3). [18] Regional lymphadenopathy is common. Resolution of the primary lesion occurs within 1 month.

FIGURE 227-3 Rickettsialpox: tâche noire. A crusted, ulcerated papule (eschar) with a red halo resembling a cigarette burn at the site of a tick bite.

Approximately 1 week after the primary lesion appears, fever, chills, sweats, malaise, headache, and myalgia, often manifesting as backache, begin. The sweating associated with febrile episodes can be drenching. The fever persists with remissions for about a week before abating. Two to 3 days after the onset of systemic symptoms, a generalized eruption occurs that is typically papulovesicular (Fig. 227-4). Small vesicles or pustules, that later crust, can form at the center of papules. Roughly 5 to 40 lesions can be found. These resolve in 1 week. Less frequently, an enanthem, photophobia, generalized lymphadenopathy, and gastrointestinal symptoms may be noted. [18]

FIGURE 227-4 Rickettsialpox: exanthem. Multiple, erythematous papules and pustules, some with central hemorrhage and crusting, on the back after hematogenous dissemination of the *R. akari* from the tick-bite site.

LABORATORY FINDINGS During the acute febrile illness a mild leukopenia can be seen. This can be accompanied by a relative lymphocytosis.
PATHOLOGY The primary lesions are characterized by extensive necrosis and an acute inflammatory infiltrate. The papulovesicular lesions display a subepidermal split with superficial edema, and a perivascular lymphohistiocytic infiltrate that can lead to vasculitis. In contrast to RMSF, Mediterranean spotted fever, louse-borne typhus fever, and murine typhus, the perivascular macrophage, not the endothelial cell, appears to be the preferentially infected cell.
DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS The Weil-Felix test is generally negative. Instead, diagnosis can be confirmed with complement fixation tests or indirect fluorescent antibody tests. Titers for antibody detection peak after 3 to 4 weeks and could be delayed for up to 8 weeks with antibiotic use. [20] More rapid diagnosis, but perhaps less specific, can be made by using the cross-reactivity of *R. akari* with *R. rickettsii*. Indeed, direct immunofluorescence of primary lesion biopsies can be performed with anti- *R. rickettsii* globulin. The generalized eruption does not contain enough inoculum to become positive by direct immunofluorescence. Varicella can resemble rickettsialpox, but can be differentiated by the morphology of individual lesions. In varicella, the “dewdrop on a rose petal” description, refers to the largely vesicular lesion surrounded by erythema. This is distinct from the erythematous papule surmounted by a vesicle seen with rickettsialpox. [18] A positive Tzanck preparation is observed in varicella, but not in rickettsialpox. Fever occurs with the rash of varicella, but precedes the eruption of rickettsialpox. Other diseases to consider with respect to the initial lesion are scrub typhus, the spotted fever group of illnesses that result in eschar formation, brown recluse spider bite, cutaneous anthrax, aspergillosis, and mucormycosis. The generalized eruption can be confused with smallpox, gonococcemia, infectious mononucleosis, echovirus (types 9 and 16), and coxsackievirus infection (A9, A16, and B5).
TREATMENT AND PROGNOSIS Tetracyclines are the most effective therapy. They can be continued for up to 5 days, although defervescence is typical within 48 h. [20] The disease is self-limited, and even without antimicrobial therapy the illness will resolve within 2 weeks. Scarring can result from the primary eschar, and postinflammatory hyperpigmentation can remain as a result of the papulovesicular lesions.

TYPHUS GROUP

Endemic Typhus (Murine Typhus)

Endemic typhus is caused by *R. typhi,* and is classically transmitted to humans by the rat flea (*Xenopsylla cheopis*) with rats serving as the reservoir. *R. felis* is a recently characterized rickettsiae that has emerged in southern Texas and southern California. In this setting, *R. felis* is thought to be an important cause of endemic typhus-residing in peridomestic animal cycles involving free-ranging cats, dogs, opossums, and their fleas (e.g., cat flea, *Ctenocephalides felis*). [21] Some authors have classified *R. felis* in the spotted fever group based upon molecular characterization.

EPIDEMIOLOGY Endemic typhus occurs worldwide, and typically occurs in temperate and subtropical seaboard regions during warm-weather months. During the early 1940s, thousands of cases occurred along the southeastern and Gulf Coast of the United States, and today, a limited number of cases are reported from southern Texas and southern California. [22] Areas of the world that have experienced outbreaks of endemic typhus include Thailand, Kuwait, and China. In 1998, five cases occurred on southwestern Kauai.
PREVENTION Control of flea populations and their respective reservoirs are effective in decreasing infection rates.
CLINICAL MANIFESTATIONS After an incubation period of 1 to 2 weeks, the illness presents abruptly with fever, and may be accompanied by headache, nausea, vomiting, diarrhea, cough, chills, and myalgia. Initially, only 18 percent of patients exhibit a rash, but this develops in 50 to 60 percent of patients over the course of the illness. [21], [22] The median onset of rash after the fever is 6 days. The rash usually consists of erythematous macules or erythematous macules and papules. Infrequently, petechiae are present. The distribution occurs mainly on the trunk, but the extremities can also be affected. Rarely, palms and soles are involved. Hepatomegaly and splenomegaly can sometimes be appreciated. In Spain, endemic typhus is an important cause of fever of intermediate duration (7 to 28 days). [23] Complications are uncommon, but include seizures, meningoencephalitis, retinitis, acute hepatitis, endocarditis, renal insufficiency, pneumonia, and respiratory failure.
LABORATORY FINDINGS The most frequent laboratory abnormalities in endemic typhus patients are elevations in hepatic enzymes. Serum aspartate aminotransferase can be elevated in up to 90 percent of patients, and elevations greater than fivefold are not unusual. Elevated erythrocyte sedimentation rate, hyponatremia, hypocalcemia, and hypoalbuminemia are also common findings. Mild leukopenia and thrombocytopenia occur during the first week in a minority of patients. A shift toward immature leukocytes can be seen without leukocytosis.
DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS Serologic tests employing IFA are the most widely used. Diagnostic titers are present in 50 percent of patients by 1 week, and in virtually 100 percent of patients by 15 days. [21] These assays do not easily differentiate among epidemic typhus or endemic typhus, however. More specific distinctions can be made by

using a combination of Western blotting and IFA, or by using serum cross-adsorption. [24] Newer methods of diagnosis (immunohistochemical diagnosis using antilipopolysaccharide antibodies) have not been standardized. The differential diagnosis is broad as a result of the nonspecific cutaneous eruption. The list includes other rickettsial infections, ehrlichioses, leptospirosis, drug eruptions, viral exanthems, meningococcemia, Kawasaki disease, and toxic shock syndrome.

TREATMENT AND PROGNOSIS Treatment for endemic typhus is similar to that of RMSF, with tetracyclines being the preferred agents. Single-dose doxycycline therapy is not recommended because of the potential for relapse. Fluoroquinolones have also been used effectively. [21] Fatalities occur in fewer than 5 percent of infected individuals. Approximately 10 percent of patients require intensive care. With institution of appropriate antibiotics, most patients have resolution of fever within 2 to 3 days. Markers for possibly more complicated courses are advanced age, alcoholism, underlying hemolytic disorders, and exposure to sulfa-containing antibiotics. [21], [22]

Epidemic (Louse-Borne) Typhus

Epidemic typhus is caused by *R. prowazekii,* and is transmitted to humans via the body louse (*Pediculus humanus var. corporis*). It may appear in two clinical forms, a primary febrile illness and a recrudescent infection [Brill-Zinsser disease (BZD)].

EPIDEMIOLOGY Louse infestation is associated with times of war, natural disasters, cold weather, and lack of hygiene. The most recent outbreak of epidemic typhus occurred in refugee camps in Burundi during the mid-1990s. [25] The major reservoir for disease seems to be humans, with body lice acquiring infection from feeding on persons with primary illness or BZD. The louse will die of infection within 3 weeks. The lice are spread through close personal or clothing contact. The infected louse will defecate while taking a blood meal, and the organisms in the feces are scratched into the skin. Since 1975 an association has been recognized between contact with southern flying squirrels and epidemic typhus. Along the eastern United States, fleas or lice from these rodents may be important vectors. Most of these cases have occurred in suburban or rural settings during the winter months. [22], [25]

PREVENTION Prevention begins with regular bathing and clothes washing. Delousing with appropriate agents, such as lindane or dichlorodiphenyltrichloroethane is effective. [25] A vaccine is available, but it is only recommended for special-risk groups.

CLINICAL MANIFESTATIONS After an incubation period of 1 week, there is an abrupt onset of headache, fever, chills, and myalgia. Typically, the rash begins in the axillary folds and upper trunk on the fifth day of illness. Initial lesions consist of erythematous macules that then become papular and petechial over several days. The eruption spreads centrifugally, but spares the face, palms, and soles. Indigenously acquired epidemic typhus in the United States appears similarly, but may be a more mild illness. [22], [25] Complications include acral gangrene cerebral thrombosis, and other neurologic sequelae. The severity of disease appears more significant than that of murine typhus, but certainly not as fulminant as RMSF. BZD occurs as a recrudescence of previous infection with *R. prowazekii*. Provocation by immunologic stress induced by poor living conditions may play a role. The illness is usually milder than primary disease.

LABORATORY FINDINGS Laboratory abnormalities include thrombocytopenia, elevated transaminases, and lactic dehydrogenase. A minority of patients has leukocytosis.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS The diagnosis of epidemic typhus should be considered when the aforementioned clinical characteristics are combined with a setting where body lice could promulgate. Additionally, in the United States, flying squirrel exposure could be an important clue. The centrifugal spread, lack of eschar, and predilection for colder months helps differentiate epidemic typhus from other *Rickettsia*. The Weil-Felix test has been largely replaced by serologic tests employing IFA. These assays do not easily differentiate among epidemic typhus or endemic typhus, however. More specific distinctions can be reached using a combination of Western blotting and IFA, or by using serum cross-adsorption. Newer methods of diagnosis (PCR and immunohistochemical diagnosis using antilipopolysaccharide antibodies) have not been standardized. The Weil-Felix test is usually negative in BZD, but low titers can be present and consist of immunoglobulin G rather than M (primary disease). [22] The differential diagnosis is similar to that of endemic typhus (see above).

