It is important and desirable to have carbon dioxide absorbents that neither release toxic particles or fumes nor produce toxic compounds when exposed to common anesthetics. Soda lime and Baralyme generally fit this description, but inhaled anesthetics do interact with absorbents to some extent. Historically speaking, an uncommon anesthetic, trichloroethylene, reacts with soda lime to produce toxic compounds. In the presence of alkali and heat, trichloroethylene degrades into the cerebral neurotoxin dichloroacetylene, which can cause cranial nerve lesions and encephalitis. Phosgene, a potent pulmonary irritant, is also produced and can cause adult respiratory distress syndrome.[116]

Sevoflurane has been shown to produce degradation products upon interaction with carbon dioxide absorbents.[104,117,118] The major degradation product produced is an olefin compound known as fluoromethyl-2,2-difluoro-1-(trifluoromethyl)vinyl ether, or compound A. During sevoflurane anesthesia, factors apparently leading to an increase in the concentration of compound A include (1) low-flow or closed-circuit anesthetic techniques, (2) use of Baralyme rather than soda lime, (3) higher concentrations of sevoflurane in the anesthetic circuit, (4) higher absorbent temperatures, and (5) fresh absorbent.[117-120] Interestingly, dehydration of Baralyme increases the concentration of compound A, but dehydration of soda lime decreases the concentration of compound A.[121,122] Apparently, the degradation products released during clinical conditions do not commonly result in adverse effects in humans, even during low-flow anesthesia,[119] but further studies are needed to verify this observation.[123-125]

Desiccated strong-base absorbents can also degrade contemporary inhaled anesthetics to clinically significant concentrations of CO, as well as trifluoromethane, which can interfere with monitoring of anesthetic gases.[104] Under certain conditions, this process can produce very high carboxyhemoglobin concentrations that reach 35% or greater.[126] Higher levels of CO are more likely after prolonged contact between absorbent and anesthetics, as well as after disuse of an absorber for at least 2 days, especially over a weekend. Thus, case reports describing CO poisoning have been most common in patients anesthetized on Monday morning, presumably because continuous flow from the anesthesia machine dehydrated the absorbents over the weekend.[127,128] Fresh gas flow rates of 5 L/min or greater through the breathing system and absorbent (without a patient connected) are sufficient to cause critical drying of the absorbent material. The situation is even worse when the breathing bag is left off the breathing circuit. Absence of the reservoir bag facilitates retrograde flow through the circle system (see Fig. 25-7).[126] Because the inspiratory valve leaflet produces some resistance to flow, fresh gas flow takes the retrograde path of least resistance through the absorbent and out the 22-mm breathing bag mount.

Several factors appear to increase the production of CO and resultant elevated carboxyhemoglobin levels, including (1) the inhaled anesthetic used (for a given MAC multiple, the magnitude of CO production from greatest to least is desflurane ≥ enflurane > isoflurane >> halothane = sevoflurane), (2) dryness of the absorbent (completely dry absorbent produces more CO than hydrated absorbent does), (3) the type of absorbent (at a given water content, Baralyme produces more CO than soda lime does), (4) the temperature (increased temperature increases CO production), (5) the anesthetic concentration (more CO is produced with higher anesthetic concentrations),[129] (6) low fresh gas flow rates, and (7) reduced experimental animal (patient) size per 100 g of absorbent.[104,130]

Several interventions have been suggested to reduce the incidence of CO exposure in humans undergoing general anesthesia.[128] Such interventions include (1) educating anesthesia personnel regarding the cause of CO production; (2) turning off the anesthesia machine at the conclusion of the last case of the day to eliminate fresh gas flow, which dries the absorbent; (3) changing the CO absorbent if fresh gas is found to be flowing during the morning machine check; (4) rehydrating desiccated absorbent by adding water to the absorbent[112]; (5) changing the chemical composition of soda lime to reduce or eliminate potassium hydroxide (such products now available include Dragersorb 800 Plus, Sofnolime, and Spherasorb), and (6) using absorbent material that is free of both sodium and potassium hydroxide, such as calcium hydroxide lime. Elimination of sodium and potassium hydroxide from desiccated soda lime diminishes or eliminates degradation of desflurane to CO and sevoflurane to compound A, but it does not compromise carbon dioxide absorption.[110,131]

One extremely rare, but potentially life-threatening complication related to the carbon dioxide absorbent used is the development of fires within the breathing system. Specifically, this can occur as a result of interactions between the strong-base absorbents (particularly Baralyme) and the inhaled anesthetic sevoflurane. In August 2003, Abbott Laboratories changed the package insert for sevoflurane to describe this rare phenomenon and the conditions under which it could occur. Almost 1 year later, in autumn 2004, several case reports describing patient injuries related to this problem were published (all involving Baralyme). It seems that when desiccated strong-base absorbents are exposed to sevoflurane, absorber temperatures of several hundred degrees may result from their interaction.[102] The buildup of very high temperatures, the formation of combustible degradation byproducts (formaldehyde, methanol, and formic acid), and the oxygen- or nitrous oxide–enriched environment provide all the substrates necessary for a fire to occur.[104] Avoidance of use of the combination of sevoflurane with strong-base absorbents, particularly Baralyme and especially if it has become desiccated, is the best way to prevent this unusual, potentially life-threatening complication.

Anesthesia Ventilators

The ventilator on the modern anesthesia workstation serves as a mechanized substitute for the hand of the anesthesia care provider in manipulating the reservoir bag of the circle system, the Bain circuit, or another breathing system. As recently as the late 1980s, anesthesia ventilators were mere adjuncts to the anesthesia machine. Today, they have attained a prominent central role in newer anesthesia workstations. In addition to the nearly ubiquitous role of the anesthesia ventilator in today's anesthesia workstation, many advanced intensive care unit (ICU)-style ventilation features have also been integrated into anesthesia ventilators (Fig. 25-27). Anesthesia care providers should be aware that even though more similarities exist between today's anesthesia ventilator and the ICU ventilator than ever before, some fundamental differences in ventilation parameters and control systems still

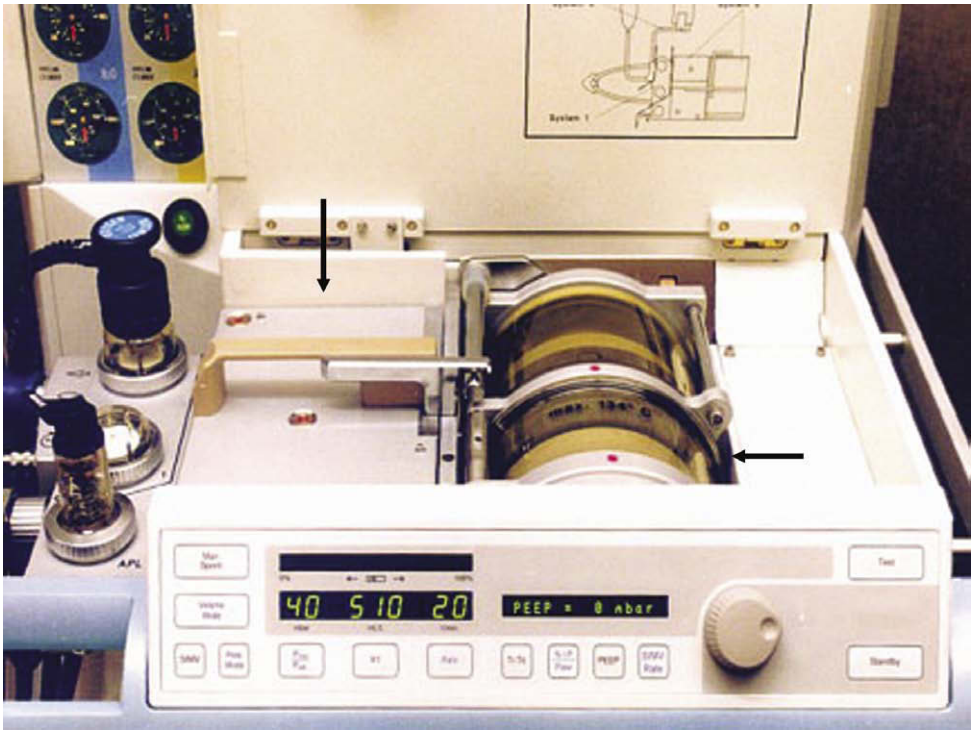

Figure 25-27 The Dräger Medical Narkomed 6000 with its single-circuit ventilator. The *horizontal arrow* indicates the piston cylinder unit of the Divan ventilator. The *vertical arrow* indicates the rectangular valve manifold for fresh gas decoupling.

remain. This discussion focuses on the classification, operating principles, and hazards associated with contemporary anesthesia ventilators.

Classification

Ventilators can be classified according to their power source, drive mechanism, cycling mechanism, and type of bellows.[132,133] The following sections review ventilator classification and terminology before the discussion of specific anesthesia workstation ventilators.

Power Source

The power source required to operate a mechanical ventilator is provided by compressed gas, electricity, or both. Older pneumatic ventilators required only a pneumatic power source to function properly. Contemporary electronic ventilators from Dräger Medical, Datex-Ohmeda, and others require either an electrical-only or both an electrical and a pneumatic power source.

Drive Mechanism and Circuit Designation

Double-circuit ventilators are most commonly used on modern anesthesia workstations. Generally, these conventional ventilators are pneumatically driven. In a double-circuit ventilator, a driving force such as pressurized gas compresses a component analogous to the reservoir bag known as the ventilator bellows. The bellows then in turn delivers ventilation to the patient. The driving gas in the Datex-Ohmeda 7000, 7810, 7100, and 7900 is 100% oxygen. In the North American Dräger AV-E and AV-2+, a venturi device mixes oxygen and air. Some newer pneumatic anesthesia workstations enable the user to select whether compressed air or oxygen is used as the driving gas.

In recent years, with the introduction of circle breathing systems that integrate fresh gas decoupling, a resurgence in the use of mechanically driven anesthesia ventilators has occurred. These "piston"-type ventilators use a computer-controlled stepper motor instead of compressed drive gas to actuate gas movement in the breathing system. In these systems, rather than having dual circuits with patient gas in one and drive gas in another, a single patient gas circuit is present. Thus, they are classified as piston-driven single-circuit ventilators. The piston operates much like the plunger of a syringe to deliver the desired tidal volume or airway pressure to the patient. Sophisticated computerized controls are able to provide advanced types of ventilatory support such as synchronized intermittent mandatory ventilation (SIMV), pressure-controlled ventilation (PCV), and pressure-support assisted ventilation, in addition to the conventional control-mode

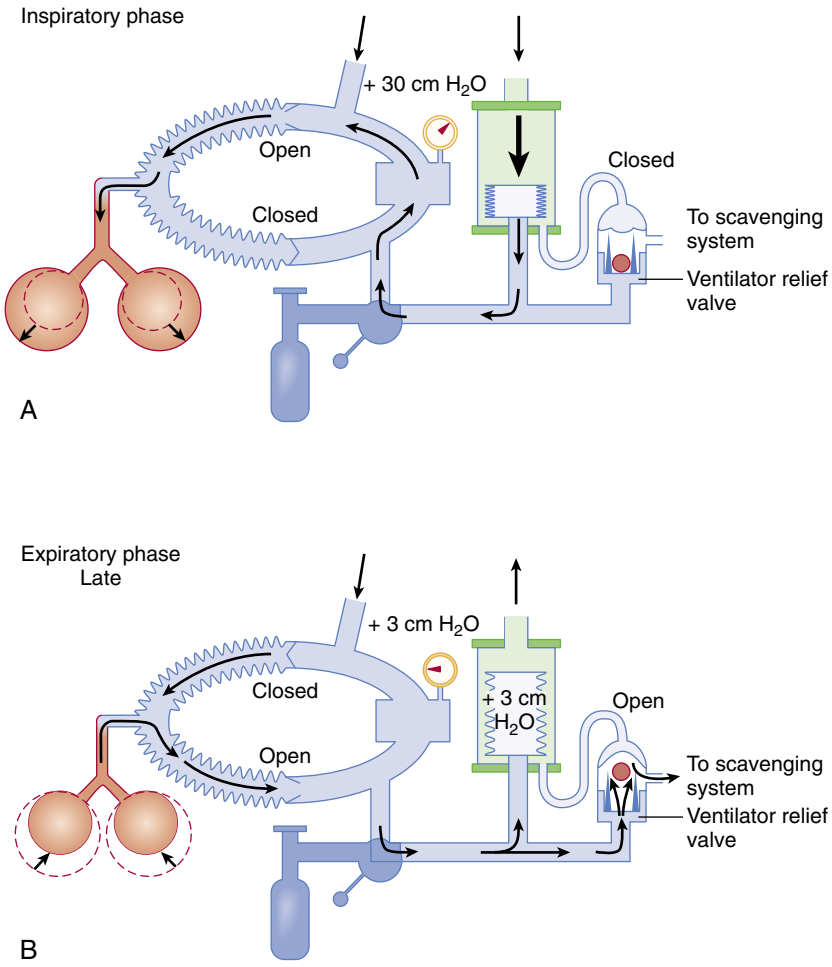
ventilation. Because the patient's mechanical breath is delivered without the use of compressed gas to actuate a bellows, these systems consume dramatically less compressed gas during ventilator operation than traditional pneumatic ventilators do. This improvement in efficiency may have clinical significance when the anesthesia workstation is used in a setting where no pipeline gas supply is available (e.g., remote locations or office-based anesthesia practices).

Cycling Mechanism

Most anesthesia machine ventilators are time cycled and provide ventilator support in the control mode. The inspiratory phase is initiated by a timing device. Older pneumatic ventilators use a fluidic timing device. Contemporary electronic ventilators use a solid-state electronic timing device and are thus classified as time cycled and electronically controlled. More advanced ventilation modes such as SIMV, PCV, and modes that use a pressure-support option may have an adjustable threshold pressure trigger as well. In these modes, pressure sensors provide feedback to the ventilator control system to allow it to determine when to initiate or terminate the respiratory cycle.

Bellows Classification

The direction of bellows movement during the *expiratory phase* determines the bellows classification. Ascending (standing) bellows ascend during the expiratory phase (Fig. 25-28B), whereas descending (hanging) bellows descend during the expiratory phase. Older pneumatic ventilators and some new anesthesia workstations use weighted descending bellows, but most contemporary electronic ventilators have an ascending bellows design. Of the two configurations, the ascending bellows is generally safer. An ascending bellows will not fill if a total disconnection occurs. However, the bellows of a descending bellows ventilator will continue its upward and downward movement despite patient disconnection. The driving gas pushes the bellows upward during the inspiratory phase. During the expiratory phase, room air is entrained into the breathing system at the site of the disconnection because gravity acts on the weighted bellows. The disconnection pressure monitor and the volume monitor may be fooled even if a disconnection is complete (see "Breathing Circuit Problems").[33] Some contemporary anesthesia workstation designs have returned to the descending bellows to integrate fresh gas decoupling (Dräger Medical Julian and Datascope Anestar). An



Figures 25-28 Inspiratory (**A**) and expiratory (**B**) phases of gas flow in a traditional circle system with an ascending bellows ventilator. The bellows physically separates the driving gas circuit from the patient gas circuit. The driving gas circuit is located outside the bellows, and the patient gas circuit is inside the bellows. During the inspiratory phase (**A**), the driving gas enters the bellows chamber, which causes the pressure within it to increase. This causes the ventilator relief valve to close, thereby preventing anesthetic gas from escaping into the scavenging system, and the bellows to compress, thereby delivering anesthetic gas within the bellows to the patient's lungs. During the expiratory phase (**B**), pressure within the bellows chamber and the pilot line decreases to zero, which causes the mushroom portion of the ventilator relief valve to open. Gas exhaled by the patient refills the bellows before any scavenging occurs because a weighted ball is incorporated into the base of the ventilator relief valve. Scavenging occurs only during the expiratory phase because the ventilator relief valve is open just during expiration. *(Reprinted with permission from Andrews JJ: The Circle System. A Collection of 30 Color Illustrations. Washington, DC, Library of Congress, 1998.)*

essential safety feature on any anesthesia workstation that uses a descending bellows is an integrated CO_2 apnea alarm that cannot be disabled while the ventilator is in use.

Operating Principles of Ascending Bellows Ventilators

Contemporary examples of ascending bellows, double-circuit, electronic ventilators include the Dräger Medical AV-E and AV-2+ and the Datex-Ohmeda 7000, 7800, and 7900 series. A generic ascending bellows ventilator is illustrated in Figure 25-28. It may be viewed as a breathing bag (bellows) located within a clear plastic box. The bellows physically separates the driving gas circuit from the patient gas circuit. The driving gas circuit is located outside the bellows, and the patient gas circuit is inside the bellows. During the inspiratory phase (see Fig. 25-28A), the driving gas enters the bellows chamber, which causes the pressure within it to increase. This increase in pressure is responsible for two events. First, the ventilator relief valve closes, thereby preventing anesthetic gas from escaping into the scavenging system. Second, the bellows is compressed, and the anesthetic gas within the bellows is delivered to the patient's lungs. This compression action is analogous to the hand of the anesthesiologist squeezing the breathing bag.[48]

During the expiratory phase (see Fig. 25-28B), the driving gas exits the bellows housing. This produces a drop to atmospheric pressure within both the bellows housing and the pilot line to the ventilator relief valve. The decrease in pressure to the ventilator relief valve causes the "mushroom valve" portion of the assembly to open. Exhaled patient gases refill the bellows before any scavenging can begin. The bellows refills first because a weighted ball (like those used in ball-type positive end-expiratory pressure [PEEP] valves) or similar device is incorporated into the base of the ventilator relief valve. Because this ball produces 2 to 3 cm H_2O of backpressure, scavenging occurs only after the bellows fills completely and the pressure inside the bellows exceeds the pressure threshold of the "ball valve." This design causes all ascending bellows ventilators to produce 2 to 3 cm H_2O of PEEP within the breathing circuit when the ventilator is in use. Scavenging occurs just during the expiratory phase because the ventilator relief valve is open only during expiration.[47]

It is important for anesthesia care providers to understand that on most anesthesia workstations, gas flow from the anesthesia machine into the breathing circuit is continuous and independent of ventilator activity. During the inspiratory phase of mechanical ventilation, the ventilator relief valve is closed (see Fig. 25-28A), and the breathing system's APL valve (pop-off valve) is most commonly out of circuit. Therefore, the patient's lungs receive the volume from the bellows plus that from the flow meters during the inspiratory phase. Factors that influence the correlation between set tidal volume and exhaled tidal volume include the flow meter settings, inspiratory time, compliance of the breathing circuit, external leakage, and the location of the tidal volume sensor. Usually, the volume gained from the flow meters during inspiration is counteracted by the volume lost to compliance of the breathing circuit, and the set tidal volume generally approximates the exhaled tidal volume. However, certain conditions such as inappropriate activation of the oxygen flush valve during the inspiratory phase can result in barotrauma or volutrauma (or both) because excess pressure and volume may not be able to be vented from the circle system.[47]

Problems and Hazards

Numerous hazards are associated with anesthesia ventilators, including problems with the breathing circuit, the bellows assembly, and the control assembly.

Traditional Circle System Problems

Breathing circuit misconnections and disconnection are a leading cause of critical incidents in anesthesia.[1,134] The most common disconnection site is at the Y-piece. Disconnections can be complete or partial (leaks). In the past, a common source of leaks with older absorbers was failure to close the APL valve (or pop-off valve) on initiation of mechanical ventilation. On today's anesthesia workstations, the bag/ventilator selector switch has virtually eliminated this problem because the APL valve is usually out of circuit when the ventilator mode is selected. Preexisting undetected leaks can exist in compressed, corrugated, disposable anesthetic circuits. To detect such a leak preoperatively, the circuit must be fully expanded before being checked for leaks.[135] As mentioned previously, disconnections and leaks are manifested more readily with the ascending bellows ventilator systems because they result in a situation in which the bellows will not refill.[33]

Several disconnection monitors exist. The most important monitor is a vigilant anesthesia care provider monitoring breath sounds and chest wall excursion in addition to both the mechanical (spirometers and pressure sensors) and physiologic monitors.

Pneumatic and electronic pressure monitors are helpful in diagnosing disconnections. Factors that influence monitor effectiveness include the disconnection site, the location of the pressure sensor, the threshold pressure alarm limit, the inspiratory flow rate, and the resistance of the disconnected breathing circuit.[136,137] Various anesthesia workstations and ventilators have different locations for the airway pressure sensor and different values for the threshold pressure alarm limit. The threshold pressure alarm limit may be preset at the factory or may be adjustable. An audible or visual alarm is actuated if the peak inspiratory pressure of the breathing circuit does not exceed the threshold pressure alarm limit. When an adjustable threshold pressure alarm limit is available, such as on many workstations from Dräger Medical, the operator should set the pressure alarm limit to within 5 cm H_2O of the peak inspiratory pressure. On systems that have an "autoset" feature, when activated, the threshold limit is automatically set at 3 to 5 cm H_2O pressure below the current peak inspiratory pressure. On such systems, failure to reset the threshold pressure alarm limit may result in either an "apnea pressure" or "threshold low" alert. Figure 25-29 illustrates how a partial disconnection (leak) may be unrecognized by the low-pressure monitor if the threshold pressure alarm limit is set too low or the factory preset value is relatively low.

Respiratory volume monitors are useful in detecting disconnections. Volume monitors may sense exhaled tidal volume, inhaled tidal volume, minute volume, or all three. The user should bracket the high and low threshold volumes slightly above and below the exhaled volumes. For example, if the exhaled minute volume of a patient is 10 L/min, reasonable alarm limits would

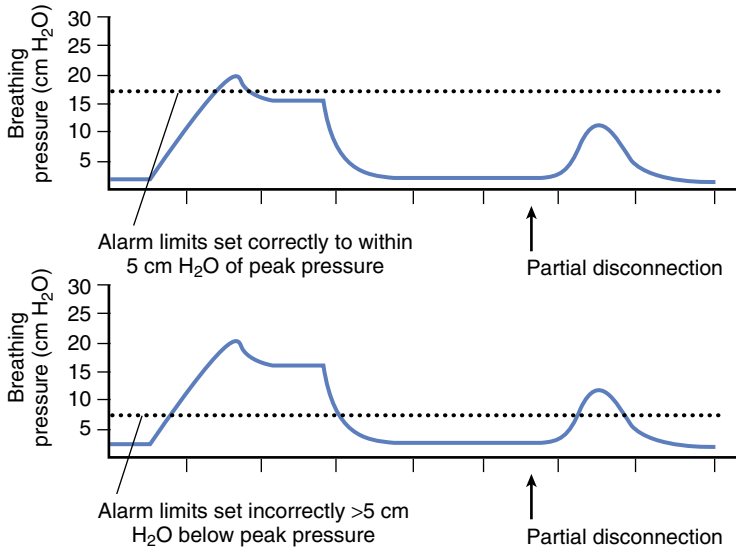


Figure 25-29 Threshold pressure alarm limit. **Top,** The threshold pressure alarm limit (*dotted line*) has been set appropriately. An alarm is actuated when a partial disconnection occurs (*arrow*) because the threshold pressure alarm limit is not exceeded by the breathing circuit pressure. **Bottom,** A partial disconnection is unrecognized by the pressure monitor because the threshold pressure alarm limit has been set too low. *(Redrawn with permission from Baromed Breathing Pressure Monitor. Operator's Instruction Manual. Telford, PA, North American Dräger, August 1986.)*

be 8 to 12 L/min. Many Datex-Ohmeda ventilators are equipped with volume monitor sensors that use infrared light/turbine technology. These volume sensors are usually located in the expiratory limb of the breathing circuit and thus measure exhaled tidal volume. In the case of the Datex-Ohmeda S/5 ADU, a special attachment known as the D-Lite spirometry connector is placed in the breathing circuit. This device is actually placed at or near the level of the patient connection and permits measurement of both inhaled and exhaled volume and pressure (see "Anesthesia Workstation Variations"). With the older infrared-type sensors, exposure to a direct beam of light from the overhead surgical lighting could cause erroneous volume readings if the surgical beam interferes with the infrared sensor.[138] Other types of expiratory volume sensors can be seen in systems such as the Datex-Ohmeda Aestiva, Aespire, and other workstations that incorporate the 7100 ventilator or 7900 SmartVent. These systems generally use differential pressure transduction technology to determine inhaled and exhaled volume, as well as to measure airway pressure. The Dräger Medical Narkomed 6000 series, 2B, and GS workstations commonly use an ultrasonic flow sensor located on the expiratory limb. Still other systems from Dräger measure exhaled volume with "hot-wire" sensor technology. With this type of sensor, a tiny array of two platinum wires is electrically heated to a high temperature. As gas flows past the heated wires, they tend to be cooled. The amount of energy required to maintain the temperature of the wire is proportional to the volume of gas flowing past it. This system has been associated in at least one report with accidental development of a fire in the breathing circuit.[103]

Carbon dioxide monitors are probably the best devices for revealing patient disconnections. The carbon dioxide concentration is measured near the Y-piece either directly (mainstream) or by aspiration of a gas sample to the instrument (sidestream). Either a sudden change in the difference between inspiratory and end-tidal carbon dioxide concentration or the acute absence of measured carbon dioxide indicates a disconnection, a nonventilated patient, or other problems.[33]

Misconnections of the breathing system are unfortunately not uncommon. Despite the efforts of standards committees to eliminate this problem by assigning different diameters to various hoses and hose terminals, they continue to occur. Anesthesia workstations, breathing systems, ventilators, and scavenging systems incorporate many of these diameter-specific connections. The ingenuity of anesthesia care providers in outwitting these "foolproof" systems has led to various hoses being cleverly adapted or forcefully fitted to inappropriate terminals and even to various other solid cylindrically shaped protrusions of the anesthesia machine.[33]

Occlusion (obstruction) of the breathing circuit may occur. Tracheal tubes can become kinked. Hoses throughout the breathing circuit are subject to occlusion by internal obstruction or external mechanical forces that can impinge on flow and have severe consequences. For example, blockage of a bacterial filter in the expiratory limb of the circle system has resulted in bilateral tension pneumothorax.[97] Incorrect insertion of flow direction–sensitive components can result in a no-flow state.[33] Examples of these components include some PEEP valves and cascade humidifiers. Depending on the location of the occlusion relative to the pressure sensor, a high-pressure alarm may alert the anesthesiologist to the problem.

Excess inflow to the breathing circuit from the anesthesia machine during the inspiratory phase can cause barotrauma. The best example of this phenomenon is oxygen flushing. Excess volume cannot be vented from the system during inspiration because the ventilator relief valve is closed and the APL valve is out of circuit.[47] A high-pressure alarm, if present, may be activated when the pressure becomes excessive. With many Dräger Medical systems, both audible and visual alarms are actuated when the high-pressure threshold is exceeded. In the Modulus II Plus System, the Datex-Ohmeda 7810 ventilator automatically switches from the inspiratory to the expiratory phase when the adjustable peak pressure threshold is exceeded.

On workstations equipped with adjustable inspiratory pressure limiters (e.g., the Datex-Ohmeda S/5 ADU and Aestiva and the Dräger Medical Narkomed 6000 series, 2B, 2C, GS, and Fabius GS), maximal inspiratory pressure may be set by the user to a desired peak airway pressure. An adjustable pressure relief valve will open when the predetermined user-selected pressure is reached. This theoretically prevents the generation of excessive airway pressure. Unfortunately, this feature is dependent on the

user having preset the appropriate "pop-off" pressure. If the setting is too low, insufficient pressure for ventilation may be generated and result in inadequate minute ventilation; if set too high, the excessive airway pressure may still occur and result in barotrauma. The piston-driven Fabius GS, as well as others, may also include a factory-preset inspiratory pressure safety valve that opens at a preset airway pressure, such as 75 cm H_2O, to minimize the risk of barotrauma. These strategies may reduce the risk of barotrauma and volutrauma; however, they are no substitute for vigilance of the anesthesia care provider.

Bellows Assembly Problems

Leaks can occur in the bellows assembly. Improper seating of the plastic bellows housing can result in inadequate ventilation because a portion of the driving gas is vented to the atmosphere. A hole in the bellows can lead to alveolar hyperinflation and possibly barotrauma in some ventilators because high-pressure driving gas can enter the patient circuit. The oxygen concentration of the patient gas may increase when the driving gas is 100% oxygen, or it may decrease if the driving gas is composed of an air-oxygen mixture.[139]

The ventilator relief valve can cause problems. Hypoventilation occurs if the valve is incompetent because anesthetic gas is delivered to the scavenging system during the inspiratory phase instead of to the patient. Gas molecules preferentially exit into the scavenging system because it represents the path of least resistance, and the pressure within the scavenging system can be subatmospheric. Ventilator relief valve incompetency can result from a disconnected pilot line, a ruptured valve, or a damaged flapper valve.[140,141] A ventilator relief valve stuck in the closed or partially closed position can produce either barotrauma or undesired PEEP.[142] Excessive suction from the scavenging system can draw the ventilator relief valve to its seat and close the valve during both the inspiratory and expiratory phases.[33] In this case, breathing circuit pressure escalates because the excess anesthetic gas cannot be vented. It is worthwhile to note that during the expiratory phase, some newer machines from Datex-Ohmeda (S/5 ADU, 7100 and 7900 SmartVent) scavenge both excess patient gas and the exhausted ventilator drive gas. That is, when the ventilator relief valve opens and waste anesthetic gases are vented from the breathing circuit, the drive gas from the bellows housing joins with it to enter the scavenging system. Under certain conditions, the large volume of exhaust gases could overwhelm the scavenging system and result in pollution of the operating room with waste anesthetic gases (see "Scavenging Systems"). Other mechanical problems that can occur include leaks within the system, faulty pressure regulators, and faulty valves. Unlikely problems such as an occluded muffler on the Dräger AV-E ventilator can result in barotrauma. In this case, obstruction of driving gas outflow closes the ventilator relief valve, and excess patient gas cannot be vented.[143]

Control Assembly and Power Supply Problems

The control assembly can be the source of both electrical and mechanical problems. Electrical failure can be total or partial; the former is the more obvious. As anesthesia workstations are becoming more dependent on integrated computer-controlled systems, power interruptions become more significant. Battery backup systems are designed to continue operation of essential electronics during brief outages (up to several hours). However, even with these systems, in the event of a failure some time may be required for "rebooting" after an electrical outage has occurred. During this time the availability of certain workstation features such as manual or mechanical ventilation can be variable. One cluster of electrical failures that could have potentially resulted in operating room fires was reported early after release of the Dräger Medical Narkomed 6000. Problems with the workstation's power supply printed circuit boards prompted a corrective recall action in November 2002.[144]

Anesthesia Workstation Variations

With the introduction of new technology often comes the need for adaptation of current technology to successfully allow its integration into existing systems. Otherwise, a more comprehensive redesign of an entire anesthesia system from the ground up could be necessary. One such example of adaptation in the anesthesia workstation can be seen with two new design variations of the circle breathing system. The first of these is found on the Datex-Ohmeda S/5 ADU (see Fig. 25-1), and the second is incorporated into the Dräger Narkomed 6000 series (see Fig. 25-2) and Fabius GS workstations. Because use of the circle system is fundamental to day-to-day practice for most anesthesiologists, a comprehensive understanding of these new systems is crucial for their safe use.

The Datex-Ohmeda S/5 ADU

The Datex-Ohmeda S/5 ADU (see Fig. 25-1) debuted as the AS/3 ADU in 1998. Along with its more comprehensive safety features and integrated design that eliminated glass flow tubes and conventional anesthesia vaporizers in exchange for a computer screen with digital fresh gas flow scales and the built-in Aladin Cassette vaporizer system, the machine had a radically different appearance in general. It is not until closer inspection that the other unique properties of the ADU begin to stand out. The principal difference in the ADU's circle system lies in incorporation of the specialized "D-lite" flow and pressure transducer fitting into the circle at the level of the Y-connector. On most traditional circle systems, exhaled tidal volume is measured by a spirometry sensor located in proximity to the expiratory valve. Placement of the D-lite fitting at the Y-connector provides a better location for measuring exhaled volume, allows monitoring of airway gas composition and pressure to be done with a single adapter instead of with multiple fittings added to the breathing circuit, and provides the ability to assess both inspiratory and expiratory gas flow and therefore the generation of complete flow-volume spirometry. Relocation of the spirometer sensor to the Y-connector also makes it possible to move the location of the fresh gas inlet to the "patient" side of the inspiratory valve without adversely affecting the accuracy of exhaled tidal volume measurement.

This atypical circle system arrangement with the fresh gas entering on the patient side of the inspiratory valve is advantageous for several reasons. It is likely to be more efficient in delivering fresh gas to the patient while preferentially eliminating exhaled gases. Importantly, it is also less likely to cause desiccation of the carbon dioxide absorbent (see "Interactions of Inhaled

Anesthetics with Absorbents"). Other notable changes on the S/5 ADU circle system include a compact proprietary carbon dioxide absorbent canister design that can be changed during ventilation without loss of circle system integrity, as well as relocation of the inspiratory and expiratory unidirectional valves from a horizontal position to a vertical position on the "compact block" assembly just below the absorbent canister. Reorientation of the unidirectional valves reduces the breathing circuit resistance encountered by a spontaneously ventilated patient. The vertically oriented unidirectional valves only have to be tipped away from the vertical position to be opened, unlike conventional horizontal valve disks, which have to be physically lifted off the valve seat against gravity to be opened.

The Dräger Medical Narkomed 6000 Series and Fabius GS

Several important differences exist between the traditional circle breathing systems of the newest Dräger products. At first glance, the most notable difference lies in the appearance and design of the ventilators used with these systems. From the inconspicuous horizontally mounted Divan piston ventilator of the Narkomed 6000 series (see Fig. 25-2) to the vertically mounted and visible piston ventilator of the Fabius GS with its absent flow tubes and glowing electronic fresh gas flow indicators, these systems appear drastically different from traditional anesthesia systems. The piston ventilator of the Dräger Narkomed 6000 and Fabius GS anesthesia systems may be classified as electrically powered, piston driven, single circuit, electronically controlled with fresh gas decoupling.

The circle breathing systems used by these Dräger workstations incorporate a feature known as *fresh gas decoupling* (FGD). Incorporation of this patient safety–enhancing technology has required a significant redesign of the traditional circle system. A functional schematic of a circle system similar to the one used by the Dräger Narkomed 6000 series during both the inspiratory and expiratory phases of mechanical ventilation can be seen in Figure 25-30A and B. To understand the operating principles of FGD, it is important to have a good understanding of gas flow in a traditional circle system during both the inspiratory and expiratory phases of mechanical ventilation. A complete discussion of this subject was presented earlier in the section "Operating Principals of Ascending Bellows Ventilators."

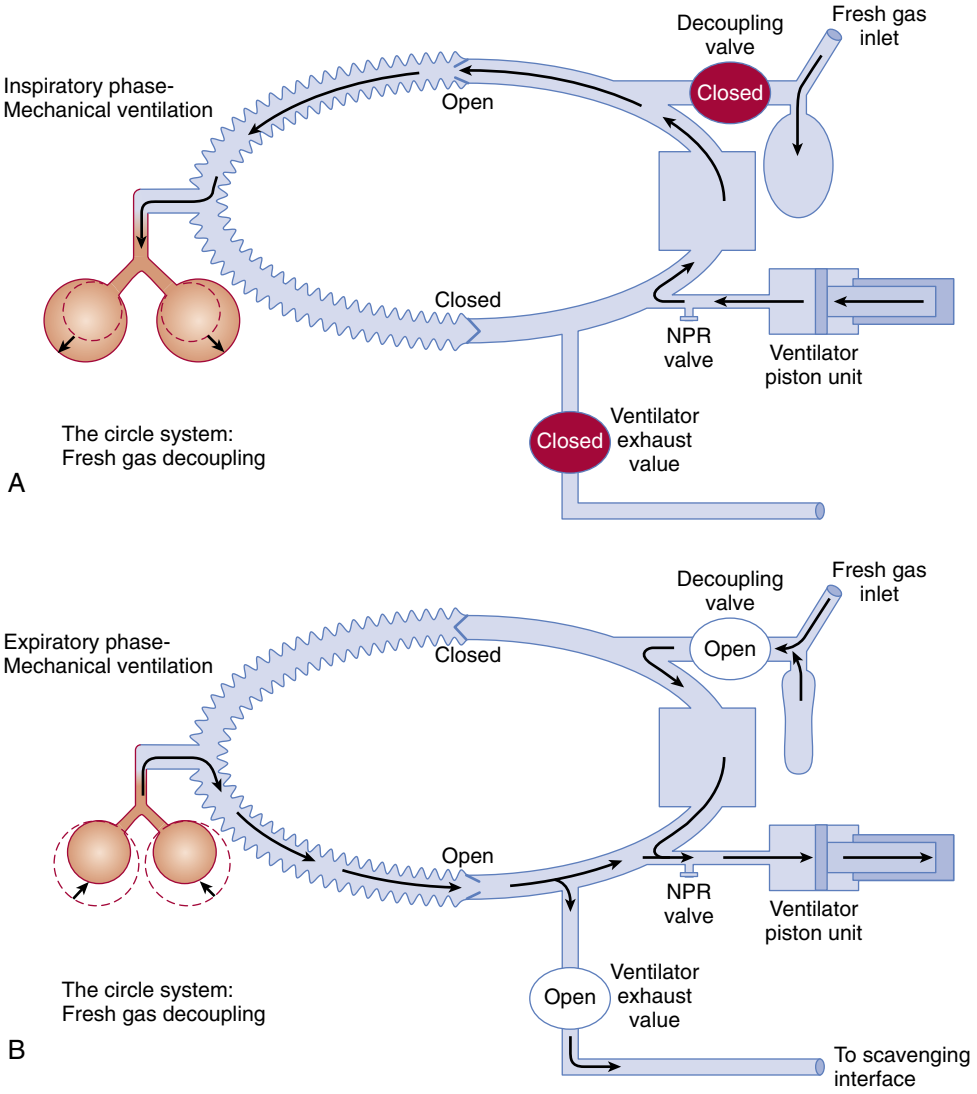
The key concept of the FGD breathing system can be illustrated during the inspiratory phase of mechanical ventilation. With the traditional circle system, several events are occurring (see Fig. 25-28A): (1) continuous fresh gas flow from the flow meters or the oxygen flush valve, or from both, is entering the circle system at the fresh gas inlet; (2) the ventilator is delivering the prescribed tidal volume to the patient's lungs; and (3) the ventilator relief valve (ventilator exhaust valve) is closed, so no gas is escaping the circle system except into the patient's lungs.[145] In a traditional circle system, when these events coincide and fresh gas inflow is coupled directly into the circle system, the total volume delivered to the patient's lungs is the sum of the volume from the ventilator plus the volume of gas that enters the circle via the fresh gas inlet. In contrast, when FGD is used, during the inspiratory phase (see Fig. 25-30A) the fresh gas coming from the anesthesia workstation via the fresh gas inlet is diverted into the reservoir bag by a decoupling valve located between the fresh gas source and the ventilator circuit. The reservoir (breathing) bag serves as an accumulator for fresh gas until the expiratory phase begins. During the expiratory phase (see Fig. 25-30B), the decoupling valve opens to allow the accumulated fresh gas in the reservoir bag to be drawn into the circle system to refill the piston ventilator chamber or descending bellows. Because the ventilator exhaust valve also opens during the expiratory phase, excess fresh gas and exhaled patient gas are allowed to escape to the scavenging system.

Current FGD systems are designed with either piston-type or descending bellows–type ventilators. Because the bellows in either of these types of systems refills under slight negative pressure, the accumulated fresh gas from the reservoir bag can be drawn into the ventilator for delivery to the patient during the next ventilator cycle. As a result of this design requirement, it is unlikely that FGD, as described here, can be used with conventional ascending bellows ventilators, which refill under slight positive pressure.

The most significant advantage of circle systems using FGD is a decreased risk for barotrauma and volutrauma. With a traditional circle system, increases in fresh gas flow from the flow meters or from inappropriate use of the oxygen flush valve may contribute directly to tidal volume, which if excessive, may result in pneumothorax or other injury. Because systems with FGD isolate fresh gas coming into the system from the patient while the ventilator exhaust valve is closed, the risk of barotrauma is greatly reduced.

Possibly the greatest disadvantage of the new anesthesia circle systems that use FGD is the possibility of entraining room air into the patient gas circuit. As discussed previously, in an FGD system the bellows or piston refills under slight negative pressure. If the volume of gas contained in the reservoir bag volume plus the returning volume of gas exhaled from the patient's lungs is inadequate to refill the bellows or piston, negative patient airway pressure could develop. To prevent this problem, a negative pressure relief valve is placed in the breathing system (see Fig. 25-30A and B). If breathing system pressure falls below a preset value, such as −2 cm H_2O, the relief valve opens and ambient air is entrained into the patient gas circuit. If this goes undetected, the entrained atmospheric gases could lead to dilution of either or both the inhaled anesthetic agents and the enriched oxygen mixture (lowering the enriched oxygen concentration toward 21%). If unchecked, this could lead to either intraoperative awareness or hypoxia. High-priority alarms with both audible and visual alerts should notify the user that fresh gas flow is inadequate and room air is being entrained.

Another potential problem with an FGD system such as seen on the Narkomed 6000 series lies in its reliance on the reservoir bag to accumulate the incoming fresh gas. If the reservoir bag is removed during mechanical ventilation or if it has a significant leak from poor fit on the bag mount or a perforation, room air may enter the breathing circuit as the ventilator piston unit refills during the expiratory phase. This may also result in dilution of either or both the inhaled anesthetic agents and the enriched oxygen mixture and potentially result in awareness during anesthesia or hypoxia. Furthermore, this type of a disruption could lead to significant pollution of the operating room with anesthetic gases because fresh gases would be allowed to escape into the atmosphere. Other FGD designs, such as those seen in the Dräger Medical Fabius GS and the soon to be released Apollo



Figures 25-30 **A** and **B,** Inspiratory- and expiratory-phase gas flows of a Dräger Narkomed 6000 circle system with a piston ventilator and fresh gas decoupling. Washington, DC, Library of Congress, 1998.)*

anesthesia systems, do not use the breathing bag as the fresh gas reservoir but instead have an alternative location for accumulation of fresh gas during the inspiratory phase.

Scavenging Systems

Scavenging is the collection and subsequent removal of waste anesthetic gases from the operating room.[146] In most cases, the amount of gas used to anesthetize a patient for a given anesthetic far exceeds the minimal amount needed. Therefore, scavenging minimizes operating room pollution by removing this excess of gases. In 1977, the National Institute for Occupational Safety and Health (NIOSH) prepared a document titled "Criteria for a Recommended Standard: Occupational Exposure to Waste Anesthetic Gases and Vapors."[147] Although it was maintained that a minimal safe level of exposure could not be defined, the NIOSH proceeded to issue the recommendations shown in Table 25-5.[147] In 1991, ASTM released the ASTM F1343-91 standard titled "Standard Specification for Anesthetic Equipment—Scavenging Systems for Anesthetic Gases."[148] The document provided guidelines for devices that safely and effectively scavenge waste anesthetic gases to reduce contamination in anesthetizing areas.[148] In 1999 the ASA Task Force on Trace Anesthetic Gases developed a booklet titled "Waste Anesthetic Gases: Information for Management in Anesthetizing Areas and the Postanesthesia Care Unit." This publication addresses analysis of the literature, the role of regulatory agencies, scavenging and monitoring equipment, and recommendations.[149]

The two major causes of waste gas contamination in the operating room are the anesthetic technique used and equipment issues.[149,150] Regarding the anesthetic technique, the following factors cause operating room contamination: (1) failure to turn off the gas flow control valves at the end of an anesthetic procedure, (2) poorly fitting masks, (3) flushing the circuit, (4) filling

Table 25-5 NIOSH Recommendations for Trace Gas Levels

Anesthetic Gas	Maximum TWA Concentration (ppm)
Halogenated agent alone	2
Nitrous oxide	25
Combination of halogenated agent plus nitrous oxide	
Halogenated agent	0.5
Nitrous oxide	25
Dental facilities (nitrous oxide alone)	50

Time-weighted average (TWA) sampling, also known as time-integrated sampling, is a sampling method that evaluates the average concentration of anesthetic gas over a prolonged period, such as 1 to 8 hours.

anesthetic vaporizers, (5) use of uncuffed endotracheal tubes, and (6) use of breathing circuits that are difficult to scavenge, such as the Jackson-Rees. Equipment failure or lack of understanding of proper equipment use can also contribute to operating room contamination. Leaks can occur in the high-pressure hoses, the nitrous oxide tank mounting, the high- and low-pressure circuits of the anesthesia machine, or the circle system, particularly at the carbon dioxide absorber assembly. The anesthesia care provider must be certain that the scavenging system is operational and adjusted properly to ensure adequate scavenging. If sidestream carbon dioxide or multigas analyzers are used, the analyzed gas (50 to 250 mL/min) must be directed to the scavenging system or returned to the breathing system to prevent pollution of the operating room.[149,150]

Components

Scavenging systems generally have five components (Fig. 25-31): (1) the gas-collecting assembly, (2) the transfer means, (3) the scavenging interface, (4) the gas disposal assembly tubing, and (5) an active or passive gas disposal assembly.[148] An "active system" uses a central evacuation system to eliminate waste gases. The "weight" or pressure of the waste gas itself produces flow through a "passive system."

Gas-Collecting Assembly

The gas-collecting assembly captures excess anesthetic gas and delivers it to the transfer tubing.[133] Waste anesthetic gases are vented from the anesthesia system either through the adjustable pressure-limiting (APL) valve or through the ventilator relief valve. All excess patient gas is either vented into the room (e.g., from a poor facemask fit or endotracheal tube leak) or exits the breathing system through one of these valves. Gas passing through these valves accumulates in the gas-collecting assembly and is directed to the transfer means. In some newer Datex-Ohmeda systems such as the S/5 ADU and others that incorporate either the 7100 or 7900 ventilators, the ventilator drive gas is also exhausted into the scavenging system. This is significant because under conditions of high fresh gas flow and high minute ventilation, the gases flowing into the scavenging interface may overwhelm the evacuation system. If this occurs, waste anesthetic gases may overflow the system via the positive-pressure relief valve (closed systems) or through the atmospheric vents (open systems) and pollute the operating room. In contrast, most other pneumatic ventilators from both Datex-Ohmeda and Dräger exhaust their drive gas (100% oxygen or oxygen/air mixture) into the operating room through a small vent on the back of the ventilator control housing.

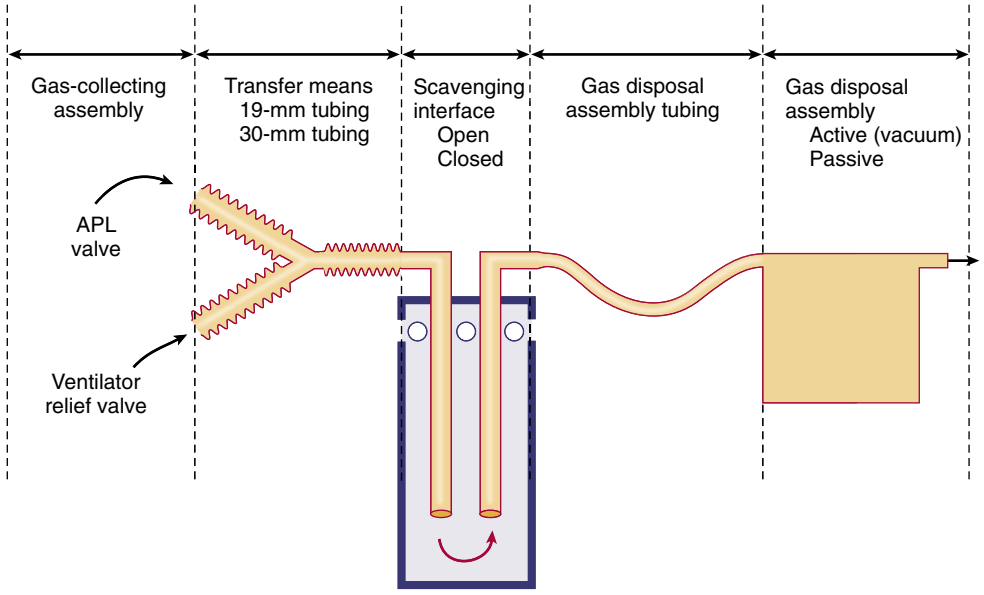

Figure 25-31 Components of a scavenging system. APL valve, adjustable pressure-limiting valve. *(Reproduced with permission from Brockwell RC: Delivery systems for inhaled anesthesia.* In *Barash PG [ed]: Clinical Anesthesia, 5th ed. Philadelphia, Lippincott Williams & Wilkins, 2006, p 589.)*

Transfer Means

The transfer means carries excess gas from the gas-collecting assembly to the scavenging interface. The tubing must be either 19 or 30 mm, as specified by the ASTM F1343-91 standard.[148] The tubing should be sufficiently rigid to prevent kinking and as short as possible to minimize the chance of occlusion. Some manufacturers color-code the transfer tubing with yellow bands to distinguish it from 22-mm breathing system tubing. Many machines have separate transfer tubes for the APL valve and for the ventilator relief valve. The two tubes frequently merge into a single hose before they enter the scavenging interface. Occlusion of the transfer means can be particularly problematic because it is upstream from the pressure-buffering features of the scavenging interface. If the transfer means is occluded, baseline breathing circuit pressure will increase and barotrauma can occur.

Scavenging Interface

The scavenging interface is the most important component of the system because it protects the breathing circuit or ventilator from excessive positive or negative pressure.[146] The interface should limit the pressure immediately downstream from the gas-collecting assembly to between −0.5 and +10 cm H_2O under normal working conditions.[148] Positive-pressure relief is mandatory, irrespective of the type of disposal system used, to vent excess gas in case of occlusion downstream from the interface. If the disposal system is an "active" system, negative-pressure relief is necessary to protect the breathing circuit or ventilator from excessive subatmospheric pressure. A reservoir is highly desirable with active systems because it stores waste gases until the evacuation system can remove them. Interfaces can be open or closed, depending on the method used to provide positive- and negative-pressure relief.[146]

Open Interfaces An open interface contains no valves and is open to the atmosphere, thereby allowing both positive- and negative-pressure relief. Open interfaces should be used only with active disposal systems that have a central evacuation system. Open interfaces require a reservoir because waste gases are intermittently discharged in surges whereas flow from the evacuation system is continuous.[146]

Many contemporary anesthesia machines are equipped with open interfaces such as those in Figure 25-32A and B.[151] An open canister provides reservoir capacity. The volume of the canister should be large enough to accommodate a variety of waste gas flow rates. Gas enters the system at the top of the canister and travels through a narrow inner tube to the canister base. Gases are stored in the reservoir between breaths. Positive- and negative-pressure relief is provided by holes in the top of the canister. The open interface shown in Figure 25-32A differs somewhat from the one shown in Figure 25-32B. The operator can regulate the vacuum by adjusting the vacuum control valve shown in Figure 25-32B.[151]

The efficiency of an open interface depends on several factors. The vacuum flow rate per minute must equal or exceed the minute volume of excess gases to prevent spillage. The volume of the reservoir and the flow characteristics within the interface are important. Spillage will occur if the volume of a single exhaled breath exceeds the capacity of the reservoir. The flow character-

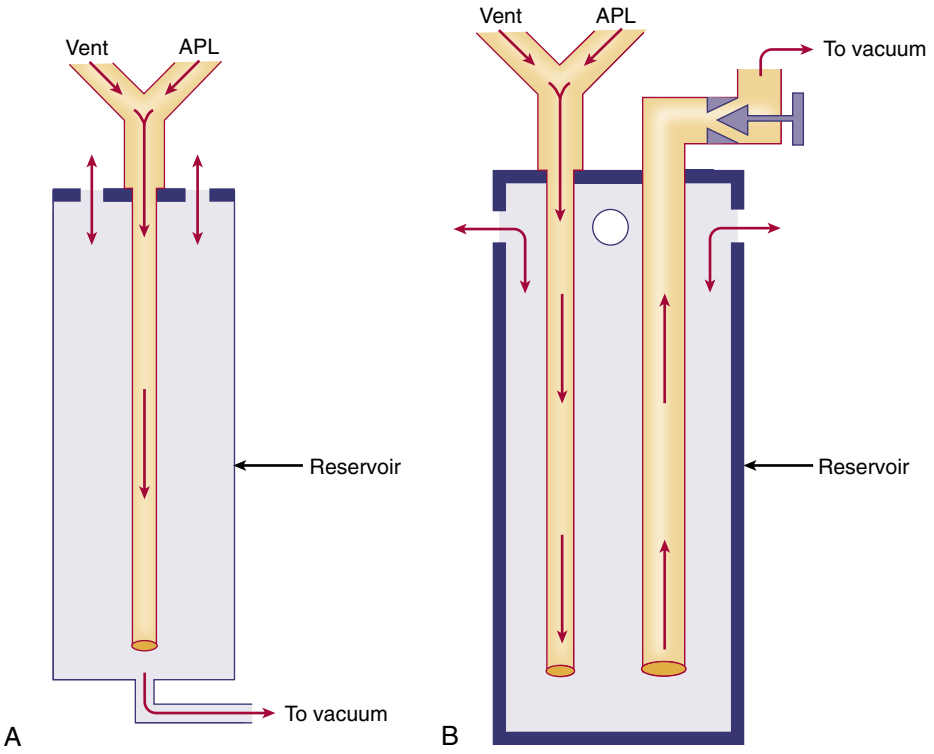

Figure 25-32 **A** and **B,** Two open scavenging interfaces. Each requires an active disposal system. APL, adjustable pressure-limiting valve; Vent, ventilator relief valve. See text for details. *(Modified with permission from Dorsch JA, Dorsch SE: Controlling trace gas levels.* In *Dorsch JA, Dorsch SE* [*eds*]*: Understanding Anesthesia Equipment, 4th ed. Baltimore, Williams & Wilkins, 1999, p 355.)*

istics of the system are important because gas leakage can occur long before the volume of waste gas equals the reservoir volume if significant turbulence occurs within the interface.[152]

Closed Interfaces A closed interface communicates with the atmosphere through valves. All closed interfaces must have a positive-pressure relief valve to vent excess system pressure if obstruction occurs downstream from the interface. A negative-pressure relief valve is mandatory to protect the breathing system from subatmospheric pressure if an active disposal system is used.[146] Two types of closed interfaces are commercially available. One has positive-pressure relief only; the other has both positive- and negative-pressure relief. Each type is discussed in the following paragraphs.

Positive-Pressure Relief Only. This interface (Fig. 25-33, left) has a single positive-pressure relief valve and is designed to be used only with passive disposal systems. Waste gas enters the interface at the waste gas inlets. Transfer of the waste gas from the interface to the disposal system relies on the "weight" or pressure of the waste gas itself because a negative-pressure evacuation system is not used. The positive-pressure relief valve opens at a preset value such as 5 cm H_2O if an obstruction between the interface and the disposal system occurs.[153] On this type of system, a reservoir bag is not required.

Positive- and Negative-Pressure Relief. This interface has a positive-pressure relief valve and at least one negative-pressure relief valve, in addition to a reservoir bag. It is used with active disposal systems. Figure 25-33 (right) is a schematic of Dräger Medical's closed interface for suction systems. A variable volume of waste gas intermittently enters the interface through the waste gas inlets. The reservoir intermittently accumulates excess gas until the evacuation system eliminates it. The operator should adjust the vacuum control valve so that the reservoir bag is properly inflated (A), not overdistended (B) or completely deflated (C). Gas is vented to the atmosphere through the positive-pressure relief valve if the system pressure exceeds +5 cm H_2O. Room air is entrained through the negative-pressure relief valve if the system pressure is more negative than −0.5 cm H_2O. On some systems, a backup negative-pressure relief valve opens at −1.8 cm H_2O if the primary negative-pressure relief valve becomes occluded.

The effectiveness of a closed system in preventing spillage depends on the rate of waste gas inflow, the evacuation flow rate, and the size of the reservoir. Leakage of waste gases into the atmosphere occurs only when the reservoir bag becomes fully inflated and the pressure increases sufficiently to open the positive-pressure relief valve. In contrast, the effectiveness of an open system in preventing spillage depends not only on the volume of the reservoir but also on the flow characteristics within the interface.[152]

Gas Disposal Assembly Conduit The gas disposal assembly conduit (see Fig. 25-31) conducts waste gas from the scavenging interface to the gas disposal assembly. It should be collapse proof and should run overhead, if possible, to minimize the chance of accidental occlusion.[148]

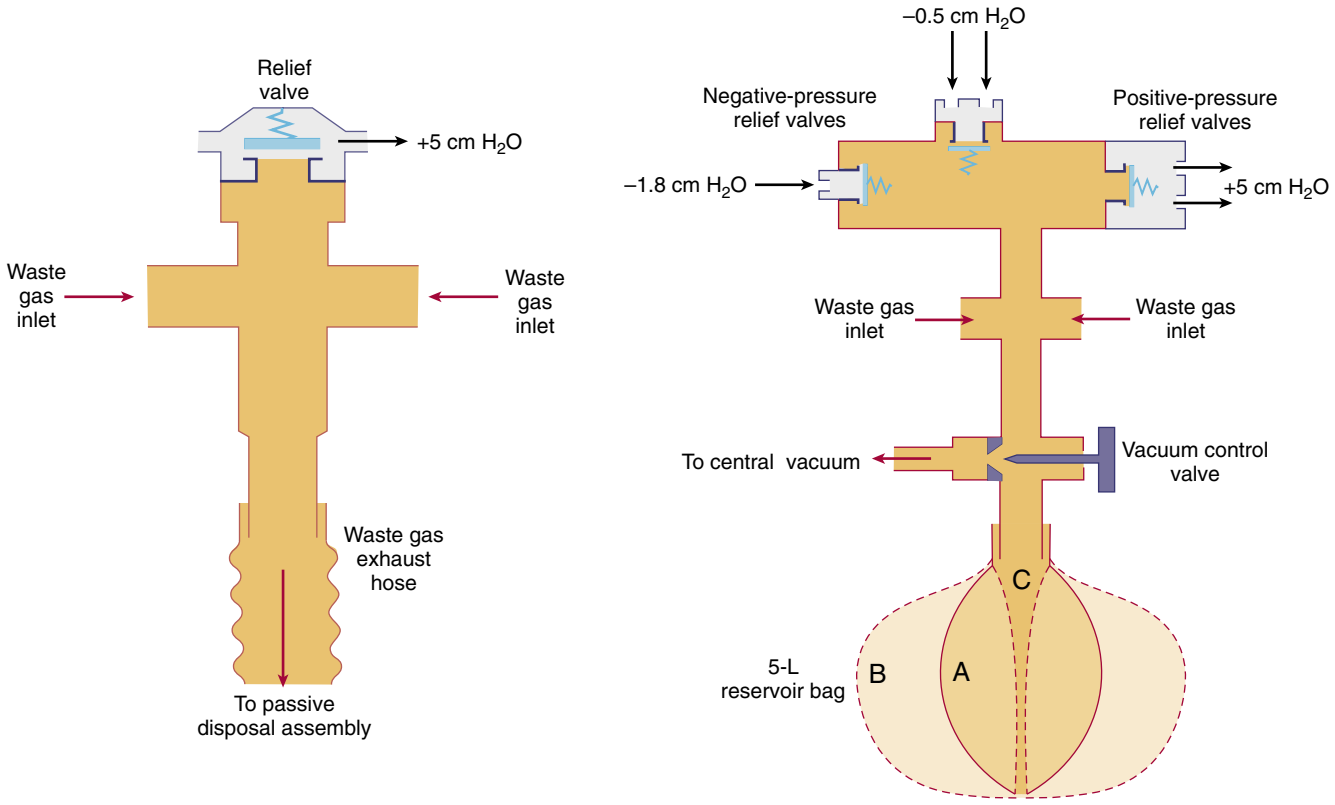

Figure 25-33 Closed scavenging interfaces. **Left,** Interface used with a passive disposal system. **Right,** Interface used with an active system. See text for details. (***Left,*** *Modified with permission from Scavenger Interface for Air Conditioning. Instruction Manual. Telford, PA, North American Dräger, October 1984;* ***right,*** *from Narkomed 2A Anesthesia System. Technical Service Manual. Telford, PA, North American Dräger, 1985.)*

Gas Disposal Assembly The gas disposal assembly ultimately eliminates excess waste gas (see Fig. 25-31). There are two types of disposal systems: active and passive. The most common method of gas disposal is the active assembly, which uses a central evacuation system. A vacuum pump serves as the mechanical flow-inducing device that removes the waste gases, usually to the outside of the building. An interface with a negative-pressure relief valve is mandatory because the pressure within the system is negative. A reservoir is very desirable, and the larger the reservoir, the lower the suction flow rate needed.[146,152]

A passive disposal system does not use a mechanical flow-inducing device. Instead, the "weight" or pressure from the heavier-than-air anesthetic gases produces flow through the system. Positive-pressure relief is mandatory, but negative-pressure relief and a reservoir are unnecessary. Excess waste gases can be eliminated from the operating room suite in a number of ways. Some include venting through the wall, ceiling, or floor or to the room exhaust grill of a non-recirculating air-conditioning system.[146,152]

Hazards

Scavenging systems minimize operating room pollution, yet they add complexity to the anesthesia system. A scavenging system functionally extends the anesthesia circuit all the way from the anesthesia machine to the ultimate disposal site. This extension increases the potential for problems. Obstruction of scavenging pathways can cause excessive positive pressure in the breathing circuit, and barotrauma can occur. Excessive vacuum applied to a scavenging system can result in undesirable negative pressures within the breathing system. Finally, in 2004 another unusual problem that resulted from waste gas scavenging was reported in the *ASA Newsletter* by Lees and coworkers. They reported fires in engineering equipment rooms that house the vacuum pumps used for evacuation of waste anesthetic gases. It seems that in some hospitals, waste gases are not directly vented outside but may be vented into machine rooms that have vents opening to the outside. Because some new anesthesia machines such as the Datex-Ohmeda S/5 ADU and Aestiva, among others, now also scavenge ventilator drive gas (which is 100% oxygen in most cases) in addition to gas from the breathing system, the environments in these machine rooms may become highly enriched with oxygen gas. The result has been the production of fires in these spaces outside the operating room. These sites may contain equipment or materials such as petroleum distillates (pumps/oil/grease) that in the presence of an oxygen-enriched atmosphere could be excessively combustible and a severe fire hazard.[154]

Summary

Rapid advances in technology within the anesthesia workstation industry have made it increasingly difficult for the anesthesia care provider to keep up with latest anesthesia workstation technologies. Nevertheless, a thorough understanding of the anesthesia workstation is mandatory for the safe practice of our specialty. Machines are equipped with dozens of safety features, yet none of them is foolproof. Anesthesia care providers must still check their workstations appropriately before surgery with the correct pre-use checkout procedures to ensure safe delivery of anesthesia for every patient.

Appendix 1

Anesthesia Apparatus Checkout Recommendations, 1993

This checkout, or a reasonable equivalent, should be conducted before administration of anesthesia. These recommendations are valid only for an anesthesia system that conforms to current and relevant standards and includes an ascending bellows ventilator and at least the following monitors: capnograph, pulse oximeter, oxygen analyzer, respiratory volume monitor (spirometer), and breathing system pressure monitor with high- and low-pressure alarms. This is a guideline that users are encouraged to modify to accommodate differences in equipment design and variations in local clinical practice. Such local modifications should undergo appropriate peer review. Users should refer to the operator's manual for the manufacturer's specific procedures and precautions, especially the manufacturer's low-pressure leak test (step 5).

Emergency Ventilation Equipment

*1. **Verify That Backup Ventilation Equipment Is Available and Functioning.**

High-Pressure System

*2. **Check Oxygen Cylinder Supply.**
   a. Open the O_2 cylinder and verify that it is at least half full (≈1000 psi).
   b. Close the cylinder.

*3. **Check Central Pipeline Supplies.**
   a. Check that hoses are connected and pipeline gauges read about 50 psi.

Low-Pressure System

*4. **Check Initial Status of Low-Pressure System.**
   a. Close the flow control valves and turn the vaporizers off.
   b. Check the fill level and tighten the vaporizers' filler caps.

*5. **Perform Leak Check of Machine Low-Pressure System.**
   a. Verify that the machine master switch and flow control valves are OFF.
   b. Attach a "suction bulb" to the common (fresh) gas outlet.
   c. Squeeze the bulb repeatedly until it is fully collapsed.
   d. Verify that the bulb stays *fully* collapsed for at least 10 seconds.
   e. Open one vaporizer at a time and repeat steps c and d as above.
   f. Remove the suction bulb and reconnect the fresh gas hose.

*6. **Turn on Machine Master Switch and All Other Necessary Electrical Equipment.**

*7. **Test Flow Meters.**
   a. Adjust the flow of all gases through their full range while checking for smooth operation of the floats and undamaged flow tubes.
   b. Attempt to create a hypoxic O_2/N_2O mixture and verify correct changes in flow and/or alarm.

Scavenging System

*8. **Adjust and Check Scavenging System.**
   a. Ensure proper connections between the scavenging system and both the APL (pop-off) valve and ventilator relief valve.
   b. Adjust the waste gas vacuum (if possible).
   c. Fully open the APL valve and occlude the Y-piece.
   d. With minimum O_2 flow, allow the scavenger reservoir bag to collapse completely and verify that the absorber pressure gauge reads about zero.
   e. With the O_2 flush activated, allow the scavenger reservoir bag to distend fully and then verify that absorber pressure gauge reads less than 10 cm H_2O.

Breathing System

*9. **Calibrate O_2 Monitor.**
   a. Ensure that the monitor reads 21% in room air.
   b. Verify that the low-O_2 alarm is enabled and functioning.
   c. Reinstall the sensor in the circuit and flush the breathing system with O_2.
   d. Verify that the monitor now reads greater than 90%.

10. **Check Initial Status of Breathing System.**
   a. Set the selector switch to "Bag" mode.
   b. Check that the breathing circuit is complete, undamaged, and unobstructed.
   c. Verify that CO_2 absorbent is adequate.
   d. Install the breathing circuit accessory equipment (e.g., humidifier, positive end-expiratory pressure [PEEP] valve) to be used during the procedure.

11. **Perform Leak Check of Breathing System.**
   a. Set all gas flows to zero (or minimum).
   b. Close the APL (pop-off) valve and occlude the Y-piece.
   c. Pressurize the breathing system to about 30 cm H_2O with an O_2 flush.
   d. Ensure that the pressure remains fixed for at least 10 seconds.
   e. Open the APL (pop-off) valve and ensure that the pressure decreases.

*If an anesthesia provider uses the same machine for successive procedures, these steps need not be repeated or may be abbreviated after the initial checkout.

Manual and Automatic Ventilation Systems

12. **Test Ventilation Systems and Unidirectional Valves.**
    a. Place a second breathing bag on the Y-piece.
    b. Set the appropriate ventilator parameters for the next patient.
    c. Switch to automatic ventilation (Ventilator) mode.
    d. Turn the ventilator ON and fill the bellows and breathing bag with an O_2 flush.
    e. Set O_2 flow to minimum and other gas flows to zero.
    f. Verify that during inspiration the bellows delivers appropriate tidal volume and that during expiration the bellows fills completely.
    g. Set the fresh gas flow to about 5 L/min.
    h. Verify that the ventilator bellows and simulated lungs fill *and empty* appropriately without sustained pressure at end expiration.
    i. Check for proper action of the unidirectional valves.
    j. Check the breathing circuit accessories to ensure proper function.
    k. Turn the ventilator OFF and switch to manual ventilation (Bag/APL) mode.
    l. Ventilate manually and ensure inflation and deflation of the artificial lungs and appropriate feel of system resistance and compliance.
    m. Remove the second breathing bag from the Y-piece.

Monitors

13. **Check, Calibrate, and/or Set Alarm Limits of All Monitors.**
    a. Capnometer
    b. Oxygen analyzer
    c. Pressure monitor with high– and low–airway pressure alarms
    d. Pulse oximeter
    e. Respiratory volume monitor (spirometer)

Final Position

14. **Check Final Status of Machine.**
    a. Vaporizers off
    b. APL valve open
    c. Selector switch to "Bag"
    d. All flowmeters to zero (or minimum)
    e. Patient suction level adequate
    f. Breathing system ready to use

Appendix 2

2007 Guidelines for Preanesthesia Checkout Procedures

Background

Improperly checking anesthesia equipment before use can lead to patient injury and has also been associated with an increased risk for severe postoperative morbidity and mortality.[1,2] In 1993, a preanesthesia checkout (PAC) was developed and widely accepted to be an important step in the process of preparing to deliver anesthesia care.[3] Despite the accepted importance of the PAC, the evidence available suggests that the current version is neither well understood nor reliably used by anesthesia providers.[4-6] Furthermore, anesthesia delivery systems have evolved to the point that one checkout procedure is not applicable to all anesthesia delivery systems currently on the market. For these reasons, a new approach to the PAC has been developed. The goal was to provide guidelines applicable to all anesthesia delivery systems so that individual departments can develop a PAC that can be performed consistently and expeditiously.

General Considerations

The following document is intended to serve not as a PAC itself but rather as a template for developing checkout procedures that are appropriate for each individual anesthesia machine design and practice setting. When using this template to develop a checkout procedure for systems that incorporate automated checkout features, items that are not evaluated by the automated checkout need to be identified and supplemental manual checkout procedures included as needed.

Simply because an automated checkout procedure exists does not mean that it can completely replace a manual checkout procedure or that it can be performed safely without adequate training and thorough understanding of what the automated checkout accomplishes. An automated checkout procedure can be incomplete or misleading, or both. For example, the leak test performed by some current automated checkouts does not test for leaks at the vaporizers. As a result, a loose vaporizer filler cap or a leak at the vaporizer mount could easily be missed.

Ideally, an automated checkout procedure should clearly reveal to the user the functions that are being checked, any deficient function that is found, and recommendations to correct the problem. Documentation of the automated checkout process should preferably be accomplished in a manner that can be recorded on the anesthesia record.

The operator manuals that accompany anesthesia delivery systems include extensive recommendations for checking the equipment out. Although these recommendations are quite extensive and typically not used by anesthesia providers, they are nevertheless important references for developing machine-specific and institution-specific checkout procedures.

Personnel Performing the Preanesthesia Checkout

The previously accepted Anesthesia Apparatus Checkout Recommendation placed all the responsibility for pre-use checkout on the anesthesia provider. This guideline identifies aspects of the PAC that could be completed by a qualified anesthesia or biomedical technician. Using technicians to perform some aspects of the PAC may improve compliance with the PAC. Steps completed by a technician may be part of the morning pre-use check or part of a procedure performed at the end of each day. Critical checkout steps (e.g., availability of backup ventilation equipment) will benefit from intentional redundancy (i.e., having more than one individual responsible for checking the equipment). *Regardless of the level of training and support by technicians, the anesthesia care provider is ultimately responsible for proper function of all equipment used to provide anesthesia care.*

Adaptation of the PAC to local needs, assignment of responsibility for the checkout procedures, and training are the responsibilities of the individual anesthesia department. Training procedures should be documented. Proper documentation should include records of completed coursework (e.g., a manufacturer course) or, for in-house training, a listing of the competency items taught and records of successful completion by trainees.

Objectives for a New Preanesthesia Checkout

- Outline the essential items that need to be available and functioning properly before delivering every anesthetic.
- Identify the frequency with which each of the items needs to be checked.
- Suggest which items may be checked by a qualified anesthesia technician, biomedical technician, or manufacturer-certified service technician.

Basic Principles

- The anesthesia care provider is ultimately responsible for ensuring that the anesthesia equipment is safe and ready for use. This responsibility includes adequate familiarity with the equipment, following relevant local policies for performing and documenting the PAC, and being knowledgeable about these procedures.
- Depending on the staffing resources in a particular institution, anesthesia technicians or biomedical technicians (or both) can participate in the PAC. Biomedical technicians are often trained and certified by manufacturers to perform on-site maintenance of anesthesia delivery systems and can therefore be a useful resource for completing regular checkout procedures. Anesthesia technicians are not commonly trained to perform checkout procedures. Involvement of anesthesia technicians is intended to enhance compliance with the PAC. Each department should decide whether the available technicians can or should be trained to assist with checkout procedures. Formal certification of anesthesia technicians by the American Society of Anesthesia Technicians and Technologists (ASATT) is encouraged but does not necessarily guarantee familiarity with checkout procedures.
- Critical items will benefit from redundant checks to avoid errors and omissions.
- When more than one person is responsible for checking an item, all parties should perform the check if intentional redundancy is deemed important, or either party may be acceptable, depending on the resources available.
- Whoever conducts the PAC should provide documentation of successful performance. The anesthesia provider should include this documentation on the patient chart.
- Whenever an anesthesia machine is moved to a new location, a complete beginning-of-the-day checkout should be performed.
- Automated checks should clearly distinguish the components of the delivery system that are checked automatically from those that require manual checkout.
- Ideally, the date, time, and outcome of the most recent check or checks should be recorded and the information made accessible to the user.
- Specific procedures for pre-use checkout cannot be prescribed in this document because they vary with the delivery systems. Clinicians must learn how to effectively perform the necessary pre-use check for each piece of equipment that they use.
- Each department or health care facility should work with the manufacturer or manufacturers of their equipment to develop pre-use checkout procedures that satisfy both the following guidelines and the needs of the local department.
- Default settings for ventilators, monitors, and alarms should be checked to determine whether they are appropriate.
- These checkout recommendations are intended to replace the preexisting Food and Drug Administration (FDA)-approved Anesthesia Apparatus Checkout Recommendations. They are not intended to be a replacement for required preventive maintenance.
- The PAC is essential for safe care but should not delay initiation of care if patient needs are so urgent that the time taken to complete the PAC could worsen the patient's outcome.

Guidelines for Developing Institution-Specific Checkout Procedures before Anesthesia Delivery

These guidelines describe a basic approach to checkout procedures and rationale to ensure that these priorities are satisfied. They should be used to develop institution-specific checkout procedures designed for the equipment and resources available. (Examples of institution-specific procedures for current anesthesia delivery systems are published at www.ASAHQ.org/clinical/FDA.htm.)

Requirements for Safe Delivery of Anesthesia Care

- Reliable delivery of oxygen at any appropriate concentration up to 100%

- Reliable means of positive-pressure ventilation
- Backup ventilation equipment available and functioning
- Controlled release of positive pressure from the breathing circuit
- Anesthesia vapor delivery (if intended as part of the anesthetic plan)
- Adequate suction
- Means to conform to standards for patient monitoring[7,8]

Specific Items

The following items need to be checked as part of a complete PAC. The intent is to identify what to check, the recommended frequency of checking, and the individual or individuals who could be responsible for the item. For these guidelines, the responsible party would fall into one of four categories: Provider, Technician, Technician or Provider, or Technician and Provider. The designation "Technician and Provider" means that the provider must perform the check regardless of whether it has been completed by a technician. It is not intended to make the use of technician checks mandatory. The intent is not to specify how an item needs to be checked because the specific checkout procedure will depend on the equipment being used.

Item 1: Verify that the auxiliary oxygen cylinder and self-inflating manual ventilation device are available and functioning.
Frequency: Daily.
Responsible Parties: Provider and technician.
Rationale: Failure to be able to ventilate is a major cause of morbidity and mortality related to anesthesia care. Because equipment failure with resulting inability to ventilate the patient can occur at any time, a self-inflating manual ventilation device (e.g., Ambu bag) should be present at every anesthetizing location for every procedure and should be checked for proper function. In addition, a source of oxygen separate from the anesthesia machine and pipeline supply, specifically, an oxygen cylinder with a regulator and a means to open the cylinder valve, should be immediately available and checked. After checking the cylinder pressure, it is recommended that the main cylinder valve be closed to avoid inadvertent emptying of the cylinder through a leaky or open regulator.

Item 2: Verify that patient suction is adequate to clear the airway.
Frequency: Before each use.
Responsible Parties: Provider and technician.
Rationale: Safe anesthetic care requires the immediate availability of suction to clear the airway if needed.

Item 3: Turn on the anesthesia delivery system and confirm that AC power is available.
Frequency: Daily.
Responsible Parties: Provider or technician.
Rationale: Anesthesia delivery systems typically function with backup battery power if AC power fails. Unless the presence of AC power is confirmed, the first obvious sign of power failure can be a complete system shutdown when the batteries can no longer power the system. Many anesthesia delivery systems have visual indicators of the power source showing the presence of both AC and battery power. These indicators should be checked and connection of the power cord to a functional AC power source confirmed.

Desflurane vaporizers require electrical power, and recommendations for checking power to these vaporizers should also be followed.

Item 4: Verify the availability of required monitors and check alarms.
Frequency: Before each use.
Responsible Parties: Provider or technician.
Rationale: Standards for patient monitoring during anesthesia are clearly defined.[7,8] The ability to conform to these standards should be confirmed for every anesthetic. The first step is to visually verify that the appropriate monitoring supplies (blood pressure cuffs, oximetry probes, etc.) are available. All monitors should be turned on and proper completion of power-up self-tests confirmed. Given the importance of pulse oximetry and capnography to patient safety, verifying proper function of these devices before anesthetizing the patient is essential. Capnometer function can be verified by exhaling through the breathing circuit or gas sensor to generate a capnogram or by verifying that the patient's breathing efforts generate a capnogram before the patient is anesthetized. Visual and audible alarm signals should be generated when this is discontinued. Pulse oximeter function, including an audible alarm, can be verified by placing the sensor on a finger and observing for a proper recording. The pulse oximeter alarm can be tested by introducing a motion artifact or removing the sensor.

Audible alarms have also been reconfirmed as essential to patient safety by the American Society of Anesthesiologists (ASA), American Association of Nurse Anesthetists (AANA), Anesthesia Patient Safety Foundation (APSF), and the Joint Commission on Accreditation of Healthcare Organizations (JCAHO). Proper monitor functioning includes visual and audible alarm signals that function as designed.

Item 5: Verify that pressure is adequate in the spare oxygen cylinder mounted on the anesthesia machine.
Frequency: Daily.
Responsible Parties: Provider and technician.
Rationale: Anesthesia delivery systems rely on a supply of oxygen for various machine functions. At a minimum, the oxygen supply is used to provide oxygen to the patient. Pneumatically powered ventilators also rely on a gas supply. The oxygen cylinder or cylinders should be mounted on the anesthesia delivery system and determined to have acceptable minimum pressure. Acceptable pressure depends on the intended use, the design of the anesthesia delivery system, and the availability of piped oxygen.

- Typically, an oxygen cylinder will be used if the central oxygen supply fails.
- If the cylinder is intended to be the primary source of oxygen (e.g., remote-site anesthesia), a cylinder supply sufficient to last for the entire procedure is required. If a pneumatically powered ventilator that uses oxygen as its driving gas will be used, a full "E" oxygen cylinder may provide only 30 minutes of oxygen. In that case, the maximum duration of oxygen supply can be obtained from an oxygen cylinder if it is used to provide only fresh gas to the patient in conjunction with manual or spontaneous ventilation. Mechanical ventilators will consume the oxygen supply if pneumatically powered ventilators

that require oxygen to power the ventilator are used. Electrically powered ventilators do not consume oxygen, so the duration of a cylinder supply will depend only on total fresh gas flow.

- The oxygen cylinder valve should be closed after it has been verified that adequate pressure is present, unless the cylinder is to be the primary source of oxygen (i.e., piped oxygen is not available). If the valve remains open and the pipeline supply should fail, the oxygen cylinder can become depleted while the anesthesia provider is unaware of the oxygen supply problem.
- Other gas supply cylinders (e.g., heliox, CO_2, air, N_2O) need to be checked only if that gas is required to provide anesthetic care.

Item 6: Verify that piped gas pressures are 50 psig or greater.
Frequency: Daily.
Responsible Parties: Provider and technician.
Rationale: A minimum gas supply pressure is required for proper function of the anesthesia delivery system. Gas supplied from a central source can fail for a variety of reasons. Therefore, the pressure in the piped gas supply should be checked at least once daily.

Item 7: Verify that the vaporizers are adequately filled and, if applicable, the filler ports are tightly closed.
Frequency: Before each use.
Responsible Parties: Provider. Technician if redundancy is desired.
Rationale: If delivery of anesthetic vapor is planned, an adequate supply is essential to reduce the risk of light anesthesia or recall, especially if an anesthetic agent monitor with a low-agent alarm is not being used. Partially open filler ports are a common cause of leaks that may not be detected if the vaporizer control dial is not open when a leak test is performed. This source of leakage can be minimized by tightly closing the filler ports. Newer vaporizer designs have filling systems that automatically close the filler port when filling is completed.

High– and low–anesthetic agent alarms are useful to help prevent overdosage or underdosage of anesthetic vapor. Use of these alarms is encouraged, and they should be set to the appropriate limits and enabled.

Item 8: Verify that there are no leaks in the gas supply lines between the flow meters and the common gas outlet.
Frequency: Daily and whenever a vaporizer is changed.
Responsible Parties: Provider or technician.
Rationale: The gas supply in this part of the anesthesia delivery system passes through the anesthetic vaporizer or vaporizers on most anesthesia delivery systems. To perform a thorough leak test, each vaporizer must be turned on individually to check for leaks at the vaporizer mount or inside the vaporizer. Furthermore, some machines have a check valve between the flow meters and the common gas outlet that requires a negative-pressure test to adequately check for leaks. Automated checkout procedures typically include a leak test but may not evaluate leaks at the vaporizer, especially if the vaporizer is not turned on during the leak test. When relying on automated testing to evaluate the system for leaks, the automated leak test would need to be repeated for each vaporizer in place. This test should also be completed whenever a vaporizer is changed. The risk of a leak at the vaporizer depends on the vaporizer design. Vaporizer designs in which the filler port closes automatically after filling can reduce the risk of leaks occurring.

Technicians can provide useful assistance with this aspect of the machine checkout because it can be time consuming.

Item 9: Test for adequate functioning of the scavenging system.
Frequency: Daily.
Responsible Parties: Provider or technician.
Rationale: A properly functioning scavenging system prevents room contamination by anesthetic gases. Proper function depends on correct connections between the scavenging system and the anesthesia delivery system. These connections should be checked daily by a provider or technician. Depending on design of the scavenging system, proper function may also require that the vacuum level be adequate, which should also be confirmed daily. Some scavenging systems have mechanical positive- and negative-pressure relief valves. Positive- and negative-pressure relief is important to protect the patient circuit from pressure fluctuations related to the scavenging system. Proper checkout of the scavenging system should ensure that positive- and negative-pressure relief is functioning properly. Because of the complexity of checking for effective positive- and negative-pressure relief and the variations in scavenging system design, a properly trained technician can facilitate this aspect of the checkout process.

Item 10: Calibrate or verify calibration of the oxygen monitor and check the low-oxygen alarm.
Frequency: Daily.
Responsible Parties: Provider or technician.
Rationale: Continuous monitoring of the inspired oxygen concentration is the last line of defense against delivering hypoxic gas concentrations to the patient. The oxygen monitor is essential for detecting adulteration of the oxygen supply. Most oxygen monitors require calibration once daily, although some are self-calibrating. For self-calibrating oxygen monitors, they should be verified to read 21% when sampling room air. This is a step that is easily completed by a trained technician. When more than one oxygen monitor is present, the primary sensor that will be relied on for oxygen monitoring should be checked.

The low-oxygen concentration alarm should also be checked at this time by setting the alarm above the measured oxygen concentration and confirming that an audible alarm signal is generated.

Item 11: Verify that the carbon dioxide absorbent is not exhausted.
Frequency: Before each use.
Responsible Parties: Provider or technician.
Rationale: Proper function of a circle anesthesia system relies on the absorbent to remove carbon dioxide from rebreathed gas. Exhausted absorbent, as indicated by the characteristic change in color, should be replaced. It is possible for absorbent material to lose the ability to absorb CO_2, yet the characteristic color change may be absent or difficult to see. Some newer absorbents do change color when desiccated. Capnography should be used for every anesthetic, and with use of a circle anesthesia system, rebreathing carbon dioxide as indicated by an inspired CO_2 concentration greater than 0 can also indicate exhausted absorbent (see Note 2).

Item 12: Test for breathing system pressure and leaks.
Frequency: Before each use.
Responsible Parties: Provider and technician.
Rationale: The breathing system pressure and leak test should be performed with the circuit configuration to be used during anesthetic delivery. If any components of the circuit are changed after this test is completed, the test should be performed again. Although the anesthesia provider should perform this test before each use, anesthesia technicians who replace and assemble circuits can also perform this check and add redundancy to this important checkout procedure.

Proper testing will demonstrate that pressure can be developed in the breathing system during both manual and mechanical ventilation and that pressure can be relieved during manual ventilation by opening the adjustable pressure-limiting (APL) valve.

Automated testing is often implemented in the newer anesthesia delivery systems to evaluate the system for leaks and also to determine the compliance of the breathing system. The compliance value determined during this testing will be used to automatically adjust the volume delivered by the ventilator to maintain constant delivery of volume to the patient. It is important that the circuit configuration that is to be used be in place during the test.

Item 13: Verify that gas flows properly through the breathing circuit during both inspiration and exhalation.
Frequency: Before each use.
Responsible Parties: Provider and technician.
Rationale: Pressure and leak testing does not identify all obstructions in the breathing circuit or confirm proper function of the inspiratory and expiratory unidirectional valves. A test lung or second reservoir bag can be used to confirm that flow through the circuit is unimpeded. Complete testing includes both manual and mechanical ventilation. The presence of unidirectional valves can be assessed visually during the PAC; however, proper function of these valves cannot be visually assessed because subtle valve incompetence may not be detected. Checkout procedures to identify valve incompetence that may not be visually obvious can be implemented but are typically too complex for daily testing. A trained technician can perform regular valve competence tests (see Note 4). Capnography should be used during every anesthetic, and the presence of carbon dioxide in the inspired gases can help detect an incompetent valve.

Item 14: Document completion of checkout procedures.
Frequency: Before each use.
Responsible Parties: Provider and technician.
Rationale: Each individual responsible for checkout procedures should document completion of these procedures. Documentation gives credit for completing the job and can be helpful if an adverse event should occur. Some automated checkout systems maintain an audit trail of completed checkout procedures that are dated and timed.

Item 15: Confirm ventilator settings and evaluate readiness to deliver anesthesia care (ANESTHESIA TIME-OUT).
Frequency: Immediately before initiating the anesthetic.
Responsible Parties: Provider.
Rationale: This step is intended to avoid errors resulting from production pressure or other sources of haste. The goal is to confirm that appropriate checks have been completed and that essential equipment is indeed available. The concept is analogous to the "time-out" used to confirm patient identity and the surgical site before incision. Improper ventilator settings can be harmful, especially if a small patient is following a much larger patient or vice versa. Pressure limit settings (when available) should be used to prevent excessive delivery of volume from improper ventilator settings.
Items to check:

- Monitors functional?
- Capnogram present?
- Oxygen saturation by pulse oximetry measured?
- Flow meter and ventilator settings proper?
- Manual/ventilator switch set to manual?
- Vaporizer(s) adequately filled?

Summary of Checkout Recommendations by Frequency and Responsible Party

To Be Completed Daily	Responsible Party
Item 1: Verify that the auxiliary oxygen cylinder and self-inflating manual ventilation device are available and functioning	Provider and tech
Item 2: Verify that patient suction is adequate to clear the airway	Provider and tech
Item 3: Turn on the anesthesia delivery system and confirm that AC power is available	Provider or tech
Item 4: Verify the availability of required monitors, including alarms	Provider or tech
Item 5: Verify that pressure is adequate on the spare oxygen cylinder mounted on the anesthesia machine	Provider and tech
Item 6: Verify that piped gas pressures are ≥50 psig	Provider and tech
Item 7: Verify that vaporizers are adequately filled and, if applicable, that filler ports are tightly closed	Provider or tech
Item 8: Verify that there are no leaks in the gas supply lines between the flow meters and the common gas outlet	Provider or tech
Item 9: Test scavenging system function	Provider or tech
Item 10: Calibrate or verify calibration of the oxygen monitor and check the low-oxygen alarm	Provider or tech
Item 11: Verify that the carbon dioxide absorbent is not exhausted	Provider or tech
Item 12: Check for proper breathing system pressure and leaks	Provider and tech
Item 13: Verify that gas flows properly through the breathing circuit during both inspiration and exhalation	Provider and tech

Item 14: Document completion of checkout procedures	Provider and tech
Item 15: Confirm ventilator settings and evaluate readiness to deliver anesthesia care (ANESTHESIA TIME-OUT)	Provider
To Be Completed before Each Procedure	
Item To Be Completed	**Responsible Party**
Item 2: Verify that patient suction is adequate to clear the airway	Provider and tech
Item 4: Verify the availability of required monitors, including alarms	Provider or tech
Item 7: Verify that vaporizers are adequately filled and, if applicable, that filler ports are tightly closed	Provider
Item 11: Verify that the carbon dioxide absorbent is not exhausted	Provider or tech
Item 12: Check for proper breathing system pressure and leaks	Provider and tech
Item 13: Verify that gas flows properly through the breathing circuit during both inspiration and exhalation	Provider and tech
Item 14: Document completion of checkout procedures	Provider and tech
Item 15: Confirm ventilator settings and evaluate readiness to deliver anesthesia care (ANESTHESIA TIME-OUT)	Provider

Supplement: Additional Notes on Preanesthesia Checkout

Note 1. *Testing the flow meters*: This step is present in the 1993 checkout recommendation and is intended to check the oxygen/nitrous oxide proportioning system. It has been eliminated from the PAC in these guidelines because proper function is verified during preventive maintenance and failures of this system in a properly maintained delivery system are rare.

Note 2. *Desiccated carbon dioxide absorbent*: It has been well established that carbon dioxide absorbents that contain sodium, potassium, or barium hydroxide may become dangerous when desiccated and produce carbon monoxide or excessive heat leading to fires (or both). Unfortunately, it is not possible to reliably identify when the absorbent material has been desiccated. Some departments elect to change all absorbent material on Monday morning to eliminate the possibility of using absorbent exposed to continuous fresh gas flow throughout the weekend. Other departments elect to use absorbent materials that do not pose a risk when desiccated. It is important to have a strategy to prevent hazards related to using absorbents containing the problematic hydroxides that have desiccated. There are no steps that could be included in the checkout recommendation that can reliably identify desiccated absorbent. If a department uses absorbent that may be hazardous when desiccated, it may be prudent to change the absorbent material whenever the duration of exposure to high fresh gas flow cannot be determined and is likely to have been prolonged.

A protocol for preventing absorbent hazards should be part of every department's risk management strategy.

Note 3. *Anesthesia information systems and automated record keepers*: These systems are being adopted by an increasing number of anesthesia departments and are the mainstay of the record-keeping process in these departments. The presence of reliably functioning systems is therefore important to the conduct of anesthesia, though not essential to patient safety in the same fashion as the anesthesia delivery system and patient monitors. For departments that rely on these systems, it would be prudent to have a protocol for checking connections and the proper functioning of associated computers, displays, and network function.

Note 4. *Testing circle system valve competence*: As part of test Item 13 (verify that gas flows properly through the breath-

ing circuit during both inspiration and exhalation), the inspiratory and expiratory valves are visually observed for proper cycling (opening and closing fully). Visual inspection will also detect a missing valve leaflet. Ascertainment of full closure of the valve is subjective. Incompetence of the valve may also be detected during Item 13 by spirometry at the expiratory limb. For malfunction of the expiratory valve, a spirometer with reverse flow detection will signal an alarm when gas flows retrogradely in the expiratory limb. For malfunction of the inspiratory valve, the measured exhaled tidal volume will be less than the expected value. Capnography may also help detect incompetence of the unidirectional valves. Intraoperatively, malfunction of an inspiratory valve may not be indicated by elevation of the inspired CO_2 baseline. If the delivered tidal volume exceeds the volume of gas in the inspiratory limb containing CO_2, rebreathing will appear on the capnogram as a gradual instead of a sharp downstroke. Malfunction of an expiratory valve is indicated by an elevated CO_2 baseline because there is typically a large volume of exhaled gas containing CO_2 that can return to the patient.

26 Intravenous Anesthetics

Key Points

1. The introduction of thiopental into clinical practice in 1934 marked the advent of modern intravenous (IV) anesthesia. Today, IV anesthetics are used for induction of anesthesia, maintenance of anesthesia, and provision of conscious sedation.
2. The most commonly used IV anesthetic is propofol, an alkylphenol presently formulated in a lipid emulsion. Propofol provides rapid onset and offset with context-sensitive decrement times of approximately 10 minutes when infused for less than 3 hours and less than 40 minutes when infused for up to 8 hours. Its mechanism of action is thought to be potentiation of γ-aminobutyric acid (GABA)–induced chloride currents. At therapeutic doses, propofol produces a moderate depressant effect on ventilation. It causes a dose-dependent decrease in blood pressure primarily through a decrease in cardiac output and systemic vascular resistance. A unique action of propofol is its antiemetic effect, which remains present at concentrations less than those producing sedation. The induction dose is 1 to 2 mg/kg for loss of consciousness with a maintenance infusion of 100 to 200 μg/kg/min. For conscious sedation, rates of 25 to 75 μg/kg/min are usually adequate.
3. Until more recently, the most commonly used IV induction agents were the barbiturates. Thiopental provides rapid onset and offset when used as a single dose, but it accumulates rapidly with prolonged administration and leads to slow recovery. Methohexital has a rapid onset and offset similar to propofol for procedures lasting less than 2 hours. The barbiturates are administered as sodium salts diluted in a water base at an alkaline pH. Similar to propofol, the barbiturates are thought to provide their hypnotic effects largely through action on the $GABA_A$ receptor. Barbiturates provide cerebral protection and are output from induction of anesthesia used primarily for this purpose. They cause a moderate dose-dependent decrease in blood pressure (primarily as a result of peripheral vasodilation) and respiratory drive. The barbiturates are contraindicated in patients with porphyria. The induction dose of thiopental is 4 mg/kg, and the induction dose for methohexital is 2 mg/kg. Methohexital can be used for maintenance of anesthesia at 100 to 200 μg/kg/min or for conscious sedation at 25 to 75 μg/kg/min.
4. The benzodiazepines are used primarily for anxiolysis and amnesia or for conscious sedation. The water-soluble benzodiazepine midazolam is the most frequently used intravenously because of its rapid onset and offset and lack of active metabolites compared with other benzodiazepines (e.g., diazepam). The onset of midazolam is slower than that of propofol and barbiturates, and its offset, especially when used at higher doses or in a prolonged infusion, is considerably longer than that of propofol or methohexital. The benzodiazepines act through the GABA receptor. Flumazenil is a specific benzodiazepine antagonist. It can be used to reverse the effects of benzodiazepines. The benzodiazepines generally produce only a mild decrease in blood pressure and mild-to-moderate respiratory depression. The dose of midazolam for anxiolysis and mild sedation is 0.015 to 0.03 mg/kg intravenously and is generally repeated in 30 to 60 minutes as needed.
5. Ketamine is a phencyclidine derivative that is uniquely different from the above-mentioned hypnotics. It produces a dissociative state of hypnosis and analgesia. It has been used for induction and maintenance of anesthesia. Ketamine acts primarily, but not entirely, through the *N*-methyl-D-aspartate (NMDA) receptor. Ketamine is associated with significant adverse psychological effects at higher doses and several other side effects. It is used now primarily for its analgesic properties. It has rapid onset and relatively rapid offset, even after an infusion of several hours. It has sympathomimetic action that preserves cardiac function. Ketamine has minimal effect on respiration and tends to preserve autonomic reflexes. The induction dose is 2 to 4 mg intravenously. An infusion of ketamine provides analgesia and can be given with propofol in a total IV anesthesia technique. A dose of 10 to 20 mg preoperatively has been shown to provide preemptive analgesia.
6. Etomidate is an imidazole derivative used primarily for induction of anesthesia, especially in elderly patients and

patients who have cardiovascular compromise. It has a rapid onset of effect and a rapid offset even after a continuous infusion. Prolonged infusion results in inhibition of adrenocortical synthesis and potential mortality in intensive care unit (ICU) patients. The major advantage of etomidate is its minimal effect on the cardiovascular and respiratory systems. It is associated with a high incidence of burning on injection, thrombophlebitis, and postoperative nausea and vomiting (PONV), limiting its popularity. The induction dose is 0.2 to 0.3 mg/kg.

7. Dexmedetomidine is the most recently released IV anesthetic. It is a highly selective α_2-adrenergic agonist that produces sedation, hypnosis, and analgesia. Dexmedetomidine is presently approved only for brief (<24 hours) postoperative sedation, although it is finding increasing use in the perioperative period as an adjunct sedative. Its primary action is as an agonist on α_2 receptors in the locus caeruleus. It has minimal effect on respiration. Dexmedetomidine produces a biphasic effect on blood pressure; at low concentrations, mean blood pressure is decreased, and at higher concentrations, blood pressure is increased. Heart rate and cardiac output show a concentration-dependent decrease. Dosing for sedation is a loading dose of 0.25 to 1 mg/kg over a 10-minute period, followed by an infusion of 0.1 to 1 μg/kg/hr.
8. Droperidol, a butyrophenone and major tranquilizer, was initially used to produce a state of neuroleptanesthesia. More recent concern regarding its effect on prolonging the QT interval has resulted in its withdrawal in several countries and its limitation to the treatment of postoperative nausea and vomiting (PONV) with a black box warning in the United States. Because the use of low-dose droperidol (<1.25 mg) for PONV has not been approved by the U.S. Food and Drug Administration (FDA), the black box warning does not relate to this use. Clinically significant prolongation of the QT interval by doses used for PONV (0.625 to 1.25 mg) has been challenged by several editorials, and this effect has not been substantiated by review of the cases reported or any literature. Low-dose droperidol remains an effective antiemetic therapy.

The introduction of thiopental into clinical practice in 1934 marked the advent of modern intravenous (IV) anesthesia. Thiopental and other barbiturates are not ideal IV anesthetics, however, primarily because they provide only hypnosis. The ideal IV anesthetic drug would provide hypnosis, amnesia, analgesia, and muscle relaxation without undesirable cardiac and respiratory depression. Because no single drug is ideal, many newer IV anesthetics, often used together, have been introduced that offer some or all of the desired effects. These drugs were introduced steadily into clinical practice with varying degrees of acceptance. With an increasing number of compounds and superior methods of IV anesthetic drug delivery available (see Chapter 28), the use of IV anesthetics continues to grow.

The future of anesthetic management involves the simultaneous use of several drugs, including inhaled anesthetics. A 1988 survey of mortality in 100,000 cases of anesthesia reveals that the practice of combined anesthetic drug use may be safer than the use of only one or two drugs[1]; the relative odds of dying within 7 days was 2.9 times greater when one or two anesthetic drugs were used than when three or more were used. Although it is exceedingly difficult to interpret these data, the use of several drugs may be beneficial to anesthetic care. The skillful use of multiple IV anesthetics is not only possible, but also preferable. This chapter provides information on the major nonopioid IV anesthetic drugs available for clinical use today.

Propofol

History

Propofol is the most frequently used IV anesthetic today. Work in the early 1970s on substituted derivatives of phenol with hypnotic properties resulted in the development of 2,6-diisopropofol. The first clinical trial, by Kay and Rolly and reported in 1977, confirmed the potential of propofol as an anesthetic to induce anesthesia.[1a] Propofol is insoluble in water and was initially prepared with Cremophor EL (BASF A.G.). Because of anaphylactoid reactions associated with Cremophor EL in this early formulation of propofol, the drug was reformulated in an emulsion. Propofol is used for induction and maintenance of anesthesia and for sedation in and outside the operating room.

Physicochemical Characteristics

Propofol (Fig. 26-1) is one of a group of alkylphenols that have hypnotic properties in animals.[2] The alkylphenols are oils at room temperature and are insoluble in aqueous solution, but they are highly lipid soluble. Numerous formulations are marketed today. The formulation that followed the removal of Cremophor consists of 1% (wt/vol) propofol, 10% soybean oil, 2.25% glycerol, and 1.2% purified egg phosphatide. Following concerns regarding microbial growth in the emulsion, disodium edetate (0.005%) was added as a retardant of bacterial growth. This formulation has a pH of 7 and appears as a slightly viscous, milky white substance. In Europe, a 2% formulation and a formulation in which the emulsion contains a mixture of medium-chain and long-chain triglycerides also are available.

All formulations available commercially are stable at room temperature and are not light sensitive. If a dilute solution of propofol is required, it is compatible with 5% dextrose in water. Changes in the diluent theoretically may result in slight changes in pharmacokinetics, cracking of the emulsion, spontaneous degradation of propofol, and possibly changes in pharmacologic effect. Commercially available formulations of propofol do not have major differences in their clinical utility.

Probably the most interesting formulation likely to be approved soon by the U.S. Food and Drug Administration (FDA) is fospropofol (Aquavan), a phosphorylated prodrug of propofol,

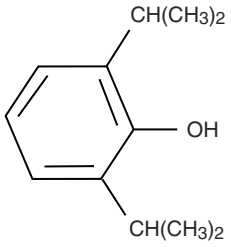

Figure 26-1 Structure of propofol, an alkylphenol derivative.

which produces a unique and distinct pharmacokinetic and pharmacodynamic profile. Compared with propofol emulsion, fospropofol is associated with a slightly longer time to peak effect and a more prolonged pharmacodynamic effect.[3]

Metabolism

Propofol is rapidly metabolized in the liver by conjugation to glucuronide and sulfate[4] to produce water-soluble compounds, which are excreted by the kidneys.[4] Less than 1% propofol is excreted unchanged in urine, and only 2% is excreted in feces.[4] The metabolites of propofol are thought to be inactive. Because clearance of propofol exceeds hepatic blood flow, extrahepatic metabolism or extrarenal elimination has been suggested. Extrahepatic metabolism has been confirmed during the anhepatic phase of patients receiving a transplanted liver.[5] In two more recent studies, the role of the kidneys in propofol metabolism was established, accounting for 30% of total body clearance.[6,7] In in vitro studies with human kidney and small intestine, microsomes in these tissues showed an ability to form propofol glucuronide.[8]

The lungs also may play an important role in this extrahepatic metabolism. The lungs are responsible for approximately 30% of the uptake and first-pass elimination after a bolus dose.[9] During a continuous infusion of propofol, there is a 20% to 30% decrease in propofol concentration measured across the lung in humans and a higher concentration of the metabolite 2,6-diisopropyl 1,4-quinol on the arterial side of the circulation.[10] Other sites of propofol metabolism also are possible. Propofol itself results in a concentration-dependent inhibition of cytochrome P-450 and may alter the metabolism of drugs dependent on this enzyme system (e.g., opiates).[11]

Fospropofol is a prodrug of propofol and is chemically described as phosphono-*O*-methyl-2,6-diisopropylphenol, disodium salt ($C_{13}H_{19}O_5PNa_2$). Phosphono-*O*-methyl prodrugs undergo hydrolysis most notably by endothelial cell surface alkaline phosphatases liberating propofol (the active metabolite), phosphate, and formaldehyde. From the molecular weights of 332.24 D for fospropofol and 178.27 D for propofol, one would expect that 1 mg of fospropofol would liberate 0.54 mg of propofol. When released, propofol undergoes the same metabolic pathway as previously described.[12]

Pharmacokinetics

The pharmacokinetics of propofol has been described by two-compartment and three-compartment models (Table 26-1). After a single bolus injection, whole-blood propofol levels decrease rapidly as a result of redistribution and elimination (Fig. 26-2). The initial distribution half-life of propofol is 2 to 8 minutes.[4,13] Studies in which the disposition of propofol is described by a three-compartment model give initial and slow distribution half-lives of 1 to 8 minutes and 30 to 70 minutes and an elimination half-life of 4 to 23.5 hours.[14,15] This longer elimination half-life indicates a deep compartment with limited perfusion, which results in a slow return of propofol back to the central compartment. Because of the rapid clearance of propofol from the central compartment, the slow return of propofol from this deep compartment contributes little to the initial rapid decrease in propofol concentrations. The context-sensitive half-time for propofol (Fig. 26-3) for infusions of up to 8 hours is less than 40 minutes.[16]

Because the required decrease in concentration for awakening after anesthesia or sedation with propofol is generally less

Table 26-1 Pharmacokinetic Variables for Commonly Used Intravenous Anesthetics

Elimination	Elimination Half-Life (hr)	Clearance (mL/kg/min)	Vd_{ss} (L/kg)
Dexmedetomidine	2-3	10-30	2-3
Diazepam	20-50	0.2-0.5	0.7-1.7
Droperidol	1.7-2.2	14	2
Etomidate	2.9-5.3	18-25	2.5-4.5
Flumazenil	0.7-1.3	5-20	0.6-1.6
Ketamine	2.5-2.8	12-17	3.1
Lorazepam	11-22	0.8-1.8	0.8-1.3
Methohexital	2-6	10-15	1.5-3
Midazolam	1.7-2.6	6.4-11	1.1-1.7
Propofol	4-7	20-30	2-10
Thiopental	7-17	3-4	1.5-3

Vd_{ss}, apparent volume of distribution at steady state.

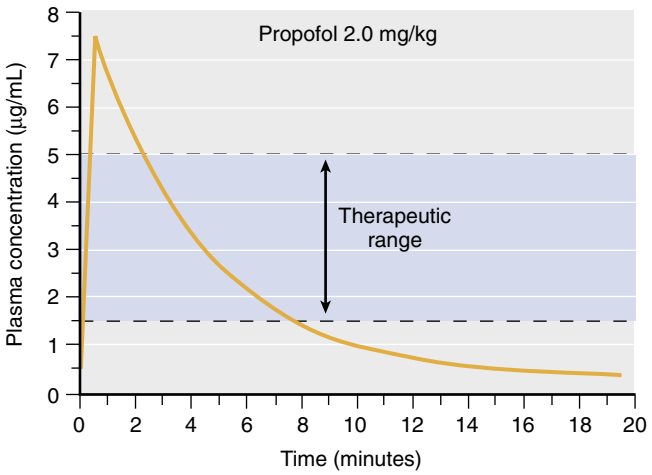

Figure 26-2 Simulated time course of whole blood levels of propofol after an induction dose of 2 mg/kg. Blood levels required for anesthesia during surgery are 2 to 5 µg/mL, with awakening usually occurring at a blood level less than 1.5 µg/mL.

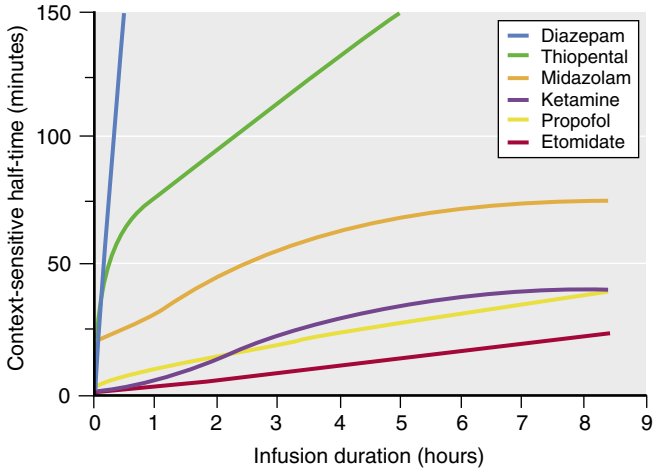

Figure 26-3 The context-sensitive half-times for commonly used IV anesthetic drugs. The context-sensitive half-time is the time for the plasma level of the drug to decrease 50% after cessation of infusion. The duration of infusion is plotted on the horizontal axis. The rapidity with which the drug level decreases is directly related to the time of infusion (i.e., the longer the drug is infused, the longer the half-time). Etomidate, propofol, and ketamine have significantly shorter half-times than thiopental and diazepam, which makes them more suitable for prolonged infusion.

than 50%, recovery from propofol remains rapid even after prolonged infusions. The volume of distribution of the central compartment has been calculated as 20 to 40 L, and the volume of distribution at steady state has been calculated as 150 to 700 L. The clearance of propofol is extremely high—1.5 to 2.2 L/min. As discussed earlier, this exceeds hepatic blood flow, and extrahepatic metabolism has been shown.[5,17]

The equilibrium constant for propofol based on suppression of the electroencephalogram (EEG) (which is strongly correlated with loss of consciousness) is about 0.3 min^{-1}, and the half-life of equilibrium between plasma concentration and EEG effect is 2.5 minutes. The time to peak effect is 90 to 100 seconds.[18] The onset of EEG effect with propofol seems to be independent of age. The onset of decreasing arterial blood pressure is much slower (double the time) and increases with age.[19] For EEG and blood pressure changes, elderly patients show a concentration-dependent increasing sensitivity (see Chapter 71).[19,20]

The pharmacokinetics of propofol may be altered by various factors (e.g., gender, weight, preexisting disease, age, and concomitant medication).[13,21-23] Propofol may impair its own clearance by decreasing hepatic blood flow.[24] Of clinical significance is that propofol may alter its own intercompartmental clearances because of its effects on cardiac output. Changes in cardiac output alter propofol concentrations after a bolus dose and during a constant infusion. Increasing cardiac output leads to a decrease in propofol plasma concentrations and vice versa.[25,26] In a hemorrhagic shock model propofol, concentrations increase 20% until uncompensated shock occurs, when there is a rapid and marked increase in propofol concentrations.[27]

In term and preterm neonates, variability of propofol clearance was accounted for largely by postmenstrual and postnatal age with very fast maturation of clearance in neonatal life. Dosing in these neonates needs to be calculated with extreme care.[28] Women have a larger volume of distribution and higher clearance rates, but the elimination half-life is similar for males and females.[13,22] Elderly individuals have decreased clearance rates, but a smaller central compartment volume.[21,22] During cardiopulmonary bypass, the central volume and initial clearance increase, necessitating higher initial infusion rates to maintain the same propofol plasma concentration.[29] Children have a larger central compartment volume (50%) and a more rapid clearance (25%).[30] In children older than 3 years, volumes and clearances should be weight adjusted.[31] Children younger than 3 years also show weight-proportional pharmacokinetic parameters, but with larger central compartment and systemic clearance values than in adults or older children.[31] This finding explains the larger dosing requirements in this age group (see Chapter 82).[32] Hepatic disease seems to result in a larger steady state and central compartment volumes; clearance is unchanged, but the elimination half-life is slightly prolonged, as is time to recovery.[33]

The effect of fentanyl administration on propofol pharmacokinetic parameters is controversial. Some studies suggest that fentanyl may reduce intercompartmental and total body clearance rates and volumes of distribution.[34] When propofol was administered with alfentanil at similar infusion rates, the measured propofol concentrations were 22% larger than when propofol was administered alone.[35] A separate study found that fentanyl did not alter propofol pharmacokinetics after a single dose of both drugs.[36] Some of these differences in propofol pharmacokinetics when given with an opioid may be explained by studies in cats that showed that pulmonary uptake of propofol is reduced by 30% when propofol is administered immediately after fentanyl, but not if it is administered 3 minutes later.[37] In addition, in vitro studies on human hepatocytes showed that propofol inhibited in a dose-dependent manner the enzymatic degradation of sufentanil and alfentanil.[38] Propofol kinetics is unaltered by renal disease.[23]

The disposition of fospropofol (the parent compound) is best described by a three-compartment model with a relatively small volume of distribution, a fast distribution, and a short terminal half-life of approximately 40 minutes. Fospropofol-delivered propofol has a different pharmacokinetic and pharmacodynamic profile than propofol emulsion, however. Decline of plasma concentrations is slower for fospropofol propofol, and area under the curve values are larger than for a propofol emulsion. Apparent clearance and volume of distribution are much higher in fospropofol propofol than those measured from a propofol emulsion. The peak propofol concentrations from calculated equipotent doses of fospropofol also are higher. Lipid-free formulations of propofol also result in higher peak concentration than equal doses of a lipid emulsion.

Fospropofol also showed a nonlinear relationship between its dose and propofol disposition. Even the propofol maximum concentration was nonlinearly related to dose. Time to maximum concentration of fospropofol was approximately 7 minutes, although at 2 minutes 70% of time to maximum concentration had been reached. Bolus administration of fospropofol achieves loss of response to a verbal command at a similar time and bispectral index (BIS) value as an equipotent amount of propofol emulsion, but shows a longer time to produce a decrease in BIS (almost double) and a more prolonged recovery profile (almost double). Differences in maximum concentration and nonlinearity make simple conversion of dosing from lipid emulsions of propofol to fospropofol difficult.[12,39,40]

Pharmacology

Effects on the Central Nervous System

The hypnotic action of propofol is mostly mediated by enhancing γ-aminobutyric acid (GABA)–induced chloride current through its binding to the β-subunit of $GABA_A$ receptor. Sites on the β_1-subunit (M 286), β_2-subunit (M 286), and β_3-subunit (N265) of the transmembrane domains are crucial for the hypnotic action of propofol.[41,42] The α-subunit and γ_2-subunit subtypes also seem to contribute to modulating the effects of propofol on the GABA receptor.[43] Propofol through its action on $GABA_A$ receptors in the hippocampus inhibits acetylcholine release in the hippocampus and prefrontal cortex.[44] The α_2-adrenoreceptor system also seems to play an indirect role in the sedative effects of propofol.[45] Propofol results in widespread inhibition of the *N*-methyl-D-aspartate (NMDA) subtype of glutamate receptor through modulation of sodium channel gating,[46] an action that also may contribute to the drug's central nervous system (CNS) effects. Studies have shown that propofol has a direct depressant effect on neurons of the spinal cord.[47] In acutely dissociated spinal dorsal horn neurons, propofol acts on $GABA_A$ and glycine receptors.[48] The hypnotic action of propofol is pressure reversible, and it adheres to the correlation exhibited by other general anesthetics between anesthetic potency and octanol/water distribution coefficient.[49] In contrast to barbiturates, propofol is not antianalgesic.

Two notable side effects of propofol are its antiemetic effect and a sense of well-being in patients. Propofol increases dopamine concentrations in the nucleus accumbens (a phenomenon noted with drugs of abuse and pleasure-seeking behavior).[50] Propofol's antiemetic action may be explained by the decrease in serotonin levels it produces in the area postrema, probably through its action on GABA receptors.[51]

The onset of hypnosis after a dose of 2.5 mg/kg is rapid (one arm–brain circulation), with a peak effect seen at 90 to 100 seconds. The median effective dose (ED_{50}) of propofol for loss of consciousness is 1 to 1.5 mg/kg after a bolus. The duration of hypnosis is dose-dependent, being 5 to 10 minutes after 2 to 2.5 mg/kg.[52] Age markedly affects the induction dose, being largest at ages younger than 2 years (ED_{95} 2.88 mg/kg) and decreasing with increasing age.[53] Increasing age decreases the propofol concentration required for loss of consciousness.[54] At subhypnotic doses, propofol provides sedation and amnesia.[55-57] Propofol infusions of at least 2 mg/kg/hr were necessary to provide amnesia in unstimulated volunteers.[58] Awareness during surgery at higher infusion rates has been reported.[59] During surgical procedures, extremely high infusion rates may be necessary to prevent awareness if propofol is used as the sole anesthetic.[54] Propofol also tends to produce a general state of well-being.[60] Hallucinations,[61] sexual fantasies, and opisthotonos[62] have been reported after propofol administration.

The effect of propofol on the EEG as assessed after 2.5 mg/kg followed by an infusion shows an initial increase in alpha rhythm followed by a shift to gamma and theta frequency. High infusion rates produce burst suppression.[63] EEG power analysis indicates that amplitude increases after induction, but is thereafter unaltered at propofol blood concentrations of 3 to 8 μg/mL.[64] At propofol concentrations greater than 8 μg/mL, amplitude markedly decreases, with periods of burst suppression.[64] Propofol causes a concentration-dependent decrease in the BIS, with 50% and 95% of patients unable to respond to a verbal command at a BIS of 63 and 51. The propofol concentration at which 50% of volunteers failed to respond to verbal command was 2.35 μg/mL. Lack of recall was observed in 95% of patients at a BIS value of 77.[65] Propofol produces a decrease in amplitude of the early components of somatosensory evoked potentials,[66] and a small nonsignificant increase in latency of the P_{40} and N_{50} components.[66]

Similar to other IV anesthetics, propofol does not alter brainstem auditory evoked potentials.[67] There are, however, a dose-dependent prolongation of latency and a decrease in amplitude of cortical middle latency auditory potentials, which are concentration-dependent.[67] Propofol effect site concentrations provide similar correlation with decreases in the spectral entropy variable derived from the EEG as it does with BIS, and a similar ability to titrate propofol anesthetic effect.[68] The effect of propofol on epileptogenic EEG activity is controversial. Seizures after propofol administration have been reported, mainly on induction or emergence from anesthesia, rarely during maintenance, and occasionally postoperatively. In various models, a direct anticonvulsant effect of propofol has been shown, which is dose-dependent.[69,70] In a few reports, propofol has been used to treat epileptic seizures.[71] Propofol also results in a shorter duration of motor and EEG seizure activity after electroconvulsive therapy compared with methohexital.[72] Propofol has been associated with grand mal seizures, however, and has been used for cortical mapping of epileptogenic foci.[73,74] There have been a few reports of convulsions after propofol administration that have occurred 6 days after anesthesia. Most of these patients had a history of previous convulsions. The incidence of this adverse effect is rare (1 in 50,000 administrations).

Tolerance to the effects of propofol remains controversial. Repeated dosing to children presenting for radiation therapy showed lack of tolerance for each treatment session,[75] whereas increasingly larger doses were required for repeated electroconvulsive therapy.[76] Of more importance are reports[77] of addiction to propofol. Propofol has been used to treat chronic refractory headache with doses of 20 to 30 mg every 3 to 4 minutes (400 mg maximum).[78]

Propofol decreases intracranial pressure (ICP) in patients with either normal or increased ICP.[79] The decrease in ICP (30% to 50%) is associated with significant decreases in cerebral perfusion pressure (CPP), however. The use of propofol in head-injured patients should be restricted to doses providing mild-to-moderate sedation (i.e., blood concentration of 2 μg/mL, infusion of 25-75 μg/kg/min) (see Chapters 47 and 63).[80] The lesser vasodilatory effects of propofol on the cerebral vasculature compared with volatile anesthetics may provide advantages in certain surgical procedures. Propofol acutely reduces intraocular pressure by 30% to 40%. Compared with thiopental, propofol produces a larger decrease in intraocular pressure and is more effective in preventing an increase in intraocular pressure secondary to succinylcholine and endotracheal intubation (see Chapter 29).[81] Normal cerebral reactivity to carbon dioxide and autoregulation are maintained during a propofol infusion.[82]

The neuroprotective effects of propofol remain controversial. Propofol administered to burst suppression results in significantly better neurologic outcome and less brain tissue injury in an incomplete ischemia model in rats compared with fentanyl.[83] Propofol administered at sedative concentrations started either

immediately after or at 1 hour after an ischemic insult significantly reduced infarct size compared with awake controls infused with intralipid.[84] Pretreatment with propofol fails to protect against focal ischemic insult.[85] In a spinal cord injury model, propofol reduced lipid peroxidation without improving ultrastructure at 1 hour after injury compared with thiopental, which reduced both.[86] The neuronal protective effect of propofol may be due to the attenuation of changes in adenosine triphosphate, calcium, sodium, and potassium caused by hypoxic injury[87] and its antioxidant action by inhibiting lipid peroxidation.[88] Current evidence indicates that propofol can protect neurons against ischemic injury caused by excitotoxicity, but neuroprotection may be sustained only if the ischemic insult is relatively mild and is not sustained after a prolonged recovery period.[89] Prolonged propofol sedation in children is associated with adverse neurologic sequelae (see Chapter 82).[90]

Many anesthetic-related drugs decrease the required dose or blood concentrations of propofol's pharmacologic action. The propofol Cp_{50} (blood concentration needed for 50% of subjects to not respond to a defined stimulus) for loss of response to verbal command in the absence of any other drug is 2.3 to 3.5 μg/mL.[54,91,92] The propofol Cp_{50} to prevent movement on skin incision is 16 μg/mL; this is markedly reduced by increasing concentrations of fentanyl or alfentanil.[54,91,92] The propofol Cp_{50} for skin incision when combined with benzodiazepine premedication (lorazepam, 1 to 2 mg) and 66% nitrous oxide is 2.5 μg/mL (venous).[22,92] This concentration is reduced to 1.7 μg/mL when morphine (0.15 mg/kg) rather than lorazepam is used for premedication.[93] The concentration of propofol (when combined with 66% nitrous oxide) required during minor surgery is 1.5 to 4.5 μg/mL,[15,22] and the concentration for major surgery is 2.5 to 6 μg/mL.[54] Awakening usually occurs at concentrations less than 1.6 μg/mL,[15,22,52] and orientation occurs at concentrations less than 1.2 μg/mL[15,22] when the propofol concentration is decreasing. When equilibration between blood and effect site is allowed, however, awakening concentrations (2.2 μg/mL) are much closer to concentrations associated with loss of verbal command.[94]

Effects on the Respiratory System

Apnea occurs after an induction dose of propofol; the incidence and duration of apnea depend on dose, speed of injection, and concomitant premedication. An induction dose of propofol results in a 25% to 30% incidence of apnea.[96] The duration of apnea occurring with propofol may be prolonged to more than 30 seconds, however. The incidence of prolonged apnea (>30 seconds) is increased further by addition of an opiate, either as premedication or just before induction of anesthesia.[96,97] The incidence of apnea with propofol is more frequent than with other commonly used IV induction anesthetics.[96,98] The onset of apnea usually is preceded by marked tidal volume reduction and tachypnea.[97] In volunteers, dose-dependent apnea was more pronounced with propofol emulsion than with fospropofol.[40]

In nearly every clinical setting propofol is used, it is a profound respiratory depressant. A maintenance infusion of propofol (100 μg/kg/min) results in a 40% decrease in tidal volume and a 20% increase in respiratory frequency, with an unpredictable change in minute ventilation.[97] Doubling the infusion rate from 100 to 200 μg/kg/min causes a further moderate decrease in tidal volume (455 to 380 mL), but no change in respiratory frequency.[97] The ventilatory response to carbon dioxide also is decreased during a maintenance infusion of propofol.[97] At 100 μg/kg/min, there is a 58% reduction in the slope of the carbon dioxide–response curve.[97] This is similar to the depression after a brief infusion of 3 mg/kg/min of thiopental. Doubling the infusion rate (and presumably the blood level) of propofol results in only a minimal further decrease in carbon dioxide responsiveness.[97] Propofol, 1.5 to 2.5 mg/kg, results in an acute (13% to 22%) increase in $Paco_2$ and a decrease in pH. Pao_2 does not change significantly. These changes are similar to the changes seen after an induction dose of thiopental. During a maintenance infusion of propofol (54 μg/kg/min), $Paco_2$ is moderately increased from 39 to 52 mm Hg. Doubling this infusion rate does not result in a further increase in $Paco_2$.

Propofol (50 to 120 μg/kg/min) also depresses the ventilatory response to hypoxia, presumably by a direct action on carotid body chemoreceptors.[99] Propofol induces bronchodilation in patients with chronic obstructive pulmonary disease.[100] Propofol attenuates vagal (at low concentrations) and methacholine-induced (at high concentrations) bronchoconstriction,[101] and seems to have a direct action on muscarinic receptors. Propofol inhibits the receptor coupled signal transduction pathway through inositol phosphate generation and inhibition of Ca^{2+} mobilization.[102] The preservative used with propofol seems to be important in its bronchodilator activity. Propofol with metabisulfite (compared with propofol without metabisulfite) does not inhibit vagal or methacholine-induced bronchoconstriction.[103]

Propofol also may have an impact on the pulmonary pathophysiology of adult respiratory distress syndrome. In an animal model of septic endotoxemia, propofol (10 mg/kg/hr) significantly reduced free radical mediated and cyclooxygenase catalyzed lipid peroxidation. In addition, Pao_2 and hemodynamics were maintained closer to baseline.[104] These benefits of propofol have not yet been confirmed in humans. Propofol at therapeutic concentrations also protects mouse macrophages from nitric oxide–induced apoptosis and cell death.[105]

Propofol also attenuates the magnitude of hypoxic pulmonary vasoconstriction.[106] The effect of propofol on pulmonary vasomotor tone inhibits acetylcholine-induced pulmonary vasodilation through nitric oxide and a cytochrome P-450 metabolite (likely endothelium-derived hyperpolarizing factor).[107]

Effects on the Cardiovascular System

The cardiovascular effects of propofol have been evaluated after its use for induction and for maintenance of anesthesia (Table 26-2).[108] The most prominent effect of propofol is a decrease in arterial blood pressure during induction of anesthesia. Independent of the presence of cardiovascular disease, an induction dose of 2 to 2.5 mg/kg produces a 25% to 40% reduction of systolic blood pressure.[108,112,113] Similar changes are seen in mean and diastolic blood pressure. The decrease in arterial pressure is associated with a decrease in cardiac output/cardiac index (±15%),[112,113] stroke volume index (±20%),[113] and systemic vascular resistance (15% to 25%).[112] Left ventricular stroke work index also is decreased (±30%). When looking specifically at right ventricular function, propofol produces a marked reduction in the slope of the right ventricular end-systolic pressure-volume relationship.[114]

In patients with valvular heart disease, pulmonary artery and pulmonary capillary wedge pressure also are reduced, a finding that implies the resultant decrease in pressure is due to a decrease in preload and afterload. Although the decrease in systemic pressure after an induction dose of propofol is due to

Table 26-2 Hemodynamic Changes after Induction of Anesthesia with Nonbarbiturate Hypnotics

	Diazepam	Droperidol	Etomidate*	Ketamine	Lorazepam	Midazolam	Propofol
HR	–9 ± 13%	Unchanged	–5 ± 10%	0-59%	Unchanged	–14 ± 12%	–10 ± 10%
MBP	0-19%	0-10%	0-17%	0 ± 40%	–7-20%	–12-26%	–10-40%
SVR	–22 ± 13%	–5-15%	–10 ± 14%	0 ± 33%	–10-35%	0-20%	–15-25%
PAP	0-10%	Unchanged	–9 ± 8%	+44 ± 47%	—	Unchanged	0-10%
PVR	0-19%	Unchanged	–18 ± 6%	0 ± 33%	Unchanged	Unchanged	0-10%
PAO	Unchanged	+25 ± 50%	Unchanged	Unchanged	—	0-25%	Unchanged
RAP	Unchanged	Unchanged	Unchanged	+15 ± 33%	Unchanged	Unchanged	0-10%
CI	Unchanged	Unchanged	–20 ± 14%	0 ± 42%	0 ± 16%	0-25%	–10-30%

dP/dt	Unchanged	—	0-18%	Unchanged	—	0-12%	Decreased

*The larger deviations are in patients with valvular disease.
CI, cardiac index; dP/dt, first derivative of pressure measured over time; HR, heart rate; LVSWI, left ventricular stroke work index; MBP, mean blood pressure; PAP, pulmonary artery pressure; PVR, pulmonary vascular resistance; PAO, pulmonary artery occluded pressures; RAP, right atrial pressure; SV, stroke volume; SVR, systemic vascular resistance.

vasodilation, the direct myocardial depressant effects of propofol are more controversial. The decrease in cardiac output after propofol administration may be via its action on sympathetic drive to the heart. Propofol at high concentrations (10 μg/mL) abolishes the inotropic effect of α but not β adrenoreceptor stimulation, and enhances the lusitropic (relaxation) effect of β stimulation.[115] Clinically, the myocardial depressant effect and the vasodilation seem to be dose-dependent and plasma concentration–dependent.[116] The vasodilatory effect of propofol seems to be due to a reduction in sympathetic activity,[117] a direct effect on intracellular smooth muscle calcium mobilization,[118] inhibition of prostacyclin synthesis in endothelial cells,[119] reduction in angiotensin II–elicited calcium entry,[120] activation of K^+ adenosine triphosphate channels, and stimulation of nitric oxide. The stimulation of nitric oxide may be modulated by intralipid rather than propofol.[121]

Heart rate does not change significantly after an induction dose of propofol. Propofol either may reset or may inhibit the baroreflex, reducing the tachycardic response to hypotension.[122] Propofol also decreases cardiac parasympathetic tone in a dose-dependent manner.[123] Propofol has a minimal direct effect on sinoatrial node function or on normal atrioventricular and accessory pathway conduction.[124] Propofol attenuates the heart rate response to atropine in a dose-dependent manner. During an infusion of 10 mg/kg/hr of propofol, a cumulative dose of atropine of 30 μg/kg increased heart rate greater than 20 beats/min in only 20% of subjects compared with 100% in the absence of propofol.[125] Propofol suppresses atrial (supraventricular) tachycardias and probably should be avoided during electrophysiologic studies.[126]

In retrospective review of 2406 patients, Reich and colleagues[127] showed that 9% of patients experienced severe hypotension 0 to 10 minutes after induction of general anesthesia. Statistically significant multivariate predictors of hypotension 0 to 10 minutes after anesthetic induction included American Society of Anesthesiologists (ASA) class III through V, baseline mean arterial pressure (MAP) less than 70 mm Hg, age 50 years or older, use of propofol for induction of anesthesia, and increasing induction dosage of fentanyl. The combination of propofol with fentanyl was a particularly potent stimulus for hypotension. A prolonged postoperative stay or death was more common in patients with versus patients without postinduction hypotension; however, the use of propofol per se was not associated with increased morbidity.[127] Limited data indicate that 0.5 mg/kg of ketamine is able to better prevent decreases in hemodynamics after a propofol induction alone or in combination with fentanyl (1 μg/kg).[128]

During maintenance of anesthesia with a propofol infusion, arterial systolic blood pressure also is decreased to 20% to 30% less than preinduction of anesthesia levels. In patients allowed to breathe room air during a maintenance infusion of 100 μg/kg/min of propofol, there is a significant decrease in systemic vascular resistance (30%), but cardiac index and stroke index are unaltered. In contrast, in patients receiving a narcotic premedication and nitrous oxide with an infusion of propofol (54 μg/kg/min and 108 μg/kg/min) for maintenance during surgery, systemic vascular resistance is not significantly decreased from baseline, but cardiac output and stroke volume are decreased. This situation is probably explained by the observation that propofol infusions produce a dose-dependent decrease of sympathetic nerve activity, attenuating the reflex responses to hypotension. In the presence of hypercarbia, the reflex sympathetic responses are better maintained.[129]

Increasing the infusion rate of propofol from 54 to 108 μg/kg/min (blood concentration 2.1 to 4.2 μg/mL) produces only a slightly greater decrease in arterial blood pressure (–10%). The peak plasma concentrations obtained after a bolus dose are substantially higher than the concentrations seen with a continuous infusion. Because the vasodilatory and myocardial depressant effects are concentration-dependent, the decrease in arterial blood pressure from propofol during the infusion phase (maintenance of anesthesia) is much less than that seen after an induction of anesthesia bolus. When propofol was compared with midazolam for sedation after coronary revascularization, propo-

fol resulted in a 17% less frequent incidence of tachycardia, a 28% less frequent incidence of hypertension, and a 17% more frequent incidence in hypotension. These differences in hemodynamic variables resulted in no difference in the number or severity of ischemic events between the two groups. An infusion of propofol results in a significant reduction in myocardial blood flow and myocardial oxygen consumption,[108,111] a finding that suggests that the global myocardial oxygen supply-to-demand ratio is preserved.

The cardioprotective effect of propofol versus volatile anesthetics in patients having cardiac surgery on or off cardiopulmonary bypass is less debatable. In two large studies comparing propofol with sevoflurane in patients undergoing cardiac surgery, postoperative troponin were lower and hemodynamic function better in patients receiving sevoflurane.[130,131] A study comparing desflurane with propofol in patients undergoing off-pump coronary artery bypass showed similar results.[132] In contrast, a small study that administered high-dose propofol (120 µg/kg/min), low-dose propofol (60 µg/kg/min) while on pump, or titrated isoflurane throughout surgery showed improved troponin levels and better hemodynamic function in the large-dose propofol group compared to the isoflurane or low-dose propofol group.[133] This study may indicate that cardioprotection with propofol is dose dependent, but needs confirmation.

Heart rate may increase,[111] decrease,[110] or remain unchanged[109] when anesthesia is maintained with propofol. The extent of hypotension, the ability for the patient to compensate, and the use of any other concomitant drugs are likely the most important factors in determining what happens to the heart rate after propofol administration.

Other Effects

Propofol, similar to thiopental, does not enhance neuromuscular blockade produced by neuromuscular blocking drugs. Propofol produces no effect on the evoked electromyogram or twitch tension; however, good intubating conditions after propofol alone have been reported.[134] Propofol does not trigger malignant hyperthermia and is an appropriate choice in patients with this condition.[135]

Propofol after a single dose or a prolonged infusion does not affect corticosteroid synthesis or alter the normal response to adrenocorticotropic hormone (ACTH) stimulation.[136] Propofol in the emulsion formulation does not alter hepatic, hematologic, or fibrinolytic function. Lipid emulsion per se reduces in vitro platelet aggregation, however.[137] Anaphylactoid reactions to the present formulation of propofol have been reported. In at least some patients, the immune response was entirely due to propofol and not to the lipid emulsion. A high percentage of the patients developing the anaphylactoid response to propofol had a previous history of allergic responses. In patients with multiple drug allergies, propofol should be used with caution.[138] Propofol alone in intralipid does not trigger histamine release.[139] Fospropofol is metabolized to propofol and formate. Formate concentrations do not increase after fospropofol administration.[40]

Propofol also possesses significant antiemetic activity at low (subhypnotic) doses. It has been used successfully to treat postoperative nausea in a bolus dose of 10 mg.[140] The median concentration of propofol that was associated with an antiemetic effect was 343 ng/mL.[141] This concentration can be achieved by a propofol infusion of 10 to 20 mg loading dose followed by 10 µg/kg/min. Propofol used as a maintenance anesthetic during breast surgery was more effective than 4 mg of ondansetron given as prophylaxis in preventing postoperative nausea and vomiting (PONV). In the same study, the maintenance propofol infusion also was superior to adding propofol only at the end of the procedure (sandwich technique).[142] Propofol as an infusion of 1 mg/kg/hr (17 µg/kg/min) also has provided excellent antiemetic action after anticancer chemotherapy. At subhypnotic doses, propofol relieves cholestatic pruritus and is as effective as naloxone in treating pruritus induced by spinal opiates,[143] although not all studies have confirmed this effect of propofol.

Propofol decreases polymorphonuclear leukocyte chemotaxis, but not adherence phagocytosis and killing. This action contrasts with the effect of thiopental, which inhibits all these chemotactic responses.[144] Propofol inhibits phagocytosis and killing of *Staphylococcus aureus* and *Escherichia coli,* however.[145] These findings are particularly pertinent in view of the observation of increased life-threatening systemic infections associated with the use of propofol.[146] In hospitals where these infections occurred, opened vials and syringes of propofol had positive cultures for the offending organisms. The intralipid that acts as the solvent for propofol is an excellent culture medium. Disodium edetate or metabisulfite has been added to the formulation of propofol in an attempt to retard such bacterial growth. Strict aseptic technique still must be observed.

The administration of propofol also has been associated with the development of pancreatitis.[147] The development of pancreatitis seems to be related to hypertriglyceridemia. Patients who developed hypertriglyceridemia tended to be older, had a longer intensive care unit (ICU) stay, and received propofol for a longer duration. It seems prudent, if propofol is being used for prolonged sedation or at higher infusion rates (especially in elderly patients), that serum triglyceride concentrations should be routinely monitored.[148]

Uses

Induction and Maintenance of Anesthesia

Propofol is suitable for the induction and maintenance of anesthesia (Table 26-3). The induction dose is 1 to 2.5 mg/kg. Physiologic characteristics that best determine the induction dose are age, lean body mass, and central blood volume.[149] Premedication with an opiate or a benzodiazepine, or both, markedly reduces the induction dose.[150,151] A dose of 1 mg/kg (with premedication) to 1.75 mg/kg (without premedication) is recommended for inducing anesthesia in patients older than 60 years (see Chapter 71).[152] As noted earlier, older and sicker (ASA class III to IV) patients develop more profound hypotension, especially when propofol is

Table 26-3 Uses and Doses of Intravenous Propofol

Induction of general anesthesia	1-2.5 mg/kg IV dose reduced with increasing age
Maintenance of general anesthesia	50-150 µg/kg/min IV combined with N_2O or an opiate
Sedation	25-75 µg/kg/min IV
Antiemetic	10-20 mg IV, can repeat every 5-10 min or start infusion of 10 µg/kg/min

N_2O, nitrous oxide.

combined with an opiate.[127] To prevent hypotension in sicker patients or in patients presenting for cardiac surgery, a fluid load should be administered as tolerated, and the propofol can be administered in small incremental doses (10 to 30 mg or as an infusion) until the patients lose consciousness. To limit the dose and retain the fastest onset time, an infusion of 80 mg/kg/hr is optimal. Diluting propofol to 0.5 mg/mL further reduces the impact of this induction dose on hemodynamics.[153] For induction in children, the ED_{95} (2 to 3 mg/kg) is increased, primarily because of pharmacokinetic differences (see Chapter 82).[154]

Propofol, when used for induction of anesthesia in briefer procedures, results in a significantly quicker recovery and an earlier return of psychomotor function compared with thiopental or methohexital, regardless of the anesthetic used for maintenance of anesthesia. The incidence of nausea and vomiting when propofol is used for induction also is markedly less than after the use of other IV anesthetics, probably because of the antiemetic properties of propofol.[155]

Because of its pharmacokinetics, propofol provides a rapid recovery and is superior to barbiturates for maintenance of anesthesia, and it seems to be equal to enflurane, isoflurane and sevoflurane.[156] Recovery from desflurane is slightly more rapid than recovery from propofol.[157] Propofol can be given as intermittent boluses or as a continuous infusion for maintenance. After a satisfactory induction dose, a bolus of 10 to 40 mg is needed every few minutes to maintain anesthesia. Because these doses need to be given frequently, it is more suitable to administer propofol as a continuous infusion.

Several infusion schemes have been used to achieve adequate plasma concentrations of propofol.[158] After an induction dose, an infusion of 100 to 200 μg/kg/min is usually needed. The infusion rate is titrated to individual requirements and the surgical stimulus. When combined with propofol, the required infusion rate and concentration of opiates, midazolam, clonidine, or ketamine is reduced. Because opioids alter the concentration of propofol required for adequate anesthesia, the relative dose of either opioid or propofol markedly affects the time from termination of drug to awakening and recovery. The infusion rate required to achieve the combination with the shortest recovery is propofol, 1 to 1.5 mg/kg followed by 140 μg/kg/min for 10 minutes followed by 100 μg/kg/min, and alfentanil, 30 μg/kg followed by an infusion of 0.25 μg/kg/min, or fentanyl, 3 μg/kg followed by 0.02 μg/kg/min. Propofol also has been used as a single mixture with alfentanil, containing 1 mg of alfentanil (2 mL) to 400 mg of propofol (40 mL). When this mixture was administered at infusion rates commonly used for propofol (i.e., 166 μg/kg/min for 10 minutes, 133 μg/kg/min for 10 minutes, and 100 μg/kg/min thereafter), it provided an outcome equal to that obtained by using the two drugs as separate infusions.[159]

Increasing age is associated with a decrease in propofol infusion requirements (see Chapter 71), whereas these requirements are higher in children and infants (see Chapter 82).[30] The blood levels of propofol alone for loss of consciousness are 2.5 to 4.5 μg/mL, and the blood concentrations (when combined with nitrous oxide) required for surgery are 2.5 to 8 μg/mL.[15,22,52,93,160,161] Similar concentrations are necessary when propofol is combined with an opioid for a total IV technique. The knowledge of these levels and of the pharmacokinetics of propofol has enabled the use of pharmacokinetic model–driven infusion systems to deliver propofol as a continuous infusion for the maintenance of anesthesia. A meta-analysis of recovery data after either propofol for maintenance or the newer volatile anesthetics indicated only minor differences in times to reach recovery goals; however, the incidence of nausea and vomiting remained significantly lower in the patients administered propofol for maintenance.[162]

Several studies have investigated the utility of propofol as a maintenance infusion regimen for cardiac surgery. Using reduced and titrated doses of propofol for induction and titrated infusion rates of 50 to 200 μg/kg/min combined with an opioid for maintenance, propofol provided intraoperative hemodynamic control and ischemic episodes similar to those with either enflurane/opioid or a primary opioid technique.[163,164]

Sedation

Propofol has been evaluated for sedation during surgical procedures[55,56,165] and for patients receiving mechanical ventilation in the ICU (see Chapter 92).[166] Propofol by continuous infusion provides the ability to titrate to a desired level of sedation and provide a rapid recovery after infusion is terminated, regardless of the duration of the infusion.[56,168] In a study of patients sedated in the ICU for 4 days with propofol, recovery to consciousness was rapid (±10 minutes). The rate of recovery and the decrease in plasma concentration were similar at 24 hours and at 96 hours, when the infusion was discontinued. In addition, the plasma concentrations required for sedation and for awakening were similar at 24 hours and 96 hours, a finding that implies that tolerance to propofol did not occur.[168] As noted earlier, there have been more recent reports of tolerance with propofol.

Infusion rates required for sedation to supplement regional anesthesia in healthy patients are half or less than the rates required for general anesthesia (i.e., 30 to 60 μg/kg/min).[55] In elderly patients (>65 years old) and in sicker patients, the infusion rates that are necessary are markedly reduced.[55,166,167] It is important to titrate the infusion individually to the desired effect. A 1992 report[169] linked propofol with several deaths in children requiring sedation for mechanical ventilation secondary to upper respiratory tract infections. This rare syndrome (propofol infusion syndrome) also may occur in adults (see later). A potential advantage of propofol for sedation of ICU patients is that it seems to possess antioxidant properties.[170]

Although the pharmacokinetic profile and to a large extent the pharmacology of propofol make it an excellent choice for long-term (days) sedation, this always must be weighed against the hemodynamic effects, the often concomitant need for an analgesic, tolerance, and rare occurrences of hypertriglyceridemia (and potential pancreatitis) or propofol infusion syndrome. Maintaining the lowest possible dose required for the desired level of sedation with potential "sedation holidays" should considered as part of a long-term propofol sedation regimen. In addition, the FDA has specifically recommended against the use of propofol for the prolonged sedation of pediatric patients. The sedation guidelines of the American College of Critical Care Medicine also recommend "that patients receiving propofol for long term sedation should be monitored for unexplained metabolic acidosis or arrhythmias. Alternative sedative agents should be considered for patients with escalating vasopressor or inotrope requirements or cardiac failure during high-dose propofol infusions."[171] The recommended maximal dose of propofol infusion rate is 80 μg/kg/min (<5 mg/kg/hr).[171]

Generally, at propofol infusion rates greater than 30 μg/kg/min, patients are amnesic.[167] Compared with midazolam when used to maintain sedation, propofol provides equal or better

control and more rapid recovery.[56,167] In mechanically ventilated patients, more rapid recovery translates to more rapid extubation when sedation is terminated.[167] Propofol also has been used successfully in patient-controlled sedation. Propofol was rated better than midazolam when used by this technique, probably owing to its much more rapid onset and offset.[172] Patient-controlled sedation has been compared with anesthesia provider sedation. Generally, patients use less propofol and recover more quickly, and there are limited differences in patient satisfaction.[173,174]

Side Effects and Contraindications

Induction of anesthesia with propofol is associated with several side effects, including pain on injection, myoclonus, apnea, hypotension, and, rarely, thrombophlebitis of the vein into which propofol is injected. Pain on injection is less than or equal to that with etomidate, equal to that with methohexital, and greater than that after thiopental.[175,154] Pain on injection is reduced by using a large vein, avoiding veins in the dorsum of the hand, and adding lidocaine to the propofol solution or changing the propofol formulation. Multiple other drugs and distraction techniques have been investigated to reduce the pain on injection of propofol. Pretreatment with a small dose of propofol, opiates, nonsteroidal anti-inflammatory drugs, ketamine, esmolol/metoprolol, magnesium, a flash of light, clonidine/ephedrine combination, dexamethasone, and metoclopramide all have been tested with variable efficacy.

Fospropofol causes less pain on injection, but an equal incidence of tingling/discomfort in the genital areas.[40] Myoclonus occurs more frequently after propofol than after thiopental, but less frequently than after etomidate or methohexital.[154] Apnea after induction with propofol is common. The incidence of apnea may be similar to that after thiopental or methohexital; however, propofol produces a greater incidence of apnea lasting longer than 30 seconds.[98,160] The addition of an opiate increases the incidence of apnea, especially prolonged apnea.[95,160]

The most common side effect during induction of anesthesia is hypotension, which is augmented by the concomitant administration of opioids.[113] Conversely, with laryngoscopy and endotracheal intubation, the changes in MAP, heart rate, and systemic vascular resistance are less significant after propofol compared with thiopental.[110,113]

Propofol infusion syndrome is a rare but lethal syndrome associated with infusion of propofol at 4 mg/kg/hr or more for 48 hours or longer. It was first described in children, but subsequently has been observed in critically ill adults. The clinical features of propofol infusion syndrome are acute refractory bradycardia leading to asystole, in the presence of one or more of the following: metabolic acidosis (base deficit >10 mmol/L^{-1}), rhabdomyolysis, hyperlipidemia, and enlarged or fatty liver.[176] Other features include cardiomyopathy with acute cardiac failure, skeletal myopathy, hyperkalemia, hepatomegaly, and lipemia.[151,177] Theories about its causality include mitochondrial toxicity, mitochondrial defects, impaired tissue oxygenation, and carbohydrate deficiency. The major risk factors for its development seem to be poor oxygen delivery, sepsis, serious cerebral injury, and high propofol dosage. In some reports, an increasing lipemia has been noted and was likely to be due to a failure of hepatic lipid regulation, possibly related to poor oxygenation or a lack of glucose or both. In some cases, an increasing lipemia was the first indication of impending propofol infusion syndrome onset, so it should not be viewed as a benign sign.[178]

Barbiturates

History

Thiopental was introduced clinically by Waters and Lundy (Fig. 26-4), and became preferred clinically because of its rapid onset of action and short duration, without the excitatory effects of hexobarbital.[179] Although criticized after many casualties during the attack on Pearl Harbor as "the ideal form of euthanasia in war surgery," the barbiturates continued to be widely used in clinical practice.[180] Although many other barbiturate derivatives have been synthesized throughout the past several decades, none have enjoyed the clinical success and popularity of thiopental.

Physicochemical Characteristics

Chemistry and Formulation

Barbiturates are hypnotically active drugs that are derivatives of barbituric acid (2,4,6-trioxohexahydropyrimidine), a hypnotically inactive pyrimidine nucleus that is formed by the condensation of malonic acid and urea (Fig. 26-5). The two major divisions of barbiturates are those with an oxygen at position 2 and those with a sulfur in position 2—the classes of oxybarbiturates and thiobarbiturates, respectively. Through keto-enol tautomerization, the oxygen or sulfur in position 2 becomes a reactive species in the enol form, allowing for the formation of water-soluble barbiturate salts in alkaline solutions. This solubility permits the IV use of barbiturates. Although tautomerization to the enol form allows for the creation of salts, it is substitution of the hydrogen attached to the carbon atom in position 5 with aryl or alkyl groups that gives the barbiturates their hypnotic activity. Only thiopental and thiamylal, thiobarbiturates, and methohexital, an oxybarbiturate, have been commonly used for induction of anesthesia (Fig. 26-6).

The formulation of barbiturates involves preparing them as sodium salts (mixed with 6% by weight anhydrous sodium carbonate) and then reconstituting with either water or normal saline to produce a 2.5% solution of thiopental, a 2% solution of thiamylal, or a 1% solution of methohexital. The thiobarbiturates are stable for 1 week if refrigerated after reconstitution, and methohexital remains available for use for 6 weeks after reconstitution. A decrease in the alkalinity of the solution can result in precipitation of the barbiturates as free acids, which is why they cannot be reconstituted with lactated Ringer's solution or mixed with other acidic solutions. Examples of drugs that are not to be coadministered or mixed in solution with the barbiturates are pancuronium, vecuronium, atracurium, alfentanil, sufentanil, and midazolam. Studies have shown that in rapid-sequence induction, the mixing of thiopental with vecuronium or pancuronium results in the formation of precipitate that may occlude the IV line.[181]

Structure-Activity Relationships

As noted earlier, substitutions at the 5, 2, and 1 positions confer different pharmacologic activities to the barbiturate nucleus. Sub-

stitutions at position 5 with either aryl or alkyl groups produce hypnotic and sedative effects. A phenyl group substitution at C5 produces anticonvulsant activity. An increase in length of one or both side chains of an alkyl group at C5 increases hypnotic potency. Barbiturates used in clinical practice have either an oxygen or sulfur at C2. Substitution of a sulfur at position 2 produces a more rapid onset of action, as with thiopental. The addition of a methyl or ethyl group at position 1 also may produce a more rapid onset of action, but excitatory side effects, including tremor, hypertonus, and involuntary movement, may occur with administration, as with methohexital.

Metabolism

The barbiturates (with the exception of phenobarbital) are hepatically metabolized. The metabolites that are formed are almost all inactive, water-soluble, and excreted in the urine. Barbiturates are biotransformed by four processes: (1) oxidation of the aryl, alkyl, or phenyl moiety at C5; (2) *N*-dealkylation; (3) desulfuration of the thiobarbiturates at C2; and (4) destruction of the barbituric acid ring.[182] Oxidation is the most important pathway, producing polar (charged) alcohols, ketones, phenols, or carboxylic acids. These metabolites are readily excreted in the urine or as glucuronic acid conjugates in the bile. The barbituric acid ring is so stable in vivo that hydrolytic cleavage of the ring is a minimal contribution to the total metabolism of barbiturates. Drugs that induce the oxidative microsomes enhance the metabolism of barbiturates. Long-term administration of barbiturates also induces the enzymes.[182] The hepatic enzyme induction of barbiturates is responsible for the recommendation that they not be administered to patients with acute intermittent porphyria because barbiturates may precipitate an attack by stimulating γ-aminolevulinic acid synthetase, the enzyme responsible for the production of porphyrins.[183]

As mentioned earlier, hepatic metabolism accounts for the elimination of all of the barbiturates with the exception of phenobarbital. Renal excretion is important in the elimination of

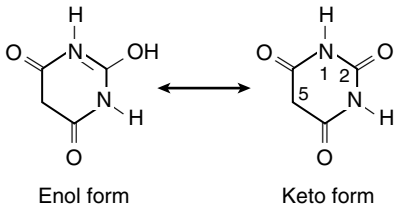

Figure 26-5 The keto and enol tautomeric forms of barbituric acid with the sites of substitution in the hypnotically active barbiturates identified as 1, 2, and 5.

phenobarbital, accounting for 60% to 90% of drug excretion in an unchanged form. Only trivial amounts of other barbiturates are excreted unchanged by the kidney. The alkalinization of urine with bicarbonate enhances the renal excretion of phenobarbital.

Methohexital is metabolized in the liver by oxidation to an alcohol and *N*-dealkylation. Compared with thiopental, methohexital exhibits similar distribution half-lives, volumes of distribution, and protein bindings. A marked difference exists, however, in plasma disappearance and elimination half-lives (4 hours for methohexital and 12 hours for thiopental). This difference is due to the threefold more rapid rate of hepatic clearance of methohexital (mean 7.8 to 12.5 mL/kg/min).[184] The hepatic extraction ratio of methohexital (clearance to hepatic blood flow) is approximately 0.5, indicating that the liver extracts 50% of the drug presented to it. This ratio contrasts to the lower hepatic extraction ratio of thiopental (0.15).

Pharmacokinetics

Barbiturate pharmacokinetics has been described in physiologic and compartmental models, with the latter gaining more support in recent years.[185] Physiologic models of barbiturates describe a rapid mixing of the drug with the central blood volume followed by a quick distribution of the drug to highly perfused, low-volume tissues (i.e., brain) with a slower redistribution of the drug to lean tissue (muscle), which terminates the effect of the induction dose. In these models, adipose tissue uptake and metabolic clearance (elimination) play only a minor role in the termination of the effects of the induction dose because of the minimal perfusion ratio compared with other tissues and the slow rate of removal. Compartmental model values for thiopental and methohexital, the most commonly used induction barbiturates, are given in Table 26-1.

Both of these pharmacokinetic models describe rapid redistribution as the primary mechanism that terminates the action of a single induction dose. The compartmental model explains the delay of recovery when a continuous infusion of a barbiturate is used. This model describes the phenomena whereby the termination of effect becomes increasingly dependent on the slower process of uptake into adipose tissue and elimination clearance through hepatic metabolism. After prolonged infusions, the pharmacokinetics of barbiturate metabolism is best approximated by nonlinear Michaelis-Menten metabolism.

In usual doses (4 to 5 mg/kg), thiopental exhibits first-order kinetics (i.e., a constant *fraction* of drug is cleared from the body per unit time); however, at very high doses of thiopental (300 to 600 mg/kg) with receptor saturation, zero-order kinetics occur (i.e., a constant *amount* of drug is cleared per unit time). The volume of distribution is slightly larger in female patients, causing longer elimination half-lives.[186] Pregnancy also increases the volume of distribution of thiopental, prolonging the elimination half-life.[187] As noted previously, the clearance rate of thiopental is not altered in patients with cirrhosis because the amount of protein available for the drug to bind to is still adequate even at fairly advanced stages of the disease process.[188]

Because of its affinity for fat, relatively large volume of distribution, and low rate of hepatic clearance, thiopental can accumulate in tissues, especially if given in large doses over a prolonged period. The plasma drug level increases when repeat doses of drug are given.[189] Appropriately designed infusion schemes ensure constant blood levels, maintaining the hypnotic effect, although this is not used in routine clinical practice.

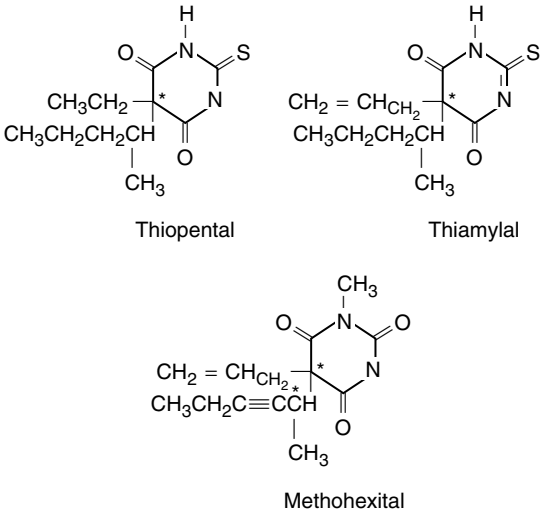

Figure 26-6 Hypnotically active barbiturates commonly used for induction, with their asymmetric centers indicated by an asterisk.

Pharmacology

Mechanism of Action

Much research has been conducted to delineate the mechanisms of action of barbiturates on the CNS, but until more recently, with the exception of their action on $GABA_A$ receptor, these have remained largely unknown.[190,191] Numerous more recent studies have begun to elucidate the role of NMDA receptors in the actions of barbiturates.[192-195] The selectivity of actions of barbiturates on CNS neurophysiologic systems has been grouped into two general categories: (1) enhancement of the synaptic actions of *inhibitory* neurotransmitters, and (2) blockade of the synaptic actions of *excitatory* neurotransmitters.[196]

GABA is the principal inhibitory neurotransmitter in the mammalian CNS, and the $GABA_A$ receptor is the only site that has been proved to be involved in barbiturate-induced anesthesia.[191] The $GABA_A$ receptor is a chloride ion channel that is composed of at least five subunits with specific sites of action for GABA, barbiturates, benzodiazepines, and other molecules.[179] Barbiturate binding to the $GABA_A$ receptor enhances and mimics the action of GABA by increasing chloride conductance through

the ion channel, causing hyperpolarization of the cell membrane and increasing the threshold of excitability of the postsynaptic neuron.[197] At low concentrations, barbiturates enhance the effects of GABA, decreasing the rate of dissociation of GABA from its receptor and increasing the duration of GABA-activated chloride ion channel openings. This enhancement of the action of GABA is considered to be responsible for the sedative-hypnotic effects of the barbiturates. At higher concentrations, the barbiturates directly activate the chloride channels without the binding of GABA, acting as the agonist itself. The GABA-mimetic effect at slightly higher concentrations may be responsible for what is termed *barbiturate anesthesia*.[191]

The barbiturates also inhibit synaptic transmission of excitatory neurotransmitters, such as glutamate and acetylcholine.[191] The actions of the barbiturates to block excitatory CNS transmission are specific for synaptic ion channels. Thiopental may exert GABA-independent effects, however, on the glutaminergic-NMDA system.[194] In two studies of rat prefrontal cortex, thiopental was shown to decrease extracellular glutamate levels in the CNS and decrease NMDA-gated currents in a concentration-dependent manner.[192,193] In a similar study in mice, thiopental has GABA-independent actions that inhibit the excitatory activities through inhibition of NMDA receptors.[194]

Effects on Cerebral Metabolism

Barbiturates, similar to other CNS depressants, have potent effects on cerebral metabolism (see Chapters 13 and 63). A dose-related depression of cerebral metabolic oxygen consumption rate ($CMRO_2$), produces a progressive slowing of the EEG, a reduction in the rate of adenosine triphosphate consumption, and protection from incomplete cerebral ischemia.[198] The relationship of depressed metabolism to drug dosage was shown in dogs in which circulation at high thiopental doses was preserved by an extracorporeal circulation pump.[199] When the results of the EEG became isoelectric, a point at which cerebral metabolic activity is roughly 50% of baseline,[200] no further decrements in $CMRO_2$ occurred. These findings support the hypothesis that metabolism and function are coupled. It is the portion of metabolic activity concerned with neuronal signaling and impulse traffic that is reduced by barbiturates, however, not the portion corresponding to basal metabolic function. The only way to suppress baseline metabolic activity concerned with cellular activity is through hypothermia.[200] The effect of barbiturates on cerebral metabolism is maximized at a 50% depression of cerebral function, in which less oxygen is required as $CMRO_2$ is diminished, leaving all metabolic energy to be used for the maintenance of cellular integrity.

With the reduction in $CMRO_2$, there is a parallel reduction in cerebral perfusion, which is seen in decreased cerebral blood flow and ICP. With reduced $CMRO_2$, cerebral vascular resistance increases, and CBF decreases.[201] The ratio of CBF to $CMRO_2$ is unchanged. The reduction in CBF after the administration of barbiturates causes a concurrent decrease in ICP. Even though the MAP decreases, barbiturates do not compromise the overall CPP because the CPP = MAP − ICP. In this relationship, ICP decreases more relative to the decrease in MAP after barbiturate use, preserving CPP.

Pharmacodynamics

Barbiturates produce the clinical effects of sedation and sleep. Sufficient doses produce a CNS depression that is termed *general anesthesia* and is attended by loss of consciousness, amnesia, and respiratory and cardiovascular depression. The response to pain and other noxious stimulation during general anesthesia seems to be obtunded. The results of pain studies reveal that barbiturates may decrease the pain threshold, however.[202] This antanalgesic effect occurs only at low blood levels of barbiturates, such as with small induction doses of thiopental or after emergence from thiopental when the blood levels are low. The amnesic effect of barbiturates has not been well studied, but it is less pronounced than that produced by benzodiazepines.

Onset of Central Nervous System Effects

Drugs with high lipid solubility and low degree of ionization cross the blood-brain barrier rapidly, producing a fast onset of action.[191] Most barbiturates exist in a nonionized form. The degree of lipid solubility of the nonionized form of the drug works in conjunction with the amount of drug that exists in the nonionized form (reflection of pK_a) to determine the rapidity with which a drug crosses the blood-brain barrier. Thiopental and methohexital are more lipid soluble than pentobarbital, which clinically corresponds to the more rapid onset of action of thiopental and methohexital compared with pentobarbital.[203,204]

Only the nonionized form of a drug can directly traverse the cellular membranes. Thiopental has a pK_a of 7.6. Approximately 50% of thiopental is nonionized at physiologic pH, which accounts partly for the rapid accumulation of thiopental in the cerebrospinal fluid (CSF) after IV administration.[205] Methohexital is 75% nonionized at pH 7.4, a fact that may explain the slightly more rapid effect of this drug compared with the effect of thiopental. As pH decreases, with poor perfusion, barbiturates have a larger proportion of nonionized drug available to cross the blood-brain barrier.[204,205]

Protein binding affects the onset of action in the CNS. Barbiturates are highly bound to albumin and other plasma proteins. Because only unbound drug (free drug) can cross the blood-brain barrier, an inverse relationship exists between the degree of plasma protein binding and the rapidity of drug passage across the blood-brain barrier.[206] Drugs have different degrees of protein binding, and generally the thiobarbiturates are more highly bound than are the oxybarbiturates.[207] The degree of protein binding of a drug is influenced by the physiologic pH and disease states, which alter the absolute amount of protein. Most barbiturates tend to experience peak protein binding at or around pH 7.5.

The final factor governing the rapidity of drug penetration of the blood-brain barrier is the plasma drug concentration. Simply as a result of concentration gradient, higher levels of drug concentrations in the plasma produce greater amounts of drug that diffuses into the CSF and brain. The two primary determinants of the plasma concentration are the *dose* administered and the *rate* (speed) of administration. As the dose of thiopental over the same time is increased, an increased percentage of patients are anesthetized.[208] Concerning absolute dose, 2 mg/kg produced anesthesia in 20% of patients, whereas a dose of 2.4 mg/kg produced anesthesia in 80% of patients. Similarly, the speed of injection influences the effect of thiopental.[209] When a fixed initial dose of thiopental of approximately 2.75 mg/kg was used, a significantly ($P < .001$) smaller amount of drug was required to produce anesthesia when the dose rate of the administration was over 5 seconds as opposed to over 15 seconds. The dose *and* rate of IV administration can profoundly affect the onset of barbiturate CNS effect.

Termination of Effect

Because there exists an equilibrium between brain concentration and plasma concentration, factors that determine the rate of onset of barbiturate effects also affect their termination. Lipid solubility, degree of ionization, and CSF drug concentration affect the movement of drugs from the CSF to plasma. As plasma levels decrease, drug levels in the brain and CSF decrease. The most important factors in the termination of drug effect are those that govern plasma disappearance of the drug. These are generally divided into a rapid redistribution phase and a slow metabolic and second redistribution phase.

In a classic pharmacologic study, Brodie and coworkers[210] conclusively showed that awakening from thiopental occurred because the plasma level rapidly declined. They further showed that the cause of the rapid plasma decay of thiopental was *not metabolism* of the drug, but rather was a *redistribution* of the drug to other tissues throughout the body (lean tissue). The role of slow phase distribution to adipose tissue and elimination clearance via metabolism from the plasma was elucidated later.[207] The relationship of the plasma drug level to the onset and termination of effect as it relates to drug redistribution is illustrated in Figure 26-7. Clinically, patients awake from a single dose of thiopental 5 to 10 minutes after administration because the drug level in the brain has decreased (along with the decline in blood level). Drug is redistributed from highly perfused CNS tissues to well-perfused lean tissues. In the case of constant infusion or repeated dosing with saturation of all tissue sites, patients awake at a much delayed rate as first-order hepatic metabolism begins to play a larger role in decreasing plasma levels of the barbiturates. The termination of effect after multiple drug administrations or constant infusion depends on the elimination of the drug from the blood, which becomes more and more dependent on metabolism than redistribution and is a function of its context-sensitive decrement time (see Fig. 26-3).

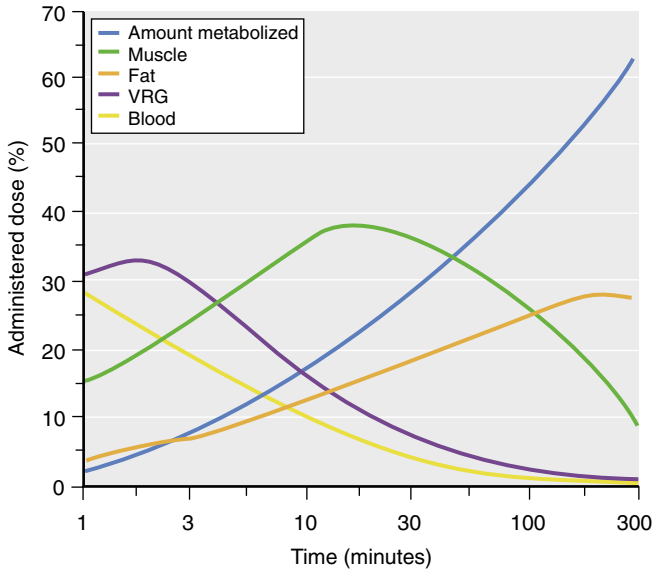

Figure 26-7 After delivery of an IV bolus, the percentage of thiopental remaining in blood rapidly decreases as drug moves from blood to body tissues. The time to attainment of peak tissue levels is a direct function of tissue capacity for barbiturate relative to blood flow. A larger capacity or smaller blood flow is related to a longer time to a peak tissue level. Initially, most thiopental is taken up by the vessel-rich group (VRG) of tissues because of their high blood flow. Subsequently, drug is redistributed to muscle and to a lesser extent to fat. Throughout this period, small but substantial amounts of thiopental are removed and metabolized by the liver. In contrast to removal by tissues, this removal is cumulative. The rate of metabolism equals the early rate of removal by fat. The sum of this early removal by fat and metabolism is the same as the removal by muscle. *(Redrawn from Saidman LJ: Uptake, distribution and elimination of barbiturates.* In *Eger EI [ed]: Anesthetic Uptake and Action. Baltimore, Williams & Wilkins, 1974.)*

Awakening may be delayed in older patients because of increased CNS sensitivity, alterations in metabolism, or decreased central volume of distribution relative to younger adults (see Chapter 71).[211] The initial volume of distribution is less in elderly patients compared with that in young patients, which explains a lower dose requirement for the onset of EEG and hypnotic effects.[211] Pediatric patients (<13 years old) seem to have a more rapid rate of total clearance and a shorter rate of plasma thiopental clearance than do adults, which theoretically might result in earlier awakening, especially after multiple doses of the drug (see Chapter 82).[212]

There is little difference in thiopental and methohexital with regard to distribution, which may explain the similar wake-up time of methohexital and thiopental. There is, however, a difference in the rate of total body clearance, with methohexital being higher. This disparity explains the difference found in the psychomotor skills of patients and the earlier full recovery after methohexital. Sensitive tests of psychomotor skills tend to show better early performance after methohexital than after thiopental use. A driving test reveals, however, abnormal skills for 8 hours after anesthesia, suggesting that despite plasma clearance there is residual CNS impairment for about 1 day.[213] Despite these residual effects, methohexital is cleared more rapidly than thiopental, which explains why methohexital is preferred for use by some clinicians when rapid awakening is desirable, such as in outpatient anesthesia. This prolongation of early and late recovery by the barbiturates is why they have been largely replaced by propofol.

Uses

Barbiturates are used clinically in the practice of anesthesia for induction and maintenance of anesthesia and premedication. Less frequently, barbiturates are used to provide cerebral protection to patients at risk of developing incomplete ischemia. The three barbiturates that are used most commonly in the United States for IV anesthesia and maintenance of anesthesia are thiopental, thiamylal, and methohexital.

Thiopental is an excellent drug to use for induction of anesthesia. The prompt onset (15 to 30 seconds) of action and smooth induction noted with its use make thiopental superior to most other available drugs. The rapid emergence, particularly after single use for induction, also was a reason for the widespread use of thiopental in this setting. Thiopental does not possess analgesic properties, and it must be supplemented with analgesic drugs to obtund reflex responses to noxious stimuli during anesthesia and surgical procedures. Thiopental can be used to maintain general anesthesia because repeated doses reliably sustain unconsciousness and contribute to amnesia. Thiopental is not a perfect choice, however, to use as the hypnotic component of a balanced anesthetic.

Table 26-4 Recommended Doses of Barbiturates for Anesthesia Induction and Maintenance

Drug	Induction Dose (mg/kg)*†	Onset (sec)	Intravenous Maintenance Infusion
Thiopental	3-4	10-30	50-100 mg every 10-12 min
Methohexital	1-1.5	10-30	20-40 mg every 4-7 min

*Adult and pediatric IV doses are roughly the same in milligrams per kilogram.
†Methohexital can be given rectally in pediatric patients as 20-25 mg/kg/dose.

Methohexital is the only IV barbiturate used for induction that offers a serious challenge to thiopental. With a dose of 1 to 2 mg/kg, induction is swift, and so is emergence. Methohexital also may be used as the hypnotic component to maintain anesthesia. Similar to thiopental, it is not an analgesic. Additional opioids or volatile anesthetics are required to provide a balanced technique satisfactory for general anesthesia during surgery. Because methohexital is cleared more rapidly than thiopental, it is superior to thiopental for the maintenance of anesthesia, as accumulation and saturation of peripheral sites takes longer. For brief infusion (<60 minutes), recovery from a methohexital infusion titrated to maintain hypnosis (50 to 150 µg/kg/min) is similar to that provided by propofol. There are probably upper limits of safe infusion doses yet to be defined, but seizures have occurred in neurosurgical patients after large doses of methohexital (24 mg/kg).[214] Finally, some clinicians advocate the use of methohexital in pediatric patients as a rectal premedication drug (see Chapter 82). Methohexital may be given rectally and is absorbed rapidly. Mean peak plasma levels occur within 14 minutes after rectal administration and are associated with a rapid hypnotic effect. The dose recommended for this use is 25 mg/kg rectal instillation (10% solution through a 14F catheter, 7 cm into rectum).[215] With this method of administration, sleep onset is rapid.

Dosing

Dosing for the three most commonly used barbiturates is listed in Table 26-4. The usual doses of thiopental (3 to 4 mg/kg) and thiamylal (3 to 4 mg/kg) are about twice the dose of methohexital (1 to 2 mg/kg). In dose-response studies, the ED_{50} for thiopental ranged from 2.2 to 2.7 mg/kg, and the ED_{50} for methohexital was 1.1 mg/kg.[208] Because the ED_{50} induces anesthesia in only 50% of a given group of patients, higher doses are needed to induce anesthesia reliably in all patients. The usual dose of thiopental is 3 to 4 mg/kg given intravenously over 5 to 15 seconds. There is less interpatient variability in the dose response to barbiturates than to benzodiazepines when used for anesthesia induction, but there still is significant variability in the doses of thiopental required to induce anesthesia.[208]

Interpatient dose variability is related to the presence of hemorrhagic shock, cardiac output, lean body mass, obesity, sex, and age. Hemorrhagic shock, lean body mass, age, and obesity explain variability of patient response owing to a decrease in the central volume of distribution. Less blood volume (patients with shock, patients with dehydration) or less lean body mass (obese patients, elderly patients, female patients) decreases the volume in which the drug is diluted (less blood volume), or decreases the volume into which it is quickly redistributed (less lean body mass). Finally, patients who have severe anemia, burns, malnutrition, widespread malignant disease, uremia, ulcerative colitis, or intestinal obstruction also require lower induction doses of barbiturate.

Side Effects

The effects of barbiturates on various organ systems have been studied extensively. Some side effects occur in unpredictable, varying proportions of patients, whereas cardiovascular and pulmonary side effects are dose related. There are no important differences between the barbiturates with regard to their effects on the various organ systems (respiratory, cardiovascular, gastrointestinal, hepatic, and renal), but there are differences in other complications with these drugs. The complications of injecting barbiturates include a garlic or onion taste (40% of patients), allergic reactions, local tissue irritation, and rarely tissue necrosis. An urticarial rash may develop on the head, neck, and trunk that lasts a few minutes. More severe reactions, such as facial edema, hives, bronchospasm, and anaphylaxis, can occur. Treatment of anaphylaxis is symptomatic.

Thiopental and thiamylal produce fewer excitatory symptoms with induction than methohexital, which produces cough, hiccough, tremors, and twitching approximately five times more often. Tissue irritation and local complications may occur more frequently with the use of thiopental and thiamylal than with methohexital. In comparative studies, pain on injection was shown to be greater with methohexital (12%) than with thiopental (9%). Results also show phlebitis occurs more frequently with methohexital use (8%) than with thiopental use (1%).[216] Tissue and venous irritation are more common if a 5% solution is used, rather than the standard 2% solution.

Rarely, intra-arterial injection can occur. The consequences of accidental arterial injection may be severe. The degree of injury is related to the concentration of the drug. Treatment consists of (1) dilution of the drug by the administration of saline into the artery, (2) heparinization to prevent thrombosis, and (3) brachial plexus block. Overall, the proper administration of thiopental intravenously is remarkably free of local toxicity.

Cardiovascular System

Cardiovascular depression from barbiturates is a result of central and peripheral (direct vascular and cardiac) effects. The hemodynamic changes produced by barbiturates have been studied in healthy subjects and in patients with heart disease.[217,218] The primary cardiovascular effect of barbiturate induction is peripheral vasodilation that results in a pooling of blood in the venous system.[219] A decrease in contractility is another effect, which is related to reduce availability of calcium to the myofibrils. There also is an increase in heart rate.[218] Mechanisms for the decrease in cardiac output include (1) direct negative inotropic action, (2) decreased ventricular filling owing to increased capacitance, and (3) transiently decreased sympathetic outflow from the CNS.[214,220]

The increase in heart rate (10% to 36%) that accompanies thiopental administration probably results from the baroreceptor-mediated sympathetic reflex stimulation of the heart in response to the decrease in output and pressure. Thiopental produces dose-related negative inotropic effects, which seem to result

from a decrease in calcium influx into the cells with a resultant diminished amount of calcium at sarcolemma sites. The cardiac index is unchanged or is reduced, and MAP is maintained or is slightly reduced. Thiopental infusions and lower doses tend to be accompanied by smaller hemodynamic changes than the changes noted with rapid bolus injections. In the dose ranges studied, no relationship between plasma thiopental level and hemodynamic effect has been found. A sympathetic discharge in response to intubation increases heart rate and blood pressure and can be attenuated by the administration of fentanyl (1 to 3 μg/kg).

There is little difference in the responses after thiopental and methohexital administration in patients with heart disease. The increase in heart rate (11% to 36%) encountered in patients with coronary artery disease anesthetized with thiopental (1 to 4 mg/kg) is potentially deleterious because of the obligatory increase in myocardial oxygen consumption that accompanies the increased heart rate. In a more recent study in dogs, thiopental prolonged the QT interval, flattened T waves, and increased QT dispersion during and after induction.[221] It is *possible* that thiopental may not be the most appropriate choice for patients with a susceptibility to ventricular dysrhythmias or a prolonged QT interval, such as acidotic patients or patients with conditions that prolong the QT interval, such as long-term dialysis or advanced cirrhosis; however, this remains to be shown in humans. Patients who have normal coronary arteries have no difficulty in maintaining adequate coronary blood flow to meet the increased myocardial oxygen consumption.[222] Thiopental should be avoided in hypovolemic patients because there is a significant reduction in cardiac output (69%) and a significant decrease in blood pressure.[223] Patients without adequate compensatory mechanisms may have serious hemodynamic depression with thiopental induction.

Respiratory System

Barbiturates produce dose-related central respiratory depression. There also is a significant incidence of transient apnea after administration of barbiturates for induction of anesthesia. The evidence for central depression is a correlation between EEG suppression and minute ventilation. With increased anesthetic effect, there is diminished minute ventilation. The time course of respiratory depression has not been fully studied, but it seems that peak respiratory depression (as measured by the slope of carbon dioxide concentration in the blood) and minute ventilation after delivery of thiopental (3.5 mg/kg) occurs 1 to 1.5 minutes after administration. These variables return to predrug levels rapidly, and within 15 minutes the drug effects are barely detectable.[224]

Patients with chronic lung disease are slightly more susceptible to the respiratory depression of thiopental. Apnea occurs during anesthesia induction with thiopental in at least 20% of cases, but the duration of apnea is short, approximately 25 seconds.[225] The usual ventilatory pattern with thiopental induction has been described as "double apnea." The initial apnea that occurs during drug administration lasts a few seconds and is succeeded by a few breaths of reasonably adequate tidal volume, which is followed by a lengthier apneic period. During the induction of anesthesia with thiopental, ventilation must be assisted or controlled to provide adequate respiratory exchange.

Similar to other barbiturates, methohexital is a central respiratory system depressant. Induction doses (1.5 mg/kg) significantly decrease the slope of the ventilatory response to carbon dioxide.[226] Maximal reduction in ventilatory response to carbon dioxide occurred 30 seconds after drug administration and began to approach normal levels within 15 minutes. The peak decrease in tidal volume occurred 60 seconds after methohexital delivery and returned to baseline within 15 minutes. In contrast to the effects on ventilation, patients were awake within about 5 minutes after the administration of methohexital (1.5 mg/kg). There is no difference in the duration of ventilatory depression after methohexital use and after thiopental delivery when the drugs are studied in a similar manner.[224]

Contraindications

Wood has listed the contraindications to IV barbiturate use.[227] (1) When there is respiratory obstruction or an inadequate airway, thiopental may worsen respiratory depression. (2) Severe cardiovascular instability or shock may preclude its use. (3) Status asthmaticus is a condition in which airway control and ventilation may be worsened further by thiopental. (4) Porphyria may be precipitated or acute attacks may be accentuated by the administration of thiopental. (5) Without proper equipment (IV instrumentation) and airway equipment (means of artificial ventilation), thiopental should not be administered.

Benzodiazepines

History

Diazepam (Valium) was synthesized by Sternbach in 1959 in a search for a new and better compound. It was first described for use as an IV anesthetic induction in 1965.[228] Oxazepam (Serax), a metabolite of diazepam, was synthesized in 1961 by Bell. Lorazepam (Ativan), a 2′ chloro-substitution product of oxazepam, was synthesized in 1971 in an attempt to produce a more potent benzodiazepine. The next major achievement was Fryer and Walser's 1976 synthesis of midazolam (Versed), the first clinically used water-soluble benzodiazepine.[229] Midazolam was the first benzodiazepine that was produced primarily for use in anesthesia.[230]

The benzodiazepines have many of the characteristics sought by anesthesiologists. Specific benzodiazepine receptors were described when ligands were found to interact with a central receptor.[231] The discovery and understanding of the mechanism of the benzodiazepine receptor have enabled chemists to develop many agonist compounds and to produce a specific antagonist for clinical use.

Physicochemical Characteristics

Three benzodiazepine receptor agonists are commonly used in anesthesia in the United States: midazolam, diazepam, and lorazepam (Fig. 26-8 and Table 26-5). All these molecules are relatively small and are lipid soluble at physiologic pH. Each milliliter of diazepam solution (5 mg) contains propylene glycol 0.4 mL, alcohol 0.1 mL, benzyl alcohol 0.015 mL, and sodium benzoate/benzoic acid in water for injection (pH 6.2 to 6.9). Lorazepam solution (2 or 4 mg/mL) contains 0.18 mL polyethyl-

ene glycol, with 2% benzyl alcohol as a preservative. Midazolam solution (1 or 5 mg/mL) contains 0.8% sodium chloride and 0.01% disodium edetate, with 1% benzyl alcohol as a preservative. The pH is adjusted to 3 with hydrochloric acid and sodium hydroxide. Midazolam is the most lipid soluble of the three drugs in vivo,[232] but because of its pH-dependent solubility, it is water soluble as formulated in a buffered acidic medium (pH 3.5). The imidazole ring of midazolam accounts for its stability in solution and rapid metabolism. The high lipophilicity of all three accounts for the rapid CNS effect and relatively large volumes of distribution.[233]

Metabolism

Biotransformation of the benzodiazepines occurs in the liver. The two principal pathways involve either hepatic microsomal oxidation (*N*-dealkylation or aliphatic hydroxylation) or glucuronide conjugation. The difference in the two pathways is significant because oxidation is susceptible to outside influences and can be impaired by certain population characteristics (e.g., old age), disease states (e.g., hepatic cirrhosis), or the coadministration of other drugs that can impair oxidizing capacity (e.g., cimetidine). Conjugation is less susceptible to these factors. Midazolam and diazepam undergo oxidation reduction or phase I reactions in the liver. The fused imidazole ring of midazolam is oxidized rapidly by the liver, much more rapidly than the methylene group of the diazepine ring of other benzodiazepines. This fast oxidation accounts for the greater hepatic clearance of midazolam compared with diazepam. Lorazepam is less affected by enzyme induction and some of the other factors known to alter the cytochrome P-450 and other phase I enzymes.

Cimetidine inhibition of oxidative enzyme function impairs the clearance of diazepam,[234] but it has no effect on lorazepam. Age decreases and smoking increases the clearance of diazepam,[235] but neither has a significant effect on midazolam biotransformation. Habitual alcohol consumption increases the clearance of midazolam.[236] Race, because of differences in isoenzymes responsible for hydroxylations, produces genetic differences in drug metabolism.[237] The high frequency of mutated alleles in Asians in the genes coding for CYP2C19 may explain the reduced hepatic biotransformation of diazepam.

The metabolites of the benzodiazepines can be important. Diazepam forms two active metabolites, oxazepam and desmethyldiazepam, which add to and prolong the drug's effects. Midazolam is biotransformed to hydroxymidazolams, which have activity, and when given over a longer time can accumulate.[238] These metabolites are rapidly conjugated and excreted in the urine, however. The α-hydroxymidazolam has an estimated clinical potency 20% to 30% of midazolam.[239] It is excreted largely by the kidneys and can cause profound sedation in patients with renal impairment.[240] The primary hydroxymetabolite is cleared more rapidly[90] than midazolam in healthy patients (Table 26-6). The metabolites are less potent and normally cleared more rapidly than midazolam, making them of little concern in patients with normal hepatic and renal function. Lorazepam has five metabolites, but the principal one is conjugated to glucuronide. This

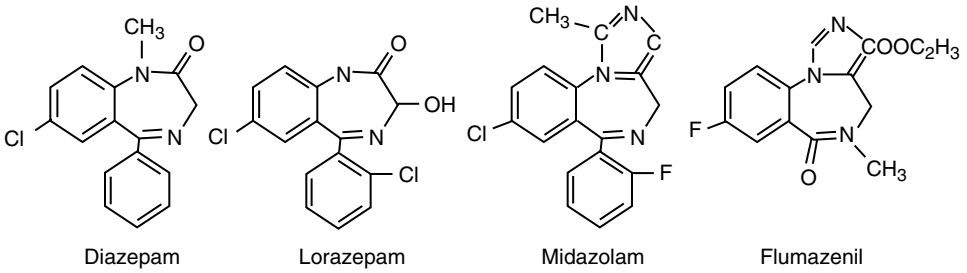

Figure 26-8 The structures of four benzodiazepines used in clinical anesthesia practice.

metabolite is inactive, water soluble, and rapidly excreted via the kidney.

Pharmacokinetics

The three benzodiazepines used in anesthesia are classified as short-lasting (midazolam), intermediate-lasting (lorazepam), and long-lasting (diazepam), according to their metabolism and plasma clearance (see Table 26-1). The plasma disappearance curves of all the benzodiazepines can be fitted to a two-compartment or three-compartment model. Protein binding and volumes of distribution are not much different among these three benzodiazepines, but the clearance is significantly different. The clearance rate of midazolam ranges from 6 to 11 mL/kg/min, whereas the clearance of lorazepam is 0.8 to 1.8 mL/kg/min, and the clearance of diazepam is 0.2 to 0.5 mL/kg/min. Because of these differences in clearance, the drugs have predictably different plasma disappearance curves (Fig. 26-9). They also have different context-sensitive half-times (see Fig. 26-3). Although the termination of action of these drugs is primarily a result of redistribution of the drug from the CNS to other tissues after use in anesthesia, after daily (long-term) repeated administration, or after prolonged continuous infusion, midazolam blood levels decrease more rapidly than blood levels of the other drugs because of greater hepatic clearance. Patients given continuous infusions of midazolam or repeated boluses over days should awaken faster than patients given diazepam or lorazepam.

Factors that may influence the pharmacokinetics of benzodiazepines are age, gender, race, enzyme induction, and hepatic and renal disease. Diazepam is sensitive to some of these factors, particularly age. Increasing age tends to reduce the clearance of diazepam[241] significantly and the clearance of midazolam to a lesser degree.[242] Lorazepam is resistant to the effects of age, gender, and renal disease on pharmacokinetics. These drugs all are affected by obesity. The volume of distribution is increased as drug goes from the plasma into the adipose tissue. Although clearance is not altered, elimination half-lives are prolonged, owing to the delayed return of the drug to the plasma in obese patients.[242] Generally, sensitivity to benzodiazepines in some groups, such as elderly patients, is greater despite relatively modest pharmacokinetic effects; factors other than pharmacokinetics must be considered when these drugs are used.

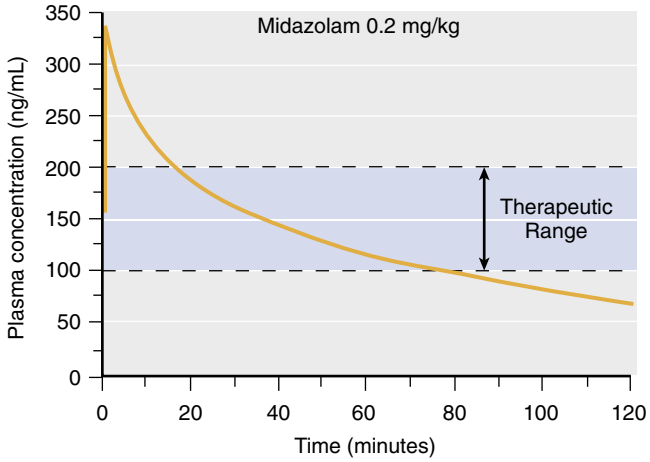

Figure 26-9 Simulated time course of plasma levels of midazolam after an induction dose of 0.2 mg/kg. Plasma levels required for hypnosis and amnesia during surgery are 100 to 200 ng/mL, with awakening usually occurring at levels less than 50 ng/mL.

Pharmacology

All benzodiazepines have hypnotic, sedative, anxiolytic, amnesic, anticonvulsant, and centrally produced muscle-relaxing properties. The drugs differ in their potency and efficacy with regard to each of the pharmacodynamic actions. The chemical structure of each drug dictates its particular physicochemical properties and pharmacokinetics and its receptor binding characteristics. The binding of benzodiazepines to their respective receptors is of high affinity and is stereospecific and saturable; the order of receptor affinity (potency) of the three agonists is lorazepam > midazolam > diazepam. Midazolam is approximately 3 to 6 times,[243] and lorazepam 5 to 10 times, as potent as diazepam.

The mechanism of action of benzodiazepines is reasonably well understood.[244-246] The interaction of ligands with the benzodiazepine receptor is one of the few examples in which the complex systems of biochemistry, molecular pharmacology, genetic mutations, and clinical behavioral patterns can be explained. More is understood about the mechanism of action of benzodiazepines than about the mechanism of action of many other general anesthetics. More recent genetic studies have found the $GABA_A$ subtypes mediate the different effects (amnesic, anticonvulsant, anxiolytic, and sleep).[246] Sedation, anterograde amnesia, and anticonvulsant properties are mediated via *α1* receptors,[246] and anxiolysis and muscle relaxation are mediated by the *a2* $GABA_A$ receptor.[246] Drug effect is a function of blood level. By using plasma concentration data and pharmacokinetic simulations, it has been estimated that a benzodiazepine receptor occupancy of less than 20% may be sufficient to produce the anxiolytic effect, sedation is observed with 30% to 50% receptor occupancy, and unconsciousness requires 60% or greater occupation of benzodiazepine agonist receptors.[247]

The benzodiazepine receptors are found in highest densities in the olfactory bulb, cerebral cortex, cerebellum, hippocampus, substantia nigra, and inferior colliculus, but lower densities are found in the striatum, lower brainstem, and spinal cord. Spinal cord benzodiazepine receptors can play an important role in analgesia, however, further elucidating the mechanism of action of this drug class.[248,249] Intrathecal midazolam reduces excitatory GABA-mediated neurotransmission in interneurons, leading to a decrease in the excitability of spinal dorsal horn neurons.[248] Intrathecal midazolam added to a bupivacaine spinal increases analgesia and shortens the time to return of motor function.[249]

A fascinating and therapeutically significant discovery regarding the benzodiazepine receptor is that the pharmacologic spectrum of ligands includes three different types or classes,[244] which have been termed *agonists, antagonists,* and *inverse agonists* (Fig. 26-10), names that connote their actions. Agonists (e.g., midazolam) alter the conformation of the $GABA_A$ receptor complex so that binding affinity for GABA is increased, with a resultant opening of the chloride channel. Agonist and antagonist bind to a common (or at least overlapping) area of the receptor by forming differing reversible bonds with the receptor. The well-known effects of an agonist then occur (anxiolysis, hypnosis, and anticonvulsant action). Antagonists (e.g., flumazenil) occupy the

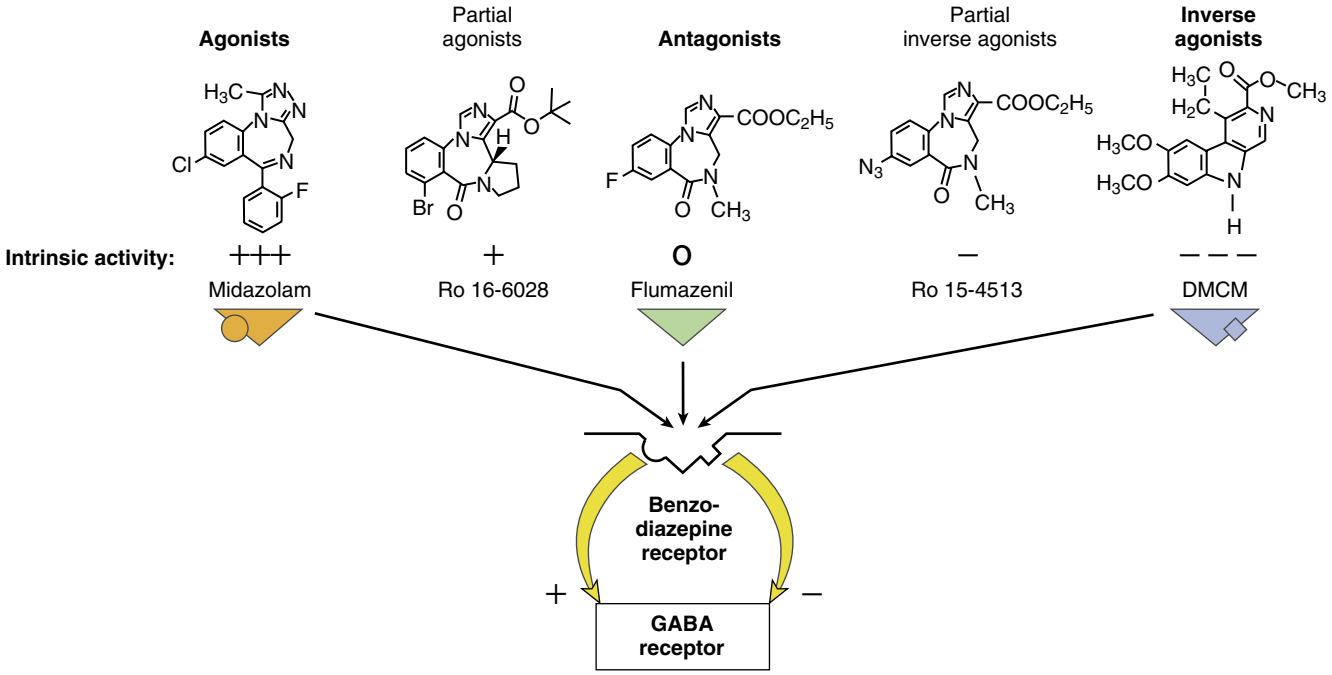

Figure 26-10 Spectrum of the intrinsic activities of benzodiazepine receptor ligands, which range from agonists to inverse agonists. Structures of agonist, partial agonist, antagonist, partial inverse agonist, and inverse agonist compounds are shown. Intrinsic activity is greatest among agonists and is least among inverse agonists. Intrinsic activities are schematically indicated as positive by a plus sign and as negative by a minus sign, with 0 indicating a lack of intrinsic activity. GABA, γ-aminobutyric acid. *(Redrawn with modification from Mohler H, Richards JG: The benzodiazepine receptor: A pharmacological control element of brain function. Eur J Anaesthesiol Suppl 2:15-24, 1988.)*

benzodiazepine receptor, but they produce no activity and block the actions of the agonists and inverse agonists. Inverse agonists reduce the efficiency of GABA-adrenergic synaptic transmission, and because GABA is inhibitory, the result of decreased GABA is CNS stimulation. The potency of the ligand is dictated by its affinity for the benzodiazepine receptor and the duration of effect by the rate of clearance of the drug from the receptor.

Long-term administration of benzodiazepines produces tolerance, which is defined as the decrease of efficacy of the drug over time.[250] Although the mechanism of chronic tolerance is not fully understood, it seems that long-term exposure to benzodiazepines causes decreased receptor binding and function (i.e., downregulation of the benzodiazepine–$GABA_A$ receptor complex). This would explain the increased dose requirements of benzodiazepines for anesthesia in patients who take them on a long-term basis. It seems that after the cessation of long-term use of benzodiazepines, there is upregulation of the receptor complex,[250] which could mean an increased susceptibility to benzodiazepines during a period after recent use.

The onset and duration of action of a bolus IV administration of a benzodiazepine depend on the lipid solubility of the drug, a finding that probably explains the differences in onset and duration of action of midazolam, diazepam, and lorazepam. Midazolam and diazepam have a more rapid onset (usually within 30 to 60 seconds) of action than lorazepam (60 to 120 seconds). The half-life of equilibrium between plasma concentration and EEG effect of midazolam is approximately 2 to 3 minutes and is not affected by age.[251] This is about two times longer[252] than that of diazepam, but compared with diazepam midazolam has a sixfold greater intrinsic potency.[243] Similar data for other benzodiazepines are unavailable. Similar to onset, the duration of effect also is related to lipid solubility and blood level. The more rapid redistribution of midazolam and diazepam compared with lorazepam (presumably because of the lower lipid solubility of lorazepam)[232] accounts for the shorter duration of their actions.

Effects on the Central Nervous System

The benzodiazepines, in a dose-related manner, reduce the $CMRO_2$ and CBF (see Chapters 13, 46, and 63). Midazolam and diazepam maintain a relatively normal ratio of CBF to $CMRO_2$. In healthy human volunteers, midazolam, 0.15 mg/kg, induces sleep and reduces CBF by 34%, despite a slight increase in $Paco_2$ from 34 to 39 mm Hg.[253] Brown and coworkers[254] studied EEG tracings after administration of 10 mg of IV midazolam and showed the appearance of rhythmic beta activity at 22 Hz within 15 to 30 seconds of administration in healthy volunteers. Within 60 seconds, there was a second beta rhythm at 15 Hz. Alpha rhythm started to reappear at 30 minutes; however, after 60 minutes, there was resistant rhythmic beta activity at 15- to 20-μV amplitude. The EEG changes were similar to EEG effects with diazepam and were not typical of light sleep, although the patients were clinically asleep.

Midazolam, diazepam, and lorazepam all increase the seizure initiation threshold to local anesthetics and decrease the mortality rate in mice exposed to lethal doses of local anesthetics.[255] Midazolam and diazepam cause a dose-related protective effect against cerebral hypoxia, shown by extending mouse survival time when mice were placed in 5% oxygen. The protection afforded by midazolam is superior to that of diazepam, but less than that of pentobarbital.[255] Antiemetic effects are not a prominent action of the benzodiazepines.

Effects on the Respiratory System

Benzodiazepines, similar to most IV anesthetics, produce dose-related central respiratory system depression. Lorazepam (2.5 mg) produces a similar but shorter lasting decrease in tidal volume and minute ventilation than diazepam (10 mg) in patients with lung disease.[256] Peak decrease in minute ventilation after midazolam (0.15 mg/kg) is almost identical to that produced in healthy patients given diazepam (0.3 mg/kg), as determined by carbon dioxide response data.[257] The slopes of the ventilatory response curves to carbon dioxide are flatter than normal (control), but not shifted to the right, as with opioids. Judging from the plasma level and steepness of the dose-response effect on $Paco_2$ curves,[258] midazolam is about five to nine times as potent as diazepam.

The peak onset of ventilatory depression with midazolam (0.13 to 0.2 mg/kg) is rapid (about 3 minutes), and significant depression remains for about 60 to 120 minutes.[224] The rate of midazolam administration affects the onset time of peak ventilatory depression; the faster the drug is given, the more quickly this peak depression occurs. The respiratory depression of midazolam is more pronounced and of longer duration in patients with chronic obstructive pulmonary disease, and the duration of ventilatory depression is longer with midazolam (0.19 mg/kg) than with thiopental (3.3 mg/kg).[224,259] Lorazepam (0.05 mg/kg) alone does not depress the carbon dioxide response, but when lorazepam is combined with meperidine, there is predictable respiratory depression.[259] Benzodiazepines and opioids produce additive or supra-additive (synergistic) respiratory depression, even though they act at different receptors.

Apnea occurs with benzodiazepines in a dose-dependent manner. The incidence of apnea after thiopental or midazolam when these drugs are given for induction of anesthesia is similar. Apnea occurred in 20% of 1130 patients given midazolam for induction and 27% of 580 patients given thiopental in clinical trials with midazolam.[230] Apnea is more likely to occur in the presence of opioids. Old age, debilitating disease, and other respiratory depressant drugs probably also increase the incidence and degree of respiratory depression and apnea with benzodiazepines.

Effects on the Cardiovascular System

The benzodiazepines used alone have modest hemodynamic effects. The hemodynamic changes reported with anesthetic induction doses of diazepam, midazolam, and lorazepam are shown in Table 26-2. These values represent the peak hemodynamic effect in the first 10 minutes after administration and are derived from studies of healthy subjects and patients with ischemic and valvular heart diseases.[260-264] The predominant hemodynamic change is a slight reduction in arterial blood pressure, resulting from a decrease in systemic vascular resistance. The mechanism by which benzodiazepines maintain relatively stable hemodynamics involves the preservation of homeostatic reflex mechanisms,[230] but there is evidence that the baroreflex is impaired by midazolam and diazepam.[265] Midazolam causes a slightly larger decrease in arterial blood pressure than the other benzodiazepines, but the hypotensive effect is minimal and about the same as seen with thiopental.[266] Despite the hypotension, midazolam, even in doses of 0.2 mg/kg, is safe and effective for induction of anesthesia even in patients with severe aortic stenosis (see Chapter 60).

The hemodynamic effects of midazolam and diazepam are dose related: the higher the plasma level, the greater the decrease in systemic blood pressure[258]; however, there is a plateau plasma drug effect above which little change in arterial blood pressure occurs. The plateau plasma level for midazolam is 100 ng/mL, and that for diazepam is about 900 ng/mL.[258] Heart rate, ventricular filling pressures, and cardiac output are maintained after induction of anesthesia with benzodiazepines. In patients with elevated left ventricular filling pressures, diazepam and midazolam produce a "nitroglycerin-like" effect by decreasing the filling pressure and increasing cardiac output.

The stresses of endotracheal intubation and surgery are not blocked by midazolam.[260] Adjuvant anesthetics, usually opioids, are often combined with benzodiazepines. The combination of benzodiazepines with opioids and nitrous oxide has been investigated in patients with ischemic and valvular heart diseases.[264,267] The addition of nitrous oxide to midazolam (0.2 mg/kg) and diazepam (0.5 mg/kg) has trivial hemodynamic consequences, whereas the combination of benzodiazepines with opioids does have a supra-additive effect. The combinations of benzodiazepines with opiates produce greater decreases in systemic blood pressure than does each drug alone. The mechanism for this synergistic hemodynamic effect is not completely understood, but it is probably related to a reduction in sympathetic tone when the drugs are given together.[268] There is evidence that diazepam and midazolam decrease catecholamines,[269] a finding consistent with this hypothesis.

Uses

Intravenous Sedation

Benzodiazepines are used for sedation as preoperative premedication, intraoperatively during regional or local anesthesia, and postoperatively. The anxiolysis, amnesia, and elevation of the local anesthetic seizure threshold are desirable benzodiazepine actions. The drugs should be given by titration for this use; end points of titration are adequate sedation or dysarthria (Table 26-7). The onset of action is more rapid with midazolam, usually with peak effect reached within 2 to 3 minutes of administration; time to peak effect is slightly longer with diazepam and is longer still with lorazepam. The duration of action of these drugs depends primarily on the dose used. Although the onset is more rapid with midazolam than with diazepam after bolus administration, the recovery is similar,[270] probably because both drugs have similar early plasma decay (redistribution) patterns (see Fig. 26-9). With lorazepam, sedation and particularly amnesia are slower in onset and are longer lasting than with the other two benzodiazepines.[238,271]

There is often a disparity in the level of sedation compared with the presence of amnesia (patients seem conscious and reasonably coherent, yet they are amnesic for events and instructions) with all three benzodiazepines. Lorazepam is particularly unpredictable with regard to duration of amnesia, and this is undesirable in patients who wish or need to have recall in the immediate postoperative period. The degree of sedation and the reliable amnesia and preservation of respiratory and hemodynamic function are better overall with benzodiazepines than with other sedative-hypnotic drugs used for conscious sedation. When midazolam is compared with propofol for sedation, the two are generally similar except that emergence or wake-up is more rapid with propofol. Propofol requires closer medical supervision because of its respiratory depression,[272] and respiratory function

Table 26-7 Uses and Doses of Intravenous Benzodiazepines

	Midazolam	Diazepam	Lorazepam
Induction	0.05-0.15 mg/kg	0.3-0.5 mg/kg	0.1 mg/kg

Sedation*	0.5-1 mg repeated 0.07 mg/kg IM	2 mg repeated	0.25 mg repeated

*Incremental doses given until desired degree of sedation is obtained.
prn, as required to keep patient hypnotic and amnestic.

must be monitored when these drugs are used for sedation to prevent undesirable degrees of respiratory depression. There may be a slight synergistic action between midazolam and spinal anesthesia with respect to ventilation.[273] The use of midazolam for sedation during regional and epidural anesthesia requires vigilance with regard to respiratory function, similar to when these drugs are given with opioids.

Sedation for longer periods, such as in the ICU, also is accomplished with benzodiazepines. Prolonged infusion results in accumulation of drug and, in the case of midazolam, significant concentration of the active metabolite. Reviews have pointed out concerns and advantages of benzodiazepine sedation.[238,274,275] The chief advantages are the amnesia and hemodynamic stability, and the disadvantage compared with propofol is the sometimes longer dissipation of effects when infusions are terminated. The superiority of one drug over the other has not been established; both drugs should always be titrated downward to maintain sedation as required. Dosing should not be fixed, but it should be reduced over time to avoid accumulation of parent or metabolites during prolonged infusion.

Finally, two more recent studies have challenged the idea that maternal sedation with midazolam may be unsafe for neonates and infants of breastfeeding mothers (see Chapter 69). Frolich and colleagues[276] showed that a single IV dose of midazolam (0.02 mg/kg) combined with a single IV dose of fentanyl (1 µg/kg) before cesarean section was a safe practice, showing no detriment in Apgar scores, neurobehavioral scores, continuous oxygen saturation, or the ability of the mother to recall the birth events.[276] Nitsun and associates[277] found that 0.005% of the maternal dose of midazolam is transferred into the breast milk during a 24-hour milk collection. Although verification of these findings is needed, they highlight an important clinical use of midazolam that may be safe for mother and infant.

Oral Sedation

For many years, diazepam was given orally for preoperative sedation. It is still used in 5- to 15-mg doses in adults for this purpose. More recently, an oral formulation of midazolam has been used primarily for oral premedication in pediatric patients (see Chapter 82). The dose is 0.5 mg/kg, and one preparation is from the Roche parenteral formulation of 0.5 mg/mL (Roche Laboratories, Inc, Nutley, NJ) mixed in with 10 mg/kg of oral acetaminophen (McNeil-PPC, Inc, Fort Washington, PA).[278] Other preparations have been developed, including strawberry-flavored glucose (pH 4.5) prepared by the pharmacy, which is stable for 8 weeks.[279] The 0.5-mg/kg oral dose is rapid-acting, providing reliable amnesia within 10 minutes and rendering children effectively sedated for anesthesia induction.[278]

Induction and Maintenance of Anesthesia

Midazolam is the benzodiazepine of choice to induce anesthesia. When midazolam is used in appropriate doses (see Table 26-7), induction occurs less rapidly than with thiopental,[230] but the amnesia is more reliable. Numerous factors influence the rapidity of action of midazolam and the other benzodiazepines when used for induction of general anesthesia, including dose, speed of injection, degree of premedication, age, ASA physical status, and concurrent anesthetic drugs.[230,280] In a well-premedicated, healthy patient, midazolam (0.2 mg/kg given in 5 to 15 seconds) induces anesthesia in 28 seconds, whereas induction occurs in 39 seconds with diazepam (0.5 mg/kg given in 5 to 15 seconds).[260] Elderly patients require smaller doses of midazolam than younger patients (Fig. 26-11).[281,282] Patients older than 55 years and patients with ASA physical status greater than III require a 20% or greater reduction in the induction dose of midazolam.[230] The usual induction dose of midazolam in premedicated patients is 0.05 to 0.15 mg/kg. When midazolam is used with other anesthetic drugs (coinduction), there is a synergistic interaction,[254,283] and the induction dose is less than 0.1 mg/kg (Fig. 26-12). The synergy is seen when midazolam is used with opioids or other hypnotics, such as thiopental and propofol.

Awakening after benzodiazepine anesthesia (defined as orientation to time and place) of young, healthy volunteers who received 10 mg of IV midazolam occurred in about 15 minutes,[254] and awakening occurred in about 17 minutes after an induction dose of 0.15 mg/kg.[284] Emergence time is related to the dose of midazolam and to the dose of adjuvant anesthetic drugs.[230] Emergence from midazolam (0.32 mg/kg)/fentanyl anesthesia is about 10 minutes longer than emergence from thiopental (4.75 mg/kg)/fentanyl anesthesia,[262] and is more prolonged than with propofol.[285] This difference accounts for some anesthesiologists' preference for propofol induction for short operations.

Benzodiazepines lack analgesic properties and must be used with other anesthetic drugs to provide sufficient analgesia; however, as maintenance anesthetic drugs during general anesthesia, benzodiazepines provide hypnosis and amnesia. Double-blind studies comparing midazolam and thiopental as the hypnotic component for balanced anesthesia[262,286] have shown that mida-

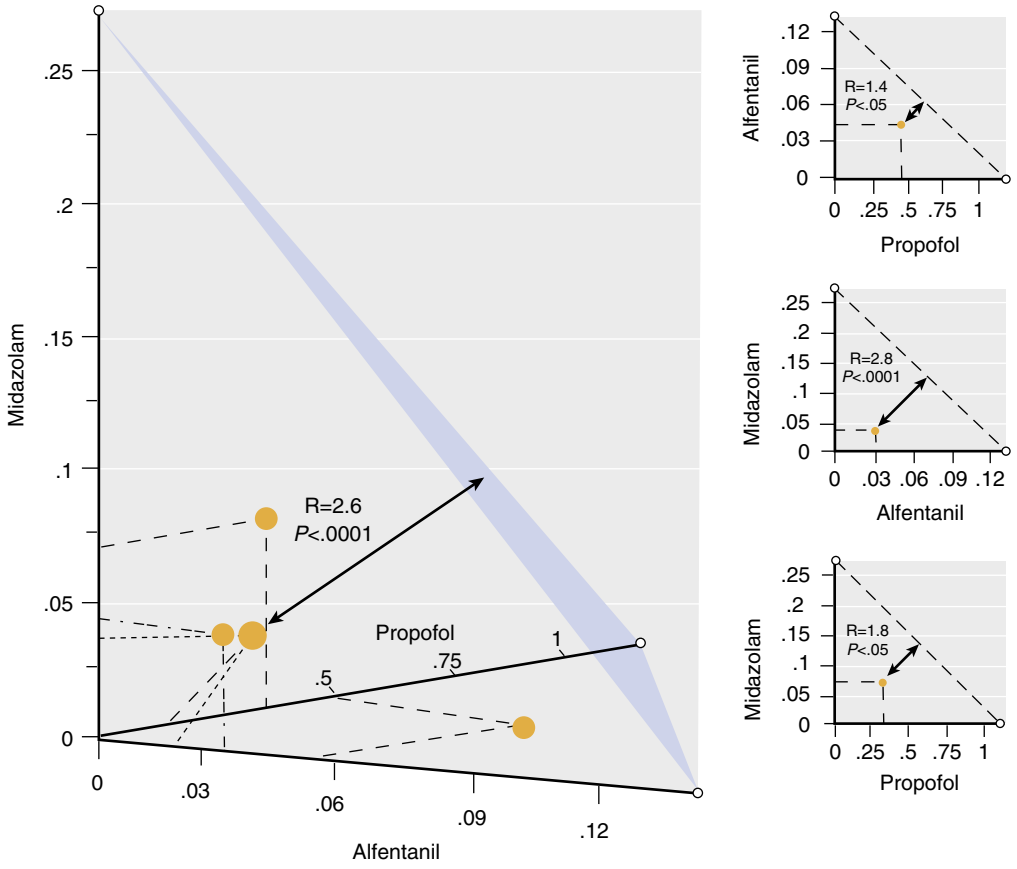

Figure 26-12 Vertical axes all represent drug dose in milligrams per kilogram. On the right, median effective dose (ED_{50}) isobolograms for the hypnotic interactions among midazolam, alfentanil, and propofol are shown. The *dotted lines* are additive effect lines; all combinations fall within the line representing synergism or supra-additive effect. On the left, a triple interaction is depicted. The *shaded area* represents an additive plane passing through three single-drug ED_{50} points (*small open circles*). The largest *closed circle* (with *arrows*) is the ED_{50} point for the triple combination. The smaller *closed circles* are ED_{50} points for the binary combinations. R ratios on all graphs represent the interaction (1.0 indicates an additive effect) of the various drug combinations. The combination of midazolam and alfentanil produces the greatest synergism, but the combination of all three also is synergistic. *P* values denote the significance of the additive effects. *(Redrawn with modification from Vinik HR, Bradley EL Jr, Kissin I: Triple anesthetic combination: Propofol-midazolam-alfentanil. Anesth Analg 76:S450, 1993.)*

zolam is superior for this use because of better amnesia and a smoother hemodynamic course. Opioid requirements are less with midazolam. Midazolam (0.6 mg/kg) decreases the minimum alveolar concentration of inhaled anesthetics.[287] The amnesic period after an anesthetic dose is about 1 to 2 hours. Infusions of midazolam have been used to ensure a constant and appropriate depth of anesthesia.[287] Experience indicates that a plasma level of more than 50 ng/mL when used with adjuvant opioids (e.g., fentanyl) or inhalation anesthetics (e.g., nitrous oxide, volatile anesthetics) is achieved with a bolus loading dose of 0.05 to 0.15 mg/kg and a continuous infusion of 0.25 to 1 µg/kg/min.[283] This plasma level is sufficient to keep the patient asleep and amnesic but arousable at the end of surgery. Smaller infusion doses may be required in some patients and with certain opioids.

Midazolam, diazepam, and lorazepam accumulate in the blood with repeated bolus administrations or with continuous infusion, just as most IV anesthetics do on repeated injection. If the benzodiazepines do accumulate with repeated administrations, prolonged arousal time can be anticipated. This is less of a problem with midazolam than with diazepam and lorazepam because of the shorter context-sensitive half-time and greater clearance of midazolam.

Nausea and Vomiting Prophylaxis

Numerous studies in the past several years have highlighted the role that benzodiazepines, specifically midazolam, may play in the prevention of PONV (see Chapter 86). Jung and colleagues[288] found that in women undergoing middle ear surgery, IV midazolam, 0.075 mg/kg after induction, reduced the incidence of PONV and the need for rescue antiemetics with no difference from placebo in pain intensity or drowsiness. Similarly, Lee and associates[289] found no difference in the incidence of PONV after minor gynecologic or urologic surgery when comparing IV ondansetron, 4 mg, and IV midazolam, 2 mg. Finally, Riad and colleagues[289a] effectively illustrated that IV midazolam, 0.05 mg/kg, reduces PONV after pediatric (4 to 12 years old) strabismus surgery compared with placebo or IV dexamethasone, 0.5 mg/kg. No child vomited with midazolam alone or with the midazolam-dexamethasone combination.

Side Effects and Contraindications

Benzodiazepines have limited allergenic effects and do not suppress the adrenal gland.[290] The most significant problem with

midazolam is respiratory depression. The major side effects of lorazepam and diazepam in addition to respiratory depression are venous irritation and thrombophlebitis, problems related to aqueous insolubility and requisite solvents.[230] When used as sedatives or for induction and maintenance of anesthesia, benzodiazepines can produce an undesirable degree or prolonged interval of postoperative amnesia, sedation, and, rarely, respiratory depression. These residual effects can be reversed with flumazenil.

Flumazenil

Flumazenil (Anexate, Romazicon) is the first benzodiazepine antagonist approved for clinical use.[291] Preclinical pharmacologic studies with flumazenil revealed it to be a benzodiazepine receptor ligand with high affinity, great specificity, and by definition minimal intrinsic effect. Flumazenil, similar to the agonists it replaces at the benzodiazepine receptor, interacts with the receptor in a concentration-dependent manner. Because it is a competitive antagonist at the benzodiazepine receptor, its antagonism is reversible and surmountable. Flumazenil has minimal intrinsic activity,[292] which means that its benzodiazepine receptor agonist effects are very weak, significantly less than those of clinical agonists. Flumazenil, similar to all competitive antagonists at receptors, does not displace the agonist, but rather occupies the receptor when an agonist dissociates from the receptor. The half-time (or half-life) of a receptor-ligand bond is a few milliseconds to a few seconds, and new ligand receptor bonds are immediately formed. This dynamic situation accounts for the ability of either an agonist or an antagonist to occupy the receptor readily.

The ratio of agonist to total receptors produces the effects of the agonist drug, but the antagonist can alter this ratio, depending on its concentration and dissociation constant. Flumazenil, which is an avid (high-affinity) ligand, replaces a relatively weak agonist, such as diazepam, as long as it is given in sufficient dose. Flumazenil is cleared rapidly, however, and the proportion of receptors occupied by agonist increases, and the potential for resedation exists (Fig. 26-13). This situation is less likely to occur when flumazenil is used to reverse midazolam, which has a more rapid clearance than other benzodiazepine agonists. Another important finding is that in the presence of extremely high doses of agonist (e.g., when a mistake in dosing has occurred, or suicide is attempted), flumazenil in a low dose attenuates the deep CNS depression (loss of consciousness, respiratory depression) by reducing the fractional receptor occupancy by the agonist without decreasing the agonist effects that occur at low fractional receptor occupancy (drowsiness, amnesia).

Conversely, large doses of flumazenil in the presence of small doses of agonist completely reverse virtually all the agonist effects. Flumazenil can precipitate withdrawal symptoms in animals or in humans physically dependent on a benzodiazepine receptor agonist.[293,294] This is not a problem when flumazenil is used to reverse benzodiazepine receptor agonists in anesthesia.

Physicochemical Characteristics

Flumazenil, synthesized in 1979, is similar to midazolam and other classic benzodiazepines except for the absence of the phenyl group, which is replaced by a carbonyl group (see Fig. 26-8).[295] It forms a colorless, crystalline powder; has a dissociation constant of 1.7; and has weak but sufficient water solubility to permit its preparation in aqueous solution. Its octanol/aqueous buffer partition coefficient is 14, showing moderate lipid solubility at pH 7.4.[295]

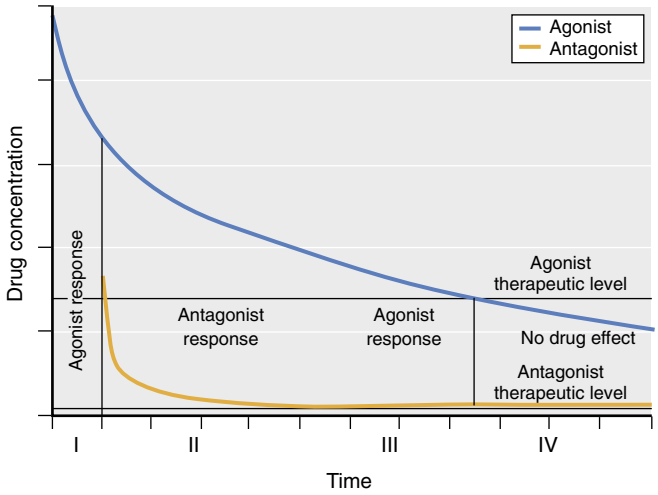

Figure 26-13 Schematic representation of the interaction of a short-acting antagonist with a longer acting agonist resulting in resedation. The *upper curve* shows disappearance of agonist from blood, and the *lower curve* shows disappearance of antagonist from plasma. Four conditions are represented: I, agonist response; II, antagonist response (the antagonist reverses the agonist effect); III, agonist response (resedation or resumption of agonist response with disappearance of short-lasting antagonist); and IV, no drug effect, with disappearance of agonist and antagonist (both drugs are below the therapeutic level).

Metabolism

Flumazenil, similar to the other benzodiazepines, is metabolized in the liver; is rapidly cleared from the plasma; and has three known metabolites, *N*-desmethylflumazenil, *N*-desmethylflumazenil acid, and flumazenil acid.[296] The activities of these metabolites and their corresponding glucuronides are unknown at present. The glucuronides probably are excreted in the urine.

Pharmacokinetics

Flumazenil is a short-lived compound. Table 26-1 includes a summary of its pharmacokinetics, which are described in various clinical settings.[251,296] Compared with benzodiazepine receptor agonists, flumazenil has the most rapid clearance and shortest elimination half-life. The plasma half-life of flumazenil is about 1 hour—it is the shortest lived of all benzodiazepines used in anesthetic practice. The potential exists for the antagonist to be cleared, leaving sufficient concentrations of agonist at the receptor site to cause resedation.[293] To maintain a constant therapeutic blood level over a prolonged time, either repeated administration or a continuous infusion is required. An infusion rate of 30 to 60 µg/min (0.5 to 1 µg/kg/min) has been used for this purpose.[297] The rapid blood clearance of flumazenil approaches hepatic blood flow, a finding that indicates that liver clearance partially depends

on hepatic blood flow. Compared with other benzodiazepines, flumazenil has a high proportion of unbound drug; its protein binding is low, with the free fraction ranging from 54% to 64%. This property of flumazenil could contribute to its rapid onset and greater clearance, but this hypothesis is unproved.

Pharmacology

When given in the absence of a benzodiazepine receptor agonist, flumazenil has little discernible CNS effect. Although intrinsic (agonist and inverse agonist) effects have been ascribed to flumazenil,[292] they are clinically unimportant. It has been postulated that in small doses a stimulating effect can be seen, and in high doses a central depressant effect becomes more likely.[298] When given to volunteers and patients in clinically relevant doses, flumazenil has no effect on the EEG or cerebral metabolism.[251,299] In animals, flumazenil has no anticonvulsant properties, and reverses the anticonvulsant properties of benzodiazepines in local anesthetic–induced seizures.[300]

When administered to patients who have benzodiazepine-induced CNS depression, flumazenil produces rapid and dependable reversal of unconsciousness, respiratory depression, sedation, amnesia, and psychomotor dysfunction.[247] Flumazenil can be given before, during, or after the agonist to block or reverse the CNS effects of the agonist. The usual clinical need is to reverse the effects of agonists given before flumazenil. Flumazenil has successfully reversed the effects of midazolam, diazepam, lorazepam, and flunitrazepam. The onset is rapid, with peak effect occurring in 1 to 3 minutes,[247] which coincides with the detection of C-flumazenil in human brain.[301] Flumazenil reverses the agonist by replacing it at the benzodiazepine receptor, and its onset and duration are governed by the law of mass action. A predicted therapeutic plasma level for flumazenil is 20 ng/mL because the relative binding characteristics of agonist and antagonist in part dictate benzodiazepine receptor occupation by the residual agonist, and different doses and plasma levels of flumazenil are required to reverse the effects of particular agonists.

Flumazenil is devoid of the respiratory and cardiovascular depressant effects of benzodiazepine receptor agonists. A large dose of flumazenil (0.1 mg/kg) given to volunteers did not produce significant respiratory depression.[302] When flumazenil is given in the presence of agonists, however, there are significant respiratory effects because it reverses respiratory depression caused by the agonists (e.g., when given to volunteers made apneic with midazolam).[303] The reversal of midazolam-induced (0.13 mg/kg) respiratory depression with flumazenil (1 mg) lasts 3 to 30 minutes. Other agonists and other doses would have different durations of antagonism of respiratory depression. If respiratory depression is related to opioid administration, flumazenil would not reverse it.[304]

Incremental doses, up to 3 mg intravenously, in patients with ischemic heart disease had no significant effect on cardiovascular variables.[303] Administration of flumazenil to patients given agonists is remarkably free of cardiovascular effects,[247,305] in contrast to the experience of opioid reversal with naloxone. Of particular interest is the effect on plasma catecholamines of benzodiazepine receptor agonist reversal with flumazenil because this effect on catecholamines is the suspected mechanism of hyperdynamic response in opioid reversal. Although flumazenil does reverse sedation, it is not associated with significantly higher catecholamines than are found in patients receiving saline,[305] but the increase in catecholamines that accompanies arousal is more rapid after flumazenil.[306]

Table 26-8 Uses and Doses of Flumazenil

Reversal of benzodiazepines*	0.2 mg repeated† up to 3 mg
Diagnosis in coma	0.5 mg repeated up to 1 mg

*The dose required to reverse each benzodiazepine (BZD) depends on residual BZD and the particular BZD (i.e., higher doses are required for more potent BZDs) (see text).
†The degree of reversal should be titrated by repeating 0.2-mg increments every 1-2 min until desired level of reversal is achieved.

Uses and Doses

Uses for a benzodiazepine antagonist (Table 26-8) include the diagnostic and therapeutic reversal of the effects of benzodiazepine receptor agonists. For diagnostic use in suspected benzodiazepine overdose, flumazenil may be given in incremental IV doses of 0.2 to 0.5 mg up to 3 mg. If there is no change in CNS sedation, it is unlikely that CNS depression is based solely on benzodiazepine overdose. More commonly in anesthesia, flumazenil is used to reverse the residual sedation of a patient after administration of a benzodiazepine for conscious sedation or for general anesthesia.

Flumazenil reliably reverses the sedation, respiratory depression, and amnesia of benzodiazepines. There is now evidence, however, of differential reversal effects on the different agonist actions. Flumazenil tends to reverse the hypnotic and respiratory effects more than the amnesic effects of the agonist benzodiazepine.[304,307] Dosage guidelines are given in Table 26-8, but large-scale dosing studies have not been performed yet. The dose varies with the particular benzodiazepine being reversed, and the duration of reversal depends on the kinetics of the agonist and of flumazenil. Surveillance is recommended if a long-lasting benzodiazepine is reversed with a single administration of flumazenil because of the relatively short-lived effect. Flumazenil may be administered by continuous infusion to prevent resedation with longer lasting benzodiazepine receptor agonists.