TREATMENT AND PROGNOSIS Treatment consists of tetracycline, doxycycline, or chloramphenicol. In fact, a single-dose of doxycycline, 100 mg, can be curative. [25] However, therapy should be continued for 2 to 3 days after defervescence. BZD is treated identically. Therapy failures have been documented with azithromycin for BZD. [26] The fever of epidemic typhus abates in 2 weeks in untreated cases. Recovery of strength can take 2 to 3 months. With early use of appropriate antibiotics, fever resolves within 48 h. Headaches may take 1 week to resolve. Fatal illness is rare if therapy is begun early. Mortality rates are highest in the elderly. Case fatality rates during recent outbreaks have been less than 5 percent, but have been recorded to be 30 percent in other instances. [22], [25]

Scrub Typhus (Tsutsugamushi fever)

Scrub typhus is a mite-transmitted zoonosis caused by *Orientia tsutsugamushi* (formerly *R. tsutsugamushi*). The vector is the larval stage (chigger) of trombiculid mites (*Leptotrombidium deliense* and several other *Leptotrombidium* sp.). The mites and rodents serve as the major reservoirs.

EPIDEMIOLOGY Scrub typhus is endemic to a region spanning eastern Asia to the western Pacific (Japan, Korea, India, Pakistan, Taiwan, Southeast Asia, and Australia). Scrub typhus is named for the type of vegetation that harbors the mite vector. This vegetation is a transitional terrain between tall forests and cleared land, composed of plantations, fields, groves, and tall grass. [27] Accordingly, the illness is more common in rural settings and is a common occupational disease.

PREVENTION Repellants that target the larval mites, such as diethyltoluamide (DEET) are effective at preventing transmission. These agents can be applied to skin or impregnated in clothing. Chemoprophylaxis with weekly doxycycline (200 mg) may be efficacious to travelers in endemic areas. [22]

CLINICAL MANIFESTATIONS The initial skin lesion is an erythematous papule that appears within 2 days of the chigger bite and undergoes ulceration and eschar formation in one-half to two-thirds of patients. The eschar may be absent in intertriginous areas. [22] Regional lymphadenopathy is followed by generalized lymphadenopathy. One to 2 weeks after the

bite, there is a sudden onset of fever. Chills, headache, cough, myalgia, anorexia, nausea, diarrhea, dyspnea, and conjunctival injection are variably present. A macular and then papular eruption sometimes occurs a few (mean, 4 to 5) days after the fever begins. [27] The eruption starts on the trunk, then spreads to the extremities, and fades within a few days. A relative bradycardia may be appreciated. Complications include pneumonitis, adult respiratory distress syndrome, meningoencephalitis, deafness, tinnitus, myocarditis, pericarditis, disseminated intravascular coagulation, hemophagocytic syndrome, retinal vein occlusion, renal failure, and hepatitis. In one retrospective study of 33 patients, 36 percent experienced pneumonitis. [28] In some HIV-1 patients who were also infected with scrub typhus, viral loads have been observed to diminish. A possible suppressive effect of *O. tsutsugamushi* on HIV has been hypothesized. [29] Clinically, HIV patients infected with *O. tsutsugamushi* do not seem to have more severe manifestations of scrub typhus.
LABORATORY FINDINGS A lymphocytosis with a normal total white blood cell count is common, but leukopenia or leukocytosis can also occur. Atypical lymphocytes are sometimes found, and multilobated nuclei have been reported. Other abnormalities include thrombocytopenia (44 percent of patients), and elevated hepatic transaminases (75 percent of patients). Cerebrospinal fluid (CSF) abnormalities, such as mild pleocytosis and elevated protein, have been documented. In a study of 75 consecutive patients with shrub typhus, 54 (72 percent) had pulmonary radiographic abnormalities. [30] These included reticulonodular opacities and ground-glass opacities.
DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS The Weil-Felix test can be used for diagnosis, but has a low sensitivity. More-sensitive techniques that are readily available are IFA and the indirect immunoperoxidase assay. [27] Tests with even higher sensitivities that are being used in some regions include ELISA, dot blot urine immunoassay, rapid immunochromatographic flow assay, and PCR. The differential diagnosis includes those found with murine typhus and those generated by the tache noire and the eschar of rickettsialpox.
TREATMENT AND PROGNOSIS Tetracycline, doxycycline, and chloramphenicol are effective for scrub typhus. Single dose or short courses (3 days) of doxycycline may prove to be as efficacious as 7-day courses of tetracycline. [27] However, naturally occurring doxycycline- and chloramphenicol-resistant strains of *O. tsutsugamushi* have been found in northern Thailand. Azithromycin, rifampin, and ciprofloxacin are alternatives in this setting. With institution of proper antibiotics, defervescence occurs abruptly, usually within 24 h. In untreated patients, fever lasts for about 2 weeks. Relapses are common, especially when therapy is less than 2 weeks in duration. There is marked strain variation in virulence. Case fatality rates are significantly diminished with use of antibiotics, and were as high as 50 percent in Japan during the preantibiotic era. [22]

Q Fever

Q fever is caused by *Coxiella burnetii,* a rickettsia-like bacteria that is infrequently associated with cutaneous disease.

EPIDEMIOLOGY Unlike the aforementioned rickettsial diseases, it is chiefly acquired through the aerosol route and is most commonly associated with cattle, sheep, and goat reservoirs. Other mammals (including cats and dogs), fish, birds, and ticks can harbor *C. burnetii.* Pregnancy can reactivate the infection and parturition exposes contacts to a heavily infected placenta. The distribution is worldwide. Immunosuppressed patients, particularly those with HIV, are at increased risk. [31]
PREVENTION Preventative measures include an investigational vaccine for those at highest risk (abattoir workers, veterinarians), avoidance of infected animals, especially at parturition, and control of ectoparasites on typical animal reservoirs. [32]
CLINICAL MANIFESTATIONS A wide range of clinical illness can occur after infection. These include a self-limited febrile illness, pneumonia, endocarditis (especially in those with abnormal heart valves or vascular prostheses and aneurysms), hepatitis, osteomyelitis, pericarditis, and meningoencephalitis. [31], [32] Acute illness begins approximately 3 weeks after exposure and presents with fever, headache, malaise, myalgia, and chills. Cutaneous manifestations in acute Q fever are variably reported and may occur in as few as 4 percent or as many as 42 percent of patients. They consist of truncal erythematous macules and papules that present during the febrile episode. Palpable purpura can result from an immune complex vasculitis seen in chronic Q fever with endocarditis. [31] Livedo reticularis, mixed cryoglobulinemia, and arterial emboli can also occur in this setting. Erythema nodosum has also been ascribed to *C. burnetii.*
LABORATORY FINDINGS Common laboratory findings are a normal white blood cell count and elevated hepatic transaminases. Less frequently noted are thrombocytopenia, antiphospholipid antibodies, smooth muscle antibodies, inappropriate secretion of antidiuretic hormone, and hemolytic anemia. [31], [32] Multiple rounded opacities on chest x-ray are suggestive of Q fever caused by infected cat placenta.
PATHOLOGY Leukocytoclastic vasculitis can be appreciated with skin biopsies of palpable purpura in chronic Q fever. With hepatitis, a “doughnut granuloma” is characteristic. The granuloma consists of a dense fibrin ring surrounding a central lipid vacuole.
DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS Diagnosis is usually confirmed with serology (complement fixation tests or others). The differential diagnosis is broad with acute Q fever's exanthem. In chronic disease associated with palpable purpura and a heart murmur, infectious emboli, atrial myxoma, and lupus erythematosus should be considered.
TREATMENT AND PROGNOSIS Tetracyclines such as doxycycline are the primary treatment for Q fever. Macrolides also are efficacious. Acute infections can be treated for 2 to 3 weeks, while chronic infections may require years of therapy. Frequently, other antimicrobials are added in the setting of chronic disease. Quinolones, rifampin, amantadine, and antimalarials have been used. [31], [32] The prognosis of Q fever is variable and ranges from an asymptomatic or self-limited febrile illness to death (2.7 percent).

EHRLICHIOSIS

Ehrlichia species are small, obligate intracellular bacteria that were originally thought to be *Rickettsia* species. Ehrlichioses are tick-borne zoonoses that have tropism for human phagocytic bone marrow-derived cells. The organisms grow within membrane-bound vacuoles, in which they form intracytoplasmic microcolonies called morulae. The main clinical classification of the ehrlichioses is human monocytic ehrlichioses (HME) caused by *E. chaffeensis* and human granulocytic ehrlichioses (HGE) caused by the *E. phagocytophilia* group. [33]

Epidemiology

E. chaffeensis is primarily transmitted by the tick *Amblyomma americanum,* although *Dermacentor variabilis* may also be a vector. HME occurs most often in the southern and south central United States. Peak incidence occurs May through July with increased outdoor exposure and males represent the majority of reported patients. [33] The main reservoirs are deer, dogs, and coyote.

HGE infection occurs in a geographically identical pattern as that of Lyme disease (primarily northeastern United States, with parts of the Pacific Northwest and upper midwest of the United States). The vector for both diseases is the *Ixodes* spp. of ticks. *Ixodes* sp. can also transmit *Babesia microti,* in addition to *Borrelia burgdorferi, Borrelia afzelii, Borrelia garinii,* and the *E. phagocytophilia* group. In the eastern United States, HGE infection peaks in July and again in November. The main reservoir is the white-footed mouse, other small mammals, and deer. [33]

Prevention

Preventative measures include avoidance of tick exposure and careful removal of attached ticks.

Clinical Manifestations

HME has a 1- to 2-week incubation period. Initial symptoms resemble those of many rickettsial diseases, with fever, chills, headache, myalgia, and malaise. Less-common symptoms include gastrointestinal illness, cough, dyspnea, and confusion. A nonspecific macular, papular, or petechial rash occurs in about one-third of patients, and is more common in children. The eruption occurs a few days after symptoms begin and is generally found on the trunk. Other less-common expressions are conjunctival injection, palatal petechiae, and acral edema with desquamation. [34] Severe complications consist of meningoencephalitis, renal failure, respiratory insufficiency, disseminated intravascular coagulation and pericarditis.