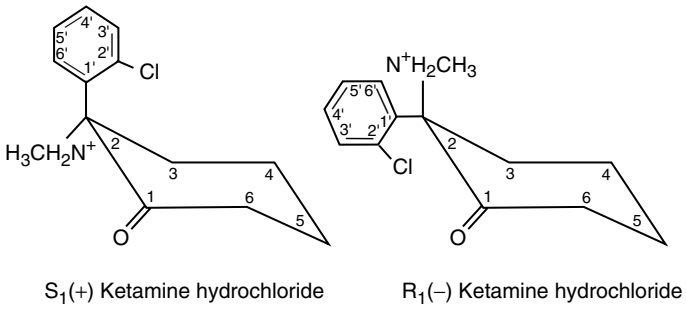
Side Effects and Contraindications

Flumazenil has been given in large oral and IV doses with remarkably few toxic reactions.[247] It is free of local or tissue irritant properties, and there are no known organotoxicities. Similar to all benzodiazepines, it apparently has a high safety margin, probably higher than the safety margins of agonists, because it does not produce prominent CNS depression. An important caution is that resedation could occur because of the relatively short half-life of the drug.

Phencyclidines (Ketamine)

History

Phencyclidine was the first drug of its class to be used for anesthesia, but had unacceptable side effects. Ketamine (Ketalar) was



S_1(+) Ketamine hydrochloride R_1(–) Ketamine hydrochloride

Figure 26-14 Stereoisomers of ketamine as it is formulated.

synthesized in 1962 by Stevens and was first used in humans in 1965 by Corssen and Domino. Ketamine was released for clinical use in 1970 and is still used in various clinical settings. Ketamine differs from most other drugs used to induce anesthesia because it has a significant analgesic effect. It usually does not depress the cardiovascular and respiratory systems,[308] but it does possess some of the adverse psychological effects found with the other phencyclidines. Ketamine consists of two stereoisomers, S(+) and R(–). The S(+) is more potent and is associated with fewer side effects. Interest in ketamine has increased more recently because of its effects on hyperalgesia and opiate tolerance, use in chronic pain states, potential neuroprotective effects, increasing popularity of total IV anesthesia, and the availability (in some countries) of S(+) ketamine.

Physicochemical Characteristics

Ketamine (Fig. 26-14) has a molecular weight of 238 kD, is partially water soluble, and forms a white crystalline salt with a pK_a of 7.5.[308] It has a lipid solubility 5 to 10 times that of thiopental.[309]

Metabolism

Ketamine is metabolized by hepatic microsomal enzymes. The major pathway involves *N*-demethylation to form norketamine (metabolite I), which is then hydroxylated to hydroxynorketamine. These products are conjugated to water-soluble glucuronide derivatives and are excreted in the urine.[308] The activity of the principal metabolites of ketamine has not been well studied, but norketamine (metabolite I) has significantly less (20% to 30%) activity than the parent compound. More recent modeling of norketamine suggests that it does contribute in prolonging the analgesia provided by either a bolus or infusion of ketamine.[310]

Pharmacokinetics

Ketamine pharmacokinetics have been examined after bolus administration of anesthetizing doses (2 to 2.5 mg/kg),[311] after a subanesthetic dose (0.25 mg/kg),[311,312] and after continuous infusion (steady-state plasma level 2000 ng/mL). Regardless of the dose, ketamine plasma disappearance can be described by a two-compartment model.[311] Table 26-1 contains the pharmacokinetic values from bolus administration studies. Of note is the rapid distribution reflected in the relatively brief distribution half-life of 11 to 16 minutes (Fig. 26-15). The high lipid solubility of ketamine is reflected in its large volume of distribution, nearly 3 L/kg. Clearance also is high, 890 to 1227 mL/min, which accounts for the short elimination half-life of 2 to 3 hours. The mean total body clearance (1.4 L/min) is approximately equal to liver blood flow, which means that changes in liver blood flow affect clearance. Low-dose alfentanil increases the volume of distribution and clearance of ketamine. In addition, alfentanil increases the distribution of ketamine into the brain.[313] The pharmacokinetic model of Clements[311] provided the best accuracy when used to administer low-dose ketamine to volunteers using a target-controlled infusion device.[314]

The pharmacokinetics of the two isomers is different. S(+) ketamine has a larger elimination clearance and larger volume of distribution than R(–) ketamine.[315] When the pharmacokinetics of S(+) ketamine was tested in a target-controlled infusion device for procedures of 1 hour and in combination with propofol, the authors found that the accuracy of the pharmacokinetic parameters was improved with a much smaller Vc (167 mL/kg). They also noted that ketamine clearance was not normally distributed, and this was not related to age.[316] The S(+) enantiomer also seems to be more potent in suppressing the EEG than either R(–) or the racemic mixture.[317]

Ketamine is increasingly being given by alternative routes, especially orally and via an intranasal spray. Administration by either of these routes is subject to significant first-pass metabolism. The bioavailability via oral administration is 20% to 30%, and via the intranasal route is approximately 40% to 50%.[318]

Pharmacology

Effects on the Central Nervous System

Ketamine produces dose-related unconsciousness and analgesia. The anesthetized state has been termed *dissociative anesthesia* because patients who receive ketamine alone appear to be in a cataleptic state, in contrast with other states of anesthesia that resemble normal sleep. Patients anesthetized with ketamine have

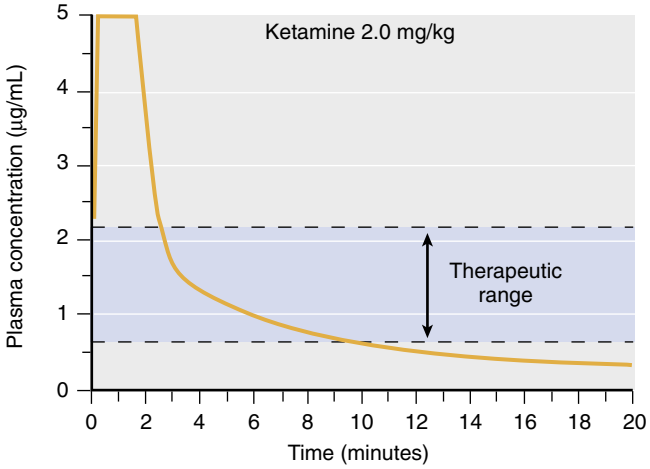


Figure 26-15 Simulated time course of plasma levels of ketamine after an induction dose of 2 mg/kg. Plasma levels required for hypnosis and amnesia during surgery are 0.7 to 2.2 µg/mL, with awakening usually occurring at levels less than 0.5 µg/mL.

profound analgesia, but keep their eyes open and maintain many reflexes. Corneal, cough, and swallow reflexes all may be present, but should not be assumed to be protective. There is no recall of surgery or anesthesia, but amnesia is not as prominent with ketamine as with the benzodiazepines. Because ketamine has a low molecular weight, a pK_a near the physiologic pH, and relatively high lipid solubility, it crosses the blood-brain barrier rapidly and has an onset of action within 30 to 60 seconds of administration. The maximal effect occurs in about 1 minute.

After ketamine administration, pupils dilate moderately, and nystagmus occurs. Lacrimation and salivation are common, as is increased skeletal muscle tone, often with coordinated but seemingly purposeless movements of the arms, legs, trunk, and head. Although there is great interindividual variability, plasma levels of 0.6 to 2 μg/mL are considered the minimum concentrations for general anesthesia; children may require slightly higher plasma levels (0.8 to 4 μg/mL).[319] The duration of ketamine anesthesia after a single IV administration of a general anesthetic dose (2 mg/kg) is 10 to 15 minutes (see Fig. 26-15), and full orientation to person, place, and time occurs within 15 to 30 minutes.

The S(+) enantiomer enables quicker recovery (by a couple of minutes) than the racemic mixture.[320,321] This is thought to be due to the lower dose necessary to produce an equianesthetic effect and to the 10% faster hepatic biotransformation.[321]

The duration of ketamine anesthesia is determined by the dose; larger doses produce more prolonged anesthesia, and the concurrent use of other anesthetics prolongs the time of emergence. Because there is a good correlation between blood level of ketamine and CNS effect, it seems that the relatively short duration of action of ketamine is due to its redistribution from the brain and blood to the other tissues in the body. The termination of effect after a single bolus administration of ketamine is caused by drug redistribution from the well-perfused to the less well-perfused tissues. Concomitant administration of benzodiazepines, a common practice, may prolong the effect of ketamine.[322] When used in combination with a benzodiazepine, the S(+) enantiomer was no different in terms of awareness at 30 minutes, but it was significantly better at 120 minutes than the racemic mixture.[323] Analgesia occurs at considerably lower blood levels than loss of consciousness.

Ketamine provides important postoperative analgesia. The plasma level at which pain thresholds are elevated is 0.1 μg/mL or greater. This means there is a considerable period of postoperative analgesia after ketamine general anesthesia, and subanesthetic doses can be used to produce analgesia. Ketamine has been shown to inhibit nociceptive central hypersensitization.[324] Ketamine also attenuates acute tolerance after opiate administration.[325]

The primary site of CNS action of ketamine seems to be the thalamoneocortical projection system. The drug selectively depresses neuronal function in parts of the cortex (especially association areas) and thalamus, while stimulating parts of the limbic system, including the hippocampus. This process creates what is termed a *functional disorganization* of nonspecific pathways in midbrain and thalamic areas.[326,327] There also is evidence that ketamine depresses transmission of impulses in the medial medullary reticular formation, which is important for transmission of the affective-emotional components of nociception from the spinal cord to higher brain centers.[328] In volunteers experiencing heat pain, functional magnetic resonance imaging (MRI) studies showed ketamine produced a dose-dependent effect on pain processing by decreasing activation of the secondary somatosensory cortex (S2), insula, and anterior cingulate cortex.[329] Blockade of CNS sodium channels has been shown not to be the mechanism of action by which ketamine produces anesthesia.[330] There is some evidence that ketamine occupies opiate receptors in the brain and spinal cord, and this property could account for some of the analgesic effects.[179,308,331] The S(+) enantiomer has been shown to have some opioid μ-receptor activity, accounting for part of its analgesic effect.[332] NMDA receptor interaction may mediate the general anesthetic effects and some analgesic actions of ketamine.[333,334] The spinal cord analgesic effect of ketamine is postulated to be due to inhibition of dorsal horn wide dynamic range neuronal activity.[335] Although some drugs have been used to antagonize ketamine, no specific receptor antagonist is yet known that reverses all the CNS effects of ketamine.

Ketamine increases cerebral metabolism, CBF, and ICP (see Chapter 63). Because of its excitatory CNS effects, which can be detected by generalized EEG development of theta wave activity and by petit mal seizure–like activity in the hippocampus,[336] ketamine increases $CMRO_2$. Although theta wave activity signals the analgesic activity of ketamine, alpha waves indicate its absence. There is an increase in CBF, which appears higher than the increase in $CMRO_2$ would mandate. With the increase in CBF and the generalized increase in sympathetic nervous system response, there is an increase in ICP after ketamine.[337,338] The increase in $CMRO_2$ and CBF can be blocked by the use of thiopental[339] or diazepam.[337,338] Cerebrovascular responsiveness to carbon dioxide seems to be preserved with ketamine; reducing $Paco_2$ attenuates the increase in ICP after ketamine.[337]

In animal models of incomplete cerebral ischemia and reperfusion, ketamine reduces necrosis and improves neurologic outcome.[340] Decreased sympathetic tone and inhibition of NMDA receptor–mediated ion currents were believed to mediate the reduction of necrotic cell death. More recently, S (+) ketamine was found to influence the expression of apoptosis-regulating proteins in rat brains 4 hours after cerebral ischemia/reperfusion.[341] The neuroprotection observed with ketamine may involve antiapoptotic mechanisms in addition to reducing necrotic cell death.

In contrast, ketamine or other NMDA receptor antagonists accentuate apoptosis in the newborn brain of animals.[342] This has been shown with other anesthetics either at high relative doses or with prolonged exposure. This finding has sparked controversy over the use of ketamine in neonates. An editorial in the journal *Anesthesiology* and the Anesthetic and Life Support Drugs Advisory Committee of the U.S. FDA cautioned changing clinical practice based on present available data.[343]

Ketamine, similar to other phencyclidines, produces undesirable psychological reactions, which occur during awakening from ketamine anesthesia and are termed *emergence reactions*. The common manifestations of these reactions, which vary in severity and classification, are vivid dreaming, extracorporeal experiences (sense of floating out of body), and illusions (misinterpretation of a real, external sensory experience).[344] These incidents of dreaming and illusion are often associated with excitement, confusion, euphoria, and fear.[345] They occur in the first hour of emergence and usually abate within 1 to several hours. It has been postulated that the psychic emergence reactions occur secondary to ketamine-induced depression of auditory and visual relay nuclei, leading to misperception or misinterpretation

of auditory and visual stimuli.[308] The incidence ranges from 3%[179,308] to 100%.[344] A clinically relevant range is probably 10% to 30% of adult patients who receive ketamine as a sole or major part of the anesthetic technique.

Factors that affect the incidence of emergence reactions are age,[346] dose,[179] gender, psychological susceptibility,[347] and concurrent drugs. Pediatric patients do not report as high an incidence of unpleasant emergence reactions as do adult patients; men also report a lower incidence compared with women. Larger doses and rapid administration of large doses seem to predispose patients to a higher incidence of adverse effects.[348,349] Finally, certain personality types seem prone to the development of emergence reactions. Patients who score high in psychotism on the Eysenck Personality Inventory are prone to develop emergence reactions,[347] and individuals who commonly dream at home are more likely to have postoperative dreams in the hospital after ketamine.[348] Numerous drugs have been used to reduce the incidence and severity of postoperative reactions to ketamine[179,308]; the benzodiazepines seem to be the most effective group of drugs to attenuate or to treat ketamine emergence reactions. Midazolam,[308] lorazepam,[350] and diazepam[351] are useful in reducing reactions to ketamine. Midazolam reduces the psychotomimetic effect of the S (+) enantiomer.[352]

Effects on the Respiratory System

Ketamine has minimal effects on the central respiratory drive as reflected by an unaltered response to carbon dioxide.[353] There can be a transient (1 to 3 minutes) decrease in minute ventilation after the bolus administration of an induction dose of ketamine (2 mg/kg intravenously). Unusually large doses can produce apnea,[354] but this is seldom seen. Arterial blood gases generally are preserved when ketamine is used alone for anesthesia or analgesia. With the use of adjuvant sedatives or anesthetic drugs, however, respiratory depression can occur. Ketamine has been shown to affect ventilatory control in children and should be considered a possible respiratory depressant when the drug is given to them in bolus doses.[355]

Ketamine is a bronchial smooth muscle relaxant. When it is given to patients with reactive airway disease and bronchospasm, pulmonary compliance is improved.[356] Ketamine is as effective as halothane or enflurane in preventing experimentally induced bronchospasm.[357] The mechanism for this effect is probably a result of the sympathomimetic response to ketamine, but there are isolated bronchial smooth muscle studies showing that ketamine can directly antagonize the spasmogenic effects of carbachol and histamine.[358] Owing to its bronchodilating effect, ketamine has been used to treat status asthmaticus unresponsive to conventional therapy.[359]

A potential respiratory problem, especially in children (see Chapter 82), is the increased salivation that follows ketamine administration. This increased salivation can produce upper airway obstruction, which can be complicated further by laryngospasm. The increased secretions also may contribute to or may complicate further laryngospasm. In addition, although swallow, cough, sneeze, and gag reflexes are relatively intact after ketamine administration, there is evidence that silent aspiration can occur during ketamine anesthesia.

Effects on the Cardiovascular System

Ketamine also has unique cardiovascular effects; it stimulates the cardiovascular system and is usually associated with increases in blood pressure, heart rate, and cardiac output (see Table 26-2). Other anesthetic induction drugs either cause no change in hemodynamic variables or produce vasodilation with cardiac depression. The S(+) enantiomer, despite hope that reducing the dose by half (equianesthetic potency) would attenuate side effects, is equivalent to the racemic mixture regarding hemodynamic response.[352] The increase in hemodynamic variables is associated with increased work and myocardial oxygen consumption. The healthy heart is able to increase oxygen supply by increased cardiac output and decreased coronary vascular resistance, so that coronary blood flow is appropriate for the increased oxygen consumption.[360] The hemodynamic changes are not related to the dose of ketamine (e.g., there is no hemodynamic difference between IV administration of 0.5 mg/kg and 1.5 mg/kg).[361] A second dose of ketamine produces hemodynamic effects less than or even opposite to the effects of the first dose.[362]

The hemodynamic changes after anesthesia induction with ketamine tend to be the same in healthy patients and in patients with various acquired or congenital heart diseases.[361] In patients with congenital heart disease, there are no significant changes in shunt directions or fraction[363] or systemic oxygenation after ketamine induction of anesthesia.[364] In patients who have elevated pulmonary artery pressure (as with mitral valvular and some congenital lesions), ketamine seems to cause a more pronounced increase in pulmonary than systemic vascular resistance.[363]

The mechanism by which ketamine stimulates the circulatory system remains enigmatic. It seems not to be a peripheral mechanism such as baroreflex inhibition, but rather to be central. There is some evidence that ketamine attenuates baroreceptor function via an effect on NMDA receptors in the nucleus tractus solitarius.[365] Ketamine injected directly into the CNS produces an immediate sympathetic nervous system hemodynamic response.[366] Ketamine also causes the sympathoneuronal release of norepinephrine, which can be detected in venous blood. Blockade of this effect is possible with barbiturates, benzodiazepines, and droperidol.[367] Ketamine in vitro probably has negative inotropic effects. Myocardial depression has been shown in chronically instrumented dogs,[368] and isolated canine heart preparations.[369] In isolated guinea pig hearts, ketamine was the least depressant of all the major induction drugs, however.[370] The finding that ketamine may exert its myocardial effects by acting on myocardial ionic currents (which may exert different effects from species to species or among tissue types) may explain the tissue and animal model variances in direct myocardial action.[371]

The centrally mediated sympathetic responses to ketamine usually override the direct depressant effects of ketamine. Some peripheral nervous system actions of ketamine play an undetermined role in the hemodynamic effects of the drug. Ketamine inhibits intraneuronal uptake of catecholamines in a cocaine-like effect,[160,161] and inhibits extraneuronal norepinephrine uptake.[372]

Stimulation of the cardiovascular system is not always desirable, and certain pharmacologic methods have been used to block the ketamine-induced tachycardia and systemic hypertension. Successful methods include use of adrenergic antagonists (α and β), various vasodilators,[373] and clonidine.[374] Probably the most fruitful approach has been prior administration of benzodiazepines. Modest doses of diazepam, flunitrazepam, and midazolam all attenuate the hemodynamic effects of ketamine. It also is possible to decrease the tachycardia and hypertension caused by ketamine by using a continuous infusion technique with or

without a benzodiazepine.[375] Inhalation anesthetics[376] and propofol blunt the hemodynamic effect of ketamine. Ketamine can produce hemodynamic depression in the setting of deep anesthesia, when sympathetic responses do not accompany its administration.

Uses

The many unique features of ketamine pharmacology, especially its propensity to produce unwanted emergence reactions, have limited its use for routine anesthesia. Nevertheless, ketamine has an important niche in the practice of anesthesiology when its unique sympathomimetic activity and bronchodilating capabilities are indicated during induction of anesthesia. It is used for premedication, sedation, induction, and maintenance of general anesthesia (Table 26-9). There has been increased interest in the routine use of ketamine in small doses (20 to 60 mg) for preventive analgesia and for the treatment or prevention of opiate tolerance and hyperalgesia.

Induction and Maintenance of Anesthesia

Most candidates for ketamine induction are poor-risk patients (ASA class IV) with respiratory and cardiovascular system disorders (excluding ischemic heart disease), in particular, patients with reactive airway disease or patients with hemodynamic compromise based on either hypovolemia or cardiomyopathy (not coronary artery disease). Ketamine bronchodilation and profound analgesia allowing the use of high oxygen concentrations make ketamine an excellent choice for induction in patients with reactive airway disease. Otherwise healthy trauma victims whose blood loss is extensive also are candidates for rapid-sequence anesthesia induction with ketamine.[377] Patients with septic shock also may benefit from ketamine.[378] The intrinsic myocardial depressant effect of ketamine may manifest in this situation, however, if trauma or sepsis has caused depletion of catecholamine stores before the patient's arrival in the operating room. Use of ketamine in these patients does not obviate the need for appropriate preoperative preparation, including restoration of blood volume.

Other cardiac diseases that can be well managed with ketamine anesthesia are cardiac tamponade and restrictive pericarditis.[379] The finding that ketamine preserves heart rate and right atrial pressure through its sympathetic stimulating effects makes ketamine an excellent anesthetic induction and maintenance drug in this setting. Ketamine also is often used in patients with congenital heart disease, especially patients in whom the propensity for right-to-left shunting exists. Use of ketamine has been reported in a patient susceptible to malignant hyperthermia.[380]

Ketamine combined with propofol or midazolam can be given by continuous infusion to produce satisfactory cardiac anesthesia for patients with valvular and ischemic heart disease. The combination of a benzodiazepine[375] or of a benzodiazepine plus sufentanil[381] with ketamine attenuates or eliminates the unwanted tachycardia and hypertension and postoperative psychological derangements. With this technique, there are minimal hemodynamic perturbations, profound analgesia, dependable amnesia, and an uneventful convalescence. The use of propofol plus low-dose ketamine also has gained increasing popularity as a total IV anesthesia technique for patients undergoing noncardiac surgery. The advantages of this combination are maintenance of stable hemodynamics and minimal ventilatory depression when allowing spontaneous ventilation.

Table 26-9 Uses and Doses of Ketamine

Induction of general anesthesia*	0.5-2 mg/kg IV 4-6 mg/kg IM
Maintenance of general anesthesia	0.5-1 mg/kg IV with N_2O 50% in O_2 15-45 µg/kg/min IV with N_2O 50-70% in O_2 30-90 µg/kg/min IV without N_2O
Sedation and analgesia	0.2-0.8 mg/kg IV over 2-3 min 2-4 mg/kg IM
Preemptive/preventive analgesia	0.15-0.25 mg/kg IV

*Lower doses are used if adjuvant drugs such as midazolam or thiopental also are given.
N_2O, nitrous oxide.

Pain Management

Ketamine administered in small doses decreases postoperative analgesic consumption (see Chapter 87). Several meta-analyses of the use of low-dose ketamine (20 to 60 mg) perioperatively have been done. These meta-analyses showed an overall decrease in opiate use or improved analgesia and a decrease in opiate-induced side effects, especially PONV. Side effects, especially psychotomimetic effects, were minimal, especially if a benzodiazepine also was administered.[382] Ketamine in a 1:1 combination with morphine using an 8-minute lockout interval provided optimal postoperative analgesia for this combination.[383] Alternatively, an initial bolus of 0.5 mg/kg of ketamine followed by a continuous infusion of 3 µg/kg/min during surgery and 1.5 µg/kg/min for 48 hours after surgery has been used successfully in total knee arthroplasty.[384]

The action of ketamine on opiate tolerance and hyperalgesia combined with its direct analgesic activity has prompted increasing use of ketamine in chronic pain states. Ketamine may be effective in the treatment of cancer pain, chronic peripheral and central neuropathic pain, phantom and ischemic limb pain, fibromyalgia, complex regional pain syndrome, visceral pain, and migraine. These indications are based largely on a few short-term trials with limited clinical application or limited nonrandomized trials and case studies.[385] There also have been a limited number of reports that indicate the value of multimodal pain therapy including ketamine in preventing postoperative chronic pain.[386,387]

The epidural/caudal administration of ketamine (0.5 to 1 mg/kg) has been increasingly reported. Although the efficacy of these doses of ketamine seems to be established, the safety of this technique has not yet received regulatory approval. The preservative of racemic mixture is potentially neurotoxic, whereas studies to date indicate preservative-free S(+) ketamine may be safe.[388]

Sedation

Ketamine is particularly suitable for sedation of pediatric patients undergoing procedures outside of the operating room (see Chapter 82). Pediatric patients have fewer adverse emergence reactions[346] than adults, and this feature makes the use of keta-

mine in pediatric patients more versatile. Ketamine is used for sedation or general anesthesia for the following pediatric procedures: cardiac catheterization, radiation therapy, radiologic studies, dressing changes,[389] and dental work.[322]

Usually, a subanesthetic dose (≤1.0 mg/kg intravenously) is used for dressing changes; this dose provides adequate operating conditions, but a rapid return to normal function, including the resumption of eating, which is important in maintaining proper nutrition in burn patients.[308,179] Often, ketamine is combined with premedication of a barbiturate or benzodiazepine and an antisialagogue (e.g., glycopyrrolate) to facilitate management. The premedications reduce the dose requirement for ketamine, and the antisialagogue reduces the sometimes troublesome salivation.

In adults and children, ketamine can be used as a supplement or an adjunct to regional anesthesia, extending the usefulness of the primary (local anesthetic) form of anesthesia (see Chapter 52). In this setting, ketamine can be used before the application of painful blocks,[390] but more commonly it is used for sedation or supplemental anesthesia during long or uncomfortable procedures. When used for supplementation of regional anesthesia, IV ketamine (0.5 mg/kg) can be combined with IV diazepam (0.15 mg/kg).[391] In outpatients, premedication with midazolam (1 to 2 mg), concurrent low-dose propofol infusion, and intermittent ketamine (for analgesia) in doses less than 3 mg/kg[392] or as an infusion of 0.15 to 0.3 μg/kg/min provides excellent sedation, analgesia, and recovery (see Chapter 78). Ketamine also may be considered for sedation of patients in a critical care unit because of its combined sedative and analgesic properties and favorable effects on hemodynamics. Although controversial, a more recent review on the use of ketamine for patients with brain injury concluded, "Ketamine can be used safely in neurologically impaired patients under conditions of controlled ventilation, coadministration of a GABA receptor agonist, and avoidance of nitrous oxide."[393]

Doses and Routes of Administration

Ketamine has been administered intravenously, intramuscularly, transcutaneously, orally, nasally, and rectally, and as a preservative-free solution epidurally or intrathecally.[394] Most clinical use involves the IV and intramuscular (IM) routes, by which the drug rapidly achieves therapeutic levels. The dose depends on the desired therapeutic effect and on the route of administration. Table 26-9 contains general recommended doses for the IV and IM administration of ketamine for various therapeutic goals.[308] Intranasal administration has an onset closer to IV administration; an oral dose of 3 to 10 mg/kg generates a sedative effect in 20 to 45 minutes.

For sedation, ketamine may be given in an IM dose of 2 to 4 mg/kg. It also has been administered orally in doses of 3 to 10 mg/kg, with 6 mg/kg providing optimal conditions in 20 to 25 minutes in one study and 10 mg/kg providing sedation in 87% of children within 45 minutes in another study.[395,396]

Side Effects and Contraindications

The common psychological emergence reactions were discussed earlier. Contraindications to ketamine relate to specific pharmacologic actions and patient diseases. Patients with increased ICP and with intracranial mass lesions breathing spontaneously should not receive ketamine because it can increase ICP and has been reported to cause apnea.[397] The S (+) enantiomer also increases CBF and is probably similarly contraindicated.[283] In ventilated patients, because ketamine retains the response of CBF to carbon dioxide, its use for sedation in head-injured patients may be valuable owing to its potential neuroprotective effect.[393]

Ketamine may be contraindicated in patients with an open eye injury or other ophthalmologic disorder, in which a ketamine-induced increase in intraocular pressure would be detrimental (see Chapter 75). Because ketamine has a propensity to cause hypertension and tachycardia, with a commensurate increase in myocardial oxygen consumption, it is contraindicated as the sole anesthetic in patients with ischemic heart disease.[398] Likewise, it is unwise to give ketamine to patients with vascular aneurysms because of the possible sudden change in arterial pressure. Psychiatric disease, such as schizophrenia, and a history of adverse reaction to ketamine or one of its congeners also are contraindications.[179] One also should consider carefully using ketamine when there is a possibility of postoperative delirium from other causes (e.g., delirium tremens, possibility of head trauma), and a ketamine-induced psychomimetic effect would confuse the differential diagnosis.

As mentioned earlier, ketamine or other NMDA receptor antagonists accentuate apoptosis in the newborn brain of animals, and the clinical implications of this are unknown. Finally, because ketamine's preservative, chlorobutanol, has been shown to be neurotoxic, this formulation of ketamine for subarachnoid or epidural administration is contraindicated.[399] S(+) ketamine is available in a preservative-free solution. The FDA has not approved the use of intrathecal or epidural ketamine.

Etomidate

History

The properties of etomidate (Amidate, Hypnomidate) include hemodynamic stability, minimal respiratory depression, cerebral protection, and pharmacokinetics enabling rapid recovery after either a single dose or a continuous infusion. In animals, etomidate also provides a wider margin of safety (ED_{50}/LD_{50}) than thiopental (26.4 versus 4.6).[400] These beneficial properties led to widespread use of etomidate for induction, for maintenance of anesthesia, and for prolonged sedation in critically ill patients. Anesthesiologists' enthusiasm for etomidate was tempered, however, by reports that the drug can cause temporary inhibition of steroid synthesis after single doses and infusions.[401,402] This effect, combined with other minor disadvantages (e.g., pain on injection, superficial thrombophlebitis, myoclonus, and a high incidence of nausea and vomiting), led to several editorials[403,404] questioning the role of etomidate in modern anesthetic practice. Use of the drug waned significantly after those editorials, but it has expanded as a result of a rediscovery of etomidate's beneficial physiologic profile combined with a lack of any new reports describing clinically significant adrenocortical suppression after an induction dose or brief infusions.

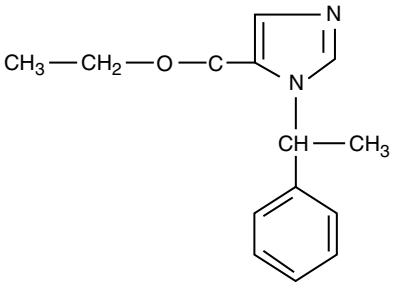

Figure 26-16 Structure of etomidate, an imidazole derivative.

Physicochemical Characteristics

Etomidate is an imidazole derivative (R-(+)-pentylethyl-1H-imidazole-5 carboxylate sulfate). Its chemical structure is illustrated in Figure 26-16. With a molecular weight of 342.36 kD,[179] etomidate exists as two isomers, the (+) isomer being the one active as a hypnotic.[179] Etomidate is water insoluble and is unstable in a neutral solution. It has been formulated with several solvents. In the United States, it is supplied as a 2-mg/mL propylene glycol (35% by volume) solution with a pH of 6.9 and an osmolality of 4640 mOsm/L. In Europe, lipid emulsion has been introduced in an attempt to reduce some of the side effects of etomidate.[405] In contrast to sodium thiopental, when etomidate is mixed with other commonly used anesthetics, such as neuromuscular blockers, vasoactive drugs, or lidocaine, it does not cause precipitation.[406]

Metabolism, Induction, and Maintenance of Anesthesia

Etomidate is metabolized in the liver primarily by ester hydrolysis to the corresponding carboxylic acid of etomidate (major metabolite) or by *N*-dealkylation.[179] The main metabolite is inactive.[406] Only 2% of the drug is excreted unchanged, the rest being excreted as metabolites by the kidney (85%) and bile (13%).[406]

Etomidate has been used for induction and maintenance of anesthesia (Table 26-10). The induction dose of etomidate is 0.2 to 0.6 mg/kg,[407] and it is reduced by premedication with an opiate, a benzodiazepine, or a barbiturate. Onset of anesthesia after a routine induction dose of 0.3 mg/kg of etomidate is rapid (one arm–brain circulation) and is equivalent to anesthesia obtained with an induction dose of thiopental or methohexital.[407] The duration of anesthesia after a single induction dose is linearly related to the dose—each 0.1 mg/kg administered provides about 100 seconds of loss of consciousness.[408] Repeat doses of etomidate by bolus or infusion prolong the duration of hypnosis. Recovery after multiple doses or an infusion of etomidate is still usually rapid.[409-411] The addition of small doses of fentanyl with etomidate for short surgical procedures reduces the required dose of etomidate and allows earlier awakening. In children, induction by rectal administration of etomidate has been obtained with 6.5 mg/kg. Hypnosis occurs in 4 minutes. At this dose, hemodynamics are unaltered, and recovery is still rapid.[412]

Various infusion schemes have been devised to use etomidate as a maintenance anesthetic for the hypnotic component of anesthesia. Most regimens aim to achieve a plasma level of 300 to 500 ng/mL, which is the concentration necessary for hypnosis.[413] Two-stage and three-stage infusions have been used successfully. These consist of an initial rapid infusion of 100 µg/kg/min for 10 minutes followed by 10 µg/kg/min thereafter,[414] or of 100 µg/kg/min for 3 minutes, 20 µg/kg/min for 27 minutes, and 10 µg/kg/min thereafter.[415] Loss of consciousness with these techniques occurs after 100 to 120 seconds.[415] The infusion is usually terminated 10 minutes before desired awakening.[415]

Table 26-10 Uses and Doses of Etomidate

Induction of general anesthesia	0.2-0.6 mg/kg IV
Maintenance of general anesthesia	10 µg/kg/min IV with N_2O and an opiate
Sedation and analgesia	Limited to periods of brief sedation because of inhibition of corticosteroid synthesis

N_2O, nitrous oxide.

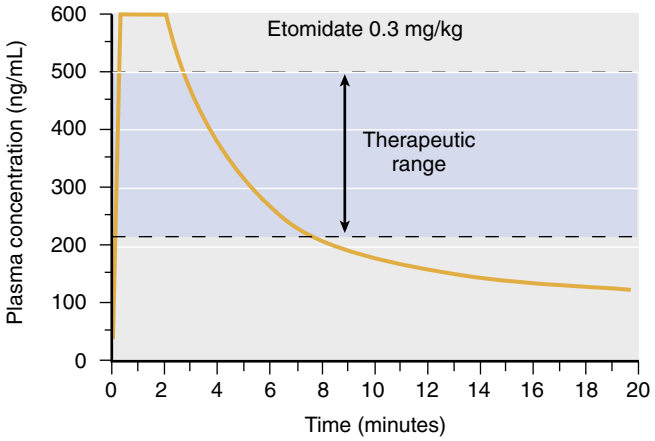

Figure 26-17 Simulated time course of plasma levels of etomidate after an induction dose of 0.3 mg/kg. Plasma levels required for hypnosis during surgery are 300 to 500 ng/mL, with awakening usually occurring at levels less than 225 ng/mL.

Pharmacokinetics

The pharmacokinetics of etomidate has been calculated after single bolus doses and after continuous infusion (see Table 26-1).[416] The time course of plasma disappearance after a 0.3-mg/kg bolus is shown in Figure 26-17. The kinetics of etomidate is best described by an open three-compartment model. The drug has an initial distribution half-life of 2.7 minutes, a redistribution half-life of 29 minutes, and an elimination half-life of 2.9 to 5.3 hours.[416] Clearance of etomidate by the liver is high (18 to 25 mL/kg/min), with a hepatic extraction ratio of 0.5 ± 0.9 [407,413] Drugs affecting hepatic blood flow alter the elimination half-life. Because redistribution is the mechanism whereby the effect of a bolus of etomidate is dissipated, hepatic dysfunction should not appreciably alter recovery from an induction dose. Etomidate is 75% protein bound.[417] Pathologic conditions altering serum proteins (e.g., hepatic or renal disease) vary the amount of the free (unbound) fraction and may cause a given dose to have an exaggerated pharmacodynamic effect.[417] A hemorrhagic shock model

in pigs bled to a mean pressure of 50 mm Hg did not alter etomidate pharmacokinetics or pharmacodynamics.[418] This finding contrasts with the marked changes seen in this same model with other IV anesthetics.

In patients with cirrhosis, the volume of distribution is doubled, whereas clearance is normal; the result is an elimination half-life that is twice normal.[419] The initial distribution half-life and clinical effect are likely unchanged. Increasing age is associated with a smaller initial volume of distribution and a decreased clearance of etomidate.[420] The short elimination half-life and the rapid clearance of etomidate make it suitable for administration in a single dose, in multiple doses, or in a continuous infusion.

Pharmacology

Effects on the Central Nervous System

The primary action of etomidate on the CNS is hypnosis, which is achieved in one arm–brain circulation after a normal induction dose (0.3 mg/kg).[407] Etomidate has no analgesic activity. Plasma levels required for the maintenance of anesthesia are approximately 300 to 500 ng/mL, for sedation are 150 to 300 ng/mL, and for awakening are 150 to 250 ng/mL (see Fig. 26-17).[413,414,416] The mechanism by which etomidate produces hypnosis is not fully elucidated; however, it seems largely (but not solely) related to GABA. Its action may be antagonized by GABA antagonists.[421] Generally, the mechanism of action of etomidate seems to be similar to that established so far for propofol (see earlier).[422] For etomidate, it seems that the β2 and β3 subunits are more important for its hypnotic action than the α1 $GABA_A$ subunit.[42,423]

At a dose of 0.2 to 0.3 mg/kg, etomidate reduces CBF (by 34%) and $CMRO_2$ (by 45%) without altering MAP.[424] CPP is maintained or increased, and there is a beneficial net increase in the cerebral oxygen supply-to-demand ratio.[424] Etomidate given in doses sufficient to produce EEG burst suppression acutely decreases ICP by 50% in patients with already increased ICP, returning increased ICP to almost normal values.[425,426] The decrease in ICP is maintained in the period immediately after intubation.[426] To maintain the effects of etomidate on ICP, high infusion rates (60 μg/kg/min) are necessary.[427] In contrast to the situation with other neuroprotective drugs such as thiopental, reduction of ICP and maintenance of burst suppression are not associated with a decrease in MAP.[426] Because cerebrovascular reactivity is still maintained after etomidate administration,[427] hyperventilation theoretically may reduce ICP further when used in conjunction with etomidate. In animals, etomidate reduced neuronal death after acute cortical ischemic insult.[428,429] Other investigators disagree on the neuroprotective qualities of etomidate.[430] Deeper structures, such as the brainstem, may not be afforded ischemic protection by etomidate.[431]

Etomidate produces changes in the EEG similar to those produced by the barbiturates.[432] There is an initial increase in alpha amplitude with sharp beta bursts followed by mixed delta-theta waves, with delta wave activity predominating before the onset of periodic burst suppression.[432] The absence of beta waves in the initial phase of induction with etomidate is the major difference in EEG changes compared with thiopental.[432] Etomidate has been associated with grand mal seizures[433,434] and produces increased EEG activity in epileptogenic foci. This feature has proved useful for intraoperative mapping of seizure foci before surgical ablation.[434] Etomidate also is associated with a frequent incidence of myoclonic movement.[409,410] Myoclonus is not thought to be associated with seizure-like EEG activity.[432] The myoclonic movement is believed to result from activity either in the brainstem or in deep cerebral structures.

The effect of etomidate on auditory evoked potentials is similar to that produced by the inhaled anesthetics. There is a dose-dependent increase in latency and a decreasing amplitude of the early cortical components (Pa and Nb).[435]

Effects on the Respiratory System

Etomidate has less effect on ventilation than other anesthetics used to induce anesthesia. It does not induce histamine release either in healthy patients or in patients with reactive airway disease.[436] Ventilatory response to carbon dioxide is depressed by etomidate, but the ventilatory drive at any given carbon dioxide tension is greater than that following an equipotent dose of methohexital.[226] Induction with etomidate produces a brief period of hyperventilation, sometimes followed by a similarly brief period of apnea,[437] which results in a slight (±15%) increase in $Paco_2$, but no change in the partial pressure of arterial oxygen (Pao_2).[438] The incidence of apnea is altered by premedication.[439] Hiccups or coughing may accompany etomidate induction, with an incidence similar to that after methohexital induction.[407]

In laboratory models, etomidate seems to be as effective as propofol in relaxing precontracted tracheal rings, but less effective than propofol in preventing tracheal ring contraction by muscarinic agonists.[440] Etomidate's action on pulmonary vascular tone are similar to the actions observed with ketamine and propofol.[441]

Effects on the Cardiovascular System

The minimal effect of etomidate on cardiovascular function sets it apart from other rapid-onset anesthetics (see Table 26-2).[442,443] An induction dose of 0.3 mg/kg of etomidate given to cardiac patients for noncardiac surgery results in almost no change in heart rate, MAP, mean pulmonary artery pressure, pulmonary capillary wedge pressure, central venous pressure, stroke volume, cardiac index, and pulmonary and systemic vascular resistance.[442] A large dose of etomidate, 0.45 mg/kg (which is 50% larger than a normal induction dose),[444] also produces minimal changes in cardiovascular variables. In patients with ischemic heart disease or valvular disease, etomidate (0.3 mg/kg) produces similar minimal alterations in cardiovascular variables.[442] In patients with mitral or aortic valve disease, etomidate may produce greater changes in MAP (an approximate 20% decrease)[438] than in patients without cardiac valvular disease. After induction (18 mg) and infusion (2.4 mg/min), etomidate produces a 50% decrease in myocardial blood flow and oxygen consumption, and a 20% to 30% increase in coronary sinus blood oxygen saturation.[108] The myocardial oxygen supply-to-demand ratio is well maintained. There is minimal effect on the QT interval.[445]

The hemodynamic stability seen with etomidate may be due partly to its unique lack of effect on the sympathetic nervous system and on baroreceptor function.[122] Etomidate lacks analgesic efficacy, however, and needs to be combined with an opiate to prevent hemodynamic perturbations during laryngoscopy and intubation.

Endocrine Effects

Ledingham and Watt[401] in 1983 first raised concerns regarding long-term etomidate infusion in critically ill patients. They pos-

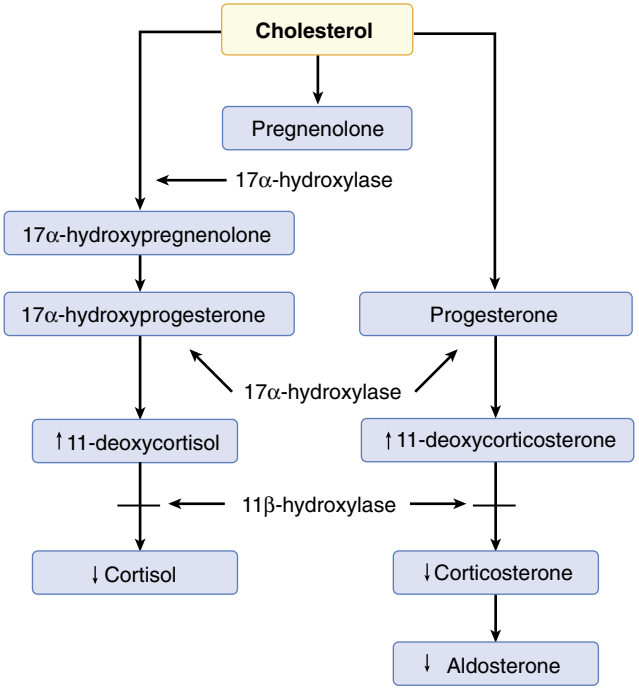

Figure 26-18 Pathway for the biosynthesis of cortisol and aldosterone. The sites at which etomidate affects cortisol-aldosterone synthesis by its action on 11β-hydroxylase (major site) and 17α-hydroxylase (minor site) are illustrated.

tulated that adrenocortical suppression secondary to long-term etomidate infusion was the cause of the increased mortality.[401]

The specific endocrine effects manifested by etomidate are a dose-dependent reversible inhibition of the enzyme 11β-hydroxylase, which converts 11-deoxycortisol to cortisol, and a relatively minor effect on 17α-hydroxylase (Fig. 26-18).[446,447] This activity results in an increase in the cortisol precursors 11-deoxycortisol and 17-hydroxyprogesterone and an increase in ACTH. The blockade of 11β-hydroxylase and, to a lesser extent, 17α-hydroxylase[446] seems to be related to the free imidazole radical of etomidate-binding cytochrome P-450.[447,448] This results in inhibition of ascorbic acid resynthesis, which is required for steroid production in humans.[448] The blockade of the cytochrome P-450–dependent enzyme 11β-hydroxylase also results in decreased mineralocorticoid production and an increase in intermediaries (11-deoxycorticosterone).[402,404] Vitamin C supplementation restores cortisol levels to normal after the use of etomidate.[448] Because minor adrenocortical suppressive effects were shown to follow even single bolus doses,[446] concerns about the use of etomidate for anesthetic induction arose.[403] No large prospective studies have been done, but several smaller studies have provided some insight into the exact nature of adrenocortical suppression after an induction dose.

Duthie and colleagues[449] showed that in otherwise healthy patients undergoing minor peripheral surgery, plasma cortisol levels were slightly depressed from the preinduction levels for 1 hour postoperatively. The nadir of mean cortisol levels did not fall out of the normal range. 11-Deoxycorticosterone, substrate for the etomidate-inhibited 11β-hydroxylase, peaked at very high levels compared with the thiopental control group.[449] In another study, patients undergoing orthopedic surgery were given an etomidate induction followed by an infusion of etomidate (average total dose 68 mg). Temporary adrenocortical suppression, as measured by a reduced response to ACTH stimulation, was documented for 6 hours postoperatively and returned to normal by 20 hours postoperatively. Postoperative cortisol levels in the etomidate study patients were not significantly different from the levels in patients who received a midazolam induction. As in the study by Duthie and colleagues,[449] mean cortisol levels in the etomidate group remained in the normal range at all times postoperatively.[450] Other studies have shown similar results when evaluating etomidate induction doses; none reported adverse outcomes secondary to short-term adrenocortical suppression.[402,446]

In each of the prospective etomidate studies documenting adrenocortical suppression without associated clinical sequelae, a conclusion of safety was not forthcoming. The reason was that these studies did not address high-stress procedures, in which the benefit of a high cortisol level in response to a major stress could be desirable, and etomidate's blockade of the response to ACTH could be detrimental. In 1994, the cortisol levels during and after coronary artery bypass surgery were compared in patients receiving total IV anesthesia with etomidate/fentanyl (mean etomidate dose of 87 ± 3 mg) versus midazolam/fentanyl. Except for the first hour after induction, cortisol levels were the same or higher in the etomidate group compared with the midazolam group, a finding implying that the body's ability to respond to a high surgical stress was still intact despite high doses of etomidate. This finding suggests that etomidate is probably safe for use in major surgery.[451]

Three facts suggest that the issue of temporary adrenocortical suppression after perioperative induction doses of etomidate is not clinically significant: (1) Although there is one questionable case report suggesting acute symptomatic postoperative adrenocortical suppression in a 74-year-old ICU patient,[452] there are no other known reports of any negative clinical outcome associated with an etomidate induction despite millions of uses. (2) After etomidate induction, the nadir of cortisol levels usually remains in the low-normal range, and the adrenocortical suppression is a short-lived phenomenon. (3) High-stress surgery can overcome the temporary adrenocortical suppression caused by etomidate.

Other Effects

Although etomidate provides stable hemodynamics and minimal respiratory depression, it is associated with several adverse effects when used for induction, including nausea and vomiting, pain on injection, myoclonic movement, and hiccups. Etomidate has been associated with a frequent (30% to 40%) incidence of nausea and vomiting.[409-411,439] More recently, etomidate in a lipid emulsion was associated with an equal incidence of postoperative nausea compared with propofol.[453]

Superficial thrombophlebitis of the vein used may occur 48 to 72 hours after etomidate injection.[454] The incidence may be 20% when etomidate is given alone through a small (21-gauge) IV needle. Intra-arterial injection of etomidate is not associated with local or vascular disease. Pain on injection, similar in incidence to pain with propofol,[175] can be essentially eliminated by injecting lidocaine immediately before injection of etomidate; 20 to 40 mg may be enough.[455] Pain on injection is reduced further by using a large vein. The incidence of pain on injection is 0 to 50%. The lipid formulation of etomidate also is associated with a much lower incidence of pain on injection, thrombophlebitis, and histamine release on injection.[456]

The incidence of muscle movement (myoclonus) and of hiccups also is highly variable (0 to 70%), but myoclonus is reduced by premedication with either a narcotic or 0.015 mg/kg of midazolam 90 seconds before induction.[457] Etomidate enhances the neuromuscular blockade of nondepolarizing neuromuscular blockers.[458] In vitro, etomidate inhibits aminolevulinic acid synthetase, but it has been administered to patients with porphyria without inducing an acute attack of porphyria.[459]

The carrier for etomidate, propylene glycol, also has been reported to have some negative effects. Some reports suggest that propylene glycol can be associated with a small degree of hemolysis.[405] Additionally, high-dose prolonged infusion has been reported to result in propylene glycol toxicity (a hyperosmolar state).[460]

Uses

Etomidate is most appropriate in patients with cardiovascular disease, reactive airway disease, intracranial hypertension, or any combination of disorders indicating the need for an induction agent with limited or beneficial physiologic side effects. The hemodynamic stability of etomidate is unique among the rapid-onset anesthetics used to induce anesthesia.

Etomidate has been used primarily in sick patients. In multiple studies, etomidate has been used for induction in patients with a compromised cardiovascular system who are undergoing coronary artery bypass surgery or valve surgery, and in patients requiring induction of general anesthesia for percutaneous transluminal coronary angioplasty, aortic aneurysm repair, and thoracic surgery. When etomidate is used in combination with fentanyl, titrating etomidate up to 0.6 mg/kg maintains blood pressure and heart rate in a narrow range, preserving coronary perfusion pressure in these patients with probable coronary artery disease, while blunting the response to intubation and avoiding unnecessary stress. For cardioversion, the rapid onset, quick recovery, and maintenance of blood pressure in these sometimes hemodynamically tenuous patients, combined with continued spontaneous respiration, make etomidate an acceptable choice,[175] although there is one report of myoclonus interfering with electrocardiographic evaluation.[461]

Although definitive proof of the neuroprotective effect of etomidate in humans is lacking, the combination of animal data and anecdotal reports of successful use of etomidate in neurosurgical procedures such as giant aneurysm clippings makes etomidate a reasonable choice during neurosurgical induction.[414,426,428] In addition, etomidate should be considered as an anesthetic to reduce increased ICP when maintenance of cerebral or coronary perfusion pressure also is important. Trauma patients with questionable volume status may be well served by an etomidate induction. Although the indirect sympathomimetic effect seen with ketamine induction is absent, there is no direct myocardial depression and no confusion in the differential diagnosis of postoperative delirium. This is especially important in patients whose trauma may be related to drug or alcohol use. When using the drug in trauma patients, loss of consciousness by itself can be associated with decreased adrenergic output, and postinduction controlled ventilation by itself can exacerbate a decreased preload (see Chapter 72). Both of these factors may cause a significant decrease in blood pressure at induction despite etomidate having no direct cardiovascular drug effect.

During an infusion, hemodynamic status is well maintained, and adequate spontaneous ventilation is present.[294] The incidence of pain on injection and of myoclonus and thrombophlebitis tends to be less with an infusion technique.[413,462]

Short-term sedation with etomidate is useful in hemodynamically unstable patients, such as patients requiring cardioversion[175] or patients requiring sedation after an acute myocardial infarction or with unstable angina for a minor operative procedure.[463] Etomidate also is useful for intubation in the emergency department and in the ICU. When used during electroconvulsive therapy, etomidate can produce longer seizures compared with other hypnotics.[464] Prolonged sedation for patients in the ICU, although initially popular after the release of etomidate, is now contraindicated owing to inhibition of corticosteroid and mineralocorticoid production, with subsequent increase in morbidity.[401,403,465]

α-Adrenergic Agonists: Dexmedetomidine

History

The α_2-adrenergic agonists provide sedation, anxiolysis, hypnosis, analgesia, and sympatholysis. The initial impetus for the use of α_2 agonists in anesthesia resulted from observations made in patients during anesthesia who were receiving clonidine therapy.[466,467] This was soon followed by a description of the minimum alveolar concentration (MAC) reduction of halothane by clonidine.[468] Dexmedetomidine is a more selective α_2 agonist with a 1600 greater selectivity for the α_2 receptor compared with the α_1 receptor. It was introduced in clinical practice in the United States in 1999 and approved by the FDA only as a short-term (<24 hours) sedative for mechanically ventilated adult ICU patients. Dexmedetomidine is now being used off-label outside of the ICU in various settings, including sedation and adjunct analgesia in the operating room, sedation in diagnostic and procedure units, and for other applications such as withdrawal/detoxification amelioration in adult and pediatric patients.[469,470]

Physicochemical Characteristics

Dexmedetomidine is the d-enantiomer of medetomidine, a substance that has been used for sedation and analgesia in veterinary medicine for many years.[471] It shows a high ratio of specificity for the α_2 receptor (α_2/α_1 1600:1) compared with clonidine (α_2/α_1 200:1), making it a complete α_2 agonist.[472] Dexmedetomidine belongs to the imidazole subclass of α_2 receptor agonists, similar to clonidine, and its structure is illustrated in Figure 26-19. It is freely soluble in water.

Metabolism and Pharmacokinetics

Dexmedetomidine is rapidly distributed and extensively metabolized in the liver and excreted in urine and feces. It undergoes conjugation (41%), n-methylation (21%), or hydroxylation fol-

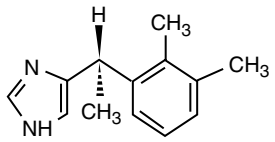

Figure 26-19 Chemical structure of dexmedetomidine.

lowed by conjugation. Dexmedetomidine is 94% protein bound, and its concentration ratio between whole blood and plasma is 0.66. Dexmedetomidine has profound effects on cardiovascular variables and may alter its own pharmacokinetics. With large doses, there is marked vasoconstriction, which probably reduces the drug's volumes of distribution. In essence, dexmedetomidine displays nonlinear pharmacokinetics.[473] Dyck and coworkers[474] found that its pharmacokinetics in volunteers is best described by a three-compartment model (see Table 26-1). These pharmacokinetic parameters apparently are unaltered by age or weight or renal failure, but clearance is a function of height.[473,475] The elimination half-life of dexmedetomidine is 2 to 3 hours, with a context-sensitive half-time ranging from 4 minutes after a 10-minute infusion to 250 minutes after an 8-hour infusion. Postoperative patients sedated with dexmedetomidine display similar pharmacokinetics to the pharmacokinetics seen in volunteers.[476]

Pharmacology

Dexmedetomidine is a nonselective α_2 agonist. Alpha$_2$ adrenoreceptors are membrane-spanning G proteins. Intracellular pathways include inhibition of adenylate cyclase and modulation of ion channels Three subtypes of α_2 adrenoreceptors have been described in humans: α_{2A}, α_{2B}, and α_{2C} (Fig. 26-20).[477] The α_{2A} adrenoreceptors are primarily distributed in the periphery, whereas α_{2B} and α_{2C} are in the brain and spinal cord. Postsynaptic located α_2 adrenoreceptors in peripheral blood vessels produce vasoconstriction, whereas presynaptic α_2 adrenoreceptors inhibit the release of norepinephrine, potentially attenuating the vasoconstriction. The overall response to α_2 adrenoreceptors agonists is related to the stimulation of α_2 adrenoreceptors located in the CNS and spinal cord. These receptors are involved in the sympatholysis, sedation, and antinociception effects of α_2 adrenoreceptors.[478]

Effects on the Central Nervous System

Sedation

The α_2 agonists produce their sedative-hypnotic effect by an action on α_2 receptors in the locus caeruleus and an analgesic action at α_2 receptors within the locus caeruleus and within the spinal cord.[479] The quality of sedation produced by dexmedetomidine seems different compared with that produced by other sedatives acting through the GABA systems. Patients receiving dexmedetomidine infusions as part of their sedation regimen in the postoperative ICU setting have been described as being very easy to wake up and having the ability to follow commands and cooperate while being tracheally intubated. Undisturbed, patients were noted to fall asleep right away.[480] Despite sound levels of sedation with dexmedetomidine, there is limited respiratory depression, providing wide safety margins.[481] This characteristic allows for "daily wake up" tests to be done in a safe fashion. This

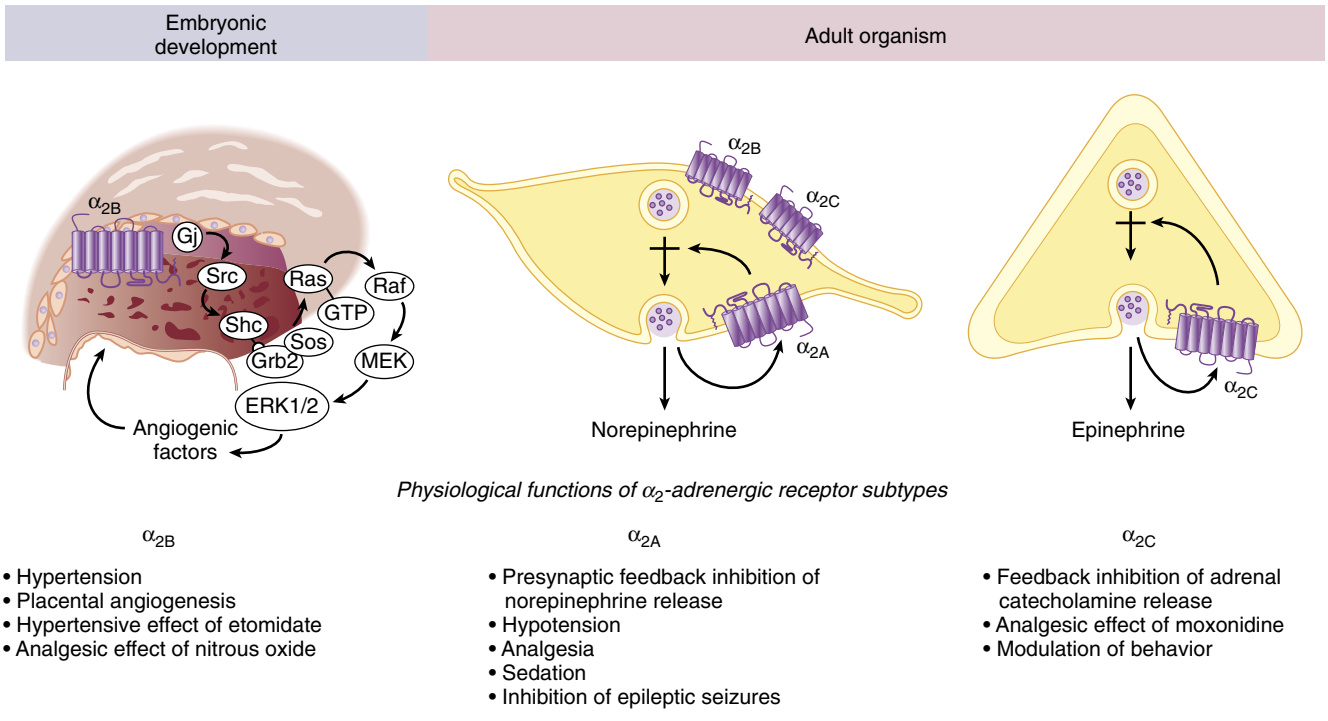

Figure 26-20 The different physiologic functions of α_2 adrenoreceptors. The *top panel* depicts the three α_2 receptor subtypes acting as presynaptic inhibitory feedback receptors to control the release of norepinephrine and epinephrine from peripheral or central adult neurons. Also, a negative feedback loop has been seen in the adrenal gland. Alpha$_{2B}$ receptors have been involved in the development of the placental vascular system during prenatal development. The *lower panel* lists a series of physiologic effects with its associated α_2 adrenoreceptors. *(From Paris A, Tonner PH: Dexmedetomidine in anaesthesia. Curr Opin Anaesthesiol 18:412-418, 2005.)*

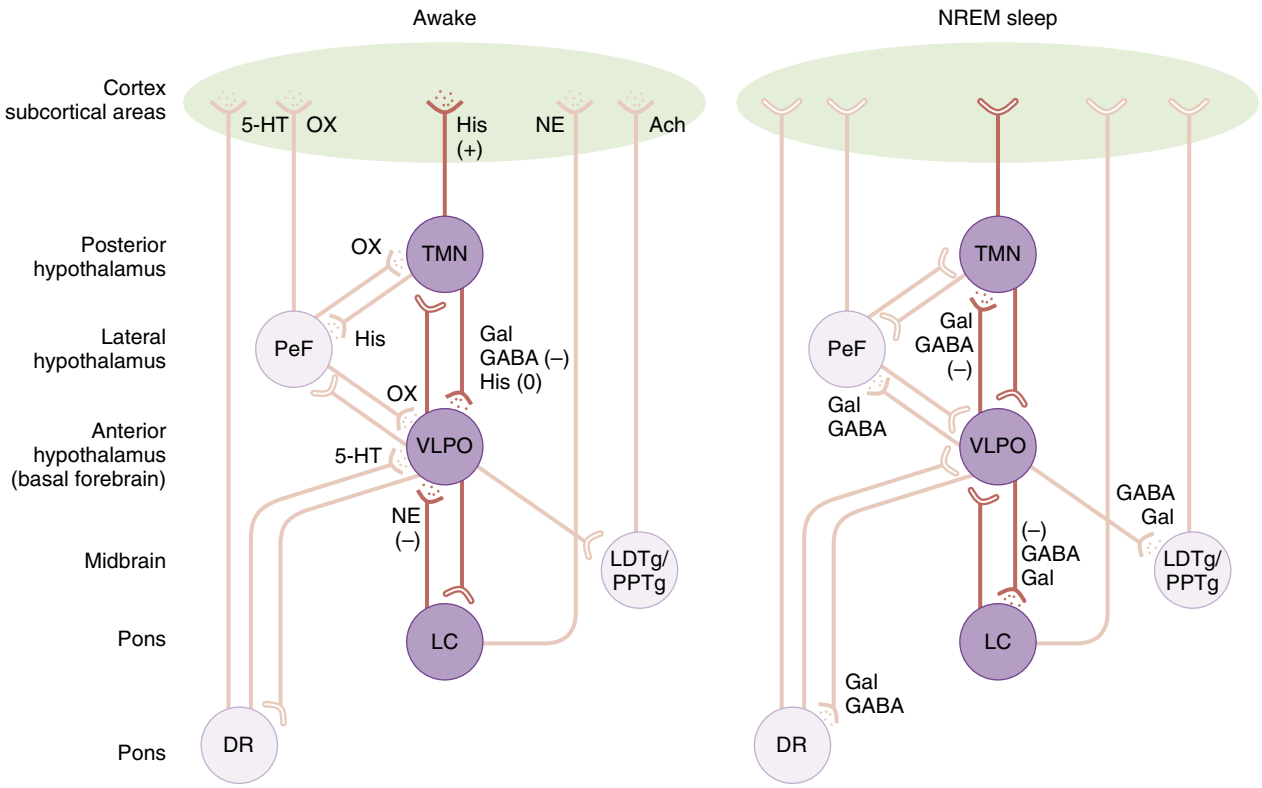

Figure 26-21 Dexmedetomidine has been shown to induce a non–rapid eye movement sleeping pattern (NREM). The stimulation of the locus caeruleus (LC) by dexmedetomidine (*right diagram*) releases the inhibition the LC has over the ventrolateral preoptic nucleus (VLPO). The VLPO subsequently releases γ-aminobutyric acid (GABA) onto the tuberomammillary nucleus (TMN). This inhibits the release of the arousal-promoting histamine on the cortex and forebrain, inducing the loss of consciousness. *(From Ebert T, Maze M: Dexmedetomidine: Another arrow for the clinician's quiver. Anesthesiology 101:569-570, 2004.)*

critical test—when ventilated ICU patients are taken off all sedatives to assess their mental status and titrate sedation—shortens their ventilated and ICU length of stay.[482]

The α_2 agonists act through the endogenous sleep-promoting pathways to exert their sedative effect (Fig. 26-21). Dexmedetomidine produces a decrease in activity of the projections of the locus caeruleus to the ventrolateral preoptic nucleus. This increases GABAergic and galanin release in the tuberomammillary nucleus, producing a decrease in histamine release in cortical and subcortical projections.[483] The α_2 agonists seem to inhibit ion conductance through L-type or P-type calcium channels and facilitate conductance through voltage-gated calcium-activated potassium channels.[484] The similarity between natural sleep (non–rapid eye movement) and dexmedetomidine-induced hypnosis has been speculated to maintain cognitive and immunologic function in the sleep-deprived states (as in the ICU).[485] Dexmedetomidine can produce profound sedation, and it has been used as a total IV anesthetic when given at 10 times the normal sedation concentration range.[486]

The α_2 agonists have the advantage that their effects are readily reversible by α_2-adrenergic antagonists (e.g., atipamezole).[487] Atipamezole is not currently approved for human use. Similar to other adrenergic receptors, the α_2 agonists also show tolerance after prolonged administration.[488] Because dexmedetomidine is approved by the FDA only for short-term sedation (24 hours), tolerance, dependence, or addiction does not seem to be a problem. Dexmedetomidine can be employed for addiction treatment; dexmedetomidine has been described for use in rapid opioid detoxification, cocaine withdrawal, and iatrogenic induced benzodiazepine and opioid tolerance after prolonged sedation.[489] In animals, dexmedetomidine, in contrast to opioids, does not result in hyperalgesia or allodynia after its withdrawal.[490] Rats rendered tolerant to morphine also show a decrease in efficacy of hypnotic and analgesic effects of dexmedetomidine. As tolerance to opioids recovers, there is a more rapid recovery of the hypnotic effect of dexmedetomidine than its analgesic efficacy.[491] These data would tend to indicate a possible cross-tolerance between receptors.

Analgesia

The analgesic effects of dexmedetomidine are complex. Alpha$_2$ agonists do have an analgesic effect when injected via the intrathecal or epidural route.[492] Clonidine injected in the neural axis helps with short-term pain, cancer pain, and neuropathic pain.[493,494] Intrathecally injected dexmedetomidine in sheep reduces blood pressure in 1 minute. When dexmedetomidine is injected into the epidural space, it rapidly diffuses into the CSF (in one study,[495] 22% of the injected dose was identified in the CSF). The effects on blood pressure are slower in onset with an epidural injection than with an intrathecal administration. Epidural effects are seen in 5 to 20 minutes. The primary site of analgesic action is thought to be the spinal cord.[495] Systemic use of dexmedetomidine shows narcotic sparing. In the postoperative ICU setting, narcotic requirements were reduced by 50% when patients were receiving a dexmedetomidine drip compared with placebo.[480]

Some of the systemic analgesic effects have been attributed to the confounding sedative effects.[496] In human pain studies, the

results of systemically administered dexmedetomidine are inconsistent. Modest reductions in pain were observed in cold pressor tests when patients were receiving dexmedetomidine.[497] More recently, in a model of heat and electrical pain in human volunteers, dexmedetomidine was not capable of attenuating the pain response in the clinical dose range when subjects were conscious.[485] The analgesic effect of dexmedetomidine has been compared with remifentanil. In a noxious heat versus pain intensity plot obtained in a group of volunteers, dexmedetomidine was less effective in reducing pain (less of a right shift of the curve) than remifentanil. Also, the slope was different, suggesting a different mechanism of action and an effect from sedation.[498] In the clinical setting, when pain is likely to occur, if dexmedetomidine is to be used, the addition of a narcotic seems warranted.

Central Nervous System Protection and Other Central Nervous System Effects

The CNS protective effects are not well defined. Dexmedetomidine in animal models of incomplete cerebral ischemia and reperfusion reduces cerebral necrosis and improves neurologic outcome. In a model of focal ischemia in rabbits, dexmedetomidine, administered at doses that reduced the MAC of halothane by 50%, resulted in less cortical neuronal damage than when halothane was administered alone at equieffective MAC concentrations.[499] In a rat model of unilateral carotid ligation accompanied by systemic hypotension, the administration of dexmedetomidine provided for lower plasma catecholamines with less neurologic and histopathologic damage.[500] The prevalent idea was that dexmedetomidine reduced the intracerebral catecholamine outflow during injury and resulted in less neural tissue damage with better neurologic outcome.[501] Others have found no reduction in cerebral catecholamines after receiving dexmedetomidine during injury.[502] The neuroprotection may be attributed to modulation of proapoptotic and antiapoptotic proteins.[341] Also, the reduction of the excitatory neurotransmitter glutamate during injury may explain some of the protective effects.[503]

The neuroprotective properties of dexmedetomidine in humans have not been investigated. Little is known of the effects of dexmedetomidine alone on ICP and CBF. In patients after pituitary surgery, a target concentration of 600 ng/mL of dexmedetomidine resulted in no increase in lumbar CSF pressure.[504] In dogs, in the presence of volatile anesthetics and dexmedetomidine, CBF was decreased, and oxygen consumption was maintained.[505,506] CBF velocity, as measured by transcranial Doppler, decreased with increasing concentrations of dexmedetomidine in parallel with decreasing MAP and increasing $Paco_2$.[507] These decreases in CBF are not accompanied by a reduction in $CRMO_2$. Despite the significant reduction in CBF with dexmedetomidine, there was no evidence of cerebral ischemia in a dog model.[551] In a preliminary study in patients undergoing cerebrovascular surgery using dexmedetomidine, there was no evidence of a detrimental effect on local brain tissue oxygenation.[508] More recently, in a study in six normal volunteers, the administration of dexmedetomidine to achieve serum levels of 0.6 ng/mL and 1.2 ng/mL (with and without hyperventilation) produced the predicted reduction of CBF with a concomitant reduction in $CRMO_2$.[509] This finding suggests the maintenance of the cerebral oxygen supply-to-demand relationship; however, further work in injured brains needs to be done.

In a rat seizure model, dexmedetomidine showed significant proconvulsant action, which is consistent with previous findings that inhibition of central noradrenergic transmission facilitates seizure expression.[510] This finding is in contrast to an anticonvulsant effect shown in rats after kainic acid–induced seizures.[511] As yet, there have been no reports of seizures in humans. Dexmedetomidine has been used in neurosurgical procedures involving neurophysiologic monitoring. Cortical evoked potentials amplitudes and latencies were minimally affected when using dexmedetomidine intraoperatively when patients underwent craniotomies.[508] Dexmedetomidine also is able to reduce muscle rigidity after high-dose opioid administration.[512] In resting volunteers, dexmedetomidine increased growth hormone secretion in a dose-dependent manner, but it had no effect on other pituitary hormones.[513,514] Dexmedetomidine ablates memory in a dose-dependent manner. In concentrations used for clinical sedation (i.e., 0.7 ng/mL), recall of picture cards is preserved. Increasing the concentration of dexmedetomidine to 2 ng/mL largely ablates recall and recognition of a picture card.[515]

Effects on the Respiratory System

In volunteers, dexmedetomidine at concentrations producing significant sedation reduces minute ventilation, but retains the slope of the ventilatory response to increasing carbon dioxide.[516] The changes in ventilation appeared similar to those observed during natural sleep. Ebert and colleagues,[515] infusing dexmedetomidine to concentrations of 15 ng/mL in spontaneously breathing volunteers, showed no change in arterial oxygenation or pH. At the highest concentrations, $Paco_2$ increased by 20%. Respiratory rate increased with increasing concentration from 14 breaths/min to 25 breaths/min.[515] When dexmedetomidine and propofol were titrated to equal sedative end points (BIS of 85), both resulted in no change in respiratory rate.[517] In a study comparing the effects of remifentanil and dexmedetomidine on respiratory parameters in normal volunteers,[518] the hypercapnic ventilatory response was unaffected even at doses that produced unresponsiveness to vigorous stimulation. $Paco_2$ increased mildly with dexmedetomidine, but it reached a plateau after the first increment. Dexmedetomidine also exhibited a hypercarbic arousal phenomenon, which has been described during normal sleep and is a safety feature. IV or inhaled dexmedetomidine has been implicated in blocking histamine-induced bronchoconstriction in dogs.[519]

Effects on the Cardiovascular System

The basic effects of α_2 agonists on the cardiovascular system are decreased heart rate; decreased systemic vascular resistance; and indirectly decreased myocardial contractility, cardiac output, and systemic blood pressure. By developing highly selective α agonists, it has been hoped to decrease some of these adverse cardiovascular effects and to maximize the desirable hypnotic-analgesic properties. The hemodynamic effects of a bolus of dexmedetomidine in humans have shown a biphasic response. An acute IV injection of 2 μg/kg resulted in an initial increase in blood pressure (22%) and decrease in heart rate (27%) from baseline that occurred at 5 minutes after injection. This initial increase in blood pressure is probably due to the vasoconstrictive effects of dexmedetomidine when stimulating peripheral α_2 receptors. Heart rate returned to baseline by 15 minutes, and blood pressure gradually declined to approximately 15% below baseline by 1 hour. After an IM injection of the same dose, the initial increase in blood pressure was not seen, and heart rate and blood pressure remained within 10% of baseline.[473]

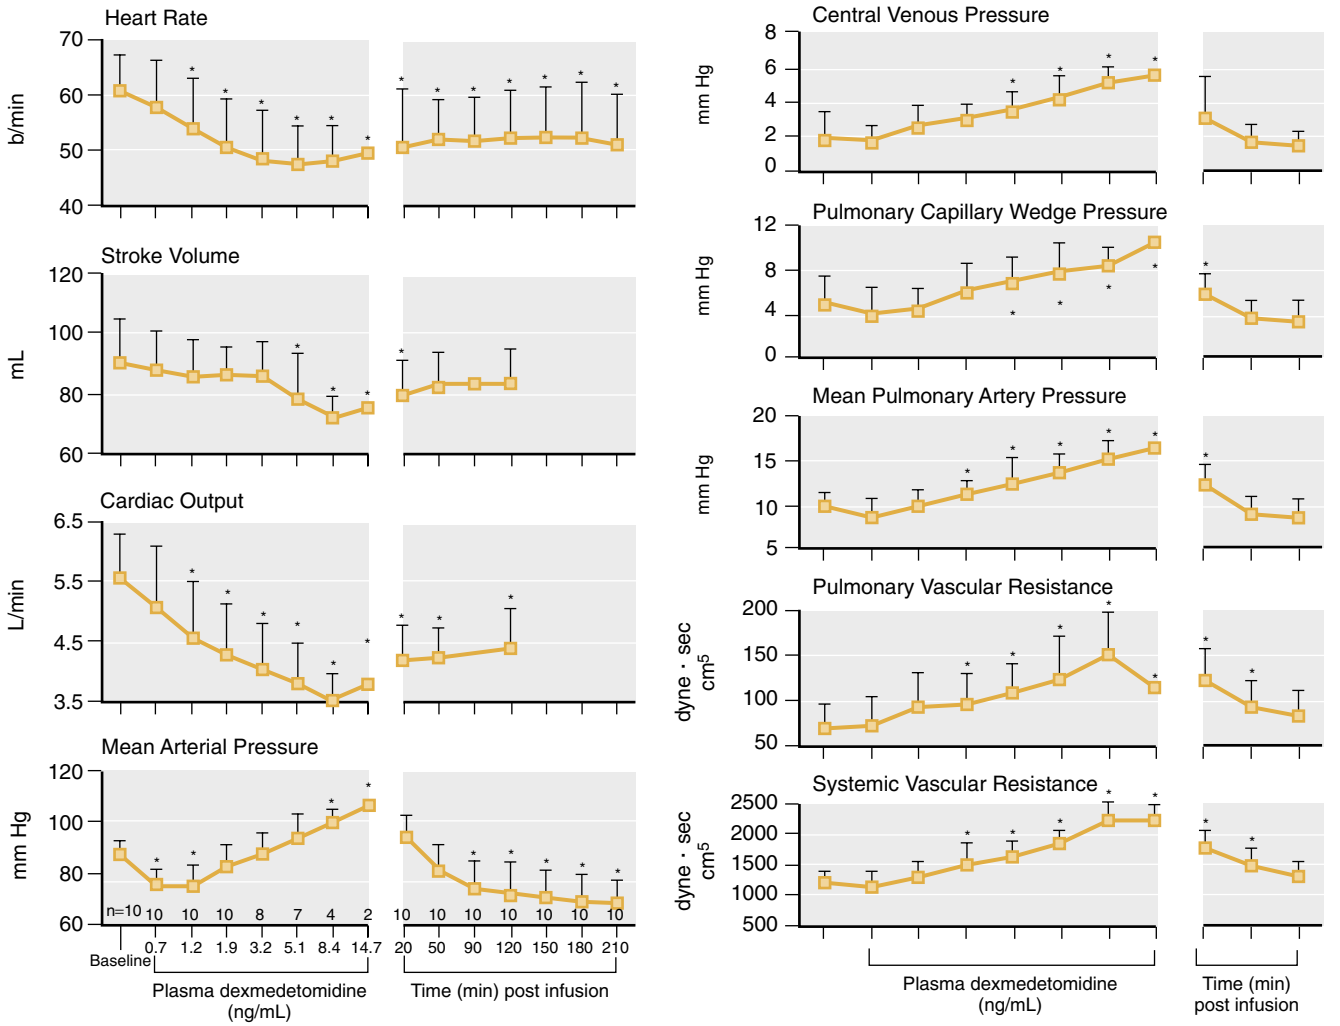

Figure 26-22 Effects of increasing plasma concentrations of dexmedetomidine.

Ebert and colleagues[515] performed an elegant study in volunteers using a target-controlled infusion system to provide increasing concentrations (0.7 to 15 ng/mL) of dexmedetomidine (Fig. 26-22). The lowest two concentrations produced a decrease in MAP (13%) followed by progressive increase (12%). Increasing concentrations of dexmedetomidine also produce progressive decreases in heart rate (maximum 29%) and cardiac output (35%).[515] Infusion of dexmedetomidine in volunteers also has been shown to result in a compensated reduction in systemic sympathetic tone without changes in baroreflex sensitivity. It also blunts the heart rate and systemic sympathetic activation owing to sweating, but is less effective in blunting cardiac sympathetic response to shivering.[520]

The incidence of hypotension and bradycardia may be related to the administration of a loading dose. Omitting the loading dose or not giving more than 0.4 μg/kg reduces the incidence of hypotension, or makes it less pronounced. Giving the loading dose over 20 minutes also minimizes the transient hypertension.[521] In several studies after IM and IV administration, dexmedetomidine caused, in a small percentage of patients, profound bradycardia (<40 beats/min) and occasionally sinus arrest/pause. Generally, these episodes resolved spontaneously or were readily treated without adverse outcome by anticholinergics. It would be expected from its profile that dexmedetomidine would be beneficial to the ischemic myocardium. In animal models, dexmedetomidine showed some beneficial effects on the ischemic heart through decreased oxygen consumption and redistribution of coronary flow from nonischemic zones to ischemic zones after acute brief occlusion.[522] Dexmedetomidine also decreases serum lactate in a dog model of coronary ischemia with an associated decrease in heart rate and measured catecholamines. It also produced an increase in the endocardial/epicardial blood flow ratio by 35%.[523]

The perioperative use of α_2 agonists reduces the incidence of perioperative myocardial ischemia.[524] More recently, Wallace and associates[525] showed that the administration of clonidine in the preoperative period reduces the incidence of perioperative cardiac ischemia from 31% to 14%, and reduces the mortality for 2 years from 29% to 15% compared with placebo. The only data on potential benefits in perioperative ischemia prevention with dexmedetomidine are provided in an underpowered study in vascular surgery patients who received the drug in the perioperative period. Blood pressure and heart rate were lower in the dexmedetomidine group, but these patients also needed the use of more

drugs intraoperatively to sustain blood pressure and heart rate. No reductions of ischemic events were noted.[189] No rebound effects have been found when discontinuing dexmedetomidine drips, even when it is given for more than 24 hours.[526]

A frequently reported side effect of dexmedetomidine has been a dry mouth. Dry mouth is due to a decrease in saliva production.[527]

Uses

Dexmedetomidine has been approved as a short-term sedative for adult intubated patients in the ICU. Given its well-documented beneficial effects of anxiolysis, sedation, analgesia, and sympatholysis with minimal respiratory depression, it also has been used in various other clinical scenarios.

Intensive Care Unit

Dexmedetomidine has advantages over propofol for sedation in mechanically ventilated postoperative patients. When both drugs were titrated to equal sedation as assessed by the BIS (approximately 50) and Ramsay sedation score (5), dexmedetomidine patients required significantly less narcotics (alfentanil 2.5 mg/hr versus 0.8 mg/hr). Heart rate was slower in the dexmedetomidine group, whereas MAP was similar. The Pao_2/Fio_2 ratio was significantly higher in the dexmedetomidine group. Time to extubation after discontinuation of the infusion was similar at 28 minutes. Patients receiving dexmedetomidine seemed to have greater recall of their stay in the ICU, but all described this as pleasant overall.[528]

Several other studies have confirmed the decreased requirement for opioids (>50%) when dexmedetomidine is used for sedation compared with propofol or benzodiazepines. Most studies also describe more stable hemodynamics during weaning when dexmedetomidine is used for sedation.[529] This is of obvious benefit in patients with high risk for myocardial ischemia. For sedation in the ICU, loading doses of 0.5 to 1 μg/kg have been used. Omitting the bolus or giving the lower dose has been associated with fewer episodes of severe bradycardia and other hemodynamic perturbations. Infusion rates of 0.1 to 1 μg/kg/hr are generally needed to maintain adequate sedation. Delirium in the ICU is a risk factor for increased length of stay and increased mortality.[530] In a double-blind, randomized controlled trial of sedation in ventilated patients with dexmedetomidine versus lorazepam, it was found that using dexmedetomidine infusions provided more days alive without delirium or coma and a greater amount of time spent at the appropriate sedation level compared with lorazepam.[531]

α_2-adrenoreceptor agonists have been used in the treatment of alcohol and drug withdrawal. In a comparison between clonidine and chlordiazepoxide in the treatment of patients with alcohol withdrawal, clonidine proved to give better anxiolysis with better hemodynamics.[532] Dexmedetomidine has been successfully used in the treatment of withdrawal of narcotics, benzodiazepines, alcohol, and recreational drugs. Maccioli[489] reported the successful use of dexmedetomidine in two adult patients, one with cocaine and alcohol withdrawal symptoms, and another with withdrawal from prolonged use of benzodiazepines and narcotics in the ICU. Dexmedetomidine controlled withdrawal behavior and allowed for successful detoxification of young cardiothoracic patients (spanning the ages of days to 17 years) who developed drug withdrawal from prolonged use of benzodiazepines and narcotics in the ICU.[533]

The unique characteristics of dexmedetomidine—providing adequate sedation with minimal respiratory depression—can be used when weaning patients from the ventilator. Siobal and colleagues[534] reported the successful weaning of five ventilated patients who had failed weaning secondary to agitation. Infusions of dexmedetomidine of 0.5 to 0.7 μg/kg/hr were used (no loading) and permitted the discontinuation of propofol in four of five patients. All patients were extubated while still on the dexmedetomidine infusion. One patient required reintubation for upper airway obstruction. The use of dexmedetomidine to facilitate daily "wake up" tests in mechanically ventilated patients seems attractive, but few data have been published.[535]

The FDA approved the use of dexmedetomidine infusions for 24 hours or less. Multiple studies have shown the safety of using this drug for longer periods, however. In data collected from prescribing patterns in 10 institutions, it was shown that dexmedetomidine was used longer than 24 hours in 33.8% of cases. It also was noted that 33% of patients received a loading dose, 27% of patients received a dose higher than the recommended maximum, and 60% of patients remained on the infusion after extubation.[536]

Anesthesia

As a premedicant, dexmedetomidine, at IV doses of 0.33 to 0.67 μg/kg given 15 minutes before surgery, seems efficacious, while minimizing the cardiovascular side effects of hypotension and bradycardia.[537] Within this dosage range, dexmedetomidine reduces thiopental requirements (by ±30%) for short procedures,[537] reduces the requirements of volatile anesthetics (by ±25%), and more effectively attenuates the hemodynamic response to endotracheal intubation compared with 2 μg/kg of fentanyl.[538] Dexmedetomidine also has been evaluated as an IM injection (2.5 μg/kg) with or without fentanyl administered 45 to 90 minutes before surgery. This regimen was compared with IM midazolam plus fentanyl and was found to provide equal anxiolysis, reduced response to intubation, smaller volatile anesthetic requirements, and a decreased incidence of postoperative shivering but a higher incidence of bradycardia. Atipamezole, a selective α_2 antagonist, at 50 μg/kg was effective in reversing the sedation of dexmedetomidine (2 μg/kg intramuscularly), when used to provide sedation for brief operative procedures.[487] This reversal of effects resulted in a more rapid recovery than occurred after equisedative doses of midazolam.

Dexmedetomidine has been used for sedation for monitored anesthesia care. In a study comparing the efficacy of dexmedetomidine or propofol as a sedative agent in a group of 40 patients receiving local anesthesia or regional blocks, dexmedetomidine (1 μg/kg given over 10 minutes) when used for intraoperative sedation resulted in a slower onset than propofol (75 μg/kg/min for 10 minutes), but similar cardiorespiratory effects when titrated to equal sedation. The average infusion rate of dexmedetomidine intraoperatively to maintain a BIS value of 70 to 80 was 0.7 μg/kg/min. Sedation was more prolonged after termination of the infusion, as was recovery of blood pressure. Smaller doses of opioid were needed in the first hour, however.[517]

Dexmedetomidine sedation has been done successfully in pediatric patients. Two studies, comprising 140 children 1 to 7 years old, reported successful sedation for MRI scans compared with midazolam or propofol.[539,540]

When dexmedetomidine is used as a premedication 10 minutes before general surgery for cataract removal, intraocular pressure is decreased (33%), catecholamine secretion is reduced, perioperative analgesic requirements are less, and recovery is more rapid.[541,542]

For maintenance of anesthesia, dexmedetomidine has been used in patients undergoing multiple types of surgery. In patients given an infusion regimen to achieve a plasma concentration of slightly less than 1 ng/mL, combined with 70% nitrous oxide, dexmedetomidine reduced isoflurane requirements by 90% compared with a control group.[543] One retrospective study and two prospective, randomized controlled trials in bariatric surgical patients have found that a balanced anesthetic with desflurane or propofol plus dexmedetomidine (0.5 to 0.8 µg/kg bolus plus 0.4 µg/kg/hr infusion) reduces postoperative pain scores and morphine consumption, and improves hemodynamics compared with desflurane-fentanyl or propofol-fentanyl anesthetics.[544-546]

In patients presenting for vascular surgery, three infusion rates of dexmedetomidine were compared with a placebo infusion starting 1 hour before surgery and administered until 48 hours after surgery. In the groups receiving dexmedetomidine, more vasoactive agents were required to maintain hemodynamics intraoperatively, but less tachycardia was noted postoperatively. No other significant differences were noted between the groups.[547]

Grant and colleagues[548] described the use of dexmedetomidine when securing the airway with a fiberoptic intubation in three patients undergoing cervical spine surgery. The procedure was well tolerated with no hemodynamic compromise or respiratory depression. Because this drug provides good sedation with minimal respiratory depression, it has been used in patients undergoing awake craniotomies with functional testing and electrocorticography[549] or awake carotid endarterectomies with fewer fluctuations from the desired sedation level and more stable hemodynamics.[550]

Another use of dexmedetomidine has been as an anesthetic adjunct or sedative agent for patients who are susceptible to narcotic-induced respiratory depression or sleep apnea. In a morbidly obese patient, the narcotic-sparing effects of dexmedetomidine were evident intraoperatively and postoperatively after bariatric surgery.[551] The addition of dexmedetomidine infusions to assist on transesophageal echocardiography examination has been described, with better hemodynamic profile and improved patient satisfaction than with benzodiazepine and narcotics alone, with no added respiratory depression.

The use of dexmedetomidine has dramatically increased. This highly selective α_2 agonist has a set of unique effects that include titratable sedation, sympatholysis, and analgesia without significant respiratory depression. Originally approved as a sedative in the ICU, it has found many off-label applications in the ICU, the operating room, and perioperative environment. The off-label use of dexmedetomidine in infants and children is rapidly increasing. More than 800 reports have been published regarding its use in this population.[470]

Droperidol

History

Janssen[552] synthesized haloperidol, the first member of the butyrophenones, which became the primary neuroleptic component in neuroleptanesthesia. In 1959, DeCastro and Mundeleer[553] combined haloperidol with phenoperidine (a meperidine derivative also synthesized by Janssen) in the forerunner to the practice of neuroleptanesthesia. Droperidol, a derivative of haloperidol, and fentanyl (a phenoperidine congener), both synthesized by Janssen, were used by DeCastro and Mundeleer[553] in a combination they reported to be superior to haloperidol and phenoperidine. This neuroleptanesthesia combination produced more rapid onset of analgesia, less respiratory depression, and fewer extrapyramidal side effects. The fixed combination of droperidol and fentanyl, marketed as Innovar in the United States, was the drug primarily used for neuroleptanesthesia.

The use of neuroleptanesthesia has largely disappeared in modern anesthetic practice. The primary use of droperidol in anesthesia has been as an antiemetic and to a lesser extent as a sedative and antipruritic. The present package insert for droperidol in the United States carries a black box warning regarding the potential for fatal arrhythmias and recommendations that it be administered only during continuous electrocardiogram monitoring. With the withdrawal of droperidol in certain countries and more stringent labeling regarding potentially lethal dysrhythmias in others, the use of droperidol has decreased tremendously. The validity of the risk of low-dose droperidol in causing QT prolongation, dysrhythmias, and death has been challenged by numerous editorials, articles, and letters reviewing the cases that prompted this action.[554-559]

Droperidol is a butyrophenone, a fluorinated derivative of phenothiazines (Fig. 26-23).[345] Butyrophenones produce CNS depression, characterized by marked apparent tranquility and cataleptic immobility. They are potent antiemetics. Droperidol is a potent butyrophenone, and, similar to the others, it produces its action centrally at sites where dopamine, norepinephrine, and serotonin act. It has been postulated that butyrophenones may occupy GABA receptors on the postsynaptic membrane, reducing synaptic transmission and resulting in a buildup of dopamine in the intersynaptic cleft.[345,552] In particular, droperidol results in a submaximal inhibition of the $GABA_A$ α_1, β_1, and γ_2 acetylcholine receptors and full inhibition of α_2 acetylcholine receptors. This submaximal inhibition of GABA receptors by droperidol may explain the anxiety, dysphoria, and restlessness that may occur with its administration.[560] An imbalance in dopamine and acetylcholine is thought to occur, which results in alteration in normal transmission of signals in the CNS. The chemoreceptor trigger

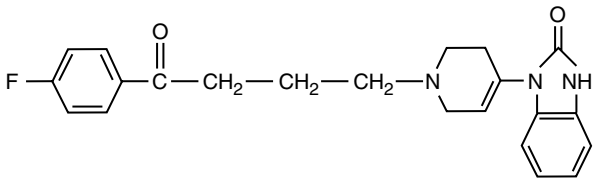

Figure 26-23 Structure of droperidol, a butyrophenone derivative.

zone is the emetic center, and "red" astrocytes transport neurolept molecules from the capillary to dopaminergic synapses in the chemoreceptor trigger zone, where they occupy GABA receptors. This is thought to be the mechanism by which droperidol exerts its antiemetic effect.[561]

Metabolism and Pharmacokinetics

Droperidol is biotransformed in the liver into two primary metabolites.[562] Its plasma decay can be described by a two-compartment model. The pharmacokinetics is shown in Table 26-1.[563]

Pharmacology

Effects on the Central Nervous System

The effects of neuroleptanesthetics on human CBF and $CMRO_2$ have not been studied. In dogs, droperidol causes potent cerebral vasoconstriction, producing a 40% reduction in CBF (see Chapter 13). No significant change in $CMRO_2$ occurs during droperidol administration.[564] The EEG in conscious patients shows some reduction in frequency, with occasional slowing.[565] Low-dose droperidol also has been shown to cause balance disturbances at the time of discharge after doses used for antiemetic prophylaxis.[566] Droperidol may produce extrapyramidal signs and worsens symptoms of Parkinson's disease. It also rarely may precipitate malignant neuroleptic syndrome.

Effects on the Respiratory System

When used alone, droperidol has little effect on the respiratory system.[567] Droperidol (0.044 mg/kg) given to surgical patients produced a slight reduction in respiratory rate,[568] and IV droperidol (3 mg) had no significant effect on tidal volume in volunteers.[569] More detailed respiratory studies are unavailable.

Effects on the Cardiovascular System

Similar to most antipsychotics, droperidol may prolong the QT interval by delaying myocardial repolarization and precipitating torsades de pointes. This seems to be dose dependent and may be of clinical significance when other causes of QT prolongation also are present.[570] Droperidol also may possess some antiarrhythmic effects that are similar to those of quinidine.[571] Droperidol produces vasodilation with a decrease in blood pressure (see Table 26-2). This effect is considered to be a result of moderate α-adrenergic blockade.[562] The dopamine-induced increase in renal blood flow (renal artery flowmeter methodology) is not significantly impaired by administration of droperidol.[572] Droperidol has little effect on myocardial contractility.[571]

Uses

Use of droperidol today in the perioperative period is largely restricted to its antiemetic and sedative effects. It is an effective antiemetic[573]; the dose for this use ranges from 10 to 20 μg/kg (0.6 to 1.25 mg for a 70-kg individual).[574] These doses of droperidol, given at the start of anesthesia for operations lasting 1 hour, reduce the incidence of nausea and vomiting by about 30%. These doses given at induction have little effect on wake-up time, but should they be given at the end of surgery, there could be some residual hypnotic effect. Overall, antiemetic efficacy of droperidol alone is equal to that of ondansetron and results in an equal number of side effects, but droperidol is more cost-effective.[575] The efficacy of droperidol as an antiemetic is enhanced when used in combination with serotonin antagonists or dexamethasone or both.

Droperidol also has been shown to be effective in the treatment and prevention of pruritus secondary to opioid administration. It has been given intravenously and into the epidural space for this purpose.[576,577] When used in this fashion, droperidol also effectively reduces nausea, but it increases sedation. The safety of droperidol administration into the epidural space has not been fully evaluated, however, and it is not approved for administration via this route.

Summary

Many different IV drugs are available for use in the care of patients requiring general anesthesia. The selection of a particular drug must be based on the individual patient's need for hypnosis, amnesia, and analgesia. Drug selection must match the physiology or the pathophysiology or both of the individual patient with the pharmacology of the particular drug. A patient in shock who requires anesthesia induction should receive the drug that would produce rapid onset of effect without causing further hemodynamic compromise. The knowledge of the clinical pharmacology of each of the IV anesthetic drugs enables the clinician to induce and maintain sedation or general anesthesia safely and effectively. There is no single perfect drug for any particular patient, but rather the informed practitioner wisely employs the appropriate drug or drugs in the practice of good anesthesia care.

27 Opioids

Key Points

1. An increased understanding of the molecular pharmacology of opioid receptors and opioid-induced cellular responses allows the use of innovative techniques for analgesia.
2. Opioids suppress pain by their action in the brain, spinal cord, and peripheral nervous system.
3. Opioids affect many organ systems, including the respiratory and cardiovascular systems, and can cause a variety of adverse effects. Proper dosing and monitoring allow the adverse effects to be minimized.
4. New pharmacokinetic principles have allowed more intelligent use of opioids along with more predictable durations of action.
5. The pharmacokinetic and pharmacodynamic properties of opioids are affected by a variety of factors, such as age, body weight, organ failure, and shock. To appropriately use opioids, these factors should be taken into consideration.
6. During total intravenous anesthesia, the use of opioids is a vital part of providing the analgesic component of anesthesia. Short-acting drugs, such as remifentanil, allow dissipation of total intravenous anesthesia even more rapidly than with inhaled anesthetics.
7. New opioid delivery systems, such as transdermal fentanyl patches, are continually being developed. Such systems allow more flexibility in providing analgesia, both inside and outside the operating room.
8. Opioids can pharmacokinetically or pharmacodynamically interact with drugs used perioperatively. Drug interaction should be understood for proper patient management.

The term *opioid* refers broadly to all compounds related to opium. The word "opium" is derived from *opos*, the Greek word for juice, inasmuch as the drug is derived from the juice of the opium poppy *Papaver somniferum*. Opiates are drugs derived from opium and include the natural products morphine, codeine, and thebaine, as well as many semisynthetic congeners derived from them.

The first undisputed reference to opium is found in the writings of Theophrastus in the third century BC. During the Middle Ages, many of the uses of opium were appreciated. Opium contains more than 20 distinct alkaloids. In 1806, Sertürner reported the isolation of a pure substance in opium that he named morphine after Morpheus, the Greek god of dreams. By the middle of the 19th century, the use of pure alkaloids rather than crude opium preparations began to spread throughout the medical world.

In addition to the remarkable beneficial effects of opioids, the toxic side effects and addictive potential of these drugs have also been known for centuries. Synthetic opioid analgesics without side effects were explored, but many of the synthetic opioids share the side effects of natural opioids. The search for new opioid agonists led to the synthesis of opioid antagonists and compounds with mixed agonist/antagonist properties, which expanded therapeutic options and provided important tools for exploring the mechanisms of opioid actions. Furthermore, new methods of opioid administration, including patient-controlled analgesia (PCA) and computer-based infusion techniques, have been developed.

Pharmacology of Opioids

Classification of Opioid Compounds

Opioids can be classified as naturally occurring, semisynthetic, and synthetic (Box 27-1). The naturally occurring opioids can be divided into two chemical classes, phenanthrenes (morphine and codeine) and benzylisoquinolines (papaverine). The semisynthetic opioids are morphine derivatives in which one of several changes have been made. Synthetic opioids are classified into four groups, the morphinan derivatives (levorphanol), the diphenyl or methadone derivatives (methadone, *d*-propoxyphene), the benzomorphans (phenazocine, pentazocine), and the phenylpiperidine derivatives (meperidine, fentanyl, alfentanil, sufentanil, and remifentanil). Structures of opioid compounds are shown in Figure 27-1[1] and Table 27-1.[1]

Box 27-1 Classification of Opioid Compounds

Naturally Occurring

Morphine

Codeine

Papaverine

Thebaine

Semisynthetic

Heroin

Dihydromorphone/morphinone

Thebaine derivatives (e.g., etorphine, buprenorphine)

Synthetic

Morphinan series (e.g., levorphanol, butorphanol)

Diphenylpropylamine series (e.g., methadone)

Benzomorphan series (e.g., pentazocine)

Phenylpiperidine series (e.g., meperidine, fentanyl, sufentanil, alfentanil, remifentanil)

Opioids can be classified as agonists, partial agonists, mixed agonist-antagonists, and antagonists on the basis of their interaction with opioid receptors.

Opioid Receptors

In 1973, based on radioligand binding assays, three types of opioid receptors were postulated. They were named μ for the morphine type, κ for the ketocyclazocine type, and σ for the SKF10047 (*N*-allylnormetazocine) type. In addition, a high-affinity receptor for enkephalins was found in the mouse vas deferens and designated the δ-receptor. Furthermore, an ε-receptor was proposed as the binding site for β-endorphin in the rat vas deferens. The pharmacologic actions of opioids and the involved receptors have been analyzed (Table 27-2).

Biochemical studies were performed to purify the opioid receptor protein but have not been successful. Since the early 1990s, molecular biologic studies have elucidated the molecular structures and signal transduction mechanisms of the opioid

Table 27-2 Pharmacologic Actions of Opioids and Opioid Receptors in Animal Models

	Actions of		
	Receptor	**Agonists**	**Antagonists**

receptors. Four different cDNAs have been isolated as members of the opioid receptor family.[2] Three of them correspond to the pharmcacologically defined μ-, δ-, and κ-opioid receptors. The fourth receptor did not bind with opioid ligands with high affinity. Later, a novel peptide named nociceptin/orphanin FQ was identified as an endogenous agonist of the fourth member of the opioid receptor family.[3,4] The characteristics of three opioid receptors and the nociceptin/orphanin FQ receptor are listed in Table 27-3.

The μ-receptors are located in both the brain and spinal cord[5] and mediate a variety of pharmacologic effects of opioids. Further pharmacologic classification of the μ-receptor as μ_1, μ_2, and μ_3 has been proposed. Perhaps post-translational modification of the μ-receptor is the molecular basis of the μ-receptor subtypes. However, the molecular identity of these receptors still remains to be clarified.

Hydropathy analysis of the primary structures of the opioid receptors indicates that the opioid receptors possess seven transmembrane domains (Fig. 27-2), a characteristic structural feature of the G protein–coupled receptor. The μ-, δ-, and κ-opioid receptors and the nociceptin receptor share approximately 50% amino acid sequence homology with each other.

Several single-nucleotide polymorphisms have been identified in the human μ-opioid receptor gene.[6] The A118G mutation, an A-to-G substitution in exon 1 that results in exchange of asparagine at position 40 for aspartate (N40D), is the most common mutation leading to a change in the gene product in the human μ-opioid receptors. It was suggested that cancer patients who were homozygous for the A118G variant required higher doses of oral morphine for long-term treatment of their pain.[7] A118G mutation of the human μ-opioid receptor gene reduces analgesic responses to morphine-6-glucuronide (M6G) but does not significantly affect the respiratory depression induced by M6G.[8] Furthermore, morphine consumption via intravenous PCA after total abdominal hysterectomy was significantly greater in women homozygous for the A118G variant than in other patients.[9]

Endogenous Opioid Peptides

Enkephalin, β-endorphin, and dynorphin were identified as endogenous agonists for the δ-, μ-, and κ-opioid receptors, respectively. After purification of these peptides from mammalian tissues, cDNAs for the precursors of these peptides were cloned. cDNA cloning and amino acid determination of proopiomelanocortin demonstrated that cleavage of this precursor protein produces not only β-endorphin but also several other neuro-

DPDPE, [D-penicillamine^2, D-penicillamine^5]enkephalin; DAMGO, [D-Ala^2, MePhe^4, Gly-ol^8]enkephaline; NorBNI, norbinaltorphimine.

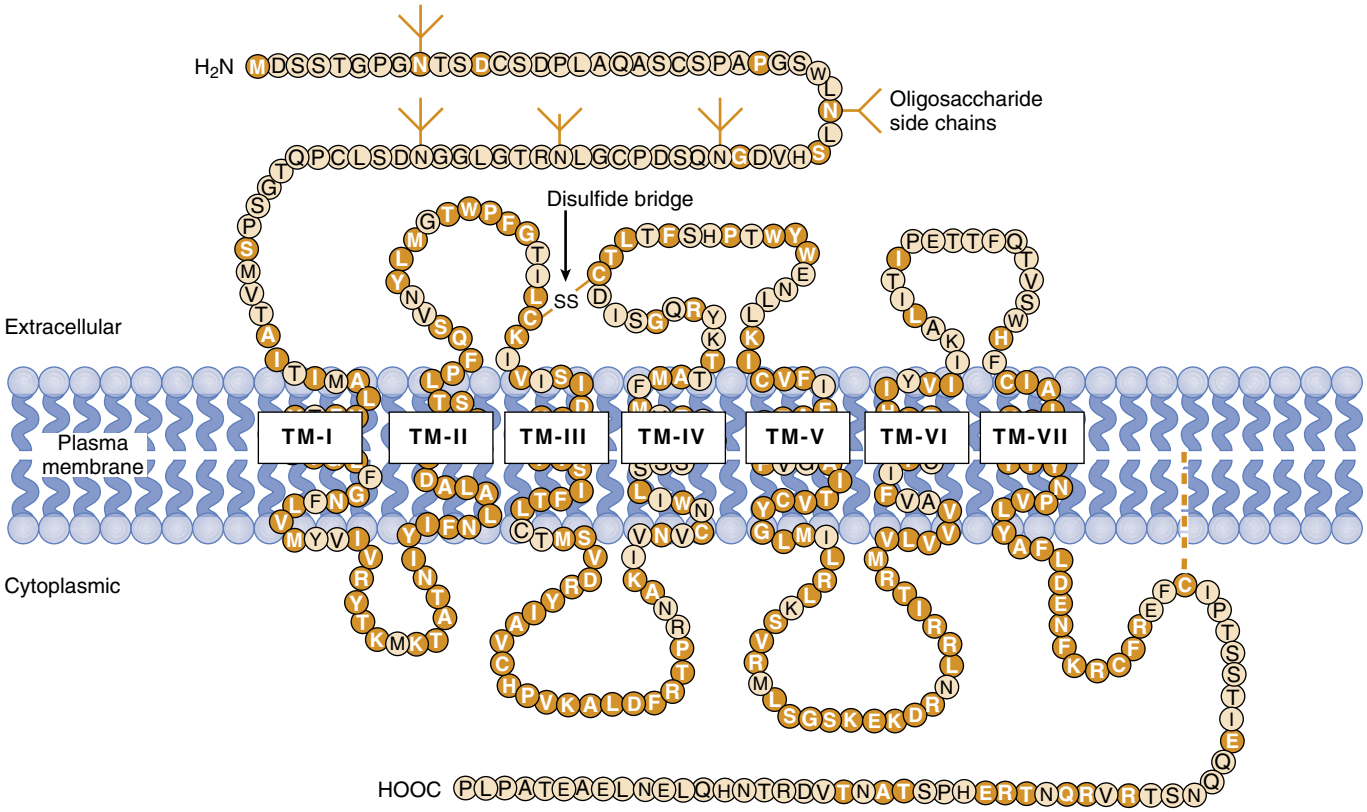

Figure 27-2 Proposed structure of the μ-opioid receptor. *Filled circles* indicate amino acid residues identical in the μ- and δ-opioid receptors. TM-I to TM-VII show putative transmembrane segments composed of hydrophobic amino acid residues.

peptides, including methionine enkephalin, adrenocorticotropic hormone, and α-melanocyte–stimulating hormone. Amino acid sequencing of preproenkephalin indicates that four methionine enkephalins and one leucine enkephalin are cleaved from this precursor. Furthermore, the primary structure of preprodynorphin, the precursor of dynorphin, was determined by cDNA cloning.

A novel endogenous opioid peptide with significant sequence homology to dynorphin was isolated in 1995.[3,4] This peptide was called orphanin FQ or nociceptin because it lowered the pain threshold under certain conditions, in contrast to the other endogenous opioid peptides. Pharmacologic and physiologic studies have demonstrated that orphanin FQ/nociceptin has behavioral and pain modulatory properties distinct from those of the three classic opioid peptides.[10] Studies of the effect of orphanin FQ/nociceptin on pain sensitivity have produced conflicting results, which may suggest that the effects of orphanin FQ/nociceptin on pain sensitivity depend on the underlying behavioral state of the subject. Prepronociceptin, the precursor of orphanin FQ/nociceptin, was cloned, and its amino acid sequence suggested the existence of prepronociceptin-derived neuropeptides other than orphanin FQ/nociceptin.[11]

The search for an endogenous ligand that binds to the μ-receptor with high affinity and high selectivity led to the discovery of a class of novel endogenous opioids termed endomorphin-1 and endomorphin-2.[12] These peptides are tetrapeptides with the sequence Tyr-Pro-Trp-Phe and Tyr-Pro-Phe-Phe, respectively. An endomorphin gene has yet to be cloned, and much remains to be learned about the anatomic distribution, mode of interaction with opioid receptors, function in vivo, and potential existence of other related peptides that are highly selective for each of the opioid receptors.

Intracellular Signal Transduction Mechanism

The opioid receptors belong to the G protein–coupled receptor family. Activation of the opioid receptors leads to activation of the pertussis toxin–sensitive G proteins (G_i and/or G_o). Expression of the cloned opioid receptors in cultured cells by transfection of the cloned cDNA has facilitated analysis of the intracellular signal transduction mechanisms activated by the opioid receptors (Fig. 27-3).[2] Adenylate cyclase is inhibited by activation of the opioid receptor, thereby resulting in a reduction in cellular cyclic adenosine monophosphate (AMP) content. Electrophysiologically, the voltage-gated Ca^{2+} channel is inhibited and the inwardly rectifying K^+ channels are activated by the opioid receptors. As a result, neuronal excitability is reduced by activation of the opioid receptors. In contrast, it was reported that opioids also stimulate the influx of Ca^{2+} into neuronal cultured cells.[13] Recently, it was shown that extracellular signal–related kinase, a class of mitogen-activated protein kinases, is activated by the opioid receptors.[14]

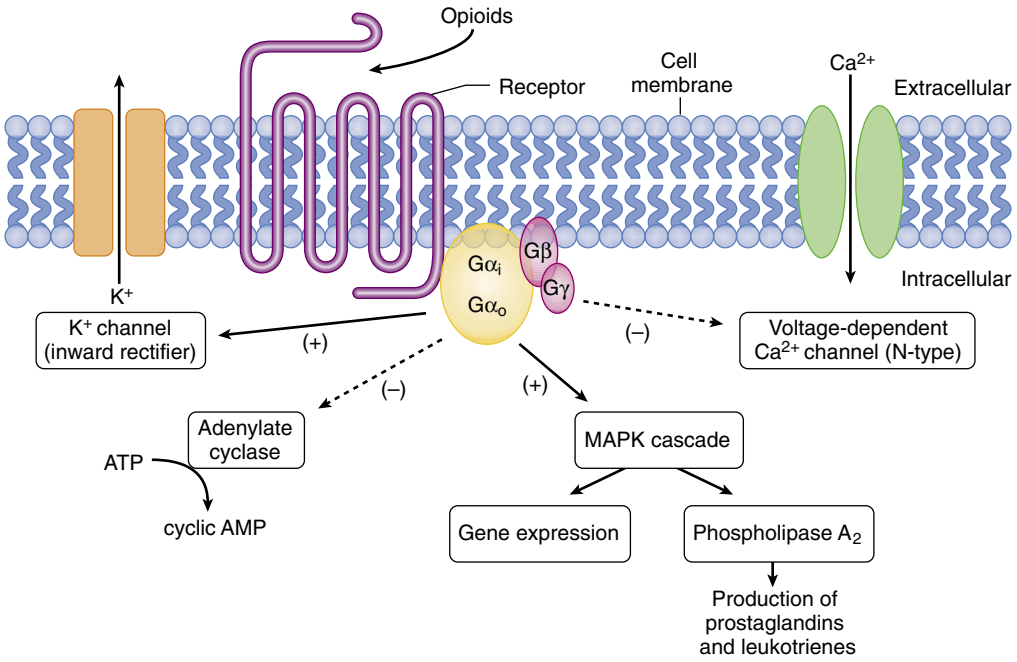

Figure 27-3 Intracellular signal transduction mechanisms linked with the opioid receptors. Binding of opioid agonists with the opioid receptors leads to activation of the G protein. The activity of adenylate cyclase and the voltage-dependent Ca^{2+} channels is suppressed. On the other hand, the inwardly rectifying K^+ channels and mitogen-activated protein kinase (MAPK) cascade are activated. AMP, adenosine monophosphate; ATP, adenosine triphosphate.

Opioid-induced activation of extracellular signal–related kinase can lead to an increase in release of arachidonate[14] and expression of the immediate early genes c-fos and junB.[15]

Chronic exposure of the opioid receptors to agonists induces cellular adaptation mechanisms that may be involved in opioid tolerance, dependence, and withdrawal symptoms. Short-term desensitization probably involves phosphorylation of the opioid receptors via protein kinase C.[16] A number of other kinases have also been implicated, including protein kinase A and β-adrenergic receptor kinase (βARK).[17] BARKs selectively phosphorylate agonist-bound receptors, thereby promoting interactions with β-arrestins, which interfere with G protein coupling and promote receptor internalization. Acute morphine-induced analgesia was enhanced in mice lacking β-arrestin 2, suggesting that this protein contributes to regulation of responsivity to opioids in vivo.[18]

Like other G protein–coupled receptors, the opioid receptors can undergo rapid agonist-mediated internalization via a classic endocytic pathway.[19,20] These processes may be induced differentially as a function of the class of the ligand. For example, certain agonists, such as etorphine and enkephalins, cause rapid internalization of the μ-receptor, whereas morphine, although it decreases adenylyl cyclase activity equally well, does not cause internalization of the μ-receptor.[21] These findings may suggest that different ligands induce different conformational changes in the receptor that lead to divergent intracellular events. Furthermore, they may provide an explanation for differences in the efficacy and abuse potential of various opioids.[22]

Long-term tolerance to opioids has been thought to be associated with superactivation of adenylyl cyclase activity—a counter-regulatory response to the decrease in cyclic AMP levels seen after acute opioid administration.[23] This effect is prevented by pretreatment of cells with pertussis toxin, thus demonstrating the involvement of G proteins (G_i and/or G_o).

Mechanism of Analgesia

Pain control by opioids needs to be considered in the context of brain circuits modulating analgesia and the functions of the various types of receptors in these circuits.[24] The analgesic effects of opioids arise from their ability to directly inhibit ascending transmission of nociceptive information from the spinal cord dorsal horn and to activate pain control circuits that descend from the midbrain, via the rostral ventromedial medulla (RVM), to the spinal cord dorsal horn. Petrovic and colleagues used an experimental pain model and positron emission tomography (PET) to study the mechanisms of action of the short-acting μ-opioid agonist remifentanil and found drug-induced activation of the rostral anterior cingulate cortex, insula, orbitofrontal cortex, and brainstem areas.[25] The latter overlapped with brain areas that have been implicated in pain modulation, such as the periaqueductal gray matter (PAG). Interestingly, placebo analgesia acts similarly on the activity of these brain areas, presumably via endogenous opioid release.[26]

Immunohistochemical studies and in situ hybridization analysis have demonstrated that opioid receptors are expressed in various areas in the central nervous system (CNS),[5] including the amygdala, mesencephalic reticular formation, PAG, and RVM. However, the role of opioid receptors in all these areas has not been completely clarified.

Microinjection of morphine into the PAG or direct electrical stimulation of this area produces analgesia that can be blocked by naloxone. Opioid actions at the PAG influence the RVM, which in turn modulates nociceptive transmission in the dorsal horn of the spinal cord through the action of the descending inhibition pathway. Thus, opioids produce analgesia not only by direct actions on the spinal cord but also by neurally mediated action in regions separate from the site of opioid administration.

The distribution of opioid receptors in descending pain control circuits indicates substantial overlap between μ- and κ-receptors. Interactions between the κ-receptor and the μ-receptor may be important for modulating nociceptive transmission from higher nociceptive centers, as well as in the spinal cord dorsal horn. The μ-receptor produces analgesia within descending pain control circuits, at least in part by the removal of GABAergic (transmitting or secreting γ-aminobutyric acid) inhibition of RVM-projecting neurons in the PAG and spinally projecting neurons in the RVM.[24] The actions of μ-receptor agonists are invariably analgesic, whereas those of κ-receptor agonists can be either analgesic or antianalgesic. The pain-modulating effects of κ-receptor agonists in the brainstem appear to oppose those of μ-receptor agonists.[27]

Local spinal mechanisms, in addition to descending inhibition, underlie the analgesic action of opioids. In the spinal cord, opioids act at synapses either presynaptically or postsynaptically. Opioid receptors are abundantly expressed in the substantia gelatinosa, where release of substance P from the primary sensory neuron is inhibited by opioids.

There is significant opioid receptor-ligand binding and little detectable receptor mRNA expression in the spinal cord dorsal horn but high levels of opioid receptor mRNA in the dorsal root ganglia. This distribution might suggest that the actions of opioid receptor agonists relevant to analgesia at the spinal level are predominantly presynaptic. It is well known that opioids decrease the pain-evoked release of tachykinins from primary afferent nociceptors. However, at least 80% of tachykinin signaling in response to noxious stimulation remains intact after the intrathecal administration of large doses of opioids.[28] These results suggest that although opioid administration may reduce release of tachykinin from primary afferent nociceptors, this reduction has little functional impact on the actions of tachykinin on postsynaptic pain-transmitting neurons.

The actions of opioids in the bulbospinal pathways are critical to their analgesic efficacy. Opioid actions in the forebrain clearly contribute to analgesia because decerebration prevents analgesia when rats are tested for pain sensitivity with the formalin test[29] and microinjection of opioids into several forebrain regions is analgesic in this test.[30] The analgesia induced by systemic administration of morphine in both the tail flick and formalin tests was disrupted either by lesioning or by reversibly inactivating the central nucleus of the amygdala, thus demonstrating that opioid actions in the forebrain contribute to analgesia after tissue damage, as well as after acute phasic nociception.[31,32]

Opioids may also produce analgesia through a peripheral mechanism.[33] Immune cells infiltrating an inflammatory site may release endogenous opioid-like substances that act on opioid receptors located on the primary sensory neuron.[33] However, others do not support this conclusion.[34,35]

Mood Alterations and Rewarding Properties

The mechanisms by which opioids produce euphoria, tranquility, and other alterations in mood (including rewarding properties) are not entirely clear. Behavioral and pharmacologic evidence points to the role of dopaminergic pathways, particularly those involving the nucleus accumbens, in drug-induced reward. Functional magnetic resonance imaging studies have demonstrated that a small intravenous dose (4 mg) of morphine induces positive signal changes in reward structures, including the nucleus accumbens, sublenticular extended amygdala, orbitofrontal cortex, and hippocampus, and decreases signal in cortical areas similar to the action of sedative-hypnotics such as propofol and midazolam.[36] These observations are consistent with results from pharmacologic studies.

The shell of the nucleus accumbens is the site that may be involved directly in the emotional and motivational aspects of drug-induced reward. All three opioid receptor types are present on the nucleus accumbens and are thought to mediate, at least in part, the motivational effects of opiate drugs.[5] Selective μ- and δ-receptor agonists are rewarding when defined by place preference and intracranial self-administration paradigms. Conversely, selective κ-receptor agonists produce aversive effects. The positive motivational effects of opioids are partially mediated by release of dopamine at the level of the nucleus accumbens.

The locus ceruleus contains both noradrenergic neurons and high concentrations of opioid receptors and is postulated to play a critical role in feelings of alarm, panic, fear, and anxiety. Neural activity in the locus ceruleus is inhibited by both exogenous opioids and endogenous opioid peptides.

Analysis of Knock-out Mice

The physiologic roles of the opioid receptors and endogenous opioid peptides have been investigated mainly by pharmacologic and physiologic methods. However, it has been difficult to analyze the functional roles of these proteins. Recently, knock-out mice, in which a specific gene is inactivated by molecular biologic methods, have been produced. By analysis of knock-out mice the physiologic significance of the respective opioid receptors and endogenous opioid peptide precursors can be deteremined.[37]

In μ-receptor knock-out mice, analgesia, the reward effect, and the withdrawal effect of morphine are lost.[38,39] Morphine-induced respiratory depression was not observed in the μ-receptor knock-out mice.[40] Therefore, the μ-receptor is a mandatory component of the opioid system for morphine action. In μ-receptor knock-out mice, ketamine-induced respiratory depression and antinociception are diminished,[41] suggesting that ketamine interacts with the μ-receptor to lead to these phenomena. Furthermore, the significantly higher minimum alveolar concentration (MAC) of sevoflurane in the μ-receptor knock-out mice than in wild-type mice suggest that the μ-receptor is involved in the anesthetic potency of sevoflurane.[40] δ-Receptor knock-out mice display a markedly reduced analgesic effect of opioids selective for δ-receptors at the spinal cord level.[42] However, at the supraspinal level, analgesia can be induced by δ-receptor agonists in δ-receptor knock-out mice, suggesting the existence of a second

δ-like analgesic system. Because disruption of the κ-receptor abolishes the analgesic, hypolocomotive, and aversive actions of the κ-receptor agonists and induces hyperreactivity in the abdominal constriction test, the κ-receptor is thought to be involved in the perception of visceral chemical pain.[43]

In mice lacking β-endorphin, morphine induces normal analgesia, but naloxone-reversible stress-induced analgesia cannot be observed.[44] Preproenkephalin knock-out mice are more anxious than wild-type mice, and males display increased offensive aggressiveness.[45] The mutant mice show a marked difference from controls in supraspinal but not in spinal responses to painful stimuli.

Thus, the functional roles of individual components of the opioid system have been elucidated by analysis of knock-out mice. However, many points remain to be clarified.

Actions of Opioids on Targets Other Than Opioid Receptors

Recent progress in molecular pharmacologic analysis has shown that opioids can interact with molecules other than the opioid receptors. In cardiac myocytes, it was shown that morphine can inhibit voltage-dependent Na^+ current in a naloxone-insensitive manner, thus suggesting the existence of a signal transduction mechanism that is not dependent on the opioid receptors.[46] Meperidine is an agonist of both μ- and κ-receptors. In addition, it was demonstrated that meperidine can block voltage-dependent Na^+ channels in amphibian peripheral nerves,[47] as well as in a *Xenopus* oocyte expression system (Fig. 27-4).[48] Furthermore, meperidine exerts agonist activity at the α_{2B}-adrenoreceptor.[49] Yamakura and coworkers have shown that high concentrations of opioids, including meperidine, morphine, fentanyl, codeine, and naloxone, directly inhibit the *N*-methyl-D-aspartate (NMDA) receptor expressed in *Xenopus* oocytes.[50] Methadone is used clinically as a racemic mixture of the *l* and *d* isomers. The opioid-like activity of the racemate seems to be almost entirely due to *l*-methadone, whereas *d*-methadone acts as an NMDA antagonist.[51] The commercially available remifentanil solution Ultiva, which contains glycine, directly activates the NMDA receptor expressed in *Xenopus* oocytes.[52] Furthermore, an electrophysiologic study involving the rat spinal cord showed that remifentanil hydrochloride does not directly activate NMDA receptors, the NMDA current recorded after the application of Ultiva is related to the

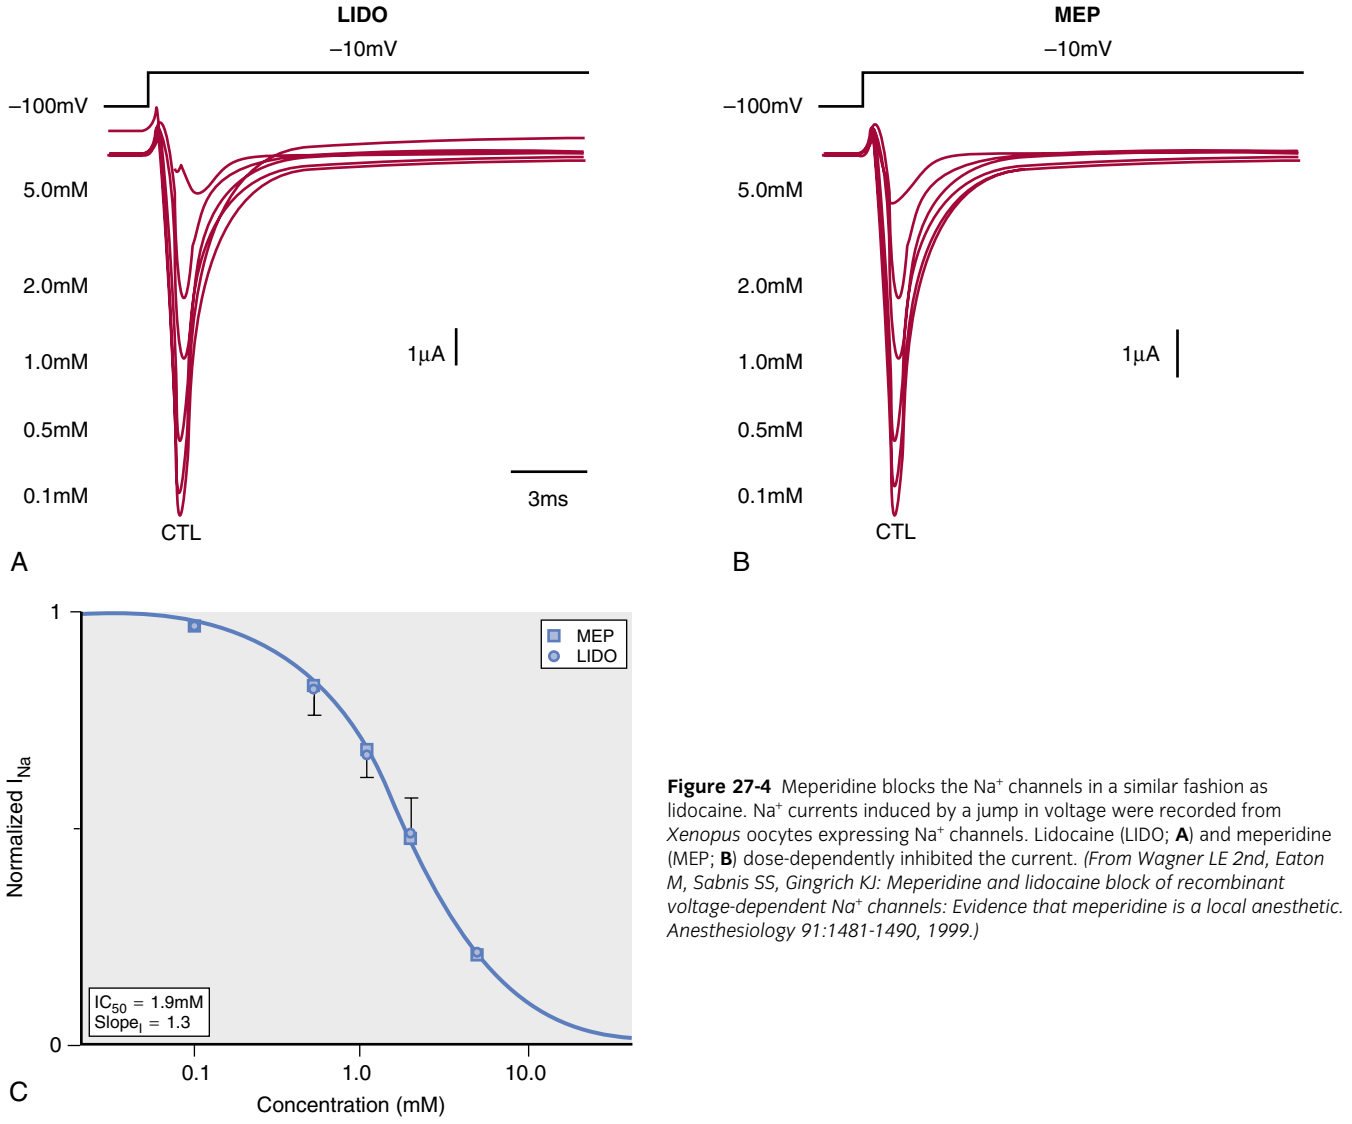

Figure 27-4 Meperidine blocks the Na^+ channels in a similar fashion as lidocaine. Na^+ currents induced by a jump in voltage were recorded from *Xenopus* oocytes expressing Na^+ channels. Lidocaine (LIDO; **A**) and meperidine (MEP; **B**) dose-dependently inhibited the current. *(From Wagner LE 2nd, Eaton M, Sabnis SS, Gingrich KJ: Meperidine and lidocaine block of recombinant voltage-dependent Na^+ channels: Evidence that meperidine is a local anesthetic. Anesthesiology 91:1481-1490, 1999.)*

presence of glycine, and the glycine-induced NMDA current is potentiated by the application of remifentanil hydrochloride through a pathway involving the μ-opioid receptor.[53] The serotonin 5-HT_{3A} receptor, which is directly and indirectly linked to gastrointestinal motility, visceral pain, nausea, and vomiting, was shown to be competitively inhibited by morphine, as well as by naloxone.[54]

Whether these actions of opioids on targets other than the opioid receptor have physiologic or clinical implications is not known.

The Role of Nociceptin/Orphanin FQ in Pain Modulation

Nociceptin/orphanin FQ is a 17–amino acid peptide, the sequence of which resembles that of opioid peptides. Nociceptin/orphanin FQ precursor mRNA and peptide are present throughout the descending pain control circuits. In the spinal cord, there is stronger nociceptin/orphanin FQ receptor mRNA expression in the ventral horn than in the dorsal horn, but higher levels of ligand binding in the dorsal horn. Targeted disruption of the nociceptin/orphanin FQ receptor in mice had little effect on basal pain sensitivity in several measures, whereas targeted disruption of the nociceptin/orphanin FQ precursor consistently elevated basal responses in the tail flick test, suggesting an important role for nociceptin/orphanin FQ in regulating basal pain sensitivity.[55,56] Intrathecal injections of nociceptin/orphanin FQ have been shown to be analgesic[57]; however, supraspinal administration has produced either hyperalgesia, antiopioid effects, or a biphasic hyperalgesic/analgesic response.[58] Nociceptin/orphanin FQ inhibits both pain-facilitating and analgesia-facilitating neurons in the RVM.[59] The effects of nociceptin/orphanin FQ on pain responses appear to depend on the preexisting state of pain in the animal. Yamamoto and Sakashita reported that intrathecal injection of nociceptin/orphanin FQ significantly attenuated the level of mechanical hyperalgesia induced by skin incision, which suggests involvement of the nociceptin/orphanin FQ receptor in maintaining postoperative pain.[57] The physiologic implications of nociceptin/orphanin FQ remain to be elucidated.

Neurophysiologic Effects of Opioids

Analgesic Action of Opioids

In human beings, morphine-like drugs produce analgesia, drowsiness, changes in mood, and mental clouding. A significant feature of opioid analgesia is that it is not associated with loss of consciousness. When morphine in the same dose is given to a normal, pain-free individual, the experience may be unpleasant. Relief of pain by morphine-like opioids is relatively selective in that other sensory modalities are not affected. Patients frequently report that the pain is still present but that they feel more comfortable. It is also important to distinguish between pain caused by stimulation of nociceptive receptors and transmitted over intact neural pathways (nociceptive pain) and pain caused by damage to neural structures, often involving neural supersensitivity (neuropathic pain). Although nociceptive pain is usually responsive to opioid analgesics, neuropathic pain typically responds poorly to opioid analgesics and may require higher doses of drug.[60] Not only is the sensation of pain altered by opioid analgesics, but the affective response is changed as well. However, alteration of the emotional reaction to painful stimuli is not the sole mechanism of analgesia.

The level of antinociception produced by an opioid is determined by the intensity of the nociceptive stimulus and the intrinsic efficacy of the opioid. When opioids are given in combination, the effects can be predicted only on the basis of the nociception experienced when the drugs are administered alone.[61] The antinociceptive effects of opioids are enhanced in animal models of inflammation. The sensitization to opioids is related to a central rather than a peripheral site of action.[62]

Animal and human studies indicate the existence of sex-related differences in opioid-mediated behavior.[63] Sarton and associates examined the influence of morphine on experimentally induced pain in healthy volunteers and demonstrated sex differences in morphine analgesia, with greater morphine potency but slower speed of onset and offset in women.[64] The mechanism of the sex difference remains to be clarified.

The analgesia produced by the peripheral actions of opioids is still a source of controversy. Recent reviews have concluded from meta-analysis that intra-articularly administered morphine has a definite, but mild analgesic effect.[65] It may be dose dependent, and a systemic effect cannot be completely excluded. The addition of opioids to brachial plexus blocks has been reported to improve the success rate and postoperative analgesia.[66,67] In contrast, the addition of sufentanil did not prolong the duration of brachial plexus blockade.[68] Because of its local anesthetic effect on peripheral nerves, meperidine was tested for intravenous regional anesthesia. However, doses of meperidine large enough to produce effective postoperative analgesia cause a significant incidence of side effects.[69]

Opioids As Anesthetics

Cortical acetylcholine originates in the basal forebrain and is essential for maintaining normal cognition and arousal. Injection of morphine into the substantia innominata or intravenous administration of morphine significantly decreased release of acetylcholine within the prefrontal cortex in the rat, which might be the neurochemical basis of opioid-induced change in consciousness.[70] Whether opioids alone are capable of producing anesthesia was a subject of debate in the past.[71] Reports of patient awareness during high-dose fentanyl anesthesia highlighted the potential for this problem (see Chapter 39). The anesthetic potential of opioids was tested by measurement of MAC.[72] Studies in rats demonstrated that opioids reduce the MAC of volatile anesthetics to a greater degree than in other animals. Interspecies differences in opioid actions are significant.[73] Fentanyl can reduce the MAC of isoflurane at skin incision in patients by at least 80%.[74] The relationship between the plasma fentanyl concentration and reduction in MAC is not linear, and there is a sub-MAC ceiling effect of fentanyl on reduction of the MAC of isoflurane. The MAC of sevoflurane was also dose-dependently reduced by fentanyl, with 3 ng/mL resulting in a 61% reduction in MAC (Fig. 27-5).[75] A ceiling effect was observed for MAC, with 6 ng/

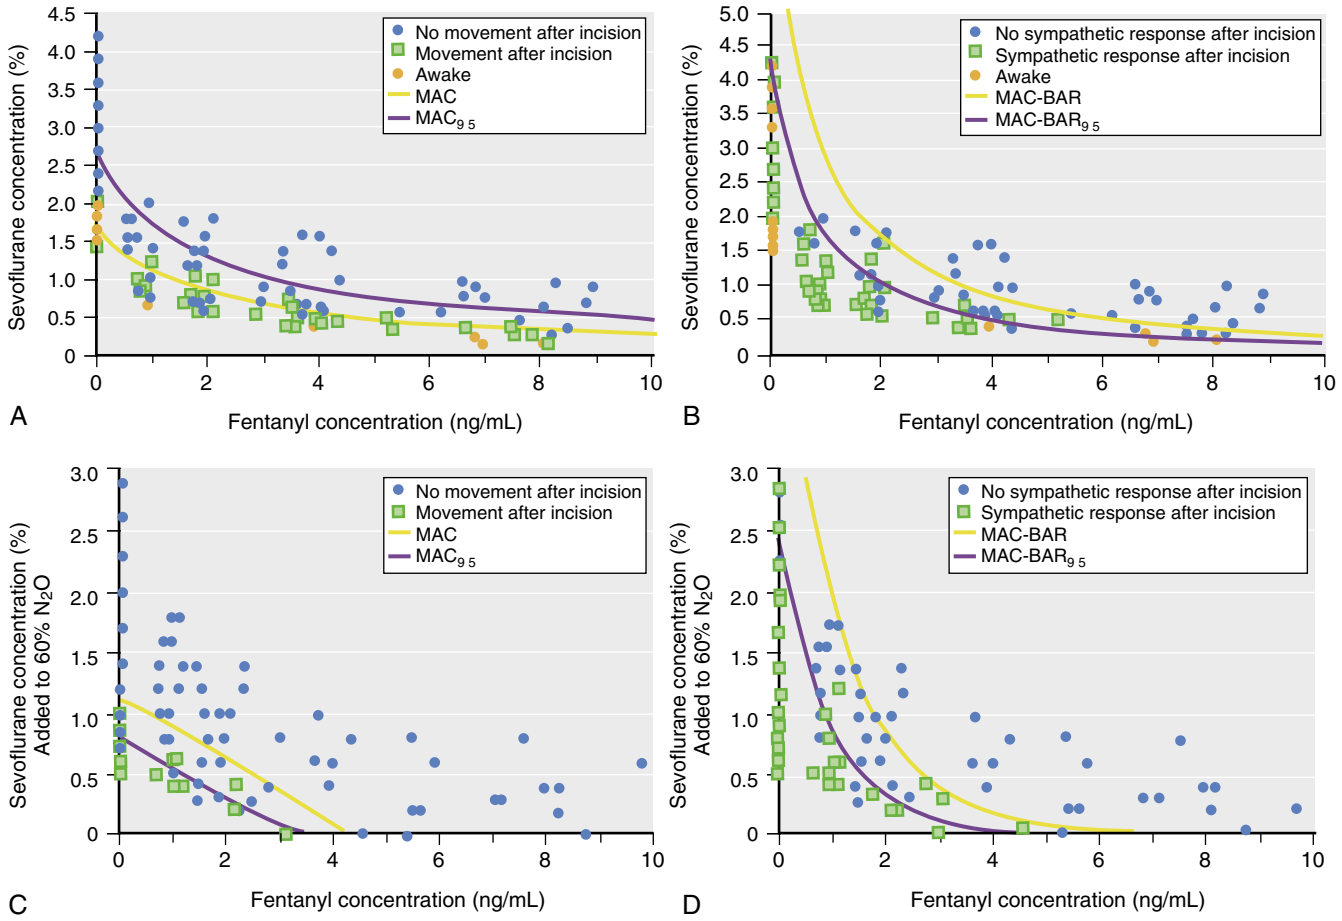

Figure 27-5 Effects of increasing concentration of fentanyl on the minimum alveolar concentration (MAC) and MAC-BAR (MAC that prevents sympathetic responses to surgical incision in 50% of patients) of sevoflurane. **A** and **C,** Reduction of the concentration of sevoflurane by increasing concentrations of fentanyl at which 50% or 95% of patients did not move at skin incision (MAC or MAC_{95}, respectively). **B** and **D,** Reduction of the concentration of sevoflurane by increasing concentrations of fentanyl at which 50% or 95% of patients did not show sympathetic responses (an increase in heart rate or mean arterial pressure >15%) at skin incision (MAC-BAR or $MAC\text{-}BAR_{95}$, respectively). Analysis was performed in the absence or presence of 60% nitrous oxide in **A** and **B** and in **C** and **D,** respectively. *(From Katoh T, Kobayashi S, Suzuki A, et al: The effect of fentanyl on sevoflurane requirements for somatic and sympathetic responses to surgical incision. Anesthesiology 90:398-405, 1999.)*

mL fentanyl providing only an additional 13% reduction in the MAC of sevoflurane. The potency ratios for fentanyl, sufentanil, alfentanil, and remifentanil, based on MAC reduction studies in humans, are approximately 1:12:0.0625:1.2.[76] Esmolol, a short-acting β_1-receptor antagonist, significantly decreased the MAC of isoflurane in the presence of alfentanil, although it did not significantly affect it in the absence of alfentanil.[77] The mechanism of the interaction is unknown. It was demonstrated that epidural fentanyl infusion reduces the awakening concentration of isoflurane more than intravenous fentanyl infusion does despite the lower plasma concentration, possibly by modulating afferent nociceptive input in the spinal cord.[78] The hypnotic effect of midazolam is also significantly enhanced by alfentanil.[79]

The MAC that prevents movement in response to laryngoscopy and tracheal intubation in 50% of patients (MAC-TI) is higher than the MAC that prevents movement in response to surgical incision (MAC). The MAC-TI of sevoflurane was 3.55% and was markedly reduced to 2.07%, 1.45%, and 1.37% by the addition of fentanyl, 1, 2, and 4 μg/kg, with no significant difference in the reduction between 2 and 4 μg/kg, thus showing a ceiling effect.[80] The MAC that prevents sympathetic responses to surgical incision in 50% of patients (MAC-BAR) decreased with increasing concentrations of fentanyl in plasma, and the initial steep reduction was followed by a ceiling effect (see Fig. 27-5).[75] In the presence of nitrous oxide, MAC and MAC-BAR decreased similarly but did not exhibit a ceiling effect.

The bispectral index (BIS) has been proposed as a measure of the effects of anesthetics on the brain (see Chapter 39). In the presence of fentanyl, alfentanil, remifentanil, or sufentanil, loss of consciousness occurred at a lower effect-site concentration of propofol and at a higher BIS value than with propofol alone.[81] This finding suggests that the hypnotic effect of propofol is enhanced by analgesic concentrations of opioids without changes in the BIS value. On the other hand, infusion of remifentanil (effect-site target concentrations of 0.25, 2.5, and 10 ng/mL), combined with propofol infusion adjusted to a BIS of approximately 60, dose-dependently decreased the BIS, thus suggesting a sedative or hypnotic effect of remifentanil.[82] Response surface analysis showed considerable synergy between opioids and hypnotics for sedation and suppression of responses to various noxious stimuli (Fig. 27-6).[83]

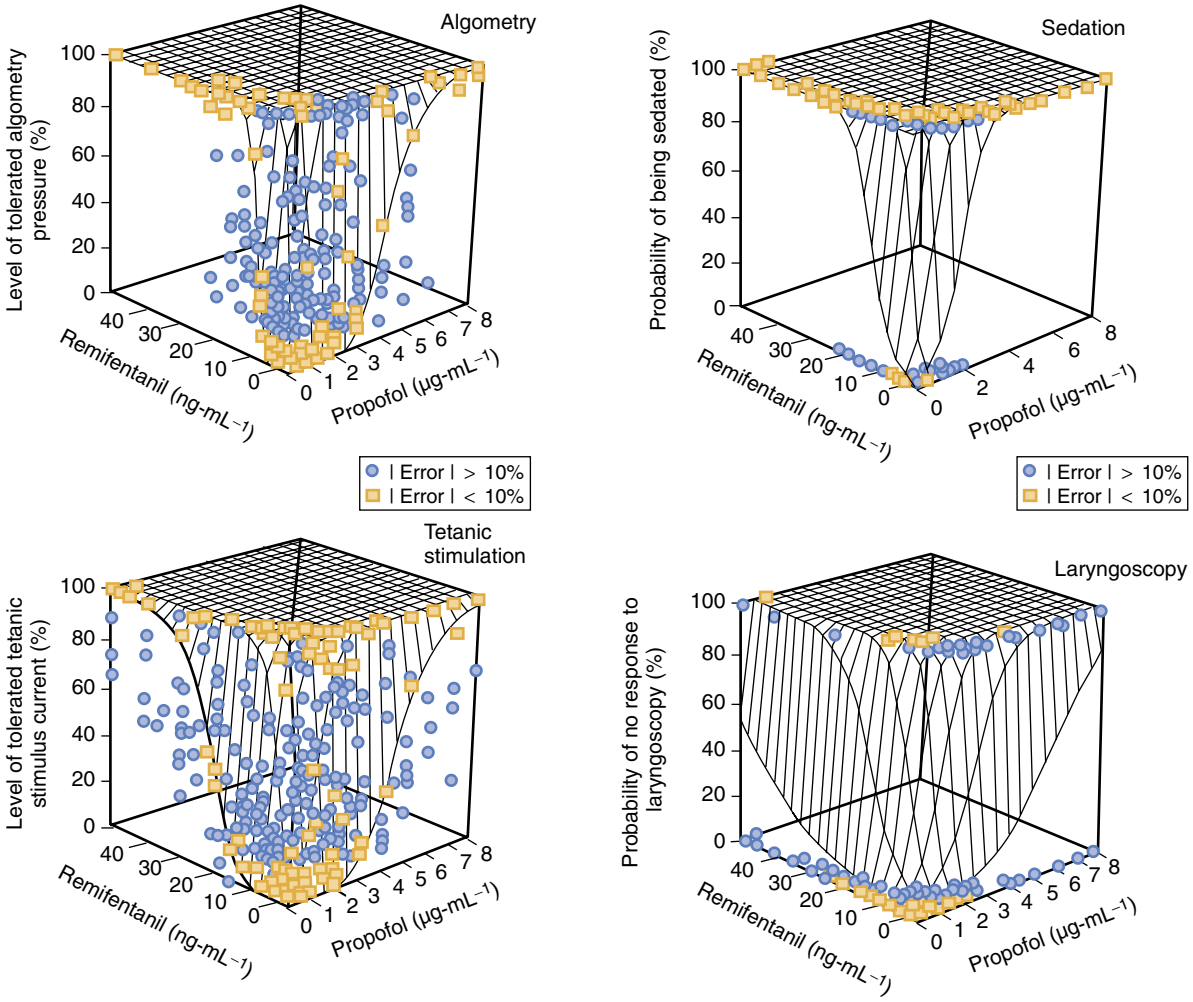

Figure 27-6 Prediction of sedation and blunting of the response to noxious stimuli, including tibial pressure algometry, electrical tetany, and laryngoscopy, by a response surface model. Sedation is indicated by an alertness/sedation score of 0 to 3 as assessed by an observer. Response to the noxious stimuli was based on whether the subjects exhibited withdrawal movement, painful verbalization, or a 20% increase in heart rate over the prestimulus level. The symbols show actual measured responses from the study subjects. *(From Kern SE, Xie G, White JL, Egan TD: A response surface analysis of propofol-remifentanil pharmacodynamic interaction in volunteers. Anesthesiology 100:1373-1381, 2004.)*

Although unconsciousness in humans can be produced with large doses of opioids alone, opioid anesthesia can be unpredictable and inconsistent.[84] Therefore, opioids are not suitable as the sole drug for intravenous induction of anesthesia.[85]

Electroencephalography

Increasing concentrations of inhaled anesthetics produce a continuum of changes on the electroencephalogram (EEG) and eventually result in burst suppression and a flat EEG. In contrast, a ceiling effect is reached with opioids. Increasing opioid dosage, when this ceiling has been attained does not further affect the EEG.[86] Problems with lead placement and signal processing need to be resolved before analysis of the EEG can be used as a routine monitor of the depth of opioid anesthesia.

Although the potency and rate of equilibrium between plasma and brain are different among opioids, the effects of fentanyl, alfentanil, sufentanil, and remifentanil are consistent (Fig. 27-7).[87] Small doses of fentanyl (200 μg) produce minimal changes on the EEG, whereas higher doses (30 to 70 μg/kg) result in high-voltage slow (δ) waves that are suggestive of a state consistent with anesthesia. Although transient isolated (usually frontotemporal) sharp wave activity can be observed after large doses of fentanyl and other opioids, it is not generalized.

As an effect-site measure, the EEG can be used to assess the onset of drug action and drug potency ratios. The spectral edge and serum concentration are closely parallel for remifentanil,[88] whereas significant time lag is found for recovery of the spectral edge for fentanyl and sufentanil (Fig. 27-8).[89] The serum concentration ratio of fentanyl and sufentanil was 12:1 at half-maximal slowing of the EEG.[89] Similar studies suggest that fentanyl and remifentanil are 75 and 16 times as potent as alfentanil, respectively.[88] Potency ratios based on the EEG are similar to those obtained from studies determining the plasma drug levels of each opioid necessary to reduce the MAC of isoflurane by 50%. Potency ratios of sufentanil:fentanyl:remifentanil: alfentanil for reducing the MAC of isoflurane are nearly 1:1/10:1/10:1/100.[74,90-92]

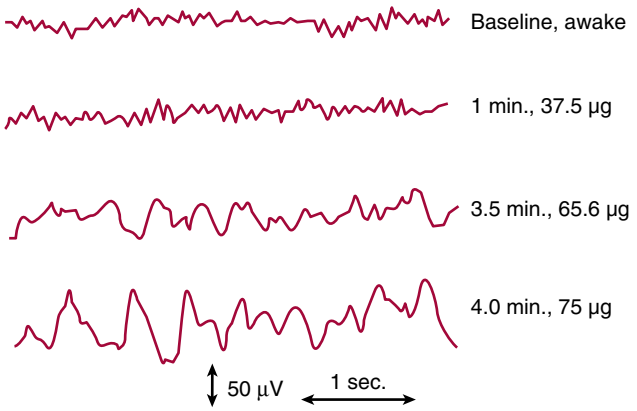

Figure 27-7 Representative 4-second tracings on the electroencephalogram (EEG) during infusion of sufentanil (total dose shown in the *right column*). The awake baseline EEG consists of mixed β and α activity. At 1 minute, the EEG showed loss of β activity and the presence of primarily α waves (8 to 13 Hz). At 3.5 minutes, the EEG consisted of mixed θ (4 to 7 Hz) and δ (<4 Hz) waves, and at 4.0 minutes, it consisted of δ waves of high amplitude. *(From Scott JC, Cooke JE, Stanski DR: Electroencephalographic quantitation of opioid effect: Comparative pharmacodynamics of fentanyl and sufentanil. Anesthesiology 74:34-42, 1991.)*

Evoked Responses

Because opioids do not appreciably alter sensory evoked potentials (SEPs) elicited at the posterior tibial or median nerve, SEPs can be used to monitor spinal cord function during anesthesia with opioids.[93] Remifentanil produced a dose-dependent reduction in auditory evoked potentials.[94] Remifentanil infusion (target plasma concentrations of 1, 2, and 3 ng/mL) did not affect evoked potential amplitudes and latencies.[95]

In healthy human volunteers receiving 3 µg/kg fentanyl, the amplitude and latency of motor evoked responses to transcranial stimulation were not significantly affected.[96] Kawaguchi and coauthors reported that intraoperative monitoring of myogenic motor evoked potentials is feasible during isoflurane or sevoflurane anesthesia with fentanyl.[97]

The middle latency auditory evoked response has been shown to change after the administration of opioids. However, it remains unclear whether these changes are due to a direct depressant effect of opioids on the middle latency auditory evoked response itself or an indirect effect because of their action in attenuating CNS arousal associated with noxious stimuli. Wright and colleagues examined the effect of remifentanil (1 or 3 µg/kg/min) on the middle latency auditory evoked response in intubated and nonintubated patients and showed that remifentanil has an effect on the middle latency auditory evoked response in attenuating the arousal associated with intubation of the trachea but has no effect in the absence of a stimulus.[98]

Cerebral Blood Flow and Cerebral Metabolic Rate

Opioids generally produce modest decreases in the cerebral metabolic rate (CMR) and intracranial pressure, although such changes are influenced by the concomitant administration of other agents and anesthetics, as well as by patient conditions (see Chapter 63). When vasodilation is produced by coadministered anesthetics, opioids are more likely to cause cerebral vasoconstriction. Opioids also decrease cerebral blood flow (CBF) when combined with N_2O. When opioids are administered alone or when the coadministered anesthetics cause cerebral vasoconstriction, opioids usually have no influence or result in a small increase in CBF.

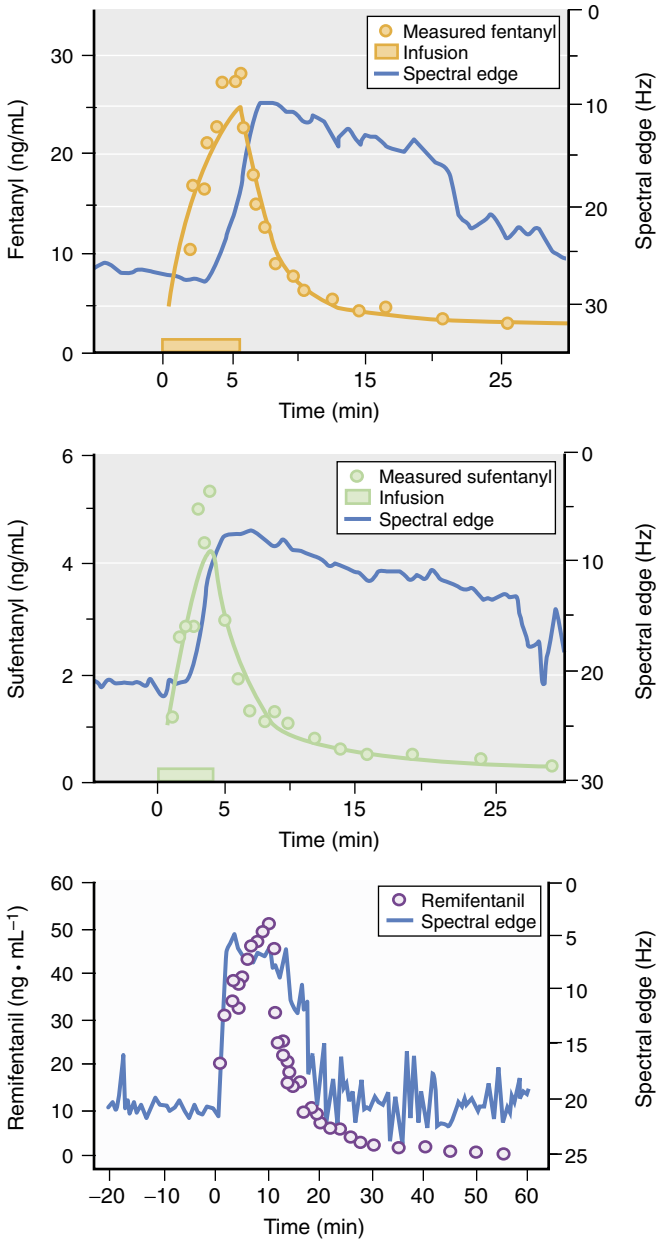

Figure 27-8 Time course of the spectral edge and serum opioid concentration. Fentanyl (*upper panel*) and sufentanil (*middle panel*) were infused at 150 and 18.75 µg/min, respectively. Remifentanil (*lower panel*) was administered at 3 µg/kg/min for 10 minutes. The spectral edge changes lag behind the changes in serum concentration in the case of fentanyl and sufentanil, whereas the spectral edge and serum concentration are closely parallel in the case of remifentanil. *(From Scott JC, Ponganis KV, Stanski DR: EEG quantitation of narcotic effect: The comparative pharmacodynamics of fentanyl and alfentanil. Anesthesiology 62:234-241, 1985; and Egan TD, Minto CF, Hermann DJ, et al: Remifentanil versus alfentanil: Comparative pharmacokinetics and pharmacodynamics in healthy adult male volunteers. Anesthesiology 84:821-833, 1996.)*

Endogenous opioid activity is present in the cerebral arteries, although exogenously administered opioids were found to exert little effect on pial artery diameter in several animal models.[99] Fentanyl (100 µg/kg) causes dose-related reductions in CBF and $CMRO_2$ in rats receiving N_2O. In the piglet, fentanyl, alfentanil, and sufentanil decrease arteriolar diameter in a dose-dependent, naloxone-reversible manner.[100] In human volunteers, PET demonstrated that the CBF changes induced by fentanyl are regionally heterogeneous.[101]

The effect of sufentanil on CBF in the dog may be dose and time dependent. It was reported that sufentanil (20 µg/kg intravenously [IV]) produces 30% to 40% decreases in CBF 5 to 10 minutes after opioid administration.[102] Another report showed that sufentanil (10 to 200 µg/kg) produces transient increases in CBF that peak 2 minutes after drug administration in the dog.[103] In humans, both fentanyl and sufentanil can increase middle cerebral artery blood flow velocity by about 25%.[104] In healthy volunteers, sufentanil (0.5 µg/kg IV) produces no significant effect on CBF.[104] Alfentanil (25 to 50 µg/kg IV), when administered to patients receiving isoflurane (0.4% to 0.6%)-N_2O anesthesia, produces minimal reductions in middle cerebral artery flow velocity.[105]

In the dog, alfentanil and remifentanil decrease regional blood flow by 40% to 50% in the cortex, hippocampus, and caudate.[106] A PET study in human volunteers showed that remifentanil induces dose-dependent changes in relative regional CBF in areas involved in pain processing, such as the lateral prefrontal cortex, inferior parietal cortex, and supplementary motor area.[107] In patients scheduled to undergo supratentorial tumor surgery and receiving N_2O, remifentanil (1 µg/kg/min), similar to fentanyl (2 µg/kg/min), reduced CBF and did not significantly affect cerebrovascular carbon dioxide reactivity.[108]

Opioids usually produce mild to moderate decreases in CMR that remain coupled to CBF. However, opioid-induced neuroexcitation and focal seizure activity can cause regional increases in brain metabolism. Regional increases in glucose utilization induced by high doses of alfentanil in the rat are associated not only with epileptiform activity but also with neuropathic lesions.[109] In humans, PET evaluation demonstrated that a 1- to 3-µg/kg/min infusion of remifentanil induces a significant increase in the CMR of glucose.[110]

Neuroprotection

Although certain early studies suggested potentially adverse effects of µ-opioid agonists on ischemic brain, other studies have documented that at least certain opioid agents, such as the κ-agonists, can be neuroprotective, at least in animal models of focal ischemia.[111,112] It was also shown that activation of δ-opioid receptors increases the survival time of mice during lethal hypoxia.[113,114] An in vitro study involving rat cerebellar brain slices demonstrated that pretreatment with morphine at clinically relevant concentrations induces acute neuroprotection mediated by activation of δ_1-opioid receptors, activation of adenosine triphosphate (ATP)-sensitive K^+ channels, and production of free radicals in mitochondria.[115] In contrast, Charchaflieh and coworkers demonstrated in the rat hippocampal slice model that fentanyl is neither neurotoxic nor protective against anoxic injury to neurons when used in concentrations comparable to those applied in clinical practice.[116] In the rat focal ischemia model, in contrast to isoflurane, fentanyl neither increased nor decreased brain injury when compared with awake unanesthetized rats.[117]

Table 27-4 Potential Problems Associated with Opioid-Induced Rigidity

System	Problem
Hemodynamic	↑CVP, ↑ PAP, ↑ PVR
Respiratory	↓ Compliance, ↓ FRC, ↓ ventilation
	Hypercapnia
	Hypoxemia
Miscellaneous	↑ Oxygen consumption
	↑ Intracranial pressure
	↑ Fentanyl plasma levels

CVP, central venous pressure; FRC, functional residual capacity; PAP, pulmonary artery pressure; PVR, pulmonary vascular resistance.
Modified from Bailey PL, Egan TD, Stanley TH: Intravenous opioid anesthetics. *In* Miller RD (ed): Anesthesia, 5th ed. New York, Churchill Livingstone, 2000, p 291.

Muscle Rigidity

Opioids can increase muscle tone and may cause muscle rigidity. The incidence of rigidity noted with opioid anesthetic techniques varies greatly because of differences in the dose and speed of opioid administration, concomitant use of N_2O, presence or absence of muscle relaxants, and patient age. Opioid-induced rigidity is characterized by increased muscle tone that sometimes progresses to severe stiffness with the potential for serious problems (Table 27-4). Clinically significant opioid-induced rigidity usually begins just as or after a patient loses consciousness. Mild manifestations of rigidity, such as hoarseness, can occur in conscious patients. It has been demonstrated that vocal cord closure is primarily responsible for the difficult ventilation with bag and mask that follows the administration of opioids. Delayed or postoperative rigidity is probably related to the second peaks that can occur in plasma opioid concentrations, similar to the recurrence of respiratory depression.

The precise mechanism by which opioids cause muscle rigidity is not clearly understood. Muscle rigidity is not due to direct action on muscle fibers because it can be decreased or prevented by pretreatment with muscle relaxants. Mechanisms of opioid-induced muscle rigidity involving the CNS have been postulated. Pharmacologic studies using selective agonists and antagonists have suggested that systemic opioid-induced muscle rigidity is primarily due to the activation of central µ-receptors, whereas supraspinal δ_1- and κ_1-receptors may attenuate this effect.[118] Some aspects of opioid-induced catatonia and rigidity (increased incidence with age, muscle movements resembling extrapyramidal side effects) are similar to Parkinson's disease and suggest similarities in neurochemical mechanisms. Parkinsonian patients, particularly if inadequately treated, may experience reactions such as dystonia after opioid administration.[119]

Pretreatment with or concomitant use of nondepolarizing muscle relaxants can decrease the incidence and severity of rigidity. Induction doses of thiopental and subanesthetic doses of diazepam and midazolam prevent, attenuate, or successfully treat rigidity. Persisting in an attempt to mask-ventilate a patient with opioid-induced rigidity will probably result in gastric insufflation

and inadequate ventilation or oxygenation until a muscle relaxant is administered. To minimize the occurrence of muscle rigidity and facilitate ventilation and airway management, anesthesiologists should anticipate the need for rapid neuromuscular blockade when doses of opioids are administered that produce rigidity.

Neuroexcitatory Phenomena

Fentanyl causes seizure activity on the EEG in animals, but evidence of seizure activity after fentanyl, alfentanil, and sufentanil is generally lacking in humans. Remifentanil induces generalized tonic-clonic seizure–like activity in otherwise healthy adults.[120] Morphine produces tonic-clonic activity after epidural and intrathecal administration.[121] Focal neuroexcitation on the EEG (e.g., sharp and spike wave activity) occasionally occurs in humans after large doses of fentanyl, sufentanil, or alfentanil.

The mechanisms underlying opioid-induced neuroexcitatory phenomena are not completely clear. Excitatory opioid actions may be related to their coupling to mitogen-activated protein kinase cascades.[122] Local increases in CBF and metabolism are also of theoretical concern because prolonged seizure activity, even if focal, could lead to neuronal injury or cellular death. In large doses in rats, fentanyl, alfentanil, and sufentanil also induce hypermetabolism and histopathologic alterations in the limbic system.[123] Midazolam, naloxone, and phenytoin prevent seizure activity on the EEG and histologically evident brain damage induced by high-dose fentanyl in rats.[124]

Measurement of CBF via magnetic resonance imaging in human volunteers has indicated that the cingulate cortex is the most susceptible to activation by remifentanil (0.05 to 0.2 μg/kg/min) and that susceptibility is affected by the apolipoprotein E genotype.[125] These findings support the notion that neuroactivation of limbic areas via the perioperative use of opioids might have a role in the genesis of postoperative cognitive dysfunction.

Pupil Size

Morphine and most μ- and κ-agonists cause constriction of the pupil by an excitatory action on the parasympathetic nerve innervating the pupil. Opioids abolish cortical inhibition of the Edinger-Westphal nucleus, thereby resulting in papillary constriction. After the intravenous administration of morphine (0.125 mg/kg), there was a 26% decrease in pupil diameter at 1 hour, and longer than 6 hours was necessary for complete recovery of pupil diameter.[126] Alfentanil in a dose-dependent manner attenuates the reflex papillary dilatation that normally follows noxious stimulation in anesthetized individuals.[127] The changes in pupil size associated with opioid action may be too slight to be of clinical utility in assessing the degree of opioid effect.

Thermoregulation and Shivering

Opioid-based anesthesia probably reduces thermoregulatory thresholds to an extent similar to that of the potent inhaled agents (see Chapter 48).[128] However, meperidine is unique among opioids in its ability to effectively terminate or attenuate shivering. The antishivering effect of meperidine is primarily related to a reduction in the shivering threshold[129] and seems to be mediated by meperidine's activity on the κ-receptor.[130] However, the relatively specific κ-receptor agonist nalbuphine did not show significant antishivering activity.[131] Meperidine exerts agonist activity at the α_{2B}-adrenoreceptor subtype, suggesting possible involvement of this novel action in the antishivering action of meperidine.[49] Alfetanil, morphine, and fentanyl are not as effective as meperidine in the treatment of postoperative shivering. Tramadol (0.5 mg/kg) suppressed post–epidural anesthetic shivering in parturients as effectively as meperidine did (0.5 mg/kg),[132] but the incidence of somnolence was lower with tramadol than with meperidine.

Pruritus

Intrathecal morphine–induced itching in monkeys was suggested to be mediated by the μ-receptor.[133] Naloxone reverses opioid-induced itching, and this finding supports a receptor-mediated central mechanism for pruritus. However, opioid antagonists are not ideal therapeutic agents against pruritus because opioid analgesia is also reversed by these agents. Perhaps some mixed opioids with low to medium efficacy at both the μ- and κ-receptors, such as nalbuphine and butorphanol, are useful antipruritics because they may partially antagonize μ actions with intact κ actions to maintain analgesic function.[134,135] Recently, ondansetron has been proposed for the treatment of spinal or epidural morphine–induced pruritus.[136] Tenoxicam, a nonsteroidal anti-inflammatory drug, was reported to be effective for pruritus induced by epidural fentanyl.[137] Intravenous administration of droperidol (1.25 mg), propofol (20 mg), or alizapride (100 mg) reduced the incidence of pruritus induced by the use of morphine, 0.2 mg intrathecally, in patients undergoing cesarean section under spinal anesthesia.[138] Histamine release, once thought to underlie this phenomenon, is not causative because non–histamine-releasing opioids also produce pruritus.

Facial itching may not necessarily be a manifestation of direct opioid action at the level of the trigeminal nucleus; instead, it may be a reflection of opioid-triggered neural transmission at a distant site. It is not known why the face is prone to pruritus even after spinal opioids. Interestingly, pruritus secondary to cholestasis is ameliorated by opioid antagonists.[139]

Respiratory Effects of Opioids

The respiratory depressant actions of opioids are their most serious adverse effect. Although significant adverse events related to opioid-induced respiratory depression are presumably preventable, they persist with a perioperative incidence of approximately 0.1% to 1%, no matter what the route of administration.[140] Even though some early studies indicated both μ- and δ-opioid receptor involvement, a recent report demonstrated that activation of the μ-opioid receptor in the caudal medullary raphe region, which is important for pain regulation and respiratory modulation, inhibits the ventilatory response to hypercapnia in anesthetized rats.[141] Furthermore, administration of morphine or M6G did not produce significant respiratory depression in μ-

opioid receptor knock-out mice.[142] Polymorphism of the μ-opioid receptor at nucleotide position 118, which is known to affect M6G-induced analgesia, does not significantly change susceptibility to the respiratory depressive effect of M6G.[8] This result may suggest that analgesia and respiratory depression are mediated by different signal transduction mechanisms activated by the μ-opioid receptor. In dogs, naltrindole, a highly selective antagonist of the δ-opioid receptor, can reverse the sufentanil-induced respiratory depression without significant effect on the analgesic action of sufentanil.[143]

Several studies have reported a depressant effect of morphine on respiratory mucus transport, which is one of the most important defenses against respiratory tract infections. However, morphine had no effect on the beating frequency of nasal cilia in vitro.[144]

Therapeutic Effects

Opioids, by decreasing pain and central ventilatory drive, are effective agents in preventing hyperventilation induced by pain or anxiety.[145,146] The lack of adequate pain relief can also cause postoperative respiratory dysfunction. Opioids can be used as postoperative analgesics to prevent respiratory dysfunction. The antitussive actions of opioids are well known and central in origin. However, fentanyl, sufentanil, and alfentanil curiously elicit a brief cough in up to 50% of patients when injected by intravenous bolus.[147] Fentanyl, administered via a peripheral intravenous cannula, provoked cough when injected rapidly, but the incidence was decreased significantly as the injection time was increased[148] or by the administration of 1.5 mg/kg lidocaine 1 minute before fentanyl administration.[149] In addition, current smokers had a lower incidence of cough than nonsmokers did, whereas heavy smokers did not.

Opioids are also excellent agents for depressing upper airway, tracheal, and lower respiratory tract reflexes, but the mechanism is not clear. Although opioids can affect the contractile responses of airway smooth muscles, the clinical significance and relevance of opioid-induced effects on airway resistance remain controversial.[150] Opioids blunt or eliminate somatic and autonomic responses to tracheal intubation. They allow patients to tolerate endotracheal tubes without coughing or "bucking." Opioids can also help avoid increases in bronchomotor tone in asthma. In addition, fentanyl has antimuscarinic, antihistaminergic, and antiserotoninergic actions and may be more effective than morphine in patients with asthma or other bronchospastic diseases.

Nontherapeutic Effects

Opioids activating the μ-receptor cause dose-dependent depression of respiration, primarily through a direct action on brainstem respiratory centers. How the various respiratory centers involved in the ventilatory drive, respiratory rhythm generation, chemoreception, and neural integration are affected by opioids is unclear.

The stimulatory effect of CO_2 on ventilation is significantly reduced by opioids. The hypercapneic response can be separated into central and peripheral components. Morphine-induced changes in the central component were equal in men and women, whereas changes in the peripheral component were larger in women.[151] In addition, the apneic threshold and resting end-tidal P_{ETCO_2} are increased by opioids (Fig. 27-9). Opioids also decrease the hypoxic ventilatory drive.

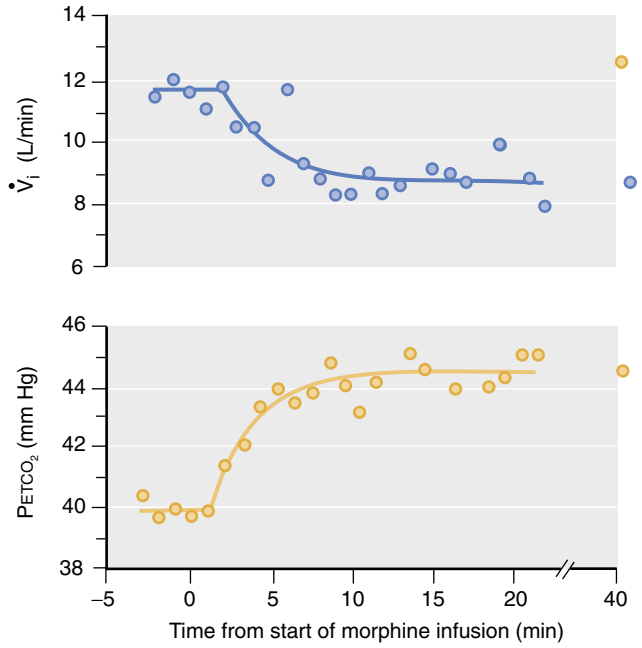

Figure 27-9 Influence of morphine administration (bolus dose of 100 μg/kg given at time t = 0 minutes, followed by a continuous infusion of 30 μg/kg/hr) on resting inspired minute ventilation and resting pressure of end-tidal CO_2 in a single subject. A one-component exponential was fitted to the data. The estimated time constant is 3.0 minutes for the V_I data and 2.6 minutes for the P_{ETCO_2} data. The time delays are between 1 and 2 minutes. *(From Sarton E, Teppema L, Dahan A: Sex differences in morphine-induced ventilatory depression reside within the peripheral chemoreflex loop. Anesthesiology 90:1329-1338, 1999.)*

The respiratory rate is usually drastically slowed in opioid overdose, although a hypoxic CNS insult can counter this effect. The prolonged expiratory time in the respiratory cycle induced by opioids frequently results in greater reductions in respiratory rate than in tidal volume. Monitoring of breath intervals can sensitively detect fentanyl-induced respiratory depression and can be used as a measure of dynamic opioid effect.[152] High doses of opioids usually eliminate spontaneous respirations without necessarily producing unconsciousness. Patients receiving high doses of opioids may still be responsive to verbal command and often breathe when directed to do so.

The peak onset of respiratory depression after an analgesic dose of morphine is slower than after comparable doses of fentanyl: 30 ± 15 minutes versus 5 to 10 minutes. The respiratory depression induced by small doses of morphine usually lasts longer than after equipotent doses of fentanyl. Sufentanil (0.1 to 0.4 μg/kg) produces shorter-lasting respiratory depression and longer-lasting analgesia than fentanyl does (1.0 to 4.0 μg/kg).[153] Plasma fentanyl concentrations of 1.5 to 3.0 ng/mL are generally associated with significant decreases in CO_2 responsiveness. With higher doses of fentanyl (50 to 100 μg/kg), respiratory depression can persist for many hours. When moderately large (20 to 50 μg/kg or greater) doses of fentanyl are used, the potential need for

Box 27-2 Factors Increasing the Magnitude or Duration of Opioid-Induced Respiratory Depression

- High dose
- Sleep
- Old age
- Central nervous system depressant
  - Inhaled anesthetics, alcohol, barbiturates, benzodiazepines
- Renal insufficiency
- Hyperventilation, hypocapnia
- Respiratory acidosis
- Decreased clearance
  - Reduction of hepatic blood flow
- Secondary peaks in plasma opioid levels
  - Reuptake of opioids from muscle, lung, fat, and intestine
- Pain

postoperative mechanical ventilation should be anticipated. The effects of remifentanil, no matter what the dose, are attenuated rapidly and completely within 5 to 15 minutes after termination of its administration. In healthy humans, the median effective concentration (EC_{50}) causing depression of minute ventilation with remifentanil and alfentanil was 1.17 and 49.4 ng/mL, respectively.[154]

Although the mechanism by which pain modulates ventilatory control is unknown, daily clinical practice provides indirect evidence that pain stimulates ventilation, especially during emergence from anesthesia. Combes and colleagues demonstrated that pain relief via a nerve block in knee surgery patients who had previously been treated with morphine PCA increases the incidence of abnormal respiratory events associated with oxygen desaturation.[155]

Naloxone is standard therapy for opioid-induced respiratory depression. However, there have been reports of naloxone-resistant respiratory depression after intrathecal morphine.[156]

Factors Affecting Opioid-Induced Respiratory Depression

Many factors affect the magnitude and duration of opioid-induced respiratory depression (Box 27-2).

Older patients are more sensitive to the anesthetic and respiratory depressant effects of opioids. They experience higher plasma concentrations of opioids when administered on a weight basis. Morphine can produce greater respiratory depression on a weight basis in neonates than in adults because it easily penetrates the brain in neonates and infants with incomplete blood-brain barriers.

The respiratory depressant effects of opioids are increased or prolonged (or both) when administered with other CNS depressants, including the potent inhaled anesthetics, alcohol, barbiturates, benzodiazepines, and most of the intravenous sedatives and hypnotics.[153] Exceptions are droperidol, scopolamine, and clonidine, which do not enhance the respiratory depressant effects of fentanyl or other opioids.[157]

Although opioid action is usually dissipated by redistribution and hepatic metabolism rather than by urinary excretion, the adequacy of renal function may influence the duration of opioid activity. In renal insufficiency, the respiratory depressant properties of the morphine metabolite M6G would become evident as it accumulated. One study indicated that M6G is a somewhat weaker respiratory depressant than morphine is.[158]

Hypocapnic hyperventilation enhances and prolongs postoperative respiratory depression after fentanyl (10 and 25 μg/kg). Intraoperative hypercapnia produces the opposite effects. Possible explanations for these findings include increased brain opioid penetration (increased un-ionized fentanyl with hypocapnia) and removal (decreased CBF with hypocapnia). In patients who hyperventilate because of anxiety or pain, even small intravenous doses of opioids can result in transient apnea because of acute shifts in apneic thresholds.

Delayed or recurring respiratory depression has been reported with most opioids. Mechanisms for this phenomenon may include augmented release of fentanyl or other opioids from skeletal muscle into the systemic circulation on rewarming, shivering, motion, or any other condition that enhances muscle perfusion.

Cardiovascular Effects of Opioids

Large doses of opioids, administered as the sole or primary anesthetic, result in hemodynamic stability throughout the operative period. The choice of opioid can affect the perioperative hemodynamic profile. For example, alfentanil is less reliable than fentanyl and sufentanil in blocking increases in heart rate and blood pressure during induction of anesthesia, sternotomy, sternal spread, and aortotomy in patients with ischemic heart disease who undergo coronary artery surgery.[159]

Neurologic Mechanisms

Key areas of the brainstem that integrate cardiovascular responses and maintain cardiovascular homeostasis are the nucleus solitarius, the dorsal vagal nucleus, the nucleus ambiguus, and the parabrachial nucleus. The nucleus solitarius and parabrachial nucleus play an important role in the hemodynamic control of vasopressin secretion. Enkephalin-containing neurons and opioid receptors are distributed in these regions. Direct administration of μ-agonists into the CNS of animals most commonly, but not always, produces hypotension and bradycardia.[160] In addition, the ventrolateral PAG region, a key central site mediating opioid analgesia, affects hemodynamic control.[161] Opioids can also modulate the stress response through receptor-mediated actions on the hypothalamic-pituitary-adrenal axis. Most opioids reduce sympathetic and enhance vagal and parasympathetic tone. Patients who are intravascularly volume depleted or individuals depending on high sympathetic tone or exogenous catecholamines to maintain cardiovascular function are predisposed to hypotension after the administration of opioids.

The predominant and usual effect of opioids on the heart rate is to produce bradycardia from stimulation of the central

vagal nucleus. Blockade of sympathetic actions may also play a role in opioid-induced bradycardia. Meperidine, in contrast to other opioids, rarely results in bradycardia but can cause tachycardia. Tachycardia after meperidine may be related to its structural similarity to atropine, to normeperidine, its principal metabolite, or to early manifestations of its toxic CNS effects.

Cardiac Mechanisms

The direct cardiac actions of opioids, in particular, the effects on myocardial contractile mechanisms, are significantly less than those of many other intravenous and inhaled anesthetics. However, opioid receptors have been demonstrated in the cardiac myocytes of several species.

Contractility

Some investigators suggest that opioids produce direct positive inotropic effects on the heart.[162] However, others report negative inotropic actions with some agents (meperidine) and no direct effects with others (morphine).[163] Some investigators suggest that local anesthetic–like effects and not receptor-related opioid actions mediate some of the negative inotropic effects of opioids, especially with high drug concentrations.

Morphine decreases Ca^{2+} transients but not cardiac contraction and enhances myofilament Ca^{2+} sensitivity through action on the δ_1-opioid receptor expressed in the heart.[164] In rabbit ventricular myocytes, morphine prolongs the action potential duration by increasing the L-type Ca^{2+} current, an effect mediated by δ- and κ-opioid receptors, and hyperpolarizes cardiac resting membrane potential by increasing the inwardly rectifying K^+ current, which is not mediated by opioid receptors.[165] On the other hand, it was demonstrated that morphine decreases the isometric force of contraction in atrial muscles from nonfailing and failing human hearts through a naloxone-insensitive mechanism.[166] Fentanyl produces little or no change in myocardial contractility.[167] Usually, most hemodynamic variables remain unchanged after large doses of fentanyl. However, fentanyl has positive inotropic effects. Possible mechanisms of the dose-dependent positive inotropic effects of fentanyl, as well as sufentanil, include release of catecholamines or direct myocardial adrenergic activation. Alfentanil, at concentrations achieved in clinical practice, increases contraction in ventricular cells by a mechanism involving an increase in the sensitivity of the contractile apparatus to Ca^{2+}.[168] The negative inotropic effect of tumor necrosis factor-α (TNF-α) and interleukin-1β (IL-1β) on ventricular myocytes caused by disruption of sarcoplasmic reticulum Ca^{2+} handling and the Ca^{2+} transient was ameliorated by alfentanil, but this response may not be mediated by opioid receptors.[169] Studies in dogs have demonstrated little change in hemodynamics with moderate doses (160 μg/kg) of alfentanil and transient cardiac stimulation (increases in left ventricular contractility, aortic blood flow velocity, and acceleration) with very large doses (5 mg/kg). In dogs, remifentanil produces hemodynamic effects that include decreases in contractility and cardiac output, as well as reductions in heart rate and blood pressure.[170]

Heart Rate and Rhythm

Opioid-induced bradycardia is primarily mediated by the CNS. Opioids have direct effects on cardiac pacemaker cells. Alfentanil significantly decreased the frequency of contractions of the right atrial–sinoatrial node in a dose-related manner in isolated cardiac tissue from young adult rabbits.[162] Premedication with or concomitant administration of β-adrenergic or Ca^{2+} channel entry blockers can exacerbate the bradycardia and may result in asystole after the administration of opioids. Periods of asystole, 10 to 12 seconds in duration, may resolve on their own, but they usually respond to atropine (0.4 to 0.8 mg IV).

Cardiac Conduction

Fentanyl may depress cardiac conduction by a mechanism mediated by direct membrane actions as opposed to opioid receptor interactions.[171] During induction of anesthesia in patients undergoing coronary artery bypass graft surgery, the QT interval increased significantly after the injection of fentanyl.[172] In contrast, both sufentanil and alfentanil have been demonstrated to be devoid of electrophysiologic effects on the normal or accessory pathways in patients with Wolff-Parkinson-White syndrome.[173,174] Clinically, cardiac conduction disturbances attributable to opioids are rare, but they may be more likely to occur in the presence of Ca^{2+} channel entry or β-adrenergic blockers.

The overall effect of opioid anesthesia is antiarrhythmogenic.[175] It was reported that naloxone, morphine, and levorphanol protected against arrhythmia induced by coronary artery occlusion in rats.[176] A direct effect on ionic currents in cardiac muscle was suggested as the mechanism of the antiarrhythmogenic activity of opioids. It was also reported that opioid antagonists are more antiarrhythmogenic than agonists in rats.[177] Some of the electrophysiologic actions of opioids resemble those of class III antiarrhythmogenic drugs.

Ischemia

Determining the effects and consequences of opioid action on myocardial ischemia is complex because the results can depend on such factors as the species studied and experimental design. Opioids can mimic ischemic preconditioning. Stimulation of the opioid receptor results in a reduction in infarct size similar to that produced by ischemic preconditioning (Fig. 27-10).[178] Although the preconditioning effect of opioids is mediated mainly by cardiac κ- and δ-opioid receptors,[179] part of the protective effect of remifentanil may be produced by μ-agonist activity outside the heart.[180] Late preconditioning, in which cardioprotective effects can be observed 24 hours after drug administration, can also be produced by morphine-induced activation of the opioid receptor in rat hearts.[181] Remote preconditioning by brief ischemia in other distant organs, such as the intestine, kidney and limb, likewise provides cardioprotection that is as effective as classic ischemic preconditioning. The myocardial κ-opioid receptors were demonstrated to mediate cardioprotection by remote preconditioning.[182] Volatile anesthetics may also be capable of protecting against ischemic injury when administered solely on reperfusion. This anesthetic-induced postconditioning can be enhanced by morphine through the activation of phosphatidyl-3-kinase and opioid receptors.[183]

Stimulation of the δ_1-opioid receptor generates oxygen radicals via mitochondrial ATP-sensitive K^+ channels and thereby results in attenuation of oxidant stress and cell death in cardiomyocytes.[184] Involvement of the adenosine A_1 receptor and protein kinase C in the cardioprotective effect of opioids was also suggested.[185,186] Whether the experimental results showing protective effects of opioid against myocardial ischemia will translate into reductions in morbidity and mortality in patients with coronary

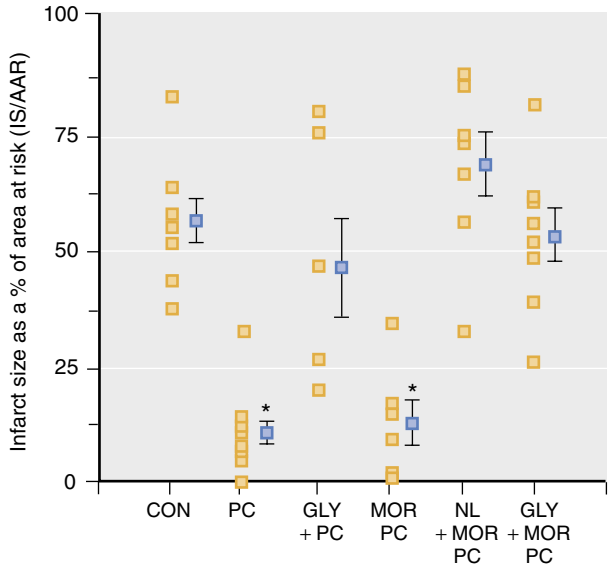

Figure 27-10 Infarct sizes in rat hearts subjected to control conditions (CON), ischemic preconditioning (PC), glibenclamide (0.3 mg/kg intravenously) given 30 minutes before ischemic PC (GLY + PC), morphine-induced PC (3 × 100 μg/kg, 5-minute intravenous infusion) (MOR PC), naloxone (3 mg/kg intravenously) given 10 minutes before morphine-induced PC (NL + MOR PC), and glibenclamide (0.3 mg/kg intravenously) given 30 minutes before morphine-induced PC (GLY + MOR PC). *(From Schultz JE, Hsu AK, Gross GJ: Morphine mimics the cardioprotective effect of ischemic preconditioning via a glibenclamide-sensitive mechanism in the rat heart. Circ Res 78:1100-1104, 1996.)*

artery disease has yet to be established in clinical trials.[187] Clinically, high doses of opioids can maintain myocardial perfusion and the O_2 supply-demand ratio as well as or better than inhalation-based techniques can.[188,189]

Coronary Circulation

Opioids appear to have no significant effect on coronary vasomotion or myocardial metabolism, do not produce steal phenomena, and do not diminish the ability of large coronary arterioles to respond to vasoactive agents.[190] Coronary conductance is regulated by arterial baroreflex control, and a vasodilator response is induced by a rise in aortic pressure. This baroreflex control is enhanced by low plasma concentrations of fentanyl (1 to 2 ng/mL) but appears to be depressed with increasing plasma concentrations of fentanyl.[191] In a study of the effects of opioids and neuroendocrine modulators on porcine coronary arteries, fentanyl, but not sufentanil or morphine, antagonized acetylcholine-induced contractions.[192] The effect of fentanyl was not reversible by naloxone and thus was thought to represent a direct smooth muscle effect.

Circulatory Reflexes

In an experiment examining baroreceptor reflex responses induced by perfusion of the carotid sinus at predetermined levels, baroreceptor reflexes were well preserved with moderate doses of fentanyl, whereas high doses of fentanyl depressed the baroreceptor reflexes.[193] The oculocardiac reflex, which is caused by traction on the extraocular muscles during strabismus surgery, was significantly augmented by fentanyl, sufentanil, and remifentanil.[194] In pediatric patients undergoing strabismus surgery and anesthetized with propofol (12 mg/kg/hr) and alfentanil (0.04 mg/kg/hr), an oculocardiac reflex developed in virtually all patients, and atrioventricular rhythm disorders were frequent.[195]

Histamine Release

Morphine causes release of histamine and sympathoadrenal activation. Codeine and meperidine induce mast cell activation with the release of histamine, probably by a mechanism other than the μ-opioid receptors.[196]

Increases in plasma histamine after morphine cause dilatation of terminal arterioles and direct positive cardiac chronotropic and inotropic actions. The cardiovascular changes after morphine are similar when patients are pretreated with diphenhydramine (histamine H_1-antagonist) or cimetidine (histamine H_2-antagonist). However, in patients pretreated with both H_1- and H_2-antagonists, cardiovascular responses were significantly attenuated despite comparable increases in plasma histamine concentration. Meperidine also causes histamine release more frequently than most other opioids do. Unlike morphine or meperidine, fentanyl, alfentanil, and remifentanil do not produce increases in plasma histamine, and hypotension is less frequent with these opioids.

Vascular Mechanisms

A new pharmacologically defined opioid receptor subtype, designated μ_3, is opiate alkaloid sensitive and opioid peptide insensitive, including peptides previously shown to have affinity for μ-opioid receptors. This receptor is expressed in human endothelial cells and is coupled to vasodilation via production of nitric oxide. Morphine-induced vasodilation may be caused in part by activation of the μ_3-receptor.[197] Pharmacologic studies evaluating alfentanil, fentanyl, and sufentanil in the dog have demonstrated direct peripheral vessel smooth muscle relaxation.[198] Measurement of forearm blood flow after infusion of sufentanil into the brachial artery indicated that sufentanil has a direct vasodilatory effect on human vascular tissue that is probably independent of a neurogenic or systemic mechanism.[199] A supraclinical dose of alfentanil attenuates the phenylephrine-induced contraction via an inhibitory effect on calcium influx by blocking the L-type calcium channels in the rat aortic vascular smooth muscle.[200] Remifentanil can cause transient instability in hemodynamic variables. However, this change may not solely be the result of autonomic or CNS inhibition or centrally mediated vagal stimulation. A pharmacologic study using rat thoracic aortic rings indicated that remifentanil vasodilates by an endothelium-dependent mechanism involving release of prostacyclin and nitric oxide from the endothelium, as well as by an endothelium-independent mechanism probably mediated by suppression of voltage-sensitive Ca^{2+} channels.[201]

Opioids may affect the pulmonary vasculature, as well as the systemic circulation. It was recently shown that phenylephrine-induced contraction of the canine pulmonary artery is mediated primarily by activation of the α_{1B}-adrenergic receptor and is attenuated by fentanyl binding to and directly inhibiting the α_{1B}-adrenergic receptor.[202] Pharmacologic studies in cats have demonstrated that sufentanil and remifentanil have potent vasodepressor activity in the pulmonary vascular bed and that these responses may be mediated by the histamine and opioid receptor–sensitive pathway.[203,204]

Activation of the muscarinic acetylcholine receptors expressed on endothelial cells results in the activation of nitric oxide synthase and release of nitric oxide, which relaxes vascular smooth muscle by activation of 3,5-cyclic guanosine monophosphate. It was shown that fentanyl attenuates acetylcholine-induced relaxation of rat aorta precontracted with phenylephrine via an inhibitory effect at a level proximal to activation of nitric oxide synthase on the pathway involving endothelial M_3 muscarinic receptor activation.[205]

Endocrinologic Effects of Opioids

The main components of the neuroendocrine stress response are the corticotropin-releasing hormone brain centers (e.g., the paraventricular hypothalamic nucleus) and the locus ceruleus–norepinephrine/autonomic nervous system.[206] Increased levels of stress hormones are considered undesirable because they promote hemodynamic instability and intraoperative and postoperative metabolic catabolism. In some circumstances, the hormonal and metabolic responses to surgery are extreme and thought to contribute to operative mortality.[207]

Opioids are capable of reducing the stress response by modulating nociception at several different levels of the neuraxis, as well as by influencing centrally mediated neuroendocrine responses. Opioids are potent inhibitors of the pituitary-adrenal axis.[208] Endogenous opioid peptides may serve as stress hormones themselves and not just as modulators of the secretion of other hormones. This activity is suggested by the finding that β-endorphin and adrenocorticotropic hormone (ACTH) are derived from the same precursor proopiomelanocortin and cosecreted during stress.

Morphine modifies hormonal responses to surgical trauma in a dose-related fashion. Morphine can prevent the release of ACTH, suppress surgically induced increases in plasma cortisol, and attenuate the pituitary-adrenal response to surgical stress. Morphine can increase some stress-responding hormones by increasing plasma histamine release, adrenal medullary release mechanisms, and release of catecholamine from sympathetic nerve endings.

Fentanyl and its congeners are more effective than morphine in modifying hormonal responses to surgery. The efficacy of fentanyl in controlling the hormonal manifestations of the stress response can be dose dependent. Fentanyl doses of 50 μg/kg or greater can help reduce the hyperglycemic response to cardiac surgery in pediatric patients to less than 200 mg/dL throughout surgery.[209] In contrast, neither fentanyl nor sufentanil alone can completely block the sympathetic and hormonal stress responses, and perhaps no dose-response relationship exists for opioid-associated control of the stress response.[71] The stress response to cardiopulmonary bypass (CPB) is difficult to suppress with sufentanil or fentanyl. Alfentanil can suppress increases in plasma cortisol and catecholamines before but not during CPB and may prevent increases in antidiuretic hormone (ADH) and growth hormone throughout coronary artery bypass surgery. A randomized controlled trial showed that remifentanil (0.85 μg/kg/min), when compared with fentanyl (total doses of 15 and 28 μg/kg), blunts the hypertensive responses and cortisol excretion associated with cardiac surgery but is associated with more hypotension.[210]

Stress Reduction and Outcome

Anesthetic techniques or drugs that minimize the stress response may reduce morbidity and mortality in a variety of circumstances. Sufentanil appears to be the most likely opioid to modify stress responses and outcome successfully.[211,212] Anand and Hickey[211] evaluated the impact of sufentanil versus morphine-halothane anesthesia on hormonal and metabolic responses and morbidity and mortality in neonates undergoing cardiac surgery. Most strikingly, a statistically significant difference in postoperative mortality was observed (0 of 30 given sufentanil versus 4 of 15 given halothane plus morphine). Mangano and coauthors[212] also reported that after myocardial revascularization, patients receiving intense postoperative analgesia with sufentanil (1 μg/kg/hr) experience a lower incidence and severity of electrocardiographically documented ischemia than do patients receiving intermittent intravenous morphine (2.2 ± 2.1 mg/hr) for postoperative analgesia. It was also shown that high-dose opioids (remifentanil, 0.85 μg/kg/min, or fentanyl, 28 μg/kg) are associated with a decreased rate of myocardial infarction after cardiac surgery.[210]

Many different hormonal changes induced by surgery have been described. However, the concomitant neural, cellular, immune, and biochemical changes have been less well defined, and little is understood or proven with regard to how modifying hormonal responses alters outcome.[213] Additional studies are necessary for complete elucidation of the relationship between control of surgically induced hormonal responses and outcome.

Opiate Tolerance and Addiction

The mechanisms of dependence and tolerance involve genetic, molecular, cellular, physiologic, and functional factors. In the locus ceruleus, the major noradrenergic nucleus in the brain, long-term opioid exposure results in inhibition of adenylyl cyclase, reduced activity of protein kinase A, and upregulation of the cyclic AMP pathway.[214] The changes in μ-receptor density that occur before or during the development of tolerance do not appear to be essential for the development of opioid tolerance.[215] Possible mechanisms involve protein kinase signal transduction cascades that link extracellular signals to cellular changes by regulating target gene expression. Central glucocorticoid receptors (GRs) have been implicated in the cellular mechanism of neuronal plasticity, which has many cellular steps in common with the mechanism of opioid tolerance. It was shown that the development of tolerance to the antinociceptive effect of morphine was substantially attenuated when a GR antagonist was coadministered with morphine but that the GR agonist dexamethasone facilitated the development of morphine tolerance, suggesting an important role of spinal GRs in the cellular mechanisms of morphine tolerance in rats.[216] Morphine tolerance occurs more rapidly in younger rats than in older rats and is unlikely to be the result of differences in drug metabolism or clearance, an observation suggesting that aging may have an impact on the molecular processes involved in the development of tolerance.[217]

Acute administration of opioids results in analgesia and side effects, whereas tolerance and dependence were thought to occur only after chronic administration. However, tolerance can also develop rapidly after acute opioid exposure in animals and humans.[218-220] Intraoperative remifentanil infusion (0.3 μg/kg/

min) in patients undergoing major abdominal surgery under desflurane anesthesia increased postoperative pain and morphine requirements when compared with low-dose remifentanil (0.1 μg/kg/min), suggesting the development of acute remifentanil tolerance.[221] In contrast, there is a report that target-controlled infusion of alfentanil and remifentanil for postoperative analgesia does not lead to opioid tolerance.[222] In human volunteers, continuous infusion of remifentanil (0.08 μg/kg/min) for 3 hours did not decrease the pain threshold.[223] Thus, the development of acute opioid tolerance in humans remains controversial. Opioids can elicit hyperalgesia in experimental models after repeated opioid administration or continuous delivery.[224] This phenomenon seems to be related to opioid tolerance.[225] In rats, thermal hyperalgesia and mechanical allodynia were observed for several days after cessation of morphine administration (40 mg/kg/day for 6 days).[226] The opioid-induced hyperalgesia is due to spinal sensitization to glutamate and substance P.[227] Furthermore, cholecystokinin and the NMDA–nitric oxide system are responsible for the development of acute tolerance to opioids,[228] which is also affected by spinal serotonin activity.[229] Opioid-induced hyperalgesia and subsequent acute opioid tolerance can be prevented by ketamine, suggesting involvement of the NMDA receptor.[230,231] Methadone is unique in possessing both μ-opioid and NMDA antagonist properties. Opioid-induced hyperalgesia resulted from the presence of *l*-methadone (μ-opioid agonist) in the racemate and was antagonized by the presence of *d*-methadone (NMDA antagonist).[232] Spinal cyclooxygenase-2 (COX-2) is upregulated and release of prostaglandin E_2 in the spinal cord is increased after morphine withdrawal in rats.[233] In humans, hyperalgesia after a 30-minute intravenous infusion of remifentanil (0.1 μg/kg/min) could be prevented by the administration of parecoxib, a COX-2 inhibitor, before the infusion of remifentanil,[234] findings suggesting involvement of COX-2 in opioid-induced hyperalgesia. Genetic analysis in mice suggested that genetic variants of the β_2-adrenergic receptor gene seem to explain some of the differences between various strains of mice in the development of opioid-induced hyperalgesia, and the selective β_2-adrenergic receptor antagonist butoxamine was shown to dose-dependently reverse opioid-induced hyperalgesia.[235] Human data generally support the existence of opioid-induced hyperalgesia in a few specific settings. The conditions under which opioid-induced hyperalgesia is expressed should be clarified and its clinical significance elucidated.[236]

The peripheral effects of morphine have been suggested to be less prone to tolerance.[237] Thus, the method and schedule of drug administration may also affect the development of tolerance.[238] However, modifying an opioid administration schedule to modulate the development of tolerance may not always be useful or effective.[239] Certain patients may appear to be tolerant to opioids but instead suffer from pathophysiologic conditions that are poorly responsive to opioids, such as neuropathies.[240]

Management of Opioid-Dependent Patients

A variety of problems should be taken into consideration in the anesthetic management of opioid-dependent patients.[241] Complications in opioid-addicted patients include cardiopulmonary problems, renal problems, and anemia. Long-term morphine administration causes adrenal hypertrophy and impairs corticosteroid secretion. Viral and nonviral hepatitis, acquired immunodeficiency syndrome, osteomyelitis, muscle weakness, and neurologic complications may be found in addicted patients. Anesthetic management of an opiate-dependent or opiate-addicted patient should include adequate premedication with opioids, administration of supplemental intraoperative and postoperative opioids, and provision of nonopioid analgesics and neural blockade. There is no ideal anesthetic approach for a chronic addict or a patient with an acute opiate overdose. Support of the circulatory system with fluids and monitoring of arterial blood gases and pulmonary function are also important.

Recently, rapid detoxification with a high dose of naloxone or naltrexone has been reported for the treatment of opioid addiction. For such treatment, general anesthesia is induced before the start of opioid antagonism and maintained for several hours to prevent the perception of withdrawal symptoms by the patient.[242,243] Blockade of μ-opioid receptors by naloxone (total dose of 12.4 mg) in opioid-addicted patients induces sympathetic neural activation, including an increase in plasma catecholamine concentration and cardiovascular stimulation, which is abolished by α_2-agonists.[244]

Renal and Urodynamic Effects of Opioids

μ-Receptor activation causes antidiuresis and decreases electrolyte excretion. κ-Receptor stimulation predominantly produces diuresis with little change in electrolyte excretion. The stable dynorphin analog E-2078 causes κ-mediated diuretic effects in the isolated perfused rat kidney.[245] Indirect actions may involve inhibiting or altering the secretion of ADH and atrial natriuretic peptide.[246] The absence of increases in plasma ADH, renin, and aldosterone indicates that fentanyl, sufentanil, alfentanil, and probably remifentanil most likely preserve or minimally alter renal function in humans. If renal function does change during opioid anesthesia and surgery, it is probably due to secondary changes in systemic and renal hemodynamics.

The mechanism by which opioids cause urinary retention is incompletely understood. Effects of opioids on the lower urinary tract include disturbances in micturition characterized by urinary retention, especially after intrathecal opioid administration. Intrathecal administration of morphine and sufentanil caused dose-dependent suppression of detrusor contractility and decreased sensation of urge.[247] Mean times to recovery of normal lower urinary tract function were 5 and 8 hours after 10 and 30 μg sufentanil and 14 and 20 hours after 0.1 and 0.3 mg morphine, respectively. Not all opioid agonists behave similarly, and morphine appears to be particularly potent with regard to producing urodynamic problems. Malinovsky and associates compared the urodynamic effects of intravenously administered morphine (10 mg), buprenorphine (0.3 mg), fentanyl (0.35 mg), and nalbuphine (20 mg).[248] All of the opioids altered bladder sensation, but detrusor contraction decreased only after the administration of fentanyl and buprenorphine. Urinary retention induced by intravenous infusion of remifentanil, 0.15 μg/kg/min, could be reversed by a single intravenous dose of methylnaltrexone, 0.3 mg/kg, or naloxone, 0.01 mg/kg.[249] Reversal of urinary retention by methylnaltrexone indicates that peripheral mechanisms may play a role in opioid-induced bladder dysfunction.

Gastrointestinal Effects of Opioids

Opioids decrease gastrointestinal motility,[250] and this action underlies their use as antidiarrheal agents. Patients receiving parenteral opioid therapy preoperatively are more likely to have "full stomachs" regardless of their "NPO" status.

Several opioid receptor types can be demonstrated on myenteric neurons, and both κ- and μ-receptor agonists regulate cholinergic transmission in the myenteric plexus. κ-Agonists appear to modulate release of acetylcholine more potently than μ-agonists do by inhibition of N-type voltage-sensitive Ca^{2+} channels via a pertussis toxin–sensitive G protein in guinea pig ileum.[251]

The effect of morphine on esophageal motility has not been explored very extensively. Morphine (80 μg/kg) increased the velocity but did not alter the amplitude or duration of primary peristalsis of the esophagus, and it decreased the duration and magnitude of swallow-induced relaxation of the lower esophageal sphincter.[252] Gastric emptying is delayed by opioids via supraspinal (vagus nerve–mediated) and spinal as well as peripheral mechanisms. Intrathecal morphine (0.4 mg) significantly decreased gastroduodenal propagation velocity and acetaminophen absorption, and intramuscular morphine (4 mg) resulted in additional effects.[253] Tramadol (1.25 mg/kg IV) has a measurable but smaller inhibitory effect on gastric emptying than codeine (1 mg/kg IV) and morphine (0.125 mg/kg IV) do.[254] Opioids administered epidurally as well as intrathecally reduce gastrointestinal motility.[255,256] It was reported that translocation of enteric microorganisms from the intestinal tract to extraintestinal sites is promoted by reduction of gut propulsion after morphine treatment in rats.[257] Propofol (0.3- mg/kg bolus and 1.0 mg/kg/hr) abolished the decrease in gastric tone induced by morphine (0.1 mg/kg IV) but did not abolish morphine-induced delay of gastric emptying.[258]

Naloxone reverses opioid-induced delays in gastric emptying. Methylnaltrexone, a quaternary naloxone derivative that does not cross the blood-brain barrier, can attenuate morphine-induced delays in gastric emptying, thus suggesting that a peripheral mechanism is involved in the opioid effect on the gastrointestinal tract.[250] Naloxone (0.7 mg/kg) significantly inhibited gastric emptying of saline and milk in rats.[259] This observation might suggest that opioids can affect the gastrointestinal tract by a mechanism independent of the opioid receptors. Intravenous, but not intramuscular metoclopramide (10 mg) can also reverse morphine-induced delays in gastric emptying.[260]

Opioid effects on the intestine are complex. Transit time from the mouth to the ileum may not be significantly altered by morphine because morphine enhances ileal propulsion before decreasing motility. Opioids increase tone and decrease propulsive activity in most of the intestine. In rats, pretreatment with epidural or intraperitoneal morphine can attenuate ischemia-induced inhibition of bowel motility.[261]

Biliary and Hepatic Effects

Opioid agonists increase biliary duct pressure and sphincter of Oddi (choledochoduodenal sphincter) tone in a dose- and drug-dependent manner through opioid receptor–mediated mechanisms. However, the clinical consequences of opioid-induced biliary tract actions are usually minimal. Although traditional teaching dictates that morphine induces "spasm" in the sphincter of Oddi and should not be used in patients with acute pancreatitis, no studies or evidence exists to indicate that morphine is contraindicated for use in acute pancreatitis.[262] Increases in biliary pressure caused by opioids are, with the exception of meperidine, reversible with naloxone. Oddi sphincter manometry via choledochoscopy demonstrated that the regular dose of morphine could increase common bile duct pressure, whereas pethidine had no effect and tramadol inhibited motility of the sphincter of Oddi.[263] Fragen and colleagues studied the effect of remifentanil (0.1 μg/kg/min) on the flow of dye from the gallbladder into the duodenum and showed that remifentanil delays the drainage of dye from the gallbladder into the duodenum but the delay is shorter than that reported after morphine or meperidine.[264] Opioids produce minimal effects on liver function during anesthesia and surgery.

Nausea and Vomiting

Postoperative nausea/vomiting is a serious problem that often embarrasses patients and anesthesiologists (also see Chapter 86).[265,266] The cause, treatment, and prevention of postoperative nausea and vomiting have been investigated extensively (Fig. 27-11).[267] Intraoperative use of opioids is a well-known risk factor for postoperative nausea and vomiting. Opioids stimulate the chemoreceptor trigger zone in the area postrema of the medulla, possibly through δ-receptors, and thereby lead to nausea and vomiting. When compared with approximately equipotent doses of fentanyl and sufentanil, alfentanil is associated with a lower incidence of postoperative nausea and vomiting.[268]

The use of propofol in balanced or total intravenous anesthesia (TIVA) significantly reduces the incidence of opioid-induced nausea and vomiting.[269] The incidence of postoperative nausea and vomiting can be as low as 5% to 20% after propofol-alfentanil anesthesia.

When opioids are administered, antiemetic prophylaxis should be considered, including drugs with anticholinergic activity, butyrophenones, dopamine antagonists, serotonin antagonists, and acupressure. Ondansetron, a serotonin type 3 receptor antagonist, was found to be effective for postoperative opioid-induced nausea and vomiting.[270] Nausea and vomiting after epidural morphine (3 mg) for post–cesarean section analgesia could be prevented by dexamethasone (8 mg IV) as efficiently as droperidol (1.25 mg IV).[271] Cannabinoid receptor agonists have been demonstrated to be effective antiemetics in some clinical settings. Animal experiments have shown that the cannabinoid agonist suppresses opioid-induced retching and vomiting by activation of the cannabinoid CB1 receptor.[272]

Other Opioid Effects

Obstetrics

Alfentanil and pethidine have been used safely as analgesics during the harvesting of human oocytes for subsequent in vitro

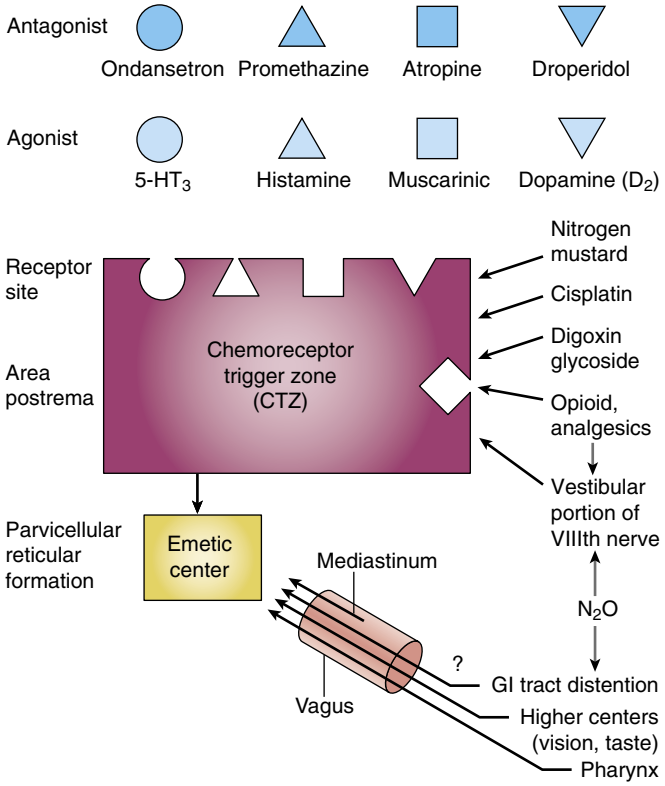

Figure 27-11 The chemoreceptor trigger zone and the emetic center with the agonist and antagonist sites of action of various anesthetic-related agents and stimuli. fertilization.[273,274] The teratogenic actions of opioids, including fentanyl, sufentanil, and alfentanil, appear to be minimal, at least in animal models.

Parenteral administration of opioids before delivery remains a commonly used method of analgesia (also see Chapter 69). Nociception as a result of uterine cervical distention could be suppressed by μ- and κ-agonists in rats,[275] but the analgesic effect of μ-agonist but not κ-agonist was reduced by estrogen.[276] Aortocaval compression and associated hypotension may be exacerbated by parenteral opioids, especially after the use of morphine or meperidine. Fatal manifestations of maternal opioid administration include decreases in heart rate variability. Adverse neonatal effects can occur after the administration of either morphine or meperidine to mothers. Fetal acidosis increases transfer of opioid from the mother. Attempts to minimize the neonatal effects of opioids include restricting opioid administration to the first stage of labor. The short-acting opioid alfentanil administered before cesarean delivery attenuated the maternal stress response but led to a slightly reduced Apgar score.[277]

In sheep, neither intravenous nor epidural injection of sufentanil (50 μg) affected maternal mean arterial pressure, uterine blood flow, maternal heart rate, fetal mean arterial pressure, fetal heart rate, or blood gases and acid-base status in the mother and fetus.[278] Because the fetus is capable of pain perception after the 26th week of gestation, adequate postoperative fetal pain management is essential after fetal surgery. It was shown that the sheep fetus absorbs sufentanil after intra-amniotic instillation and that significantly greater plasma concentrations were achieved in the fetal lamb than in the ewe.[279]

Morphine and meperidine have been found in the breast milk of mothers receiving intravenous opioid analgesia.[280,281] Although both fentanyl and morphine are concentrated in breast milk in milk-to-plasma ratios of 2:1 to 3:1, newborn exposure is reported to be insignificant. Newborns of addicted mothers can exhibit opioid withdrawal and require observation and appropriate treatment.[282]

Anaphylactoid Reactions

True allergic reactions and systemic anaphylactoid reactions to opioids are rare. More commonly, local reactions caused by preservatives or histamine may occur. In 32% of heroin addicts dying suddenly after injection, the concentration of tryptase was elevated (>10 μg/L), but no correlation was found between IgE levels and tryptase, thus supporting the hypothesis that mast cell degranulation was not mediated by allergic reaction.[283] This report suggests that many heroin fatalities are caused by an anaphylactoid reaction.

Ocular Effects

The use of fentanyl, sufentanil, and alfentanil during induction of anesthesia can help prevent increases in intraocular pressure (see Chapter 75). Fentanyl, alfentanil, and sufentanil doses as low as 2.5, 10, and 0.1 μg/kg, respectively, may be sufficient as long as appropriate anesthetic depth is achieved before tracheal intubation. Remifentanil (1 μg/kg) combined with propofol (2 mg/kg) or thiopental (5 mg/kg) is effective for prevention of changes in intraocular pressure after succinylcholine and tracheal intubation.[284,285]

Immune Effects

It is now firmly established that opioids influence immune regulation. Direct effects of opioid agonists include modulation of immune cellular activity, as well as modulation of specific enzymatic degradation and regulation processes.[286] Several immune cell populations, including T cells, macrophages, and natural killer (NK) cells, serve as targets for the effects of opioids. It was shown that maximal suppression of NK cell activity, proliferation of splenic T and B cells, and interferon-γ production are observed 0.5 to 1 hour after the injection of 15 mg/kg morphine into rats.[287] The time course was nearly concordant with the antinociceptive effect of morphine. Postoperative administration of morphine (10 mg intramuscularly [IM]) did not significantly affect NK cell activity, whereas tramadol (100 mg IM) did enhance NK cell activity.[288] It was reported that intravenously administered fentanyl causes a rapid increase in NK cell cytotoxicity, which was coincident with an increase in the percentage of $CD16^+$ and $CD8^+$ cells in peripheral blood.[289] When compared with fentanyl (1000 μg), administration of morphine (40 mg) as part of a balanced anesthetic technique suppressed several components of the inflammatory response (IL-6, CD11b, CD18, postoperative hyperthermia) to cardiac surgery and CPB.[290]

Table 27-5 Physicochemical and Pharmacokinetic Data for Commonly Used Opioid Agonists

	Morphine	Meperidine	Fentanyl	Sufentanil	Alfentanil	Remifentanil
pK_a	8.0	8.5	8.4	8.0	6.5	7.1
% Un-ionized at pH 7.4	23	<10	<10	20	90	67?

As a potential mechanism of the immunosuppressive effects of morphine, it was demonstrated that activation of the nuclear factor NF-κB by an inflammatory stimulus was inhibited by morphine-induced activation of μ_3-opioid receptors in a nitric oxide–dependent manner.[291] Several investigators have independently reported direct effects of morphine on apoptosis in cultured human peripheral blood lymphocytes, which may result in compromised immune function.[292,293] However, there is also a report that morphine has no effect on apoptosis-related molecules and does not promote apoptosis of human peripheral blood lymphocytes.[294]

Pharmacokinetics and Pharmacodynamics of Opioids

With the advent of modern drug assay technology and the widespread availability of computers, it is now possible to analyze pharmacologic data with combined pharmacokinetic-pharmacodynamic models to separate drug response into its pharmacokinetic and pharmacodynamic components. Pharmacokinetic parameters govern the relationship between opioid dose and opioid concentrations in blood (or other body fluid). Pharmacodynamic parameters describe the relationship between the opioid concentration in blood (or other fluid) and opioid effect.

Physicochemical Properties

Opioids are weak bases. When dissolved in solution, they are dissociated into protonated and free-base fractions, with the relative proportions depending on the pH and pK_a. The free-base fraction is more lipid soluble than the protonated fraction. High lipid solubility facilitates transport of opioid into the biophase or site of action. Therefore, highly lipid-soluble opioids have a more rapid onset of action. However, because the opioid receptor "recognizes" an opioid molecule in the protonated form, the intensity of opioid effects is closely related to the ionized concentration of drug in the biophase.

All opioids are to some extent bound to plasma proteins, including albumin and α_1-acid glycoprotein. It is only the un-ionized, unbound fraction that constitutes the diffusible fraction and provides the concentration gradient that promotes diffusion of opioid from blood to the tissue of interest. Thus, the speed of onset of opioid effect is affected by both lipid solubility and protein binding.

Common Pharmacokinetic Features of Opioids

Representative pharmacokinetic parameters for the opioids commonly used in anesthesia are displayed in Table 27-5.

After intravenous injection, arterial plasma concentrations of opioids rise to a peak within one circulation time. Thereafter, they exhibit a rapid redistribution phase and a slower elimination phase typical of drugs whose pharmacokinetics is described by compartmental models. After administration into a central compartment, opioids are either eliminated from the central compartment (by excretion or biotransformation) or distributed to peripheral compartments. In general, opioids are cleared from plasma by biotransformation in the liver. However, extrahepatic metabolism is important for some opioids.

As a rule, because of their high lipid solubility, opioids are widely distributed in body tissues. In pharmacokinetic terms, this means that opioids typically have a high apparent volume of distribution at steady state. Because opioids are distributed so widely and so rapidly to various body tissues, redistribution has a prominent impact on the decline in opioid concentration, particularly

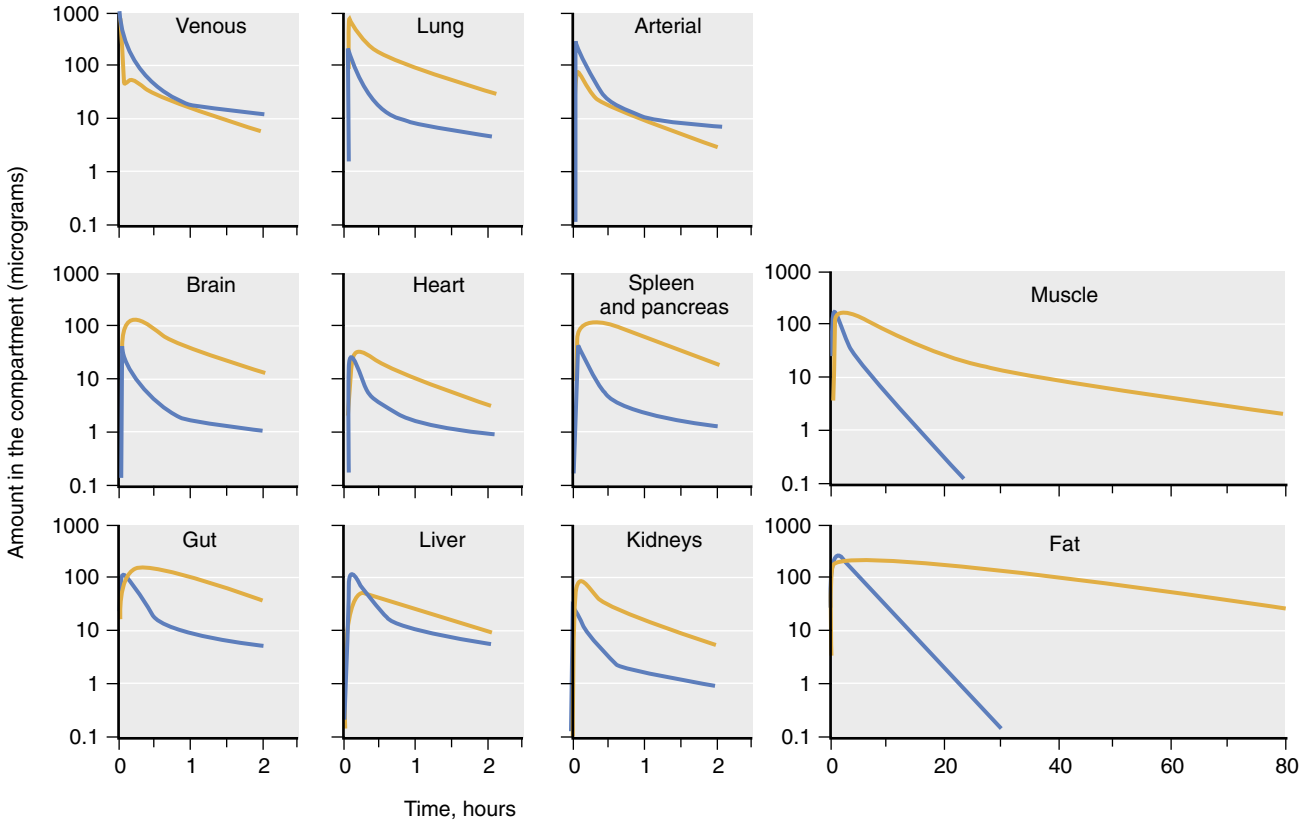

Figure 27-12 Computer simulations of the amounts of fentanyl (*yellow lines*) or alfentanil (*blue lines*) in various organs and tissues in a 70-kg human after a bolus intravenous injection of 1 mg of each drug. *(From Bjorkman S, Stanski DR, Verotta D, Harashima H: Comparative tissue concentration profiles of fentanyl and alfentanil in humans predicted from tissue/blood partition data obtained in rats. Anesthesiology 72:865-873, 1990.)*

in the early period after injection. Figure 27-12 shows a computer simulation of opioids in various organs. The difference in physicochemical properties between fentanyl and alfentanil causes the marked overall difference in disposition. Distribution to muscle and fat is extensive and declines slowly because of limited blood flow.

Opioid uptake by the lung has a significant implication in opioid pharmacokinetics. The time necessary to reach the peak concentration of an opioid is influenced by the degree of pulmonary uptake. Pulmonary uptake of fentanyl is more extensive than the pulmonary uptake of alfentanil, which may be explained by the difference in sequestration into pulmonary endothelial cells. Pulmonary uptake of opioids can affect the pharmacokinetics of other drugs. It was shown that pulmonary uptake of propofol is significantly reduced by the administration of fentanyl 30 seconds before the injection of propofol in cats.

Pharmacokinetic Features of Individual Drugs

Morphine

Morphine pharmacokinetics is notably different from that of the fentanyl congeners. This difference is due in large part to morphine's comparatively low lipid solubility. There is relatively little transient first-pass uptake of morphine by the lung.

The pK_a of morphine (8.0) is greater than physiologic pH, and thus after intravenous injection only a small fraction (10% to 20%) of morphine is un-ionized. Penetration of morphine into and out of the brain is presumably slower than that of other opioids. Approximately 20% to 40% of morphine is bound to plasma proteins, mostly albumin.

Morphine is principally metabolized by conjugation in the liver, but the kidney plays a key role in the extrahepatic metabolism of morphine. Morphine-3-glucuronide (M3G) is the major matabolite of morphine, but it does not bind to opioid receptors and possesses little or no analgesic activity. M3G may actually antagonize morphine, and this effect may contribute to both variability in response and resistance to morphine analgesic therapy. M6G accounts for nearly 10% of the morphine metabolite; it is a more potent μ-receptor agonist than morphine is and has a similar duration of action. It was reported that M6G contributes substantially to morphine's analgesic effects, even in patients with normal renal function. Especially in patients with renal dysfunction, accumulation of M6G can lead to an increased incidence of adverse effects, including respiratory depression. A recent report suggested that a single-nucleotide polymorphism at the μ-opioid receptor affects the susceptibility to M6G-related opioid toxicity. Because the hepatic extraction ratio of morphine is high, the bioavailability of orally administered morphine is significantly lower (20% to 30%) than after intramuscular or subcutaneous injection. It appears that M6G is in fact the primary active compound when morphine is administered orally (Fig. 27-13). In contrast to

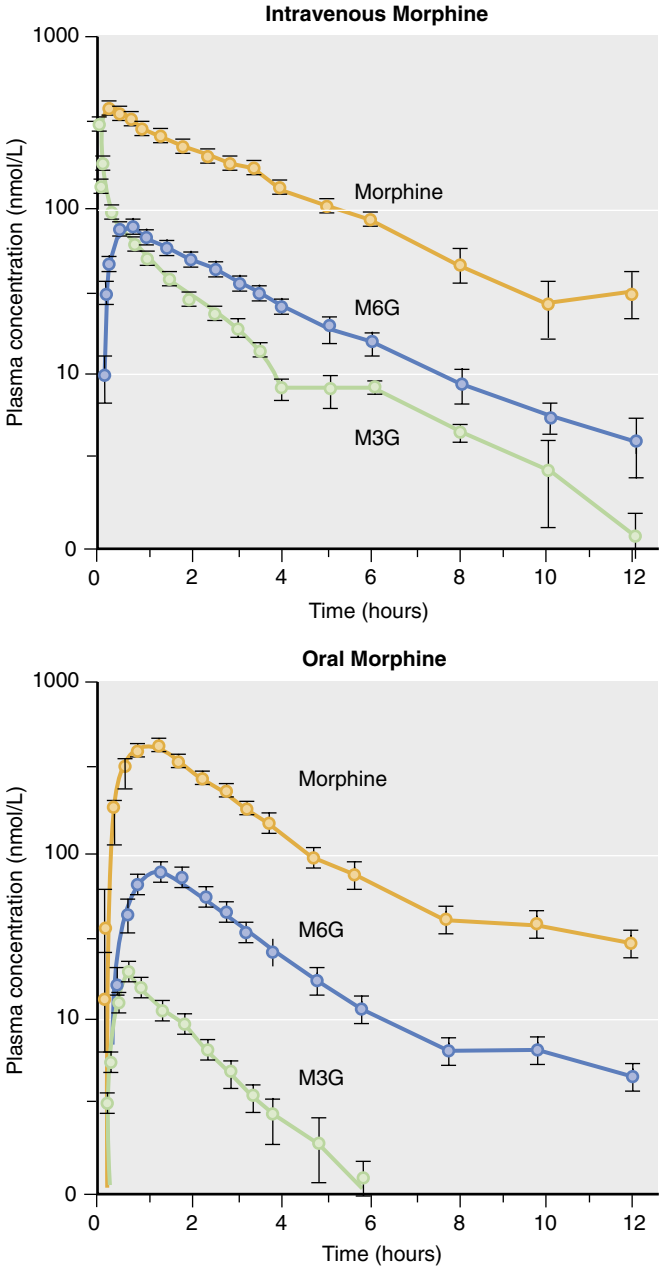

Figure 27-13 Mean plasma concentrations (± SEM) of morphine, morphine-6-glucuronide (M6G), and morphine-3-glucuronide (M3G) after intravenous and oral administration of morphine. *(From Osborne R, Joel S, Trew D, Slevin M: Morphine and metabolite behavior after different routes of morphine administration: Demonstration of the importance of the active metabolite morphine-6-glucuronide. Clin Pharmacol Ther 47:12-19, 1990.)*

reports suggesting a high potency of M6G, others have shown that short-term intravenous administration of M6G does not provide effective analgesia.

Meperidine

Unlike morphine, after intravenous injection, first-pass uptake of meperidine by the lungs is approximately 65%. Meperidine is more highly bound to plasma proteins than morphine is, principally (70%) to α_1-acid glycoprotein. As with morphine, a relatively high hepatic extraction ratio results in biotransformation that is dependent on hepatic blood flow. Normeperidine, the major metabolite, has analgesic activity and is roughly twice as potent as meperidine in producing seizures in animals. The elimination half-life of normeperidine is considerably greater than that of meperidine, and thus repeated doses can easily cause this toxic metabolite to accumulate in patients with renal disease and potentially produce seizures.