HGE greatly resembles HME in its clinical presentation. Rash is not as frequent as HGE, with fewer than 10 percent of patients affected. [33] Severe complications can include shock, renal failure, and respiratory insufficiency. Reported neurologic manifestations are meningoencephalitis, facial diplegia, brachial plexopathy, and demyelinating polyneuropathy. Concurrent illness with ehrlichioses and babesiosis or Lyme disease (up to one-fifth of HGE patients) has been documented.

E. sennetsu causes a mononucleosis-like illness in the Far East. *E. canis* has been reported to cause asymptomatic human infection. *E. ewingii* has infrequently been associated with human illness and may be clinically indistinguishable from HME or HGE infection. [35]

Laboratory Findings

HME and HGE most often result in thrombocytopenia, leukopenia, and elevations of hepatic transaminase levels during the first week of illness. The platelet count in HME usually is between 50,000 and 140,000/µL, whereas the mean white blood count is 3500/µL. [33] In HME, the leukopenia is the result of neutropenia or lymphopenia, or both. HGE results in thrombocytopenia more often than leukopenia. The leukopenia is the result of a relative and absolute lymphopenia with an increased number of band neutrophils during the first week of illness. Anemia is less often found, and occurs after the first week of illness. Serum creatinine is often elevated, especially in HGE. [34]

Pathology

E. chaffeensis primarily infects monocytes and macrophages. In the bone marrow, granulomas, myeloid hyperplasia, and erythrophagocytosis are common. Other findings include hepatic granulomas, hepatocellular necrosis, interstitial mononuclear cell pneumonitis, perivascular lymphohistiocytic infiltrates of various organs, and diffuse mononuclear phagocyte hyperplasia of the spleen and lymph nodes. [33] In contrast to the rickettsioses, vasculitis is not found in pathologic specimens. [33] A single retrospective case study suggests HME may rarely be associated with cutaneous vasculitis such as polyarteritis nodosa. [36]

The *E. phagocytophilia* group primarily infects neutrophils. This selectivity is mediated by adhesion to fucosylated leukocyte P-selectin glycoprotein ligand, PSGL-1. [37] Pathologic findings can include erythrophagocytosis in mononuclear phagocytic organs, hyper- or normocellular bone marrow, and hepatic apoptosis.

Diagnosis and Differential Diagnosis

Microscopic examination of leukocytes for the presence of morulae should be performed if ehrlichioses are suspected. Sensitivity is greater in HGE (20 to 80 percent) than in HME (7 percent). False positives occur with toxic granulation, superimposed platelets, and Döhle bodies. The major diagnostic criterion used for HME and HGE is IFA using acute and convalescent serum samples. Other, less-frequently employed, but more specific techniques are PCR, protein immunoblotting, and direct cultivation.

The differential diagnosis is extensive and includes such entities as RMSF, babesiosis, viral syndromes, pneumonia, gastroenteritis, Lyme disease, relapsing fever, endemic and epidemic typhus, tularemia, Q fever, Colorado tick fever, autoimmune systemic vasculitides, leptospirosis, hepatitis, toxic shock syndrome, thrombotic thrombocytopenic purpura, Kawasaki disease and endocarditis. RMSF is more likely with the presence of rash, normal white blood count, lack of morulae, and pathologic evidence of vasculitis. *Babesia microti* can be visualized in Giemsa- or Wright-stained

erythrocytes as ring forms with a central paler area, tetrads ("Maltese cross"), or as a single chromatic dot. Other findings with babesioses include emotional lability, hemolytic anemia, frequently normal or slightly depressed white blood count, dark urine with proteinuria, and hemoglobinuria.

Therapy and Prognosis

Tetracyclines are the drugs of choice, with doxycycline the most often used. Defervescence occurs within 1 to 2 days. Therapy for 5 to 7 days is generally effective, but one may want to continue therapy for 14 days if coinfection with *B. burgdorferi* is likely. [33] Children should also receive doxycycline (see RMSF therapy discussion for rationale).

The median duration of the ehrlichioses is 1 to 2 weeks. Fatalities have occurred in approximately 2 to 4 percent of patients with HME. [34] The clinical course ranges from asymptomatic seroconversion to multisystem organ failure with death. Initiation of antibiotics leads to decreased morbidity and mortality. Predictors of more fulminant disease include immunosuppression (e.g., organ transplant patients, HIV, glucocorticoid use), and patients with cough, diarrhea, and lymphadenopathy. More aggressive illness has been reported in patients with HME taking trimethoprim-sulfamethoxazole. HGE is also more severe in the immunosuppressed and can lead to opportunistic infections (disseminated candidiasis, aspergillosis, etc.).

Syphilis is caused by *Treponema pallidum* (ssp. *pallidum*), a microaerophilic spirochete that infects only humans and a few other primates. The organism is too delicate to be grown in vitro, yet so aggressive that it invades almost any organ in the body, and so evasive that it can elude a miasmal immune attack and occasionally it may even survive massive doses of antibiotics. [1] The infection is usually contracted through sexual contact with infected lesions or body fluids; less commonly, transplacentally from mother to unborn child; and rarely through blood transfusion, accidental inoculation, or puncture with contaminated instruments, such as those used for tattooing.

Dermatologists have a decisive advantage in diagnosing syphilis because of their skill in evaluating skin lesions. However, although the diagnosis is usually made by examination of mucocutaneous lesions, the infection is systemic, even in the absence of symptoms. The variable clinical course and diverse manifestations were recognized long before Sir William Osler dubbed syphilis “the great imitator,” but much remains to be learned about the pathogenesis of this infection, which continues to baffle and challenge even experienced clinicians, investigators, and epidemiologists.

HISTORY

Syphilis probably evolved from yaws between 15,000 and 3000 B.C. However, it is commonly cited that syphilis was contracted by Spanish sailors from Haitian natives during Columbus' first trip to the New World. Columbus, himself, reportedly died from syphilitic aortitis. Several infected sailors joined Spanish troops supporting the struggle of Alfonso II of Naples against Charles VIII of France and infected Neapolitan women. The women, in turn, infected mercenaries from different countries fighting for the French army. After the army's disbandment, the mercenaries spread the disease throughout Europe. Concurrently, Portuguese sailors under Vasco da Gama transmitted the infection in Asia.

Probably, syphilis was already present in a more attenuated form in several continents well before the discovery of the Americas. Ancient documents describe “venereal leprosy” in the populations of Rome, Greece, and China in terms that closely resemble the manifestations of syphilis. However, a devastating epidemic of a virulent, destructive, and disfiguring form of syphilis, that swept through Europe at the end of the fifteenth century stimulated previously

unprecedented preoccupation with the disease. In each country, syphilis was named after a rival nation. The French called it the Neapolitan itch, the Russians named it the Polish disease, and the Italian term *morbus Gallicus* (French disease) became particularly popular. In 1530, the physician and poet Girolamo Fracastoro published the third book of his poem *Syphilis sive Morbus Gallicus,* about the affliction of the handsome shepherd Syphilus with a repulsive disease as punishment for blasphemy to the sun god. The poem included a detailed description of the incubation period, symptoms, prevention, and treatment, and the name of the shepherd became synonymous with the infection. [2] The other name by which the disease is commonly known, *lues* (from the Latin for plague or pestilence), was introduced by the sixteenth century physician-poet Jean Fennel, who first differentiated between the primary and secondary stages. By the end of the sixteenth century, the clinical manifestations and treatment with guaiac wood and mercury (two minutes with Venus, two years with Mercury) were well documented. But the major contributions were made after the eighteenth century (Table 228-1). None had a greater impact than the introduction of penicillin as treatment for syphilis in the 1940s. Within 10 years, the number of cases had so dramatically declined that the extinction of the disease was predicted, prompting the American Academy of Dermatology to drop the term *Syphilology* from its original name.

1797	John Hunter concludes that syphilis and gonorrhea are the same disease after developing both infections from a self-administered inoculation of urethral discharge.
1837	Phillipe Ricord distinguishes syphilis from gonorrhea and classifies primary, secondary, and tertiary stages.
1854	John Diday writes popular manual on congenital syphilis.
1856	Ricord generates definitive description of the biology of syphilis.
1880	Jonathan Hutchinson describes triad of congenital syphilis (keratitis, labyrinthitis, and notched teeth).
1891	Caesar Boeck studies the natural course of the disease in 2181 patients who are not treated for fear that complications of mercury are greater than those of syphilis.
1905	Fritz Schaudinn and Erich Hoffman identify treponemes in chancres.
1909	Paul Erlich treats syphilis with a "magic bullet"—arsenic.
1910	August von Wasserman develops complement fixation diagnostic test.
1933	John Nelson generates a treponemal-specific serologic test.
1943	John Mahoney reports that penicillin cures syphilis.

TABLE 228-1 **Landmarks in Syphilology**

EPIDEMIOLOGY

In the early part of the twentieth century, 10 percent of the population of the United States and Europe was infected with syphilis. [1] During World War I, the US Congress launched several public health measures after syphilis was detected in 13 percent of military draftees. These included quarantines and compulsory premarital screening. The incidence of syphilis peaked between 1935 and 1947 as efforts to combat the disease were restrained by a conspiracy of silence. Surgeon General Thomas Parran, in his ambitious campaign to wipe out the "shadow on the land," called for a serologic dragnet to screen the population and to institute partner notification through "shoe leather" epidemiology. These aggressive public health policies were largely ineffective.