Fentanyl

A three-compartment model is typically used to describe decay of plasma fentanyl concentrations. The lungs exert a significant first-pass effect and transiently take up approximately 75% of an injected dose of fentanyl. Approximately 80% of fentanyl is bound to plasma proteins, and significant amounts (40%) are taken up by red blood cells. Fentanyl is relatively long acting, in large part because of this widespread distribution in body tissues.

Fentanyl is primarily metabolized in the liver by *N*-dealkylation and hydroxylation. Metabolites begin to appear in plasma as early as 1.5 minutes after injection. Norfentanyl, the primary metabolite, is detectable in urine for up to 48 hours after intravenous fentanyl in humans.

Alfentanil

After intravenous injection, plasma concentrations of alfentanil are described by either a two-compartment or a three-compartment model. Alfentanil is bound to plasma proteins (mostly glycoproteins) in higher proportions (90%) than fentanyl is. At physiologic pH, it is mostly (90%) un-ionized because of its relatively low pK_a (6.5). Thus, despite more intense protein binding, alfentanil's diffusible fraction is higher than that of fentanyl. This explains, in part, its short latency to peak effect after intravenous injection.

The main metabolic pathways of alfentanil are similar to those of sufentanil and include oxidative *N*-dealkylation and *O*-demethylation, aromatic hydroxylation, and ether glucuronide formation. The degradation products of alfentanil have little, if any, opioid activity. Human alfentanil metabolism may be accomplished predominantly, if not exclusively, by cytochrome P450 3A3/4 (CYP3A3/4). This enzyme is known to display at least an eightfold difference in activity in humans. Alfentanil is also metabolized by human liver microsomal CYP3A5, which shows more than 20-fold pharmacogenetic variability in expression and thus results in significant differences in human liver alfentanil metabolism. An in vitro study demonstrated that propofol in clinically relevant concentrations interferes with oxidative metabolic degradation of alfentanil and sufentanil in the microsomal fraction of pig and human liver.

Sufentanil

The pharmacokinetic property of sufentanil is adequately described by a three-compartment model. After intravenous injection, first-pass pulmonary extraction, retention, and release are similar to those of fentanyl. The pK_a of sufentanil at physiologic pH is the same as that of morphine (8.0), and therefore only a small amount (20%) exists in the un-ionized form. Sufentanil is twice as lipid soluble as fentanyl and is highly bound (93%) to plasma proteins, including α_1-acid glycoprotein.

The major metabolic pathways of sufentanil include *N*-dealkylation, oxidative *O*-demethylation, and aromatic hydroxylation. Major metabolites include *N*-phenylpropanamide.

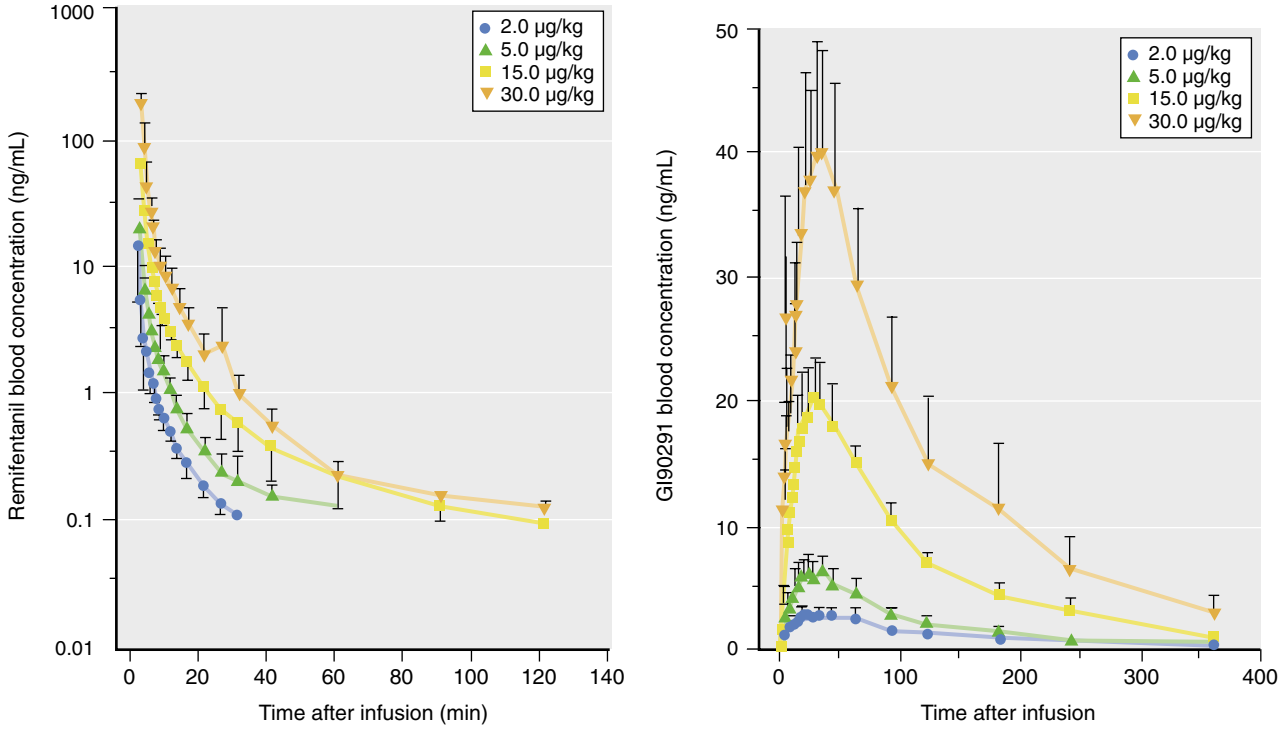

Figure 27-14 Mean (± SD) blood concentration-time curves of remifentanil and its metabolite GI90291 after a 1-minute transfusion of remifentanil of 2, 5, 15, and 30 µg/kg; $n = 6$ for each dose. *(From Westmoreland CL, Hoke JF, Sebel PS, et al: Pharmacokinetics of remifentanil (GI87084B) and its major metabolite (GI90291) in patients undergoing elective inpatient surgery. Anesthesiology 79:893-903, 1993.)*

Remifentanil

Although chemically related to the fentanyl congeners, remifentanil is structurally unique because of its ester linkages. Remifentanil's ester structure renders it susceptible to hydrolysis by blood- and tissue-nonspecific esterases, which results in rapid metabolism and rapid reduction of blood concentrations after cessation of infusion (Fig. 27-14). Remifentanil thus constitutes the first "ultrashort"-acting opioid for use as a supplement to general anesthesia.

The pharmacokinetic properties of remifentanil are best described by a three-compartment model.[88] Its clearance is several times more rapid than normal hepatic blood flow, consistent with widespread extrahepatic metabolism. However, remifentanil is not significantly metabolized or sequestered in the lungs. It is a weak base with a pK_a of 7.07. It is highly lipid soluble with an octanol-water partition coefficient of 19.9 at pH 7.4. Remifentanil is highly bound (70%) to plasma proteins (mostly α_1-acid glycoprotein). The remifentanil free base is formulated with glycine. Because glycine has been shown to act as an inhibitory neurotransmitter that causes a reversible motor weakness when injected intrathecally into rodents, remifentanil is not approved for spinal or epidural use.

The primary metabolic pathway of remifentanil is de-esterification to form a carboxylic acid metabolite, GI90291 (Fig. 27-15), which is 0.003 to 0.001 times as potent as remifentanil. The low in vivo potency of GI90291 can be explained by low affinity to the µ-receptor in combination with poor brain penetration. Excretion of GI90291 is dependent on renal clearance mechanisms. Evidence from dogs suggests that the remifentanil metabolites are, for practical purposes, completely inactive, even in patients with renal failure. Its pharmacokinetics is not appreciably influenced by renal or hepatic failure. In blood, remifentanil is metabolized primarily by enzymes within erythrocytes. Remifentanil is not a good substrate for pseudocholinesterase and therefore is not influenced by pseudocholinesterase deficiency.

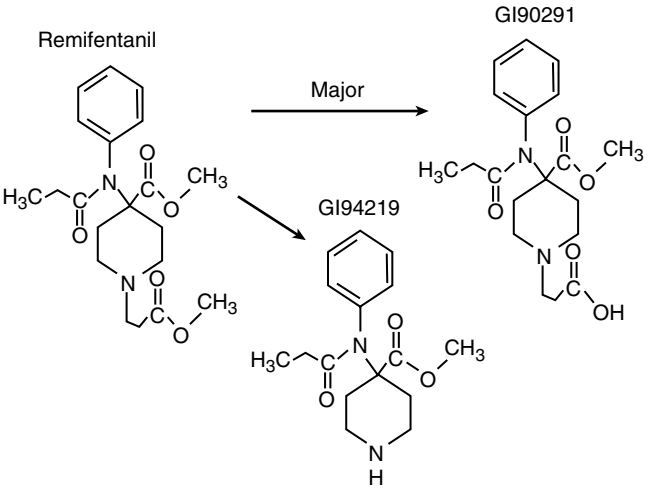

Figure 27-15 Metabolic pathway of remifentanil. De-esterification by nonspecific plasma and tissue esterases to form a carboxylic acid metabolite (GI90291) that has only 1/300 to 1/1000 the potency of the parent compound is the primary metabolic pathway. *N*-Dealkylation of remifentanil to GI94219 is a minor metabolic pathway. *(From Egan TD, Lemmens HJ, Fiset P, et al: The pharmacokinetics of the new short-acting opioid remifentanil [GI87084B] in healthy adult male volunteers. Anesthesiology 79:881-892, 1993.)*

Computerized Delivery Methods in Clinical Practice

Advances in pharmacokinetic modeling and infusion pump technology have made it possible to administer opioids (and other drugs) via a computer-controlled infusion pump (CCIP).[295] The physician operating a CCIP designates a target concentration to achieve rather than specifying an infusion rate. The CCIP then calculates the necessary infusion rates to achieve the targeted concentration.

Delivery of an opioid via a CCIP requires a different approach by clinicians. Rather than setting an infusion rate based on clinical experience and literature recommendations, the anesthesiologist using a CCIP designates a target concentration, and the CCIP calculates the infusion rates necessary to achieve the concentration over time. It has been reported that target-controlled infusion of alfentanil and remifentanil was useful for intraoperative and postoperative analgesia.[296,297] Successful use of a CCIP thus requires knowledge of the therapeutic concentrations appropriate for the clinical setting.

Surrogate Measures of Opioid Potency

Because a high-resolution measure of analgesia is not available, opioid potencies are usually estimated by some surrogate measures. Reduction of the MAC required to produce lack of movement to skin incision has been a frequently used surrogate measure for estimation of opioid potency (Fig. 27-16).[90,92] However, the MAC is not useful as a surrogate measure of opioid potency outside the operating room.

The EEG has been another widely used surrogate measure in estimating opioid potency.[89] The EEG is advantageous because it is noninvasive and can be used as an effect measure when an experimental subject is unconscious or apneic. When processed by Fourier spectral analysis, the raw changes on the EEG translate into a significant decrease in the value of the spectral edge, a parameter that quantitates the frequency below which a given percentage (usually 95%) of the power in the signal of the EEG is found. Although the clinical meaning of the changes on the EEG produced by opioids is unclear, the opioid potencies estimated by using the EEG as a surrogate measure appear to be clinically reliable because they relate to clinically determined potencies in a proportional, reproducible fashion.

For opioids, because the surrogate measures do not always assess the drug effect of clinical interest (analgesia), estimations of potency based on surrogate measures must be interpreted with some caution.

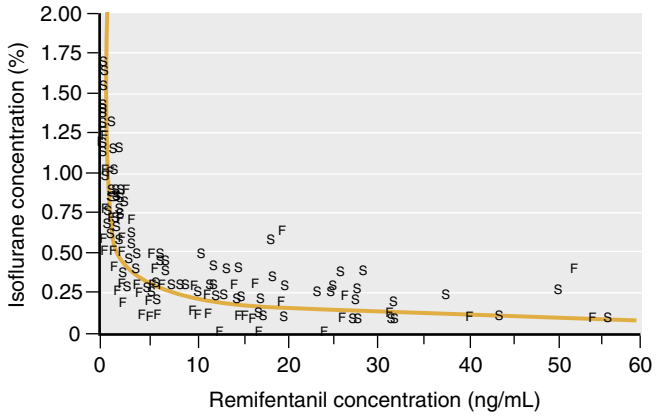

Figure 27-16 The reduction in isoflurane concentration to prevent movement at skin incision in 50% of patients by increasing measured remifentanil whole-blood concentrations. F represents a patient who moved and S a patient who did not move. The *solid line* is the logistic regression solution for a patient 40 years of age. *(From Lang E, Kapila A, Shlugman D, et al: Reduction of isoflurane minimal alveolar concentration by remifentanil. Anesthesiology 85:721-728, 1996.)*

Factors Affecting the Pharmacokinetics and Pharmacodynamics of Opioids

Age

The pharmacokinetics and pharmacodynamics of opioids can be influenced by age (see Chapter 71). It is clear that neonates exhibit a reduced rate of elimination of essentially all opioids,[298] presumably because of immature metabolic mechanisms, including the cytochrome P450 system. The prolonged elimination of opioids observed in the neonatal period quickly normalizes toward adult values within the first year of life.[298]

With advanced age, although pharmacokinetic changes may play a minor role, pharmacodynamic differences are primarily responsible for the decreased dose requirement in the elderly. Age was inversely correlated with the central volume of distribution, clearance, and potency of remifentanil (Fig. 27-17).[299] These combined pharmacokinetic and pharmacodynamic changes mandate a reduction in remifentanil dosage by at least 50% or more in the elderly.

Body Weight

Many opioid pharmacokinetic parameters, especially clearance, appear to be more closely related to lean body mass, which means that opioid dosage regimens may best be based on lean body mass and not total body weight. Total body weight–based dosing in an obese patient results in much higher remifentanil effect-site concentrations than lean body mass–based dosing does.[300] In contrast, for lean patients, the concentrations that result from total body weight–based dosing are not much greater than those based on body mass (Fig. 27-18). Clinically, context-sensitive half-times are not significantly different between obese and lean subjects (Fig. 27-19). Mounting evidence suggests that lean body mass is a better predictor of metabolic capacity than total body weight is. Ideal body weight, a parameter closely related to lean body mass and one that is perhaps more easily estimated by the clinician, is probably an acceptable alternative.

Renal Failure

Renal failure has implications of major clinical importance with respect to morphine and meperidine.[301] For the fentanyl congeners, the clinical importance of renal failure is less marked.

Morphine is an opioid with active metabolites that are dependent on renal clearance mechanisms for elimination. Morphine is principally metabolized by conjugation in the liver, and the water-soluble glucuronides (M3G and M6G) are excreted via the kidney. The kidney also plays a role in the conjugation of morphine and accounts for nearly 40% of its metabolism. Very

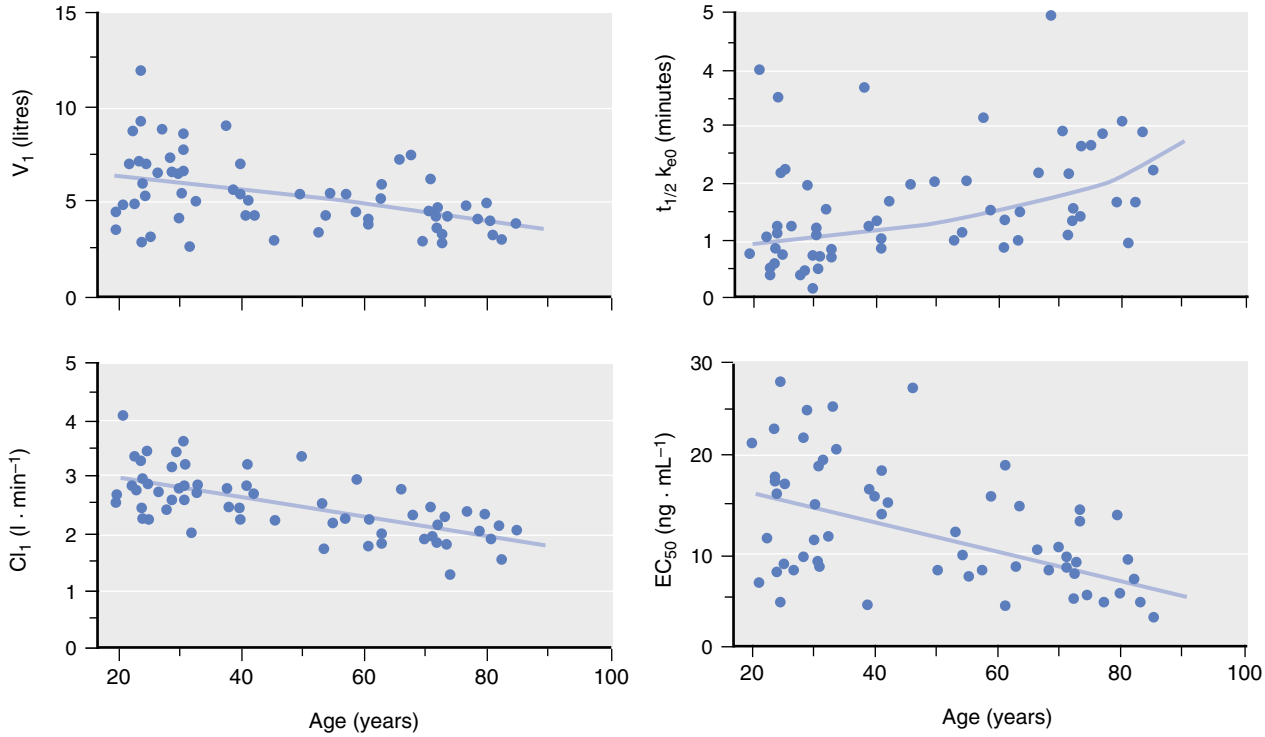

Figure 27-17 Relationship between pharmacokinetic and pharmacodynamic parameters and age for remifentanil. V_1 and Cl_1 are estimated from a three-compartment model. $t_{½}k_{e0}$ is a half-life corresponding to k_{e0}, a first-order rate constant for elimination of drug from the effect compartment. *(From Minto CF, Schnider TW, Shafer SL: Pharmacokinetics and pharmacodynamics of remifentanil. II. Model application. Anesthesiology 86:24-33, 1997.)*

high levels of M6G and life-threatening respiratory depression can develop in patients with renal failure (Fig. 27-20).[302] In view of these changes induced by renal failure, morphine may not be a good choice in patients with severely altered renal clearance mechanisms.

The clinical pharmacology of meperidine is also significantly altered by renal failure. Normeperidine, the main metabolite, has analgesic and excitatory CNS effects. Because the active metabolites are subject to renal excretion, this potential CNS toxicity secondary to accumulation of normeperidine is especially a concern in patients with renal failure.

The clinical pharmacology of the fentanyl congeners is not grossly altered by renal failure, although a decrease in plasma protein binding may potentially alter the free fraction of the fentanyl class of opioids.[301] In the presence of renal impairment, fentanyl, alfentanil, sufentanil, and remifentanil do not deliver a

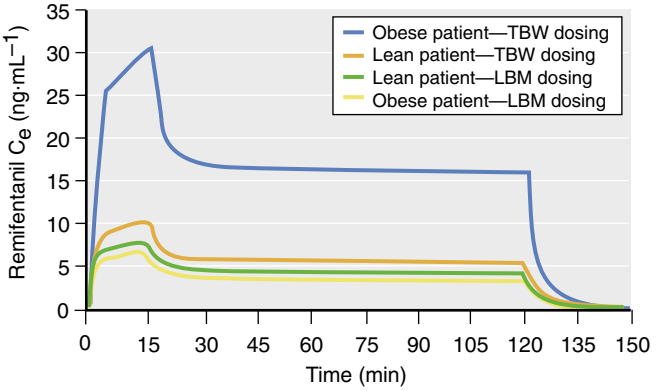

Figure 27-18 Computer simulation of the time course of change in remifentanil concentration when the dosage regimen is calculated according to lean body mass (LBM) or total body weight (TBW) for both obese and lean patients. Note that TBW-based dosing in an obese patient results in dramatically higher concentrations. *(From Egan TD, Huizinga B, Gupta SK, et al: Remifentanil pharmacokinetics in obese versus lean patients. Anesthesiology 89:562-573, 1998.)*

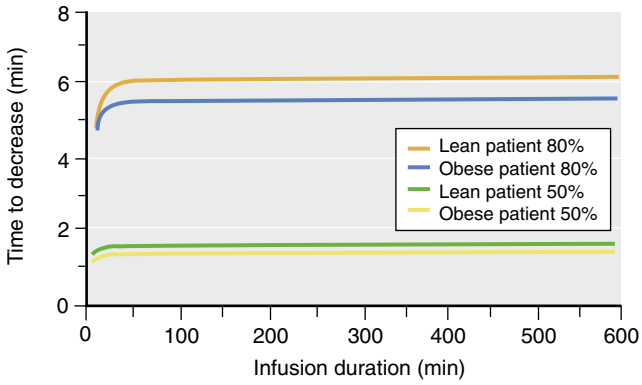

Figure 27-19 Computer simulation of the context-sensitive half-times (50% decrement times) and 80% decrement times of remifentanil in obese versus lean subjects. Note that in clinical terms the curves are not grossly different in obese versus lean subjects. *(From Egan TD, Huizinga B, Gupta SK, et al: Remifentanil pharmacokinetics in obese versus lean patients. Anesthesiology 89:562-573, 1998.)*

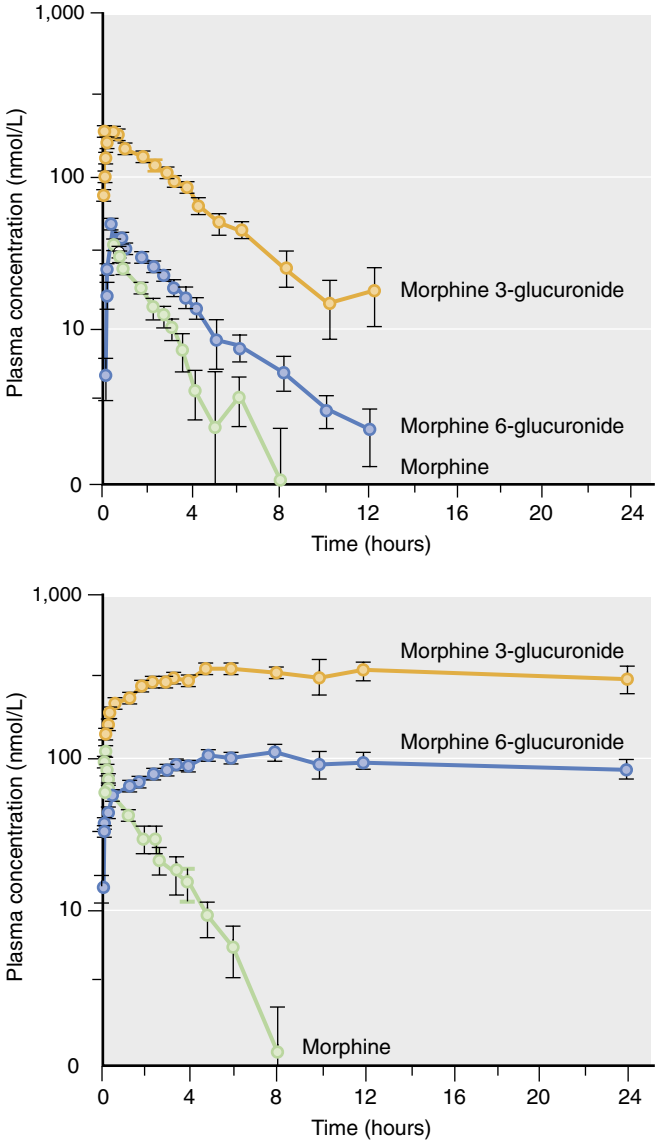

Figure 27-20 Effect of renal failure on the pharmacokinetics of morphine. The graphs show the time-dependent change in serum concentration of morphine and its metabolite in patients with normal renal function (*top*) and those with renal failure (*bottom*) who received 0.1 mg/kg of morphine intravenously. *(From Osborne R, Joel S, Grebenik K, et al: The pharmacokinetics of morphine and morphine glucuronides in kidney failure. Clin Pharmacol Ther 54:158-167, 1993.)*

high active metabolite load or suffer from significantly prolonged clearance.[303] Neither the pharmacokinetics nor the pharmacodynamics of remifentanil is altered by impaired renal function. The levels of GI90291 that develop during remifentanil infusion in patients with renal failure are not likely to produce any clinically significant effects.

Hepatic Failure

Even though the liver is the metabolic organ primarily responsible for opioid biotransformation, the degree of liver failure typically observed in perioperative patients, with the exception of patients undergoing liver transplantation, does not have a major impact on the pharmacokinetics of most opioids. In addition to reduced metabolic capacity (i.e., cytochrome P450 system and conjugation), liver disease may also lead to reductions in hepatic blood flow, hepatocellular mass, and plasma protein binding. The increase in total body water and the edema of advanced liver disease may alter the distribution characteristics of a drug. Enzyme induction, such as that observed in early alcoholism, can actually increase the metabolic capacity of the liver.

The pharmacokinetics of morphine is relatively unchanged by developing liver disease, such as liver cirrhosis and hepatic carcinoma, because of the substantial compensatory extrahepatic metabolism of morphine. A reduction in hepatic blood flow would be expected to slow the decline in morphine plasma concentrations. After liver resection, M6G/morphine and M3G/morphine ratios were significantly reduced and the circulating morphine concentration was increased, mainly as a result of lower morphine clearance.[304] In patients with cirrhosis the metabolism of meperidine is decreased, which leads to accumulation of the parent drug and possible CNS depressive effects similar to hepatic encephalopathy. Although elimination of normeperidine is decreased as well in these patients, the ratio of normeperidine to meperidine is generally low, and the narcotic effects of meperidine usually predominate.[305] The disposition of fentanyl and sufentanil appears to be unaffected by liver disease.[306] The reductions in liver blood flow that result from either liver disease or some other disorder (e.g., shock) can affect the pharmacokinetic parameters of alfentanil, fentanyl, and sufentanil.[307] A significant decrease in clearance of alfentanil was demonstrated in patients with mild to moderate cirrhosis when compared with volunteers from the historical control group.[308] Greater elimination half-lives (3.7 ± 2.6 hours) have also been observed for alfentanil in patients undergoing abdominal aortic surgery.[309] Remifentanil is an opioid whose phamacokinetics is completely unchanged by liver disease (Fig. 27-21). Its kinetics does not change during the anhepatic phase of orthotopic liver transplantation.[310]

Cardiopulmonary Bypass

CPB produces significant alterations in the pharmacokinetics of most opioids (see Chapter 60).[311] These alterations are a result of CPB-induced modifications in distribution volumes (secondary to priming) and changes in acid-base balance, organ blood flow, plasma protein concentrations, and body temperature. Binding of drugs to components of the bypass circuit can also alter opioid pharmacokinetics.

When morphine is given as a premedicant before cardiac anesthesia, its concentrations decline significantly on initiation of CPB.[312] Miller and colleagues examined the effect of CPB on plasma fentanyl concentrations and showed that the total concentration of fentanyl in plasma was significantly decreased and the unbound fraction of fentanyl rose on initiation of CPB.[313] The total fentanyl concentration remained relatively stable during bypass until near the end of CPB, at which time the mean total concentration increased, coincident with rewarming. Population pharmacokinetic modeling applied to concentration-versus-time data from patients undergoing coronary artery bypass grafting with CPB demonstrated that the effect of CPB on fentanyl pharmacokinetics is clinically insignificant and that a simple three-compartment model accurately predicts fentanyl concentrations throughout surgery involving the use of CPB.[314] Elimination of alfentanil is prolonged by CPB primarily because of increased distribution.[315] The volume of distribution in steady state (Vd_{ss}) and the volume of the central compartment for alfentanil were

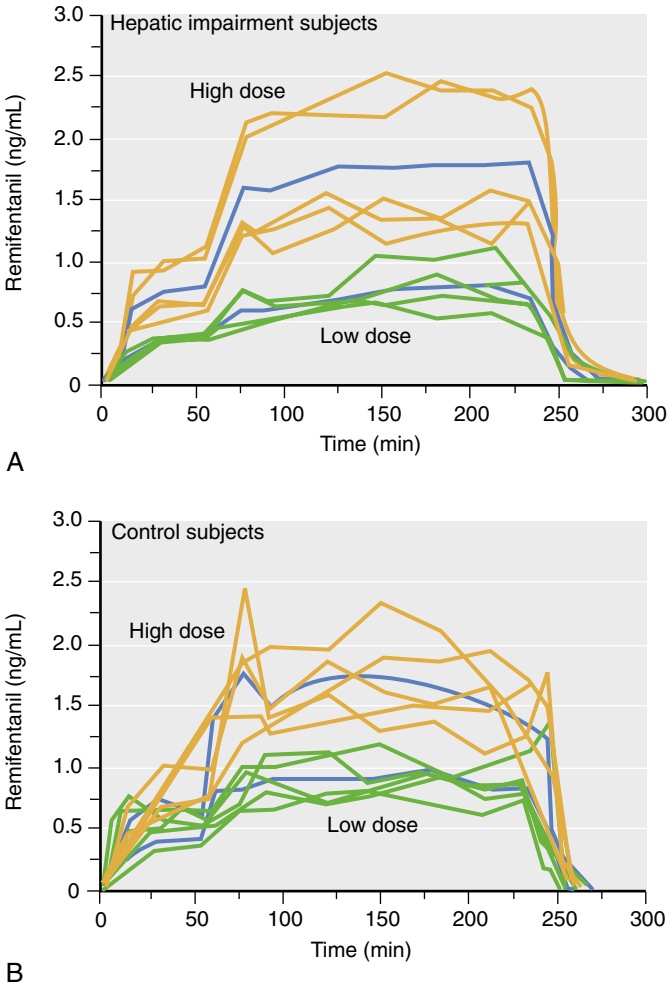

Figure 27-21 Time-dependent changes in the blood concentration of remifentanil in patients with liver disease (*top*) and control subjects (*bottom*). In the low-dose group, remifentanil was infused at 0.0125 µg/kg/min for 1 hour and then at 0.025 µg/kg/min for 3 hours. In high-dose group, the infusion rate of remifentanil was 0.025 µg/kg/min for 1 hour and then 0.05 µg/kg/min for 3 hours. *(From Dershwitz M, Hoke JF, Rosow CE, et al: Pharmacokinetics and pharmacodynamics of remifentanil in volunteer subjects with severe liver disease. Anesthesiology 84:812-820, 1996.)*

significantly greater in the CPB groups than in the nonbypass group.[316] However, the elimination half-life $(T_{½\beta})$ of alfentanil did not differ significantly between the normothermic CPB, hypothermic CPB, and nonbypass groups. No significant differences in Vd_{ss}, clearance, or $T_{½\beta}$ were found between the normothermic and hypothermic CPB groups. The free fraction of alfentanil during CPB remains constant despite complex changes in binding protein concentrations.[317] In adult patients undergoing elective myocardial revascularization with hypothermic CPB who received continuous infusions of remifentanil, 1.0 to 2.0 µg/kg/min, no evidence of accumulation or sequestration was found. Russell and coauthors reported that normothermic CPB did not significantly affect the clearance of remifentanil but that hypothermic CPB reduced it by an average of 20%, which was attributed to the effect of temperature on blood and tissue esterase activity (Fig. 27-22).[318] In pediatric patients undergoing CPB for repair of atrial septal defects, there was no change in Vd_{ss}, volume of the central compartment, $T_{½\alpha}$ and $T_{½\beta}$, but clearance values increased 20% in the postbypass period.[319] In patients undergoing coronary artery bypass graft surgery with hypothermic CPB and receiving a continuous infusion of remifentanil, the volume of distribution increased by 86% with the institution of CPB and remained increased after CPB, and elimination clearance decreased by 6.37% for each degree lower than 37°C.[320] Thus, although clearance of remifentanil is reduced during CPB, remifentanil remains a very short-acting drug, even during CPB.

Acid-Base Changes

Changes in pH influence the protein binding of fentanyl, sufentanil, and alfentanil such that protein binding increases with alkalosis and decreases with acidosis.[307] These effects are greater for fentanyl than for sufentanil and for sufentanil than for alfentanil. Relative changes in the free drug fraction with variation in pH from 7.4 to 7.0 were much higher for fentanyl (52%) than for sufentanil (29%) and alfentanil (6%). The dependence of plasma protein binding of the opioids on pH significantly correlates with their partition between an organic and aqueous phase, thus suggesting the hydrophobic character of the interaction between plasma proteins and opioids. Increased ionization decreases the amount of fentanyl available for hepatic metabolism or renal excretion. Intraoperative hyperventilation during surgical procedures can significantly influence the pharmacokinetics of sufentanil and result in an increased distribution volume and prolonged elimination half-time. Thus, both intraoperative respiratory alkalosis and respiratory acidosis, especially in the immediate postoperative period, can prolong and exacerbate opioid-induced respiratory depression.

Hemorrhagic Shock

It is common practice to administer reduced doses of opioids to patients suffering from hemorrhagic shock to minimize any adverse hemodynamic consequences and prevent prolonged opioid effect. This is at least partially attributable to a pharmacokinetic mechanism. Analysis of pigs receiving fentanyl suggested that central clearance and central and second compartment distribution volumes were significantly reduced in hemorrhagic shock, with higher fentanyl concentrations for any given dosage and a prolonged context-sensitive half-time (Fig. 27-23).[321] Hemorrhagic shock also altered the pharmacokinetics of remifentanil, suggesting that less remifentanil would be required to maintain a target plasma concentration (Fig. 27-24).[322] However, because of its rapid metabolism, changes in context-sensitive half-time are small.

Anesthetic Techniques Using Opioids

Analgesia

Opioids are frequently used to relieve pain during monitored anesthesia care and regional anesthesia.

A single bolus of opioids can provide significant pain relief. Morphine is slow in onset and does not allow rapid titration to effect. Meperidine (50 to 100 mg IV) produces variable degrees of pain relief and is not always effective in patients with severe

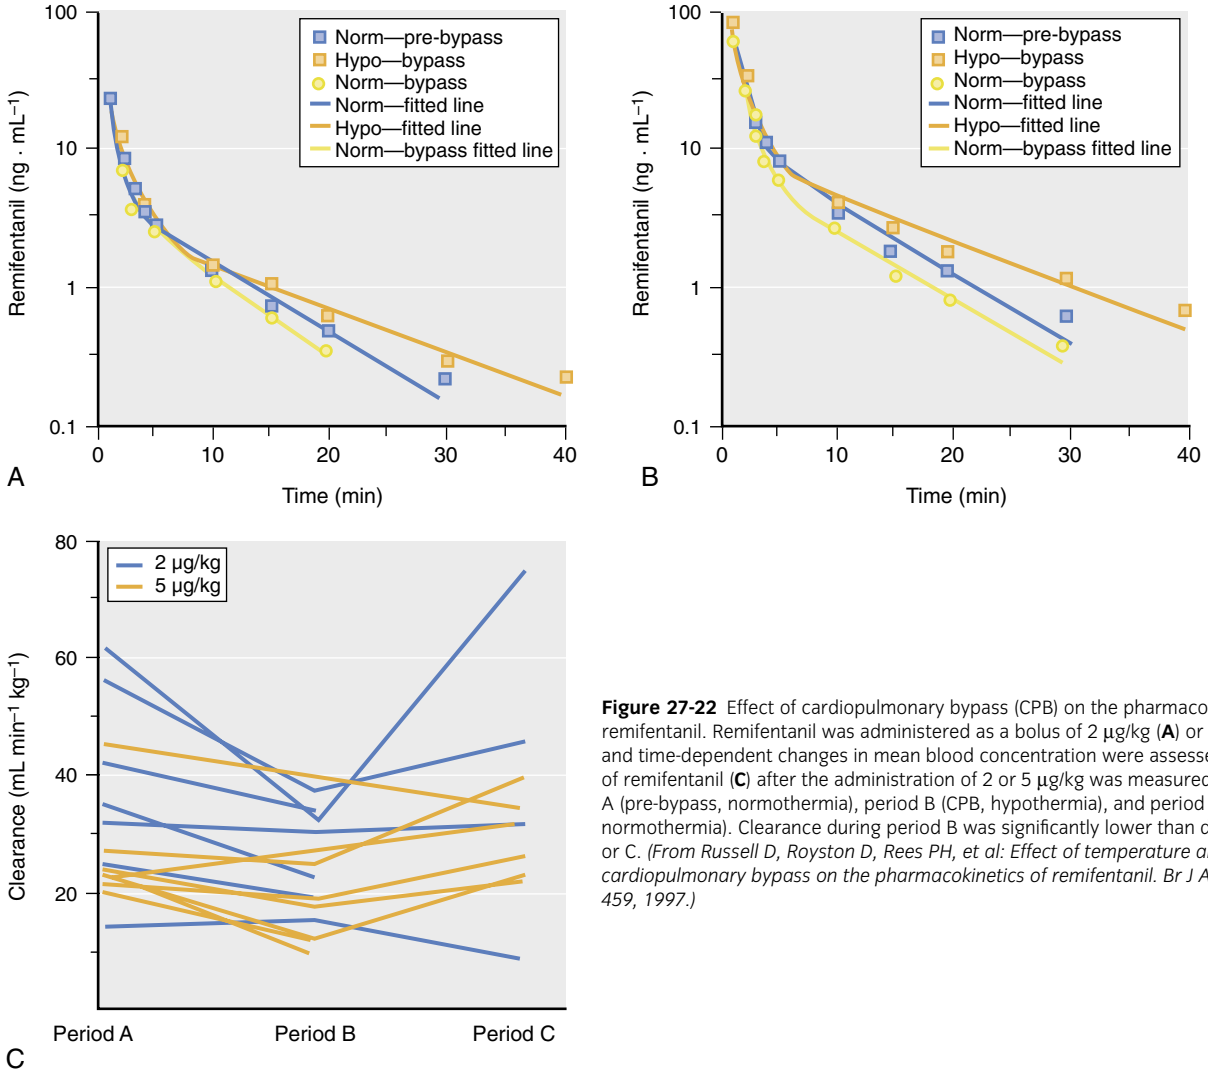

Figure 27-22 Effect of cardiopulmonary bypass (CPB) on the pharmacokinetics of remifentanil. Remifentanil was administered as a bolus of 2 μg/kg (**A**) or 5 μg/kg (**B**), and time-dependent changes in mean blood concentration were assessed. Clearance of remifentanil (**C**) after the administration of 2 or 5 μg/kg was measured during period A (pre-bypass, normothermia), period B (CPB, hypothermia), and period C (CPB, normothermia). Clearance during period B was significantly lower than during period A or C. *(From Russell D, Royston D, Rees PH, et al: Effect of temperature and cardiopulmonary bypass on the pharmacokinetics of remifentanil. Br J Anaesth 79:456-459, 1997.)*

pain. Intravenous boluses of fentanyl (1 to 3 µg/kg), alfentanil (10 to 20 µg/kg), or sufentanil (0.1 to 0.3 µg/kg) can produce potent and short-lasting analgesia. Infusion rates range from 0.01 to 0.05 µg/kg/min for fentanyl, 0.0015 to 0.01 µg/kg/min for sufentanil, 0.25 to 0.75 µg/kg/min for alfentanil, and 0.05 to 0.25 µg/kg/min for remifentanil. The plasma concentrations of opioids needed for various purposes are listed in Table 27-6.

Changes in the excitability of central neurons play an important role in the establishment of pain. Low doses of fentanyl block the synaptic form of central sensitization in the rat spinal cord in vivo, suggesting the possibility of preemptive analgesia by fentanyl, but larger doses do not have this effect.[323] Reductions in postoperative pain and improved recovery have been attributed to preemptive analgesia with either epidural fentanyl or bupivacaine after radical prostatectomy.[324] In contrast, in patients undergoing transperitoneal tumor nephrectomy, preoperative intravenous administration of a combination of morphine, ketamine, and clonidine failed to exert a clinically relevant effect on postoperative pain.[325] Aida and coauthors reported that the effectiveness of preemptive analgesia varies according to the type of surgery and that preemptive analgesia with epidural morphine was reliably effective in limb and breast surgery but ineffective in abdominal surgery.[326] A meta-analysis demonstrated that the results of preemptive analgesia with systemic administration of opioids are equivocal.[327] Thus, whether preemptive analgesia can be effectively achieved clinically by the early administration of opioids remains uncertain.

PCA with opioids is now a cornerstone of postoperative analgesia (see Chapter 87). PCA with opioids may improve outcome.[328] Nevertheless, pharmacokinetic optimization of opioid treatment in acute pain is a complex matter.[329] Without considering effect-site drug concentrations over time, the choice of opioid and the amount, method, and frequency of its administration cannot be optimized.[329] Morphine remains a popular and rational choice for PCA therapy[330] (see also Chapter 87).

Sedation

Critically ill subjects in the intensive care unit (ICU) often experience anxiety and agitation while being exposed to numerous stressful or noxious stimuli. ICU patients generally require a combination of analgesia and sedation to relieve their state of anxiety, improve adaptation to the endotracheal tube, and aid compliance with mechanical ventilation. Morphine is the most frequently used intravenous analgesic agent in the ICU.[331] A randomized double-blind study indicated that remifentanil (0.15 µg/kg/min) and morphine (0.75 µg/kg/min) could provide comparable levels of sedation and that the remifentanil-based regimen allowed more rapid emergence from sedation and facilitated earlier extubation.[332]

Balanced Anesthesia

The term "balanced anesthesia" was introduced by Lundy in 1926. Lundy suggested that a balance of agents and techniques be used to produce the different components of anesthesia (i.e., analgesia, amnesia, muscle relaxation, and abolition of autonomic reflexes with maintenance of homeostasis). Anesthesia with a single agent can require doses that produce excessive hemodynamic depression.[333] The inclusion of an opioid as a component of balanced anesthesia can reduce preoperative pain and anxiety, decrease somatic and autonomic responses to airway manipulation, improve hemodynamic stability, lower requirements for inhaled anesthetics, and provide immediate postoperative analgesia. Opioids interact synergistically and markedly reduce the dose of propofol and other sedative-hypnotics required for loss of consciousness and during noxious stimulation such as skin incision (Fig. 27-25).[334] Although the intent of combining opioids with sedative-hypnotics or volatile anesthetics (or with both) is to produce anesthetic conditions with stable hemodynamics before as well as after noxious stimulation, this ideal is not always achieved.[335,336]

The timing, rate of administration, and dose of supplemental opioid should also be tailored to the specific condition of the patient and the expected duration of the operation to avoid problems. Giving a large dose of any opioid shortly before the end of surgery is very likely to result in postoperative respiratory depression. However, analgesic concentrations of opioids have little effect on the MAC-awake of inhaled anesthetics.[337]

Choice of Opioid

The ideal opioid would permit rapid titration, successfully prevent unwanted responses to noxious stimuli, require little supplementation, not depress cardiovascular function, permit the return of adequate spontaneous ventilation in a timely manner, and produce residual, if not complete, postoperative analgesia with minimal side effects. Alfentanil and remifentanil provide the greatest ability to titrate opioids rapidly because of their extremely rapid time to onset (1 to 2 minutes) of peak effect. Sufentanil, alfentanil, and remifentanil are arguably superior to fentanyl in most respects. Antagonism of opioid action with naloxone for troublesome respiratory depression is required less frequently after alfentanil and sufentanil than after fentanyl. Pharmacologic antagonism is rarely required after administration of remifentanil.

Fentanyl

Anesthetic induction is usually achieved by combining a loading dose of fentanyl (2 to 6 µg/kg) with a sedative-hypnotic, most commonly thiopental or propofol, and a muscle relaxant. Maintenance of anesthesia can be achieved with N_2O (60% to 70%) in O_2, low concentrations of potent inhaled anesthetics, and additional fentanyl (intermittent boluses of 25 to 50 µg every 15 to 30 minutes or a constant infusion of 0.5 to 5.0 µg/kg/hr).

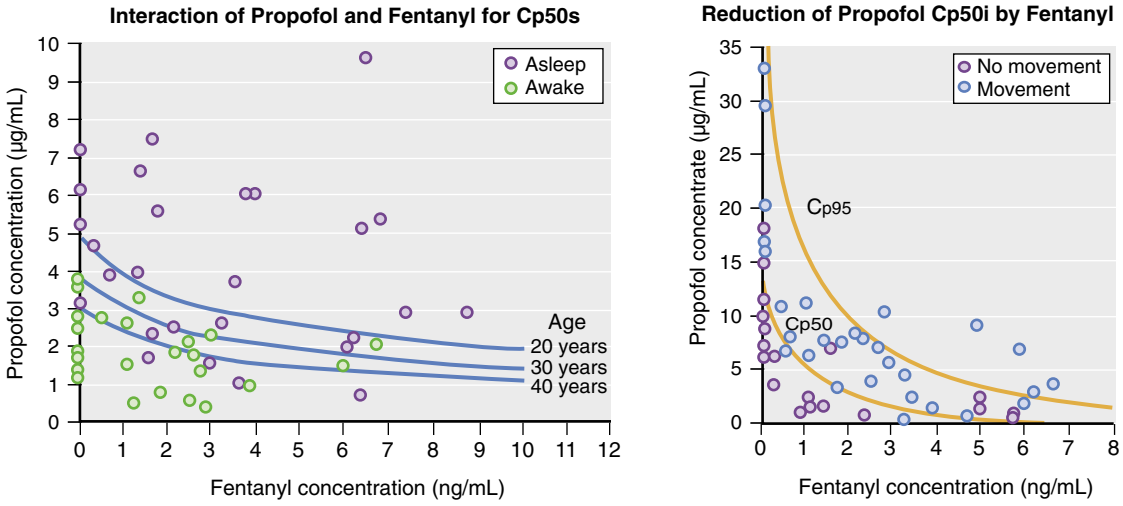

Figure 27-25 Left, Measured arterial propofol and fentanyl concentrations at which patients did and did not respond to a verbal command at 10 minutes after initiation of infusion of these drugs. *Solid lines* represent the modeled concentration of propofol according to decade of age when combined with measured fentanyl concentrations at which 50% of patients did not respond to verbal command (Cp_{50}). **Right,** Reduction of the propofol concentration at which 50% or 95% of patients did not move at skin incision by increasing the concentration of fentanyl (Cp_{50} and Cp_{95}, respectively). *Sold lines* represent logistic regression solutions. *(From Smith C, McEwan AI, Jhaveri R, et al: The interaction of fentanyl on the Cp_{50} of propofol for loss of consciousness and skin incision. Anesthesiology 81:820-828, 1994.)*

The plasma concentration of fentanyl required for postoperative analgesia was approximately 1.5 ng/mL,[338] but levels of at least 2 to 3 ng/mL are usually required during surgery if the only inhaled agent is N_2O. In unpremedicated patients anesthetized with a fentanyl infusion and N_2O in O_2, the Cp_{50} (minimal steady-state plasma concentration of an intravenous analgesic/anesthetic required to prevent a somatic response in 50% of patients after skin incision) and Cp_{50}-BAR (minimal plasma concentration of an intravenous analgesic/anesthetic required to prevent either a somatic, hemodynamic, or autonomic response in 50% of patients after skin incision) for fentanyl at skin incision are 3.26 and 4.17 ng/mL, respectively.[339] The MAC of isoflurane at skin incision can be reduced by 50% and 63% with plasma fentanyl concentrations of 1.67 and 3.0 ng/mL, respectively.[74] Increasing plasma fentanyl concentrations from 3.0 to 10 ng/mL only further reduced the MAC of isoflurane from 63% to 82%. The intraoperative requirement for propofol is also reduced by fentanyl. In patients undergoing spine fusion, to keep mean arterial pressure within 15% of the control value when fentanyl was infused to keep the plasma concentration at 0, 1.5, 3.0, and 4.5 ng/mL, average propofol infusion rates were 10.1 ± 2.5 (mean ± SD), 7.5 ± 1.2, 5.7 ± 1.1, and 4.9 ± 1.2 mg/kg/hr, respectively.[340]

Opioid pharmacokinetics and pharmacodynamics vary considerably among patients. It was reported that basing the fentanyl dose on total body weight may cause overdosing in obese patients.[338] Nevertheless, a balanced technique with fentanyl, titrated in anticipation of various stimuli and patient responses with pharmacokinetic guidelines in mind, will often result in a stable hemodynamic course and rapid awakening in a pain-free patient. Repeated doses or continuous infusions of fentanyl are most likely to result in significant depression of spontaneous ventilation.

Alfentanil

Because alfentanil penetrates the brain so rapidly, equilibration of alfentanil between plasma and the CNS can be achieved while plasma alfentanil levels are quite high relative to those of sufentanil and fentanyl. This property explains how low doses (10 to 30 µg/kg) of alfentanil, administered just before or simultaneously with a sedative-hypnotic, are effective.

Alfentanil (25 to 50 µg/kg IV), followed by small titrated sleep doses of any sedative-hypnotic (e.g., 50 to 100 mg sodium thiopental), is usually successful in preventing significant hemodynamic stimulation from laryngoscopy and intubation. Further opioid supplementation can be achieved with an alfentanil infusion (0.5 to 2.0 µg/kg/min) or intermittent boluses of alfentanil (5 to 10 µg/kg) for shorter procedures. In balanced anesthetic techniques in which potent inhaled anesthetics are also administered, relatively low plasma alfentanil concentrations (e.g., 29 ng/mL) can reduce the MAC of isoflurane by approximately 50%.[90] The EC_{50} of alfentanil during propofol anesthesia, in which the plasma concentration of propofol was kept at target concentrations of 3 µg/mL, was 92 ng/mL for intubation, 55 ng/mL for skin incision, 84 ng/mL for opening of the peritoneum, and 66 ± 38 ng/mL for the intra-abdominal portion of the surgery.[341] It was reported that the hemodynamic changes induced by propofol might have an important influence on the pharmacokinetics of alfentanil. Propofol (target concentration, 1.5 µg/mL) decreased the elimination clearance of alfentanil by 15%, rapid distribution clearance by 68%, slow distribution clearance by 51%, and lag time by 62%.[342] Alfentanil infusions or repeated doses should be minimized 15 to 30 minutes before the end of surgery to avoid problematic residual respiratory depression.

Sufentanil

The mean plasma sufentanil concentration reported to be the Cp_{50} for prevention of hemodynamic responses to laryngoscopy and tracheal intubation was 1.08 ng/mL with a range of 0.73 to 2.55. Maintenance of anesthesia can be achieved with N_2O (60% to 70%) in O_2 and additional sufentanil (intermittent boluses of 0.1 to 0.25 µg/kg or a constant infusion of 0.5 to 1.5 µg/kg/hr). The Cp_{50} for sufentanil during skin incision (2.08 ± 0.62 ng/mL)

is twice as great as that for intubation in unpremedicated patients.[343] Cp_{50} ratios at skin incision for sufentanil, fentanyl, and alfentanil in N_2O-O_2 anesthesia are approximately 1:2:150 and represent different and probably more accurate potency ratios than those traditionally published on the basis of drug dose. In patients undergoing coronary artery bypass grafting, sufentanil doses greater than 1.25 ± 0.21 ng/mL reduced isoflurane requirements to less than 0.5% throughout the operation.[344]

Remifentanil

The very short duration of action of remifentanil mandates that an infusion (0.1 to 1.0 µg/kg/min) be started before or soon after the bolus dose to ensure a sustained opioid effect. Maintenance infusion rates of remifentanil range from 0.1 to 1.0 µg/kg/min for balanced anesthesia. Remifentanil can reliably suppress autonomic, hemodynamic, and somatic responses to noxious stimulation and allows predictable and rapid emergence from anesthesia.[345]

The use of remifentanil permits rapid (5 to 15 minutes) emergence without postoperative respiratory depression.[346] Infusion rates of 0.1 ± 0.05 µg/kg/min should allow the return of spontaneous ventilation and responsiveness with maintenance of analgesia. A randomized, double-blind, placebo-controlled study demonstrated that the combination of 0.05 to 0.1 µg/kg/min remifentanil and 2 mg midazolam provided effective sedation and analgesia during outpatient surgical procedures performed under local anesthesia.[347] Administration of remifentanil, 1 µg/kg followed by 0.5 µg/kg/min, with propofol and 66% N_2O provided sufficient anesthesia for craniotomy with stable hemodynamics and rapid tracheal extubation.[348]

During emergence from remifentanil anesthesia, the need for alternative analgesic therapies should be anticipated and administered in timely fashion. It was reported that perioperative administration of morphine (0.15 or 0.25 mg/kg IV) or fentanyl (0.15 mg) did not provide entirely adequate immediate postoperative pain control after remifentanil-based anesthesia for major abdominal surgery.[349,350] Administration of ketamine (0.15 mg/kg followed by 2 µg/kg/min) decreased intraoperative remifentanil use during abdominal surgery and postoperative morphine consumption without increasing the incidence of side effects.[351] In children undergoing strabismus surgery, the combination of sevoflurane (2.5%) and remifentanil (1 µg/kg followed by 0.1 to 0.2 µg/kg/min) produced less frequent postoperative vomiting but higher postoperative pain scores than fentanyl did (2 µg/kg followed by 1 µg/kg every 45 minutes).[352]

Postoperative pain relief with low-dose remifentanil infusion was also reported. After general anesthesia with propofol (75 µg/kg/min) and remifentanil (0.5 to 1.0 µg/kg/min) for abdominal or thoracic surgery, continuous infusion of remifentanil (0.05 or 0.1 µg/kg/min) provided adequate analgesia.[353]

Neuroleptanalgesia-Neuroleptanesthesia

In 1949, Laborit and Huygenard introduced the concept of an anesthetic technique that blocked not only cerebrocortical responses but also some cellular, endocrine, and autonomic mechanisms usually activated by surgical stimulation. This state was called "ganglioplegia" or "neuroplegia" (artificial hibernation) and was achieved with the use of a lytic cocktail consisting of chlorpromazine, promethazine, and meperidine. From this idea, in 1959 De Castro and Mundeleer derived the concept of neuroleptanalgesia, which involved the combination of a major tranquilizer (usually the butyrophenone droperidol) and a potent opioid analgesic (fentanyl) to produce a detached, pain-free state of immobilization and insensitivity to pain. Neuroleptanalgesia is characterized by analgesia, absence of clinically apparent motor activity, suppression of autonomic reflexes, maintenance of cardiovascular stability, and amnesia in most patients. The addition of an inhaled agent, usually N_2O, improves amnesia and has been called neuroleptanesthesia.

"Neuroleptic" drugs traditionally include the phenothiazines (e.g., chlorpromazine) and the butyrophenones (e.g., haloperidol and droperidol). Butyrophenones cause sedation, tranquility, immobility, antiemesis, an extrapyramidal syndrome with face and neck dyskinesia, oculogyric crises, torticollis, agitation, and hallucinations. Administering droperidol alone, without analgesics or other sedatives, often produces feelings of discomfort or dysphoria in patients. The cardiovascular effects of droperidol are most often limited to mild hypotension, which is thought to be mediated through α-adrenergic blockade. There is little respiratory depression induced by droperidol, although significant variability exists and respiratory depression may be noted occasionally. Droperidol and other butyrophenones may enhance hypoxic-induced increases in ventilation in humans because of their antidopaminergic effects at the carotid body. Droperidol can be used as a premedicant (0.025 to 0.075 mg/kg IM), an antiemetic (0.01 to 0.02 mg/kg IV), an adjunct for awake intubation (0.025 to 0.1 mg/kg IV), and therapy for agitated, belligerent, or psychotic patients (0.05 to 0.2 mg/kg IV or IM).

Neuroleptanalgesia or neuroleptanesthesia is contraindicated in patients receiving monoamine oxidase inhibitors (MAOIs), in those who abuse drugs or alchohol, or in patients with Parkinson's disease.

Total Intravenous Anesthesia

Many different intravenous compounds can be used in a number of combinations to provide TIVA. Most commonly, an opioid is combined with another drug more likely to provide hypnosis and amnesia. For example, the combination of alfentanil and propofol produces excellent TIVA. Alfentanil provides analgesia and hemodynamic stability while blunting responses to noxious stimuli. On the other hand, propofol provides hypnosis and amnesia and is antiemetic. Profound synergism also exists when more than two agents, such as propofol-alfentanil-midazolam, are combined.[354,355] Induction of anesthesia with alfentanil (25 to 50 µg/kg) and propofol (0.5 to 1.5 mg/kg), followed by infusions of alfentanil at 0.5 to 1.5 µg/kg/min and propofol at 80 to 120 µg/kg/min, will produce anesthesia in patients ventilated with air and O_2 with or without N_2O for a variety of procedures. It is proposed that alfentanil concentrations as low as 85 ng/mL, when combined with a blood propofol concentration of 3.5 µg/mL, can produce both optimal anesthetic conditions and speed of recovery.[355] Stanski and Shafer suggested that bolus doses and initial infusion rates would be 30 µg/kg and 0.35 µg/kg/min for alfentanil and 0.7 mg/kg and 180 µg/kg/min for propofol.[356] Recognizing that these calculations were based on EC_{50} data in patients undergoing only moderately painful procedures, anesthesiologists should adjust these doses accordingly. Premedication before alfentanil-propofol anesthesia can prolong postoperative recov-

ery and should be avoided if appropriate.[357] In patients undergoing ear-nose-throat surgery, TIVA with remifentanil and propofol provided more rapid respiratory recovery after brief surgical procedures than TIVA with alfentanil and propofol did.[358]

The optimal propofol-opioid concentrations that ensure adequate anesthesia and rapid emergence were determined by computer modeling. The optimal propofol concentration decreases in the order of fentanyl > alfentanil > sufentanil ≫ remifentanil. A shorter context-sensitive half-time allows the administration of greater amounts of opioid (and less propofol) during anesthesia without creating prolonged opioid effects.

Maintenance infusions vary according to patient condition and surgical stimuli. Propofol (75 to 125 μg/kg/min) and alfentanil (1.0 to 2.0 μg/kg/min) are initially recommended. Drug infusions should be terminated 10 to 20 minutes before the end of anesthesia if N_2O is used. Otherwise, propofol infusions should be terminated 5 to 10 minutes before anticipated patient awakening. Alfentanil infusion rates do not need to be less than 0.25 to 0.5 μg/kg/min until surgery is terminated. A multicenter evaluation demonstrated that in patients undergoing elective inpatient surgery, remifentanil, 1 μg/kg intravenously, followed by 1.0 μg/kg/min, when combined with propofol, 75 μg/kg/min, effectively controlled responses to tracheal intubation.[346] Reduction of the remifentanil infusion rate to 0.25 to 0.40 μg/kg/min after tracheal intubation was also recommended.

Midazolam-opioid combinations can also provide complete anesthesia. However, midazolam-alfentanil TIVA has not been found to compare favorably with propofol-alfentanil TIVA, even with flumazenil reversal of benzodiazepine action.[359]

TIVA techniques are especially useful when delivery of inhaled agents is compromised. By keeping the goals of balanced anesthesia in mind, combining modern opioids and other drugs, using infusion pumps, and having an increased understanding of pharmacokinetics, clinicians can successfully perform a variety of TIVA techniques. Approximate opioid doses and infusion rates for TIVA are listed in Table 27-7.

Opioid-Based (High-Dose Opioid) Anesthesia for Cardiac Surgery

Opioids can be administered as the primary or sole anesthetic in opioid-based anesthetic techniques. High-dose opioid anesthesia was introduced as a stress-free anesthetic method for cardiac surgery (also see Chapter 60). However, several factors have diminished the popularity of high-dose opioid anesthesia, even in cardiac anesthesia, including the lack of evidence substantiating any significant outcome benefit associated with the use of large doses of opioids, the added drug costs, and the trend toward "fast-track" approaches to cardiac patients that can be impeded by large doses of opioids, especially fentanyl.[212,360] Nonetheless, opioids, particularly when administered by continuous infusion, are still among the most effective anesthetics for patients undergoing cardiac or other extensive operations. High-dose opioid anesthesia was first performed with morphine. However, fentanyl and sufentanil were recommended later.

In an attempt to decrease the cost of cardiac surgery, fast-track programs have become popular. Engoren and associates reported that the more expensive but shorter-acting opioids sufentanil and remifentanil produce equally rapid extubation, similar stays, and similar costs to fentanyl, indicating that any of these opioids can be recommended for fast-track cardiac surgery.[361]

Table 27-7 Approximate Opioid Loading (Bolus) Doses, Maintenance Infusion Rates, and Additional Maintenance Doses for Total Intravenous Anesthesia

	Loading Dose (μg/kg)	Maintenance Infusion Rate	Additional Boluses
Alfentanil	25-100	0.5-2 μg/kg/min	5-10 μg/kg
Sufentanil	0.25-2	0.5-1.5 μg/kg/hr	2.5-10 μg
Fentanyl	4-20	2-10 μg/kg/hr	25-100 μg
Remifentanil	1-2	0.1-1.0 μg/kg/min	0.1-1.0 μg/kg

From Bailey PL, Egan TD, Stanley TH: Intravenous opioid anesthetics. *In* Miller RD (ed): Anesthesia, 5th ed. New York, Churchill Livingstone, 2000, p 335.

Fentanyl

Many different techniques have been used to achieve anesthesia with fentanyl.[360,362] Rapid or slow bolus injections of fentanyl range from 5 to 75 μg/kg. These doses will establish plasma fentanyl concentrations (10 to 30 ng/mL) that are often sufficient to provide stable hemodynamics throughout the induction/intubation sequence. Continuous infusions of fentanyl for cardiac surgery range from 0.1 to 1.0 μg/kg/min up to or continuing through CPB. High-dose fentanyl anesthesia has also proved effective and safe for pediatric heart surgery. It was indicated that fentanyl, 25 to 50 μg/kg, combined with isoflurane, 0.2% to 0.4%, was sufficient to obtund hemodynamic and stress responses in the pre-CPB phase of open heart surgery in infants and young children (Fig. 27-26).[363] On the other hand, high-dose fentanyl, 75 to 100 μg/kg, was shown to cause prolonged suppression of NK cell function.[364] It was reported that 57 of 59 eligible patients were successfully extubated at 34 ± 14 minutes after termination of fentanyl (total dose, 127 ± 64 μg/kg) with naloxone (total bolus, 3.4 ± 2.6 μg/kg) and recovered fully without ventilatory support under the naloxone infusion, which was terminated at 11 ± 7 hours.[365] These results suggest that naloxone infusion with individual dose titration facilitates the use of high-dose opioid anesthesia while maintaining the advantage of this anesthesia. It was recently shown that high-dose fentanyl (50 μg/kg) is not associated with a difference in the incidence of postoperative cognitive dysfunction at 3 or 12 months after coronary artery bypass surgery in the elderly, whereas low-dose fentanyl (10 μg/kg) leads to shorter postoperative ventilation times and may be associated with a greater incidence of postoperative cognitive dysfunction 1 week after surgery.[366]

Alfentanil

Induction of anesthesia with large doses of alfentanil has been applied to cardiac surgery.[367] Large doses of alfentanil (150 μg/kg) may be used with or without thiopental to induce anesthesia. Other investigators claim that anesthesia cannot be reliably induced with alfentanil alone, at least in young and healthy adults.[85] Continuous infusions of alfentanil (2 to 12 μg/kg/min) have been used to maintain moderate to very high plasma alfentanil concentrations (<3000 ng/mL) during cardiac surgery. Enthusiasm for high-dose alfentanil anesthesia techniques is limited by the amount (and cost) of drug required and sugges-

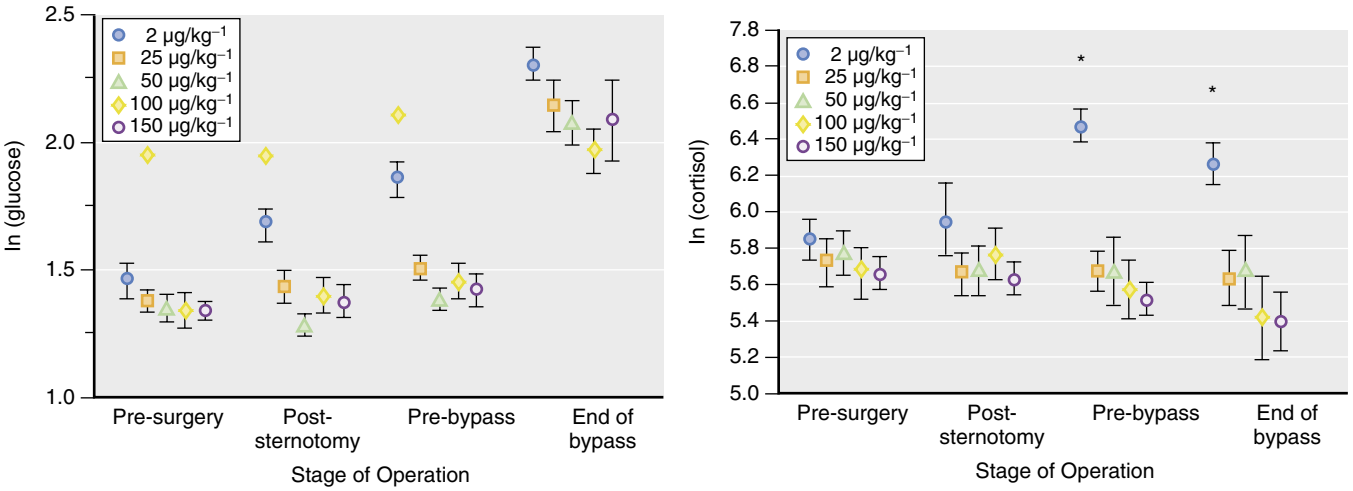

Figure 27-26 Suppression of stress responses in the pre-bypass phase of open heart surgery in infants and young children by fentanyl combined with a low concentration (0.2% to 0.4%) of isoflurane: mean (± SE) ln (glucose) (*left*) or ln (cortisol) (*right*) versus stage of surgery for each dose of fentanyl. The values for the 2-μg/kg group indicated by *asterisks* were significantly higher ($P < .01$) than in the other groups. ln, natural logarithm. *(From Benthuysen JL, Foltz BD, Smith NT, et al: Prebypass hemodynamic stability of sufentanil-O_2, fentanyl-O_2, and morphine-O_2 anesthesia during cardiac surgery: A comparison of cardiovascular profiles. J Cardiothorac Anesth 12:749-757, 1988.)*

tions that alfentanil anesthesia for cardiac surgery is inadequate and associated with more cardiovascular adverse effects than is the case with fentanyl and sufentanil. More modest doses of alfentanil have been successfully administered in combination with sedative-hypnotics such as propofol for cardiac anesthesia.[368]

Sufentanil

Advantages of high-dose sufentanil include more rapid induction, better blunting or elimination of hypertensive episodes, greater reduction in left ventricular stroke work, and higher cardiac output and more stable hemodynamics intraoperatively and postoperatively.[369] Induction doses of sufentanil range from 2 to 20 μg/kg administered as a bolus or infused over a period of 2 to 10 minutes. Total doses of sufentanil used in high-dose techniques usually range from 15 to 30 μg/kg, but no additional benefit could be demonstrated in terms of hemodynamic control or EEG signs by increasing the dose of sufentanil from 3 to 15 μg/kg for induction of anesthesia in patients premedicated with lorazepam.[370] It has been thought that muscle rigidity during induction of anesthesia with high-dose opioid causes difficult ventilation with a mask. However, it was shown that the difficult ventilation during induction of anesthesia with sufentanil, 3 μg/kg, is due to upper airway closure at the level of the glottis or above.[371]

The amount of sufentanil required can be markedly influenced by the supplements administered concomitantly. For patients undergoing coronary artery surgery, induction (0.4 ± 0.2 μg/kg) and total maintenance (2.4 ± 0.8 μg/kg) doses of sufentanil were used in combination with propofol (1.5 ± 1 mg/kg for induction and 32 ± 12 mg/kg total). Interestingly, sufentanil requirements tripled when midazolam was used instead of propofol.[372] Etomidate, combined with an opioid, can provide excellent anesthetic conditions with minimal hemodynamic perturbations. Inducing anesthesia with sufentanil (0.5 to 1.0 μg/kg) and etomidate (0.1 to 0.2 mg/kg) frequently confers hemodynamic stability. Maintenance of anesthesia with an infusion of sufentanil (1.0 to 2.0 μg/kg/hr) in a balanced anesthetic technique achieves the advantages of opioid-based anesthesia and avoids prolonged opioid action into the postoperative period.

Remifentanil

Remifentanil has been used in cardiac anesthesia.[318] It was shown that induction with remifentanil, 2 μg/kg, and propofol and maintenance with remifentanil at 0.25 or 0.5 μg/kg/min provided appropriate anesthesia for minimally invasive coronary artery bypass surgery with rapid awakening and tracheal extubation (Fig. 27-27).[373] Kazmaier and coworkers compared high-dose remifentanil (2.0 μg/kg/min) and remifentanil (0.5 μg/kg/min) combined with propofol (target-controlled infusion aiming at a plasma concentration of 2.0 μg/mL) in patients undergoing elective coronary artery bypass grafting.[374] It was demonstrated that high-dose remifentanil reduces the stroke volume index, heart rate, mean arterial pressure, myocardial blood flow, and myocardial oxygen uptake and that its effects do not differ from those of remifentanil/propofol anesthesia. Geisler and colleagues examined the efficacy and safety of high-dose remifentanil anesthesia in patients undergoing coronary artery bypass graft surgery.[375] It was demonstrated that continuous infusions of remifentanil at 1.0 to 2.0 μg/kg/min in combination with propofol, 3 mg/kg/hr, provided profound suppression of responses to surgical stimuli in the majority of patients, but there was a high incidence of muscle rigidity when remifentanil was used to induce anesthesia. They concluded that there was no apparent advantage in starting the remifentanil infusion rate above 1.0 μg/kg/min and that remifentanil is not suitable for use as a sole induction agent.

Other Applications of Opioids

Transdermal Therapeutic System

Transdermal drug delivery generally requires high solubility in both water and oil, low molecular weight, high potency, and little or no skin irritation. Fentanyl is available in a transdermal therapeutic system (TTS). Potential advantages of delivering fentanyl

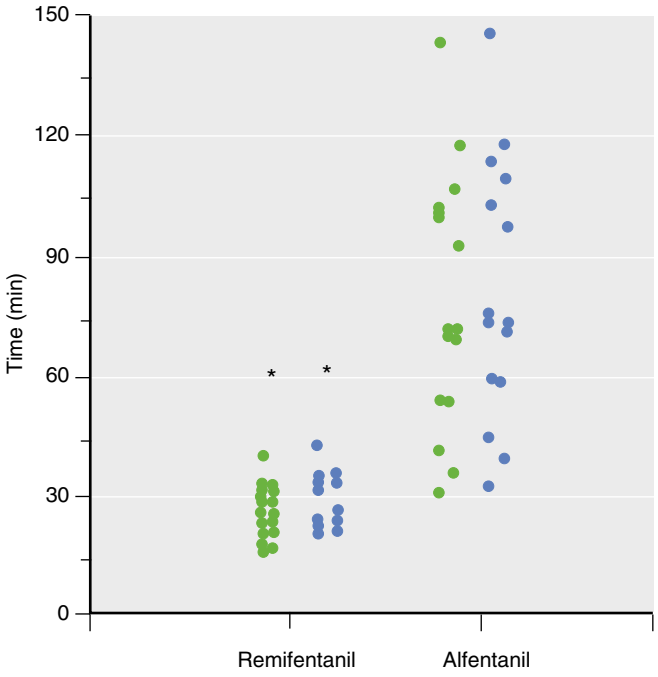

Figure 27-27 Times to awakening (*green circles*) and tracheal extubation (*blue circles*) in patients who underwent minimally invasive direct coronary artery bypass surgery after intravenous anesthesia with remifentanil-propofol or alfentanil-propofol. *(From Ahonen J, Olkkola KT, Verkkala K, et al: A comparison of remifentanil and alfentanil for use with propofol in patients undergoing minimally invasive coronary artery bypass surgery. Anesth Analg 90:1269-1274, 2000.)*

transdermally include no first-pass drug metabolism by the liver; improved patient compliance, convenience, and comfort; and consistent analgesia. Doses of TTS fentanyl include 20, 50, 75, and 100 µg/hr, and blood levels ranging from less than 1.0 to 2.0 ng/mL are achieved, although significant variability exists.[376] The pharmacokinetics of transdermally delivered fentanyl (50 µg/hr) was compared in 10 young adult (25- to 38-year-old) and 8 elderly (64- to 82-year-old) patients.[377] It was shown that the mean half-time (time for plasma concentrations to double after patch application) was 4.2 and 11.1 hours and the mean maximum plasma concentration was 1.9 and 1.5 ng/mL in the younger and elderly groups, respectively. There were no differences in the time at which maximum plasma concentrations occurred or the elimination half-life after patch removal. Elevated body temperature accelerates either release of fentanyl from the patch or distribution from the subcutaneous fat depot. Portenoy and coworkers demonstrated that a steady-state serum concentration was achieved by repeated application of TTS fentanyl and that the apparent half-life following system removal after repeated application was relatively long, presumably because of ongoing absorption from a subcutaneous depot (Fig. 27-28).[378]

The results of clinical trials using the transdermal fentanyl system for postoperative analgesia have demonstrated a high incidence of significant respiratory depression, and this application is not recommended.[376] In cancer pain, TTS fentanyl offers an alternative to oral morphine, and its effectiveness and tolerability for this indication have been demonstrated in a number of trials.[379] Its usefulness in chronic pain of nonmalignant origin remains to be confirmed in controlled trials. In general, TTS fentanyl produces the same adverse effects as other opioids, mainly sedation, nausea, vomiting, and constipation. In comparison to oral morphine, TTS fentanyl causes fewer gastrointestinal adverse events. The risk of hypoventilation is comparatively low in cancer patients. Sufentanil and buprenorphine may also be suitable for transdermal delivery, but clinical results are not yet available. Transdermal morphine is useful only if applied to de-epithelialized skin.

Iontophoresis

Iontophoresis is a technique by which drug passage through the skin is augumented with an external electric current. Clinically significant doses of morphine and fentanyl can be delivered iontophoretically.[380] The fentanyl HCl iontophoretic transdermal system (fentanyl ITS) is a novel PCA system that has been approved in the United States and Europe for the management of acute, moderate to severe postoperative pain.[381] This system allows patients to self-administer preprogrammed doses of fentanyl noninvasively through the use of iontophoretic technology. To assess the efficacy and safety of patient-controlled fentanyl ITS (40-µg infusion over a 10-minute period) versus standard intravenous morphine PCA (1-mg bolus every 5 minutes; maximum of 10 mg/hr), a prospective, randomized, controlled, parallel-group trial was performed.[382] The results indicated that the fentanyl ITS can provide pain control equivalent to that of standard morphine PCA, with a similar incidence of opioid-related adverse events. Fentanyl ITS may offer a number of clinical advantages over existing PCA modalities.[381] Its method of drug delivery avoids the risk of complications from needle-related injuries and infection, and its preprogrammed electronics eliminate the potential for manual programming errors and excessive dosing. In addition, the compact size of the system could enable greater patient mobility after surgery. Patient-controlled fentanyl ITS has the potential to become a valuable option in the management of acute postoperative pain.

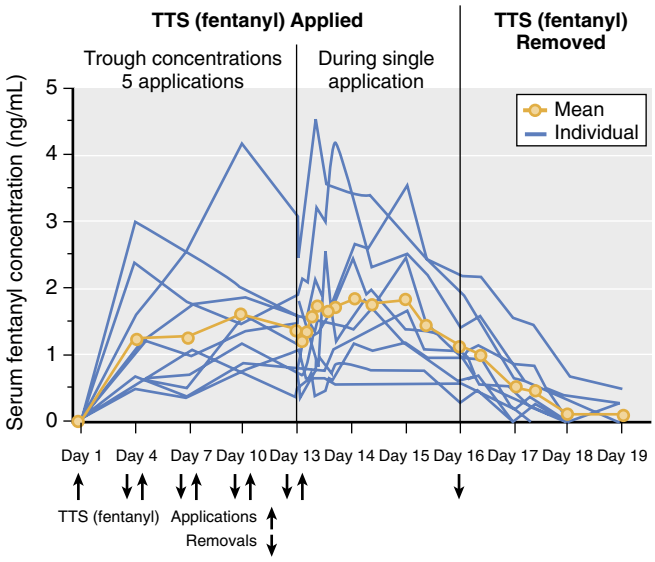

Figure 27-28 Individual and mean (SE) serum fentanyl concentration-time profiles measured in 10 patients during five consecutive applications of the transdermal fentanyl system. *(From Portenoy RK, Southam MA, Gupta SK, et al: Transdermal fentanyl for cancer pain. Repeated dose pharmacokinetics. Anesthesiology 78:36-43, 1993.)*

Transmucosal Drug Delivery

Similar to transdermal drug delivery, transmucosal delivery through the oropharynx and nasopharynx eliminates hepatic first-pass metabolism (drugs are absorbed directly into the systemic circulation) and improves patient comfort, convenience, and compliance.

Buprenorphine, a potent synthetic morphine analog with mixed opioid agonist-antagonist properties and a long half-time, is readily absorbed from sublingual mucosal tissues. The portion of the drug that is swallowed is almost completely metabolized by the liver, and only a small fraction can reach the systemic circulation when swallowed. Systemic bioavailability after sublingual buprenorphine is approximately 50% of that after intravenous administration. In several studies, sublingual buprenorphine (0.4 mg) was compared with conventional intramuscular morphine or meperidine and found to provide comparable and satisfactory analgesia.[383]

The initial experience with buccal morphine for postoperative analgesia had been promising. However, in female patients undergoing lower abdominal surgical procedures, buccal morphine did not significantly reduce postoperative pethidine consumption when compared with placebo, and all patients receiving buccal morphine reported a taste that reduced its acceptability.[384] The low lipid solubility of morphine makes it an unlikely candidate for effective transmucosal absorption. Opioids with high lipid solubility, such as buprenorphine, fentanyl, and methadone, are more effectively absorbed sublingually than those with low lipid solubility, such as morphine.

Oral transmucosal fentanyl citrate (OTFC) is a solid dosage form of fentanyl that consists of fentanyl incorporated into a sweetened lozenge on a stick. A portion of the fentanyl is absorbed through the oral mucosa, and the rest is swallowed and absorbed through the gastrointestinal tract. The swallowed fentanyl has low bioavailability because of hepatic first-pass metabolism. Recommended doses range from 5 to 20 µg/kg.[385,386] OTFC should be administered approximately 30 minutes before surgery (or a painful procedure) to obtain peak effect. Plasma concentrations after administration of OTFC peak at 2.0 ± 0.5 ng/mL 15 to 30 minutes after administration and then decline to less than 1 ng/mL an hour later.[387] Unlike transdermal fentanyl, OTFC leaves no significant depot in mucosal tissues after it is removed. The systemic bioavailability of OTFC is 50%, and this figure reflects both buccal and gastrointestinal absorption. OTFC bioavailability is similar to that of buprenorphine (55%), but much greater than the bioavailability of buccal morphine and other opioids with low lipid solubility. Egan and associates demonstrated that the pharmacokinetics of OTFC did not change with repeated dosing and that the decline in plasma concentration was as rapid as when administered intravenously (Fig. 27-29).[388] Preoperative OTFC was reported to be effective for postoperative analgesia in pediatric tonsillectomy patients.[389] However, OTFC can induce perioperative emesis and respiratory depression. It is also being evaluated for the treatment of breakthrough cancer pain.[390] OTFC may be ideally suited to treat breakthrough cancer pain because fentanyl is rapidly absorbed from OTFC and patients can easily self-administer OTFC.

Delivery of opioids through the nasal mucosa has also been investigated. Pharmacokinetic studies in volunteers have been reported for fentanyl, alfentanil, sufentanil, butorphanol, oxycodone, and buprenorphine.[391] Mean times to achieve maximum serum concentrations vary from 5 to 50 minutes, whereas bioavailability varies from 46% to 71%. Fentanyl, pethidine, and butorphanol have been studied for postoperative pain. Mean onset times vary from 12 to 22 minutes and times to peak effect from 24 to 60 minutes. Transnasal butorphanol provides superior and more prolonged analgesia than do similar doses given intravenously for postoperative pain after cesarean section.[392] PCA with intranasal fentanyl was demonstrated to be effective for postoperative pain management.[393] Side effects of intranasal sufentanil in children include reduced ventilatory compliance (chest wall rigidity), hypoxemia, impaired manual ventilation, and nausea and vomiting.[394,395] It appears that further exploration of the transnasal approach to drug delivery for pain management is merited. Improvements in nasal sprayer devices and opioid formulations may improve the clinical outcome.

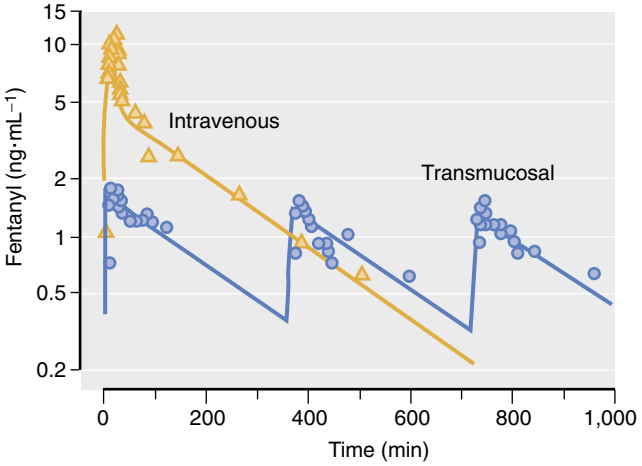

Figure 27-29 Typical result of the time-dependent change in plasma concentration of fentanyl after the application of oral transmucosal fentanyl citrate OTFC) and intravenous administration. Three 800-µg doses of OTFC were administered at 6-hour intervals, and fentanyl was infused at a constant rate of 50 µg/min to a total of 15 µg/kg. *(From Egan TD, Sharma A, Ashburn MA, et al: Multiple dose pharmacokinetics of oral transmucosal fentanyl citrate in healthy volunteers. Anesthesiology 92:665-673, 2000.)*

Inhalation of fentanyl (300 µg) produces a low plasma drug level (0.1 ng/mL) after 15 minutes and analgesia that may be disproportionately greater than expected.[396] Inhaled liposome-encapsulated fentanyl was also demonstrated to be a noninvasive route of administration that provides a rapid increase in and prolonged maintenance of the plasma fentanyl concentration.[397] Inhaled nebulized fentanyl citrate significantly improved patient perception of breathing, the respiratory rate, and oxygen saturation in terminally ill cancer patients.[398] This inexpensive and readily available treatment may offer substantial relief of end-of-life dyspnea. The advent of specialized and efficient pulmonary drug delivery systems has facilitated the evaluation of inhaled opioids, such as morphine and fentanyl, for the management of severe pain associated with surgery or malignant disease.[399]

The rectal mucosa is another site for transmucosal drug delivery. The bioavailability of a 30-mg morphine sulfate controlled-release suppository formulation was significantly greater than that of 30-mg oral controlled-release morphine sulfate tablets, which may be the result of partial avoidance of hepatic biotransformation with rectal administration.[400] The hydrogel formulation of rectal morphine may also be useful for premedication and analgesia in pediatric patients.[401]

Oral Controlled-Release Medications

Despite the high first-pass metabolism of opioid analgesics, morphine has been formulated into an oral, sustained-release tablet (MST) and evaluated for premedication, for postoperative analgesia, and as an analgesic for chronic cancer pain. MST provides unreliable preoperative anxiolysis and postoperative pain relief, possibly because of delayed time to the onset of peak effects (3 to 5 hours), which can be increased by impaired gastric emptying and absorption from the small intestine. As an analgesic for chronic cancer pain, MST was shown to be an excellent choice.[402]

A controlled-release formulation of oxycodone administered every 12 hours for a maximum of 7 days was shown to provide adequate pain control in patients undergoing abdominal, orthopedic, or gynecologic surgery.[403] The relative analgesic potency of single doses of oral controlled-release oxycodone (20 or 40 mg) and oral controlled-release morphine (45 or 90 mg) was compared in a randomized, double-blind trial in women with moderate to severe pain after abdominal hysterectomy.[404] Controlled-release oxycodone at doses of 20 or 40 mg was comparable to controlled-release morphine at doses of 45 or 90 mg, respectively, in total and peak analgesic effects, thus indicating that oral controlled-release oxycodone was twice as potent as oral controlled-release morphine. A randomized, double-blind, crossover trial indicated that controlled-release oxycodone is as safe and effective as controlled-release morphine in the treatment of cancer pain.[405]

Other Opioid Agonists

Codeine (methylmorphine) is half as potent as morphine and has a high oral-parenteral potency ratio (2:3) and a plasma half-life of 2 to 3 hours. Codeine has mild to moderate analgesic but strong cough-suppressant properties after oral administration. CYP2D6 is the enzyme responsible for *O*-demethylation of codeine to morphine.[406] Intravenous codeine produces profound hypotension and is neither approved nor recommended.[407]

Hydromorphone is structurally related to morphine but is approximately 5 to 10 times as potent. Analgesia after hydromorphone lasts 4 to 5 hours.[408] The effects of hydromorphone are essentially indistinguishable from those of heroin.[409] Hydromorphone has been used for both acute and chronic pain conditions in adults and children.[410] It was reported that hydromorphone PCA provided adequate postoperative analgesia with improved mood and that it can be an alternative to morphine PCA.[411]

Levorphanol is an opioid agonist of the morphinan series with a long (12- to 19-hour) half-life. It is five times as potent as morphine with an intramuscular-oral potency ratio of 1:2. Levorphanol may have particular utility in patients who have chronic pain and demonstrate morphine tolerance, perhaps because of differences in opioid receptor activity. The analgesia produced by levorphanol is mediated via its interactions with μ-, δ-, and κ-opioid receptors. Levorphanol is also an NMDA receptor antagonist. The long half-life of the drug increases the potential for drug accumulation.[412]

Methadone has equivalent potency but a longer duration of action than morphine does. The plasma half-life of methadone is very long and variable (13 to 100 hours). Despite this property, many patients require dosing every 4 to 8 hours to maintain analgesic effects. Its major clinical applications are for the prevention of opioid withdrawal symptoms and the treatment of chronic pain. It was shown that the same intravenous dose of methadone (20 mg) that is effective for postoperative pain is also suitable for induction of anesthesia in combination with etomidate and that methadone may have the potential to produce histamine release.[413]

Oxymorphone is a semisynthetic opioid agonist that is specific for the μ-opioid receptor and approved to treat both acute and chronic pain. Because of extensive liver metabolism, oral oxymorphone is contraindicated in patients with moderate to severe hepatic impairment.[414] Oxymorphone, structurally related to morphine, is almost 10 times as potent as morphine but has a similar duration of action. It was shown that in patients with acute moderate to severe postsurgical pain, oral immediate-release oxymorphone, 10, 20, or 30 mg, provided significant dose-related pain relief in comparison to placebo and that this relief was maintained for a period of several days with a safety profile comparable to that of immediate-release oxycodone.[415]

Piritramide, a synthetic opioid structurally related to meperidine, is devoid of emetic activity and is used for postoperative analgesia in several European countries.[416] Pharmacokinetic analysis has shown that piritramide is distributed extensively and eliminated slowly, and intermittent bolus administration is recommended.[417]

Tramadol is a synthetic 4-phenyl-piperidine analog of codeine with a dual mechanism of action. Tramadol stimulates the μ-receptor and, to a lesser extent, the δ- and κ-opioid receptors, and like tricyclic antidepressants, it also activates spinal inhibition of pain by decreasing the reuptake of norepinephrine and serotonin.[418] It is suggested that tramadol may have a direct serotonin-releasing action.[419] Tramadol is one fifth to one tenth as potent as morphine. In rats, tramadol could reduce the MAC of isoflurane in a naloxone-sensitive manner.[420] It was shown that intravenously administered tramadol was effective for post-thoracotomy pain relief.[421] Analgesic doses of tramadol may produce less respiratory depression, in part because of its non–opioid receptor–mediated actions,[422] and have minimal effects on gastrointestinal motor function.[423] Seizures have been reported in patients taking the drug. Caution should be exercised when combining tramadol with MAOIs, neuroleptic agents, and other drugs that lower the seizure threshold. It was suggested that tramadol has local anesthetic properties on peripheral nerves when used alone.[424] Tramadol added to lidocaine for intravenous regional anesthesia provided a shorter time to onset of sensory blockade.[425]

Sameridine possesses both local anesthetic and opioid properties. In patients undergoing arthroscopic knee joint surgery, sameridine was administered intrathecally and provided clinically adequate anesthesia.[426] A large intravenous dose of sameridine depressed resting ventilation and the hypercapnic ventilatory response, whereas a smaller clinical dose did not.[427,428]

M6G is a potent metabolite of morphine. In contrast to morphine, M6G is not metabolized but excreted via the kidneys and exhibits enterohepatic cycling inasmuch as it is a substrate for multidrug resistance transporter proteins in the liver and intestines.[429] M6G exhibits a delay in its analgesic effect (blood effect-site equilibration half-life of 4 to 8 hours), which is partly related to slow passage through the blood-brain barrier and distribution within the brain compartment. In humans, the potency

of M6G is just half of that of morphine. Trials to use M6G as an analgesic have been reported. Osborne and colleagues reported that 0.5 to 4 mg of M6G intravenously was effective for cancer pain for 2 to 24 hours without nausea and vomiting.[430] M6G, 100 µg and 125 µg given intrathecally, provided excellent analgesia after total hip replacement, as did intrathecal morphine sulfate, 500 µg.[431]

Agonist-Antagonist Opioid Compounds

Nalorphine, the first agonist-antagonist opioid, was successfully synthesized by Weijland and Erickson in 1942 and found to be strongly antagonistic to almost all the properties of morphine. Although nalorphine was found to possess strong analgesic actions, it was unsuitable for clinical use because of its psychotomimetic effects. Nalorphine was used in lower doses as an opioid antagonist.

Agonist-antagonist opioids are usually produced by alkylation of the piperidine nitrogen and addition of a three-carbon side chain such as a propyl, allyl, or methyl allyl to morphine. Buprenorphine is a partial agonist at the µ-receptor. The other compounds are µ-antagonists and full or partial agonists at the κ-receptor. Agonist-antagonist opioids are less prone (but not immune) to abuse because they cause less euphoria and are associated with less drug-seeking behavior and physical dependence.

Dosing data of these compounds are shown in Table 27-8. Agonist-antagonist compounds depress respiration in a similar manner as morphine, but ceiling effects exist (Table 27-9). Effects on the cardiovascular system differ among these compounds (Table 27-10).

Pentazocine

The analgesia produced by pentazocine is primarily related to stimulation of the κ-receptor. Pentazocine is one half to one fourth as potent as morphine. Ceilings in both analgesia and respiratory depression occur after 30 to 70 mg of pentazocine. Although the potential for abuse is less than with morphine, prolonged use of pentazocine can lead to physical dependence.

Table 27-8 Dosing Data for Agonist-Antagonist Opioids and Morphine

	Equianalgesic Intramuscular Dose (mg)	Duration of Analgesia (hr)	Oral-Intramuscular Efficacy Ratio
Morphine	10	4-5	1 : 6
Buprenorphine	0.3-0.4	>6	1 : 2*
Butorphanol	2	3-4	—
Nalbuphine	10	3-6	1 : 4-5
Pentazocine	40	3	1 : 3

*Sublingual-intramuscular ratio.

Table 27-9 Respiratory Depressant Effects of Agonist-Antagonists Compared with Morphine*

Drug	Correlation of Respiratory Depression with Dose
Morphine	Increases proportionally with dose
Buprenorphine	Ceiling effect at 0.15-1.2 mg in adults
Butorphanol	Ceiling effect at 30-60 µg/kg
Nalbuphine	Ceiling effect at 30 mg in adults
Pentazocine	Ceiling effect suggested, but difficult to study because of psychotomimetic effects

*Low or moderate naloxone doses readily reverse the respiratory effects produced by therapeutic doses of all the drugs listed except buprenorphine.
From Zola EM, McLeod DC: Comparative effects of analgesic efficacy of the agonist-antagonist opioids. Drug Intell Clin Pharm 17:411, 1983.

Nalorphine-like dysphoric side effects are common, especially after high doses (>60 mg) of pentazocine in the elderly. The dysphoric effects of pentazocine can be reversed with naloxone. Pentazocine depresses myocardial contractility and increases arterial blood pressure, heart rate, systemic vascular resistance, pulmonary artery pressure, and left ventricular work index. Pentazocine also increases blood catecholamine levels.

Pentazocine inhibited gastric emptying and gastrointestinal transit in rats, whereas U50488H, a pure κ-agonist, did not significantly inhibit either.[432] Therefore, it might be speculated that pentazocine affects gastrointestinal function through a mechanism other than the opioid receptors.

Pentazocine has limited application because it is associated with a high incidence of postoperative nausea and vomiting, provides limited analgesia, partially antagonizes other opioids, and can produce undesirable cardiovascular and psychotomimetic effects.

Butorphanol

Butorphanol is an agonist at κ-receptors. Its activity at µ-receptors is either antagonistic or partially agonistic. It is five to eight times as potent as morphine and is available only in parenteral form. After intramuscular injection, the onset of effect is rapid,

Table 27-10 Hemodynamic Effects of Agonist-Antagonist Compounds Compared with Morphine

Drug	Cardiac Workload	Blood Pressure	Heart Rate	Pulmonary Artery Pressure
Morphine	↓	↓	=↓	=↓
Buprenorphine	↓	↓	↓	?
Butorphanol	↑	=↑	=	↑
Nalbuphine	↓	=	=↓	=
Pentazocine	↑	↑	↑	↑

From Zola EM, McLeod DC: Comparative effects of analgesic efficacy of the agonist-antagonist opioids. Drug Intell Clin Pharm 17:411, 1983.

and peak analgesia occurs within 1 hour. Whereas the duration of action of butorphanol is similar to that of morphine, its plasma half-life is only 2 to 3 hours. Although butorphanol (10 mg IM) causes as much respiratory depression as the same dose of morphine, higher doses reach a ceiling. Side effects after butorphanol include drowsiness, sweating, nausea, and CNS stimulation. In healthy volunteers, butorphanol (0.03 or 0.06 mg/kg IV) produces no or minimal cardiovascular changes. However, in patients with cardiac disease, butorphanol causes significant increases in cardiac index, left ventricular end-diastolic pressure, and pulmonary artery pressure.

Because butorphanol decreases the MAC for enflurane by only a small fraction, it cannot serve as an anesthetic agent like the fentanyl congeners. Butorphanol is subject to less abuse and has less addictive potential than morphine or fentanyl does. Acute biliary spasm can occur after butorphanol, but increases in biliary pressure are less than after equipotent doses of fentanyl or morphine. Transnasal butorphanol is effective in relieving migraine and postoperative pain.[433]

Buprenorphine

Buprenorphine is a thebaine derivative, μ-receptor partial agonist and similar in structure to morphine but approximately 33 times more potent. Whereas fentanyl dissociates rapidly from μ-receptors (half-life of 6.8 minutes), buprenorphine has higher affinity and takes much longer (half-life of 166 minutes). The onset of action of buprenorphine is slow, its peak effect may not occur until 3 hours, and its duration of effect is prolonged (<10 hours). The volume of distribution of buprenophine is 2.8 L/kg and its clearance is 20 mL/kg/min. The metabolites of buprenorphine, buprenorphine-3-glucuronide and norbuprenorphine, are significantly less potent and have lower affinity for the μ-receptor.

The subjective effects (e.g., euphoria) of buprenorphine are similar to those of morphine. Buprenorphine produces depression of minute ventilation, which leveled off at doses higher than 3.0 μg/kg to about 50% of baseline, in contrast to fentanyl, in which dose-dependent respiratory depression results in apnea at doses higher than 2.9 μg/kg (Fig. 27-30).[434] Buprenorphine has been used successfully for premedication (0.3 mg IM), as the analgesic component in balanced anesthesia (4.5 to 12 μg/kg), and for postoperative pain control (0.3 mg IM). Buprenorphine, like the other agonist-antagonist compounds, is not acceptable as a sole anesthetic, and its receptor kinetic profile restricts its usefulness if other μ-agonists are used. Opioid withdrawal symptoms develop slowly (5 to 10 days) when buprenorphine is discontinued after long-term use.

Nalbuphine

Nalbuphine is an agonist-antagonist opioid that is structurally related to oxymorphone and naloxone and binds to μ-receptors, as well as to κ- and δ-receptors. Nalbuphine acts as an antagonist at the μ-receptor and as an agonist at the κ-receptor. Activation of supraspinal and spinal κ-receptors results in limited analgesia, respiratory depression, and sedation. Nalbuphine, like other agonist-antagonist compounds, interferes with the analgesia produced by pure μ-agonists. In rats, coadministration of nalbuphine with morphine dose-dependently blocked the development of morphine tolerance and dependence, without attenuation of the antinociceptive effect of morphine.[435] Nalbuphine is available only for parenteral use. The onset of effect is rapid (5 to 10 minutes), and its duration is long (3 to 6 hours) because of an extended plasma elimination half-life (5 hours).

Premedication with nalbuphine (0.1 mg/kg) in patients scheduled for cardiac surgery results in sedation, relief of anxiety, and respiratory depression similar to morphine (0.1 mg/kg), but

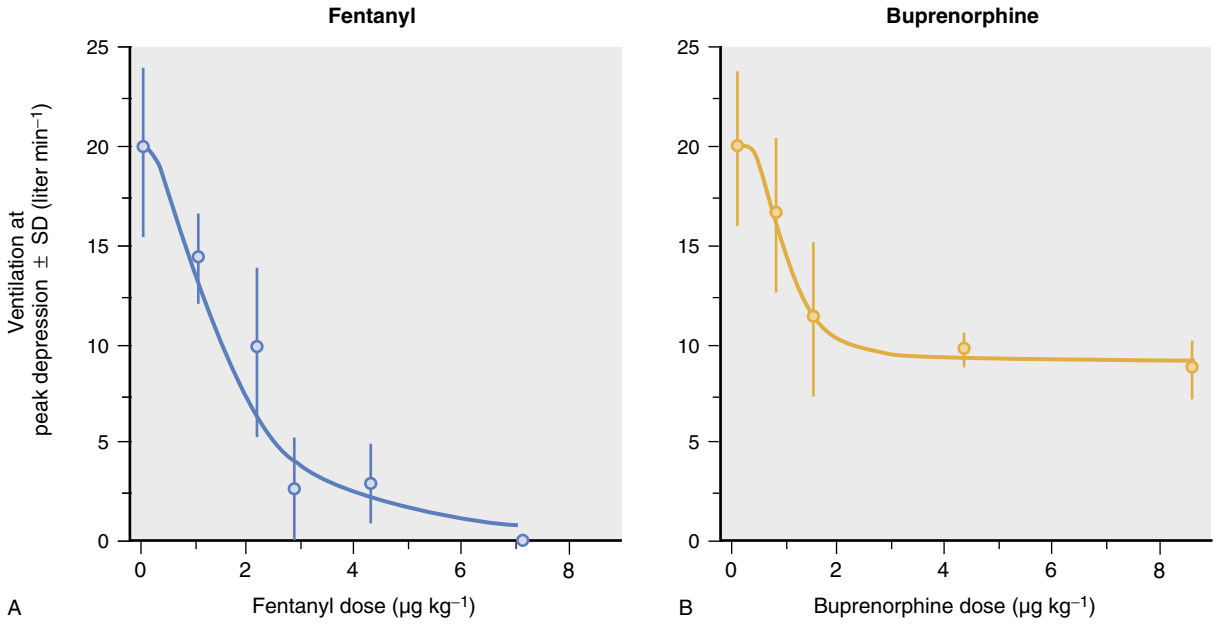

Figure 27-30 Dose-response relationships for reduction of minute ventilation induced by fentanyl (**A**) and buprenorphine (**B**). The response is the peak ventilatory depression at each dose. The line through the data is the fit to the Hill equation; 0 μg/kg is placebo. Data are means ± SD. *(From Dahan A, Yassen A, Bijl H, et al: Comparison of the respiratory effects of intravenous buprenorphine and fentanyl in humans and rats. Br J Anaesth 94:825-834, 2005.)*

it causes no significant hemodynamic changes. Nalbuphine (10 mg) caused no significant changes in systemic, pulmonary arterial, and pulmonary capillary wedge pressure in patients experiencing myocardial infarction.

Nalbuphine has been administered as an analgesic supplement for conscious sedation or balanced anesthesia and as an analgesic for postoperative and chronic pain problems. For postoperative patient-controlled epidural analgesia, the combination of hydromorphone, 0.075 mg/mL, and nalbuphine, 0.04 mg/mL, resulted in a lower incidence of nausea and decreased need for bladder catheterization when compared with hydromorphone alone.[436] In patients undergoing myocardial revascularization, continuous infusion of nalbuphine (0.05 to 0.1 mg/kg/min) and fentanyl (0.15 to 0.3 μg/kg/min) was compared.[437] It was shown that nalbuphine lacks the ability to attenuate cardiovascular and hormonal responses to tracheal intubation and surgical procedures, and it was concluded that continuous infusion of nalbuphine cannot be recommended for anesthesia in patients undergoing myocardial revascularization.

A prospective randomized double-blind study demonstrated that nalbuphine (4 mg IV) was as effective as ondansetron (4 to 8 mg IV) for the prevention of intrathecal morphine–induced pruritus after cesarean delivery.[438] Some reports showed that nalbuphine provides a rapid and potent antishivering effect, similar to meperidine.[439] However, a quantitative systematic review of randomized controlled trials did not support this conclusion.[440]

Other Compounds

Dezocine

Dezocine is slightly more potent and acts faster than morphine; it has a similar duration of action and is a partial agonist at μ- and probably δ-receptors. Its side effects are similar to those of morphine. Although shown to be an effective alternative to fentanyl when administered during outpatient laparoscopy with propofol and nitrous oxide, dezocine was associated with a high incidence of postoperative nausea and a delayed discharge time.[441] In adult patients who underwent arthroscopic surgery with general anesthesia, dezocine (5 mg IV) and morphine (5 mg IV) were similarly effective for postoperative analgesia and showed comparable side effects.[442]

Meptazinol

Meptazinol has been reported to cause minimal respiratory depression because of its selectivity for μ_1 (high-affinity) receptors. In patients receiving meptazinol (2.5 mg/kg) with a barbiturate, no cardiovascular changes were observed at tracheal intubation, whereas blood pressure and heart rate were significantly increased in patients receiving fentanyl (5 μg/kg).[443] Side effects (nausea and vomiting) limit its use to relief of severe pain.

Opioid Antagonists

Naloxone

Clinically, opioid antagonists are used to restore spontaneous ventilation in patients who breathe inadequately after opioid overdose or opioid anesthesia. In addition, opioid antagonists can reduce or reverse opioid-induced nausea and vomiting, pruritus, urinary retention, rigidity, and biliary spasm associated with numerous therapies using opioids, such as neuraxial analgesic techniques. It was reported that the naloxone-nalbuphine potency ratio for antagonism of the pruritic effects of epidural morphine was approximately 40 : 1.[444]

Morphine requirements were significantly less in patients receiving naloxone, thus suggesting that naloxone enhances analgesia.[445] Possible mechanisms proposed for this apparent paradoxical effect of naloxone include enhanced release of endogenous opioids and opioid receptor upregulation.

Although naloxone is generally considered to be a pure opioid receptor antagonist, it delays gastric emptying of saline or milk, as does morphine in the rat.[259] Furthermore, high-dose naloxone possesses partial agonistic activity on μ- and κ-opioid receptors in cultured cells.[446]

Reversal of Respiratory Depression by Naloxone

In the early 1950s, nalorphine and levallorphan were evaluated as opioid antagonists. They were often found unacceptable because of a high incidence of side effects, as well as incomplete reversal. Naloxone was introduced into clinical practice in the late 1960s. There have been reports of side effects (increases in heart rate and blood pressure) and more serious complications (e.g., pulmonary edema). Initial naloxone dose recommendations ranged from 0.4 to 0.8 mg. The onset of action of intravenous naloxone is rapid (1 to 2 minutes), and its half-life and duration of effect are short, approximately 30 to 60 minutes. If intravenous access is not available, naloxone, in doses similar to those given intravenously, is effectively absorbed after intratracheal administration.[447] Reversal with naloxone is limited by high affinity for and slow dissociation from the μ-opioid receptor of buprenorphine and depends on the buprenorphine dose and the correct naloxone dose window (Fig. 27-31).[448] Because respiratory depression from buprenorphine may outlast the effects of naloxone boluses or short infusions, continuous infusion of naloxone may be required to maintain reversal of respiratory depression.[448]

Several mechanisms produce increases in arterial blood pressure and heart rate, as well as other significant hemodynamic alterations, after naloxone reversal of opioids. These mechanisms include pain, rapid awakening, and sympathetic activation not necessarily caused by pain. When patients receiving naloxone for opioid agonist reversal are hypothermic because of intraoperative heat loss, O_2 consumption and minute ventilation can increase twofold to threefold.[449] Such metabolic demands also stress the cardiovascular system by increasing cardiac output. In addition, greater degrees of hypercapnia at the time of opioid antagonism will result in greater degrees of cardiovascular stimulation because of associated sympathetic stimulation. Opioid reversal may be particularly hazardous in patients with pheochromocytoma or chromaffin tissue tumors.[450] However, it was also reported that intravenous administration of 10-mg naloxone did not significantly change the plasma catecholamine concentration and blood pressure.[451]

Recurrence of respiratory depression after naloxone is due to the short half-life of naloxone. "Renarcotization" occurs more frequently after the use of naloxone to reverse longer-acting opioids such as morphine. Short-acting opioids such as alfentanil rarely pose a danger of renarcotization because of a rapid plasma decay curve and weaker opioid receptor binding than with fentanyl and sufentanil.

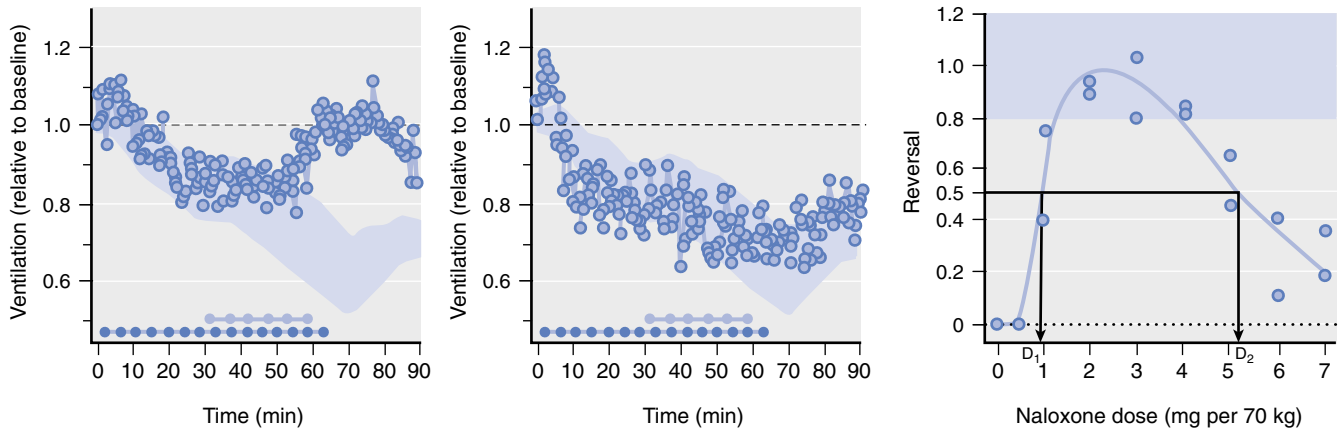

Figure 27-31 Reversal of buprenorphine-induced respiratory depression with naloxone depends on the correct naloxone dose window. Respiratory depression induced by 0.2 mg buprenorphine was reversed by naloxone, 2 mg (**left**) and 6 mg (**middle**), given over a 30-minute period in one subject. The *light blue field* in the background is the result of the placebo group, in which saline was infused instead of naloxone. *Dark blue dots* and *light blue dots* represent buprenorphine and naloxone infusion, respectively. **Right,** Influence of 0 (placebo) and 0.5 to 7 mg naloxone on respiratory depression induced by 0.2 mg intravenous buprenorphine. Reversal was calculated from the naloxone-induced change in ventilation and ranged from 0 (effect not different from placebo) to 1 (reversal to predrug baseline level). *(From van Dorp E, Yassen A, Sarton E, et al: Naloxone reversal of buprenorphine-induced respiratory depression. Anesthesiology 105:51-57, 2006.)*

Naloxone, though active at μ-, δ-, and κ-receptors, has greatest affinity for μ-receptors, which mediate most potent opioid effects, including respiratory depression and analgesia. Careful titration of naloxone can often restore adequate spontaneous ventilation without reversal of adequate analgesia.

Other Applications of Naloxone

Reversal of the effects of alcohol, barbiturates, and benzodiazepines by naloxone has been reported. However, it was also reported that naloxone potentiates the anxiolytic-like action of benzodiazepines and barbiturates in the rat.[452] It is not advisable to try to reverse the effects of overdose of benzodiazepines and barbiturates with naloxone. Although it was suggested that the μ-opioid receptor is involved in the antinociceptive action of ketamine in mice,[41] naloxone did not affect the action of ketamine on secondarty hyperalgesia induced by burn injury in humans.[453]

Evidence indicates that endogenous opioid peptides participate in the control of cardiovascular regulation during hemorrhagic shock. Intracerebroventricular administration of 10 mg of naloxone resulted in a significant increase in the bleeding volume required to lower arterial pressure from 60 to 40 mm Hg in rats.[454] In patients with documented septic shock and resistance to a 1-L fluid challenge, administration of naloxone by an initial bolus of 0.03 mg/kg followed by infusion at a rate of 0.2 mg/kg/hr significantly increased mean arterial pressure but did not affect survival.[455] This effect may be due to centrally mediated increases in sympathetic tone and decreases in parasympathetic output or antagonism of endogenous opioids. However, the clinical usefulness of naloxone in treating shock remains to be determined, and additional randomized clinical trials are needed to assess its usefulness.[456]

It has been reported that naloxone may ameliorate the neurologic deficit after an ischemic or traumatic neurologic insult in animals.[457] In humans, a randomized controlled trial demonstrated that naloxone (a bolus of 5.4 mg/kg, followed by infusion at 4.0 mg/kg/hr for 23 hours) does not improve neurologic recovery after acute spinal cord injury.[458] However, it was reported that combined use of cerebrospinal fluid drainage and naloxone reduces the risk of paraplegia in patients undergoing thoracoabdominal aneurysm repair.[459] Naloxone may also have a therapeutic role in heat stroke disorders[460] and cholestasis-induced pruritus.[461] Although intravenous naloxone has been claimed to produce pain relief in opioid-resistant central poststroke pain, a double-blind trial concluded that intravenous naloxone was of no value in alleviating central poststroke pain.[462]

Other Opioid Antagonists

Naltrexone

Naltrexone is a μ-, δ-, and κ-opioid receptor antagonist. It is longer acting than naloxone (plasma half-life of 8 to 12 versus 0.5 to 1.5 hours), and it is active when taken orally. A double-blind, placebo-controlled study of patients undergoing cesarean section indicated that naltrexone (6 mg) was an effective oral prophylactic against the pruritus and vomiting associated with intrathecal morphine but was associated with a shorter duration of analgesia.[463]

Nalmefene

Nalmefene has a greater preference for μ-receptors than for δ- or κ-receptors. It is equipotent to naloxone.[464] Nalmefene is long acting after oral (0.5 to 3.0 mg/kg) and parenteral (0.2 to 2.0 mg/kg) administration. Bioavailability after oral administration is 40% to 50%, and peak plasma concentrations are reached in 1 to 2 hours. The mean terminal elimination half-life of nalmefene is 8.5 hours as compared with 1 hour for naloxone. Prophylactic administration of nalmefene significantly decreased the need for antiemetics and antipruritic medications in patients receiving intravenous PCA with morphine.[465]

Methylnaltrexone

Methylnaltrexone is the first quarternary ammonium opioid receptor antagonist that does not cross the blood-brain barrier. It

can reverse the adverse effects of opioid medications mediated by peripheral opioid receptors, whereas the opioid effects mediated by opioid receptors in the CNS, such as analgesia, are not affected. The delayed gastric emptying induced by 0.09 mg/kg morphine could be attenuated by 0.3 mg/kg methylnaltrexone in healthy volunteers.[250] It was also reported that methylnaltrexone was effective in reversing the constipation from chronic methadone use.[466] Because methylnaltrexone does not cross the dura, it might have potential to reverse the peripherally mediated side effects of epidural opioids.[467]

Drug Interactions with Opioids

Opioids are frequently combined with other anesthetic agents to produce optimal anesthetic conditions. In anesthesia, most concomitantly administered drugs interact. Although some of these interactions are intentionally sought, others are unwanted and adverse. There are three general types of mechanisms of drug interactions: pharmaceutical, pharmacokinetic, and pharmacodynamic.[468]

Pharmaceutical interactions are chemical in nature, as illustrated when an alkaline solution of thiopental and an acidic solution of succinylcholine precipitate when simultaneously administered intravenously.

Pharmacokinetic interactions occur when the administration of one agent alters the pharmacokinetics or disposition of another. The hemodynamic changes induced by one agent can affect the pharmacokinetic behavior of the other agent. Sufentanil, which has a greater hepatic extraction ratio than alfentanil does, is more likely to be affected by decreases in hepatic blood flow. Opioid plasma levels also increase in the presence of propofol.[469] Decreased opioid metabolism by the CYP3A4 isoform of the cytochrome P450 enzyme responsible for the oxidative metabolism of more than 50 drugs may also underlie the pharmacokinetic interactions. A wide range of chemical compounds, including many drugs, can interact with the cytochrome P450 system and cause either increased activity (enzyme induction) or enzyme inhibition (Box 27-3).[468]

Pharmacodynamic interactions between opioids and inhaled anesthetics were assessed by evaluating classic MAC reduction in animals and humans. Although marked synergism between opioids and inhaled anesthetics occurs with analgesic doses of opioids, there is a ceiling effect to MAC reduction by opioids. The pharmacodynamic synergism between opioids and sedative-hypnotics such as propofol is profound. Choosing an opioid with a short context-sensitive half-life allows greater doses of that opioid to be administered, along with reduced doses of propofol, without compromising the time needed for recovery from anesthesia. Thus, the optimal plasma level of propofol is estimated to be approximately 30% less when it is combined with remifentanil instead of alfentanil.[469]

Drug dosing regimens and a plasma concentration of opioid and sedative-hypnotics that provide optimal hemodynamic control during a range of noxious stimuli are necessary. However, complicating our understanding of drug interactions is the observation that the same degree of interaction does not apply across different types of stimuli.

Box 27-3 Drugs That Inhibit or Induce Cytochrome P450 Enzymes

Inhibitors

- Antibiotics
  - Maclorides
    - Troleandromycin
    - Erythromycin
  - Fluoroquinolones
  - Isoniazid
- Azole antifungal drugs
  - Ketoconazole
  - Itraconazole
- Calcium entry blockers
  - Diltiazem
  - Verapamil
- Omeprazole
- Cimetidine
- Propofol
- Grapefruit juice

Inducers

- Barbiturates
- Antiepileptics
  - Carbamazepine
  - Phenytoin
  - Primidone
- Rifampicin
- Dichloralphenazone
- Ethanol
- Tobacco smoke

From Bovill JG: Adverse drug interactions in anesthesia. J Clin Anesth 9:3S, 1997.

Sedative-Hypnotics

Alfentanil was found to reduce the median effective dose (ED_{50}) of midazolam for induction of anesthesia in a dose-dependent fashion. The smallest dose of alfentanil (3 μg/kg) that causes a marked shift in the midazolam dose-response curve to the left along the dose axis (from an ED_{50} of 270 μg/kg to an ED_{50} of 142 μg/kg) represents approximately 2% of the alfentanil ED_{50} for induction of unconsciousness (130 μg/kg).[463] On the contrary, with regard to the antinociceptive effect, interaction between these two types of drugs may be less than additive.[470,471] Midazolam enhances opioid-induced antinociception at the spinal level but inhibits it at the supraspinal level.[472] Many studies reveal that benzodiazepine-opioid interactions for many properties other than analgesia are synergistic (supra-additive). Both the cardiovascular and respiratory actions of opioids can be significantly altered by the concomitant administration of benzodiazepines.[473] In anesthetized rabbits, fentanyl and midazolam synergistically caused depression of phrenic nerve activity.[474] Combinations of benzodiazepines and opioids, though occasionally preserving ventricular function, can result in significant and occasionally profound decreases in blood pressure, cardiac index, heart rate, and systemic vascular resistance. Fluid loading may

attenuate the circulatory depression that occurs when benzodiazepines and opioids are combined.

Barbituraes can potentiate or produce hypotension if a large dose is administered with opioids. Hypotension after a barbiturate-opioid combination is due to venodilatation, decreased cardiac filling, myocardial depression, and decreased sympathetic nervous system activity. Reducing induction doses of barbiturates administered concomitantly with opioids is recommended.

The administration of propofol-opioid combinations provides unconsciousness and blocks responses to noxious stimuli. However, when given as an intravenous bolus for induction of anesthesia, propofol can create moderate to severe preintubation hypotension. The addition of 2 to 4 μg/kg fentanyl significantly potentiated the decrease in mean blood pressure induced by 2.0 to 3.5 mg/kg propofol.[475] Propofol-fentanyl and propofol-sufentanil anesthesia for coronary artery bypass surgery may provide acceptable conditions, but mean arterial pressure can decrease to levels that may jeopardize coronary perfusion, especially during induction of anesthesia.[476] In healthy volunteers, the addition of alfentanil (effect-site concentration of 50 or 100 ng/mL) did not affect the changes in BIS induced by propofol but blocked the increase in BIS induced by painful stimuli.[477] In patients undergoing spine fusion, infusion of fentanyl (blood levels of 1.5 to 4.5 ng/mL) reduced the infusion rate of propofol necessary to maintain mean arterial pressure but delayed spontaneous eye opening and recovery of orientation.[340] In patients undergoing ambulatory gynecologic laparoscopy, administration of fentanyl (25 to 50 μg IV) at the time of induction of anesthesia reduced the maintenance propofol requirement but failed to provide effective postoperative analgesia and increased the need for postoperative use of antiemetics.[478] Pharmacokinetic interaction, as well as pharmacodynamic interaction, between propofol and opioids has been reported. Target-controlled infusion of alfentanil (target concentration, 80 ng/mL) was shown to increase the blood propofol concentration by 17% and decrease the elimination clearance, distribution clearance, and peripheral volume of distribution of propofol.[479]

Other anesthetic induction agents such as etomidate and ketamine can be combined in low doses with opioids with little loss of cardiovascular stability. In patients scheduled for coronary artery bypass grafting, etomidate (0.25 mg/kg) plus fentanyl (6 μg/kg) resulted in less hypotension after induction and intubation than propofol (1 mg/kg) plus fentanyl (6 μg/kg) did.[480] As described in the previous section, opioid-induced hyperalgesia and subsequent acute opioid tolerance can be prevented by ketamine in rats, suggesting the usefulness of the combination of ketamine and opioids for postoperative analgesia. However, it was reported that the combination of ketamine (2.5 or 10 mg IV) and alfentanil (0.25 or 1 mg IV) provides no advantage over a larger dose of either drug alone in relieving pain caused by intradermal capsaicin injection in healthy volunteers.[481] Furthermore, the combination of ketamine, 1 mg/mL, and morphine, 1 mg/mL, for PCA did not provide benefit to patients undergoing major abdominal surgery.[482] In contrast, Lauretti and coauthors reported that oral ketamine and transdermal nitroglycerin effectively reduced the daily consumption of oral morphine in patients with cancer pain.[483]

Gabapentin, a structural analog of GABA, is a novel anticonvulsant drug that has analgesic effects in patients with neuropathic pain. It was suggested that pharmacodynamic and pharmacokinetic interaction between morphine and gabapentin leads to increased analgesic effects.[484] Furthermore, intrathecal administration of gabapentin was shown to prevent the development of opioid tolerance induced by repeated intrathecal injection of morphine.[485] $GABA_A$ receptors contribute to inhibitory control at the spinal cord level. Intrathecal administration of muscimol or baclofen, $GABA_A$ and $GABA_B$ receptor agonists, respectively, increased the analgesic action of morphine in intensity and duration.[486]

Inhaled Anesthetics

N_2O produces analgesia that is in part mediated by release of the proenkephalin-derived family of endogenous opioid peptides.[487] This may imply that interaction between opioids and N_2O is neither synergistic nor additive. Combining N_2O with an opioid in a balanced technique may not best take advantage of drug interaction synergism. Although amnesia and intraoperative conditions may be improved somewhat, N_2O does not produce any effects that are not already produced by either an opioid or a sedative-hypnotic. The advent of short-acting intravenous anesthetics and volatile anesthetics with a blood-gas partition coefficient comparable to that of N_2O has decreased the popularity of N_2O in balanced anesthesia.

Volatile anesthetics are frequently combined with opioids to ensure amnesia and promote immobility and hemodynamic stability. Clinical trials of opioids supplemented with newer volatile anesthetics for cardiac surgery demonstrate well-preserved cardiac output and minimal decreases in mean arterial blood pressure.[488,489] Myocardial ischemia may not, however, always be ameliorated by approaches that combine opioids with potent inhaled agents despite apparent "good" hemodynamic control. Some of the potent inhaled anesthetics can increase sympathetic nervous system activity and may increase the risk for myocardial ischemia in cardiac patients.[490,491] Prior administration of fentanyl, in doses as low as 1.5 μg/kg, can markedly attenuate such responses.[490] Alfentanil (10 μg/kg) is also effective in attenuating these effects.

Muscle Relaxants

Pancuronium bromide has been used frequently for muscle relaxation during high-dose opioid anesthesia. It was reported that the vagolytic action of pancuronium can attenuate opioid-induced bradycardia and support blood pressure,[492] but other reports have cautioned against the use of pancuronium with high-dose opioids.[493] In patients undergoing coronary artery bypass grafting and administered sufentanil (3 to 8 μg/kg), pancuronium (120 μg/kg) caused a significant increase in mean arterial pressure, heart rate, and cardiac output but did not induce myocardial ischemia.[494] Pancuronium-induced tachycardia was easily and rapidly treated and caused no differences in ischemia or perioperative myocardial infarction. Many factors alter the impact of pancuronium and other muscle relaxants on hemodynamics when combined with opioids, including the dose, timing, and rate of administration of each relaxant, as well as the premedication, intravascular volume, left ventricular function, and presence of other drugs with autonomic nervous system actions.[492]

Combinations of vecuronium and high doses of opioids produce negative chronotropic and inotropic effects that result in

decreases in heart rate, cardiac output, and blood pressure and increases in the need for vasopressor support.[495] In patients scheduled for coronary artery surgery and administered 40 μg/kg sufentanil in combination with vecuronium (0.1 mg/kg), heart rate, mean arterial pressure, and systemic vascular resistance decreased from baseline values after tracheal intubation with neither a significant change in cardiac output nor evidence of new myocardial ischemia.[492]

In patients anesthetized with fentanyl, 50 μg/kg, and scheduled to undergo elective coronary artery bypass grafting, rocuronium, 0.6 mg/kg (approximately equivalent to 2 × ED_{95} doses), was associated with changes of only small magnitude in hemodynamic variables, including increases in stroke volume index (+15%) and cardiac index (+11%) and a decrease in pulmonary capillary wedge pressure (−25%).[496] In patients undergoing coronary artery bypass surgery under fentanyl anesthesia, mivacurium, 0.15 or 0.2 mg/kg, produced decreases in mean arterial pressure and systemic vascular resistance, possibly mediated by histamine release, whereas atracurium (0.5 mg/kg) produced no significant hemodynamic changes.[497] Pipecuronium (150 μg/kg) has been found to be devoid of circulatory actions in patients undergoing coronary artery bypass grafting surgery with midazolam-sufentanil (3 to 8 μg/kg) anesthesia.[494] In patients administered 50 μg/kg fentanyl, doxacurium caused a small decrease in mean arterial pressure.[498]

Miscellaneous

MAOIs can underlie the most serious and potentially fatal interactions of opioid and other drugs. It was reported that the combination of meperidine and an MAOI can induce the serotonin syndrome, which is caused by excess availability of serotonin in the CNS at the 5-HT_{1A} receptor and characterized by confusion, fever, shivering, diaphoresis, ataxia, hyperreflexia, myoclonus, and diarrhea.[499] The phenylpiperidine series opioids, including meperidine, tramadol, and methadone, appear to be weak serotonin reuptake inhibitors and have all been involved in serotonin toxicity reactions with MAOIs, whereas morphine, codeine, oxycodone, and buprenorphine are known to not be serotonin reuptake inhibitors and do not precipitate serotonin toxicity with MAOIs.[500] Alfentanil and remifentanil could be used with MAOIs without complications.[501,502]

Because opioids can inhibit voltage-dependent Ca^{2+} channel activity through the activation of G proteins, it may be possible that opioid action is potentiated by Ca^{2+} channel blockers. Numerous animal studies and few clinical studies have documented that opioid-induced analgesia is potentiated by L-type Ca^{2+} channel blockers. Systemically administered nifedipine was shown to potentiate morphine analgesia in both rats and humans.[503] Furthermore, intrathecal administration of verapamil, diltiazem, and nicardipine enhanced the antinociceptive effect of low-dose morphine in rats.[504] However, there is also a report that L-type Ca^{2+} channel blockers do not potentiate morphine analgesia at clinically relevant doses.[505] N-type Ca^{2+} channels are involved in the release of neurotransmitters from sensory neurons in the spinal cord. It was reported that intrathecal administration of a blocker of this channel, ω-conotoxin GVIA, produces antinociception and interacts synergistically with opioids at the spinal cord level.[506]

Erythromycin can inhibit the metabolism of several compounds. It supposedly reduces the oxidizing activity of cytochrome P450. Alfentanil, but not sufentanil, may have its action prolonged as a result of impaired metabolism in patients receiving erythromycin.[507,508] Cimetidine can prolong opioid effects by decreasing hepatic blood flow or diminishing hepatic metabolism (or by both means). Other drugs that inhibit certain cytochrome systems can increase endogenous morphine production from codeine.[406]

Magnesium has been shown to have antinociceptive effects, probably because of its antagonistic action on the NMDA receptor. Intravenous administration of magnesium sulfate, 50 mg/kg preoperatively and 8 mg/kg/hr intraoperatively, significantly reduced the intraoperative and postoperative fentanyl requirement.[509] However, passage of magnesium across the blood-brain barrier is limited. Intrathecal administration of fentanyl, 25 μg, plus magnesium sulfate, 50 mg, provided significantly prolonged analgesia when compared with fentanyl alone in patients requesting analgesia for labor.[510] It is likely that magnesium can potentiate opioid analgesia by both central and peripheral mechanisms.[511]

Nonsteroidal anti-inflammatory drugs such as ibuprofen, diclofenac, and ketorolac have been administered perioperatively to reduce the opioid requirement. Preoperative administration of ibuprofen (2 × 800 mg) to patients scheduled for lower abdominal gynecologic surgery was shown to reduce postoperative morphine consumption without an increase in side effects.[512] It was also reported that perioperative administration of diclofenac (75 mg twice daily) reduces morphine consumption and the incidence of adverse effects such as sedation and nausea after total abdominal hysterectomy.[513] In healthy volunteers, ketoprofen (1.5 mg/kg IV) reduced the respiratory depression induced by morphine (0.1 mg/kg).[514]

The tricyclic antidepressants are widely used to treat various chronic inflammatory and neuropathic pain conditions. Results in clinical studies were not consistent with respect to interactions between opioids and tricyclic antidepressants. An isobolographic analysis demonstrated that systemic administration of amitriptyline and morphine synergistically inhibits cutaneous orofacial inflammatory pain in rats.[515]

Diphenhydramine, a histamine H_1-receptor antagonist, is used as a sedative, an antipruritic, and an antiemetic drug. When administered alone, it modestly stimulates ventilation by augmenting the interaction of hypoxic and hypercapnic ventilatory drives. Diphenhydramine counteracts the alfentanil-induced decrease in the slope of the ventilatory response to carbon dioxide.[516]

28 Intravenous Drug Delivery Systems

Key Points

1. Anesthetic drugs are described by multicompartmental models. Accurate intravenous drug delivery requires adjusting the dose for accumulation of drug in peripheral tissues.
2. The biophase is the site of action of anesthetic drugs. Initiation, maintenance, and titration of intravenous anesthetics must account for the delay in equilibration between plasma and the site of drug effect.
3. Some drug effects directly reflect the concentration of drug in the biophase (direct-effect models). Other drug effects reflect the alteration of feedback systems by anesthetics (indirect-effect models). The influence of opioids on ventilation reflects the dynamic influence of opioids on the feedback between ventilation and carbon dioxide and is thus an example of an indirect drug effect.
4. The target concentration in the effect site is the same as the target concentration in plasma at steady state. The target concentration is influenced by patient physiology, surgical stimulation, and concurrent drug administration. Typically, one must set a target concentration for the hypnotic (volatile anesthetic or propofol) and the analgesic (opioid) that properly accounts for the synergy between them.
5. To achieve an effective target concentration, the conventional teaching of administering a loading dose calculated as target concentration times volume of distribution, followed by a maintenance rate calculated as target concentration times clearance, is inaccurate. The initial loading dose may be calculated as the target concentration times the volume of distribution at peak effect. Maintenance rates must initially account for distribution of drug in peripheral tissues and are turned down to the target concentration times clearance only after equilibration with peripheral tissues.
6. The terminal half-life does not reflect the clinical time course of drug concentration. The context-sensitive decrement time is the time for a given decrement in drug concentration as a function of the duration of infusion for an infusion that maintains a steady plasma concentration. Context-sensitive decrement times properly incorporate the multicompartmental behavior of intravenous anesthetics. The context-sensitive half-time is the time for a 50% decrement in concentration.
7. Alfentanil, fentanyl, sufentanil, remifentanil, propofol, thiopental, methohexital, etomidate, ketamine, and midazolam can all be given by intravenous infusion. Specific caveats, infusion rates, and titration guidelines are presented in the text.
8. Target-controlled infusions use pharmacokinetic models to titrate intravenous anesthetics to specified plasma or effect-site drug concentrations. The Diprifusor is a propofol target-controlled infusion system that is available worldwide except in North America.
9. Closed-loop drug delivery systems have used the median electroencephalographic frequency, bispectral index, and auditory evoked potentials to control intravenous anesthetic delivery. These systems have generally performed well clinically but remain investigational.

Anesthetic drugs must reach their site of action to be effective. In 1628, William Harvey proved in *Exercitatio Anatomica de Motu Cordis et Sanguinis in Animalibus* that venous blood was transported to the arterial circulation and thus to the organs of the body by the heart. It was recognized almost immediately that drugs injected into veins could be rapidly carried to the entire body. In 1657 Christopher Wren injected opium intravenously by means of a quill and bladder (Fig. 28-1A) into dogs and humans and rendered them unconscious. Eight years later, Sigismund Elsholtz gave an opioid solution for the purpose of rendering subjects insensitive, but it was not until 1874 that Pierre-Cyprien Ore administered chloral hydrate intravenously for a surgical procedure. This landmark event followed unsuccessful attempts by the Russian surgeon Pirogoff to administer ether intravenously in

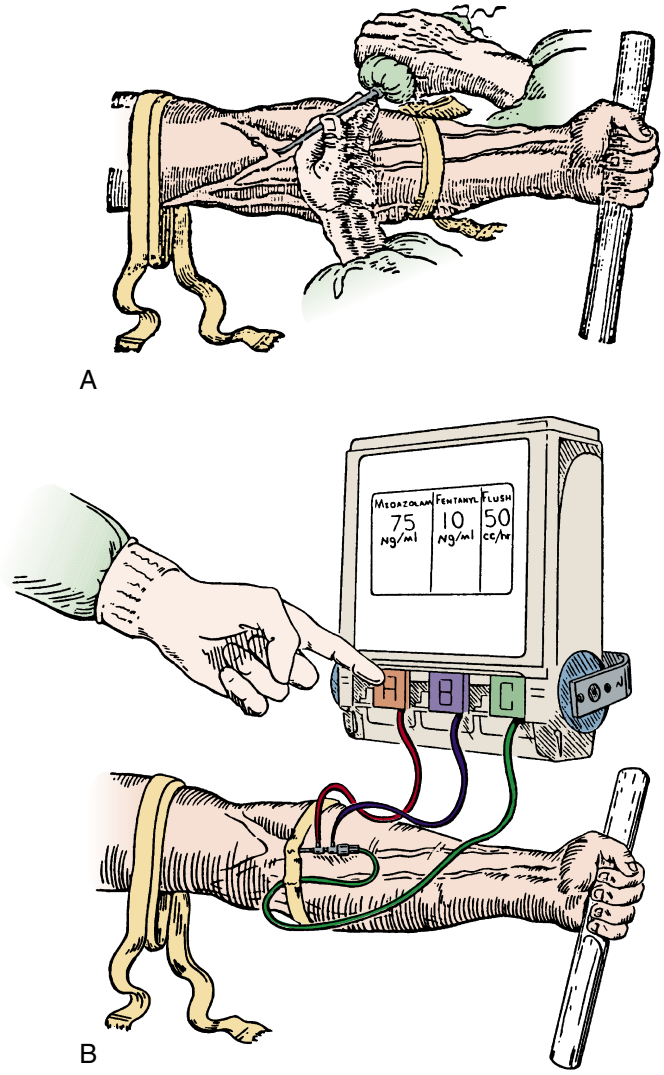

Figure 28-1 Intravenous drug delivery, past and future. **A,** A depiction of the first intravenous injection of opium with a quill and bladder. **B,** The future of intravenous drug delivery. Drugs are delivered with the aid of a small, sophisticated infusion pump, which permits dosing in terms of plasma drug concentration rather than amount.

1846, shortly after Crawford Long and William Morton had independently demonstrated the efficacy of ether inhalation for surgery.[1]

Intravenous methods of anesthetic drug delivery have depended on steady improvement in technology. The quill and bladder used by Wren were not significantly improved until Alexander Wood used a needle and syringe to administer intravenous medications in 1853. The hollow hypodermic needle and a functional syringe were developed by Frances Rynd and Charles Pravaz, respectively.[1] Contemporary needles, catheters, and syringes are descendants of these early devices. A more recent technologic development in intravenous anesthesia was the introduction of computerized pharmacokinetic model–driven continuous-infusion devices (see Fig. 28-1B), first reported by Helmut Schwilden[2] in 1981. Schwilden demonstrated the ability to attain desired plasma levels of an intravenous anesthetic drug by using a computer-controlled infusion pump operated in accordance with the published pharmacokinetics of the drug. These efforts resulted in release of the first commercial target-controlled infusion (TCI) device in Europe, developed by Zeneca specifically for the administration of propofol. The March 1998 issue of the journal *Anaesthesia* was devoted entirely to a review of TCI and the role of TCI devices in clinical practice. Since that time, nearly the rest of the world, with the notable exception of the United States, has approved TCI devices for the delivery of anesthetic drugs.

The ultimate development in anesthetic delivery systems will be devices for closed-loop administration of intravenous drugs during anesthesia. Systems have been developed for closed-loop administration of sodium nitroprusside and muscle relaxants based on defined and measurable end points. The lack of an unequivocal measure of "anesthetic depth" has hindered the development of closed-loop anesthetic delivery systems. Most such systems have been developed with the electroencephalogram (EEG) used as the measure of anesthetic drug effect. Schwilden developed closed-loop systems for infusion of methohexital[3,4] and propofol[5] on the basis of the median EEG frequency. Other investigators have developed closed-loop systems based on other derivatives of the EEG (e.g., auditory evoked potentials[6] or the bispectral index [BIS][7]).

The development of new techniques has coincided with the development of new drugs. Rapid intravenous induction became popular with the introduction of sodium thiopental in 1934. The pharmacokinetics of thiopental, however, prevented its becoming popular for maintenance of anesthesia. During the past 50 years, numerous intravenous hypnotics (methohexital, 1957; propanidid, 1957; althesin, 1971; etomidate, 1973; propofol, 1977), anxiolytics (diazepam, 1966; midazolam, 1978), and analgesics (fentanyl, 1959; ketamine, 1966; sufentanil, 1979; alfentanil, 1980; remifentanil, 1996; dexmedetomidine, 1999) have been introduced. The general trend in the introduction of these newer agents has been to provide drugs with further shortening of the time needed for recovery from drug effect. In this context, the newer intravenous drugs propofol and remifentanil provide a rapid onset of anesthesia, a stable maintenance phase, and rapid recovery.

Before reviewing delivery techniques and devices for intravenous anesthesia, this chapter presents pharmacokinetic and pharmacodynamic principles as background for understanding how to administer intravenous drugs to their best advantage. Specifically, intravenous anesthesia delivery systems can be used to rationally determine the dose of intravenous drugs used in clinical practice. Further discussion of the principles of pharmacokinetics and pharmacodynamics can be found in Chapter 19.

Pharmacokinetic Considerations

The goal of administering anesthetics is to produce the clinically desired time course of anesthetic effect. Usually, such a course includes a rapid onset, smooth maintenance, and rapid recovery after termination of the anesthetic. Conventional pharmacokinetic models assume that a bolus of drug is instantaneously mixed into plasma and produces an immediate peak in its plasma concentration. The concentration then declines continuously until the next bolus. Except for a transient perioperative stimulus (endotracheal intubation, surgical incision, bowel traction), the

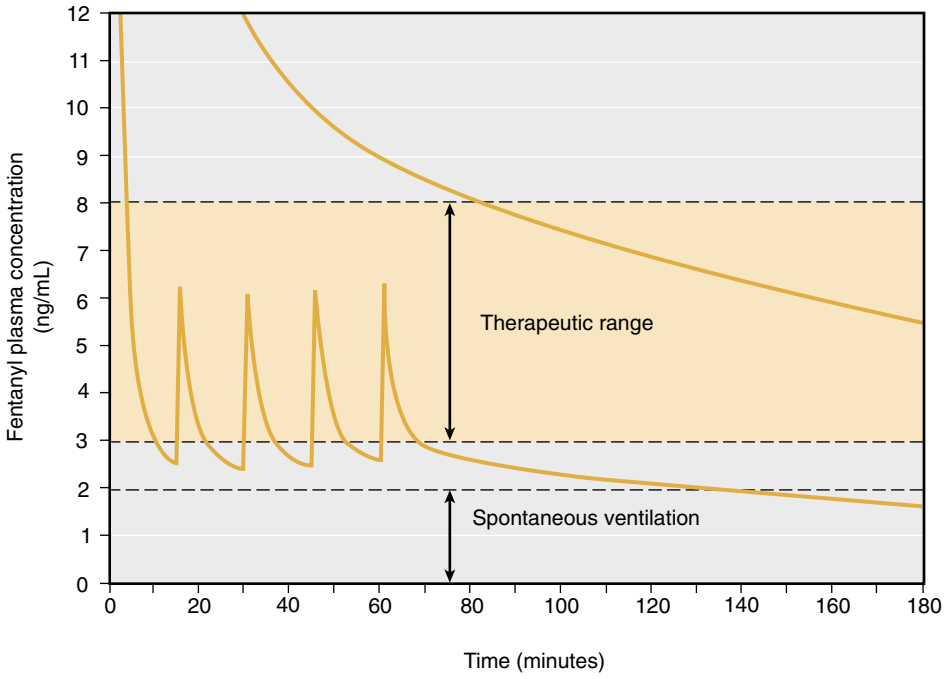

Figure 28-2 Pharmacokinetic simulation of a single large bolus of fentanyl (*upper curve*; 50 μg/kg) and a smaller fentanyl bolus (*lower curve*; 8 μg/kg) followed by intermittent boluses (1.5 μg/kg) every 15 minutes. The single large bolus results in plasma drug concentrations far in excess of those required, whereas the intermittent bolus scheme results in plasma concentrations that periodically fall below the therapeutic range. Ideally, the plasma drug concentration should be continuously within the therapeutic range, which can best be accomplished with a continuous infusion.

patient's anesthetic requirements will probably not follow the saltatory time course of anesthetic effect seen with repeated bolus injections. Thus, the technique of intermittent boluses results in excessive drug effect at the time of the bolus, inadequate drug effect before the next bolus, or both (Fig. 28-2). The technique of giving the entire anesthetic as an initial bolus produces a needlessly huge initial peak and, depending on the dose, grossly excessive or possibly subtherapeutic levels later in the procedure. This technique is well tolerated for opioids in paralyzed patients whose lungs are mechanically ventilated. However, this approach would produce considerable hypotension if attempted with propofol.

To produce a time course of drug effect that follows the time course of anesthetic requirement, a continuous infusion titrated to the perceived anesthetic requirement should be used. Ideally, just enough drug is given to achieve the therapeutic blood or plasma drug concentration, and it is then continuously titrated throughout surgery (Fig. 28-3). This method of drug delivery avoids the peaks and valleys in drug concentration seen with intermittent drug boluses. Theoretical advantages of continuous infusions over intermittent bolus injections include fewer periods of poor anesthetic control, a reduction in the total amount of drug used, and more rapid recovery from anesthesia.[8,9]

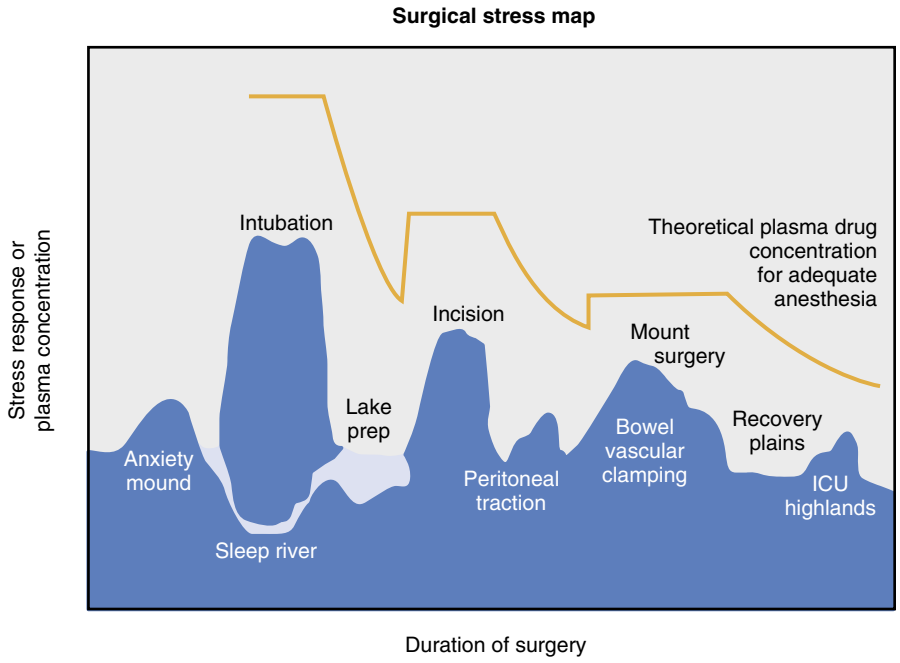

Figure 28-3 Landscape of surgical anesthesia. The stimuli of surgery are not constant; therefore, the plasma concentration of the anesthetic drug should be titrated to match the needs of the patient.

The dose of anesthetic needed to produce the desired time course of plasma concentration can be calculated from pharmacokinetic models. Pharmacokinetic models exist for every intravenous anesthetic drug, but they are of limited use without computer simulation. In this chapter we will describe how pharmacokinetic models can be used to develop rational dosing guidelines for use with intravenous infusion delivery systems. We first review some basic pharmacokinetic concepts and define the relevant terminology.

Pharmacokinetic models are mathematical descriptions of how the body "disposes" of drugs. The parameters describing this process are estimated by administering a known dose of the drug and measuring the resulting plasma concentrations. A mathematical model then relates the input over time, I(t), with the concentrations over time, C(t). These models can take many forms. Figure 28-4 shows concentrations in plasma over time after a single intravenous bolus of drug at time 0. Drug concentrations continuously decrease after the bolus, and the rate of decrease is approximately proportional to the amount of drug in plasma. Typically, it is convenient to describe this behavior with the use of exponential models. The curve might have a single exponent, in which case the plasma concentrations over time might be described by the function $C(t) = Ae^{-kt}$, where A is the concentration at time 0 and k is a constant that describes the rate of decrease

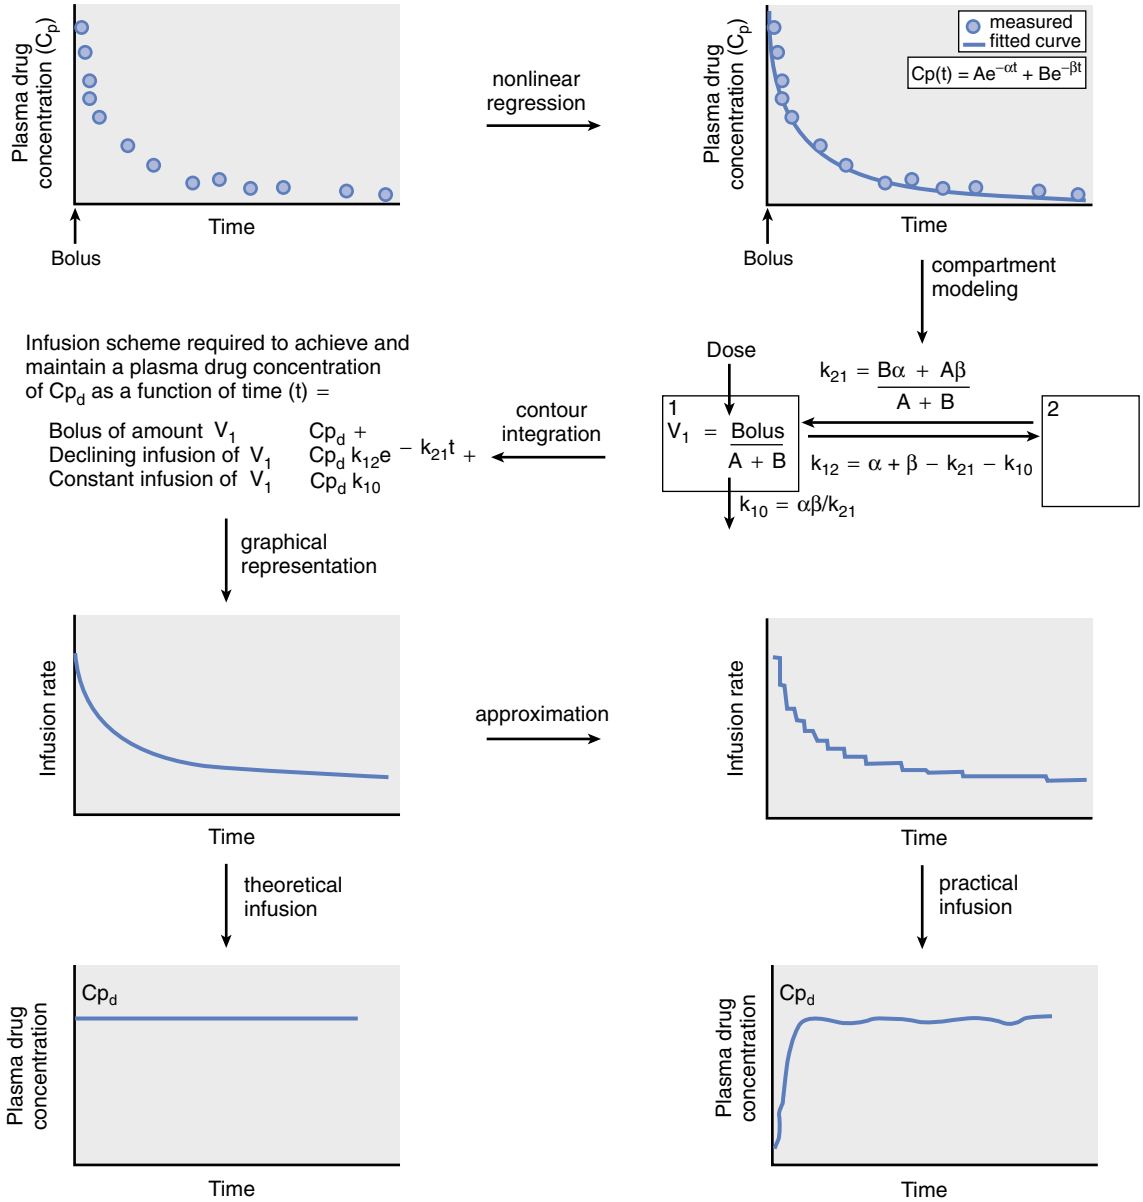

Figure 28-4 Steps involved in pharmacokinetic model–driven infusion. Typically, pharmacokinetic models are derived from experiments in which plasma drug concentrations are measured at intervals after bolus administration of the drug. Nonlinear regression is used to fit a monoexponential, biexponential, or triexponential curve to the resulting concentration-versus-time data. There is an algebraic relationship between the exponential decay curves and a one-, two-, or three-compartment pharmacokinetic model. The "BET" infusion scheme is developed and consists of a bolus, a continuous infusion to replace drug eliminated from the body, and an exponentially declining infusion to replace drug transferred out of plasma to other body compartments. BET infusion results in maintenance of a constant specified plasma drug concentration. Practical implementation of the BET scheme with real infusion pumps and infusion rates that change only at discrete intervals of time results in a plasma drug concentration profile that approximates that resulting from a BET infusion.

in concentration. The relationship appears to be a straight line when graphed as the log of concentration versus time. The pharmacokinetics of intravenous anesthetic drugs is more complex because after the bolus, a period of rapid decline is observed before the terminal "log-linear" portion (e.g., the part that is a straight line when described as log concentration versus time). It is possible to model this process by taking several monoexponential (i.e., one exponent) curves and adding them together. The result is a polyexponential curve. For example, the concentrations after an intravenous bolus might be described by an equation with two exponents, $C(t) = Ae^{-\alpha t} + Be^{-\beta t}$, or an equation with three exponents, $C(t) = Ae^{-\alpha t} + Be^{-\beta t} + Ce^{-\gamma t}$.

There are ways of administering intravenous anesthetic drugs besides single boluses. A more general way to think of pharmacokinetics is to decompose the input into a series of small bits (boluses) and consider each bit of drug separately. The general pharmacokinetic model of drug disposition commonly used in anesthesia considers each bit of drug independently and analyzes its contribution by means of polyexponential decay over time. The formal mathematical description of each bit of drug in terms of polyexponential decay over time is the relationship

$$C(t) = I(t) * \sum_{i=1}^{n} A_i e^{-\lambda_i t} \quad (1)$$

where C(t) is the plasma concentration at time t and I(t) is drug input (i.e., a bolus or infusion). The summation after the asterisk (described later) is the function describing how each bit of drug is disposed of (hence its name the "disposition" function). Note that this is again a sum of *n* exponentials, as described in the previous paragraph.

Pharmacokinetic modeling is the process of estimating the parameters within this function. The integer *n* is the number of exponentials (i.e., compartments) and is usually two or three. Each exponential term is associated with a coefficient A_i and an exponent λ_i. The λ values are inversely proportional to the half-lives (half-life = $0.693/\lambda$), with the smallest λ representing the longest (terminal) half-life. The A values are the relative contribution of each half-life to overall drug disposition. If a drug has a very long terminal half-life but a coefficient that is much smaller than the other coefficients, the long half-life is likely to be clinically meaningless. Conversely, if a drug has a very long half-life with a relatively large coefficient, the drug will be long lasting even after brief administration. The * operator is the mathematical process called "convolution," which is simply the process of breaking the infusion into "bits" of drug and then adding up the results to see the overall concentrations.

The pharmacokinetic model shown has some useful characteristics that account for its enduring popularity in pharmacokinetic analysis. Most important, the model describes observations from studies reasonably well, the sine qua non for models. Second, these models have the useful characteristic of "linearity." Simply stated, if you double the dose, I, (e.g., give a bolus twice as large or an infusion twice as fast), you double the concentrations.

More generally, linearity implies that the system (i.e., the body acting to produce a plasma drug concentration output from a drug dosage input) behaves in accordance with the principle of superposition. The superposition principle states that the response of a linear system with multiple inputs can be computed by determining the response to each individual input and then summing the individual responses. In other words, when the body treats each bit of drug by polyexponential decay over time, the "disposing" of each bit of drug does not influence the disposing of other bits of drug.

The third reason for the continuing popularity of these models is that they can be mathematically transformed from the admittedly unintuitive exponential form shown earlier to a more easily intuitive compartmental form, as shown in Figure 28-5. The fundamental parameters of the compartment model are the volumes of distribution (central, rapidly equilibrating, and slowly equilibrating peripheral volumes) and clearances (systemic, rapid, and slow intercompartmental). The central compartment (V_1) represents a distribution volume and includes the rapidly mixing portion of the blood and first-pass pulmonary uptake. The peripheral compartments are composed of tissues and organs that show a time course and extent of drug accumulation (or dissipation) different from that of the central compartment. In the three-compartment model, the two peripheral compartments may correspond roughly to splanchnic and muscle tissues (rapidly equilibrating) and fat stores (slowly equilibrating). The sum of the compartment volumes is the apparent volume of distribution at steady state (Vd_{ss}) and is the proportionality constant relating the plasma drug concentration at steady state to the total amount of drug in the body. The intercompartmental rate constants (k_{12}, k_{21}, and so on) describe the movement of drug between the central and peripheral compartments. The elimination rate constant (k_{10}) encompasses processes acting through biotransformation or elimination that irreversibly remove drug from the central compartment.

Despite their physiologic flavor, compartmental models are simply mathematical transformations of the polyexponential disposition functions computed from observed plasma concentrations. Thus, physiologic interpretation of volumes and clearances (with the possible exception of systemic clearance and Vd_{ss} [the algebraic sum of the volumes]) is entirely speculative.

The last reason that these models have been popular is that they can be used to design infusion regimens, the point of introducing them in this chapter. If we abbreviate the disposition function

$$\sum_{i=1}^{n} A_i e^{-\lambda_i t} \quad (2)$$

as simply D(t), we can rewrite the relationship among concentration, dose, and the pharmacokinetic model D(t) as

$$C(t) = I(t) * D(t) \quad (3)$$

where * is the convolution operator, as noted earlier. In the usual pharmacokinetic study we know I(t), the dose that we gave the patient, and we measure C(t), the concentrations over time. Our goal is to find D(t), the pharmacokinetic disposition function. Pharmacokinetic analysis can be thought of as a simple rearrangement of Equation 3 to solve for D(t):

$$D(t) = \frac{C(t)}{I(t)} \quad (4)$$

where the symbol $\frac{}{\times}$ means deconvolution, the inverse operation of convolution. Deconvolution is like division, but of functions rather than simple numbers. When we design dosing regimens from known pharmacokinetic models and a desired course for the plasma concentration over time, the known values

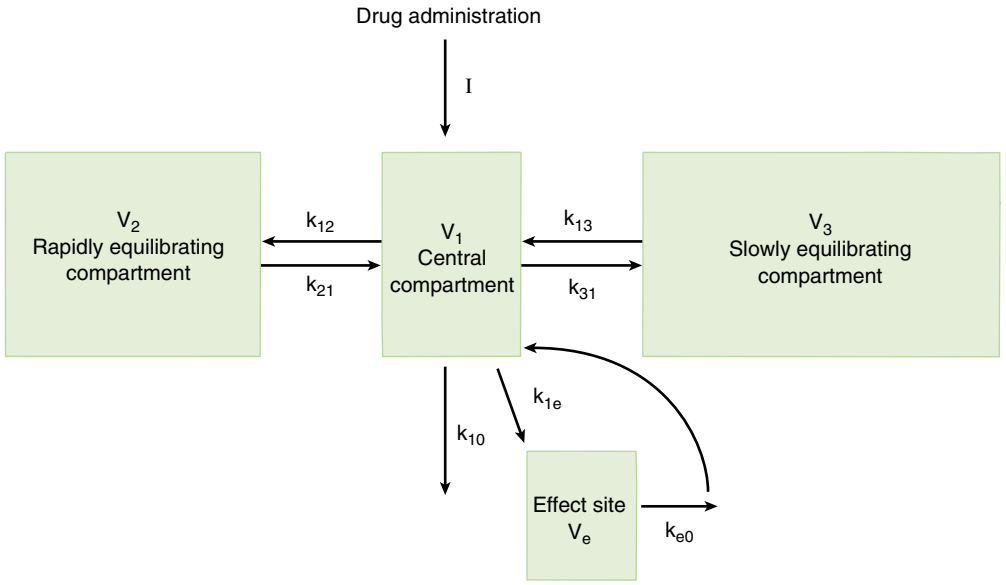

Figure 28-5 Three-compartment model (including the biophase) schematizing the basic pharmacokinetic processes that occur after intravenous drug administration. I, dosing scheme as a function of time; k_{10}, rate constant reflecting all processes acting to irreversibly remove drug from the central compartment; k_{ij}, intercompartmental rate constants; V_1, central compartment volume, usually expressed in liters or liters per kilogram.

are D(t) (the pharmacokinetics) and $C_T(t)$ (the desired target concentrations), and the drug dosing scheme is:

$$I(t) = C_T(t) \otimes D(t) \quad (5)$$

Thus, one can calculate the necessary infusion rates, I(t), given desired target concentrations, $C_T(t)$, and the pharmacokinetics, D(t), by applying the same tools used to calculate the original pharmacokinetics. Unfortunately, such a solution might require some negative infusion rates, which are obviously impossible. Because we cannot suck drug out of the body (i.e., give negative infusions), we must restrict ourselves to plasma concentrations over time that can be achieved with non-negative infusion rates.

The standard pharmacokinetic model has one glaring shortcoming. It assumes that after a bolus injection there is complete mixing within the central compartment such that the peak concentration occurs precisely at time 0. It actually takes about 30 to 45 seconds for the drug to make its transit from the venous injection site to the arterial circulation. This model misspecification over the first minute or so may not seem significant, but it can cause problems in attempts to relate the drug effect after a bolus to drug concentrations in the body.[10] Researchers are modifying the standard polyexponential pharmacokinetic models to provide more accurate models of plasma drug concentration in the first minute after bolus injection.[11]

Pharmacodynamic Considerations

The Biophase

Although the plasma concentration after an intravenous bolus peaks nearly instantaneously, no anesthesiologist would push an intravenous bolus of hypnotic and immediately intubate the patient's trachea. The reason, of course, is that although the plasma concentration peaks almost instantly, additional time is required for the drug concentration in the brain to rise sufficiently to induce unconsciousness. This delay between peak plasma concentration and peak concentration at the effect site is called *hysteresis*. Hysteresis is the clinical manifestation of the fact that plasma is not the site of anesthetic action, only the mechanism of transport. Drugs exert their pharmacologic effect in the *biophase*, which is also called the "effect site." Physically, the biophase is the immediate milieu in which the drug acts on the body, including membranes, receptors, and enzymes.

The concentration of drug in the biophase cannot be measured for two reasons. First, it is usually inaccessible, at least in human subjects. Second, even if we could take tissue samples, the drug concentration in the microscopic environment of the receptive molecules would not be the same as the concentration measured in, for example, homogenated brain. Although it is not possible to actually measure drug concentration in the biophase, we can characterize the time course of drug effect by using rapid measures of drug effect. Knowing the time course of drug effect, we can characterize the rate of drug flow in and out of the biophase (or "effect site") with the use of mathematical models,[12,13] as well as the apparent drug concentration in the biophase in terms of the steady-state plasma concentration that would produce the same effect.

Measures of effect used to characterize the time course of drug between plasma and the biophase will vary with the drug being evaluated. For neuromuscular blockers, the twitch response is an ideal measure of effect. For opioids and hypnotics, the measure of effect is more challenging. The desired effect for opioids is analgesia, which is a subjective measure that is difficult to monitor and quantify moment by moment. Similarly for hypnotics, until recently there has been no validated monitor of drug effect. For these reasons investigators have turned to the EEG as an objective measure of opioid and hypnotic drug effect. Even if the EEG did not measure the clinically desired effect of opioids

and hypnotics, it was assumed that changes in the EEG would at least reflect the time course of clinical effects. Thus, the time course for opioids and hypnotics to equilibrate between plasma and the biophase has largely been defined from the EEG. The validity of this approach has been confirmed by several studies. Glass and colleagues measured the blood concentration of remifentanil and its analgesic response in volunteers.[14] The time course for equilibration between plasma and the biophase calculated in this study was essentially identical to the time course determined by using the spectral edge of the EEG as the measure of effect.[15] Ludbrook and associates measured propofol concentrations in the carotid artery and jugular bulb to establish movement of propofol into and equilibration with the brain.[16] They measured the BIS simultaneously and found close correlation between brain concentration (calculated by mass balance) and changes in the BIS.

Direct-Effect Models

Just as shown for plasma pharmacokinetics earlier, the biophase concentration is the convolution of an input function (in this case, the plasma drug concentration over time) and the disposition function of the biophase. This relationship can be expressed as

$$C_{biophase}(t) = C_{plasma}(t) * D_{biophase}(t) \quad (6)$$

The disposition function of the biophase is typically modeled as a single exponential decay:

$$D_{biophase}(t) = k_{e0} e^{-k_{e0}t} \quad (7)$$

The monoexponential disposition function implies that the effect site is simply an additional compartment in the standard compartmental model that is connected to the plasma compartment (see Fig. 28-5). The effect site is the hypothetical compartment that relates the time course of plasma drug concentration to the time course of drug effect, and k_{e0} is the rate constant of elimination of drug from the effect site. By definition, the effect compartment receives such small amounts of drug from the central compartment that it has no influence on plasma pharmacokinetics.

We cannot directly measure either $C_{biophase}(t)$ or $D_{biophase}(t)$, but we can measure drug effect. Knowing that the observed drug effect is a function of the drug concentration in the biophase, we can predict the drug effect as

$$\text{Effect} = f_{PD}\left[C_{plasma}(t) * D_{biophase}(t), P_{PD}, k_{e0}\right] \quad (8)$$

where f_{PD} is a pharmacodynamic model (typically sigmoidal in shape), P_{PD} represents the parameters of the pharmacodynamic model, and k_{e0} is the rate constant for equilibration between plasma and the biophase. Nonlinear regression programs are used to find values of P_{PD} and k_{e0} that best predict the time course of drug effect. Knowledge of these parameters can then be incorporated into dosing regimens that produce the desired time course of drug effect.[17,18]

If a constant plasma concentration is maintained, the time required for the biophase concentration to reach 50% of the plasma concentration ($t_{½}\ k_{e0}$) can be calculated as $0.693/k_{e0}$. After a bolus dose, the time to peak biophase concentration is a function of both plasma pharmacokinetics and k_{e0}. For drugs with a very rapid decline in plasma concentration after a bolus (e.g., adenosine, which has a half-life of several seconds), the effect-site concentration peaks within several seconds of the bolus, regardless of k_{e0}. For drugs with a rapid k_{e0} and a slow decrease in concentration after a bolus injection (e.g., pancuronium), the peak effect-site concentration is determined more by k_{e0} than by plasma pharmacokinetics. The time to peak effect and the $t_{½}\ k_{e0}$ for several intravenous anesthetics are listed in Table 28-1.

Table 28-1 Time to Peak Effect and $t_{½}\ k_{e0}$ after a Bolus Dose

Drug	Time to Peak Drug Effect (min)	$t_{½}\ k_{e0}$ (min)
Fentanyl	3.6	4.7
Alfentanil	1.4	0.9
Sufentanil	5.6	3.0
Remifentanil	1.6	1.3
Propofol	2.2	2.4
Thiopental	1.6	1.5
Midazolam	2.8	4.0
Etomidate	2.0	1.5

$t_{½}\ k_{e0} = 0.693/k_{e0}$, the rate constant for transfer of drug from the site of drug effect to the environment.

Indirect-Effect Models

Thus far, effects that are an instantaneous function of drug concentration at the site of drug effect have been discussed, as implied by Equation 8. For example, once hypnotics reach the brain or muscle relaxants reach the muscles, drug action is seen almost instantaneously. On the other hand, some effects are much more complex. For example, consider the effect of opioids on ventilation. Initially, opioids depress ventilation, and as a result of this ventilatory depression, CO_2 starts to accumulate. Accumulation of CO_2 acts to stimulate ventilation, thereby partly counteracting the ventilatory depressant effects of opioids. Ventilatory depression is an example in which there is a direct and indirect drug effect. The direct effect of the opioid is to depress ventilation, and the indirect effect is to increase CO_2. Modeling the time course of opioid-induced ventilatory depression requires consideration of both components. Bouillon and colleagues have developed a model of ventilatory depression that incorporates both direct and indirect effects.[19,20] As is generally the case with indirect-effect models, characterizing drug-induced ventilatory depression requires considering the entire time course of drug therapy, which is embodied by the following differential equation:

$$\frac{d}{dt}Pa_{CO_2} = k_{el} \cdot Pa_{CO_2}(0) - k_{el} \cdot \left[1 - \frac{Cp(t)\gamma}{C_{50}\gamma + Cp(t)\gamma}\right] \cdot \left[\frac{P_{biophase}CO_2(t)}{P_{biophase}CO_2(0)}\right]^F \cdot Pa_{CO_2}(t) \quad (9)$$

where Pa_{CO_2} is arterial CO_2, $P_{biophase}CO_2$ is CO_2 in the biophase (i.e., ventilation control centers), k_{el} is the rate constant for elimination of CO_2, C_{50} is the effect-site opioid concentration associated with a 50% reduction in ventilatory drive, and F is the steepness or "gain" of the effect of CO_2 on ventilatory drive.

Dose Implications of the Biophase

The delay in onset has important clinical implications. After a bolus, the plasma concentration peaks nearly instantly and then declines steadily. The effect-site concentration starts at zero and increases over time until it equals the descending plasma concentration. The plasma concentration continues to decline, and after the moment of identical concentrations, the gradient between plasma and the effect site favors removal of drug from the effect site, and the effect-site concentration decreases. The rate at which the effect site rises toward the peak after a bolus dictates how much drug must be injected into plasma to produce a given effect. For alfentanil, its rapid plasma effect-site equilibration (large k_{e0}) causes the effect-site concentration to rise rapidly, with a peak produced in about 90 seconds. At the time of the peak, about 60% of the alfentanil bolus has been distributed into peripheral tissues or eliminated from the body. For fentanyl, the effect site concentration rises much more slowly and peaks 3 to 4 minutes after the bolus.[21] At the time of the peak, more than 80% of the initial bolus of fentanyl has been distributed into tissues or eliminated. As a result of slower equilibration with the effect site, relatively more fentanyl than alfentanil must be injected into plasma, which makes the rate of offset of drug effect after a fentanyl bolus slower than after an alfentanil bolus.

This difference in pharmacokinetics suggests that k_{e0} must be incorporated into dosing strategies. For rapid onset of effect, a drug with a large k_{e0} (short $t_{1/2}$ k_{e0}) should be chosen. For example, for rapid-sequence induction, alfentanil or remifentanil may be the opioid of choice because the peak opioid effect-site concentration coincides with endotracheal intubation. However, for a slower induction in which a nondepolarizing neuromuscular blocking drug is used, it may be appropriate to choose an opioid with a slower onset of drug effect to coincide with the peak effect of the muscle relaxant. In this case, a bolus of fentanyl or sufentanil at the time of induction may be more appropriate. The time to peak effect for the commonly used opioids is shown in Figure 28-6. Knowing k_{e0} (or time to peak effect) also improves titration of the drug by identifying the time at which the clinician should make an assessment of drug effect. For example, midazolam has a slow time to peak effect, and repeat bolus doses should be spaced at least 3 to 5 minutes apart to avoid inadvertent overdosing.

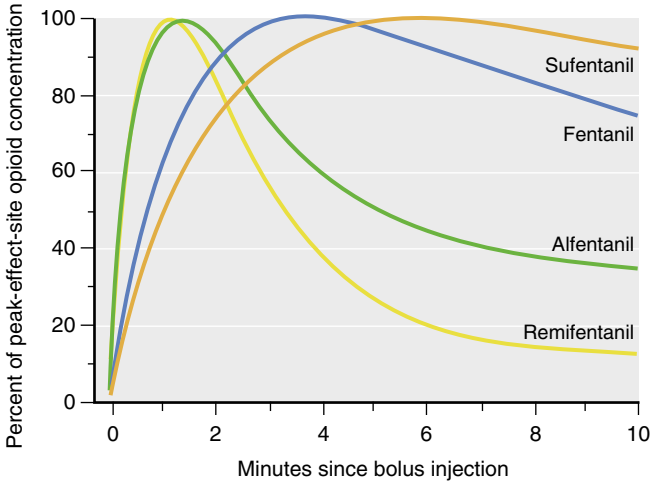

Figure 28-6 Simulated onset and time to peak effect of commonly used opioids based on their k_{e0} and pharmacokinetic parameters. k_{e0}, rate constant for transfer of drug from the site of drug effect to the environment.

Drug Potency

Having established that we can produce almost any desired concentration time course at the effect site, what concentration should we choose? The pharmacokinetics and pharmacodynamics of inhaled anesthetics are greatly simplified by the equilibrium established at the alveolar gas-blood interface, which permits measurement of the minimum alveolar concentration (MAC) associated with a 50% likelihood of movement in response to noxious stimulation.[22] Considerable effort has gone into developing a concept equivalent to MAC for intravenous anesthetic drugs.

The pharmacodynamics of intravenous anesthetics is reported in terms of C_{50}, the concentration that produces 50% of the maximum possible drug effect. There are many ways of thinking about C_{50}. It might be the drug concentration that prevents response (e.g., movement, hypertension, release of catecholamines) to a particular stimulus (e.g., incision, intubation, sternal spreading) in 50% of patients. In this case, each combination of stimulus and response may have a unique C_{50}. For example, Ausems and colleagues defined the C_{50} for alfentanil in the presence of 66% nitrous oxide for several noxious stimuli.[23] When C_{50} is defined as the drug concentration that produces a given response in 50% of patients, it is also the concentration associated with a 50% probability of response in a given patient. Note that defining C_{50} as the concentration that produces a given effect in 50% of individuals implicitly assumes that the effect can be achieved in all individuals. Some drugs exhibit a ceiling effect. For example, there appears to be a ceiling on the ability of opioids to suppress response to noxious stimulation. When a ceiling in drug effect exists, some patients may not exhibit the drug effect even at infinitely high doses. In this case, C_{50} is not the concentration that causes the drug effect in 50% of patients but is the concentration associated with the drug effect in half of whatever fraction of patients are able to respond.

Several studies have been performed to establish appropriate concentrations of intravenous anesthetics. C_{50} values for alfentanil, fentanyl, and remifentanil in the presence of 70% nitrous oxide have been defined for skin incision (Table 28-2). C_{50} values for loss of consciousness and skin incision have also been defined for the hypnotics thiopental,[24,25] propofol,[26-28] and midazolam (see Table 28-2).[29] Defining the C_{50}, like MAC, provides a measure of relative potency between intravenous anesthetics.

Another interpretation of C_{50} is the concentration that produces 50% of the maximum possible physiologic response. For example, the C_{50} for an EEG response is the drug concentration that provides 50% of the maximal EEG effect. The C_{50} for EEG response has been measured for the opioids alfentanil,[30] fentanyl,[30] sufentanil,[31] and remifentanil.[32-34] It has also been determined for thiopental,[24,35,36] etomidate,[37] propofol,[38] and benzodiazepines (see Table 28-2).[39]

Although C_{50} values for all combinations of stimuli and measures have not been determined experimentally for each opioid, they can be estimated accurately by scaling the values of C_{50} determined experimentally for other opioids according to their relative potency.[40] For example, the C_{50} of alfentanil for

Table 28-2 Steady-State Concentrations for Predefined Effects*

Drug	C_{50} for EEG Depression†	C_{50} for Incision or Painful Stimulus‡	C_{50} for Loss of Consciousness§	C_{50} for Spontaneous Ventilation¶	C_{50} for Isoflurane MAC Reduction	MEAC
Propofol (μg/mL)	3-4	4-8	2-3	1.33	Not studied	—
Thiopental (μg/mL)	15-20	35-40	8-16	—	—	—
Midazolam (ng/mL)	250-350	—	125-250	—	—	—
Alfentanil (ng/mL)	500-600	200-300	—	170-230	50	10-30
Fentanyl (ng/mL)	6-10	4-6	—	2-3	1.7	0.5-1
Sufentanil (ng/mL)	0.5-0.75	(0.3-0.4)	—	(0.15-0.2)	0.15	0.025-0.05
Remifentanil (ng/mL)	10-15	4-6	—	2-3	1.2	0.5-1

*Values in parentheses are estimated by scaling to the alfentanil C_{50} (see text for details).
†The C_{50} for depression of the electroencephalogram (EEG) is the steady-state serum concentration that causes a 50% slowing of the maximal EEG, except for midazolam, where the C_{50} is associated with 50% activation of the EEG.
‡The C_{50} for skin incision is the steady-state plasma concentration that prevents a somatic or autonomic response in 50% of patients.
§The C_{50} for loss of consciousness is the steady-state plasma concentration for absence of a response to a verbal command in 50% of patients.
¶The C_{50} for spontaneous ventilation is the steady-state plasma concentration associated with adequate spontaneous ventilation in 50% of patients.
MEAC, minimum effective plasma concentration providing postoperative analgesia.

spontaneous ventilation is about 40% of the C_{50} for EEG response (see Table 28-2). Knowing this, we can estimate the C_{50} of sufentanil for spontaneous ventilation (which has not yet been determined experimentally) as 0.2 to 0.3 ng/mL, that is, 40% of the C_{50} for EEG response (0.7 ng/mL).

To be entirely independent of dosing history, C_{50} must be determined at steady state, which is rarely possible because most anesthetic drugs do not reach steady state during a continuous infusion until many hours have passed. However, if the drug exhibits rapid equilibration between plasma and the effect site and the investigator waits long enough after starting the infusion, this choice can be reasonably satisfactory. For example, in their experiments Ausems and colleagues[23,41] used a continuous infusion of alfentanil, which equilibrated quickly. They also took their measurements after the effect-site concentration had equilibrated with plasma.

A second alternative to performing a true steady-state experiment is to use mathematical modeling to calculate the effect-site concentrations of drug at the time of measurement, as proposed by Hull and colleagues[12] and Sheiner and colleagues.[13] The relationship between effect-site and plasma concentrations is represented graphically in Figure 28-5 and mathematically in Equation 6. Calculating effect-site concentrations is the same as attempting to determine the steady-state plasma concentrations that would produce the observed drug effect. When the C_{50} reflects effect-site concentrations, it is represented as Ce_{50} to distinguish it from values of C_{50} that are based on plasma concentrations, which are then termed Cp_{50}. However, the distinction is artificial. In both cases, C_{50} is intended to represent the steady-state plasma drug concentration associated with a given drug effect.

A third alternative to performing a steady-state experiment is to establish a pseudo–steady state with the use of computer-controlled drug delivery. This has become the state-of-the-art method for determining the C_{50} for anesthetic drugs, and many of the C_{50} values referenced earlier were determined at pseudo–steady state with the use of computer-controlled drug delivery. Typically, maintaining a constant plasma steady-state concentration for four to five plasma effect-site equilibration half-lives (e.g., 10 to 15 minutes for fentanyl) is required. Such a long delay is not necessarily needed when computer-controlled drug delivery is used. For example, computer-controlled infusions can be used to target initially higher plasma target concentrations to provide more rapid achievement of the desired effect-site concentration.[42] This can be automated by having the computer actually target the concentration at the effect-site rather than plasma and thereby rapidly establish plasma–effect site equilibration.[17,18]

Thus, there are several ways to establish C_{50} in terms of steady-state concentrations. C_{50} can be estimated through mathematical effect-site modeling or can be measured experimentally with the use of computer-controlled drug delivery to quickly establish a pseudo–steady state. Either way, when performing studies to define the concentration-effect relationship, equilibrium must exist or be modeled for between the biophase (the site of effect) and plasma or blood (where the concentration is actually measured).

When C_{50} is defined in terms of the concentration associated with a response in half of a population, that same C_{50} is the concentration associated with a 50% probability of response in a typical individual. However, individual patients are not typical individuals but instead will have their own value for C_{50}. Expressed in clinical terms, different patients have different anesthetic requirements for the same stimulus. For example, the minimal effective analgesic concentration of fentanyl is 0.6 ng/mL, but it varies among patients from 0.2 to 2.0 ng/mL.[43] The minimal effective analgesic concentrations of alfentanil[44,45] and sufentanil[46] similarly vary among patients by a factor of 5 to 10. This range encompasses both variability in the intensity of the stimulus and variability of the individual patient. However, this wide range reflects the clinical reality that must be accounted for when dosing regimens are designed. Because of this variability, intravenous anesthetics should be titrated to each patient's unique anesthetic requirement for the given stimulus.

Pharmacodynamic Drug Interactions

Drug interactions cause the C_{50} of one drug to shift in response to administration of a second drug. We have already referred to

the ability of opioids to reduce MAC, a clinically useful drug interaction with a long history. In 1901, George Crile suggested that opioids be administered with supplemental drugs for intravenous anesthesia. In 1959, DeCastro and Mundeleer introduced the term "neurolept anesthesia," which consists of a tranquilizer, opioid, and nitrous oxide. Today, the term coined by John Lundy, "balanced anesthesia," is used to describe the concurrent administration of several anesthetic drugs so that no single drug is given in a dosage sufficient to produce toxicity during or after surgery. The interaction of hypnotics and opioids in producing the anesthetic state is complex but predictable.

The MAC of volatile anesthetics appears to be additive when several inhaled anesthetics are administered concurrently.[47,48] The additivity of MAC suggests a uniform mechanism of action for the inhaled anesthetics, although the "unitary theory" of inhalational anesthesia has fallen into disfavor.[49,50] The intravenous anesthetics encompass categories of drugs (hypnotics, opioids, psychotomimetics, anxiolytics, neuroleptics, local anesthetics, and so on) with different receptors and mechanisms of action. In the absence of a uniform mechanism of action, there is no reason to anticipate simple additivity, for example, that maintaining 30% C_{50} of drug A plus 40% C_{50} of drug B will produce the same effect as 70% C_{50} of either drug A or drug B.

The assumption of balanced anesthesia is that drug combinations will be synergistic in anesthetic effect (however defined) but not in toxicity. Such synergism has been demonstrated for a variety of drug combinations but not for others.[51,52] For example, Smith and coworkers[28] found minimal synergy between propofol and fentanyl for the end point loss of consciousness, but profound synergy between propofol and fentanyl for the end point loss of response to skin incision (Fig. 28-7). More profound synergy for such end points related to analgesia and hypnosis has also been demonstrated for the interaction between propofol and alfentanil[27] and for that between sevoflurane and fentanyl.[53] Thus, when anesthetic regimens are designed that rely on synergy to produce the anesthetic state, it is important to distinguish the desired end point—loss of consciousness or ablation of response to noxious stimulation. Different combinations of drugs may be required to achieve each end point.

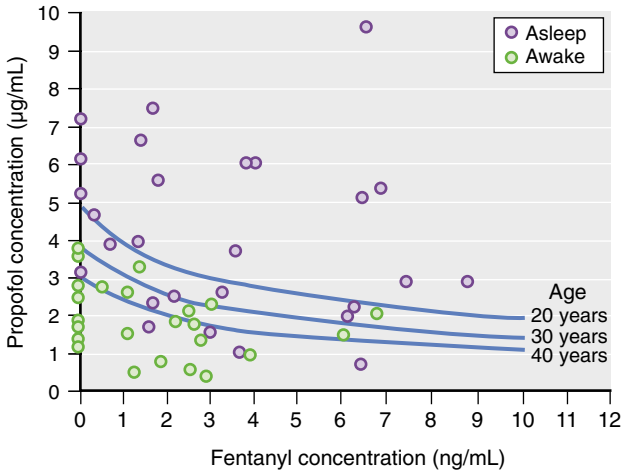

Figure 28-7 Interaction of propofol and fentanyl in preventing a somatic response at skin incision. The *solid line* represents the concentrations of propofol and fentanyl when administered together that are required to prevent purposeful movement in 50% of patients at skin incision. The *dashed line* represents the concentration of propofol and fentanyl when administered together that is required to prevent purposeful movement in 95% of patients at skin incision. *(From Smith C, McEwan AI, Jhaveri R, et al: Reduction of propofol Cp_{50} by fentanyl. Anesthesiology 77:A340, 1992.)*

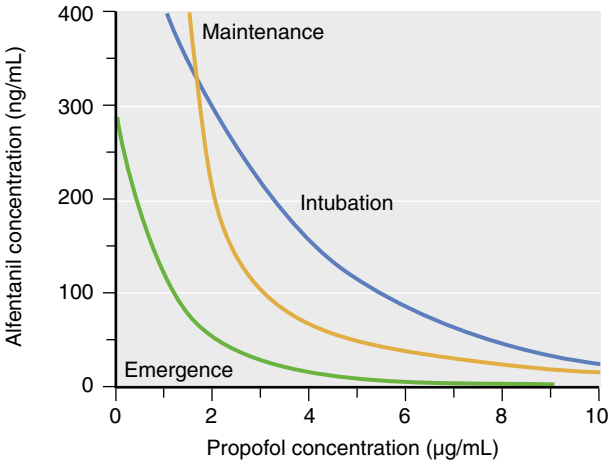

Figure 28-8 Interaction between alfentanil and propofol on three different end points: response to intubation (*blue line*), maintenance of anesthesia (*orange line*), and concentrations associated with emergence from anesthesia (*green line*). The curve shows the concentrations associated with a 50% probability of the respective end point. *(Adapted from Vuyk J, Lim T, Engbers FH, et al: The pharmacodynamic interaction of propofol and alfentanil during lower abdominal surgery in women. Anesthesiology 83:8-22, 1995.)*

Vuyk and colleagues characterized the interaction between propofol and alfentanil for several end points: loss of response to intubation, loss of response to intraoperative stimulation, and emergence from anesthesia (Fig. 28-8).[27] The most profound stimulation was tracheal intubation, and abolition of that stimulus required a propofol concentration of at least 2 µg/mL.

MAC is defined as the steady-state alveolar concentration of anesthetic gas that inhibits movement upon incision in 50% of patients. It is a well-established measure of potency. MAC is also a useful guideline for clinical dosage, provided that the clinician remembers that it is the concentration in 50% of patients that inhibits a movement response and that it is defined in terms of an analgesic end point—loss of movement in response to noxious stimulation. To establish the interaction between volatile anesthetics and opioids, the reduction in MAC can be used. When such studies are performed, it is important that both the volatile anesthetic and the opioid be maintained at stable concentrations and have equilibrated with their effect site. For the volatile anesthetic, this is readily achieved with use of a calibrated vaporizer. For the opioid, target-controlled delivery devices described in this chapter are used to maintain constant opioid concentrations within the effect compartment.

Reduction of the MAC of isoflurane by fentanyl,[54] sufentanil,[55] alfentanil,[56] and remifentanil[57] (see also Chapter 27) has been defined for all. The concentrations of these opioids that provide a 50% reduction in MAC are listed in Table 28-2. McEwan and associates[54] demonstrated that the MAC of isoflurane is reduced by 50% at a fentanyl concentration of 1.7 ng/mL (Fig. 28-9). This corresponds with a fentanyl loading dose of 4 µg/kg followed by a 1.75-µg/kg/hr infusion. The minimum effective analgesic concentration of fentanyl is 0.6 ng/mL,[43] and clinically significant respiratory depression may occur with plasma fentanyl concentrations above 2 ng/mL.[58] The steepest reduction in MAC

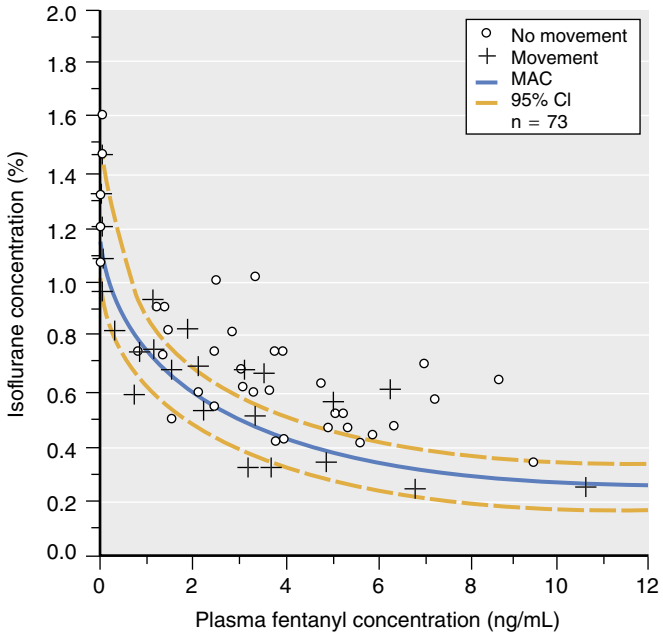

Figure 28-9 Interaction of isoflurane and fentanyl in preventing a somatic response at skin incision (i.e., minimum alveolar concentration [MAC] reduction of isoflurane). The *blue line* represents the concentrations of isoflurane and fentanyl when administered together that are required to prevent purposeful movement in 50% of patients at skin incision. The *yellow lines* represent the 95% confidence interval of the MAC at each combination of fentanyl and isoflurane. *(From McEwan AI, Smith C, Dyar O, et al: Isoflurane MAC reduction by fentanyl. Anesthesiology 78:864-869, 1993.)*

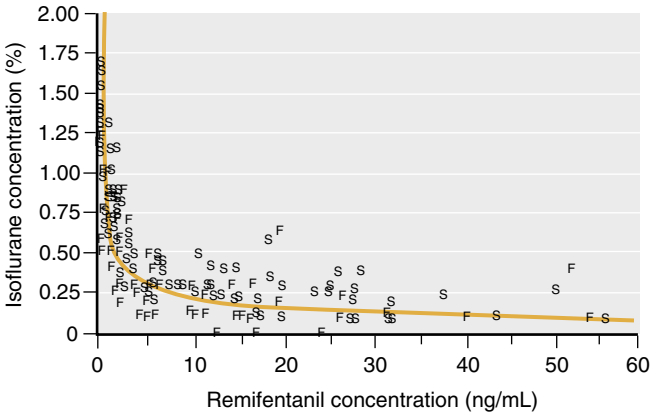

Figure 28-10 Interaction of isoflurane and remifentanil in preventing a somatic response at skin incision (i.e., minimum alveolar concentration [MAC] reduction of isoflurane). The *solid line* represents the concentrations of isoflurane and remifentanil when administered together that are required to prevent purposeful movement in 50% of patients at skin incision. *(From Lang E, Kapila A, Shlugman D, et al: Reduction of isoflurane minimal alveolar concentration by remifentanil. Anesthesiology 85:721-728, 1996.)*

thus occurs within the useful analgesic range for fentanyl (i.e., 0.6 to 2 ng/mL). In other words, by maintaining fentanyl within an analgesic range, the MAC of isoflurane can be reduced by 50%. The study by McEwan and colleagues also demonstrated that beyond a fentanyl plasma concentration of 5 ng/mL, a plateau is seen with a maximum MAC reduction of approximately 80%. The maximum reduction in isoflurane was to a concentration of ±0.3%, that is, a value close to the MAC-awake value for isoflurane.[59]

Alfentanil,[56] sufentanil,[55] and remifentanil[57] produce similar reductions in isoflurane MAC, with an initial steep reduction at lower concentrations and a ceiling effect at higher concentrations. Because remifentanil is metabolized rapidly,[15] it is possible to give huge doses during MAC studies and still awaken patients after surgery. The reduction in isoflurane MAC by remifentanil is shown in Figure 28-10.[57] Even with very high plasma concentrations (>30 ng/mL), a ceiling of opioid effect is observed, and the MAC of isoflurane is not reduced below 0.2% to 0.3%. Similar results have been demonstrated with the other volatile anesthetics and opioids. Thus, there is little clinical benefit in administering opioid at concentrations exceeding those that produce a ceiling in MAC reduction. This occurs at a concentration of 3 to 5 ng/mL for fentanyl and remifentanil, 200 to 400 ng/mL for alfentanil, and 0.25 to 0.5 ng/mL for sufentanil. Keeping the opioid dose within an analgesic range prevents the very slow recovery that is associated with high opioid concentrations.

The relationship between opioids and hypnotics on the C_{50}, the concentration of drug associated with 50% of maximum effect, has been examined. The interaction between two drugs describes a surface in which each drug has its own axis and the third axis is the effect from any combination of the two drugs. Figure 28-11 shows the relationship between the three-dimensional response surfaces and the more commonly shown relationship in two dimensions between the C_{50} of two drugs. Minto and colleagues published "response surfaces" for combinations of midazolam-alfentanil, propofol-alfentanil, and midazolam-propofol associ-

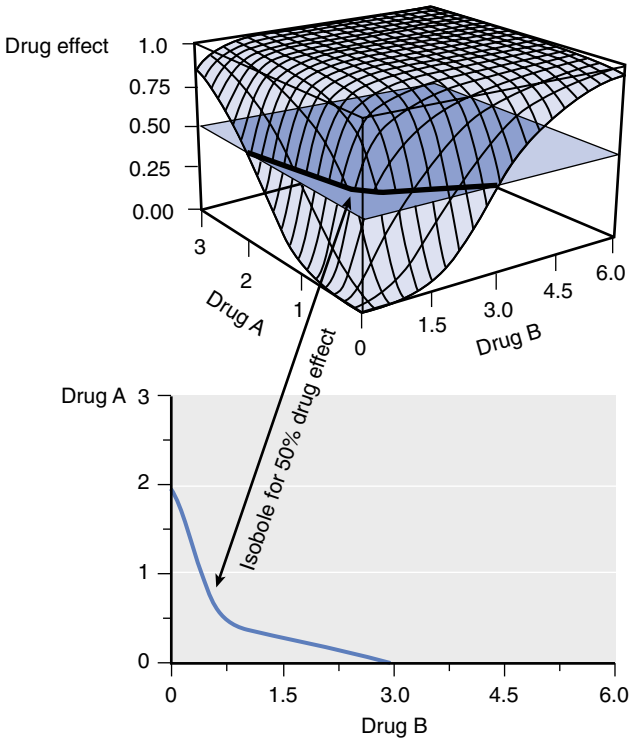

Figure 28-11 Relationship between a response surface and a standard isobologram. Conventional "isobolographic" analysis, whether for doses or concentrations, describes only the concentration of both drugs that yields a 50% drug effect and thus fails to capture the entire response surface. *(From Minto CF, Schnider TW, Short TG, et al: Response surface model for anesthetic drug interactions. Anesthesiology 92:1603-1616, 2000.)*

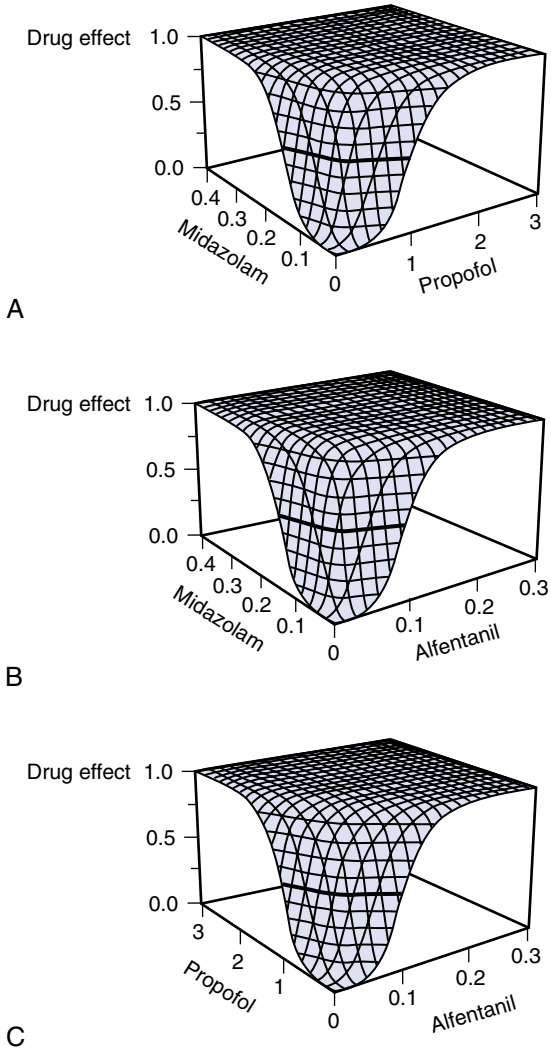

Figure 28-12 Response surface for each of the paired interactions between propofol and midazolam (**A**), alfentanil and midazolam (**B**), and alfentanil and propofol (**C**) on the probability of opening eyes to verbal command. The isoboles for a 10%, 20%, 30%, 40%, 50%, 60%, 70%, 80%, and 90% response are shown. *(From Minto CF, Schnider TW, Short TG, et al: Response surface model for anesthetic drug interactions. Anesthesiology 92:1603-1616, 2000.)*

ated with loss of response to verbal command, as shown in Figure 28-12.[60] They also extended response surface methodology to describe the simultaneous interaction of three drugs. Rendering the full interaction surface for three drugs would require drawing the graph in four dimensions. If the graph is limited to the interaction at 50% drug effect, it can be rendered in three dimensions, as shown in Figure 28-13.

Sensitivity varies from patient to patient, as well as in the level of stimulation associated with different surgical procedures. Thus, each patient is a challenge, with the clinician learning the individual patient's C_{50} for the combination of drugs used during the administration of each anesthetic. Despite this variability, dosing guidelines play an important role in the practice of anesthesia. The concentration ranges of intravenous anesthetics for anesthesia, sedation, and analgesia are given in Table 28-3. These ranges provide starting estimates on which subsequent titration can be based. They also provide a means of estimating whether the patient is having a typical or an atypical response. If the patient's dosing requirements deviate greatly from established guidelines, it is reasonable to determine whether something else might be affecting either the patient or the drug delivery system.

Designing Dosing Regimens

Bolus Dose Calculations

The definition of concentration is amount divided by volume. We can rearrange the definition of concentration to find the amount of drug required to produce any desired concentration for a known volume:

$$\text{Amount} = C_T \cdot \text{Volume} \tag{10}$$

where C_T is the desired or "target" concentration. Many introductory pharmacokinetic texts suggest using this formula to calculate the loading bolus required to achieve a given concentration. The problem with applying this concept to anesthetic drugs is that there are several volumes: V_1 (central compartment), V_2 and V_3 (the peripheral compartments), and Vd_{ss}, the sum of the individual volumes. V_1 is usually much smaller than Vd_{ss}, and thus it is tempting to say that the loading dose should be something between $C_T \times V_1$ and $C_T \times Vd_{ss}$.

Consider the dose of fentanyl required to attenuate the hemodynamic response to intubation when combined with thiopental. The C_{50} for fentanyl, combined with thiopental for intubation, is approximately 3 ng/mL. The V_1 and Vd_{ss} for fentanyl are 13 and 360 L, respectively. The aforementioned equations can thus be interpreted as suggesting that an appropriate dose of fentanyl to attenuate the hemodynamic response is between 39 µg (3 ng/mL × 13 L) and 1080 µg (3 ng/mL × 360 L). A fentanyl bolus of 39 µg achieves the desired concentration in plasma for an initial instant, but plasma levels almost instantly decrease

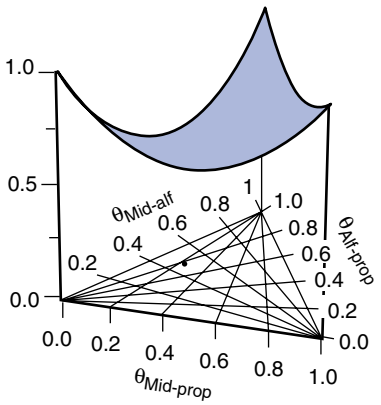

Figure 28-13 Interaction at 50% drug effect between propofol, midazolam, and alfentanil. Downward deflection of the surface represents synergy, in units of fractional reduction in C_{50}. The three edges represent relative amounts of propofol to midazolam ($\theta_{Mid\text{-}prop}$), alfentanil to midazolam ($\theta_{Mid\text{-}alf}$), and alfentanil to propofol ($\theta_{Alf\text{-}prop}$). The surface between the edges represents the relative synergy of all three drugs taken together. *(From Minto CF, Schnider TW, Short TG, et al: Response surface model for anesthetic drug interactions. Anesthesiology 92:1603-1616, 2000.)*

Table 28-3 Plasma Drug Concentration Ranges

Drug*	Stimulus			Spontaneous Ventilation	Awakening	Analgesia or Sedation
	Skin Incision	Major Surgery	Minor Surgery			
Alfentanil (ng/mL)	200-300	250-450	100-300	<200-250	—	50-100
Fentanyl (ng/mL)	3-6	4-8	2-5	<1-2	—	1-2
Sufentanil (ng/mL)	1-3	2-5	1-3	<0.2	—	0.02-0.2
Remifentanil (ng/mL)	4-8	4-8	2-4	<1-3	—	1-2
Propofol (µg/mL)	2-6	2.5-7.5	2-6	—	0.8-1.8	1.0-3.0
Methohexital (µg/mL)	5-10	5-15	5-10	—	1-3	2-5
Thiopental (µg/mL)	7.5-12.5 (with N_2O) 35-45 (without N_2O)	10-20	10-20	—	4-8	7.5-15.0
Etomidate (ng/mL)	400-600	500-1000	300-600	—	200-350	100-300
Midazolam (ng/mL)	—	50-250 (combined with an opioid)	50-250 (combined with an opioid)	—	15-200 (reduced to 20-70 in the presence of an opioid)	40-100
Ketamine (µg/mL)	—	—	1-2	—	—	0.1-1
Dexmedetomidine† (ng/mL)						0.1-0.6

*Drug levels when combined with 65% to 70% nitrous oxide (N_2O) unless otherwise stated. Effective plasma concentrations may differ markedly, depending on premedication and intraoperative drug combinations.
†Dexmedetomidine provides sedation and mild analgesia at the concentrations listed. It may be combined with other sedatives or analgesics to reduce their C_{50} for the end points listed.

below the desired target. Levels at the effect site will never be close to the desired target concentration of 3 ng/mL. A fentanyl bolus of 1080 µg, not surprisingly, produces a marked overshoot in plasma levels that persists for hours (Fig. 28-14). Additionally, it is absurd to use equations to calculate the fentanyl dose if the resulting recommendation is "pick a dose between 39 and 1080 µg."

The usual dosing guidelines for a bolus dose, presented earlier, are designed to produce a specific plasma concentration. Because plasma is not the site of drug effect, it is illogical to base calculation of the initial bolus on a desired plasma concentration. As pointed out previously, by knowing the k_{e0} of an intravenous anesthetic, we can design a dosing regimen that yields the desired concentration at the site of drug effect. If we do not want to overdose the patient, we should select a bolus that produces the desired peak concentration at the effect site.

The decline in plasma concentration between the initial concentration after the bolus (amount/V_1) and the concentration at the time of peak effect can be thought of as dilution of the bolus into a larger volume than the volume of the central compartment. This introduces the concept of Vd_{pe}, the apparent volume of distribution at the time of peak effect,[17,61] or pseudo-equilibration between plasma and the site of drug effect.[62] The size of this volume can readily be calculated from the observation that the plasma and effect-site concentrations are the same at the time of peak effect:

$$Vd_{pe} = \frac{\text{Bolus amount}}{C_{pe}} \qquad (11)$$

where C_{pe} is the plasma concentration at the time of peak effect.

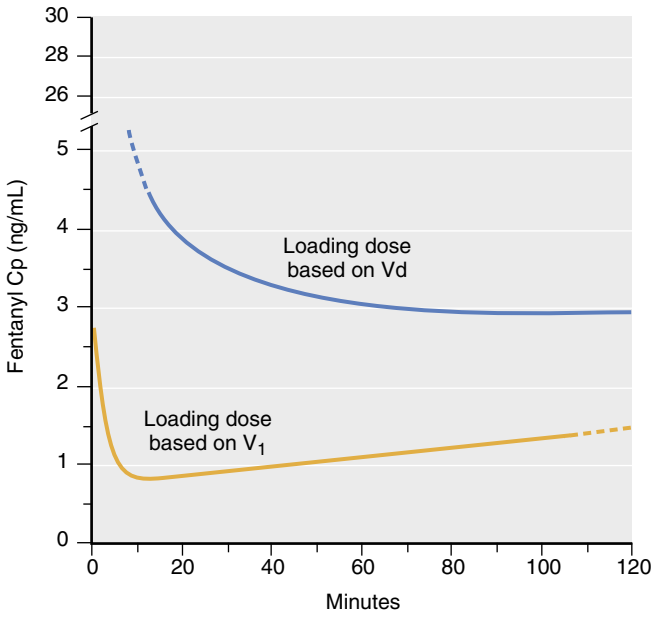

Figure 28-14 Pharmacokinetic simulation demonstrating the limitations of infusion regimens based on simple pharmacokinetic parameters, with fentanyl used as an example. These infusion schemes were designed to achieve a plasma fentanyl concentration of 3 ng/mL. The *upper blue curve* shows that a regimen using a loading dose based on the volume of distribution followed by a constant infusion based on clearance results in a transient period of very high plasma concentrations. If the same maintenance infusion is given but the loading dose is based on the volume of the central compartment, distribution of drug to the peripheral compartments causes the plasma concentration to fall below the desired level until the compartments reach steady-state concentrations, as shown in the *lower yellow curve*. Cp, plasma drug concentration.

Table 28-4 Volume of Distribution at the Time of Peak Effect

Drug	V_1 (L)	Vd_{pe} (L)
Fentanyl	12.7	75
Alfentanil	2.19	5.9
Sufentanil	17.8	89
Remifentanil	5.0	17
Propofol	6.7	37
Thiopental	5.6	14.6
Midazolam	3.4	31

V_1, volume of the central compartment; Vd_{pe}, apparent volume of distribution at the time of peak effect.

Let us assume that our clinical goal is to select the dose required to achieve a certain drug effect without producing an overdose. We can rearrange Equation 11 by substituting C_T, the target concentration (which is the same in plasma and the effect site at the moment of peak effect), for C_{pe} to calculate the size of the initial bolus:

$$\text{Loading dose} = C_T \cdot Vd_{pe} \quad (12)$$

The Vd_{pe} for fentanyl is 75 L. To achieve a peak fentanyl effect-site concentration of 3.0 ng/mL requires 225 µg, which produces a peak effect in 3.6 minutes. This is a much more reasonable dosing guideline than the previous recommendation of a dose between 39 and 1080 µg. Table 28-4 lists V_1 and Vd_{pe} for fentanyl, alfentanil, sufentanil, remifentanil, propofol, thiopental, and midazolam. Table 28-1 lists the time to peak effect and the $t_{½}$ k_{e0} of the commonly used intravenous anesthetics.

Maintenance Infusion Rate

By definition, the rate at which drug exits the body is systemic clearance, Cl_S, times the plasma concentration. To maintain a given target concentration, C_T, drug must be delivered at the same rate that it is exiting the body. Thus,

$$\text{Maintenance infusion rate} = C_T \cdot Cl_S \quad (13)$$

For drugs with multicompartmental pharmacokinetics, which includes all of the intravenous drugs used in anesthetic practice, drug is distributed into the peripheral tissues as well as cleared from the body. The rate of distribution into tissues changes over time as the tissues equilibrate with plasma. Equation 13 is correct only after the peripheral tissues have fully equilibrated with plasma, which requires many hours. At all other times, this maintenance infusion rate underestimates the infusion rate to maintain a target concentration.

In some situations this simple maintenance rate calculation may be acceptable. For example, if an infusion at this rate is used along with a bolus dose based on Vd_{pe} and the drug has a long delay between the bolus and peak effect, much of the distribution of drug into tissues may have occurred by the time that the effect-site concentration reaches the target concentration. In this case, the maintenance infusion rate calculated as clearance times target concentration may be accurate because Vd_{pe} is sufficiently higher than V_1 to account for the distribution of drug into peripheral tissues. Unfortunately, most drugs used in anesthesia achieve sufficiently rapid equilibration between plasma and the effect site that Vd_{pe} does not adequately encompass the distribution process, thus making this approach unsuitable.

Another example of calculating infusion rates for drugs with multicompartmental pharmacokinetics is the two-step approach proposed by Wagner.[63] In this method, two infusions, Q_1 and Q_2, are administered in sequence. The loading infusion, Q_1, is selected on the basis of convenience and the degree of overshoot in plasma concentration that will be clinically acceptable. The second infusion, Q_2, is calculated as $C_T \times Cl_S$, exactly as noted earlier. The Wagner two-step approach does not consider the time course of drug effect and thus is probably not appropriate for most anesthetic drugs.

Having considered two approaches that do not work very well, we now turn to approaches that are mathematically and clinically sound. Because the net flow of drug into peripheral tissues decreases over time, the infusion rate required to maintain any desired concentration must also decrease over time. If the initial bolus has been based on Vd_{pe}, no infusion need be administered until the effect-site concentrations peak. After the peak in effect-site concentration, the (nearly) correct equation to maintain the desired concentration is

$$\text{Maintenance infusion rate} = C_T \times V_1 \times \left(k_{10} + k_{12}e^{-k_{21}t} + k_{13}e^{-k_{31}t}\right) \quad (14)$$

This equation indicates that a high infusion rate is initially required to maintain C_T. Over time, the infusion rate gradually decreases (see Fig. 28-4). At equilibrium ($t = \infty$), the infusion rate decreases to $C_T \times V_1 \times k_{10}$, which is the same as $C_T \times Cl_S$. Few anesthesiologists would choose to mentally solve such an equation during administration of an anesthetic. Fortunately, there are simple techniques that can be used in place of solving such a complex expression.

Figure 28-15 is a nomogram in which Equation 14 has been solved; the infusion rates at different times necessary to maintain any desired concentration of fentanyl, alfentanil, sufentanil, and propofol are shown. This nomogram is complex, so we will review it in detail. The *y* axis represents the target concentration C_T. The *x* axis is the time since the beginning of the anesthetic (i.e., since the initial bolus). The suggested initial target concentrations (shown in red) are based on the work of Vuyk and colleagues[27] with propofol and alfentanil (see Fig. 28-8) and are scaled to fentanyl and sufentanil according to their relative potencies.[61] The intersections of the target concentration line and the diagonal lines indicate the infusion rate appropriate at each point in time. For example, to maintain a fentanyl concentration of 1.5 ng/mL, the appropriate rates are 4.5 µg/kg/hr at 15 minutes, 3.6 µg/kg/hr at 30 minutes, 2.7 µg/kg/hr at 60 minutes, 2.1 µg/kg/hr at 120 minutes, and 1.5 µg/kg/hr at 180 minutes. Of course, it is possible to select target concentrations and different times of rate adjustment, depending on clinical circumstances and your assessment of how accurately the intravenous drug needs to be titrated.

Another recent approach to manually determine infusion rates for maintenance of anesthesia to a desired target concentration is through the application of concepts involving the use of a slide rule.[64] Figure 28-16 illustrates such a slide rule for propofol. As described by Bruhn and colleagues, "The bolus dose required to reach a given target plasma concentration is the product of the (weight-related) distribution volume and required concentration.

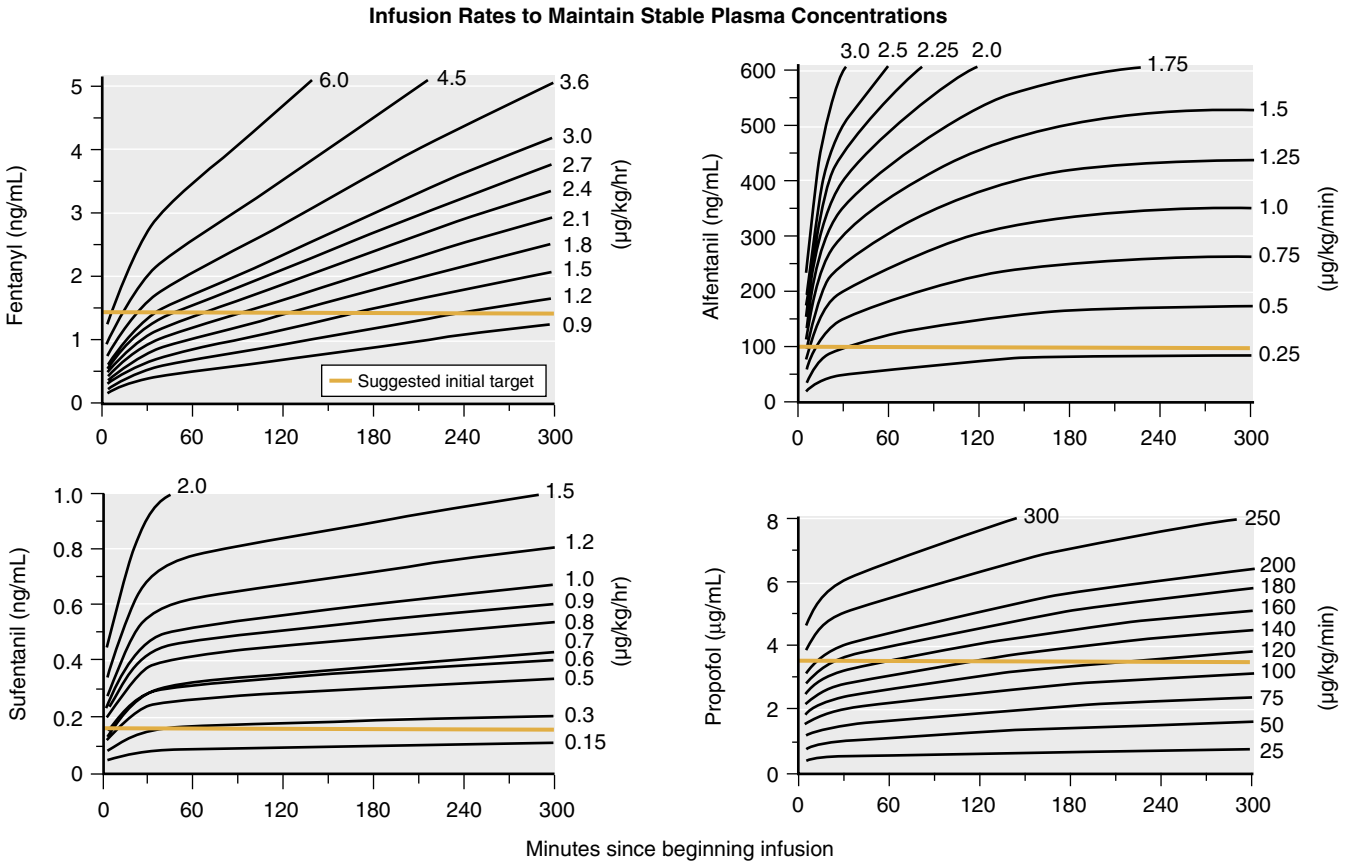

Figure 28-15 Nomogram for calculating maintenance infusion rates to maintain a stable concentration of fentanyl, alfentanil, sufentanil, or propofol. The *y* axis is the desired concentration. The *x* axis is the time relative to the initial bolus. The *diagonal lines* show the infusion rates at different times required to maintain the desired concentration selected on the *y* axis.

Similarly, the infusion rate at a particular time point is the product of target concentration, body weight, and a correction factor that depends on the time elapsed from the start of the initial infusion. This factor can be determined for each time point using a PK simulation program."[64] When compared with computer simulation programs, this manual device performed within an acceptable degree of accuracy (within 7% of the simulated target concentration) for a single target concentration and decreased in accuracy (within 20%) when applied to changing target concentrations.

Recovery from Anesthesia

Recovery from anesthesia is determined by the pharmacokinetic principles that govern the rate of decrease in drug from the effect compartment once drug administration is terminated, as well as by the pharmacodynamics of the drug. Although the terminal elimination half-life is often interpreted as a measure of how short or long lasting a drug is, the rate at which drug decreases is dependent on both elimination and redistribution of the drug from the central compartment. The contribution of both

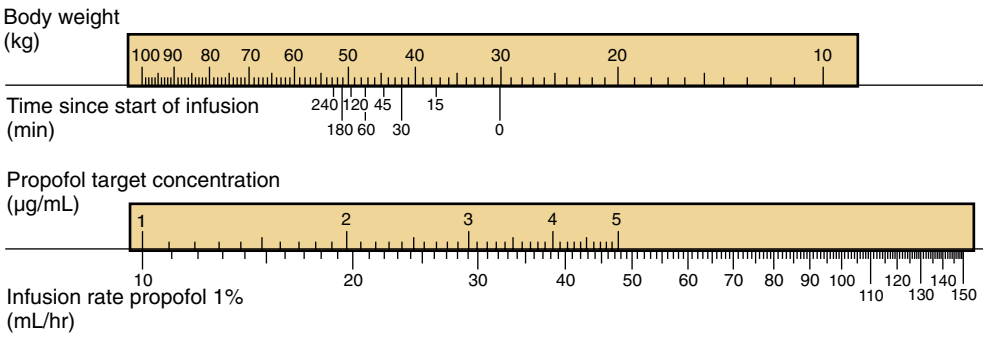

Figure 28-16 Slide rule for calculating the maintenance propofol infusion rate from the patient's weight, the desired target concentration, and the elapsed time. *(Adapted from Bruhn J, Bouillon TW, Ropcke H, Hoeft A: A manual slide rule for target-controlled infusion of propofol: Development and evaluation. Anesth Analg 96:142-147, 2003.)*

redistribution and elimination toward the rate of decrease in drug concentration varies according to the duration for which the drug has been administered.[61,65]

In 1985, Schwilden[66] developed a mathematical model to relate the time course of offset of action of inhaled anesthetics to the duration of anesthetic drug delivery. Similarly, Fisher and Rosen[67] demonstrated how accumulation of muscle relaxants in peripheral volumes of distribution results in slowed recovery with increasing duration of administration. They introduced two measures of the time course of recovery, the time for twitch tension to recover from 5% to 25% and the time for twitch tension to recover from 25% to 75%.

Since then, the time for the plasma concentration to decrease by 50% from an infusion that maintains a constant concentration (e.g., the infusion given by Equation 14) has been termed the "context-sensitive half-time" (Fig. 28-17),[65] with the context being the duration of the infusion. The 50% decrease was chosen both for tradition (e.g., half-lives are the time for a 50% decrease with a one-compartment model) and because, very roughly, a 50% reduction in drug concentration appears to be necessary for recovery after the administration of most intravenous hypnotics at the termination of surgery. Depending on circumstances, decreases other than 50% may be clinically relevant. Additionally, sometimes it is the plasma concentration that is of interest, and sometimes it is the effect-site concentration that is of interest. A more general term is the context-sensitive "decrement time,"[68] in which the decrement in concentration is specifically noted, as is the compartment where the decrease is modeled (plasma or effect site). For example, the relationship between

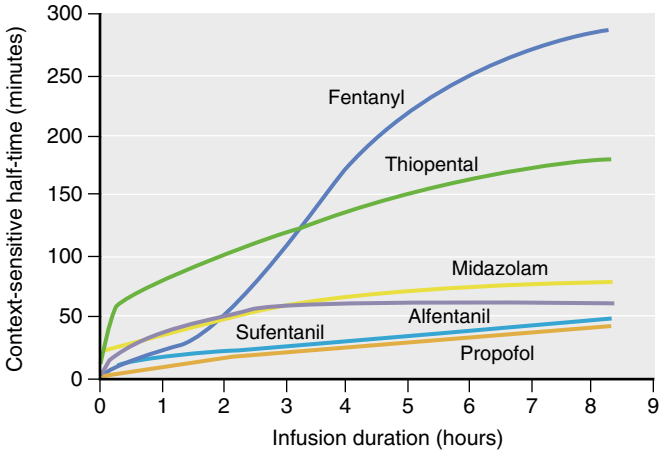

Figure 28-17 Context-sensitive half-times as a function of infusion duration (the "context") derived from pharmacokinetic models of fentanyl, sufentanil, alfentanil, propofol, midazolam, and thiopental. *(From Hughes MA, Glass PSA, Jacobs JR: Context-sensitive half-time in multicompartment pharmacokinetic models for intravenous anesthetic drugs. Anesthesiology 76:334-341, 1992.)*

infusion duration and time required for a 70% decrease in fentanyl effect-site concentration is the "context-sensitive 70% effect-site decrement time."

Context-sensitive effect-site decrement times for varying percent decreases in alfentanil, fentanyl, and remifentanil concentration are illustrated in Figure 28-18. To determine when an infusion should be terminated (to enable awakening of the patient

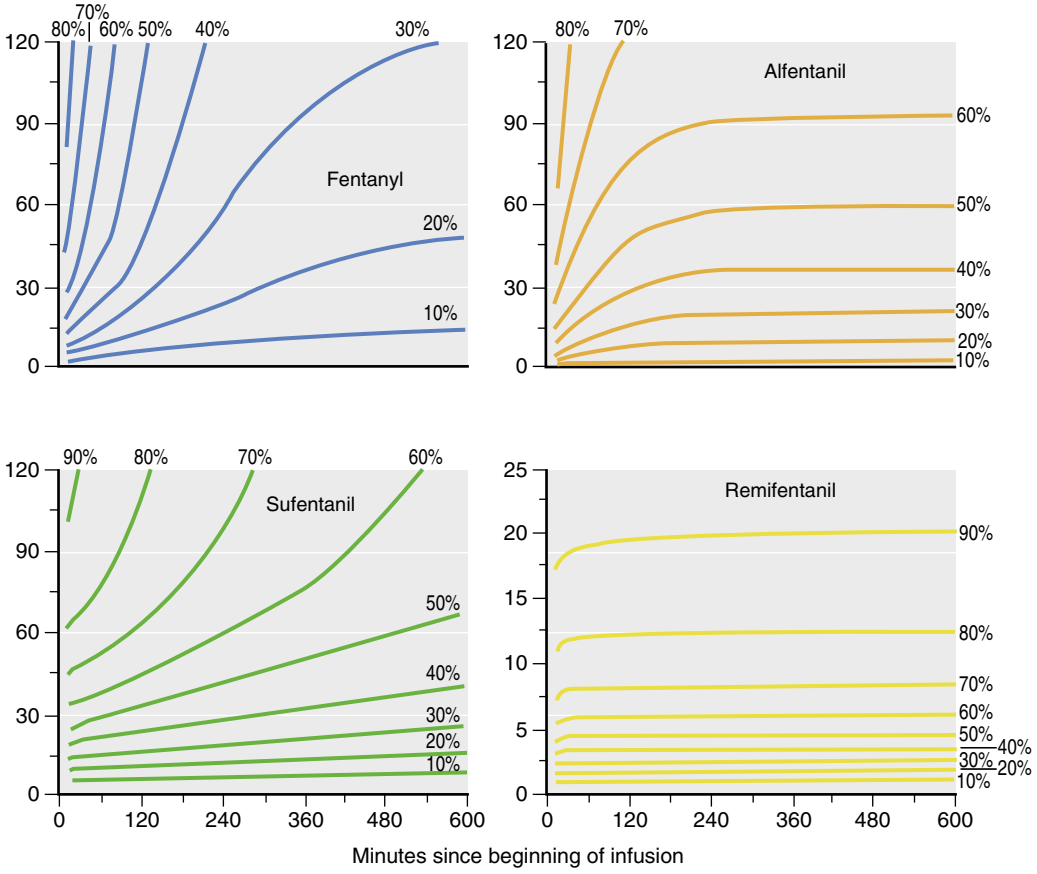

Figure 28-18 Context-sensitive effect-site decrement times for alfentanil, fentanyl, sufentanil, and remifentanil showing the time required for decreases of a given percentage (labeled for each curve) from the maintained effect-site concentration after termination of the infusion.

at the end of surgery), the clinician needs to bear in mind the decrease in concentration necessary for recovery, the duration of the infusion (the context), and the context-sensitive effect-site decrement time required for the necessary decrease.

Context-sensitive decrement times are fundamentally different from the elimination half-life. With monoexponential decay, each 50% decrease in concentration requires the same amount of time, and this time is independent of how the drug is given. This is not true for the context-sensitive half-time. First, as the name is intended to imply, the time needed for a 50% decrease is absolutely dependent on how the drug was given, with infusion duration being the context to which the name refers. In addition, small changes in percent decrement can result in surprisingly large increases in the time required. As can be seen from Figure 28-18, in some situations the time required for a 60% decrease in drug concentration can be more than twice the time required for a 50% decrease.

Context-sensitive decrement times are based on the assumption that plasma or the effect site is maintained at a constant concentration. Such is rarely the case clinically, but maintenance of constant concentrations is a necessary assumption to provide a unique mathematical solution to the time required for a given percent decrement in plasma or effect-site concentration. Because plasma and effect-site concentrations are rarely kept constant, it is important that context-sensitive decrement times be used as general guidelines for interpreting the pharmacokinetics of intravenous drugs and not as absolute predictions for any given case or infusion regimen. Automated drug delivery systems can provide more precise predictions of the time required for the plasma or effect-site concentration to decrease to any desired concentration based on the actual drug dosing in the individual patient. This provides the clinician with guidance for the most appropriate time to terminate the infusion.

Context-sensitive decrement times focus on the role of pharmacokinetics in recovery from anesthesia. Pharmacodynamics plays an important role in recovery as well. Bailey[69] used integrated pharmacokinetic/pharmacodynamic models to define the "mean effect time" as the average time to responsiveness after maintenance of anesthesia at the 90% probability of unresponsiveness. The mean effect time demonstrates that when drugs have a very shallow concentration-versus-response relationship, concentrations must decrease by a significant fraction to provide adequate emergence. This delays recovery from anesthesia. In contrast, recovery is hastened by a steep concentration-versus-response relationship, in which emergence from anesthesia occurs after a relatively small fractional decrease in concentration. Most intravenous hypnotics have a fairly steep concentration-versus-response relationship.