During World War II, the armed forces instituted successful preventive interventions that included public education, prostitution control, distribution of condoms, and availability of immediate treatment without punitive repercussions. As treatment with penicillin became widely available, the incidence decreased dramatically. The resurgence of sexually transmitted diseases seen in the 1960s was blamed on looser sexual attitudes (permissiveness, promiscuity, and the pill), but in the 1970s, enhanced control efforts again lowered the number of syphilis cases. Since then, the pattern has been sudden bursts in the rate of infected cases followed approximately every 5 to 10 years by periods of low prevalence. [3] The most effective public health strategies have been the selection and confidential screening of high-risk populations, partner notification, free treatment of infected persons and partners, behavior counseling, and rapid response to outbreaks. Still, kindled by the exchange of sex for money to buy crack cocaine, the rate of infectious syphilis catapulted in 1991 to a 50-year high of 102.3/100,000 population, only to decline in 1999 to an all-time low rate of 2.5/100,000 population. [4] Encouraged by this success, the Centers for Disease Control launched a National Plan for Elimination of Syphilis from the United States. However, recently, several outbreaks of syphilis among homosexual and bisexual men, including those who are HIV-seropositive, have been reported. [5] The facilitation of casual sex promoted by Internet sites may prove to be an important cause for future outbreaks in industrialized countries.

In many parts of the world, syphilis continues to be a major public health problem. Despite therapeutic "magic bullets," the disease has proven to be a formidable opponent.

ETIOLOGY

The cause of syphilis is *T. pallidum,* a motile, corkscrew-shaped, prokaryotic bacterium with a flexible, helically coiled cell wall (Fig. 228-1). The organism is microscopically indistinguishable from treponemes that cause pinta, yaws, or endemic syphilis, and closely resembles the bacteria that cause Lyme disease, borreliosis, and leptospirosis.

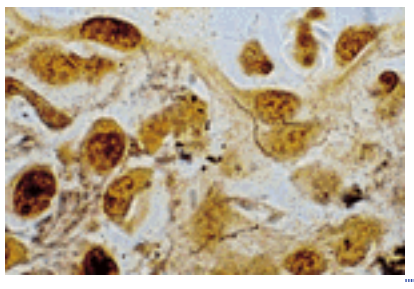

FIGURE 228-1 Silver stain of syphilis lesion showing the corkscrew-shaped treponemes.

T. pallidum measures between 6 and 15 µm in length and 0.10 and 0.18 µm in width. It has tapered ends between which are 6 to 14 regularly spaced tight spiral coils. When fixed, the spirals impart a wavelike configuration. Its narrow width renders the organism undetectable by light microscopy without silver staining. Under dark-field microscopic examination, the treponemes resemble strings of beads with a characteristic rotatory motion and a flexion and back-and-forth squiggle. This motion is said to be characteristic of virulent treponemes and to facilitate penetration through tissue. However, in fluid medium, the bacteria lack locomotion, which distinguishes them from most saprophytic treponemes.

The spirochete has three main components. The protoplast is the central part of the treponeme and contains the genome and the organelles responsible for metabolism. [6] The axial filament (flagellum) consists of six to eight elastic fibrils twisted around the protoplast. It imparts a helicoid shape and contributes to the spirochete's mobility. The outer envelope contains a heteropolymer peptidoglycan macromolecule that preserves the organism's shape, protects the fragile cytoplasm against injury, and filters large molecules. An extracellular amorphous slime layer may protect the organism against phagocytosis. Because the outer envelope contains a paucity of integral transmembrane proteins that stimulate specific antibodies, the organism more easily evades immune attack.

Replication occurs through fission, with an interval of 30 to 33 h between divisions. The outer envelope, where growth requires approximately 30 steps and several enzymes, is susceptible to damage by antibiotics.

IMMUNOLOGY

Our knowledge of the disease has been hampered by the difficulty of growing the organism in culture and the laboriousness involved in growing treponemes in rabbits, the only animal model. In addition, the immune responses in patients with syphilis may differ during the various stages of infection. For this reason, contradictory conclusions have been reported.

T. pallidum penetrates mucosal surfaces and abraded skin of humans. Chemotactic factors attract neutrophils to the inoculation site. Skin breakdown results in a chancre, initiating the *primary stage*. In more mature chancres, neutrophils are replaced by lymphocytes that, through secretion of lymphokines, attract and activate macrophages. In the presence of exogenous antibody, macrophages ingest and destroy the organisms. Consistent with a T_H1-predominant local cellular response, the lesions contain interleukin (IL)-2, interferon-?, IL-10, and IL-12. [7] Plasma cells are also present in the infiltrate and a humoral response is elicited. Antibodies to *T. pallidum* are detectable at the time or shortly after the chancre appears. Production of IgM precedes that of IgG. The combined humoral and cell-mediated immune responses appear to eliminate the spirochetes locally, resulting in the end of the primary stage. PCR studies indicate that *T. pallidum* spirochetemia occurs during the primary stage (as well as the secondary and relapsing stages). [8]

After a few weeks, proliferation of spirochetes markedly increases, and the disease becomes generalized. During this *secondary stage,* antibody levels skyrocket in response to the huge numbers of organisms. The antibody response modifies the appearance of the secondary syphilis lesions, which would otherwise resemble primary chancres. At this time, resistance to new infection develops, although delayed-type hypersensitivity to *T. pallidum* becomes unexpectedly deficient. This suppression of cell-mediated immunity allows proliferation of the organisms despite rising antibody levels.

The secondary stage is followed by an asymptomatic stage called *latency*. During this period, delayed-type hypersensitivity reappears. In *the tertiary stage,* the immune response results in the formation of granulomas, although treponemes are rarely detected, even by immunofluorescence.

Immunity to reinfection develops only in untreated patients. After treatment, most reinfected patients develop typical chancres. The majority of patients with congenital syphilis are refractory to reinoculation and do not develop lesions or elevated antibody levels. A few develop dark-field–negative lesions associated with high antibody titers or gummas at the inoculation site.

The means by which some treponemes resist the immune attack, which effectively clears practically every organism from early lesions, is unknown. Possible explanations include inhibition of cell-mediated responses, refuge of treponemes in anatomic sites (central nervous system, eye, aorta, bone, lymph nodes, or perilymph of middle ear) that shield the organisms from detection by the immune system, and protection by the slimy mucopolysaccharide coat surrounding the spirochetal cell wall. Some answers are provided by experimental infection in rabbits. Early on, immunity is normal, resulting in annihilation of most treponemes. However, treponemal antigens are able to induce the host macrophages to secrete twice as much prostaglandin E_2. As a result, IL-2 synthesis by these cells is halved and, consequently, T cell proliferation is inhibited, leading to suppressed immunity that enables the remaining intact organisms to proliferate, even in the presence of antibody. The suppression persists for at least 1 month and can be reversed by indomethacin or a combination of IL-1 and IL-2. [9]

CLASSIFICATION

Syphilis has been described as an on- and off- and on-again disease. Its course is divided into three clinically distinct stages and two asymptomatic epidemiologic stages. Early syphilis includes the primary stage (chancre), secondary disease (mucocutaneous lesions and/or lymphadenopathy, with or without organ involvement), and subsequent clinical relapses. Latent disease is subdivided into early (less than 1 year) and late (1 year or longer) stages. Tertiary (late) disease can present with cutaneous, cardiovascular, or neurologic involvement (Table 228-2).

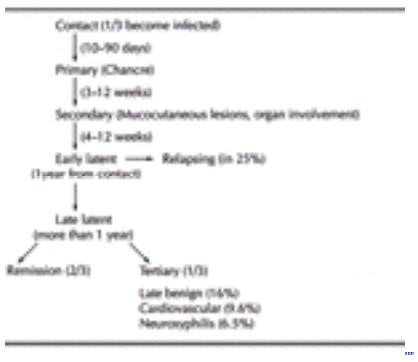

TABLE 228-2 **Stages of Syphilis**

PATHOGENESIS

The natural course of syphilis was studied in three large studies. In the Oslo study conducted in Oslo, Norway, between 1891 and 1910, the records of 953 patients with untreated syphilis were analyzed. The data has been criticized for its emphasis on autopsies, death certificates, and hospital admissions, which biased the results toward a more serious prognosis. In the notorious Tuskegee experiment, 412 African American men with untreated latent syphilis were followed from 1936 to 1972, during which time they were discouraged from receiving treatment. [10] The conclusions of this unfortunate study are limited by its restriction to a single race, sex, and socioeconomic class, and by the lack of a unified protocol. Furthermore, the study has been accused of having as a prime objective the procuring of body tissues and fluids to create and commercialize serologic tests. Conclusions from the Rosahn study, the third in this series, which was a review of autopsies, are distorted by the obviously poor prognosis of the studied population.

In the Oslo study, the median duration of the primary stage was 30 days in men and 27 days in women. [11] The secondary stage lasted 2.1 months in men and 3.5 months in women. Approximately 25 percent of patients experienced relapsing syphilis, and in this group, one-quarter had multiple episodes. Six months after contracting syphilis, 95 percent of patients become uninfectious, even without treatment. Although the danger of direct transmission is exceedingly low after 5 years of infection, inoculation from gummas has been reported. Latent syphilis follows the secondary stage and may persist for life in an asymptomatic form in about two-thirds of untreated patients. The rest develop tertiary syphilis, which usually becomes manifest as cutaneous (16 percent), cardiovascular (9.6 percent), or central nervous system (CNS) (6.5 percent) disease (see Table 228-2). Syphilis was the cause of death in 11 percent of the patients in the Oslo study. In African American men with untreated syphilis, the mortality appears to be even higher as cardiovascular disease was found in approximately half of autopsies from persons participating in the Tuskegee experiment. [10]

More recent analyses indicate that 1 in 25 persons with untreated syphilis become crippled, 1 in 44 insane, and 1 in 200 blind.