Pharmacodynamic drug interactions also play a role in recovery from anesthesia. Interaction relationships predict that the same anesthetic state can be achieved by different ratios of two drugs. One way of selecting the best ratio might be the combination that offers the most rapid recovery. For example, when an opioid is combined with a hypnotic, recovery from anesthesia depends on the opioid and hypnotic concentrations, the rate of decrease in both drugs, and the relative synergy between them for loss of response to noxious stimulation (i.e., the state maintained during anesthesia) versus the relative synergy for loss of consciousness. Although the time course of decreases in opioid and hypnotic concentrations can be approximately described by their respective context-sensitive decrement times for both drugs

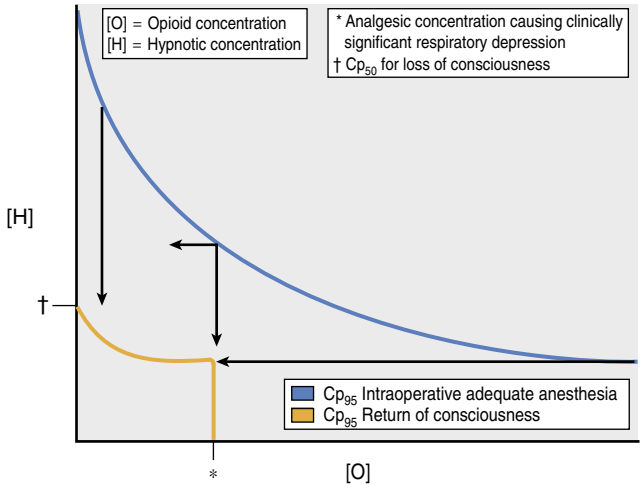

Figure 28-19 Interaction between hypnotics and opioids for prevention of movement after a noxious stimulus and for awakening and adequate spontaneous ventilation at the end of a surgical procedure. From this it can be seen that the time to recover at the end of a procedure is dependent on the concentration of both drugs used during surgery and the time for both to decrease below that required for consciousness and adequate spontaneous ventilation (i.e., their context-sensitive decrement times).

(Fig. 28-19; for propofol/alfentanil, see Fig. 28-8), the influence of relative synergy for different end points must be captured by separate models of the interaction of the drugs for adequate anesthesia and emergence from anesthesia.

Vuyk and coworkers[70] modeled the predicted time to awakening when propofol is combined with fentanyl, sufentanil, alfentanil, or remifentanil on the basis of the interaction between propofol and these opioids to provide adequate anesthesia and the interaction between propofol and opioids on emergence from anesthesia, as seen in Figures 28-20 and 28-21. Recovery times vary with the choice of opioid and the relative balance of opioid and propofol during maintenance of anesthesia. For example, in the upper left of Figure 28-20 is a simulation of emergence from a propofol/fentanyl anesthetic of 10 minutes' duration. The simulations assume a steady concentration of fentanyl and propofol throughout the anesthesia, similar to the underlying assumption of context-sensitive decrement times. The red curve in the lower plane is the interaction curve between fentanyl and propofol; it ranges from no fentanyl and 12 µg/mL of propofol on the left to 6 ng/mL of fentanyl and 1.8 µg/mL of propofol on the right. In theory, any point along this curve would provide equivalent maintenance of anesthesia. When the infusion is turned off after 10 minutes of anesthesia, the concentrations of both drugs decrease. The decreasing concentrations of propofol and fentanyl when the infusion is turned off can be found by the upward lines drawn from different points on the interaction curve, with the distance away from the lower plane representing time. Taken together, these upward lines represent a "recovery surface." The red line drawn on the recovery surface shows the points at which the fentanyl-propofol interaction model predicts emergence.

Figure 28-20 shows that after 10 minutes of maintaining 1.8 µg/mL of propofol and 6 ng/mL of fentanyl (right edge of the interaction curve), approximately 12 minutes is needed for the concentrations of both drugs to decrease enough to permit emergence. However, if one maintains concentrations of 3.5 µg/mL of propofol and 1.5 ng/mL of fentanyl (toward the middle of the

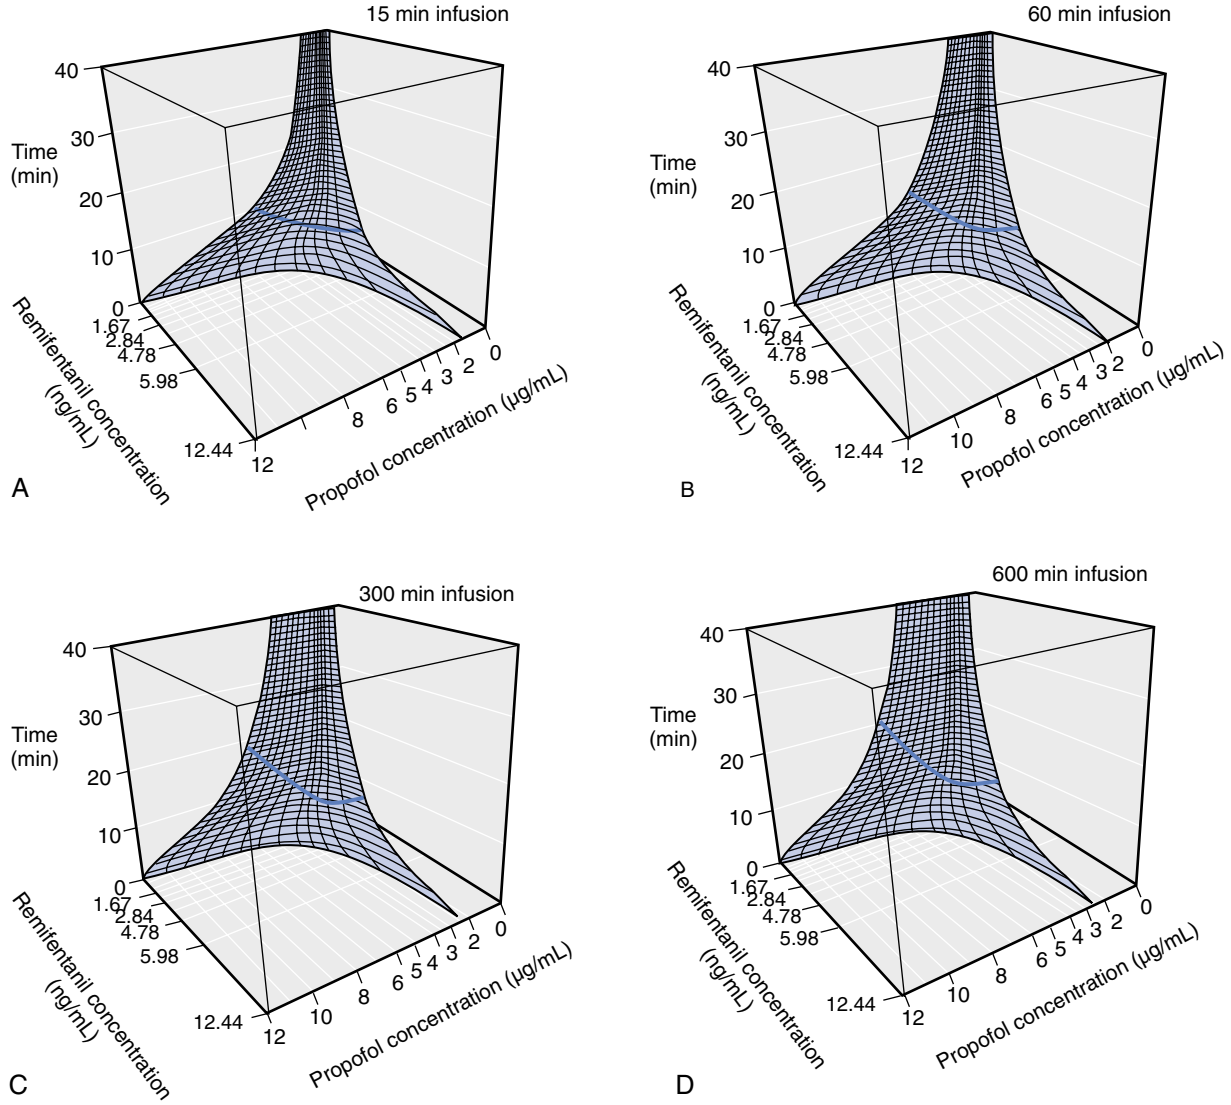

Figure 28-20 Simulation of the interaction of propofol and fentanyl in preventing a somatic response at skin incision and time to recovery. On the *x* axis is the fentanyl concentration, and on the *y* axis, the propofol concentration. The *blue curve* in the lower plane shows the propofol-fentanyl interaction required to provide adequate anesthesia. When the infusion is turned off, the concentrations of each drug decrease, as shown on the *z* axis. The *blue curve* drawn on the recovery surface shows the time to emergence from anesthesia for combinations of fentanyl and propofol after an anesthetic of 15 minutes' (**A**), 60 minutes' (**B**), 180 minutes' (**C**), or 600 minutes' (**D**) duration. Note that the optimal combination for the most rapid recovery is a propofol concentration of 3.0 to 3.5 µg/mL combined with 1.5 ng/mL fentanyl. As the concentration of propofol or fentanyl increases, the time for recovery increases. In addition, the longer the duration of drug infusion, the longer recovery takes, especially if the optimal combination is not used. *(Adapted from Vuyk J, Mertens MJ, Olofsen E, et al: Propofol anesthesia and rational opioid selection: Determination of optimal EC_{50}-EC_{95} propofol-opioid concentrations that assure adequate anesthesia and a rapid return of consciousness. Anesthesiology 87:1549-1562, 1997.)*

interaction curve), emergence can be expected just 8 minutes after the infusions are turned off. Examination of the curves for 60, 300, and 600 minutes of propofol/fentanyl anesthesia suggests that the fentanyl target concentration that provides the most rapid emergence is approximately 1.0 to 1.5 ng/mL, which requires a propofol concentration of approximately 3.0 to 3.5 µg/mL to maintain adequate anesthesia. This is consistent with the earlier observation that most of the MAC reduction benefit of fentanyl occurs within the analgesic range and that exceeding this range is of little benefit during anesthesia. In similar simulations, Vuyk and colleagues demonstrated that maintaining alfentanil and sufentanil concentrations in excess of the analgesic range (i.e., approximately 80 ng/mL for alfentanil and 0.15 ng/mL for sufentanil) is of little clinical benefit but can be expected to delay recovery from anesthesia. A second conclusion from these simulations is that if the patient demonstrates inadequate anesthesia, to prevent prolongation of recovery, it is preferable to increase the hypnotic concentration than to increase the opioid concentration beyond the analgesic range.

The situation is different for remifentanil because of its unusual pharmacokinetic properties (Fig. 28-21). When a remifentanil infusion is terminated, the extraordinary clearance of remifentanil results in very rapid offset of opioid drug effect. In Figure 28-21, the lower plane again shows equivalent anes-

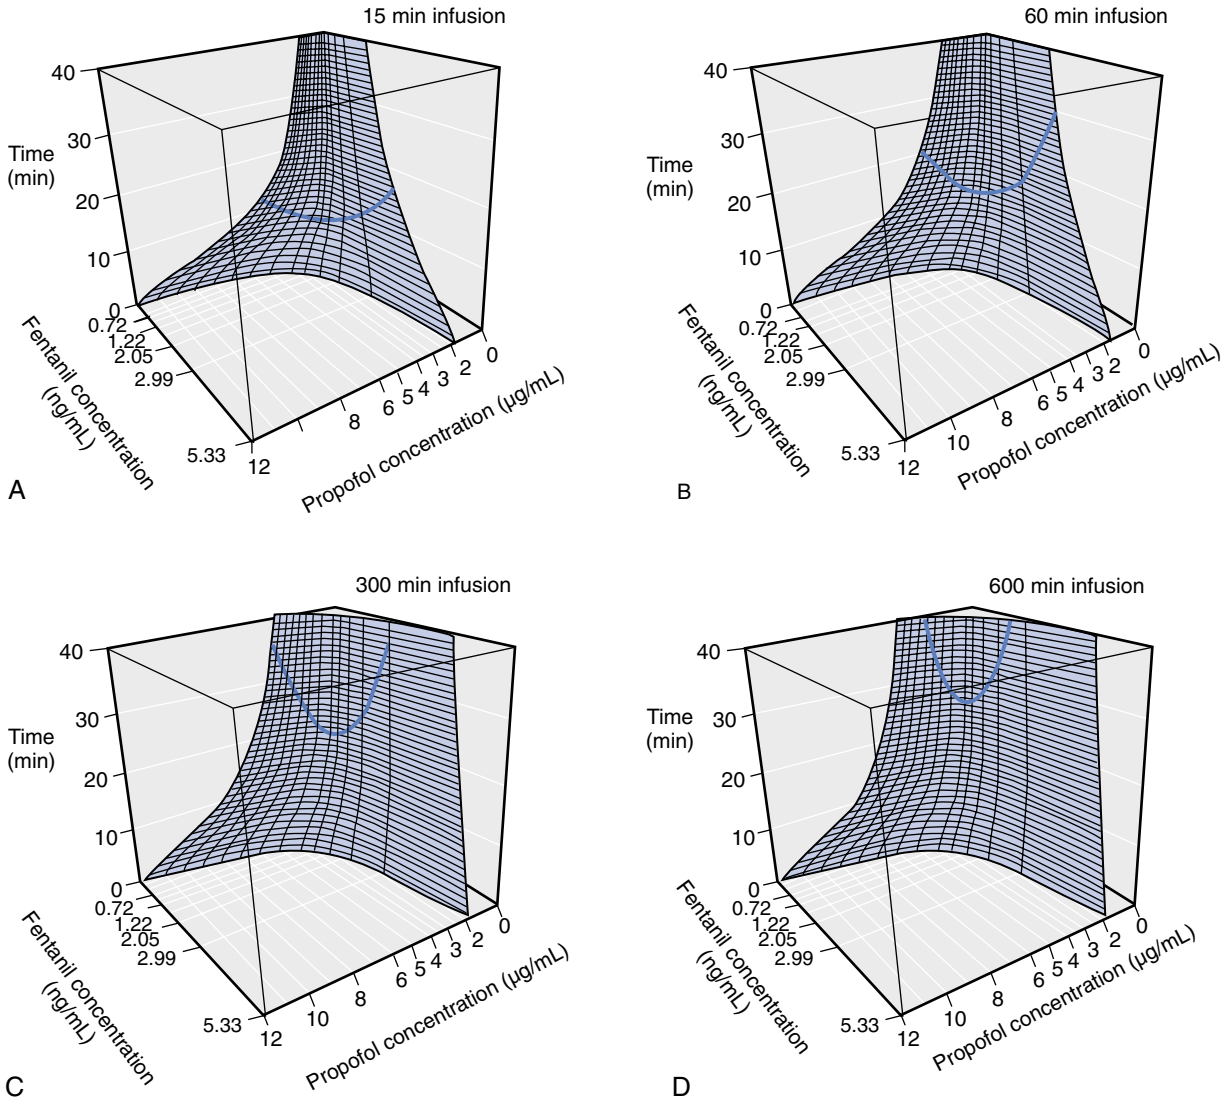

Figure 28-21 Simulation of the interaction of propofol and remifentanil in preventing a somatic response at skin incision and time to recovery. Note that with remifentanil, the optimal combination is a propofol concentration of 2.5 µg/mL and, with remifentanil, 5 to 7 ng/mL; also note that increasing the duration of the infusion has minimal impact on recovery time if the optimal dose of remifentanil is not used. However, if the propofol dose is increased, recovery is prolonged. *(Adapted from Vuyk J, Mertens MJ, Olofsen E, et al: Propofol anesthesia and rational opioid selection: Determination of optimal EC_{50}-EC_{95} propofol-opioid concentrations that assure adequate anesthesia and a rapid return of consciousness. Anesthesiology 87:1549-1562, 1997.)*

thetic states during maintenance with an opioid, remifentanil, and propofol. High doses of remifentanil permit a modest reduction in the dose of propofol needed for adequate anesthesia. However, the recovery surfaces show that high doses of remifentanil, with a modest reduction in the propofol dose, permit considerably faster emergence from anesthesia. For example, it takes approximately 12 minutes to awaken from 600 minutes of anesthesia maintained with 3 µg/mL of propofol and 2.5 ng/mL of remifentanil (Fig. 28-20, lower left graph). If the remifentanil concentration is increased to 5 ng/mL, the propofol concentration can be reduced to 2 to 2.5 µg/mL, and emergence can be anticipated within 6 minutes of discontinuation of the infusions. One might be concerned that such a technique places patients at increased risk for awareness because a propofol concentration of 2 µg/mL is below the C_{50} value for wakefulness.[26,28] Therefore, it is probably reasonable to combine such a technique with intraoperative EEG monitoring to assess anesthetic adequacy.

The offset of isoflurane and sevoflurane is similar to that of propofol. The offset of desflurane is slightly quicker than that of propofol. We can draw some logical extrapolations from these propofol/opioid simulations to anesthesia consisting of volatile anesthetics combined with opioids. When fentanyl, alfentanil, or sufentanil is combined with a volatile anesthetic, the most rapid recovery occurs when the opioid concentration is maintained at an analgesic concentration equivalent to 1 to 1.5 ng/mL of fentanyl (Table 28-5). Concurrently, the volatile anesthetic should be administered at the lowest concentration required to provide adequate anesthesia but no less than an end-tidal concentration of 0.3 MAC, the MAC value for return of consciousness. If the patient demonstrates signs of inadequate anesthesia, it is preferable to increase the volatile anesthetic because this has less of an effect on prolonging the wake-up time than increasing the opioid does (with the exception of remifentanil) and is more likely to ensure that awareness does not occur.

Table 28-5 Infusion Rates for Opioids to Achieve Preset Concentrations

Drug	Target Plasma Concentration (ng/mL)	Bolus (μg/kg)	Infusion Rate (μg/kg/min)
Fentanyl (low)	1	3	0.02
Fentanyl (high)	4	10	0.07
Alfentanil (low)	40	20	0.25
Alfentanil (high)	160	80*	1
Sufentanil (low)	0.15	0.15	0.003
Sufentanil (high)	0.5	0.5	0.01
Remifentanil (low)	2	0.5-1*	0.06-0.1
Remifentanil (high)	10	1-2*	0.3-0.5

*Give as a rapid infusion over a 1- to 2-minute period.

Infusion Devices

Manual Delivery

When an infusion of an intravenous anesthetic is administered, the infusion regimen can be controlled by a variety of mechanisms varying from the simple Cair clamp or Dial-a-Flo (Abbott Laboratories) to complex computer-controlled infusion pumps. Simplicity of mechanical design, however, is not necessarily correlated with ease of use. This has prompted ongoing advances in infusion device technology.

Infusion devices can be classified as either controllers or positive displacement pumps. Explicit in their title, controllers contain mechanisms that control the rate of flow produced by gravity, whereas positive displacement pumps contain active pumping mechanisms.

The most commonly used pumps for administration of intravenous anesthetics are positive displacement syringe pumps that use a variety of mechanisms. These pumps are highly accurate and have several features that make them particularly suitable for anesthetic delivery. An important advance has been the introduction of a calculator feature within the pump so that the clinician can set the weight of the patient, the drug concentration, and the infusion rate in dose/unit weight/unit time and the pump will then calculate the infusion in volume/unit time. These pumps also permit simple application of a staged infusion scheme (e.g., the two-stage approach of Wagner[63]) by allowing a loading dose and a maintenance infusion rate to be programmed into the pump. Numerous syringe pumps also now include automated recognition of syringe size. Further enhancements are drug libraries by class of drug, suggested dosing schemes, and maximal dosing alerts. These modest advances in pump technology and design enable intravenous anesthetics to be delivered conveniently.

Table 28-6 offers recommendations for delivering intravenous anesthetics via conventional infusion pumps based on integrated pharmacokinetic-pharmacodynamic models. However, it is the patient's response, demonstrating adequate or inadequate anesthesia, that ultimately determines the rate of drug administration. Individuals vary markedly in their response to a given drug dose or concentration, and it is therefore essential to titrate to an adequate drug level for each individual patient. Drug concentrations required to provide adequate anesthesia also vary according to the type of surgery (e.g., surface surgery versus upper abdominal surgery). The end of surgery requires lower drug levels, and hence titration often involves judicious lowering of the infusion rate toward the end of surgery to facilitate rapid recovery.

If the infusion rate proves to be insufficient to maintain adequate anesthesia, both an additional loading (bolus) dose and an increase in infusion are required to rapidly raise the plasma (biophase) drug concentration. Various interventions also require greater drug concentrations, usually for brief periods (e.g., laryngoscopy, endotracheal intubation, skin incision) (see Fig. 28-3). Therefore, the infusion scheme should be tailored to provide peak concentrations during these brief periods of intense stimulation. An adequate drug level for endotracheal intubation is often achieved with the initial loading dose, but for procedures such as skin incision, a further bolus dose may be necessary.

Infusion schemes such as those shown in Table 28-6 do not approach the convenience and precision of use associated with the delivery of an inhaled anesthetic via a calibrated vaporizer. This level of precision can be achieved by using TCI devices (such as the commercially available Diprifusor). Such devices go beyond simple calculator pumps to the creation of pumps with automated drug delivery.

Automated Delivery

Automated drug delivery implies that electronic or mechanical instrumentation performs adjustments in dose rate independent of human intervention (in contrast with the manual devices described in the previous section). The desired target (e.g., drug concentration and clinical response) is still chosen by the clinician. Preprogrammed dosing (either bolus or infusion) is the simplest form of automated drug delivery. It consists of a preprogrammed infusion (usually calculated to provide a single target blood or effect concentration) that is automatically implemented by the microprocessor in the pump.[71] Preprogrammed devices are limited in their application for intravenous anesthetic drugs because of their inability to allow the user to vary the target concentration.[72] There are two different methods of automated target-based anesthetic drug delivery: model-based (a form of open-loop control) and closed-loop systems.

Terms and Definitions

Open- and closed-loop systems require a set point (Fig. 28-22).[73] The set point is a quantifiable entity (e.g., plasma concentration, percent T1 of the electromyogram, or BIS value) related to the clinical objective (e.g., level of anesthesia, neuromuscular blockade). Accordingly, the set point is the value (i.e., target) that the automated system is attempting to maintain. The feedback signal is the measured (e.g., percent T1 of the electromyogram) or predicted (e.g., predicted effect-site concentration from pharmacokinetic simulation) value that has resulted from the automated delivery process.

Open-loop model-based drug delivery is most useful when the feedback signal cannot be readily measured and clinical judgment is required to assess drug effect. The model is the mathematical (e.g., pharmacokinetic) relationship between dose and predicted concentration in plasma and at the site of drug effect.

Table 28-6 Manual Infusion Schemes*

	Anesthesia		Sedation or Analgesia	
Drug	**Loading Dose (μg/kg)**	**Maintenance Infusion (μg/kg/min)**	**Loading Dose (μg/kg)**	**Maintenance Infusion (μg/kg/min)**
Alfentanil	50-150	0.5-3	10-25	0.25-1
Fentanyl	5-15	0.03-0.1	1-3	0.01-0.03
Sufentanil	0.5-5	0.01-0.05	0.1-0.5	0.005-0.01
Remifentanil	0.5-1.0	0.1-0.4	†	0.025-0.1
Ketamine	1500-2500	25-75	500-1000	10-20
Propofol	1000-2000	50-150	250-1000	10-50
Midazolam	50-150	0.25-1.5	25-100	0.25-1
Methohexital	1500-2500	50-150	250-1000	10-50
Dexmedetomidine‡			0.5-1 over 10 min	0.2-0.7

*After the loading dose, an initially high infusion rate to account for redistribution should be used and then titrated to the lowest infusion rate that will maintain adequate anesthesia or sedation. When using opiates as part of a nitrous-narcotic technique or for cardiac anesthesia, the dosing scheme listed under anesthesia is used. When the opiate is combined as part of balanced anesthesia, dosing listed for analgesia is needed.
†For analgesia or during sedation, an initial loading dose of remifentanil should not be given because its very rapid onset may result in apnea or muscle rigidity.

Consequently, the accuracy of any model-based control system depends on how well the model represents the process under control. In an open-loop system, it is the clinician who learns about the patient and adapts drug administration to the needs of the individual patient.

In a closed-loop "adaptive" controller, the device itself makes a measurement of drug effect and adjusts the internal model to better represent the individual patient. Closed-loop signals require precisely measured end points. For example, a closed-loop system to control blood pressure with sodium nitroprusside will have an expected dosing regimen that is likely to be quite conservative to avoid profound hypotension. As the system learns about individual patient sensitivity, it will adjust the dosing of sodium nitroprusside to the sensitivity of the individual patient by adapting the internal pharmacokinetic/pharmacodynamic model to better reach the clinical target. In anesthesia, closed-loop systems have typically used some signal derived from the EEG as the basis of adaptive closed-loop control.

Target Control Infusion Systems

Devices

In 1968, Kruger-Thiemer[74] described the infusion regimen theoretically required to quickly achieve and maintain a constant plasma concentration of an intravenously administered drug whose kinetics is described by a two-compartment model. This regimen has become known as the "BET scheme" (see Fig. 28-4) and consists of an initial bolus of $C_T V_1$, infusion at a rate of $C_T Cl_S$ to replace drug eliminated from the body, and an exponentially decreasing infusion at a rate given by Equation 14 to replace drug transferred to the peripheral tissues. The earlier section on designing dosage regimens demonstrates that the bolus portion, calculated as $C_T V_1$, will probably be inadequate for reaching the desired effect-site concentration. Mathematically, the "ET" portion of the BET scheme is identical to the exponentially declining maintenance infusion rate shown in the section "Designing Dosing Regimens." Precise implementation of this complex dosage regimen requires infusion rates that change continuously as a function of time until steady state is achieved.

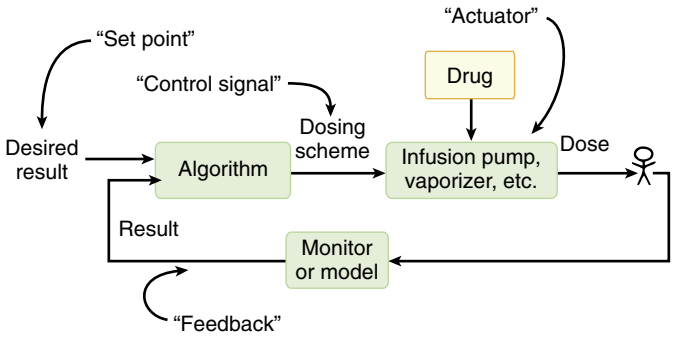

Figure 28-22 Components of a typical automated drug delivery system.

More than a decade after publication of Kruger-Thiemer's classic paper, Schwilden and colleagues[2,75,76] interfaced a microcomputer to an infusion pump and demonstrated clinical application of the BET infusion scheme. Many other groups have since implemented either the BET algorithm or modifications of this algorithm on microcomputers connected to infusion pumps. These algorithms are based on the same polyexponential equations or compartment models described previously and calculate the infusion rates theoretically required to obtain the desired plasma or effect-site drug concentration. In implementing these algorithms it is necessary to consider the physical limitations of the system. For example, infusion rates must be positive or zero. Additionally, some pumps have limitations on precision and accuracy that can reduce the accuracy of the infusion.

Although there are minor differences in the approaches taken by different investigators using pharmacokinetic model–driven infusion systems, all are conceptually similar. Each consists of a microcomputer interfaced to an infusion pump, as seen in Figure 28-23. The microcomputer executes a program that incorporates the pharmacokinetic model. In using the device, the anesthesiologist enters a target plasma or effect-site drug concentration (Fig. 28-24). This target concentration is based on knowledge of the pharmacokinetic-pharmacodynamic relationship of

Figure 28-23 The CACI system used at Duke University Medical Center. The CACI consists of a laptop computer electronically linked to an infusion pump. The desired drug plasma or effect-site concentration is entered via the keyboard.

the drug and the desired effect, as well as on the individual responses of the patient. At frequent intervals (e.g., every 9 to 15 seconds), the program compares the target concentration with the current prediction of the plasma or effect-site drug concentration, which is computed by real-time simulation of a pharmacokinetic model of the drug being infused. The computer calculates the infusion rate required to achieve the desired target concentration and transmits this rate to the pump after adjusting the rate to reflect the physical capabilities of the pump. The pump then delivers drug to the patient at the desired rate.

At each step the computer makes sure that the pump has delivered the drug that it was instructed to give and checks for errors reported by the infusion pump (e.g., air in the line, out of drug). The computer then calculates what the pump delivered during the previous interval and updates the internal pharmacokinetic model on the basis of the reported drug delivered. The cycle is completed when the computer calculates the infusion rate required over the next interval to reach the desired target concentration and transmits this rate to the infusion pump. Concurrently, the computer supplies the anesthesiologist with information about the state of the model, the state of the pump, any problems reported by the pump, the anticipated time course for elimination of drug from the patient, the total amount of drug delivered, the current infusion rate, and other information that may be of assistance in providing clinical care.

As a result of the increasing popularity of intravenous anesthesia and continuous-infusion techniques, the inherent reasonableness of pharmacokinetically based drug delivery, and the promising results achieved with automated administration of a variety of drugs by research groups around the world, pharmacokinetic model–driven infusion of propofol has become widely available worldwide except in the United States.[77] This system consists of a commercial pump and software that provides the control algorithm.

Several device companies are now providing TCI pumps that permit users to select from a variety of drugs and patient groups. Pharmacokinetic parameters for various drugs are already programmed into the device, and the devices have the ability to target the plasma concentration or the concentration at the site of drug effect. Such devices are well adapted to the need for rapid titration in anesthesia. The user selects the drug to be infused, enters information about the patient (e.g., weight, age, and gender), and ensures that the infusion setup is primed with drug at a specified concentration. The user titrates the target concentration during anesthesia in the same manner as for adjustment of the inspired concentration of an inhaled anesthetic.

Pharmacokinetic models are being incorporated into the next generation of anesthesia workstations. These workstations could then control many different brands of infusion pumps and provide a common platform for implementing precise titration of intravenous anesthetics in the concentration domain.

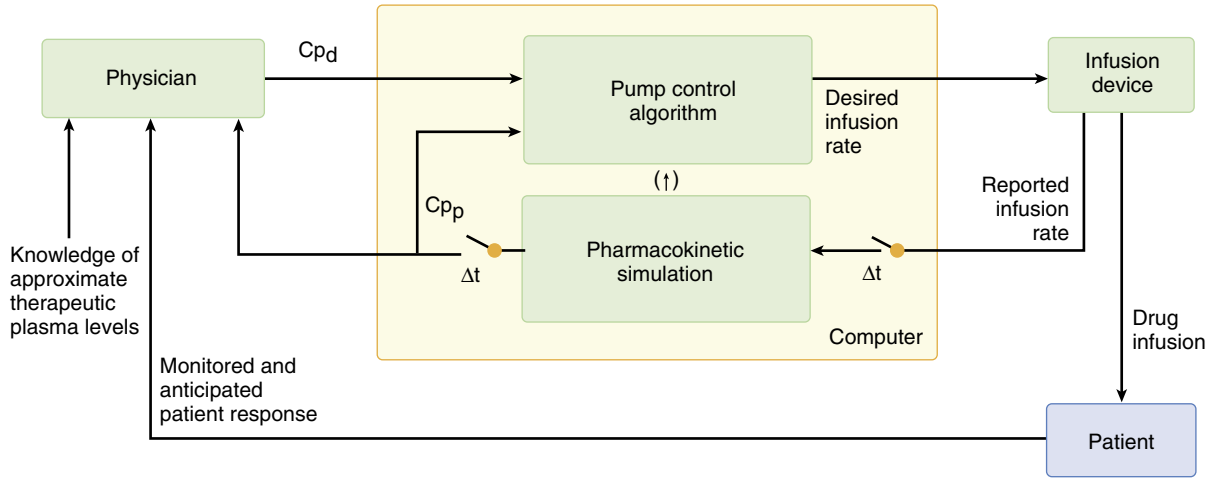

Figure 28-24 Schematic illustration of pharmacokinetic model–driven drug delivery. The physician enters the target plasma or biophase drug concentration (Cp_d). An infusion device control algorithm uses a pharmacokinetic model for the drug being infused to determine what the infusion rate should be for the next infusion interval (e.g., 9 to 15 seconds). The infusion device delivers drug to the patient, and the infusion rate is fed into a simulation of the pharmacokinetic model to compute the current predicted plasma drug concentration (Cp_p). The variables computed in the simulation are available to the infusion algorithm, which then calculates the infusion rate necessary for the next 9 to 15 seconds to achieve the target concentration. On the basis of monitored and anticipated patient responses, knowledge of approximate therapeutic plasma drug concentrations (e.g., Cp_{50}), and Cp_p, the physician can titrate Cp_d as necessary.

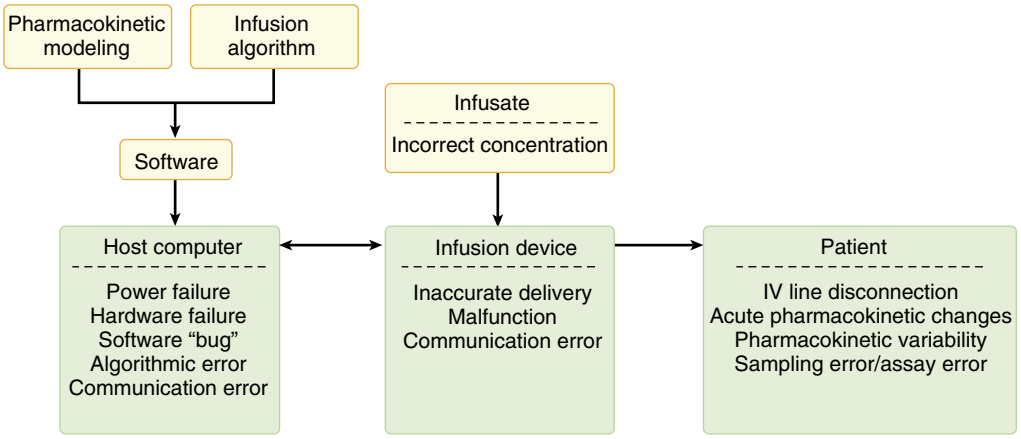

Figure 28-25 Major sources of potential error in pharmacokinetic model–driven drug delivery. In a commercial device, the computer functions would be incorporated into the infusion device itself.

Evaluation of Target-Controlled Drug Delivery

Acceptance of target-controlled drug delivery of intravenous anesthetics requires evaluation of both accuracy, defined as the difference between predicted and measured concentrations, and outcome of patients in whom automated drug delivery has been used. Sources of inaccuracy with pharmacokinetic model–driven devices include the software, the hardware, and pharmacokinetic variability (Fig. 28-25).

Inaccuracy in the software results from incorrect mathematical implementation of the pharmacokinetic model. Computer simulations can be used to test the infusion rates calculated by a software program, and thus software errors are fairly simple to identify and correct.[78] Inaccurate drug delivery from the infusion pump occurs infrequently with present syringe-pump technology and thus contributes little to the overall inaccuracy of these devices. The major cause of inaccuracy is biologic variability, of which there are two sources: (1) the pharmacokinetic model is always wrong, and (2) the pharmacokinetics of the patient is never that programmed into the model. The pharmacokinetic model is always wrong because individuals are far more complex than implied by simple compartmental models, and thus no such model can precisely predict the concentrations, even if the pharmacokinetic parameters in the individual were known with absolute precision. However, even if the pharmacokinetic model truly reflected the underlying biology, the parameters of the model would be average parameters for the population and not the parameters in the individual patient. Even if the parameters are modified to reflect the influence of demographic factors such as age, gender, hypovolemia, and coadministration of other drugs, they will still deviate from the true pharmacokinetic parameters in the individual. Thus, biologic variability fundamentally precludes the possibility of precisely achieving the desired target concentration when automated drug delivery devices are used. It is important to realize that biologic variability always exists, no matter how drugs are given, and that this same biologic variability affects all methods of drug delivery. Indeed, the variability with TCI devices will always be less than the variability observed after a single bolus injection.[79]

Optimization of Target-Controlled Drug Delivery

The performance of computer-controlled drug administration must be interpreted in terms of the therapeutic expectations of the clinician. Possible goals include accurately producing a desired concentration in plasma, precisely titrating the plasma drug concentration, achieving the desired drug effect, and producing the desired time course of drug effect. Over the past decade, investigators have addressed each of these goals and have refined the performance of automated drug delivery devices accordingly.

The ability of an automated drug delivery system to rapidly achieve and then maintain a selected target concentration is a logical measure of the performance of such a device. There are several ways of expressing the difference between the measured and target concentrations. The most simple means is either to diagram a plot of the target and measured concentration of each sample in each individual patient (Fig. 28-26) or to diagram an *xy* plot of the measured to target concentration and observe how much the plots vary from the line of identity (Fig. 28-27).[58] The primary concern is how far the measured concentration is from the predicted one, and this is now most frequently described in terms of performance error, which is the difference between the measured and target concentrations as a percentage of the desired target (i.e., [measured − target]/target × 100%).[80] The median value of the performance error for a patient or a population is referred to as the median performance error (MDPE) and represents the average overshoot or undershoot of the system. The median absolute performance error (MDAPE) is the median of the absolute values of all performance errors. The MDAPE is commonly used as a measure of the inaccuracy of an automated drug delivery device. An MDAPE of zero is perfect performance, and an MDAPE of 20% means that half the plasma concentrations will be within 20% of the target and half will be outside that range. A further assessment of accuracy is whether the system maintains a stable target concentration. This is best measured by the wobble of the system. Varvel and colleagues[80] asked a group of clinicians to evaluate the performance of automated drug delivery devices and demonstrated that the MDAPE best predicted the adequacy of performance of the automated delivery device, as judged by experienced clinicians.

As observed earlier, it is not reasonable to expect all performance errors to be zero. However, it would be desirable if positive and negative errors offset each other so that the MDPE of an automated drug delivery device were 0%. The MDPE does not indicate the range of performance errors (because positive and negative performance errors offset each other), but it does indicate whether the plasma concentrations achieved with the

device tend to overshoot (+MDPE) or undershoot (–MDPE) the desired target.

Many groups have evaluated the accuracy of many different pharmacokinetic sets for virtually all the intravenous analgesics and hypnotics.[23,58,71,81-88] Based on many of these studies the expected performance of such devices, at best, tends to be around 20% to 30% MDAPE. The pharmacokinetics of propofol has been the most frequently tested. Coetzee and coworkers[87] tested the accuracy of three parameter sets and found those of Marsh[88] Tackley[89] and their colleagues to provide the best accuracy in adult patients (Fig. 28-28). To demonstrate the effect of the three different pharmacokinetic parameters on propofol dosing, the infusion rates required to produce a set of target concentrations are plotted in Figure 28-29. The pharmacokinetic parameter set of Marsh and colleagues is the one included in the Diprifusor software. Better accuracy has been obtained in children[81] because they may have less pharmacokinetic variability as a result of their general lack of chronic disease and more narrow distribution of weight at any given age than found in adults.

There are numerous published pharmacokinetic parameter sets for each of the drugs used in anesthesia. The pharmacokinetic parameters within each set may vary considerably depending on a variety of factors, such as the mode of drug administration (e.g., bolus versus infusion), duration of sampling, site of drug sampling (arterial versus venous), sensitivity of the assay, and evalu-

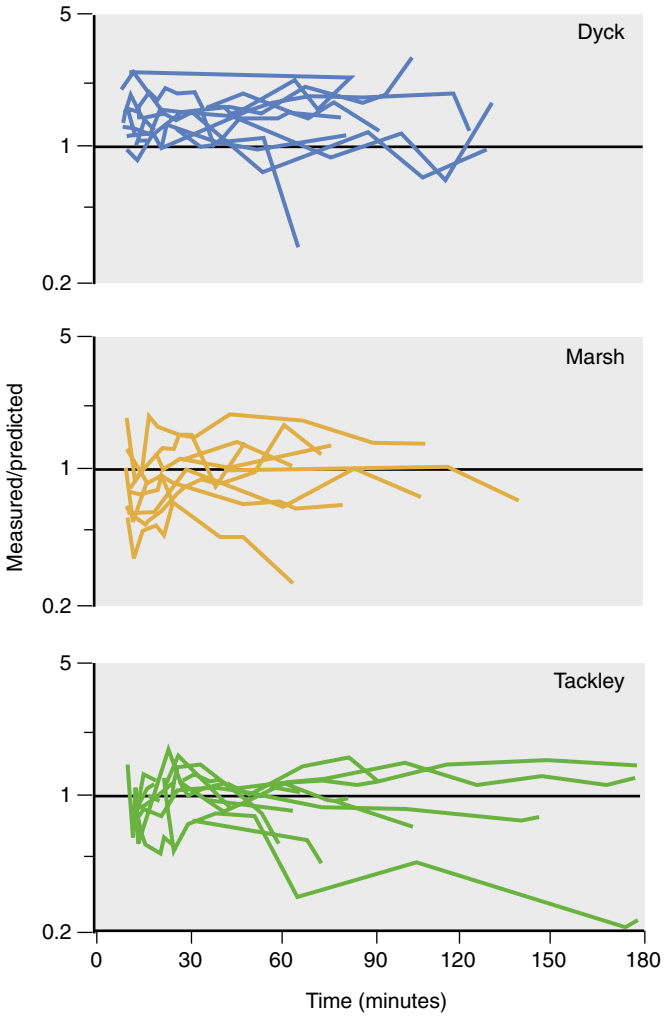

Figure 28-28 Evaluation of three pharmacokinetic parameter sets for propofol. Plotted is the measured-to-predicted ratio for samples obtained during administration of propofol via a target-controlled infusion device programmed with pharmacokinetics derived by Dyck, Marsh, or Tackley (*n* = 10 per group). A ratio of 1 means that measured equals predicted. Note that the pharmacokinetic parameters of Dyck provide a consistently positive bias.

ation of population covariates in determining the model parameters. The implications of such differences are not always obvious and it is therefore important to test the parameter set to determine whether the parameters provide adequate accuracy for clinical use. For example, as shown in Figure 28-30A-C,[85] the accuracy of fentanyl delivered according to the pharmacokinetics reported by Scott and Stanski[30] is much better than the accuracy of fentanyl delivered on the basis of the pharmacokinetics reported by McClain and Hug.[90] Glass and coworkers[58] examined the performance of a pharmacokinetic model–driven infusion device by using the same fentanyl pharmacokinetics described by McClain and Hug.[90] They demonstrated an MDAPE of 21% and an MDPE of +4% (i.e., an almost completely unbiased performance), much better performance than demonstrated by Shafer and associates[85] for the same pharmacokinetic set. This is explained by differences in study methodology, such as arterial versus venous samples, rapid sampling after changes in target concentration versus sampling only when a pseudo–steady state was achieved, and a different set of patients—cardiac versus noncardiac.

With the goal of improving pharmacokinetic model–driven infusion device performance, Shafer and coworkers[85] recalculated the optimal pharmacokinetic parameters of fentanyl directly from the observed concentrations that were obtained when fentanyl was administered via a pharmacokinetic model–driven infusion device by use of the initial pharmacokinetics of McLean and Hug.[90] Figure 28-30C shows the performance errors over time for the optimal fentanyl pharmacokinetics estimated for that population of patients (versus those of McLean and Hug[90] and Scott and associates[30] in the same group of patients). The optimal pharmacokinetic parameter set still had a median residual error of 21% when retrospectively tested against the same group of patients. This represents the limit imposed by pharmacokinetic variability on the possible performance of any fentanyl parameter set for dosing to a similar adult population. In other words, it is unlikely that any fentanyl pharmacokinetic parameter set would produce less than a 21% MDAPE.

Marsh and colleagues[88] took the same approach to optimizing the performance of a pharmacokinetic model–driven infusion device for administration of propofol to children. They initially used a pharmacokinetic parameter set derived from adult subjects in their device and obtained an MDAPE of 25% and an MDPE of −18.5%. They subsequently derived new propofol pharmacokinetics for children and prospectively demonstrated that they had decreased the MDAPE to 16%, with a bias of less than 3%. This is highly accurate performance for a model-based device. Ginsberg and coworkers[91] similarly derived a pharmacokinetic set for fentanyl in children, as did Fiset and associates[92] for alfentanil. Several other studies have also demonstrated that pharmacokinetic parameters vary with certain subsets of patients. For example, the pharmacokinetic parameters of propofol for patients about to undergo open heart surgery are different from the previously verified pharmacokinetic parameters for the general population. These new pharmacokinetic parameters for propofol also vary both during bypass and after bypass.[93] Similarly for patients undergoing liver transplantation, the Marsh pharmacokinetics performs poorly.[94]

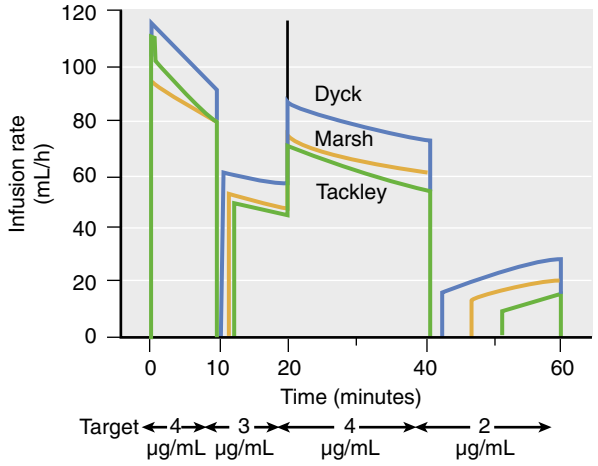

Figure 28-29 Infusion rates (mL/hr) calculated to achieve propofol target concentrations of 4 (10 minutes), 3 (10 minutes), 4 (20 minutes), and 2 μg/mL (20 minutes) based on the three pharmacokinetic parameter sets of Dyck, Marsh, and Tackley.

Anesthesiology 73:1091-1102, 1990.)*

Interest has recently focused on what other factors may be responsible for alterations in pharmacokinetic with the objective of reducing variability and increasing the accuracy of TCI systems. Such factors include, among others, the influence of age, gender, hemorrhagic shock, and administration of a second drug. Numerous studies have investigated the effect of age (both young and old) on pharmacokinetic parameters. For propofol and fentanyl, it has been shown that an adult pharmacokinetic set performs poorly in children and that age-specific parameters improve accuracy.[88,91] Although it is well known that pharmacokinetic parameters are altered in the elderly, it has not been well established whether these changes are sufficiently different to impact the accuracy of the adult parameter sets that are used in a TCI device. The effect of gender on pharmacokinetics has been variable. For propofol, Vuyk and colleagues have recently demonstrated an effect of gender on propofol pharmacokinetic parameters in the elderly.[95] In a pharmacokinetic analysis of several pooled databases of propofol, Schuttler and Ihmsen found that gender was not a significant covariate.[96] Similarly, there is no clear indication that gender has a significant effect on opioids pharmacokinetic parameters. Several authors have looked at the effect of hemorrhagic shock on pharmacokinetic parameters. In a pseudo–steady-state model of propofol, compensated hemorrhage increased propofol concentrations by only 20%; however, when uncompensated shock was induced, propofol concentrations increased by 375%.[97] Using a non–steady-state model, Egan and associates found that hemorrhagic shock reduced central clearance and central volumes of fentanyl[98] and remifentanil,[99] thereby resulting in higher fentanyl concentrations in animals in shock. Investigators have also focused on the impact of simultaneous administration of a second drug, especially another anesthetic. Propofol, midazolam, and etomidate have been shown in in vitro studies to reduce the clearance of opioids because of an interaction on the cytochrome P450 system. In turn, several studies have shown that alfentanil may alter the pharmacokinetic parameters of propofol.[100-102] The exact mechanism of this interaction is unclear. It is unlikely to be related to any interaction with cytochrome P450 systems because the pharmacokinetics of propofol are limited by liver blood flow and thus are not likely to be affected by modest alterations in hepatic metabolic capacity. The differences may

result from alterations in cardiac output or reductions in hepatic blood flow. In contrast with alfentanil, remifentanil at concentrations of 0 to 4 ng/mL did not alter the pharmacokinetics of propofol.[103] However, propofol decreased the central volume of distribution and distributional clearance of remifentanil by 41% and elimination clearance by 15%. Of interest in a study of propofol administered to critically ill patients, two covariates established in the model that best described the pharmacokinetics of these patients were temperature and serum triglyceride concentration for terminal clearance.[104] Not all of the factors that have been shown to alter pharmacokinetic parameters have been associated with a change in outcomes or in the utility of TCI devices. However, some have, and thus in principle, pharmacokinetic sets adapted to the appropriate clinical milieu should be determined for each of the commonly used drugs to enhance the accuracy of TCI drug administration. It is incumbent on users to be aware of which pharmacokinetic set is being used in their TCI system and the reasonableness of this set in providing sufficient accuracy for clinical application in the particular patient in which it is being used.

Not only is there interindividual variability, but there may also be significant intraindividual variability. Hill and colleagues[105] studied volunteers to learn the individual's own pharmacokinetics for morphine and alfentanil. These investigators then used that volunteer's unique pharmacokinetic values to subsequently control a pharmacokinetic model–driven infusion device. With this technique of personalized pharmacokinetics, they reduced the average error to just less than 20%. It appears that studies in which the pharmacokinetics of an individual is used to infuse the same drug to the same individual later result in bias and an MDAPE similar to those seen when an optimal pharmacokinetic set derived from the general population is used. The implication of these data is that although highly specific pharmacokinetic sets are desirable, they may not necessarily improve overall accuracy. They also demonstrate that biologic variability precludes obtaining better than approximately 20% accuracy with TCI devices.

It is unlikely that we will have the opportunity to conduct a full pharmacokinetic study on patients *during a single anesthetic*. However, bayesian forecasting is a statistical technique by which a few measured plasma concentrations from an individual can be incorporated into pharmacokinetic parameters to improve the performance of a pharmacokinetic model–driven infusion device. Maitre and Stanski[106] demonstrated the theoretical improvement in such devices when using bayesian forecasting for alfentanil. In this study, Maitre and Stanski demonstrated that measurement of a single plasma alfentanil concentration could potentially reduce the inaccuracy by half, to a 14% average performance error. Unfortunately, a rapid assay does not exist for any of the intravenous drugs used in anesthetic practice. However, there are rapid assays for lidocaine, and at least one pharmacokinetic model–driven infusion device (STANPUMP, developed by Shafer and Maitre at Stanford and available at http://anesthesia.stanford.edu/pkpd) performs real-time bayesian forecasting from measured lidocaine levels for use in coronary care units.

In the absence of rapid assays for anesthetic drugs, the obvious method to decrease variability is to observe the drug effect and adjust the target to the concentration that produces the desired level of drug effect.[17,18] As discussed earlier under "Pharmacodynamic Considerations," by knowing the rate constant k_{e0}, it is possible to model the concentration at the site of drug effect. Figure 28-31 shows the plasma fentanyl concentrations that could theoretically be obtained over the course of a brief operation. Figure 28-31B shows the fentanyl concentrations at the effect site for the same anesthetic shown in Figure 28-31A. Even if the pump produced precisely the concentrations shown in Figure 28-31A (i.e., had perfect performance), the lag between concentrations in plasma and the site of drug effect would, at best, produce a very slurred response because of the delay in equilibration between plasma and the effect site. Several pharmacokinetic model–driven infusion devices now simultaneously display both plasma and effect-site concentrations. Such devices permit the clinician to target the concentration in the effect site rather than plasma to provide more precise control of drug effect.

By targeting the effect site there is an overshoot in the plasma concentration of the drug. The k_{e0} used to model the effect site for intravenous anesthetics has been derived from surrogate measures of effect (i.e., derivatives of the EEG). Thus, for TCI devices that target the effect site, it is important to establish that the k_{e0} value used actually results in the desired effect. Glass[107] and Struys[108] and their colleagues conducted similar studies in which they targeted either plasma or an effect-site concentration of propofol and then observed the time and plasma versus effect-site concentration at loss of consciousness. In both studies, regardless of whether the effect-site or plasma concentration was targeted,

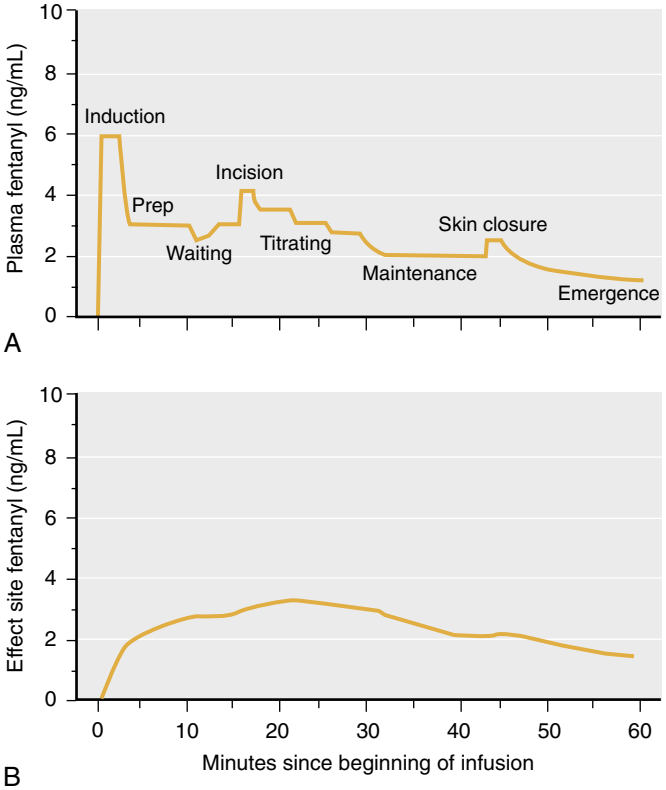

Figure 28-31 **A,** Simulated plasma fentanyl concentrations over time for a brief anesthetic showing the rapid rise and fall and impression of precise titration that can be created by a target-controlled drug delivery device. **B,** Effect-site concentrations for the same anesthetic course demonstrating that precise control of the plasma concentration does not necessarily translate into precise control at the site of drug effect. *(Adapted from Shafer SL, Gregg K: Algorithms to rapidly achieve and maintain stable drug concentrations at the site of drug effect with a computer controlled infusion pump. J Pharmacokinet Biopharm 20:147-169, 1992.)*

loss of consciousness occurred when the appropriate *effect-site* concentration for loss of consciousness was achieved, thus validating the concept. Two other important observations were made during these studies. First, hemodynamics was not different whether plasma or the effect site was targeted, even though higher plasma concentrations were achieved in the effect-site group. This implies, at least for propofol, that the time course for its hemodynamic effects is similar (or longer)[109] to that for its anesthetic effects. Second, k_{e0} is dependent on the pharmacokinetic set from which it is derived.[110] One cannot take a k_{e0} value from one pharmacokinetic set and use it with another pharmacokinetic set. Just as various demographics may alter the pharmacokinetics, they may also alter k_{e0}. Hence, it is desirable to use the k_{e0} best adapted for the clinical milieu. An ideal test of whether targeting plasma or the effect site is better is to compare their use in a closed-loop system where a measure of effect (e.g., the BIS) is used as the target of control. In a small study of 10 patients per group, Absalom and Kenny showed that maintenance of the targeted BIS (as measured by MDPE, MDAPE, and wobble) was somewhat improved and induction times were significantly shorter when the pharmacokinetic model was for the effect site rather than plasma.[111]

In summary, automated drug delivery devices appear to be able to achieve and maintain desired plasma concentrations with a median expected error of about 20% to 30% of the target. Although pharmacokinetic analysis after automated drug delivery results in a reduction in the median error to closer to 20% in adults and possibly lower in children, biologic variability sets a limit on the expected accuracy of these devices. More accurate performance could be obtained with bayesian feedback and the use of rapid intraoperative assays, but this is unavailable for the intravenous drugs used in anesthetic practice. However, the delay in equilibration between plasma and the effect site is such that excessive focus on plasma concentrations may be unwarranted. Instead, learning about the pharmacokinetic/pharmacodynamic characteristics of the specific patient by titrating to a readily measured drug effect appears to be the most promising method for optimizing the performance of automated drug delivery devices to the clinical needs of the individual patient.

Outcome

Evaluation of outcome with TCI devices is more difficult than evaluation of accuracy because of the difficulty of precisely measuring patient outcome. Because contemporary anesthetic practice produces very little morbidity, outcome measures are usually based on readily measured variables, such as blood pressure, heart rate, and duration of recovery room stay, rather than on substantive measures of patient morbidity. Evaluation of outcome with automated drug delivery devices requires a comparison of manual methods of administration of the same drug with automated drug delivery of intravenous anesthetics and volatile anesthetics. Several studies have evaluated administration of intravenous anesthetics by automated drug delivery devices for both brief and complex surgery, in children and in adults, in short-term sedation, in prolonged sedation (days), and in chronic pain management.

Two decades ago, Ausems and coworkers[9] compared pharmacokinetic model–driven administration with intermittent bolus administration of alfentanil. Automated drug delivery produced fewer episodes of muscular rigidity, hypotension, and bradycardia on induction. Automated drug delivery during maintenance resulted in a significantly lower incidence of hemodynamic response, which resulted in a greater percentage of anesthesia time within 15% of the desired blood pressure and heart rate. Recovery after TCI was associated with significantly less use of naloxone for adequate ventilation.

Pharmacokinetic model–driven infusion of fentanyl during cardiac surgery resulted in better hemodynamic control with fewer additional drug interventions and significantly fewer episodes of either hypotension or hypertension than occurred with bolus dose administration.[86] A small study comparing manual alfentanil administration with pharmacokinetic model–driven infusion of alfentanil showed no statistical differences during maintenance or recovery.[112] Theil and colleagues[113] compared double-blind manual administration of fentanyl/midazolam with pharmacokinetic model–driven infusion of these two anesthetics in a small group of patients undergoing cardiac surgery. Both systems were titrated simultaneously (one containing placebo), with the aim of maintaining hemodynamics within 20% of baseline values. Both systems were equally effective in providing hemodynamic control as dictated by the protocol. The most significant difference between the two modes of delivery was the greater variability in drug plasma concentrations in the manual group. This suggested that pharmacokinetic model–driven infusion maintained patients within a narrower therapeutic range.

Several comparative studies have been performed with the commercial TCI device for propofol. Struys and colleagues[114] ($N = 90$), Russel and colleagues[115] ($N = 160$), and Servin,[116] in a large multicenter study ($N = 562$), found when they compared manual infusion of propofol with TCI administration that there were small differences between the two means of propofol administration. Of interest in the TCI groups, the maintenance infusion rate tended to be higher, which was associated with a lower incidence of patient movement. Both Servin and Russel and their coworkers noted that there was a marked preference of clinicians for the TCI system, even though this was their first use of the device. In contrast, when TCI propofol or manual propofol was titrated to a target BIS, no differences were observed between the two groups.[117] Remifentanil delivered manually and by TCI has also been evaluated in patients undergoing carotid surgery.[118] TCI remifentanil provided improved hemodynamic control both intraoperatively and postoperatively with less remifentanil and similar propofol infusion rates. As discussed, targeting the plasma concentration does not provide optimal control of effect. When manual propofol administration has been compared with target effect-site administration, there was a lower incidence of movement, improved hemodynamic stability, and more rapid recovery with the latter.[119]

Pharmacokinetic model–driven infusion of propofol compares favorably with thiopental/isoflurane anesthesia for general surgery lasting several hours.[120] Induction, maintenance, and recovery were similar between the two groups. Godet and colleagues compared sevoflurane, propofol followed by isoflurane, and TCI propofol in patients undergoing carotid surgery. They found minor differences in hemodynamics that tended to favor TCI propofol and no differences in recovery parameters.[121] Sneyd and coworkers compared TCI propofol with sevoflurane in patients undergoing neurosurgical procedures and similarly found little difference between the two techniques.[122] This implies that given the appropriate means for administration, intravenous anesthetics can be equal to inhaled anesthetics in providing the objectives of anesthesia, that is, rapid induction and recovery with stable maintenance. Suttner and associates examined the cost and

recovery characteristics of target-controlled propofol infusion regimens and standard methodologies.[123] They found that "target-controlled infusion/total IV anesthesia was associated with the largest intraoperative costs but allowed the most rapid recovery from anesthesia, was associated with fewest postoperative side effects, and permitted earlier discharge from the postanesthesia care unit."

In noncomparative studies, pharmacokinetic model–driven infusion has been used to administer most of the potent opioids, as well as the hypnotics. Different anesthetic techniques have also been tested with pharmacokinetic model–driven infusion devices, including nitrous-opioid anesthesia, supplementation of volatile anesthetics, total intravenous anesthesia, sedation for monitored anesthesia care, and intensive care unit sedation. In all these studies, outcome, as measured by hemodynamics and recovery, has been within the expectations of normal clinical care. Etomidate, methohexital, midazolam, propofol, thiopental, dexmedetomidine, alfentanil, fentanyl, remifentanil, and sufentanil have all been used with TCI. When these drugs were used with target-controlled drug delivery systems for total intravenous anesthesia or to supplement nitrous oxide or volatile anesthetics, hemodynamics was well maintained during induction and intubation, as well as during maintenance. Recovery milestones were reached at times comparable to those achieved with similar drug combinations used in manual infusion schemes. In none of these studies have authors commented on adverse outcomes resulting from target-controlled drug delivery.

TCI devices have also been used to provide patient-controlled analgesia. Hill and colleagues studied patient-controlled analgesia devices using morphine, fentanyl, or alfentanil[105,124] and demonstrated the clinical utility of such devices.[125-128] Van den Nieuwenhuyzen and colleagues[44] demonstrated advantages of such a system with alfentanil over routine morphine patient-controlled anesthesia.

From the body of literature presently available, it appears that automated drug delivery of intravenous anesthetics is at least equal to manual delivery of these drugs. Intravenous drug administration via target-controlled drug delivery is analogous to inhaled vapor delivery via a calibrated vaporizer. Like the vaporizer, pharmacokinetic model–driven infusion facilitates drug delivery based on plasma or biophase concentration rather than on drug dosage. There is variability with the use of a calibrated vaporizer, including variability in the accuracy of drug delivery with vaporizers, slow equilibration between the fresh gas flow and the circuit at low flow rates, and variable uptake by the patient. This variability does not particularly complicate the titration of inhaled anesthetics. The variability with target-controlled drug delivery is of a similar magnitude and can be demonstrated to be less than the variability associated with vaporizers, and likewise, it does not particularly complicate titration of intravenous anesthetics. Indeed, the time-varying stresses of surgery and the variability in patient response require that the anesthesiologist titrate the administration of potent inhaled anesthetics by using the calibrated vaporizer as a tool. These same factors require that the anesthesiologist vigilantly titrate the infusion of intravenous anesthetic drugs when using automated drug delivery as a tool.

Target-controlled drug delivery has advantages beyond a delivery system to simplify the clinical administration of intravenous anesthetics. Another significant contribution of these delivery devices is their use in research. The pseudo–steady state that can be almost instantly achieved with these devices permits the plasma and effect site to rapidly come into equilibrium. This is critically important in studies examining concentration-response relationships (i.e., C_{50} values) for anesthetic drugs.[9,24,42] In addition, these systems enable interactions involving intravenous drugs to be clearly defined.[54-56] Closed-loop target delivery will eventually enable unbiased and more precise comparisons between drugs. Finally, as noted earlier, target-controlled delivery has provided us with the ability to prospectively test pharmacokinetic parameter sets and modeling approaches and may ultimately provide the most suitable pharmacokinetic parameters for any intravenous drug delivery.[85,88,92,129]

Closed-Loop Drug Delivery Systems

The next step in automated drug delivery is to feed the measured drug effect directly back into the automated drug delivery device so that the model can be updated from observed measures of drug effect, thus providing a closed-loop system.[3-7,130-137] In this instance the set point is the measured effect rather than a particular drug concentration. It has been proposed that closed-loop control of anesthesia may provide several advantages: increased stability of the control variable because of more frequent sampling of the effect with more frequent adjustment of drug delivery; more customized dose delivery to account for interindividual pharmacokinetic and pharmacodynamic differences; and as a result of the first two advantages, improvement in hemodynamic stability, inadvertent awareness, and recovery.[137]

Closed-loop systems fall into two general categories. All controllers are based on measuring the error between the target effect and the observed effect. Conventional "proportional/integral/derivative" (PID) controllers adjust the infusion rates in a manner that is proportional to the magnitude of the error, the integral of the error over time, and the derivative of the error over time. A "model-based" controller has an internal model of the system, typically set up as an integrated pharmacokinetic/pharmacodynamic model relating dose to concentration (pharmacokinetics) and concentration to drug effect (pharmacodynamics). The model is updated to explain the difference between the measured and predicted drug effect.

An example of the model-based approach is the system described by Struys and colleagues in which the response to a loading propofol bolus was used to estimate the sigmoidal concentration-versus-effect relationship for the individual patient.[134] As shown in Figure 28-32, the device starts with a population estimate that a particular concentration, C_1, will produce the desired effect. It then monitors the drug effect in response to the initial bolus of propofol. As shown by point X, the patient did not reach the desired effect at an effect-site concentration of C_1. The device recalculates the shape of the concentration-versus-response relationship and determines that C_2 is the proper target effect-site concentration. The device then raises the target concentration to C_2 to produce the desired effect.

Bayesian optimization is used in pharmacokinetic-dynamic modeling to individualize a drug dosing regimen by combining individual information with the knowledge of an a priori probability density function containing the statistical properties of the parameter to be estimated. These values are adjusted to reflect the patient's own parameters over time based on the observed response of the individual patient under varying circumstances. In a simulation study, De Smet and colleagues compared a PID

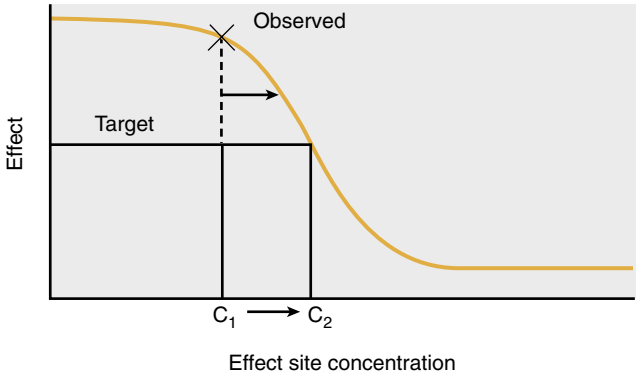

Figure 28-32 Real-time model–based adjustment of the "Hill equation" describing the relationship between propofol concentration and hypnotic effect. The system sets a target concentration and starts out with an assumed value of the effect-site concentration, C_1, needed to reach the effect. After administering an adequate dose, the system discovers that the desired effect has not been reached. It then re-estimates the concentration-versus-effect relationship based on the observed data point (X) and now has a more precise estimation of the concentration, C_2, required to reach the desired effect. *(Adapted from Struys MM, De Smet T, Versichelen LF, et al: Comparison of closed-loop controlled administration of propofol using bispectral index as the controlled variable versus "standard practice" controlled administration. Anesthesiology 95:6-17, 2001.)*

controller with a bayesian model–based controller, both targeting a BIS of 30, 50, and 70.[138] They demonstrated robust performance under a variety of challenging scenarios.

As mentioned earlier, the ability to measure adequacy of anesthesia is limited. Anesthesia is a composite of several effects: hypnosis or loss of consciousness, amnesia, analgesia, lack of movement, and hemodynamic stability. There are now several derivatives of the EEG that show a strong correlation with hypnosis/loss of consciousness. Fortunately, amnesia is also reflected by the EEG signal and appears to precede the derived EEG values associated with drug-induced loss of consciousness. The major component of anesthesia for which we do not have a monitor of effect is analgesia. This continues to constitute an impediment to the general application of closed-loop anesthesia. Noxious stimuli during surgery are extremely variable. Intravenous hypnotics (with the exception of ketamine and dexmedetomidine) have limited or no analgesic activity. Thus, a closed-loop system based solely on a derivative of the EEG may provide perfect hypnosis in the absence of a stimulus, but awakening and movement are likely to occur as soon as a noxious stimulus is administered. To overcome this hurdle, investigators have taken several approaches to test closed-loop systems for anesthesia in patients. They have been used in combination with a regional anesthetic, thereby preventing any painful stimulus from reaching the brain. Most have used a low-dose constant opioid concentration for superficial surgery or a high-dose opioid concentration for more extensive surgery. Another interesting approach is a combination of an analgesic concentration of opioid and application of a noxious stimulus (e.g., tetany) at regular short intervals to minimize oscillations as a result of surgical stimuli.

It is unclear whether closed-loop systems offer any benefits over open-loop TCI systems. Morley and coworkers compared closed-loop administration of isoflurane or a propofol/alfentanil mixture and manual control of these agents to provide a BIS of 50.[139] The closed-loop system used a PID control algorithm. The authors were unable to demonstrate any advantage of their closed-loop system over manual control when intraoperative control of the BIS, hemodynamic stability, intraoperative drug use, or recovery parameters were used as measures of outcome. More recently, Locher and coworkers demonstrated that their closed-loop system for controlling the BIS with isoflurane provided significantly better performance than manual isoflurane administration did in terms of periods of inadequate control (BIS >65 for longer than 3 minutes) or time beyond a BIS of less than 40 or a BIS greater than 60.[140]

Struys and associates also performed a study to determine whether there are any advantages of a closed-loop system over manual administration of propofol for lower abdominal surgery.[134] The closed-loop control group achieved statistically significant better control of both its control variable (BIS, 89% ± 10%) and systolic pressure (51% ± 27%) than the manual group did (systolic pressure, 34% ± 31%; BIS, 49% ± 29%). In addition, recovery was also improved in the closed-loop group (Fig. 28-33). This study does not definitively answer whether closed-loop delivery of anesthesia is better than any manual system, nor does it define what an optimal closed-loop control system is; however, its results are encouraging and should further stimulate work on developing closed-loop anesthetic drug delivery for day-to-day anesthesia.[141]

In a multicenter study of 164 patients randomized to either closed-loop control of propofol or manual TCI propofol with a target BIS of 40 to 60, Lin and colleagues found that the closed-loop system performed significantly better in nearly all performance metrics: lower overall drug dose, BIS closer to the target level throughout anesthesia, and faster recovery.[142] During maintenance the control system made more frequent and smaller adjustments in the propofol dose and enabled more rapid recovery to endotracheal extubation. The performance parameters MDPE, MDAPE, and wobble, as well as the percentage of time that the BIS was maintained between 40 and 60, was significantly better in the closed-loop group. This study demonstrated the feasibility of using a closed-loop system in daily anesthesia practice with a large variation in age and patient comorbid conditions.

Closed-loop control is also a valuable investigative tool. It can be used to determine the unbiased interaction between two drugs. It has been used with neuromuscular blockers to determine their interaction with various anesthetics.[143,144] Similarly, closed-loop control can be used to determine the interaction between opioids and intravenous anesthetics.[145,146] Closed-loop systems may also have the potential to diagnose different pathologic states based on drug dosing. Albrecht and coworkers observed that when using closed-loop sedation with propofol, trauma patients required lower EEG set points and needed more propofol to achieve the same level of sedation.[147] As the number of investigators who have access to closed-loop systems for anesthesia increases, the utility of such devices for research is likely to increase substantially.

Summary

When compared with intermittent bolus administration, continuous infusion of intravenous anesthetic drugs provides greater control of anesthetic depth, thus ensuring (1) better hemodynamic control with fewer episodes of hemodynamic instability, (2) smaller total drug doses, and (3) more rapid return to the awake state. Improved drug administration techniques combined with several new intravenous anesthetic agents have provided greater impetus for the use of intravenous anesthesia in clinical practice. Devices for the administration of intravenous

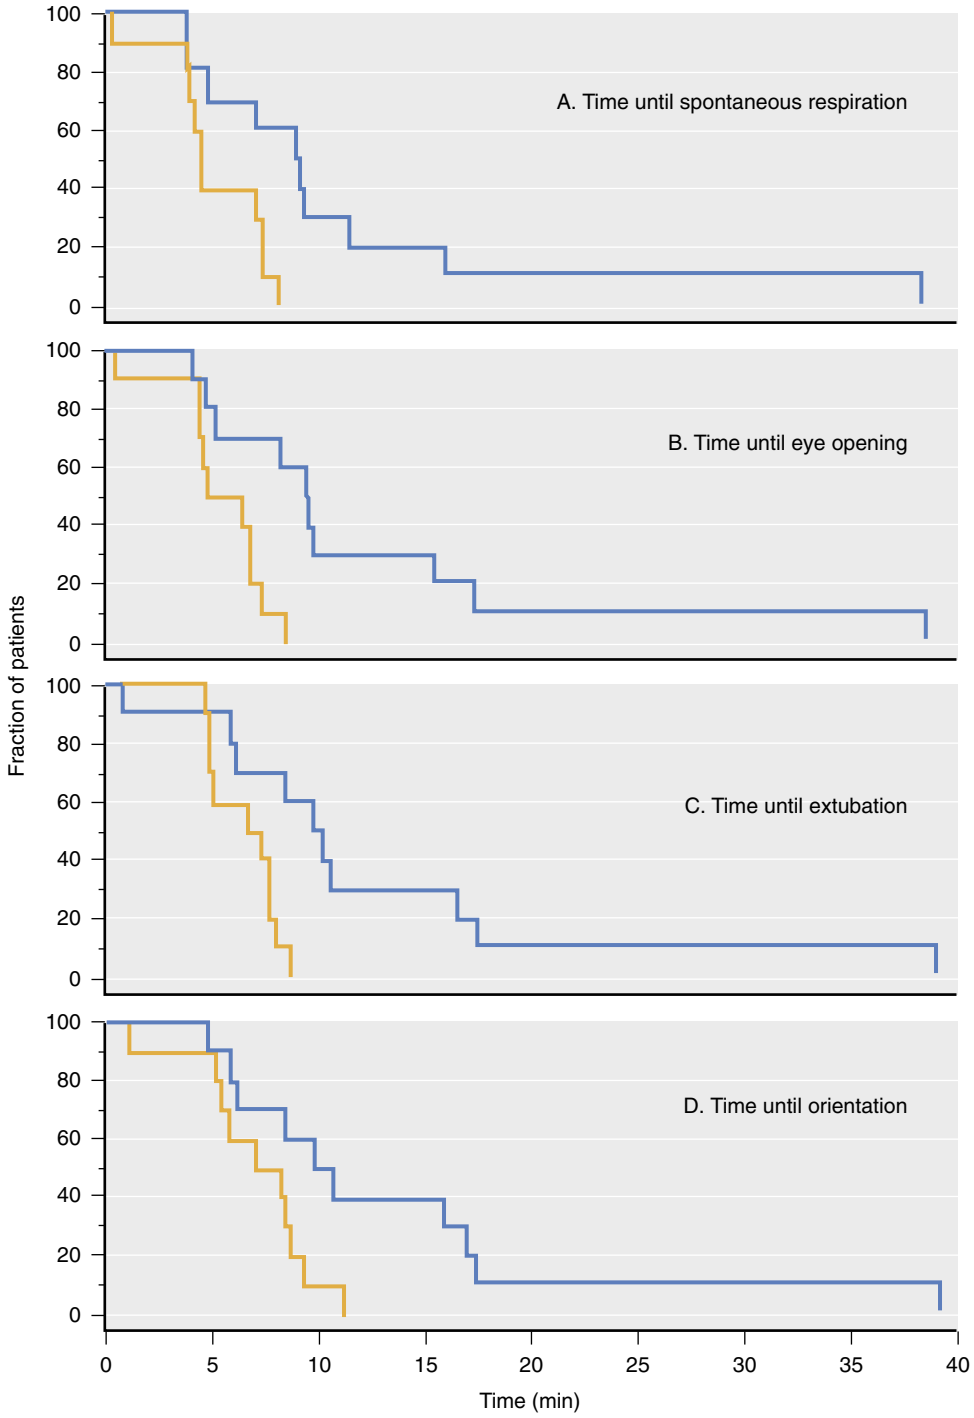

Figure 28-33 Comparison of manual and closed-loop anesthetic control on the time course of return of spontaneous ventilation (**A**), eye opening (**B**), extubation (**C**), and orientation (**D**). In each case, the more rapid curve is the closed-loop control, and the slower curve is the manual control. *(Adapted from Struys MM, De Smet T, Versichelen LF, et al: Comparison of closed-loop controlled administration of propofol using bispectral index as the controlled variable versus "standard practice" controlled administration. Anesthesiology 95:6-17, 2001.)*

anesthetics are continuing to evolve. The introduction of pumps designed specifically for continuous intravenous delivery of anesthetic drugs has enhanced intravenous anesthesia. Automated drug delivery is becoming routine in many countries. There are several theoretical advantages of pharmacokinetic model–driven infusion over manual infusion systems, such as further improvements in hemodynamic control and more predictable rapid awakening. Studies comparing outcomes with automated drug delivery of intravenous anesthetics versus manual methods or inhaled anesthetics have either demonstrated improved outcome or been equivocal. No studies have identified clinical or safety problems with automated anesthetic drug delivery. It thus appears that pharmacokinetic model–driven infusion systems, though limited by the same biologic variability that affects manual drug delivery, are safe and effective in clinical use.

With the advent of monitors of hypnosis and increased understanding of the components of anesthesia, closed-loop drug delivery for anesthesia is showing promise to provide further advantages. Many hurdles still need to be overcome before such devices will come into routine use. However, present knowledge and the results of recent studies are sufficiently encouraging to pursue this goal.

29 Pharmacology of Muscle Relaxants and Their Antagonists

Key Points

1. Two different populations of nicotinic acetylcholine receptors exist at the mammalian neuromuscular junction. In adults, the nicotinic acetylcholine receptor at the postsynaptic (muscular) membrane is composed of $\alpha_2\beta\delta\varepsilon$-subunits. Each of the two α-subunits has an acetylcholine binding site. The presynaptic (neuronal) nicotinic receptor is also a pentameric complex composed of $\alpha_3\beta_2$-subunits.
2. Nondepolarizing muscle relaxants produce neuromuscular blockade by competing with acetylcholine for postsynaptic α-subunits. In contrast, succinylcholine produces prolonged depolarization that results in decreased sensitivity of the postsynaptic nicotinic acetylcholine receptor and inactivation of sodium channels so that propagation of the action potential across the muscle membrane is inhibited.
3. Different forms of neuromuscular stimulation test for neuromuscular blockade at different areas of the motor end plate. Depression of the response to single-twitch stimulation is probably due to blockade of postsynaptic nicotinic acetylcholine receptors, whereas fade in the response to tetanic and train-of-four stimuli results from blockade of presynaptic nicotinic receptors.
4. Succinylcholine is the only available depolarizing neuromuscular blocker. It is characterized by rapid onset of effect and ultrashort duration of action because of its rapid hydrolysis by butyrylcholinesterase.
5. The nondepolarizing neuromuscular blockers available can be classified according to chemical class (steroidal, benzylisoquinolinium, or other compounds) or, alternatively, according to onset or duration of action (long-, intermediate-, and short-acting drugs) of equipotent doses.
6. The speed of onset is inversely proportional to the potency of nondepolarizing neuromuscular blocking agents. With the exception of atracurium, molar potency is highly predictive of a drug's rate of onset of effect. Rocuronium has a molar potency ($ED_{95} \approx 0.54$ μM/kg) that is about 13% that of vecuronium and 9% that of cisatracurium. Its onset of effect is more rapid than that of either of these agents.
7. Neuromuscular blockade develops faster, lasts a shorter time, and is recovered from more quickly in the more centrally located neuromuscular units (e.g., laryngeal adductors, diaphragm, and masseter muscle) than in the more peripherally located adductor pollicis.
8. The long-acting neuromuscular blockers undergo minimal or no metabolism, and they are eliminated, largely unchanged, primarily by renal excretion. Neuromuscular blockers with an intermediate duration of action have more rapid clearance than the long-acting agents do because of multiple pathways of degradation, metabolism, and elimination. Mivacurium, a short-acting neuromuscular blocker, is cleared rapidly and almost exclusively via metabolism by butyrylcholinesterase.
9. After the administration of nondepolarizing neuromuscular blocking agents, it is essential to ensure adequate return of normal neuromuscular function. Residual paralysis decreases upper esophageal tone, coordination of the esophageal musculature during swallowing, and the hypoxic ventilatory drive.

History and Clinical Use

In 1942, Griffith and Johnson[1] suggested that *d*-tubocurarine (dTc) is a safe drug to use during surgery to provide skeletal muscle relaxation. One year later, Cullen[2] described its use in 131 patients who had received general anesthesia for their surgery. In 1954, Beecher and Todd[3] reported a sixfold increase in mortality in patients receiving dTc in comparison with those who had not received a relaxant. The increased mortality was due to a general lack of understanding of the pharmacology of neuromuscular blockers and their antagonism. The effect of residual neuromuscular blockade postoperatively was not appreciated, guidelines for monitoring muscle strength had not been established, and the importance of pharmacologically antagonizing any residual blockade was not understood.

Succinylcholine, introduced by Thesleff[4] and Foldes and colleagues[5] in 1952, changed anesthetic practice drastically. Its rapid onset of effect and ultrashort duration of action permitted rapid endotracheal intubation.

In 1967, Baird and Reid[6] first reported on clinical administration of the synthetic aminosteroid pancuronium.

Development of the intermediate-acting neuromuscular blockers built on the compounds' metabolism and resulted in the introduction of vecuronium,[7] an aminosteroid, and atracurium,[8] a benzylisoquinolinium, into clinical practice in the 1980s.

Mivacurium, the first short-acting nondepolarizing neuromuscular blocker, was introduced into clinical practice in the 1990s,[9] as was rocuronium,[10] an intermediate-acting nondepolarizing blocker with rapid onset of effect.

Other neuromuscular blockers have been introduced into clinical practice since the use of dTc was first advocated. Such blockers include pipecuronium, doxacurium, cisatracurium, and rapacuronium. Although all do not remain in use, each represented an advance or improvement in at least one aspect over its predecessors. Still other neuromuscular blockers, such as gantacurium,[11] are undergoing investigation.

Neuromuscular blockers should be administered only to anesthetized individuals to provide relaxation of skeletal muscles. They should not be administered to stop patient movement because they have no analgesic or amnestic properties. Awareness during surgery[12] and in the intensive care unit (ICU)[13] has been described in multiple publications. Neuromuscular blockers are valuable adjuncts to general anesthetics and should be used as such. As stated by Cullen and Larson, "muscle relaxants given inappropriately may provide the surgeon with optimal [operating] conditions in … a patient [who] is paralyzed but not anesthetized—a state that [is] wholly unacceptable for the patient." Additionally, "muscle relaxants used to cover up deficiencies in total anesthetic management … represent an … inappropriate use of the valuable adjuncts to anesthesia." To administer relaxants for maintenance of neuromuscular blockade intraoperatively, the patient's depth of neuromuscular blockade must be monitored and the depth of anesthesia continuously assessed.

That said, the use of neuromuscular blockers in the operating room is quite common and has been important in the growth and development of anesthesia and surgery. As stated by Foldes and colleagues,[5] "… [the] first use of … muscle relaxants … not only revolutionized the practice of anesthesia but also started the modern era of surgery and made possible the explosive development of cardiothoracic, neurologic, and organ transplant surgery." Certainly, neuromuscular blockers are now used routinely to facilitate endotracheal intubation and mechanical ventilation and are commonly used to maintain neuromuscular blockade through any number of different surgical procedures. This chapter reviews the pharmacology and clinical use of neuromuscular blocking agents and anticholinesterases in the anesthesia and intensive care settings. Finally, the economics of providing neuromuscular blockade is considered.

Principles of Action of Neuromuscular Blockers at the Neuromuscular Junction

For a comprehensive overview of neuromuscular blocker effects, see Chapter 14. This section provides a brief introduction to the principles of action of these agents. In the following, a brief introduction is made for the purpose of this chapter.

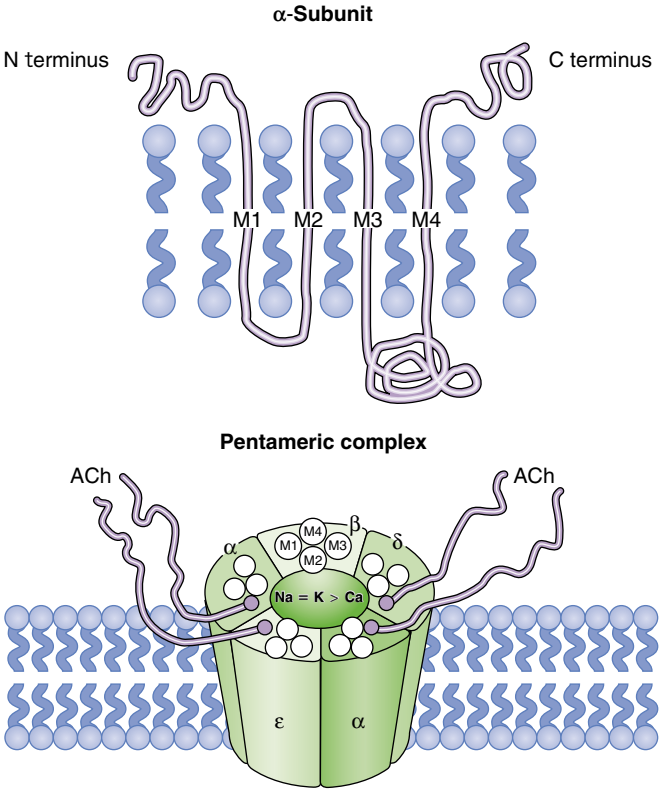

Figure 29-1 Subunit composition of the nicotinic acetylcholine (ACh) receptor (nAChR) in the end-plate surface of adult mammalian muscle. The adult AChR is an intrinsic membrane protein with five distinct subunits ($\alpha_2\beta\delta\varepsilon$). Each subunit contains four helical domains, labeled M1 to M4. The M2 domain forms the channel pore. The *upper panel* shows a single α-subunit with its N and C termini on the extracellular surface of the membrane lipid bilayer. Between the N and C termini, the α-subunit forms four helices (M1, M2, M3, and M4) that span the membrane bilayer. The *lower panel* shows the pentameric structure of the nAChR of adult mammalian muscle. The N termini of two subunits cooperate to form two distinct binding pockets for ACh. These pockets occur at the ε-α– and the δ-α–subunit interface. The M2 membrane-spanning domain of each subunit lines the ion channel. The doubly liganded ion channel has equal permeability to Na^+ and to K^+; Ca^{2+} contributes approximately 2.5% to the total permeability. *(From Naguib M, Flood P, McArdle JJ, Brenner HR: Advances in neurobiology of the neuromuscular junction: Implications for the anesthesiologist. Anesthesiology 96:202-231, 2002, with permission from Anesthesiology.)*

Postjunctional Effects

In adult mammalian skeletal muscle, the nicotinic acetylcholine receptor (nAChR) is a pentameric complex of two α-subunits in association with single β-, δ-, and ε-subunits (Fig. 29-1). These subunits are organized to form a transmembrane pore (i.e., a channel), as well as extracellular binding pockets, for acetylcholine and other agonists or antagonists.[14] Each of the two α-subunits has an acetylcholine binding site. These sites are proteins located in pockets approximately 3.0 nm above the surface membrane at the interfaces of the α_H-ε- and α_L-δ-subunits.[15] α_H and α_L indicate the high- and low-affinity binding sites, respectively, for dTc and probably result from the contribution of the different neighboring subunits.[16] For instance, the binding affinity of dTc for the α_H-ε site is approximately 100 to 500 times higher than that for the α_L-δ site.[16] The fetal nAChR contains a γ-subunit instead of an adult ε-subunit. The mature nAChR has a shorter

burst duration and higher conductance for Na^+, K^+, and Ca^{2+} than the fetal nAChR does.[14]

Functionally, the ion channel of the acetylcholine receptor is closed in the resting state. Simultaneous binding of two acetylcholine molecules to the α-subunits initiates conformational changes that open the channel. On the other hand, it is enough for one molecule of a nondepolarizing neuromuscular blocker (i.e., a competitive antagonist) to bind to one subunit to produce blockade. Paul and coworkers[17] found a correlation between the ED_{50} (the dose that produces a 50% depression in twitch tension) and the potency of nondepolarizing blockers at the adult nAChR.

Depolarizing neuromuscular blockers such as succinylcholine produce prolonged depolarization of the end-plate region, which results in (1) desensitization of the nAChR, (2) inactivation of voltage-gated sodium channels at the neuromuscular junction, and (3) increases in potassium permeability in the surrounding membrane. The end result is failure of action potential generation, and blockade ensues. It should be noted that although acetylcholine produces depolarization, it results in muscle contraction under physiologic conditions because it has a very short duration of action (a few milliseconds). Acetylcholine is rapidly hydrolyzed by acetylcholinesterase to acetic acid and choline. Administration of large doses of acetylcholine to experimental animals, however, produces neuromuscular blockade.

The fetal nAChR is a low-conductance channel, in contrast to the high-conductance channel of the adult nAChR. Thus, release of acetylcholine causes brief activation and a reduced probability of opening of the channel.[14] The upregulation of nAChRs found in states of functional or surgical denervation is characterized by the spreading of predominantly fetal-type nAChRs. These receptors are resistant to nondepolarizing neuromuscular blockers and more sensitive to succinylcholine.[18] When depolarized, the immature isoform has a prolonged open channel time that exaggerates the efflux of K^+.[19]

Prejunctional Effects

Prejunctional receptors are involved in modulating the release of acetylcholine in the neuromuscular junction. The existence of both nicotinic and muscarinic receptors on motor nerve endings has been described. Bowman[20] suggested that the prejunctional nicotinic receptors are activated by acetylcholine and function in a positive-feedback control system that serves to maintain the availability of acetylcholine when demand for it is high (e.g., during tetany).[20] Blockade of these receptors by nondepolarizing neuromuscular blockers would explain the "fade" phenomenon seen with tetanic and train-of-four (TOF) stimulation (four stimuli delivered over a period of 2 seconds).[20,21] The G protein–coupled muscarinic receptors are also involved in feedback modulation of acetylcholine release.[22] The prejunctional muscarinic M_1 and M_2 receptors are involved in facilitation and inhibition of acetylcholine release, respectively, via modulation of Ca^{2+} influx.[22] The prejunctional nicotinic receptors are involved in mobilization of acetylcholine but not directly in the release process.[23] Hence, blockade of the prejunctional nicotinic receptors by nondepolarizing neuromuscular blockers prevents acetylcholine from being made available fast enough to support tetanic or TOF stimulation. In contrast, the prejunctional muscarinic receptors are involved in upregulation or downmodulation of the release mechanism.

Monitoring Neuromuscular Function

Details of monitoring neuromuscular function are discussed in Chapter 47. In this chapter, only the general concepts of monitoring as they relate to the clinical use of neuromuscular blockers are presented.

Monitoring of neuromuscular function after the administration of neuromuscular blocking agents is extremely important for appropriate dosing of these agents and for better guaranteeing patient safety. In the operating room or ICU, the depth of neuromuscular blockade is typically monitored by observing the response to stimulation of any superficially located neuromuscular unit. Most commonly, contraction of the adductor pollicis muscle associated with stimulation of the ulnar nerve, either at the wrist or at the elbow, is monitored. In certain circumstances, depending on patient positioning, when access to the patients' arms may be limited or because of the nature of the patient's injury, the peroneal nerve or the facial nerve may be monitored.

The pattern of response to TOF stimulation or a tetanic stimulus varies with the type of neuromuscular blocker administered because of the different mechanisms of action of the two relaxant types, depolarizing and nondepolarizing. With complete blockade, no response to either mode of stimulation should occur. However, during partial neuromuscular blockade, different responses to these modes of stimulation are seen, depending on the agent administered. Nondepolarizing neuromuscular blocking agents are competitive inhibitors of the acetylcholine receptor and compete with acetylcholine for the active, or binding, sites on the α-subunits of the receptor. Because of a decrease in the amount of acetylcholine released from the prejunctional nerve terminal with repetitive or intense stimulation, the response to stimulation fades over time. The fourth response to a TOF stimulus is decreased relative to the first response (Fig. 29-2) because the lesser amount of acetylcholine released into the synaptic cleft with the fourth stimulus cannot overcome the competitive blockade as readily. Similarly, fading is seen in response to tetanic

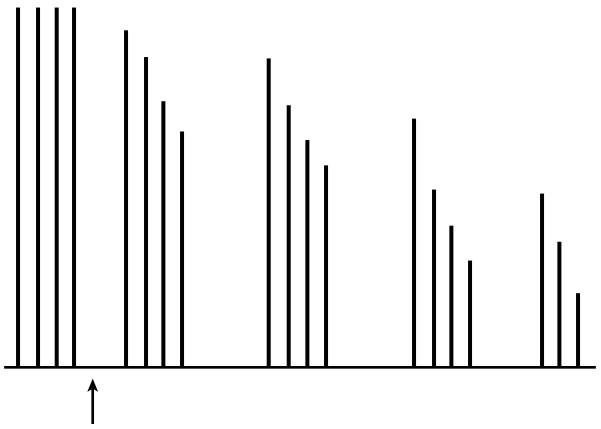

Figure 29-2 Schematic representation of the onset of neuromuscular blockade after the administration of a nondepolarizing neuromuscular blocking agent at the *arrow*. Neuromuscular function is monitored with repetitive train-of-four stimuli (four stimuli 0.5 msec in duration administered over a 2-second period).

stimuli when partial nondepolarizing neuromuscular blockade is present. During neuromuscular blockade with nondepolarizing agents, if one administers a TOF stimulus shortly after a tetanic stimulus, the response to stimulation is augmented and neuromuscular function appears stronger than it did just a couple of minutes earlier. This presumably occurs because with the tetanic stimuli, acetylcholine is mobilized toward the presynaptic portion of the nerve terminal and then, with subsequent stimulation (TOF), an increased amount of acetylcholine is released into the synaptic cleft and the blockade imposed by the nondepolarizing agent is more readily overcome. It may take 1 to 10 minutes for recovery to return to pretetanic or baseline values.[24] In the case of administration of a depolarizing neuromuscular blocking agent such as succinylcholine, the response that has classically been described is quite different. With repetitive TOF stimuli after the administration of doses of succinylcholine that cause 100% paralysis, four equal responses are seen with each stimulus, but there is a weakening of response with each successive TOF stimulus (Fig. 29-3). Similarly, there is no fading or weakening of the response to a tetanic stimulus; however, the entire response will be weaker than it was at baseline. The onset of blockade after the administration of small doses of succinylcholine, 0.05 to 0.3 mg/kg, is accompanied by fading of the TOF response, as has been described for nondepolarizing agents. Interestingly, although one would not necessarily anticipate that there would be posttetanic potentiation after the administration of succinylcholine, it has been described.[25] The reason for this observation has yet to be elucidated.

The neuromuscular blockade develops faster in centrally located muscles, such as the larynx, jaw, and diaphragm, than in more peripherally located muscles, such as the adductor pollicis.[26] In addition to developing more quickly, neuromuscular blockade in these regions, at a given dose, is less profound and recovers more quickly (Fig. 29-4) (for details, see the later section "Neuromuscular Blockers and Tracheal Intubation").[26] Consequently, the choice of monitoring site is important.

To determine the depth of blockade during maintenance and recovery of neuromuscular function, the response of the adductor pollicis to stimulation of the ulnar nerve should be monitored. If recovery in this neuromuscular unit is complete,

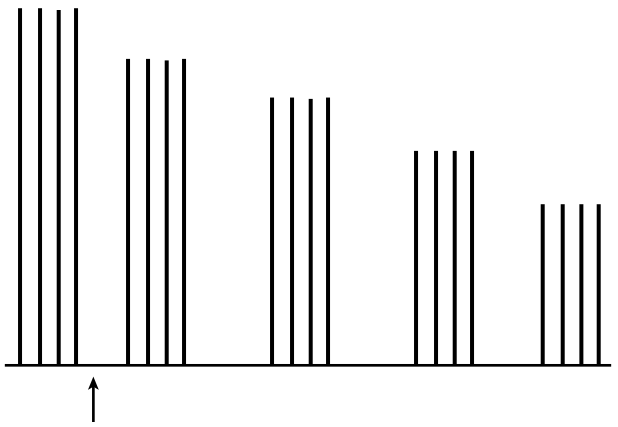

Figure 29-3 Schematic representation of the onset of neuromuscular blockade after the administration of a depolarizing neuromuscular blocking agent at the *arrow*. Neuromuscular function is monitored by repetitive train-of-four stimuli (four stimuli 0.5 msec in duration administered over a 2-second period).

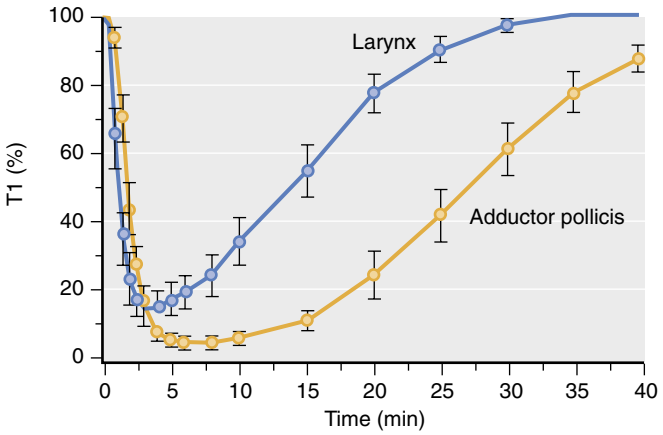

Figure 29-4 Evolution of neuromuscular blockade in the larynx and thumb (adductor pollicis) after a 0.07-mg/kg dose of vecuronium. Onset and recovery from blockade occur more rapidly in the larynx. (*From Donati F, Meistelman C, Plaud B: Vecuronium neuromuscular blockade at the adductor muscles of the larynx and adductor pollicis. Anesthesiology 74:833-837, 1991.*)

recovery in the musculature of the airway should also be complete.[26] It is recommended that objective monitoring (e.g., the TOF ratio displayed digitally in real time) be used clinically. Subjective (visual or tactile) evaluation of the evoked muscular response to TOF stimulation is extremely inaccurate.

Pharmacology of Succinylcholine

Structure-Activity Relationships

All neuromuscular blockers, being quaternary ammonium compounds, are structurally related to acetylcholine. Positive charges at these sites in the molecules mimic the quaternary nitrogen atom of the transmitter acetylcholine and are the principal reason for the attraction of these drugs to muscle- and neuronal-type nAChRs at the neuromuscular junction. These receptors are also located at other physiologic sites of acetylcholine in the body, such as the neuronal-type nicotinic receptors in autonomic ganglia and as many as five different muscarinic receptors on both the parasympathetic and sympathetic sides of the autonomic nervous system. In addition, populations of neuronal nicotinic and muscarinic receptors are located prejunctionally at the neuromuscular junction.

The depolarizing neuromuscular blocker succinylcholine is composed of two molecules of acetylcholine linked back to back through the acetate methyl groups (Fig. 29-5). As described by Bovet,[27] succinylcholine is a long, thin, flexible molecule. Like acetylcholine, succinylcholine stimulates cholinergic receptors at the neuromuscular junction and at nicotinic (ganglionic) and muscarinic autonomic sites, thereby opening the ionic channel in the acetylcholine receptor.

Pharmacokinetics and Pharmacodynamics

Succinylcholine is the only available neuromuscular blocker with a rapid onset of effect and an ultrashort duration of action. The

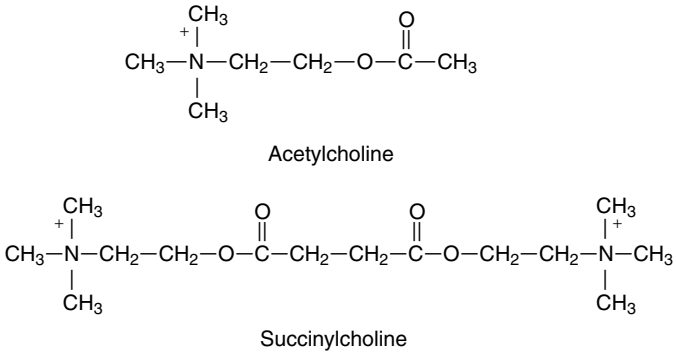

Figure 29-5 Structural relationship of succinylcholine, a depolarizing neuromuscular blocking agent, and acetylcholine. Succinylcholine consists of two acetylcholine molecules linked through the acetate methyl groups. Like acetylcholine, succinylcholine stimulates nicotinic receptors at the neuromuscular junction.

ED_{95} of succinylcholine (the dose causing on average 95% suppression of neuromuscular response) is 0.51 to 0.63 mg/kg.[28] Using cumulative dose-response techniques, Kopman and coworkers[29] estimated that its potency is far greater, with an ED_{95} of less than 0.3 mg/kg.

Administration of 1 mg/kg of succinylcholine results in complete suppression of response to neuromuscular stimulation in approximately 60 seconds.[30] In patients with genotypically normal butyrylcholinesterase (also known as plasma cholinesterase or pseudocholinesterase) activity, recovery to 90% muscle strength after the administration of 1 mg/kg succinylcholine requires 9 to 13 minutes.[31]

The short duration of action of succinylcholine is due to its rapid hydrolysis by butyrylcholinesterase to succinylmonocholine and choline. Butyrylcholinesterase has an enormous capacity to hydrolyze succinylcholine, and only 10% of the administered drug reaches the neuromuscular junction.[32] The initial metabolite, succinylmonocholine, is a much weaker neuromuscular blocking agent than succinylcholine and is metabolized much more slowly to succinic acid and choline. The elimination half-life of succinylcholine is estimated to be 47 seconds.[33]

Because there is little or no butyrylcholinesterase at the neuromuscular junction, the neuromuscular blockade of succinylcholine is terminated by its diffusion away from the neuromuscular junction back into the circulation. Butyrylcholinesterase, therefore, influences the onset and duration of action of succinylcholine by controlling the rate at which the drug is hydrolyzed before it reaches and after it leaves the neuromuscular junction.

Dibucaine Number and Butyrylcholinesterase Activity

Butyrylcholinesterase is synthesized by the liver and found in plasma. The neuromuscular blockade induced by succinylcholine is prolonged by a decreased concentration or activity of the enzyme. The activity of the enzyme refers to the number of substrate molecules (μmol) hydrolyzed per unit of time, often expressed in international units (IU). The normal range of butyrylcholinesterase activity is quite large[31]; significant decreases in butyrylcholinesterase activity result in modest increases in the time required to return to 100% twitch recovery (Fig. 29-6).

Factors that have been described as lowering butyrylcholinesterase activity are liver disease,[34] advanced age,[35] malnutrition, pregnancy, burns, oral contraceptives, monoamine oxidase inhibitors, echothiophate, cytotoxic drugs, neoplastic disease, anticholinesterase drugs,[36] tetrahydroaminacrine,[37] hexafluorenium, and metoclopramide.[38] The histamine type 2 receptor antagonists have no effect on butyrylcholinesterase activity or the duration of succinylcholine's effect.[39] Bambuterol, a prodrug of terbutaline, produces marked inhibition of butyrylcholinesterase activity and causes prolongation of succinylcholine-induced blockade.[40] The β-blocker esmolol inhibits butyrylcholinesterase but causes only minor prolongation of succinylcholine blockade.[41]

Despite all the publications and efforts to identify situations in which normal butyrylcholinesterase enzyme activity may be low, this has not been a major concern in clinical practice because even large decreases in butyrylcholinesterase activity result in only moderate increases in the duration of action of succinylcholine. When butyrylcholinesterase activity is reduced to 20% of normal by severe liver disease, the duration of apnea after the administration of succinylcholine increases from a normal duration of 3 minutes to just 9 minutes. Even when treatment of glaucoma with echothiophate decreased butyrylcholinesterase activity from 49% of control to no activity, the increase in duration of neuromuscular blockade varied from 2 to 14 minutes. In no patient did the total duration of neuromuscular blockade exceed 23 minutes.[42]

Dibucaine Number and Atypical Butyrylcholinesterase Activity

Succinylcholine-induced neuromuscular blockade can be significantly prolonged if the patient has an abnormal genetic variant

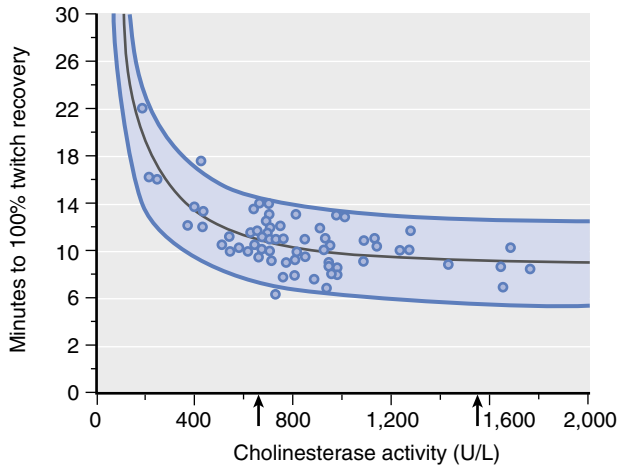

Figure 29-6 Correlation between the duration of succinylcholine neuromuscular blockade and butyrylcholinesterase activity. The normal range of activity lies between the *arrows*. *(From Viby-Mogensen J: Correlation of succinylcholine duration of action with plasma cholinesterase activity in subjects with the genotypically normal enzyme. Anesthesiology 53:517-520, 1980.)*

Table 29-1 Relationship between Dibucaine Number and Duration of Succinylcholine or Mivacurium Neuromuscular Blockade

Type of Butyrylcholinesterase	Genotype	Incidence	Dibucaine Number*	Response to Succinylcholine or Mivacurium
Homozygous typical	$E_1^uE_1^u$	Normal	70-80	Normal
Heterozygous atypical	$E_1^uE_1^a$	1/480	50-60	Lengthened by 50%-100%
Homozygous atypical	$E_1^aE_1^a$	1/3200	20-30	Prolonged to 4-8 hr

*The dibucaine number indicates the percentage of enzyme inhibited.

of butyrylcholinesterase. The variant was found by Kalow and Genest[43] to respond to dibucaine differently than normal butyrylcholinesterase does. Dibucaine inhibits normal butyrylcholinesterase to a far greater extent than it inhibits the abnormal enzyme. This observation led to development of the test for dibucaine number. Under standardized test conditions, dibucaine inhibits expression of the normal enzyme by about 80% and the abnormal enzyme by about 20% (Table 29-1). Subsequently, many other genetic variants of butyrylcholinesterase have been identified, although the dibucaine-resistant variants are the most important. The review by Jensen and Viby-Mogensen[44] can be consulted for more detailed information on this topic.

Although the dibucaine number indicates the genetic makeup of an individual with respect to butyrylcholinesterase, it does not measure the concentration of the enzyme in plasma, nor does it indicate the efficiency of the enzyme in hydrolyzing a substrate such as succinylcholine or mivacurium. Both of the latter factors are determined by measuring butyrylcholinesterase activity, which may be influenced by genotype.

The molecular biology of butyrylcholinesterase is well understood. The amino acid sequence of the enzyme is known, and the coding errors responsible for most genetic variations have been identified.[44] Most variants are due to a single amino acid substitution error or sequencing error at or near the active site of the enzyme. For example, in the case of the "atypical" dibucaine-resistant (A) gene, a mutation occurs at nucleotide 209, where guanine is substituted for adenine. The resultant change in this codon causes substitution of glycine for aspartic acid at position 70 in the enzyme. In the case of the fluoride-resistant (F) gene, two amino acid substitutions are possible, namely, methionine for threonine at position 243 and valine for glycine at position 390. Table 29-1 summarizes three of the known genetic variants of butyrylcholinesterase: the amino acid substitution at position 70 is written as Asp Ø Gly. New variants of butyrylcholinesterase genotypes continue to be discovered.[45]

Side Effects

Cardiovascular Effects

Succinylcholine-induced cardiac dysrhythmias are many and varied. The drug stimulates all cholinergic autonomic receptors: nicotinic receptors on both sympathetic and parasympathetic ganglia[46] and muscarinic receptors in the sinus node of the heart. At low doses, both negative inotropic and chronotropic responses may occur. These responses can be attenuated by prior administration of atropine. With large doses of succinylcholine, these effects may become positive[47] and result in tachycardia. A prominent clinical manifestation of generalized autonomic stimulation is the development of cardiac dysrhythmias, principally manifested as sinus bradycardia, junctional rhythms, and ventricular dysrhythmias. Clinical studies have described these dysrhythmias under various conditions in the presence of the intense autonomic stimulus of tracheal intubation. It is not entirely clear whether the cardiac irregularities are due to the action of succinylcholine alone or to the added presence of extraneous autonomic stimulation. An in vitro study using the ganglionic acetylcholine receptor subtype $\alpha_3\beta_4$ expressed in *Xenopus laevis* oocytes suggested that at clinically relevant concentrations, succinylcholine had no effect on the expressed receptors.[48] Only at high doses of succinylcholine was inhibition of ganglionic acetylcholine receptors noted.[48] The significance of these findings is difficult to extrapolate into clinical practice because the method used (*Xenopus laevis* oocyte expression model) does not match clinical reality.

Sinus Bradycardia. The autonomic mechanism involved in sinus bradycardia is stimulation of cardiac muscarinic receptors in the sinus node. This is particularly problematic in individuals with predominantly vagal tone, such as children who have not received atropine. Sinus bradycardia has also been noted in adults and appears more commonly after a second dose of the drug is given approximately 5 minutes after the first.[49] The bradycardia may be prevented by the administration of thiopental, atropine, ganglion-blocking drugs, and nondepolarizing neuromuscular blockers.[50] The implication of this information is that direct myocardial effects, increased muscarinic stimulation, and ganglionic stimulation may all be involved in the bradycardia response. The higher incidence of bradycardia after a second dose of succinylcholine suggests that the hydrolysis products of succinylcholine (succinylmonocholine and choline) may sensitize the heart to a subsequent dose.

Nodal (Junctional) Rhythms. Nodal rhythms commonly occur after the administration of succinylcholine. The mechanism probably involves relatively greater stimulation of muscarinic receptors in the sinus node, which suppresses the sinus mechanism and allows emergence of the atrioventricular node as the pacemaker. The incidence of junctional rhythm is greater after a second dose of succinylcholine but is prevented by prior administration of dTc.[50]

Ventricular Dysrhythmias. Under stable anesthetic conditions, succinylcholine lowers the threshold of the ventricle to catecholamine-induced dysrhythmias in the monkey and dog. Circulating catecholamine concentrations increase fourfold and potassium concentrations increase by a third after administration of succinylcholine to dogs.[51] Similar increases in catecholamine levels after administration of succinylcholine to humans are also observed.[52] Other autonomic stimuli, such as endotracheal intubation, hypoxia, hypercapnia, and surgery, may be additive to the

effect of succinylcholine. The possible influence of drugs such as digitalis, tricyclic antidepressants, monoamine oxidase inhibitors, exogenous catecholamines, and anesthetic drugs such as halothane and cyclopropane, all of which may lower the ventricular threshold for ectopic activity or increase the arrhythmogenic effect of catecholamines, must also be considered. Ventricular escape beats may also occur as a result of severe sinus and atrioventricular nodal slowing secondary to succinylcholine administration. The development of ventricular dysrhythmias is further encouraged by the release of potassium from skeletal muscle as a consequence of the depolarizing action of the drug.

Hyperkalemia

Administration of succinylcholine to an otherwise well individual for an elective surgical procedure increases plasma potassium levels by approximately 0.5 mEq/dL. This increase in potassium is due to the depolarizing action of the relaxant. With activation of the acetylcholine channels, movement of sodium into the cells is accompanied by movement of potassium out of the cells. This slight increase in potassium is well tolerated by most individuals and generally does not cause dysrhythmias.

Several early reports suggested that patients in renal failure may be susceptible to a hyperkalemic response to succinylcholine.[53] Nevertheless, more controlled studies have shown that such patients are no more susceptible to an exaggerated response to succinylcholine than those with normal renal function are.[54] One might postulate that patients who have uremic neuropathy may be susceptible to succinylcholine-induced hyperkalemia, although the evidence supporting this view is scarce.[53,54]

However, severe hyperkalemia may follow the administration of succinylcholine to patients with severe metabolic acidosis and hypovolemia.[55] In rabbits, the combination of metabolic acidosis and hypovolemia results in a high resting potassium level and an exaggerated hyperkalemic response to succinylcholine.[56] In this situation, the potassium originates from the gastrointestinal tract, not from muscle as in the classic hyperkalemic response.[57] In patients with metabolic acidosis and hypovolemia, correction of the acidosis by hyperventilation and administration of sodium bicarbonate should be attempted before administration of succinylcholine. Should severe hyperkalemia occur, it can be treated with immediate hyperventilation, 1.0 to 2.0 mg of calcium chloride intravenously, 1 mEq/kg of sodium bicarbonate, and 10 units of regular insulin in 50 mL of 50% glucose for adults or, for children, 0.15 units of regular insulin per kilogram in 1.0 mL/kg of 50% glucose.