CLINICAL MANIFESTATIONS

Primary Syphilis

Approximately one-third of persons who come in contact with a lesion of early syphilis become infected. At the site of treponemal penetration, after an incubation period that ranges from 10 to 90 days (average 3 weeks), a dusky red macule appears that grows into a papule and becomes a chancre by ulcerating in the center (Fig. 228-2). The length of the incubation period varies inversely with the number of inoculated treponemes. The chancre is round or oval, approximately 1 cm in diameter, with sharply defined, regular, raised, indurated borders (Fig. 228-3). It is firm, rubbery, and, if uncomplicated by trauma or impetiginization, nontender. The ulcer base is smooth, brownish-red, and it may be covered with a yellowish or grayish slough. [12] Untreated, the chancre persists from 1 to 6 weeks; it resolves within 1 to 2 weeks after treatment and heals without scarring. However, deviation from the above description is common, and the classic “Hunterian” chancre is now seen in only approximately 60 percent of cases. In 15 to 30 percent of cases, the lesions go unnoticed. Multiple chancres (Fig. 228-4) may be present in up to 47 percent of cases, and edema, phimosis, erosive balanitis, lymphangitis, and thrombophlebitis of the dorsal vein may be found. In industrialized countries, coinfection with herpes genitalis is the most plausible explanation for the presence of multiple chancres. In men, the commonly involved locations are the glans, the coronal sulcus, and the foreskin. Chancres in the urethral orifice have been reported to cause an inflammatory phimosis that may eventuate in penile gangrene. Retraction of the foreskin with a chancre in its mucosal surface causes the foreskin to flip briskly, a sign known as the “dory flop.”

FIGURE 228-2 Early chancre presenting as a flat, eroded papule with raised, indurated borders and a smooth, clean base.

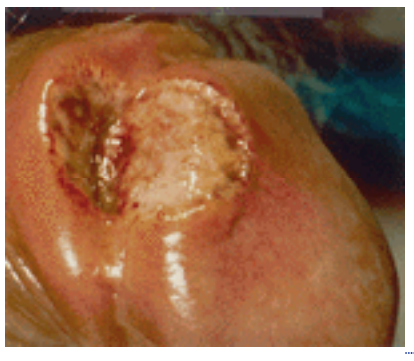

FIGURE 228-3 Classic “Hunterian” chancre with raised, indurated borders and a slightly hemorrhagic necrotic base.

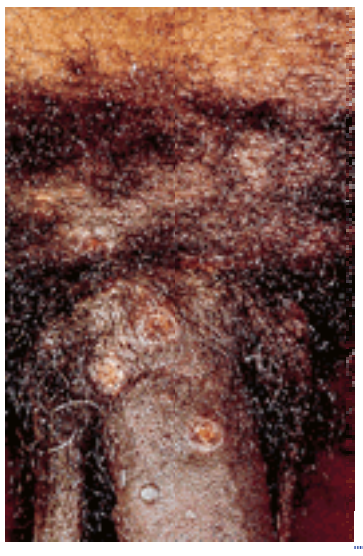

FIGURE 228-4 Multiple chancres at the base of the penis and adjacent pubis. Chancres in this location are associated with use of condoms.

In women, the labia, fourchette, urethra (Fig. 228-5), and perineum are affected, in descending order of frequency. Chancres in women tend to have an edematous rather than a cartilaginous induration. *Edema indurativum* is a unilateral labial swelling with rubbery consistency and intact surface, characteristic of a deep-seated chancre in this site. Chancres develop in the cervix in as many as 44 percent of infected women but are rarely detected. Kissing chancres are common in areas of skin-to-skin contact such as the vulva.

FIGURE 228-5 Chancre in a female. An ulcer covered with fibrin and necrotic slough at the orifice of the urethra.

Extragenital chancres are more commonly related to oral sex. Approximately two-thirds of extragenital chancres occur above the neck, and approximately half of these are seen on the lips, the perioral region, or in the oral cavity (Fig. 228-6). The rest appear on the fingers, breasts, trunk, abdomen, and extremities. Chancres on the fingers may be painful. Anorectal chancres constitute at least 4 to 10 percent of extragenital primary syphilis cases and are common in men who have sex with men. Anorectal primary syphilis is underdiagnosed and should be considered in any at-risk person with rectal pain, bloody stools, anal fissures, or a precipitously appearing mass or ulcer in the anorectal area.

FIGURE 228-6 Extragenital chancre. A deep ulcer with an indurated border and base. Most extragenital chancres are located on the lips or the perioral region.

In 70 to 80 percent of all primary syphilis cases, enlarged, rubbery, movable, nontender, nonsuppurative, discrete lymph nodes (buboes, also scleradenitis) appear during the first week of infection. The nodes are usually unilateral at first and most commonly palpated in the inguinal area, although in women the femoral nodes are often enlarged. In one study, the nodes were tender in 14 percent of patients. Relapses of primary syphilis, called monorecidive syphilis or chancre redux, are rare.

Differential Diagnosis

The diseases most frequently misdiagnosed as primary syphilis are chancroid, traumatic ulcers, and herpes genitalis. The differential diagnosis also includes granuloma inguinale, lymphogranuloma venereum, bacterial infections, squamous or basal cell carcinoma, lymphoma, Behçet's disease, aphthous ulcers, fixed-drug eruption, and balanitis or vulvitis caused by candidiasis, psoriasis, or lichen planus.

Secondary Syphilis

Lesions of secondary syphilis erupt 3 to 12 weeks after the appearance of the chancre but may develop months later or, in up to 15 percent of cases, before the chancre disappears. The secondary stage usually recedes in 4 to 12 weeks. [12] Not all patients present with the classic textbook presentation. In fact, the symptoms and clinical findings may be subtle, transient, and easily overlooked or so severe that hospitalization is required. Almost 60 percent of patients with latent or late syphilis deny ever experiencing signs or symptoms of secondary disease. One-quarter of these patients cannot recall the appearance of a chancre. Patients with secondary syphilis may experience symptoms such as malaise, appetite loss, fever, headache, stiff neck, lacrimation, myalgias, arthralgias, nasal discharge, and depression. However, the majority of patients present with only an eruption. The frequency of organ involvement differs among studies. In a series of 2269 cases of secondary syphilis, the skin was involved in 81.1 percent, the oral cavity and pharynx in 36.3 percent, the genitalia in 19.9 percent, the CNS in 9.9 percent, the eyes in 4 percent, and visceral organs in 0.2 percent. Wise clinicians learn to consider the “great imitator” when confronting a combination of signs and symptoms that cannot be readily explained.

Skin eruptions develop in 80 to 95 percent of cases. Greater than 95 percent of the eruptions are macular, maculopapular, papular, or annular. [12] Nodular and pustular eruptions occur infrequently, and vesiculobullous lesions are seen only in prenatal syphilis, and not at all in adults. Lesions of secondary syphilis often have a symmetric pattern early in the disease and become polymorphic later. In 8 to 42 percent of cases the lesions are pruritic. Itching may be more common among African Americans. With or without treatment, all secondary lesions heal without scar formation in 2 to 10 weeks.

Macular eruptions (roseola syphilitica) consist of .05- to 2-cm, pink, discrete, nonscaling, oval macules and patches, which predominantly involve the trunk and flexor aspects of the upper extremities (Fig. 228-7). The face is usually spared, but any area, including the palms and soles, may be involved.

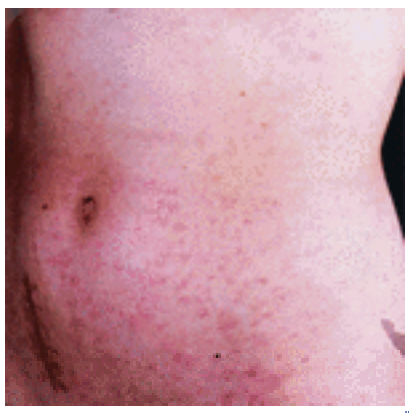

FIGURE 228-7 Macular syphilis (roseola syphilitica) with nonscaling, oval pink, ill-defined macules and patches on the chest and abdomen.

Maculopapular eruptions represent an evolution of the macular lesions toward papules and plaques, as some macules

become thickened and develop a dark coppery hue (Fig. 228-8 and Fig. 228-9). Lesions are often present on the genitalia, face, palms, and soles. Lesions around the hairline form a crown-like pattern known as the “corona veneris.”

FIGURE 228-8 Syphilis showing a combination of erythematous macules and coppery papules.

FIGURE 228-9 Generalized papulopustular syphilitic eruption. Note coppery tone of the papules and central crusting of some of the pustular lesions.

Papular eruptions include papulosquamous, follicular, lenticular, corymbose, nodular, annular, and follicular varieties. They may be disseminated and generalized (Fig. 228-9) or grouped, aggregated, and localized to defined sites (Fig. 228-10 and Fig. 228-11).

FIGURE 228-10 Papulosquamous syphilitic eruption with erythematous, well-demarcated, flattened plaques covered with scales (Biette's collarette).

FIGURE 228-11 Lichenoid syphilitic eruption with pink to violaceous, planar, polygonal papules resembling lichen

planus.

Papulosquamous eruptions have discoid, copper-colored or erythematous, oval or circular, indurated papules or plaques with a flat, shiny, scaly surface (Fig. 228-10). When the lesions are pruritic and lichenoid, the eruption may be difficult to distinguish from lichen planus (Fig. 228-11) and, when hyperkeratosis is pronounced, the eruption may resemble psoriasis. The occasional presence of the Koebner's phenomenon further contributes to this confusion. A thin, white ring of scales on the surface of a lesion (Biet's collarette) is a valuable but not pathognomonic diagnostic sign. The palms and soles are often involved (Fig. 228-12). On the soles, the lesions may become hyperkeratotic and be mistaken for calluses (clavi syphilitici) or tinea pedis.

FIGURE 228-12 Characteristic secondary syphilis lesions on the palms (**A**) and soles (**B**). Palmoplantar lesions may be macular or papular, discrete or diffuse, and nonscaling, slightly scaly, or hyperkeratotic (“syphilitic corn”).

Lenticular eruptions consist of pinhead to lentil-size, brown to red papules with smooth surfaces or fine scaling. The face, especially the forehead, oral commissures, nasolabial folds, and the genitalia, are favored sites.

Corymbose (bombshell) eruptions are rare and seldom occur before 6 to 8 months of infection. Typically a large central papule or plaque is surrounded by smaller satellite papules (Fig. 228-13).

FIGURE 228-13 Corymbose syphilitic eruptions occur late in the secondary stage, usually after 6 to 8 months of infection. A larger papule or plaque is surrounded by smaller satellite papules.

Nodular eruptions consist of dermal nodules, which are frequently misdiagnosed as lymphoma or a granulomatous disease (Fig. 228-14).

FIGURE 228-14 Nodular secondary syphilis on the face of a man. Such lesions are frequently misdiagnosed as lymphoma or a granulomatous disease, such as sarcoidosis, leprosy, or lupus vulgaris.

Annular eruptions consist of oval or round ringlike papules and plaques with a predilection for the face, anogenital area, body folds, palms, and soles. The eruption is often misdiagnosed as sarcoid, granuloma annulare, or tinea corporis. Serpiginous, concentric, or arcuate configurations may be seen.

Follicular eruptions consist of pinpoint, acuminate or rounded, erythematous papules that arise in crops on the torso and extremities. This eruption is uncommon and has been reported predominantly in debilitated persons such as alcoholics.

Pustular eruptions include several morphologic variants. In miliary pustular eruptions, small acuminate pustules and papules resolve with depressed pigmented scars. In acneiform, varioliform, or obtuse eruptions, there are large, acuminate perifollicular pustules, often with polymorphism (Fig. 228-9). In impetiginoid or ecthymiform eruptions, flat pustules become confluent and covered with a large crust called a carapace. Malignant syphilis (lues maligna, rupial syphilis, pustuloulcerative syphilis) presents with widespread papulopustules or nodules that become necrotic and break down into ulcers covered by layers of rupioid crust resembling an oyster shell (Fig. 228-15). The eruption is associated with toxicity, fever, arthralgias, and, occasionally, hepatitis. Oral ulcers and mucous patches may develop. Most patients have abnormal immune systems or poor health. Infected contacts usually have a more benign course, and there is no evidence that the treponemes causing the infection are more virulent. Noduloulcerative syphilis with or without systemic symptoms is more common in immunocompromised HIV-infected persons.

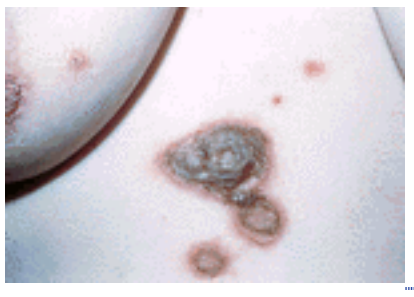

FIGURE 228-15 Sharply marginated, necrotic ulcers covered by “rupioid,” thick dirty crusts (like oyster shells) are the characteristic lesions of malignant syphilis.

Pigmentary changes may remain after healing of lesions. On the sides of the neck an interesting pattern consisting of hypopigmented macules superimposed on linear pigmented reticulated patches, has been called leukoderma colli syphiliticum or the necklace of Venus. In dark-skinned individuals, intense loss of pigment within the affected areas may resemble vitiligo. Hypopigmentation in syphilis results from partial inhibition of melanogenesis as the number of melanocytes is normal or only slightly reduced. When dermal atrophy, possibly related to inflammation-induced elastin degradation, is present, the appearance resembles anetoderma.

Mucous membrane lesions are extremely infectious. The three manifestations are condylomata lata, mucous patches, and pharyngitis. The last two heal spontaneously within 2 to 3 weeks, but condylomata may persist for months.

Condylomata lata consist of flesh-colored or hypopigmented, moist, oozing papules that become flattened and macerated (Fig. 228-16). They have been reported in 9 to 44 percent of cases. Their surface may be smooth, papillated, or covered with cauliflower-like vegetations. The common sites are the genital and anal areas and, less frequently, the oral commissures, face, axillae, inframammary folds, and toe webs (Fig. 228-17). [13] Lesions in intertriginous areas may erode or proliferate, forming elevated, brown velvety plaques or grouped hypertrophic, nodular lesions that resemble raspberries (frambesiform syphilis). Overgrowth of bacteria produces a foul odor.

FIGURE 228-16 Rounded, gray, moist, vegetating papules (condylomata lata) develop most frequently on the anogenital area, but may arise on the lips, groin, and toe webs. The lesions are often confused with condylomata acuminata (venereal warts).

FIGURE 228-17 Coppery, eroded, and crusted papules of secondary syphilis may also be found in the toe webs, where they may be mistaken for tinea, erythrasma or, as in this case, Kaposi's sarcoma.

Mucous patches are painless, shallow, rounded erosions covered with gray macerated scaling (Fig. 228-18). Present in 7 to 12 percent of secondary syphilis cases, the lesions may appear anywhere in the mouth but are more common on the tongue and lips. [14] The tonsils and epiglottis may be affected, resulting in hoarseness. Confluence of several denuded lesions on the tongue has been termed *plaques fauches en prairie*. Mucous patches also arise on the glans penis, inner vulva, and anus. In these areas, the lesions are more likely to become eroded or ulcerated due to friction. Split papules are elevated mucous patches with central fissures in the oral commissures (Fig. 228-18).

FIGURE 228-18 Mucous patches on the lips. These erosions covered with gray-white, macerated scales are seen on the lips, oral mucosa, tonsils, and larynx. Lesions in the buccal commissure are fissured in the center (split papules).

Pharyngitis of variable severity may occur in up to a quarter of cases, although soreness is rare. Diffuse redness of the pharynx, palate, and tonsils may be very mild or severe with edema and erosions. Pseudomembranes and necrosis have been reported, and laryngeal involvement may produce hoarseness.

NAIL DISEASE In secondary syphilis, nail changes may result from involvement of either the nail matrix or the nail folds. In the nail plate, brittleness, splitting, onycholysis, pitting, lunular elkonyxis (pits) with fissuring, and dystrophy have been described. The nail plate growing during the infectious episode may become dull, dry, thickened, and Beau's lines or latent *onychomadesis* (separation) may appear. Paronychia of the lateral and proximal nail folds may develop. The nail bed may become ulcerated, producing an exudate that may cause separation, shedding, and even permanent deformity of the nail plate. Amber-colored plates resembling artificial nails have been reported to be characteristic of late secondary syphilis. Cyanotic, painful toes (the blue-toe syndrome) are an unusual manifestation. [15] Alopecia may be the only sign of secondary syphilis. It has been described in 3 to 7 percent of cases, and may be either patchy, diffuse, or both. [16] The more characteristic type consists of small irregular patches of nonscarring alopecia throughout the scalp but predominantly on the occipital and parietal regions. Because the margins are not sharp, the term *moth-eaten* is often used descriptively (Fig. 228-19). In some cases, the lesions resemble trichotillomania or alopecia areata. Occasionally the eyebrows, beard, and other hair-bearing areas are affected. Diffuse hair loss may occur as a result of scalp involvement by secondary syphilis or as a telogen effluvium, clinically noticeable 3 to 5 months after the infection begins.

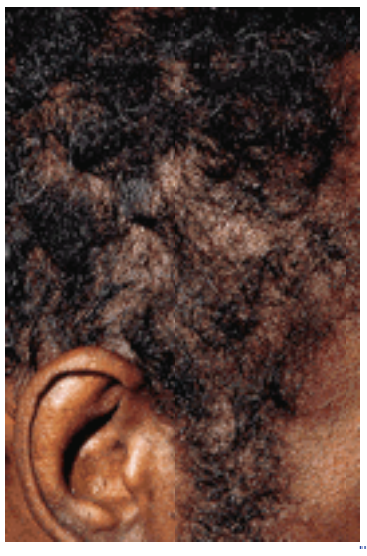

FIGURE 228-19 Moth-eaten alopecia is the more common form of hair loss. Irregular, patchy, nonscarring alopecia is present more frequently on the occipital scalp, and occasionally affects the eyebrows and beard.

Other Associated Clinical Manifestations

LYMPHORETICULAR SYSTEM Enlarged lymph nodes are present in 50 to 80 percent of cases. In descending order of frequency, the inguinal, axillary, cervical, epitrochlear, femoral, and superclavicular chains are involved. Typically, the nodes are movable, firm, rubbery, discrete, bilateral, symmetric, and nontender. [12] Mild splenomegaly is common.
OPHTHALMOLOGIC Iritis, the most common eye complication, occurs in fewer than 3 percent of all cases, late in the course of secondary syphilis, or in relapsing syphilis. The patient presents with red, injected eyes and complains of pain, lacrimation, and photophobia. Uveitis, chorioretinitis, and, rarely, vasculitic occlusion of the central retinal vein and artery are also observed. A recent report concluded that 4.3 percent of 552 cases of uveitis were syphilitic. [17] Symptoms include photophobia; lacrimation; red, painful eyes; and blindness. Topical glucocorticoids without antibiotics are contraindicated.
AUDITORY There are a few reports of sensorineural hearing loss in early acquired syphilis. The condition worsens rapidly and tends to be bilateral. Vestibular involvement with labyrinthitis is uncommon. However, 6 percent of all cases of Ménière's disease are caused by congenital or acquired syphilis. [18] The pathogenesis is usually basilar meningitis with damage to the eighth nerve. Immediate treatment with antibiotics and a prolonged course of prednisone preserves hearing in almost all cases.
MUSCULOSKELETAL Because bone and joint involvement are not readily apparent, the impression has been that they are rare. However, different studies have found rates ranging from 0.15 to 4 percent clinically and 9 percent by imaging. The principal symptoms are local pain, erythema, doughy tumefaction, and warmth. Favored affected sites are the long bones of the extremities, especially the tibia, and the skull, with resulting persistent headaches. Radiographs and more sensitive bone scans demonstrate various combinations of periostitis, osteomyelitis, bone destruction, and sclerosis. Radiographic changes may take up to 11 months for complete resolution after appropriate therapy. Back pain, arthralgias, arthritis, tenosynovitis, and bursitis may be severe and persist for several months. Patients may experience generalized myalgias and muscle weakness that resembles an inflammatory myopathy.
HEMATOLOGIC Abnormalities include anemia, leukocytosis, relative lymphopenia, and elevated sedimentation rate.
RENAL Acute membranous glomerulonephritis, usually manifested by the nephrotic syndrome, is reversible with treatment.
HEPATIC Although usually subclinical, the incidence of luetic hepatitis was 9.7 percent in one study. Jaundice is seldom detected.
GASTRIC Epigastric pain and postprandial vomiting may be caused by eroded, ulcerated, or polypoidal stomach lesions, which heal with antibiotics. Erosive syphilitic gastritis usually affects the antrum of the stomach.

LATENT SYPHILIS

The secondary stage is followed by an asymptomatic stage with no clinical findings in which the only evidence of the disease is reactive serologic testing. Latency may remain indefinitely, be interrupted by a relapse of secondary syphilis, or progress to the tertiary stage. Being a diagnosis of exclusion, careful examination for mucocutaneous lesions and organ involvement is required. Ultrasound evaluation of the aorta to exclude cardiovascular disease should be considered. Although neurosyphilis should be excluded by examination of the cerebrospinal fluid (CSF), spinal taps are not routinely done because of concern about complications, unless neurologic signs or symptoms are present or the patient is HIV-infected. The duration of infection should be determined by history and previous serologic tests, because, for therapeutic and epidemiologic purposes, the latent stage is divided into early (less than 1 year) and late (1 year or longer) stages. However, this determination may not always be possible, and the clinician must settle for a diagnosis of indeterminate latency, which is treated in the same manner as late latent syphilis.

In clinical practice, patients who were adequately treated but who continue to have low titers of nontreponemal tests are commonly seen. If previous treatment or lack of reinfection cannot be confirmed, then, from a public health standpoint, these patients should be assumed to be infected and treated. A record of the nontreponemal test titer and the administered therapy should be given to the patient. Too often patients are unnecessarily retreated repeatedly because such records are not readily available.

RELAPSING SYPHILIS

Approximately 25 percent of untreated patients experience a relapse of secondary lesions despite the absence of reinfection. More than two-thirds of the relapses occur within 6 months, 90 percent occur within the first year, and 95 percent occur within 2 years. Relapses may present with the reappearance of chancres or, more frequently, an eruption of secondary syphilis, including mucous patches and condylomata lata. Relapsing syphilis lesions tend to be less extensive and are frequently confined to the anogenital and oral areas. Because patients may be unaware of the lesions

or insufficiently concerned to seek medical help, relapsing syphilis is particularly alarming from an epidemiologic standpoint. Other presentations include periostitis (usually tibial), iritis, and hepatitis.

TERTIARY SYPHILIS

Approximately one-third of patients with untreated latent syphilis develop tertiary syphilis, while the other two-thirds remain in perpetual latency. The three principal presentations during this stage are late benign syphilis, cardiovascular disease, and neurosyphilis.

Late Benign (Tertiary) Syphilis

Late benign syphilis includes any symptomatic syphilitic manifestation after the secondary and relapsing stages that does not involve the cardiovascular or nervous systems. The lesions are caused by a cell-mediated inflammatory response to a small number of treponemes present in the affected tissues. At the beginning of the twentieth century, the incidence in untreated men and women was 14.4 and 16.7 per 100,000 population, respectively, but now this stage is rare, possibly as a result of widespread use of antibiotics for other infections. The more commonly involved organs are the skin (70 percent), mucous membranes (10.3 percent), and bones (9.6 percent), but gummas may appear in practically any organ, including the parotid glands, thyroid, esophagus, stomach, liver, breasts, pancreas, kidneys, adrenal glands, spleen, bladder, and cervix, as well as the brain and heart. Chronic iritis, chorioretinitis, interstitial keratitis, and atrophy of the optic nerve are rare. Painless, fibrosing interstitial orchitis can result in atrophy.

LATE BENIGN SYPHILIS OF THE SKIN Tertiary skin lesions can be divided into three types: granulomatous nodules, psoriasiform granulomatous plaques, and gummas. “Precocious” lesions develop within the first 2 years after the resolution of the secondary stage, and “late” lesions at any time after that. Most lesions develop within 3 to 7 years, but gummas have appeared as long as 60 years after infection. The longer the interval before the appearance of the skin lesions, the more solitary and destructive the process. Precocious tertiary syphilis develops during the first 2 years of infection and occasionally within weeks. Infiltrated grouped papules that tend to ulcerate may be localized to one site or be more widespread. The papules have features of both secondary stage lesions and tertiary stage granulomas. Bacteria are rarely detected. The lesions heal with little or no scarring. Nodular and noduloulcerative tertiary lesions (Fig. 228-20) are superficial, firm, painless, dull-red, shiny, flat cutaneous nodules that measure several millimeters to 2 cm in size. The nodules appear in a grouped configuration and coalesce into plaques. [19] The skin overlying the lesions breaks down, resulting in irregular ulcers covered with crust. Over weeks or months, central healing and advancing borders produce plaques with annular, arciform, serpiginous, or polycyclic configurations that may grow to more than 30 cm (Fig. 228-21). Some plaques may be psoriasiform (Fig. 228-22). The lesions are most commonly seen on the arms, back, and face. Even without treatment the granulomas heal over the years, leaving noncontractile, atrophic scars with increased or decreased pigmentation.

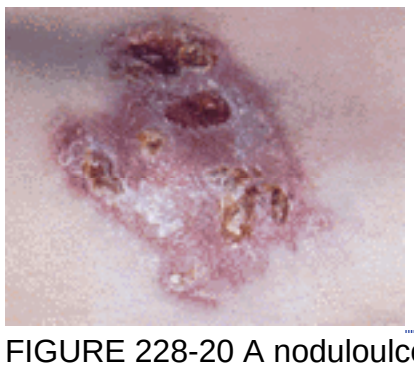

FIGURE 228-20 A noduloulcerative tertiary syphilitic lesion is a sharply defined and irregularly shaped flat nodule of a dull red color, firm consistency and superficial ulcerations.

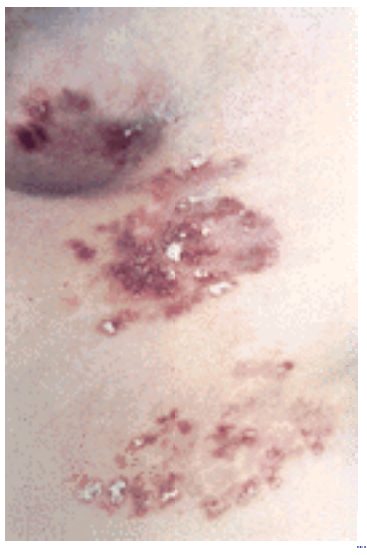

FIGURE 228-21 Crusted and scaly noduloulcerative tertiary syphilis plaques with characteristic serpiginous borders and scarring.

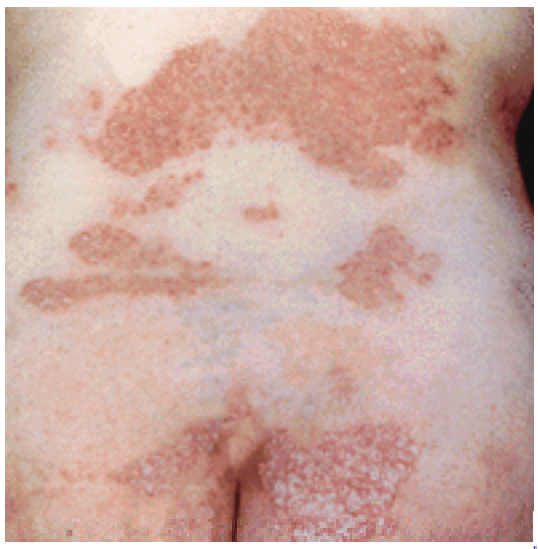

FIGURE 228-22 Plaque of tertiary syphilis may be brick-red in color, covered with scales, and may be indistinguishable from psoriasis.

Gummas are nontender pink to dusky-red nodules or plaques that vary in size from millimeters to many centimeters in diameter. [20] They favor sites of previous trauma and may arise anywhere in the body but are more common on the scalp, forehead (Fig. 228-23), buttocks, and presternal, superaclavicular or pretibial areas. The nodule is initially firm but develops a gummy consistency due to accumulation of necrotic tissue. Gummas may grow horizontally as well as vertically. Small ulcerations and abscesses may be present within the lesions (Fig. 228-23). Various geometric configurations are assumed. As the central gumma heals, new lesions may develop on the periphery, forming scalloped borders. Gummas are more destructive and deeper than noduloulcerative lesions (Fig. 228-24). Tissue necrosis eventuates in cylindrical, punched-out ulcers with clean granulomatous bases covered with adherent yellow-white slough (Fig. 228-25). The ulcer may enlarge, remain unchanged, or heal spontaneously even as the gumma enlarges. More superficial gummas heal with noncontractile atrophic scars, whereas deeper lesions leave thickened, pitted, ridged scars. Gummas are rarely contagious, but infection following contact with gummas has been reported.

FIGURE 228-23 Disfiguring gummatous infiltration of the glabella and forehead with scattered ulcerations in a 60-year-old female with late benign syphilis.

FIGURE 228-24 Aggressive gumma of the forehead causing destruction of the calvarium, mimicking advanced, destructive basal cell carcinoma.

FIGURE 228-25 Two deep, punched-out ulcers in the popliteal fossa, covered with an adherent yellow slough at the base. This is the classical appearance of nodular gummas.

Mucous Membrane Lesions of Late Benign Syphilis

Discrete gummas or diffuse gummatous infiltration may involve mucous membranes, especially the palate, nasal mucosa, tongue, tonsils, and pharynx. The lesions ulcerate and are disfiguring. Destruction of the nasal cartilage and bone (saddle nose) (Fig. 228-26A) and perforation of the nose and palate are disease hallmarks (Fig. 228-26B). Chronic interstitial glossitis remains premalignant even after penicillin treatment (Fig. 228-27). Gummas of the larynx, trachea, and bronchi are rare. Pulmonary findings include chronic infection with miliary lesions, a nodule, or pleural effusion. Pseudochancre redux is a solitary gumma of the penis.

FIGURE 228-26 *A*. Destruction of the nasal cartilage and bone by a gumma leads to a saddle nose and (*B*) to the perforation of the nasal cartilage and skin and thus to considerable mutilation.

FIGURE 228-27 Premalignant, chronic interstitial glossitis secondary to gummatous infiltration of the tongue.

Skeletal late syphilis includes gummatous osteitis, periostitis, and sclerosing osteitis. The bones most commonly affected are the tibia, clavicle, skull, fibula, femur, and humerus, but the disease can involve almost any bone. Symptoms include nocturnal pain, swelling, and tenderness.

Cardiovascular Syphilis

Although currently regarded as a medical curiosity, new cases of cardiovascular syphilis continue to be reported. In early syphilis, cardiovascular disease is rare and limited to conduction defects. However, cardiovascular disease is a common manifestation of tertiary disease. In the Oslo study, the disease was clinically apparent in 13.6 percent of men and 7.6 percent of women, and was the primary cause of death in 15.1 percent of men and 8.2 percent of women. Before the availability of penicillin, syphilis constituted 25 to 30 percent and 5 to 10 percent of all cardiac diseases in African Americans and whites, respectively. Symptoms usually develop 15 to 30 years after the initial infection. Only 7 percent of patients with cardiovascular syphilis develop symptoms or signs within 5 years of infection.

Presumably, during the early stages of syphilis, treponemes invade the aortic wall, where they can remain dormant indefinitely. The treponemes have a predilection for the aortic vasa vasorum and produce chronic low-grade inflammation

that eventuates in an obliterative endarteritis. This results in necrosis of the muscular and elastic tissues and scarring. Fibrous thickening of the adventitia and atherosclerotic plaques in the intima impart the tree bark appearance that is highly suggestive of syphilis. The most common complications are aortitis, aortic aneurysm, aortic valve incompetence, coronary ostial stenosis, and myocardial gummatous disease.

Uncomplicated aortitis occurs predominantly in the ascending aorta, with fewer than 10 percent of the cases involving the abdominal aorta and only 2 percent affecting the portion below the renal artery. [21] The disease comprises between 27 and 36 percent of cardiovascular syphilis cases, but is asymptomatic and is usually found inadvertently at postmortem examination. The diagnosis is suspected when linear eggshell calcifications of the anterolateral aortic wall are present in chest radiographs.

Aortic aneurysms comprise 20 percent of cases of cardiovascular syphilis. The proportion is actually 40 percent if patients who also have coronary ostial or aortic valvular disease are included. Focal weakening of the wall results in a saccular aneurysm, whereas diffuse weakening produces fusiform involvement of the ascending and transverse aorta with subsequent dilation of the aortic ring. More than 60 percent of aneurysms involve the ascending aorta, and 25 percent the transverse arch. Abdominal aneurysms usually form above the renal arteries.

Coronary ostial stenosis constitutes 25 to 30 percent of cases of cardiovascular syphilis. Like ischemic heart disease, the main symptoms are angina pectoris and congestive heart failure. Clues to the diagnosis are the relative young age of the patient, absence of arteriosclerotic changes, reactive syphilis serology, poor response to vasodilators, and concomitant aortic regurgitation. Acute myocardial infarctions rarely occur because the stenosis is gradual and stimulates the development of an adequate collateral circulation.

Aortic valvular incompetence is found in approximately 30 percent of patients with tertiary disease. It is a late complication caused by aortic ring dilation and stretching of the valve. The soft diastolic blowing murmur of aortic regurgitation is best heard over the second right intercostal space. Myocardial disease occurs in only 2.4 percent of cardiovascular syphilis patients. In diffuse gummatous myocarditis, the most common locations are the left ventricle and septum, where gummas can cause heart block and conduction defects.

Neurosyphilis (Table 228-3)

I. Asymptomatic
II. Meningeal
A. Acute meningitis (headache, fever, photophobia, stiff neck, confusion)
1. With hydrocephalus (severe headache, nausea, vomiting, papilledema)
2. With vertex involvement (seizures, aphasia, hemiplegia)
3. With basilar involvement (tinnitus, deafness, Bell's palsy)
B. Spinal pachymeningitis (cervical pain, muscle atrophy, sensory loss, spastic paraplegia)
III. Meningovascular
A. Cerebral (prodromal symptoms, hemiparesis, hemiplegia, aphasia, seizures)
B. Spinal
1. Meningomyelitis (paresthesia, spastic weakness of legs, sensory loss, sphincter disturbances)
2. Acute transverse meningitis (sudden flaccid paraplegia, hemiparesis, sensory loss, urinary retention)
IV. Parenchymatous
A. General paresis (impaired judgement, irritability, delusions, dysarthria, tremors, incontinence)
B. Tabes dorsalis (paresthesia, lightning pains, ataxia, incontinence, impotence, pupillary disturbances)
C. Optic atrophy (visual loss)
V. Gummatous
A. Cerebral
B. Spinal

TABLE 228-3 **Classification of Neurosyphilis**

Hematogenous invasion of the meninges by *T. pallidum* occurs early. The resulting infection may resolve spontaneously or proceed to either chronic asymptomatic or acute symptomatic meningitis. Meningitis may progress to involve other areas of the CNS. In one study, *T. pallidum* was recovered from half the patients with secondary syphilis, the only patient with primary syphilis, and from no patient with latent syphilis. In another report, 16 percent of patients with indeterminate latent syphilis had reactive CSF serologies and pleocytosis, and one-quarter of these patients were asymptomatic.

After resolution of secondary syphilis, the spirochetes presumably remain dormant in the CNS of untreated, and even in some treated, patients. In 9.4 percent of men and 5 percent of women, this asymptomatic state progresses to clinically overt neurologic disease.

Symptoms occur from 5 to 35 years after the initial infection. The clinical manifestations of neurosyphilis are protean, but the classification (Table 228-3) is useful and widely used. Neurosyphilis is divided into asymptomatic, meningeal, meningovascular, parenchymatous, and gummatous disease.

Asymptomatic neurosyphilis is the presence of CNS infection as indicated by CSF abnormalities in the absence of neurologic signs or symptoms. CSF findings, such as reactive serologic or elevated cell counts and protein, peak at 12 to 18 months after infection, but disappear in 70 percent of cases even without treatment. Nontreponemal tests may be nonreactive in up to 39 percent of patients, but treponemal tests are usually positive in the serum as well as in the CSF. [21]

Meningeal syphilis may occur early or late. Most cases of acute syphilitic meningitis occur during the first year of infection. Meningitis is the initial presentation of syphilis in up to 25 percent of patients. Fewer than 10 percent of these patients have skin eruptions at the onset of their meningitis. The symptoms are consistent with any aseptic meningitis and include headache, fever, photophobia, stiff neck, confusion, nausea, and vomiting. One-third of patients present with

acute hydrocephalus and one-quarter of all cases of syphilitic meningitis have focal involvement of the cerebral vertex (vertex meningitis) or posterior fossa, possibly resulting in seizures, aphasia, and hemiplegia. Cranial nerve palsies caused by basilar involvement are a common complication of meningitis. The more frequent palsies involve the oculomotor, auditory, and facial nerves. Reversible sensorineural deafness, which characteristically involves the higher frequencies, develops within days in up to 20 percent of patients, even in the absence of meningitis or other signs of secondary syphilis. The hearing loss is often preceded by tinnitus. Response of meningeal syphilis to penicillin is usually good.

Spinal pachymeningitis with inflammation and thickening of the dura mater usually involves the cervical area and causes pain, muscle atrophy, sensory loss, diminished tendon reflexes, and, ultimately, spastic paraplegia with sensory loss.

Meningovascular syphilis constitutes 10 percent of all neurosyphilis cases. The disease may involve the cerebrum (cerebrovascular) or spinal cord (spinal meningovascular).

Cerebrovascular syphilis is caused by endarteritis of the medium and large arteries (Heubner's arteritis) or small arteries and arterioles (Nissl arteritis) that results in thrombotic infarction. The name is somewhat misleading because the underlying pathogenesis is a chronic meningitis. Because the neurologic signs are focal, the clinical picture resembles atherosclerotic occlusive disease, but the typical patient is an adult 30 to 50 years of age. Symptoms may develop as early as 2 years, but usually develop between 4 and 7 years after the initial infection. Weeks to months before the abrupt onset, approximately half the cases experience prodromes, with symptoms such as dizziness, headaches, insomnia, memory loss, and mood changes. [22] Depending on the artery involved, patients may present with almost any neurologic deficit. The most frequent is hemiparesis or hemiplegia, followed in frequency by aphasia and seizures. [22] Therefore, this diagnosis should be considered in anyone with adult-onset epilepsy or strokes.

Spinal meningovascular syphilis is divided into meningomyelitis and acute transverse myelitis. Meningomyelitis, the more common form, usually begins more than 20 years after the initial infection, with paresthesia and spastic weakness of the legs. These symptoms are followed by combinations of sensory loss, sphincter disturbances, pain, and muscular atrophy. Acute transverse myelitis produces sudden flaccid paraplegia, sensory deficits, and urinary retention.

Parenchymatous neurosyphilis is divided into three well-known syndromes: tabes dorsalis, general paresis, and optic atrophy. [21]

Tabes dorsalis is caused by infection of the parenchyma of the posterior columns and posterior root of the spinal cord. It once developed in 5 percent of patients with untreated syphilis of 20 to 25 years duration, but is now rare. The three stages are preataxia, ataxia, and paralysis. The early symptoms are recurrent attacks of paresthesia and paroxysms of lightning pain. Stabbing pains in visceral organs such as the abdomen, rectum, and larynx (10 to 15 percent of cases) may simulate surgical emergencies. As the disease progresses, the patient may develop impotence, urinary retention, visual loss, and rectal incontinence. Locomotor ataxia begins with stumbling and difficulty in walking. Because position sense is lost, the ataxia is more prominent in the dark and is compensated by visual orientation. The Romberg sign is positive, which means that the patient stumbles when the feet are held close together with the eyes closed. Pupil reactivity becomes sluggish early and is seen in 90 percent of cases. The distinctive Argyll-Robertson pupils in which the pupil accommodates (to objects), but does not react (to light) are seen later. Hearing loss as a result of eighth nerve involvement is found in approximately 25 percent of cases. Charcot joints are enlarged, painless, uninflamed joints, with or without deformity or effusion, in the lower extremities and spine and result from repeated traumatic injury. Serum and CSF serologic tests are reactive in early tabes dorsalis but may be negative late in the course. The disease is rarely fatal, but patients become disabled and dependent.