Kohlschütter and associates[58] found that four of nine patients with severe abdominal infections had an increase in serum potassium levels of as much as 3.1 mEq/L after the administration of succinylcholine. These investigators found that in patients with intra-abdominal infections persisting for longer than 1 week, the possibility of a hyperkalemic response to succinylcholine should be considered.

Stevenson and Birch[59] described a single, well-documented case of a marked hyperkalemic response to succinylcholine in a patient with a closed head injury but no peripheral paralysis.

In studying soldiers who had undergone trauma during the Vietnam War, Birch and colleagues[60] found that a significant increase in serum potassium did not occur in 59 patients until about 1 week after the injury, at which time a progressive increase in the serum potassium level was noted after the infusion of succinylcholine. Three weeks after injury, three of these patients with especially severe trauma showed marked hyperkalemia with an increase in serum potassium of greater than 3.6 mEq/L, sufficient to cause cardiac arrest. Birch and coworkers[60] found that prior administration of 6 mg of dTc prevented the hyperkalemic response to succinylcholine. In the absence of infection or persistent degeneration of tissue, a patient is susceptible to the hyperkalemic response for probably at least 60 days after massive trauma or until adequate healing of damaged muscle has occurred.

In addition, patients with any number of conditions that result in the proliferation of extrajunctional acetylcholine receptors, such as neuromuscular disease, are likely to have an exaggerated hyperkalemic response after the administration of succinylcholine. The response of these patients to neuromuscular blocking agents is reviewed in detail later in this chapter. These disease states include cerebrovascular accident with resultant hemiplegia or paraplegia, muscular dystrophies, and Guillain-Barré syndrome (see also Chapter 37). The hyperkalemia occurring after the administration of succinylcholine may be of such an extent that cardiac arrest ensues. For a recent review on succinylcholine-induced hyperkalemia in patients with acquired pathologic states, see Martyn and Richtsfeld.[61]

Increased Intraocular Pressure

Succinylcholine usually causes an increase in intraocular pressure (IOP). The increased IOP is manifested within 1 minute after injection, peaks at 2 to 4 minutes, and subsides by 6 minutes.[62] The mechanism by which succinylcholine increases IOP has not been clearly defined, but it is known to involve contraction of tonic myofibrils or transient dilatation of choroidal blood vessels (or both). Sublingual administration of nifedipine has been reported to attenuate the increase in IOP from succinylcholine, thus suggesting a circulatory mechanism.[63] Despite this increase in IOP, the use of succinylcholine for eye operations is not contraindicated unless the anterior chamber is open. Although Meyers and associates[64] were unable to confirm the efficacy of precurarization in attenuating increases in IOP after the administration of succinylcholine, numerous other investigators have found that prior administration of a small dose of nondepolarizing neuromuscular blocker (such as 3 mg of dTc or 1 mg of pancuronium) will prevent a succinylcholine-induced increase in IOP.[65] Furthermore, Libonati and coauthors[66] described the anesthetic management of 73 patients with penetrating eye injuries who received succinylcholine; no loss of global contents resulted. Thus, despite the potential concerns of Meyers and coworkers,[64] Libonati and colleagues[66] found that the use of succinylcholine in patients with penetrating eye injuries, after pretreatment with a nondepolarizing neuromuscular blocker and with carefully controlled, rapid-sequence induction of anesthesia, is an acceptable technique. Succinylcholine is only one of many factors, such as endotracheal intubation and "bucking" on the tube, that may elevate IOP.[64] Of prime importance is ensuring that the patient is well anesthetized and not straining or coughing. Because nondepolarizing neuromuscular blockers with shorter times to onset of effect are now available, providing an anesthetic that allows the trachea to be intubated rapidly without administering succinylcholine is now an option. Finally, should a patient's anesthesia become too light over the course of intraocular surgery, succinylcholine should not be given to immobilize the patient. Rather, the surgeon should be asked to pause while the anesthesia is deepened. If necessary, the depth of neuromuscular blockade can also be increased with nondepolarizing relaxants.

Increased Intragastric Pressure

Unlike the rather consistent increase in IOP, the increase in intragastric pressure (IGP) caused by succinylcholine is quite variable. The increase in IGP from succinylcholine is presumed to be due to fasciculations of abdominal skeletal muscle. This is not surprising because more coordinated abdominal skeletal muscle activity (e.g., straight-leg raising) may increase IGP to values as high as 120 cm H_2O. In addition to skeletal muscle fasciculations, the acetylcholine-like effect of succinylcholine may be partly responsible for the observed increases in IGP. Greenan[67] noted consistent increases in IGP of 4 to 7 cm H_2O with direct vagal stimulation.

Miller and Way[68] found that 11 of 30 patients had essentially no increase in IGP after the administration of succinylcholine, yet 5 of the 30 had an increase in IGP of greater than 30 cm H_2O. The increase in IGP from succinylcholine appeared to be related to the intensity of the abdominal skeletal muscle fasciculations. Accordingly, when fasciculations were prevented by prior administration of a nondepolarizing neuromuscular blocker, no increase in IGP was observed.

Are the increases in IGP after succinylcholine administration enough to cause incompetence of the gastroesophageal junction? Generally, an IGP of greater than 28 cm H_2O is required to overcome the competence of the gastroesophageal junction. However, when the normal oblique angle of entry of the esophagus into the stomach is altered, as may occur with pregnancy, an abdomen distended by ascites, bowel obstruction, or a hiatal hernia, the IGP required to cause incompetence of the gastroesophageal junction is frequently less than 15 cm H_2O.[68] In these circumstances, regurgitation of stomach contents after the administration of succinylcholine is a distinct possibility, and precautionary measures should be taken to prevent fasciculation. Endotracheal intubation may be facilitated by administration of either a nondepolarizing neuromuscular blocker or a defasciculating dose of a nondepolarizing relaxant before the succinylcholine.

Apparently, succinylcholine does not increase IGP appreciably in infants and children, which may be related to the minimal or absent fasciculations from succinylcholine in these age groups.[69]

Increased Intracranial Pressure

Succinylcholine has the potential to increase intracranial pressure.[70] The mechanisms and clinical significance of this transient increase are unknown, but the rise in intracranial pressure does not occur after pretreatment with nondepolarizing neuromuscular blockers.[70]

Myalgias

The incidence of muscle pain after the administration of succinylcholine varies from 0.2% to 89%.[71] It occurs more frequently after minor surgery, especially in women and in ambulatory rather than bedridden patients.[72] Waters and Mapleson[72] postulated that the pain is secondary to damage produced in muscle by the unsynchronized contractions of adjacent muscle fibers just before the onset of paralysis. That damage to muscle may occur has been substantiated by finding myoglobinemia and increases in serum creatine kinase after succinylcholine administration.[73] Prior administration of a small dose of a nondepolarizing neuromuscular blocker clearly prevents succinylcholine-related fasciculations.[73] However, the efficacy of this approach in preventing muscle pain is questionable. Although some investigators claim that pretreatment with a defasciculating dose of a nondepolarizing neuromuscular blocker has no effect,[71] many believe that the pain from succinylcholine is at least attenuated.[73] Pretreatment with a prostaglandin inhibitor (e.g., lysine acetyl salicylate) has been shown to be effective in decreasing the incidence of muscle pain after succinylcholine.[74] This suggests a possible role for prostaglandins and cyclooxygenases in succinylcholine-induced myalgias. Other investigators have found that myalgias after outpatient surgery occur even in the absence of succinylcholine.[75]

Masseter Spasm

An increase in tone of the masseter muscle is a frequent response to succinylcholine in adults[76] and children.[77] Meakin and coworkers[77] suggested that the high incidence of spasm in children may be due to an inadequate dosage of succinylcholine. In all likelihood, this increase in tone is an exaggerated contractile response at the neuromuscular junction and cannot be used to establish a diagnosis of malignant hyperthermia. Although an increase in tone of the masseter muscle may be an early indicator of malignant hyperthermia, it is not consistently associated with that syndrome.[78] There is currently no indication to change to a "nontriggering" anesthetic in instances of isolated masseter spasm.[79]

Clinical Uses

Despite its many adverse effects, succinylcholine remains in common use. Its popularity is probably due to its rapid onset of effect, the profound depth of neuromuscular blockade that it produces, and its short duration of action. Although it may be less commonly used than in the past for routine endotracheal intubation, it is the neuromuscular blocker of choice for rapid-sequence induction of anesthesia. In a study comparing intubating conditions after the administration of 1 mg/kg of succinylcholine with those after the administration of 0.1 mg/kg of vecuronium or 0.1 mg/kg of pancuronium 30 seconds after administration of the relaxant and at 30-second intervals after that up for 120 seconds, intubation could be accomplished in all patients receiving succinylcholine at 30 seconds, in contrast with the other neuromuscular blockers studied.[80] Furthermore, at all time points studied up to 90 seconds, intubating conditions were better after the administration of succinylcholine than after either of the other neuromuscular blockers. Although 1.0 mg/kg of succinylcholine has long been recommended to facilitate endotracheal intubation at 60 seconds, a recent study indicated that 0.5 to 0.6 mg/kg of succinylcholine should allow adequate intubating conditions 60 seconds after administration.[81] Reduction of the succinylcholine dose from 1.0 mg/kg to 0.6 mg/kg decreased the incidence of hemoglobin saturation from 85% to 65% but did not shorten the time to spontaneous diaphragmatic movement.[82] However, a significant fraction of patients would be at risk if there were failure to intubate and ventilate regardless of whether succinylcholine is administered or the dose of succinylcholine administered.[82]

A small dose of nondepolarizing neuromuscular blocker is commonly given 2 minutes before the intubating dose of succinylcholine. This defasciculating dose of nondepolarizing neuromuscular blocker will attenuate any increases in IGP and intracranial pressure and minimize the incidence of fasciculations in response to succinylcholine. Prior administration of a

Table 29-2 Clinical Characteristics of Phase 1 and Phase 2 Neuromuscular Blockade during Succinylcholine Infusion

Characteristic	Phase 1	Transition	Phase 2
Tetanic stimulation	No fade	Slight fade	Fade
Post-tetanic facilitation	None	Slight	Yes
Train-of-four fade	No	Moderate fade	Marked fade
Train-of-four ratio	>0.7	0.4-0.7	<0.4
Edrophonium	Augments	Little effect	Antagonizes
Recovery	Rapid	Rapid to slow	Increasingly prolonged
Dose requirements (mg/kg)*	2-3	4-5	>6
Tachyphylaxis	No	Yes	Yes

*Cumulative dosage of succinylcholine by infusion under nitrous oxide anesthesia supplemented with intravenous agents. The dosage required to cause a phase 2 block is less in the presence of potent anesthetic vapors, such as isoflurane.

nondepolarizing agent will render the muscle relatively resistant to succinylcholine, however, so the succinylcholine dose should be increased by 50%.[83] The use of a defasciculating dose of a nondepolarizing neuromuscular blocker may also slow the onset of succinylcholine and produce less favorable conditions for tracheal intubation.[73]

Typically after administration of succinylcholine for intubation, a nondepolarizing neuromuscular blocker is given to maintain neuromuscular blockade. Succinylcholine given first may enhance the depth of blockade induced by a subsequent dose of nondepolarizing neuromuscular blocker.[84-86] However, the effect on duration of action is variable. Succinylcholine has no effect on the duration of action of pancuronium, pipecuronium, or mivacurium[86,87] but increases that of atracurium and rocuronium.[84,85] The reasons for these differences are not clear.

The changing characteristics of succinylcholine neuromuscular blockade over the course of prolonged administration have been reviewed by Lee and Katz[88] and are summarized in Table 29-2. TOF stimulation is a very safe and useful guide for detecting the transition from a phase 1 to a phase 2 block. A phase 1 block has all the characteristics of a depolarizing block as described previously in the monitoring section. A phase 2 block has the characteristics of a nondepolarizing block. With the administration of large doses of succinylcholine, the nature of the block, as determined by a neuromuscular blockade monitor, changes from that of a depolarizing agent to that of a nondepolarizing agent. Clearly, both the dose and the duration of administration of succinylcholine are important variables, although the relative contribution of each has not been established. In practical terms, if administration of the drug is terminated shortly after TOF fading is clearly evident, rapid return of normal neuromuscular function should ensue. In addition, the decision whether to attempt antagonism of a phase 2 block has always been controversial. However, if the TOF ratio is less than 0.4, administration of edrophonium or neostigmine should result in prompt antagonism. Ramsey and associates[89] recommended that antagonism of a succinylcholine-induced phase 2 block with edrophonium or neostigmine be attempted after spontaneous recovery of the twitch has been observed for 20 to 30 minutes and has reached a plateau phase with further recovery proceeding slowly. These researchers stated that in this situation, edrophonium and neostigmine invariably produce "dramatic" acceleration of the return of the TOF ratio toward normal.[89] In any event, monitoring neuromuscular function via TOF stimuli will help avoid succinylcholine overdose, detect the development of phase 2 blockade, observe its rate of recovery, and assess the effect of edrophonium or neostigmine on recovery.

A recent study showed that post-tetanic potentiation and fade in response to TOF and tetanic stimuli are characteristics of neuromuscular blockade after bolus administration of different doses of succinylcholine.[25] It seems that some characteristics of phase 2 blockade are evident after an initial dose of succinylcholine (i.e., as small as 0.3 mg/kg).[25]

Interactions with Anticholinesterases

Another interaction with succinylcholine involves neostigmine or pyridostigmine. For example, after dTc has been used for intra-abdominal surgery of long duration and the neuromuscular blockade has been reversed by neostigmine, the surgeon announces that another 15 minutes is needed to retrieve a missing sponge. Succinylcholine should not be administered to reestablish neuromuscular blockade because it produces relaxation that will last up to 60 minutes when given soon after the administration of neostigmine. Sunew and Hicks[36] found that the effect of succinylcholine (1 mg/kg) was prolonged from 11 to 35 minutes when given 5 minutes after the administration of neostigmine (5 mg). This can be partly explained by the inhibition of butyrylcholinesterase by neostigmine and, to a lesser extent, by pyridostigmine. Ninety minutes after the administration of neostigmine, butyrylcholinesterase activity will have returned to less than 50% of its baseline value.

Nondepolarizing Neuromuscular Blockers

The use of neuromuscular blocking drugs in anesthesia has its origin in the South American Indians' arrow poisons or curare. Several nondepolarizing neuromuscular blockers are still purified from naturally occurring sources. For example, although dTc can be synthesized, it is still less expensive to isolate from the Amazonian vine *Chondodendron tomentosum*. Similarly, intermediates for the production of metocurine and alcuronium, which are semisynthetic, are obtained from *Chondodendron* and *Strychnos toxifera*. Malouetine, the first steroidal neuromuscular blocking drug, was originally isolated from *Malouetia bequaertiana*, which grows in the jungles of the Democratic Republic of Congo in central Africa. The agents pancuronium, vecuronium, pipecuronium, rocuronium, rapacuronium, atracurium, doxacurium, mivacurium, cisatracurium, gantacurium, and gallamine are entirely synthetic.

The available nondepolarizing neuromuscular blockers can be classified according to chemical class (steroidal, benzylisoquinolinium, or other compounds) or, alternatively, according to

Table 29-3 Classification of Nondepolarizing Neuromuscular Blockers According to Duration of Action (Time to T1 = 25% of Control) after Twice the ED_{95}

Class of Blocker	Clinical Duration			
	Long-Acting (>50 min)	**Intermediate-Acting (20-50 min)**	**Short-Acting (15-20 min)**	**Ultrashort-acting (<10-12 min)**
Steroidal compounds	Pancuronium Pipecuronium	Vecuronium Rocuronium		
Benzylisoquinolinium compounds	*d*-Tubocurarine Metocurine Doxacurium	Atracurium Cisatracurium	Mivacurium	
Others				
Asymmetrical mixed-onium chlorofumarates				Gantacurium
Phenolic ether	Gallamine			
Diallyl derivative of toxiferine	Alcuronium			

A majority of nondepolarizing neuromuscular blockers are bisquaternary ammonium compounds. *d*-Tubocurarine, vecuronium, rocuronium, and rapacuronium are monoquaternary compounds, and gallamine is a trisquaternary ammonium compound.

onset or duration of action (long-, intermediate-, and short-acting drugs) of equipotent doses (Table 29-3).

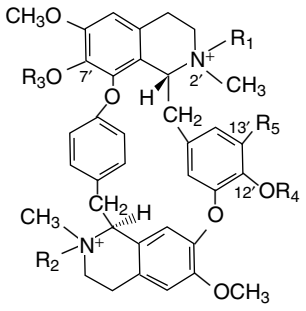
Structure-Activity Relationships

Nondepolarizing neuromuscular blocking drugs were originally classified by Bovet[27] as pachycurares, or bulky molecules having the amine functions incorporated into rigid ring structures. Two extensively studied chemical series of synthetic nondepolarizing neuromuscular blockers are the aminosteroids (steroidal), in which the interonium distance is maintained by an androstane skeleton, and the benzylisoquinolinium series, in which the distance is maintained by linear diester-containing chains or, in the case of curare, by benzyl ethers. For a detailed account of structure-activity relationships, see Lee.[90]

Benzylisoquinolinium Compounds

dTc is a neuromuscular blocker in which the amines are present in the form of two benzyl-substituted tetrahydroisoquinoline structures (Fig. 29-7). The quaternary or tertiary nature of the two amines was initially questioned; however, with the use of nuclear magnetic resonance spectroscopy and methylation-demethylation studies, Everett and coworkers[91] demonstrated that dTc contains only three *N*-methyl groups. One amine is quaternary (i.e., permanently charged with four nitrogen substituents) and the other is tertiary (i.e., pH-dependent charge with three nitrogen substituents). At physiologic pH, the tertiary nitrogen is protonated to render it positively charged. The structure-activity relationships of the bis-benzylisoquinolines (see Fig. 29-7) have been described by Waser[92] and by Hill and associates[93] as follows:

1. The nitrogen atoms are incorporated into isoquinoline ring systems. This bulky molecule favors nondepolarizing rather than depolarizing activity.
2. The interonium distance (distance between charged amines) is approximately 1.4 nm.
3. Both the ganglion-blocking and the histamine-releasing properties of dTc are probably due to the presence of the tertiary amine function.
4. When dTc is methylated at the tertiary amine and at the hydroxyl groups, the result is metocurine, a compound with greater potency (by a factor of 2 in humans) but much weaker ganglion-blocking and histamine-releasing properties than dTc has (see Fig. 29-7). Metocurine contains three additional methyl groups, one of which quaternizes the tertiary nitrogen of dTc; the other two form methyl ethers at the phenolic hydroxyl groups.
5. Bisquaternary compounds are more potent than their monoquaternary analogs. The bisquaternary derivative of dTc, chondocurine, has more than double the potency of dTc (Fig. 29-7).
6. Substitution of the methyl groups on the quaternary nitrogen with bulkier groups causes a reduction in both potency and duration of action.



Cyclic benzylisoquinoline

Cyclic benzylisoquinoline derivatives

Name	R_1	R_2	R_3	R_4	R_5	1	1'
d-Tubocurarine	CH_3	H	H	H	H	*S*	*R*
Metocurine	CH_3	CH_3	CH_3	CH_3	H	*S*	*R*
Chondocurine	CH_3	CH_3	H	H	H	*S*	*R*

Figure 29-7 Chemical structures of *d*-tubocurarine, metocurine, and chondocurine.

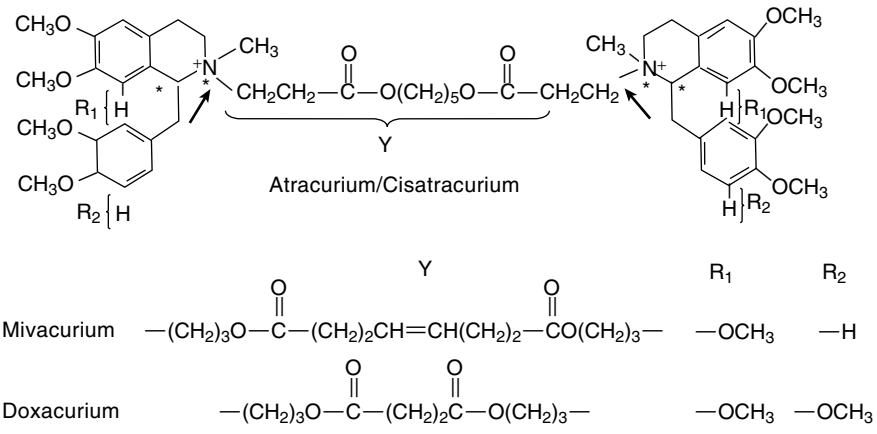

Figure 29-8 Chemical structures of atracurium, cisatracurium, mivacurium, and doxacurium. The *asterisks* indicate chiral centers; *arrows* show cleavage sites for Hofmann elimination.

Atracurium is a bis-benzyltetrahydroisoquinolinium with isoquinolinium nitrogens connected by a diester-containing hydrocarbon chain (Fig. 29-8). The presence (in duplicate) of two-carbon separations between quaternary nitrogen and ester carbonyl provides the basis for a Hofmann elimination reaction.[94] Furthermore, it can undergo ester hydrolysis. In a Hofmann elimination reaction, a quaternary ammonium group is converted to a tertiary amine by cleavage of a carbon-nitrogen bond. This is a pH- and temperature-dependent reaction in which higher pH and temperature favor elimination. The actual structure of the quaternary centers is the laudanosinium moiety, as in metocurine. Atracurium has four chiral centers at each of the adjacent chiral carbons of the two amines. The marketed product has 10 isomers.[94] These isomers have been separated into three geometric isomer groups that are designated *cis-cis*, *cis-trans*, and *trans-trans* according to their configuration about the tetrahydroisoquinoline ring system.[94] The ratio of the *cis-cis*, *cis-trans*, and *trans-trans* isomers is approximately 10:6:1, which corresponds to 50% to 55% *cis-cis*, 35% to 38% *cis-trans*, and 6% to 7% *trans-trans* isomers.

Cisatracurium is the 1R *cis*–1′R *cis* isomer of atracurium and represents about 15% of the marketed atracurium mixture by weight but more than 50% in terms of potency or neuromuscular blocking activity (see Fig. 29-8). R designates the absolute stereochemistry of the benzyl tetrahydroisoquinoline rings and *cis* represents the relative geometry of the bulky dimethoxy and 2-alkyester groups at C(1) and N(1), respectively.[95,96] Cisatracurium is metabolized by Hofmann elimination. It is approximately four times as potent as atracurium, but unlike atracurium, it does not cause release of histamine in the clinical dose range.[95,97] This indicates that the phenomenon of histamine release may be stereospecific.[95,98] Cisatracurium is the second benzylisoquinolinium (after doxacurium) to be largely free of this side effect.

Mivacurium differs from atracurium by the presence of an additional methylated phenolic group (see Fig. 29-8). When compared with other isoquinolinium neuromuscular blockers, the interonium chain of mivacurium is longer (16 atoms).[93] Mivacurium consists of a mixture of three stereoisomers.[99] The two most active are the *trans-trans* and *cis-trans* isomers (57% and 37% wt/wt, respectively), which are equipotent; the *cis-cis* isomer (6% wt/wt) has only a 10th the activity of the others in cats and monkeys.[99] Mivacurium is metabolized by butyrylcholinesterase at 70% to 88% the rate of succinylcholine to a monoester, a dicarboxylic acid.[9]

Doxacurium is a bisquaternary benzylisoquinolinium diester of succinic acid (see Fig. 29-8). The interonium chain is shorter than that of either atracurium or mivacurium. Lee[90] pointed out that the number of methoxy groups on benzylisoquinolinium heads is increased from four (atracurium) and five (mivacurium) to six (doxacurium).[93] This increase was associated with both an increase in potency and a reduction in the propensity to release histamine.[90,93]

Steroidal Neuromuscular Blockers

In the steroidal compounds, it is probably essential that one of two nitrogen atoms in the molecule be quaternized. The presence of acetyl ester (acetylcholine-like moiety) is thought to facilitate its interaction with nAChRs at the postsynaptic muscle membrane.

Pancuronium is characterized by the presence of two acetyl ester groups on the A and D rings of the steroidal molecule. Pancuronium is a potent neuromuscular blocking drug with both vagolytic and butyrylcholinesterase-inhibiting properties (Fig. 29-9).[100] Deacetylation of the 3-OH or 17-OH groups decreases its potency.[101]

Vecuronium is the *N*-demethylated derivative of pancuronium in which the 2-piperidine substituent is not methylated (i.e., vecuronium lacks the *N*-methyl group at position 2) (see Fig. 29-9).[7] At physiologic pH, the tertiary amine is largely protonated, as it is in dTc. The minor molecular modification relative to pancuronium results in (1) a slight change in potency; (2) a marked reduction in vagolytic properties; (3) molecular instability in solution, which explains in part the shorter duration of action of vecuronium than pancuronium; and (4) increased lipid solubility, which results in greater biliary elimination of vecuronium than pancuronium.[93]

Pancuronium and vecuronium are very similar in structure, yet vecuronium is prepared as a lyophilized powder. Vecuronium is degraded by the hydrolysis of acetyl esters at either or both the C3 and C17 positions. Hydrolysis at the C3 position is the primary degradation product. The acetate at position 3 is more susceptible to hydrolysis in aqueous solutions. Vecuronium is less stable in solution because of the group effect of the adjacent basic piperidine at position 2, which facilitates hydrolysis of the 3-acetate. Therefore, vecuronium cannot be prepared as a ready-to-use solution with a sufficient shelf life, even as a buffered solution. In pancuronium, the 2-piperidine is quaternized and no

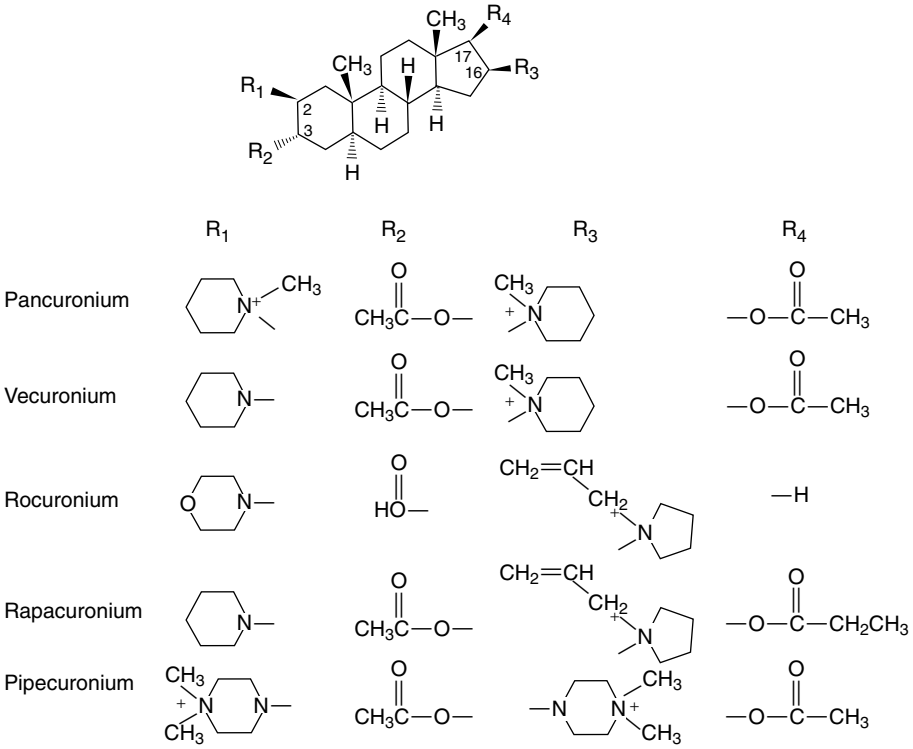

Figure 29-9 Chemical structures of different steroidal neuromuscular blockers.

longer alkaline. Thus, it does not participate in catalysis of the 3-acetate hydrolysis.

Pipecuronium, like pancuronium, is a bisquaternary compound. Pipecuronium has piperazine rings attached to the A and D rings of the steroid nucleus, whereas pancuronium has piperidine rings (see Fig. 29-9).[93] Pipecuronium is a nonvagolytic substitute for pancuronium. Changes in the quaternary groups in which the quaternary nitrogen atoms are placed at the distal (4-position) aspect of the 2,16-β-substitutions lessen the vagolytic effects.[93] As a result, pipecuronium is about 10 times less vagolytic than pancuronium.

Rocuronium lacks the acetyl ester that is found in the steroid nucleus of pancuronium and vecuronium in the A ring (see Fig. 29-9). The introduction of cyclic substituents other than piperidine at the 2- and 16-positions results in a fast-onset compound.[102] The methyl group attached to the quaternary nitrogen of vecuronium and pancuronium is replaced by an allyl group in rocuronium. As a result, rocuronium is about 6 and 10 times less potent than vecuronium and pancuronium, respectively.[102-104] Replacement of the acetyl ester attached to the A ring by a hydroxy group has made it possible to present rocuronium as a stable solution. At room temperature, rocuronium is stable for only 60 days, whereas pancuronium is stable for 6 months. The reason for this difference in shelf life is related to the fact that rocuronium is terminally sterilized in manufacturing and pancuronium is not. Terminal sterilization causes some degree of degradation.

Asymmetric Mixed-Onium Chlorofumarates

Gantacurium (Fig. 29-10) represents a new class of nondepolarizing neuromuscular blockers called asymmetric mixed-onium chlorofumarates. The presence of three methyl groups between the quaternary nitrogen and oxygen atom at each end of the carbon chain suggests that similar to mivacurium, this compound will not undergo Hofmann elimination.[105] Gantacurium has an ultrashort duration of action in human volunteers and in different animal species. A study in anesthetized human volunteers using an earlier formulation of gantacurium estimated the ED_{95} to be 0.19 mg/kg.[106] The pattern of blockade resembled that of succinylcholine. The time to onset of 90% blockade ranged from 1.3 to 2.1 minutes, depending on the dose. Clinical durations ranged from 4.7 to 10.1 minutes and increased with increasing dose. Spontaneous recovery to a TOF of 0.9 develops in the thumb within about 12 to 15 minutes after the administration of doses as large as 0.54 mg/kg (or three times the ED_{95}). Recovery is accelerated by edrophonium. Transient cardiovascular side effects were observed at doses beginning at three times the ED_{95} and were suggestive of histamine release.[106]

Phenolic Ether Derivative

Gallamine is a trisquaternary compound (Fig. 29-11). Its potent vagolytic activity is due to the presence of three positively charged nitrogen atoms. Gallamine was originally synthesized by Bovet[27] as part of an extensive structure-activity study that helped evolve the concepts of "pachycurares" and "leptocurares." Succinylcholine also evolved from this work, for which Bovet received the Nobel Prize.

Diallyl Derivative of Toxiferine

Introduced in 1964, alcuronium is a long-acting agent that is the semisynthetic diallyl derivative of toxiferine (Fig. 29-12). The latter is purified from *Strychnos toxifera*. The advantage of alcuronium at the time of its introduction was a relative lack of side effects. It is mildly vagolytic and is excreted unchanged by the kidney with a minor secondary biliary pathway.

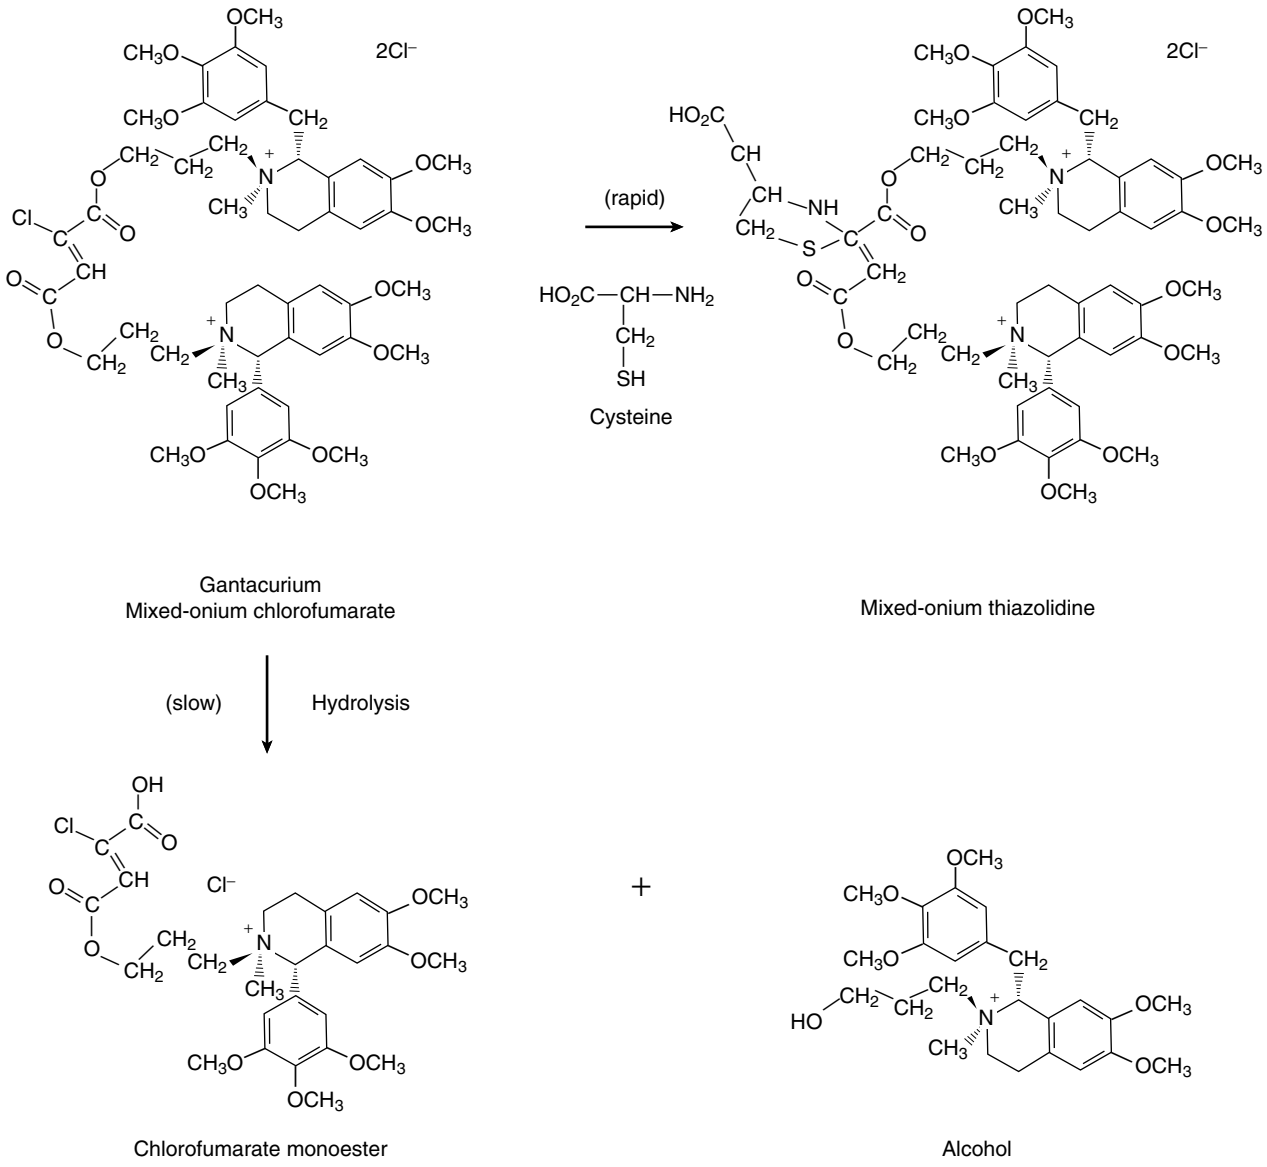

Figure 29-10 Chemical structure of gantacurium (a mixed-onium chlorofumarate). In whole human blood, two pathways of deactivation occur, neither of which is enzymatic: (1) rapid formation of an apparently inactive cysteine adduction product, with cysteine replacing chlorine, and (2) slower hydrolysis of the ester bond adjacent to the chlorine substitution to chlorofumarate monoester and alcohol. *(From Boros EE, Samano V, Ray JA, et al: Neuromuscular blocking activity and therapeutic potential of mixed-tetrahydroisoquinolinium halofumarates and halosuccinates in rhesus monkeys. J Med Chem 46:2502-2515, 2003.)*

Potency of Nondepolarizing Neuromuscular Blockers

Drug potency is commonly expressed by the dose-response relationship. The dose of a neuromuscular blocking drug required to produce an effect (e.g., 50%, 90%, or 95% depression of twitch height, commonly expressed as ED_{50}, ED_{90}, and ED_{95}, respectively) is taken as a measure of its potency.[9,11,103,107-117] The neuromuscular blocking drugs have different potencies, as illustrated in Table 29-4 and Figure 29-13. For factors affecting the potency of neuromuscular blockers, see the section on drug interactions later in this chapter. The dose-response relationship for nondepolarizing neuromuscular blockers is sigmoidal in shape (see Fig. 29-13) and has been derived in various ways. The simplest method is to perform linear regression over the approximately linear portion of a semilogarithmic plot between 25% and 75% neuromuscular blockade. Alternatively, the curve can be subjected to probit or logit transformation to linearize it over its whole length or can be subjected to nonlinear regression using the sigmoid E_{max} model of the form

$$\text{Effect}(e) = .\backslash F\left(\text{dose}_e{}^{\gamma}, \text{dose}_e{}^{\gamma} + \text{dose}_{e50}{}^{\gamma}\right)$$

This can be applied to the raw data.[119] More complex models relating the concentration of neuromuscular blockers at the neuromuscular junction to their pharmacologic effect have been developed, as discussed later.[120,121]

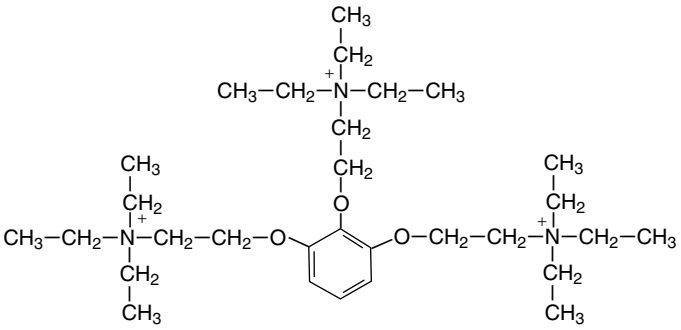

Figure 29-11 Chemical structure of gallamine, a trisquaternary ether of gallic acid. Gallamine is the only trisquaternary compound available. Its strong vagolytic property is probably due to its trisquaternary structure.

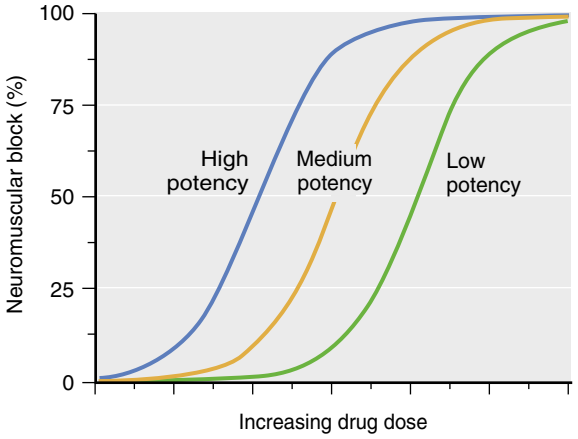

Figure 29-13 Schematic representation of a semilogarithmic plot of a muscle relaxant dose versus neuromuscular blockade. A drug of high potency is doxacurium; one of medium potency, atracurium; and one of low potency, gallamine. The graph illustrates that the relative potencies of muscle relaxants span a range of approximately 2 orders of magnitude.

Pharmacokinetics and Pharmacodynamics

As defined by Wright,[122] pharmacokinetics and pharmacodynamics are "empirical mathematical model[s] … that [describe] drug effect time course after administration." In pharmacokinetic modeling, the concept of "compartments" represents different organs or tissues (or both) grouped together on the basis of their degree of blood perfusion (high or low). After a neuromuscular blocker is injected into the circulation, its concentration in plasma decreases rapidly at first and then more slowly (Fig. 29-14). The shape of this curve is determined by the processes of distribution and elimination. Classically, this curve is divided into an initial (distribution) phase and a terminal (elimination) phase. This curve can be represented mathematically by biexponential or triexponential equations in the form

$$\text{Concentration (at time t)} = Ae^{-\alpha t} + Be^{-\beta t}\left(+Pe^{-\pi t}\right)$$

These multiexponential equations express the concept of drug distribution between two or three theoretical compartments.

Figure 29-15 illustrates the classic model, in which the drug is administered intravenously into a central compartment with volume V_1 and is distributed and eliminated from this compartment only. The drug is distributed very rapidly throughout this

Data are medians and ranges of reported values. ED_{50}, ED_{90}, and ED_{95} are the doses of each drug that produce, respectively, a 50%, 90%, and 95% decrease in the force of contraction or amplitude of the electromyogram of the adductor pollicis muscle after ulnar nerve stimulation.

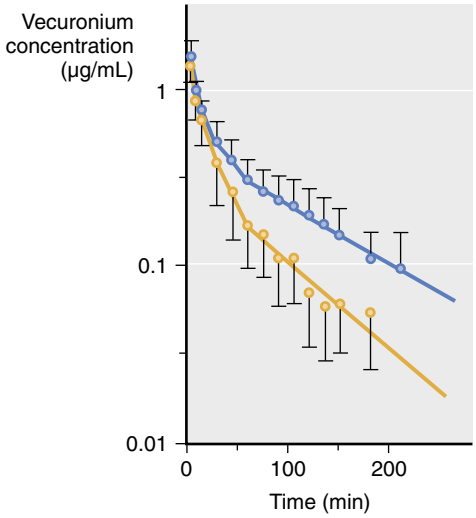

Figure 29-14 Disappearance of vecuronium from plasma after a single bolus dose of 0.2 mg/kg as shown in a semilogarithmic plot of mean concentration versus time for patients with normal hepatic function (*yellow circles*) and cirrhotic patients (*blue circles*). *Error bars* are the standard deviation for that value. *(From Lebrault C, Berger JL, D'Hollander AA, et al: Pharmacokinetics and pharmacodynamics of vecuronium (ORG NC 45) in patients with cirrhosis. Anesthesiology 62:601-605, 1985.)*

central compartment, which includes the plasma volume and the organs of elimination; in the case of neuromuscular blockers, the organs of elimination are the kidneys and liver. The "k" terms are the rate constants for movement of drug between compartments in the direction of the arrows. The peripheral compartments (usually one or two, here represented by V_2 and V_3) can be thought of as the "tissues." The "effect" compartment, which will be discussed later, is the neuromuscular junction. For computational purposes, it has infinitesimal volume and therefore does not influence overall drug distribution. Drug administration and elimination are unidirectional; distribution is bidirectional.

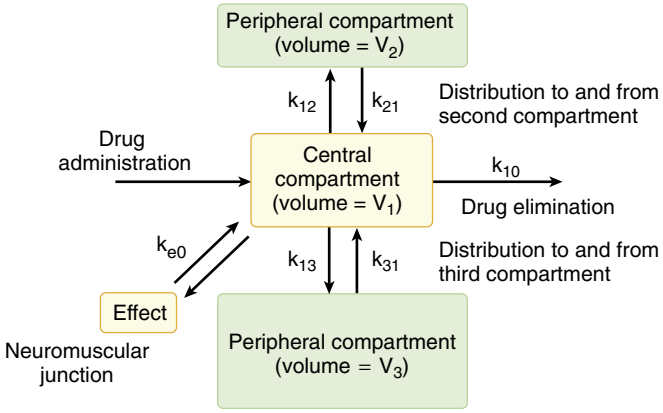

Figure 29-15 Schematic representation of drug disposition into different compartments. These compartments are mathematical concepts only and do not represent real physiologic spaces. The effect compartment in this case would be the neuromuscular junction; for computational purposes, it has infinitesimal volume. The terms k_{nm} are the rate constants for drug movement, in the direction of the *arrow*, between these theoretical compartments. See text for further discussion.

Initially, the drug concentration in the central compartment (i.e., the plasma concentration) will exceed that in the peripheral compartment (i.e., the tissue concentration), and the drug will move from plasma to tissues. Later, as the plasma concentration decreases, it becomes less than the tissue concentration, and the net direction of drug movement is now from tissues to plasma. In general, this conceptual model is appropriate for all the neuromuscular blockers, with the exception of atracurium and cisatracurium, which also undergo elimination (by degradation) from tissues.[123] For simplicity, the following discussion assumes the presence of only one peripheral compartment.

The volume of distribution is the volume to which the drug has distributed when the processes of distribution and elimination are in equilibrium. Elimination is represented by the variable plasma clearance, that is, the volume of plasma from which the drug is irreversibly and completely eliminated per unit time. For most nondepolarizing neuromuscular blockers, the process of distribution is more rapid than the process of elimination, and the initial rapid decline in plasma concentration is due primarily to distribution of the drug to tissues. An exception to this rule is mivacurium, which has such rapid clearance, because of metabolism by butyrylcholinesterase, that elimination is the principal determinant of the initial decline in plasma concentration.

After the initial process of drug distribution to tissues, the plasma concentration falls more slowly (the terminal phase). The rate of decrease in plasma concentration during this terminal phase is often expressed in terms of elimination half-life, which equals the natural logarithm of 2 divided by the rate constant of decline (i.e., the slope of the terminal phase). During this terminal phase, the concentration of drug in the tissue exceeds that in plasma, and the rate of decrease in plasma concentration is determined by two factors: the rate at which drug can move from tissues back into plasma and clearance of drug from plasma. In classic theory for neuromuscular blockers, the drug can move rapidly from tissues into plasma, and its elimination from plasma (i.e., clearance) is the rate-limiting step. For this reason, the terminal portion of the curve is often termed the elimination phase, even though the distribution of drug from tissues into plasma occurs continually throughout. The volume of distribution can also influence the terminal portion of the curve: the greater the volume of distribution, the slower the decline in plasma concentration.

The neuromuscular blockers are polar drugs, and their volume of distribution is classically thought to be limited to a volume roughly equivalent to a portion of the extracellular fluid space, namely, 150 to 450 mL/kg (see Tables 29-13 and 29-14).[124] With this model of drug distribution, the potential rate of drug movement from tissues to plasma exceeds the rate of elimination, and plasma clearance is the process that limits the rate of decline in plasma drug concentration. However, there is evidence that neuromuscular blockers are distributed more widely into tissues with low blood flow (e.g., connective tissue),[125] and the true volume of distribution of dTc has been estimated to be as high as 3.4 L/kg and its elimination half-life as long as 40 hours (compare with values in Tables 29-13 and 29-14).[126] Because the rate of drug movement from such tissues is less than that of plasma clearance, this becomes the limiting step in the rate of decline in plasma drug concentration. This phase becomes obvious only when drug is administered for many days or when sampling is continued for 24 to 96 hours after drug administration. In normal operating room use of neuromuscular blockers, the amount of drug that is

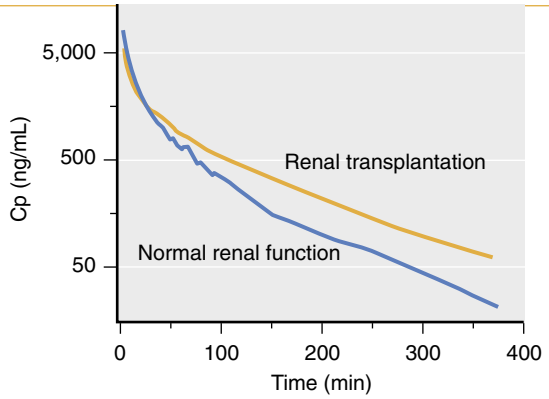

Figure 29-16 "Average" plasma concentration (Cp) versus time after a dose of 0.6 mg/kg rocuronium in patients with normal renal function (*blue line*) or patients undergoing renal transplantation (*yellow line*). *(From Szenohradszky J, Fisher DM, Segredo V, et al: Pharmacokinetics of rocuronium bromide (ORG 9426) in patients with normal renal function or patients undergoing cadaver renal transplantation. Anesthesiology 77:899-904, 1992.)*

distributed to this compartment does not affect clinical response to the drug. In conditions in which clearance of the neuromuscular blocker is reduced, such as renal or hepatic disease, the terminal portion of the plasma concentration-versus-time curve is most affected (see Fig. 29-14).[127] The rate of decline in plasma concentration is slowed, and recovery from paralysis is potentially delayed.[127] In conditions associated with an increased volume of distribution, such as renal or hepatic disease, early plasma concentrations of drug may be less than those observed when organ function is normal: with a greater volume of distribution, the plasma concentration should be less, whereas the total amount of a drug would be greater (Fig. 29-16). Decreased protein binding of a drug results in a larger distribution volume, but because the degree of protein binding of neuromuscular blockers is small, changes in protein binding will have minimal effect on their distribution.[128]

Recovery of neuromuscular function takes place as plasma concentrations decline, and the greater part of this decrease occurs primarily because of distribution. Thus, processes that primarily affect elimination of the drug, such as renal failure, may not be associated with prolonged duration of blockade.[129,130] However, as recovery comes to rely more on drug elimination than on distribution (i.e., from 25% to 75% or greater) or after the administration of larger or repeated doses, the duration of action may be prolonged.[123,131]

After the injection of a neuromuscular blocker, the plasma drug concentration immediately starts to decrease. The effect (neuromuscular blockade) takes approximately 1 minute to begin, increases initially, and does not start to recover for many more minutes despite the continually decreasing plasma concentration of drug. This discrepancy between plasma concentration and drug effect occurs because the action of neuromuscular blockers is not in plasma but at the neuromuscular junction. To produce paralysis, the drug must diffuse from plasma into the neuromuscular junction, and the effect is terminated later by diffusion of drug back into plasma (see Fig. 29-15). Thus, concentrations at the neuromuscular junction lag behind those in plasma, and they are lower during the onset of blockade and greater during recovery. The plasma concentration-effect relationship exhibits hysteresis; that is, for a given level of blockade, plasma concentrations are greater during onset than during recovery. For this reason, a concentration-effect relationship cannot be obtained simply by directly relating the plasma concentration to the level of neuromuscular blockade.

To overcome this problem, pharmacodynamic models have been developed to incorporate a factor for the delay caused by diffusion of drug to and from the neuromuscular junction.[84,120,132-143] This factor, k_{e0}, is the rate constant for equilibration of drug between plasma and the neuromuscular junction. By measuring plasma drug concentrations and neuromuscular blockade during both the onset and recovery phases and using the technique of simultaneous pharmacokinetic/pharmacodynamic modeling, it is possible to collapse the hysteresis in the plasma concentration-effect curve, estimate actual drug concentrations at the neuromuscular junction, and derive true concentration-effect relationships (Ce_{50} and k_{e0}) for the neuromuscular blockers (Table 29-5).[120]

Clinical Management

Neuromuscular blockers are used mainly to facilitate tracheal intubation and provide surgical relaxation. The intensity of neuromuscular blockade required varies with the surgical procedure. Important safety issues arise with the use of neuromuscular blockers: cardiovascular and respiratory side effects and the adequacy of recovery to normal neuromuscular function.

Several clinical alternatives to neuromuscular blockers are available that provide adequate surgical relaxation. It is important to keep them all in mind to avoid relying only on neuromuscular blockade to achieve a desired degree of relaxation. Such options include adjustment of the depth of general anesthesia, the use of regional anesthesia, proper positioning of the patient on the operating table, and proper adjustment of the depth of neuromuscular blockade. The choice of one or several of these options is determined by the estimated remaining duration of surgery, the anesthetic technique, and the surgical maneuver required.

Dosage

General Dosage Guidelines

It is important to select the proper dosage of a nondepolarizing neuromuscular blocker to ensure that the desired effect is achieved without overdosage (Tables 29-6 and 29-7). In addition to general knowledge of the guidelines, precise practice requires the use of a peripheral nerve stimulator to adjust the relaxant dosage for the individual patient. Overdosage must be avoided for two reasons: to limit the duration of drug effect to match the anticipated length of surgery and to avoid unwanted cardiovascular side effects.

Initial and Maintenance Dosage

The initial dose is determined by the purpose of administration. Traditionally, doses used to facilitate tracheal intubation are twice the ED_{95} (this also approximates four times the ED_{50}) (see Table 29-6). If the trachea has already been intubated without the use of a nondepolarizing blocker or with succinylcholine and the purpose is simply to produce surgical relaxation, a dose slightly less than the ED_{95} (see Table 29-7) should be given, with adjustment upward as indicated by responses evoked by peripheral

nerve stimulation. Downward adjustment of the initial dose is necessary in the presence of any of the potent inhaled anesthetics (see the subsection later on drug interactions).

To avoid prolonged residual paralysis, inadequate antagonism of residual blockade, or both, the main goal should be to use the lowest possible dose that will provide adequate relaxation for surgery. Management of individual patients should always be guided by monitoring with a peripheral nerve stimulator. In an adequately anesthetized and monitored patient, there is little reason to completely abolish twitch or TOF responses to peripheral nerve stimulation during maintenance of relaxation. Supplemental (maintenance) doses of neuromuscular blockers should be about one-fourth (in the case of intermediate- and short-acting neuromuscular blockers) to one-tenth (in the case of long-acting neuromuscular blockers) the initial dose and should not be given until there is clear evidence of beginning of recovery from the previous dose.

Maintenance of relaxation by continuous infusion of intermediate- and short-acting drugs can be performed and is useful to keep the relaxation smooth and to rapidly adjust the depth of relaxation according to surgical needs. The depth of blockade in each patient is kept moderate, if possible, to ensure prompt spontaneous recovery or easy reversal at the end of the procedure. Table 29-6 lists the approximate dose ranges that are usually required during infusion to maintain 90% to 95% blockade of the twitch (one twitch visible on TOF stimulation) under nitrous oxide–oxygen anesthesia supplemented with intravenous anesthetics. The infusion dosage is usually decreased by 30% to 50% in the presence of potent inhaled anesthetics.

Neuromuscular Blockers and Tracheal Intubation

The speed of onset of neuromuscular blockade is one of the requirements for rapidly securing the airway, and it is affected by several factors, including the rate of delivery of drug to the

*The suggested dosages provide good intubating conditions under light anesthesia. Satisfactory abdominal relaxation may be achieved at the dosages listed after intubation without a relaxant or with succinylcholine. This table is intended as a general guide to dosage. Individual relaxant requirements should be confirmed with a peripheral nerve stimulator.

†The potentiation of nondepolarizing relaxants by different anesthetic vapors has been reported to vary 20% to 50%. Recent data suggest, however, that this variation may be much less, particularly in the case of intermediate- and short-acting relaxants. Therefore, for the sake of simplicity, this table assumes a potentiation of 40% in the case of all volatile anesthetics.

neuromuscular junction, receptor affinity, plasma clearance, and the mechanism of neuromuscular blockade (depolarizing versus nondepolarizing).[101,155,156] The speed of onset is inversely proportional to the potency of nondepolarizing neuromuscular blockers.[101,155] A high ED_{95} (i.e., low potency) is predictive of rapid onset of effect and vice versa (Fig. 29-17; Table 29-7). Except for atracurium,[157] the molar potency (the ED_{50} or ED_{95} expressed as μM/kg) is highly predictive of a drug's initial rate of onset of effect (at the adductor pollicis).[155] A drug's measured molar potency is the end result of many contributing factors: the drug's intrinsic potency (Ce_{50}—the biophase concentration resulting in 50% twitch depression), the rate of equilibration between plasma and the biophase (k_{e0}), the initial rate of plasma clearance, and probably other factors as well.[158] Rocuronium has a molar potency (ED_{95}) of 0.54 μM/kg, which is about 13% that of vecuronium and only 9% that of cisatracurium. Thus, rapid onset of rocuronium's effect (at the adductor pollicis) is not unexpected.

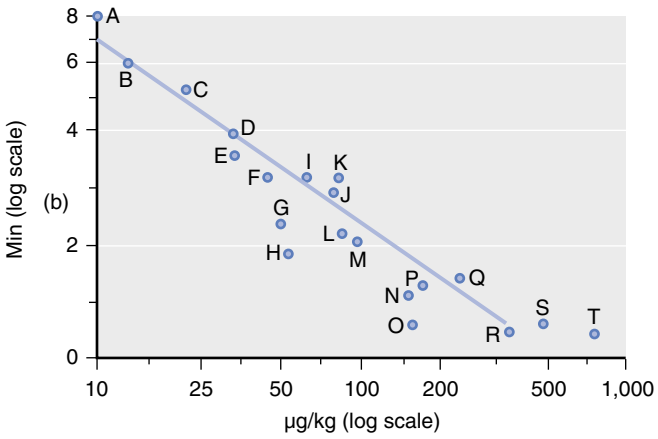

Figure 29-17 Linear regression of the onset of neuromuscular blockade (ordinate) versus potency of a series of steroidal relaxants studied in the cat model by Bowman and colleagues.[101] The data show that onset may be increased in compounds of low potency and encouraged the eventual development of rocuronium and rapacuronium (ORG 9487). A, pipecuronium; C, pancuronium; D, vecuronium.

Donati and Meistelman[156] proposed a model to explain this inverse potency-onset relationship. Nondepolarizing neuromuscular blockers of low potency (e.g., rocuronium) have more molecules to diffuse from the central compartment into the effect compartment. Once in the effect compartment, all molecules act promptly. Weaker binding of the low-potency drugs to receptors prevents buffered diffusion,[156] a process that occurs with more potent drugs. Buffered diffusion causes repetitive binding and unbinding to receptors, which keeps potent drugs in the neighborhood of the effector sites and potentially lengthens the duration of effect.

The times to 95% blockade at the adductor pollicis after administration of the ED_{95} dose of succinylcholine, rocuronium, vecuronium, atracurium, mivacurium, and cisatracurium are shown in Figure 29-18.[117,155,157] This illustration shows that the most potent compound, cisatracurium, has the slowest onset and that the least potent compound, rocuronium, has the most rapid onset.[117,155,157] Bevan[159] also proposed that rapid plasma clearance is associated with a rapid onset of action. The fast onset of succinylcholine's action is related to its rapid metabolism and plasma clearance.

Table 29-7 Pharmacodynamic Effects of Succinylcholine and Nondepolarizing Neuromuscular Blockers

For atracurium and mivacurium, slower injection (30 seconds) is recommended to minimize circulatory effects.
*Time from injection of the intubating dose to recovery of twitch to 25% of control.

The onset of neuromuscular blockade is much more rapid in the muscles that are relevant to obtaining optimal intubating conditions (laryngeal adductors, diaphragm, and masseter) than in the muscle that is typically monitored (adductor pollicis) (see Fig. 29-4).[160] Thus, neuromuscular blockade develops faster, lasts a shorter time, and recovers more quickly in these muscles (Table 29-8).[26,160-163] These observations may seem contradictory because there is also convincing evidence that the median effective concentration (EC_{50}) for almost all drugs studied is between 50% and 100% higher at the diaphragm or larynx than it is at the adductor pollicis. Fisher and coworkers[164] explain this apparent contradiction by postulating more rapid equilibration (shorter $t_{½}k_{e0}$) between plasma and the effect compartment at these central muscles. This accelerated rate of equilibrium probably represents little more than differences in regional blood flow. Therefore, muscle blood flow rather than the drug's intrinsic potency may be more important in determining the onset and offset time of nondepolarizing neuromuscular blockers. More luxuriant blood flow (greater blood flow per gram of muscle) at the diaphragm or larynx would result in delivery of a higher peak plasma concentration of drug to the central muscle in the brief period before rapid redistribution is well under way.

Onset of blockade occurs 1 to 2 minutes earlier in the larynx than at the adductor pollicis after the administration of nondepolarizing neuromuscular blocking agents. The pattern of blockade (onset, depth, and speed of recovery) in the orbicularis oculi is similar to that in the larynx.[165] By monitoring the onset of neuromuscular blockade at the orbicularis oculi, one can predict the quality of intubating conditions. The onset of maximal blockade in the larynx also corresponds to the point at which the adductor pollicis begins to show palpable evidence of weakening. Furthermore, the return of thumb responses to normal suggests that the efferent muscular arc of the protective airway reflexes is intact.

Rapid Tracheal Intubation

Succinylcholine remains the drug of choice when rapid tracheal intubation is needed because it consistently provides muscle relaxation within 60 to 90 seconds. When succinylcholine is considered undesirable or contraindicated, the onset of action of

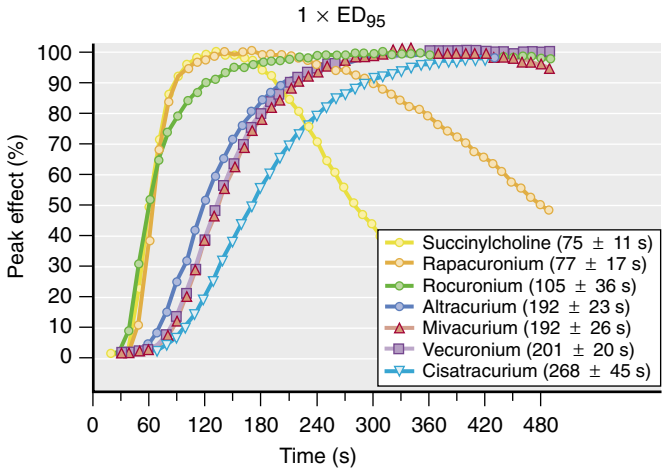

Figure 29-18 Percentages of peak effect after an ED_{95} of succinylcholine, rocuronium, rapacuronium, vecuronium, atracurium, mivacurium, and cisatracurium at the adductor pollicis muscle. Times (mean ± SD) in seconds to 95% of peak effect are shown in parentheses. *(Data from Kopman AF, Klewicka MM, Ghori K, et al: Dose-response and onset/offset characteristics of rapacuronium. Anesthesiology 90:425-431, 1999; and Kopman AF, Klewicka MM, Neuman GG: Molar potency is not predictive of the speed of onset of atracurium. Anesth Analg 89:1046-1049, 1999.)*

nondepolarizing neuromuscular blocking drugs can be accelerated by preceding the intubating dose with a priming dose of neuromuscular blocker,[166] by using high doses of an individual agent,[148] or by using combinations of neuromuscular blockers.[149] Although some combinations of mivacurium and rocuronium can achieve rapid onset without undue prolongation of action and without undesirable side effects,[149] combination therapy may not consistently result in rapid onset of effect.

The Priming Technique. Since the introduction of rocuronium, the use of priming has decreased considerably. Several groups of investigators have recommended that a small subparalyzing dose of the nondepolarizer (about 20% of the ED_{95} or about 10% of the intubating dose) be given 2 to 4 minutes before a large second dose for tracheal intubation.[166] This procedure, termed priming, has been shown to accelerate the onset of blockade for most nondepolarizing neuromuscular blockers by 30 to 60 seconds, which means that intubation can be performed within approximately 90 seconds of the second dose. However, the intubating conditions that occur after priming do not match those that occur after succinylcholine. Moreover, priming carries the risks of aspiration and difficulty swallowing, and the visual disturbances associated with subtle degrees of blockade are uncomfortable for the patient.[167]

The High-Dose Regimen for Rapid Tracheal Intubation. Larger doses of neuromuscular blockers are usually recommended when intubation must be accomplished in less than 90 seconds. High-dose regimens, however, are associated with a considerably prolonged duration of action and potentially increased cardiovascular side effects (see Table 29-7).[148,168] Increasing the dosage of rocuronium from 0.6 mg/kg (twice the ED_{95}) to 1.2 mg/kg (four times the ED_{95}) shortened the onset time of complete neuromuscular blockade from 89 ± 33 seconds (mean ± SD) to 55 ± 14 seconds but significantly prolonged the clinical duration (i.e., recovery of the first twitch of TOF [T1] to 25% of baseline) from 37 ± 15 minutes to 73 ± 32 minutes.[148]

Whatever technique of rapid-sequence induction of anesthesia and intubation is elected, the following four principles are important: (1) preoxygenation must be performed, (2) sufficient doses of intravenous drugs must be administered to ensure that the patient is adequately anesthetized, (3) intubation within 60 to 90 seconds must be considered acceptable, and (4) cricoid pressure should be applied subsequent to injection of the induction agent.

Low-Dose Relaxants for Tracheal Intubation

The low-dose technique is not suitable for rapid-sequence induction, but several studies have demonstrated that low doses of neuromuscular blocking drugs can be used for routine tracheal intubation. The use of low doses of neuromuscular blockers has advantages: (1) it shortens the time to recovery from

Table 29-8 Time Course of Action and Peak Effect at the Laryngeal Adductors and Adductor Pollicis

		Laryngeal Adductors			Adductor Pollicis			
Dose (mg/kg)	Anesthesia	Onset Time (sec)	Maximum Block (% Depression)	Clinical Duration (min)	Onset Time (sec)	Maximum Block (% Depression)	Clinical Duration (min)	Reference

Clinical duration is the time until T1 recovers to 25% of its control value. Values are means ± SD[161-163] or SEM.[26,160]

neuromuscular blockade and (2) it reduces the requirement for anticholinesterase drugs. Rocuronium has the shortest onset time of all the nondepolarizing neuromuscular blocking agents currently available.[160,161] The maximal effect of either 0.25 or 0.5 mg/kg of rocuronium at the laryngeal muscles occurs after 1.5 minutes.[160] This interval is shorter than the 3.3 minutes reported after the administration of equipotent doses of vecuronium (0.04 or 0.07 mg/kg)[26] and only slightly more than the 0.9 minute reported after 0.25 or 0.5 mg/kg of succinylcholine (see Table 29-8).[169]

With a better understanding of the multiple factors that contribute to satisfactory conditions for intubation, it is now possible to take full advantage of the onset profile for rocuronium. Intubating conditions are related more closely to the degree of neuromuscular blockade of the laryngeal adductor muscles than to the degree of blockade typically monitored at the adductor pollicis. Figure 29-19 demonstrates this principle.[158] Complete blockade at the larynx, diaphragm, or both may not be a prerequisite for satisfactory tracheal intubating conditions.

Kopman and associates[171] noted that 0.5 mg/kg of rocuronium (1.5 times the ED_{95}) provided very satisfactory conditions for intubation (25 intubations were rated excellent and 5 were rated good) in patients anesthetized with 12.5 µg/kg of alfentanil and 2.0 mg/kg of propofol if laryngoscopy were delayed for 75 seconds after drug administration. They estimated that 1.5 times the ED_{95} of rocuronium will produce at least 95% blockade in 98% of the population.[171] A similar or lower multiple of rocuronium's ED_{95} was shown to have a more rapid onset and shorter duration of action than atracurium[172] or cisatracurium.[112] The onset of cisatracurium's effect is too slow to provide good conditions for intubation in less than 2 minutes, even after a dose twice the ED_{95}.

In the vast majority of patients receiving 15 µg/kg of alfentanil followed by 2.0 mg/kg of propofol and 0.45 mg/kg of rocuronium, good to excellent conditions for intubation will be present 75 to 90 seconds after the completion of drug administration.

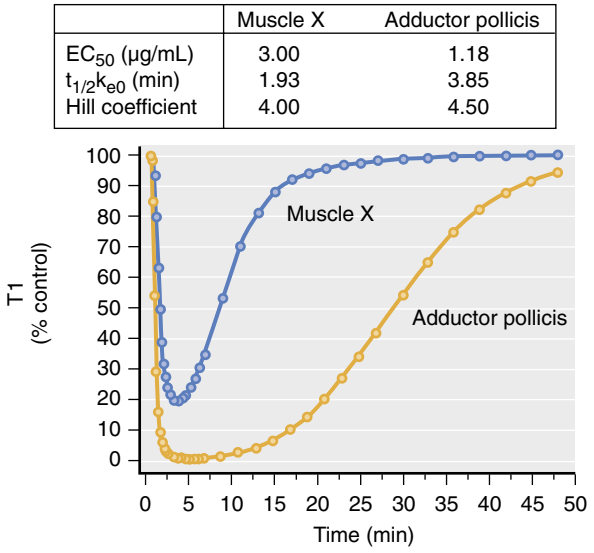

Figure 29-19 Computer simulation based on Sheiner's model[120] and data reported by Wierda and colleagues.[170] The ED_{95} of rocuronium at the adductor pollicis from this model is 0.33 mg/kg. Rocuronium, 0.45 mg/kg, is given as a bolus at time zero. Muscle X represents a muscle (such as the diaphragm or the laryngeal adductors) that is less sensitive to the effects of nondepolarizing relaxants than the adductor pollicis but has greater blood flow. In this example, the concentration of rocuronium producing a 50% block (EC_{50}) of muscle X is 2.5 times that of the adductor pollicis, but the half-life of transport between plasma and the effect compartment ($t_{1/2}k_{e0}$) of muscle X is only half as long. The rapid equilibration between plasma concentrations of rocuronium and muscle X results in more rapid onset of blockade of muscle X than the adductor pollicis. The greater EC_{50} at muscle X explains the faster recovery of this muscle than of the adductor pollicis from neuromuscular blockade. Lower blood concentrations of rocuronium must be achieved at the adductor pollicis than at muscle X before recovery begins. *(From Naguib M, Kopman AF: Low dose rocuronium for tracheal intubation. Middle East J Anesthesiol 17:193-204, 2003.)*

Metabolism and Elimination

The specific pathways of the metabolism (biotransformation) and elimination of neuromuscular blocking drugs are summarized in Table 29-9. Of the nondepolarizing neuromuscular blockers listed, pancuronium, pipecuronium, vecuronium, atracurium, cisatracurium, and mivacurium are the only ones that are metabolized or degraded. Nearly all nondepolarizing neuromuscular blocker molecules contain ester linkages, acetyl ester groups, and hydroxy or methoxy groups. These substitutions, especially the quaternary nitrogen groups, confer a high degree of water solubility with only slight lipid solubility. The hydrophilic nature of relaxant molecules enables easy elimination in urine by glomerular filtration, with no tubular resorption or secretion. Therefore, all nondepolarizing neuromuscular blockers show elimination of the parent molecule in urine as the basic route of elimination; those with a long duration of action thus have a clearance rate that is limited by the glomerular filtration rate (1 to 2 mL/kg/min).

Steroidal Compounds

Long-Acting Neuromuscular Blockers. Pancuronium is cleared largely by the kidney.[173] Its hepatic uptake is limited. A small amount (15% to 20%) is deacetylated at the 3-position in the liver, but this makes a minimal contribution to the total clearance. Deacetylation also occurs at the 17-position, but to such a small extent that it is clinically irrelevant. The three known metabolites have been studied individually in anesthetized humans.[151] The 3-OH metabolite is the most potent of the three, being approximately half as potent as pancuronium, and is the only one present in detectable concentrations in plasma. This metabolite has pharmacokinetics and a duration of action similar to those of pancuronium.[151] In addition, the 3-OH metabolite is most likely excreted largely by the kidney.[151] The parent compound and the 3-OH metabolite are also cleared in small amounts via a minor liver pathway. Total clearance is delayed, and the duration of action is significantly lengthened by severe disorders of renal or hepatic function.[129,174,175]

Intermediate-Acting Neuromuscular Blockers. Vecuronium, the 2-desmethyl derivative of pancuronium, is more lipid soluble than pancuronium because of absence of the quaternizing methyl group at the 2-position. It undergoes two to three times more metabolism than pancuronium does. Vecuronium is taken up into the liver by a carrier-mediated transport system[176] and then deacetylated at the 3-position by liver microsomes. About 12% of clearance of vecuronium occurs by conversion to 3-desacetylvecuronium,[177] and 30% to 40% is cleared in

Table 29-9 Metabolism and Elimination of Neuromuscular Blocking Drugs

Drug	Duration	Metabolism (%)	Elimination		Metabolites
			Kidney (%)	Liver (%)	
Succinylcholine	Ultrashort	Butyrylcholinesterase (98%-99%)	<2%	None	Monoester (succinyl monocholine) and choline; monoester metabolized much more slowly than succinylcholine
Gantacurium	Ultrashort	Cysteine (fast) and ester hydrolysis (slow)	?	?	Inactive cysteine adduction product, chloroformate monoester, and alcohol
Mivacurium	Short	Butyrylcholinesterase (95%-99%)	<5% (Metabolites eliminated in urine and bile)	None	Monoester and quaternary alcohol. The metabolites are inactive. They are most likely not themselves metabolized any further.
Atracurium	Intermediate	Hofmann elimination and nonspecific ester hydrolysis (60%-90%)	10%-40% (Metabolites eliminated in urine and bile)	None	Laudanosine, acrylates, alcohols, and acids. Although laudanosine has CNS-stimulating properties, the clinical relevance of this effect is negligible.
Cisatracurium	Intermediate	Hofmann elimination (77%?)	Renal clearance is 16% of total		Laudanosine and acrylates. Ester hydrolysis of the quaternary monoacrylate occurs secondarily. Because of the greater potency of cisatracurium, laudanosine quantities produced by Hofmann elimination are 5 to 10 times lower than in the case of atracurium, thus making this not an issue in practice.
Vecuronium	Intermediate	Liver (30%-40%)	40%-50% (Metabolites excreted in urine and bile, ≈40%)	50%-60%	The 3-OH metabolite accumulates, particularly in renal failure. It has about 80% the potency of vecuronium and may be responsible for delayed recovery in ICU patients.
Rocuronium	Intermediate	None	10%-25%	>70%	None
Pancuronium	Long	Liver (10%-20%)	85%	15%	The 3-OH metabolite may accumulate, particularly in renal failure. It is about two thirds as potent as the parent compound.
d-Tubocurarine	Long	None	80% (?)	20%	None

CNS, central nervous system; ICU, intensive care unit.

bile as parent compound.[127] Although the liver is the principal organ of elimination for vecuronium, the drug also undergoes significant (up to 25%) renal excretion, and this combined organ elimination gives it a clearance rate of 3 to 6 mL/kg/min.[177,178]

The principal metabolite of vecuronium, 3-desacetylvecuronium, is a potent (~80% of vecuronium) neuromuscular blocking drug in its own right. The metabolite, though, has slower plasma clearance and a longer duration of action than vecuronium does.[177] 3-Desacetylvecuronium has a clearance rate of 3.5 mL/kg/min, and renal clearance accounts for approximately a sixth of its elimination.[177] In patients in the ICU with renal failure, 3-desacetylvecuronium can accumulate and produce prolonged neuromuscular blockade.[179] Other putative metabolites are 17-desacetylvecuronium and 3,17-bisdesacetylvecuronium, neither of which occurs in clinically significant amounts.

Rocuronium is eliminated primarily by the liver, with a small fraction (~10%) eliminated in urine.[180] It is taken up into the liver by a carrier-mediated active transport system.[181] The putative metabolite, 17-desacetylrocuronium, has not been detected in significant quantities.

Benzylisoquinolinium Compounds

Short-Acting Neuromuscular Blockers. Mivacurium is hydrolyzed in plasma by butyrylcholinesterase to a monoester and an amino alcohol,[9] which are excreted in urine and bile. The metabolites are positively charged, thus making their entry into the central nervous system (CNS) unlikely. They show less than 1% of the neuromuscular blocking activity of the parent compound and do not affect the autonomic nervous system. Less than 5% is excreted in urine as the parent compound.

Mivacurium consists of three stereoisomers, and clearance rates for the two most pharmacologically active isomers, *cis-trans* and *trans-trans*, are approximately 100 and 50 to 70 mL/kg/min,

respectively.[99,182,183] These two isomers show elimination half-lives of 2 to 3 minutes.[99] The third stereoisomer, *cis-cis*, is present as only 4% to 8% of the mivacurium mixture and has less than 10% of the neuromuscular blocking potency of the other two isomers.[99] Consequently, even though it has a much longer elimination half-life (55 minutes) and lower clearance (~4 mL/kg/min) than the two other isomers, it does not contribute significantly to the duration of action of mivacurium.[99] This rapid enzymatic clearance of mivacurium accounts for its short duration of action,[9,99] which is much shorter than that of vecuronium and atracurium but about twice that of succinylcholine.[184] When butyrylcholinesterase activity is severely deficient, however, such as in the rare patients (1/3000) who are homozygous for genetically atypical enzymes, the duration of action of mivacurium is prolonged for up to several hours.[185-188]

Intermediate-Acting Neuromuscular Blockers. Theoretically, atracurium is metabolized by two pathways: Hofmann elimination and ester hydrolysis by nonspecific esterases. Hofmann elimination is a purely chemical process that results in loss of the positive charges by molecular fragmentation to laudanosine (a tertiary amine) and a monoquaternary acrylate, compounds that were thought to have no neuromuscular and little or no cardiovascular activity of clinical relevance.[189] Under the proper chemical conditions, however, these breakdown products may actually be used to synthesize the parent compound.

Because it undergoes Hofmann elimination, atracurium is relatively stable at pH 3.0 and 4°C and becomes unstable when injected into the bloodstream. Early observations of breakdown of the drug in buffer and plasma showed faster degradation in plasma, thus suggesting possible enzymatic hydrolysis of the ester groups. Further evidence suggested that this second pathway, ester hydrolysis, may be more important than originally realized in the breakdown of atracurium.[190] By pharmacokinetic analysis, Fisher and colleagues[191] concluded that a significant amount of clearance of atracurium may be accomplished by routes other than ester hydrolysis and Hofmann elimination. Hence, it appears that atracurium's metabolism is complicated and may not be completely understood.[191]

Laudanosine, a metabolite of atracurium, has CNS-stimulating properties. Unlike atracurium, laudanosine is dependent on the liver and kidney for its elimination and has a long elimination half-life.[192] Laudanosine concentrations are elevated in patients with liver disease[193] and those who have received atracurium for many hours in an ICU.[194] Laudanosine freely crosses the blood-brain barrier.[192] Beemer and coworkers[195] found that patients awakened at a 20% higher arterial concentration of thiopental when atracurium had been given; this was attributed to the CNS-stimulatory effect of laudanosine. These relatively low concentrations of laudanosine, however, did not influence an animal model of epilepsy[196] or lidocaine-induced seizures.[197] In the ICU, blood levels of laudanosine can be as high as 5.0 to 6.0 µg/mL.[186] Though not known in humans, the seizure threshold in animals ranges from 5.0 µg/mL in rabbits[198] to 17 µg/mL in dogs.[199] Thus, adverse effects are unlikely to occur with the use of atracurium in the operating room or ICU.

Laudanosine also has cardiovascular effects. In dogs, hypotension occurs at a blood concentration of about 6 µg/mL,[199] a level higher than that usually found in patients in the ICU. However, there is one case report of a patient who experienced severe hypotension and bradycardia while receiving atracurium, which resolved only when vecuronium was substituted.[200] Laudanosine enhances the stimulation-evoked release of norepinephrine,[201] a finding that may also partly account for its CNS-stimulating effect.

Atracurium is a mixture of 10 optical isomers. Cisatracurium is the 1R *cis*–1′R *cis* isomer of atracurium.[95] Like atracurium, cisatracurium is metabolized by Hofmann elimination to laudanosine and a monoquaternary acrylate.[202,203] In contrast, however, there is no ester hydrolysis of the parent molecule. Hofmann elimination accounts for 77% of the total clearance of 5 to 6 mL/kg/min. Twenty-three percent of the drug is cleared through organ-dependent means, with renal elimination accounting for 16% of this figure.[203] Because cisatracurium is about four or five times as potent as atracurium, about five times less laudanosine is produced, and accumulation of this metabolite is not thought to be of any consequence in clinical practice.

Long-Acting Neuromuscular Blockers. With these agents, there is no active metabolism of dTc. The kidney is the major pathway of elimination, with approximately 50% of a dose being eliminated through renal pathways. The liver is probably a secondary route of elimination. Therefore and because more suitable agents are available, these drugs are not indicated for use in patients with either renal[130] or hepatic failure.

Asymmetric Mixed-Onium Chlorofumarates (Gantacurium)

Gantacurium appears to be degraded by two chemical mechanisms, neither of which is enzymatic: (1) rapid formation of an apparently inactive cysteine adduction product, with cysteine replacing chlorine, and (2) slower hydrolysis of the ester bond adjacent to the chlorine substitution, presumably to inactive hydrolysis products (see Fig. 29-10).[105]

In summary, the only short-acting neuromuscular blocker currently available for clinical use, mivacurium, is cleared rapidly and almost exclusively via metabolism by butyrylcholinesterase, which results in much greater plasma clearance than with any other nondepolarizing neuromuscular blocker.[9] Neuromuscular blockers of intermediate duration, such as vecuronium, rocuronium, atracurium, and cisatracurium, have clearance rates in the range of 3 to 6 mL/kg/min because of multiple pathways of degradation, metabolism, and elimination. Atracurium is cleared two to three times more rapidly than the long-acting drugs.[123,193,204,205] Similar clearance values have been obtained for rocuronium[206-210] and cisatracurium.[202,203,211] Finally, the long-acting neuromuscular blockers undergo minimal or no metabolism, and they are eliminated largely unchanged, mostly by renal excretion. Hepatic pathways are less important in their metabolism.

Adverse Effects of Neuromuscular Blockers

Neuromuscular blocking agents seem to play a prominent role in the incidence of adverse reactions that occur during anesthesia. The Committee on Safety of Medicines in the United Kingdom reported that 10.8% (218 of 2014) of adverse drug reactions and 7.3% of deaths (21 of 286) were attributable to neuromuscular blocking drugs.[212]

Autonomic Effects

Neuromuscular blocking agents may interact with nicotinic and muscarinic cholinergic receptors within the sympathetic and

parasympathetic nervous systems and with nicotinic receptors at the neuromuscular junction.

Dose-response ratios to compare the neuromuscular blocking potencies of these agents (the ED_{95}) with their potencies in blocking vagal (parasympathetic) or sympathetic ganglionic transmission (the ED_{50}) can be constructed (Table 29-10). These ratios are termed the autonomic margin of safety of the relaxant in question. The higher the dose ratio, the lower the likelihood of or the greater the safety ratio for the occurrence of the particular autonomic effect. The side effect is considered absent (none) in clinical practice if the safety ratio is greater than 5; it is weak or slight if the safety ratio is 3 or 4, moderate if 2 or 3, and strong or prominent if the ratio is 1 or less.

These autonomic responses are not reduced by slower injection of the relaxant. They are dose related and additive over time if divided doses are given. If identical to the original dose, subsequent doses will produce a similar response; that is, no tachyphylaxis will occur. This is not the case, however, when the side effect of histamine release is in question. Cardiovascular responses secondary to histamine release are decreased by slowing the injection rate, and the response undergoes rapid tachyphylaxis. The autonomic effects of neuromuscular blocking drugs are summarized in Table 29-11.

Table 29-11 Clinical Autonomic Effects of Neuromuscular Blocking Drugs

Pancuronium	None	Blocks moderately	None

Histamine Release. Quaternary ammonium compounds such as neuromuscular blockers are generally weaker histamine-releasing substances than tertiary amines such as morphine are. Nevertheless, when large doses of certain neuromuscular blockers are administered rapidly, erythema of the face, neck, and upper part of the torso may develop, as well as a brief decrease in arterial pressure and a slight to moderate increase in heart rate. Bronchospasm in this setting is very rare. The clinical effects of histamine are seen when plasma concentrations increase to 200% to 300% of baseline values, and these effects involve chemical displacement of the contents of mast cell granules containing histamine, prostaglandin, and possibly other vasoactive substances.[213] The serosal mast cell, located in the skin and connective tissue and near blood vessels and nerves, is principally involved in the degranulation process.[213]

The side effect of histamine release is most often noted after administration of the benzylisoquinolinium class of muscle relaxants, although it has also been noted with steroidal relaxants of low potency. The effect is usually of short duration (1 to 5 minutes), is dose related, and is clinically insignificant in healthy patients. Hatano and associates[214] showed that the hypotensive cardiovascular response to 0.6 mg/kg of dTc in humans is prevented not only by antihistamines but also by nonsteroidal anti-inflammatory drugs (e.g., aspirin). These investigators concluded that the final step in dTc-induced hypotension is modulated by prostaglandins that are vasodilators.[214] This side effect can be reduced considerably by using a slower injection rate. It is also prevented by prophylaxis with combinations of $histamine_1$ and $histamine_2$ blockers.[215] If a minor degree of histamine release such as just described occurs after an initial dose of a neuromuscular blocker, subsequent doses will generally cause no response at all, as long as they are no larger than the original dose. This is clinical evidence of tachyphylaxis, an important characteristic of histamine release. A much more significant degree of histamine release occurs during anaphylactic or anaphylactoid reactions; these reactions are very rare.

Clinical Cardiovascular Manifestations of Autonomic Mechanisms

Hypotension. The hypotension seen with the use of atracurium and mivacurium is due to release of histamine, whereas dTc causes hypotension via histamine release and ganglion blockade.[216,217] The effects of dTc occur closer to the dose required to achieve neuromuscular blockade.[116] The safety margin for histamine release is about three times greater for atracurium and mivacurium than it is for dTc.[213,214,217] Rapid administration of atracurium in doses greater than 0.4 mg/kg and mivacurium in doses greater than 0.15 mg/kg has been associated with transient hypotension as a result of release of histamine (Fig. 29-20).

Tachycardia. Pancuronium causes a moderate increase in heart rate and, to a lesser extent, in cardiac output, with little or no change in systemic vascular resistance.[218] Pancuronium-induced tachycardia has been attributed to (1) vagolytic action,[218] probably secondary to inhibition of M_2 receptors, and (2) sympathetic stimulation that involves both direct (blockade of neuronal uptake of norepinephrine) and indirect (release of norepinephrine from adrenergic nerve endings) mechanisms.[219] In studies in humans, Roizen and colleagues[220] surprisingly found decreases in plasma norepinephrine levels after the administration of either pancuronium or atropine. They postulated that the increase in

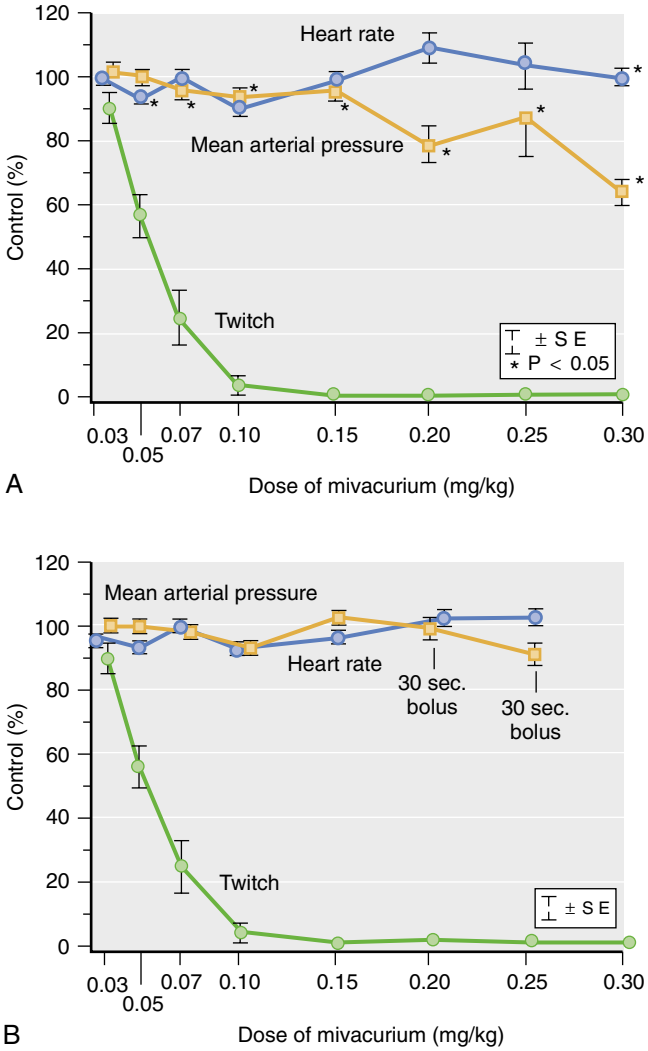

Figure 29-20 Dose response to mivacurium in patients under nitrous oxide–oxygen–opioid anesthesia. Maximum changes at each dose are shown; $n = 9$ subjects per group. **A,** With fast injection, a 15% to 20% decrease in arterial pressure occurred at 2.5 to 3 times the ED_{95} (0.20 to 0.25 mg/kg). **B,** The changes were less than 10% with a slower injection (30 seconds). *(From Savarese JJ, Ali HH, Basta SJ, et al: The cardiovascular effects of mivacurium chloride [BW B1090U] in patients receiving nitrous oxide–opiate–barbiturate anesthesia. Anesthesiology 70:386-394, 1989.)*

heart rate or rate-pressure product occurs because pancuronium (or atropine) acts through baroreceptors to reduce sympathetic outflow.[220] More specifically, the vagolytic effect of pancuronium increases the heart rate and, hence, blood pressure and cardiac output, which in turn influences the baroreceptors to decrease sympathetic tone. Support for this concept is provided by the fact that prior administration of atropine will attenuate or eliminate the cardiovascular effects of pancuronium.[218] However, a positive chronotropic effect that places emphasis on the vagolytic mechanism has not been found in humans.[221] The tachycardia seen with benzylisoquinolinium compounds is due to release of histamine.

DYSRHYTHMIAS. Succinylcholine and dTc actually reduce the incidence of epinephrine-induced dysrhythmias.[222] Possibly because of enhanced atrioventricular conduction,[223] the incidence of dysrhythmias caused by pancuronium appears to increase during halothane anesthesia.[218] Edwards and associates[224] observed a rapid tachycardia (more than 150 beats/min) that progressed to atrioventricular dissociation in two patients anesthetized with halothane who also received pancuronium. The only other factor common to these two patients was that both were taking tricyclic antidepressant agents.

BRADYCARDIA. Several case reports[225,226] have described the occurrence of severe bradycardia and even asystole after the administration of vecuronium or atracurium. All of these cases were also associated with opioid administration. Subsequent studies indicated that administration of vecuronium or atracurium alone does not cause bradycardia.[227] When combined with other drugs that do cause bradycardia (e.g., fentanyl), however, the nonvagolytic relaxants such as vecuronium, cisatracurium, and atracurium allow this mechanism to occur unopposed. Thus, the moderate vagolytic effect of pancuronium is often used to counteract opioid-induced bradycardia.

Respiratory Effects

The muscarinic cholinergic system plays an important role in regulating airway function. Five muscarinic receptors have been cloned,[228] three of which—M_1 to M_3—exist in the airways.[229] M_1 receptors are under sympathetic control, and they mediate bronchodilation.[230] M_2 receptors are located presynaptically (Fig. 29-21) at the postganglionic parasympathetic nerve endings, and they function in a negative-feedback mechanism to limit the release of acetylcholine. M_3 receptors, which are located postsynaptically (Fig. 29-21), mediate contraction of the airway smooth muscles (i.e., bronchoconstriction).[230] Nondepolarizing neuromuscular blockers have different antagonistic activities at both the M_2 and M_3 receptors.[231] For example, blockage of M_3 muscarinic receptors on airway smooth muscle inhibits vagally induced bronchoconstriction (i.e., causes bronchodilation), whereas blockage of M_2 receptors results in increased release of acetylcholine, which will act on M_3 receptors and cause bronchoconstriction.

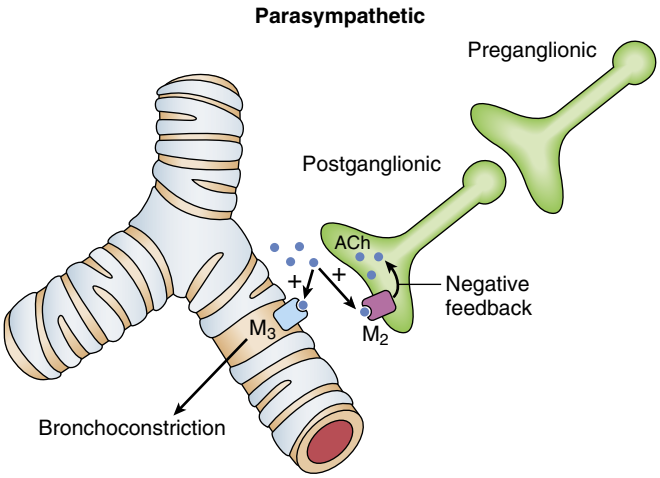

Figure 29-21 The muscarinic M_3 receptors are located postsynaptically on airway smooth muscle. Acetylcholine (ACh) stimulates M_3 receptors to cause contraction. M_2 muscarinic receptors are located presynaptically at the postganglionic parasympathetic nerve endings, and they function in a negative-feedback mechanism to limit the release of ACh.

The affinity of the compound rapacuronium to block M_2 receptors is 15 times higher than its affinity to block M_3 receptors.[231] This explains the high incidence (>9%) of severe bronchospasm[232-234] that was seen with this drug and resulted in its withdrawal from the market.

The administration of benzylisoquinolinium neuromuscular blocking drugs (with the exception of cisatracurium) is associated with histamine release, which may result in increased airway resistance and bronchospasm in patients with hyperactive airway disease.

Allergic Reactions

The frequency of life-threatening anaphylactic (immune-mediated) or anaphylactoid reactions occurring during anesthesia has been estimated to be between 1 in 1000 and 1 in 25,000 anesthetizations, with about a 5% mortality rate.[235,236] In France, the most common causes of anaphylaxis in patients who experienced allergic reactions were reported to be neuromuscular blocking drugs (58.2%), latex (16.7%), and antibiotics (15.1%).[237] Anaphylactic reactions are mediated through immune responses involving immunoglobulin E antibodies fixed to mast cells. Anaphylactoid reactions are not immune mediated and represent exaggerated pharmacologic responses in very rare and very sensitive individuals.

Neuromuscular blocking drugs contain two quaternary ammonium ions, which are the epitopes commonly recognized by specific immunoglobulin E.[238] Cross-reactivity has been reported between neuromuscular blocking drugs and food, cosmetics, disinfectants, and industrial materials.[238] Cross-reactivity is seen in 70% of patients with a history of anaphylaxis to a neuromuscular blocking drug.[237]

Steroidal compounds (e.g., rocuronium, vecuronium, pancuronium) result in no significant histamine release.[217] For example, four times the ED_{95} of rocuronium (1.2 mg/kg) causes no significant release of histamine.[239] Nevertheless, rocuronium and succinylcholine are reportedly associated with a 43.1% and 22.6% incidence of anaphylaxis in France.[237] Rose and Fisher[240] classified rocuronium and atracurium as having intermediate levels of risk for causing allergic reactions. They also noted that the increased number of reports of anaphylaxis with rocuronium is in line with the market share of that drug's use. Watkins[241] stated, "The much higher incidence of rocuronium reactions reported in France is currently inexplicable and is likely to remain so if investigators continue to seek a purely antibody-mediated response as an explanation of all anaphylactoid reaction presentations." There are currently no standards against which diagnostic tests (skin prick test, interdermal test, or immunoglobulin E testing) are performed, and new recommendations are still only in the proposal stage.[242] For instance, Laxenaire and Mertes[243] used a 1:10 dilution of rocuronium for interdermal skin testing, whereas Rose and Fisher[240] used a 1:1000 dilution. Levy and colleagues[244] showed that rocuronium in a 1:10 dilution can produce false-positive results on intradermal testing and suggested that rocuronium be diluted at least 100-fold to prevent such results. These authors also reported that high concentrations ($\geq 10^{-4}$ M) of both rocuronium and cisatracurium are capable of producing a wheal-and-flare response to intradermal testing, which was associated with mild to moderate mast cell degranulation in the cisatracurium group only.[244]

All neuromuscular blocking drugs can cause noncompetitive inhibition of histamine-*N*-methyltransferase, but the concentrations required for such inhibition far exceed those that would be used clinically, except in the case of vecuronium, with which the effect becomes manifested at 0.1 to 0.2 mg/kg.[245] This could explain the occurrence of occasional severe bronchospasm in patients after receiving vecuronium.[246]

Drug Interactions and Other Factors Affecting Response to Neuromuscular Blockers

A drug-drug interaction is an in vivo phenomenon that occurs when the administration of one drug alters the effects or kinetics of another drug. In vitro physical or chemical incompatibilities are *not* considered drug interactions.[247]

Many drugs have been shown to interact with neuromuscular blockers or their antagonists, or both, and it is beyond the scope of this chapter to review them all.[247,248] Some of the more important drug interactions with neuromuscular blockers and their antagonists are discussed in the following sections.

Interactions Among Nondepolarizing Neuromuscular Blockers

Mixtures of two nondepolarizing neuromuscular blockers are considered to be either additive or synergistic. Antagonistic interactions have not been reported in this class of drugs. Additive interactions have been demonstrated after the administration of chemically related agents, such as atracurium and mivacurium,[249] or after the coadministration of various pairs of steroidal neuromuscular blockers.[103] On the other hand, combinations of structurally dissimilar (e.g., a steroidal with a benzylisoquinolinium) neuromuscular blockers, such as pancuronium and dTc,[250] pancuronium and metocurine,[250] rocuronium and mivacurium,[149] or rocuronium and cisatracurium,[112] produce a synergistic response.

The administration of two neuromuscular blockers in combination was first introduced by Lebowitz and coworkers[250] in an attempt to reduce the cardiovascular side effects of neuromuscular blockers by giving smaller doses of each drug as a combination. An additional advantage (rapid onset and short duration) is noted for mivacurium-rocuronium combinations.[149] Although the precise mechanisms underlying a synergistic interaction are not known, hypotheses that have been put forward include the existence of multiple binding sites at the neuromuscular junction (presynaptic and postsynaptic receptors)[251] and the nonequivalence of binding affinities of the two α-subunits (α_H and α_L). Furthermore, inhibition of butyrylcholinesterase by pancuronium results in decreased plasma clearance of mivacurium and marked potentiation of the neuromuscular blockade.[252]

It should be noted that the pharmacodynamic response to the use of two different nondepolarizing blockers during the course of anesthesia depends not only on the specific drugs used

but also on the sequence of their administration.[253,254] Approximately three half-lives will be required for a clinical changeover (so that 95% of the first drug has been cleared) and for the duration of the blockade to begin to take on the characteristics of the second drug. After the administration of pancuronium, recovery from the first two maintenance doses of vecuronium is reportedly prolonged, although this effect becomes negligible by the third dose.[253] Similarly, Naguib and coauthors[249] noted that the mean duration of the first maintenance dose of mivacurium to 10% recovery of the first twitch was significantly longer after atracurium (25 minutes) than after mivacurium (14.2 minutes). However, the duration of the second maintenance dose of mivacurium after atracurium (18.3 minutes) was similar to that of mivacurium after mivacurium (14.6 minutes).

The apparent prolongation of action of the first maintenance dose of mivacurium administered after atracurium[249] and the prolongation reported with vecuronium after pancuronium[253,254] are not related to synergism. Combinations of atracurium and mivacurium[249] and vecuronium and pancuronium[103] are simply additive. However, this prolongation of the duration of action could be attributed to the relative concentrations of these drugs at the receptor site. Because most receptors remain occupied by the drug administered initially, the clinical profile depends on the kinetics or dynamics (or both) of the drug administered first rather than on those of the second (maintenance) drug. However, with further incremental doses of the second drug, a progressively larger proportion of the receptors are occupied by that drug, and its clinical profile becomes evident.

Interactions Between Succinylcholine and Nondepolarizing Neuromuscular Blockers

The interaction between succinylcholine and nondepolarizing neuromuscular blockers depends on the order of administration and the doses used.[86,255,256] Small doses of different nondepolarizing neuromuscular blockers administered before succinylcholine to prevent fasciculations have an antagonistic effect on the development of a subsequent depolarizing block produced by succinylcholine.[28,86] Therefore, it is recommended that the dose of succinylcholine be increased after the administration of a defasciculating dose of a nondepolarizing neuromuscular blocker.[28]

Studies on the effects of administration of succinylcholine before nondepolarizing neuromuscular blockers have produced conflicting results. Several investigators reported potentiation of the effects of pancuronium,[255] vecuronium, and atracurium[256] by prior administration of succinylcholine. In contrast, others found no significant influence of succinylcholine on the subsequent administration of pancuronium, rocuronium, or mivacurium.[86,257,258]

Interactions with Inhaled Anesthetics

Deep anesthesia induced with potent volatile anesthetics (in the absence of neuromuscular blockade) may cause a slight reduction in neuromuscular transmission, as measured by depression of sensitive indicators of clinical neuromuscular function, such as tetanus and TOF.[259] Inhaled anesthetics also enhance the neuromuscular blocking effects of nondepolarizing neuromuscular blockers. Inhaled anesthetics will decrease the dose of neuromuscular blockers needed, as well as prolong both the duration of action of the blocker and recovery from neuromuscular blockade,[260] depending on the duration of anesthesia,[259,261,262] the specific inhaled anesthetic,[263] and the concentration (dose) given.[264] The rank order of potentiation is desflurane > sevoflurane > isoflurane > halothane > nitrous oxide–barbiturate–opioid or propofol anesthesia (Fig. 29-22).[265-267]

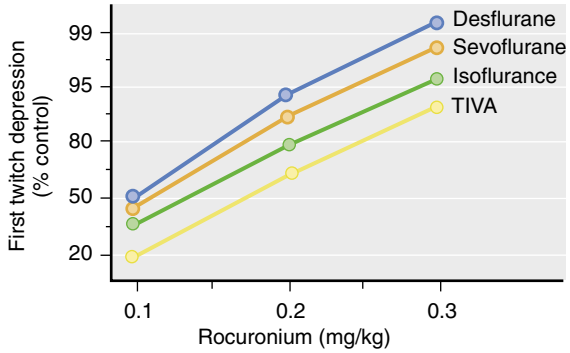

Figure 29-22 Cumulative dose-response curves for rocuronium-induced neuromuscular blockade during 1.5 minimum alveolar concentration (MAC) anesthesia with desflurane, sevoflurane, isoflurane, and total intravenous anesthesia (TIVA). *(From Wulf H, Ledowski T, Linstedt U, et al: Neuromuscular blocking effects of rocuronium during desflurane, isoflurane, and sevoflurane anaesthesia. Can J Anaesth 45:526-532, 1998, with permission from the Canadian Journal of Anaesthesia.)*

The greater clinical muscle-relaxing effect produced by less potent anesthetics is mainly due to their larger aqueous concentrations.[268] Desflurane and sevoflurane have low blood-gas and tissue-gas solubility, so equilibrium between the end-tidal concentration and the neuromuscular junction is reached more rapidly with these anesthetics than with older inhaled anesthetics.

The interaction between volatile anesthetics and neuromuscular blockers is one of pharmacodynamics, not pharmacokinetics.[143] The proposed mechanisms behind this interaction include (1) a central effect on α motoneurons and interneuronal synapses,[269] (2) inhibition of postsynaptic nAChRs,[270] and (3) augmentation of the antagonist's affinity at the receptor site.[268]

Interactions with Antibiotics

Most antibiotics can cause neuromuscular blockade in the absence of neuromuscular blocking agents. The aminoglycoside antibiotics, the polymyxins, and lincomycin and clindamycin primarily inhibit the prejunctional release of acetylcholine and also depress postjunctional nAChR sensitivity to acetylcholine. The tetracyclines, on the other hand, exhibit postjunctional activity only. When combined with neuromuscular blockers, the aforementioned antibiotics can potentiate neuromuscular blockade.[271] The cephalosporins and penicillins have not been reported to potentiate neuromuscular blockade. Because antagonism of neuromuscular blockade has been reported to be more difficult after the administration of aminoglycosides,[272] ventilation should be controlled until the neuromuscular blockade terminates spontaneously. Calcium should not be used to hasten the recovery of neuromuscular function for two reasons: the antagonism that it

produces is not sustained, and it may prevent the antibacterial effect of the antibiotics.

Temperature

Hypothermia prolongs the duration of action of nondepolarizing neuromuscular blockers.[273-275] The force of contraction of the adductor pollicis decreases by 10% to 16% per degree Celsius decline in muscle temperature below 35.2°C.[276,277] To maintain muscle temperature at or above 35.2°C, central temperature must be maintained at 36.0°C.[273] Recovery to 10% twitch height with 0.1 mg/kg of vecuronium increases from 28 minutes at a mean central temperature of 36.4°C to 64 minutes at 34.4°C.[273] The mechanism or mechanisms underlying this prolongation may be pharmacodynamic, pharmacokinetic, or both.[275] They include diminished renal and hepatic excretion, changing volumes of distribution, altered local diffusion receptor affinity, changes in pH at the neuromuscular junction, and the net effect of cooling on the various components of neuromuscular transmission.[273,278] Hypothermia decreases the plasma clearance and prolongs the duration of action of rocuronium and vecuronium.[275] Temperature-related differences in the pharmacodynamics of vecuronium have also been reported: k_{e0} decreases (0.023/min/°C) with lower temperature, suggesting slightly delayed equilibration of drug between the circulation and the neuromuscular junction during hypothermia.[275] The Hofmann elimination process of atracurium is slowed by a decrease in pH and especially by a decrease in temperature.[279] In fact, atracurium's duration of action is markedly prolonged by hypothermia.[274] For instance, the duration of action of a 0.5-mg/kg dose of atracurium is 44 minutes at 37°C but 68 minutes at 34.0°C.

Changes in temperature will also affect interpretation of the results of monitoring neuromuscular blockade. For example, the duration of action of vecuronium measured in an arm cooled to a skin temperature of 27°C is prolonged, and monitoring by post-tetanic count in that arm is unreliable.[280] In the same patient, TOF responses are different if the arms are at different temperatures, and correlation of responses in the two arms becomes progressively poorer as the temperature difference between the arms increases.[281]

The efficacy of neostigmine is not altered by mild hypothermia.[282-284] Hypothermia does not change the clearance, maximum effect, or duration of action of neostigmine in volunteers.[284]

Interactions with Magnesium and Calcium

Magnesium sulfate, given for the treatment of preeclampsia and eclamptic toxemia, potentiates the neuromuscular blockade induced by nondepolarizing neuromuscular blockers (see Chapter 69).[285,286] After a dose of 40 mg/kg of magnesium sulfate, the ED_{50} of vecuronium was reduced by 25%, the onset time was nearly halved, and the recovery time nearly doubled.[286] Neostigmine-induced recovery is also attenuated in patients treated with magnesium.[285] The mechanisms underlying the enhancement of nondepolarizing blockade by magnesium probably involve both prejunctional and postjunctional effects. High magnesium concentrations inhibit calcium channels at the presynaptic nerve terminals that trigger the release of acetylcholine.[14] Furthermore, magnesium ions have an inhibitory effect on postjunctional potentials and cause decreased excitability of muscle fiber membranes. In patients receiving magnesium, the dose of nondepolarizing neuromuscular blocker must be reduced and carefully titrated with a nerve stimulator to ensure adequate recovery of neuromuscular function at the end of surgery.

The interaction between magnesium and succinylcholine is controversial. However, more recent results suggest that magnesium antagonizes the block produced by succinylcholine.[287]

Calcium triggers the release of acetylcholine from the motor nerve terminal and enhances excitation-contraction coupling in muscle.[14] Increasing calcium concentrations decreased the sensitivity to dTc and pancuronium in a muscle-nerve model.[288] In hyperparathyroidism, hypercalcemia is associated with decreased sensitivity to atracurium and thus a shortened time course of neuromuscular blockade.[289]

Interactions with Lithium

Lithium remains the drug of choice for the treatment of bipolar affective disorder (manic-depressive illness). The lithium ion resembles sodium, potassium, magnesium, and calcium ions and may therefore affect the distribution and kinetics of all of these electrolytes.[290] Lithium enters cells via sodium channels and tends to accumulate within the cells.

By its activation of potassium channels, lithium inhibits neuromuscular transmission presynaptically and muscular contraction postsynaptically.[291] The combination of lithium and pipecuronium results in a synergistic inhibition of neuromuscular transmission, whereas the combination of lithium and succinylcholine results in additive inhibition.[291] Prolongation of neuromuscular blockade was reported in patients taking lithium carbonate and both depolarizing[282] and nondepolarizing neuromuscular blockers.[292] Only one report did not demonstrate prolongation of recovery from succinylcholine in patients receiving lithium.[293] In patients who are stabilized on lithium therapy and undergoing surgery, neuromuscular blockers should be administered in incremental and reduced doses and titrated to the degree of blockade required.

Interactions with Local Anesthetic and Antidysrhythmic Drugs

Local anesthetics act on the presynaptic, postsynaptic, and muscle membranes. In large intravenous doses, most local anesthetics block neuromuscular transmission; in smaller doses, they enhance the neuromuscular blockade produced by both nondepolarizing and depolarizing neuromuscular blockers.[294] The ability of neostigmine to antagonize a combined local anesthetic–neuromuscular blockade has not been studied. Procaine also inhibits butyrylcholinesterase and may augment the effects of succinylcholine and mivacurium by decreasing their hydrolysis by the enzyme.

In small intravenous doses, local anesthetics depress post-tetanic potentiation, and this is thought to be a neural prejunctional effect.[295] In larger doses, local anesthetics block acetylcholine-induced muscular contractions, which suggests that local anesthetics have a stabilizing effect on the postjunctional

membrane.[296] Procaine displaces calcium from the sarcolemma and thus inhibits caffeine-induced contracture of skeletal muscle.[297] Most of these mechanisms of action probably apply to all of the local anesthetics.

Several drugs used for the treatment of dysrhythmias augment the blockade induced by neuromuscular blockers. Single-fiber electromyography has disclosed that verapamil and amlodipine impair neuromuscular transmission in subjects without neuromuscular disease.[298] Clinical reports have suggested potentiation of neuromuscular block with verapamil[299] and impaired reversal of vecuronium in a patient receiving disopyramide.[300] However, the clinical significance of these interactions is probably minor.

Interactions with Antiepileptic Drugs

Anticonvulsants have a depressant action on release of acetylcholine at the neuromuscular junction.[301] Patients receiving chronic anticonvulsant therapy demonstrated resistance to nondepolarizing muscle blockers (except mivacurium[302] and probably atracurium as well),[301] as evidenced by accelerated recovery from neuromuscular blockade and the need for increased doses to achieve complete neuromuscular blockade. Clearance of vecuronium is increased twofold in patients receiving chronic carbamazepine therapy.[303] Some investigators, however, attribute this resistance to increased binding (i.e., decreased free fraction) of the neuromuscular blockers to α_1-acid glycoproteins or to upregulation of neuromuscular acetylcholine receptors (or to both mechanisms).[204] The latter could also explain the hypersensitivity seen with succinylcholine.[205] The slight prolongation of succinylcholine's action in patients taking anticonvulsants has few clinical implications. On the other hand, the potential hyperkalemic response to succinylcholine in the presence of receptor upregulation is of concern.

Interactions with Diuretics

In patients undergoing renal transplantation, the intensity and duration of dTc neuromuscular blockade is increased after a dose of furosemide (1 mg/kg intravenously).[306] Furosemide reduced the concentration of dTc required to achieve 50% twitch tension depression in the indirectly stimulated rat diaphragm and intensified the neuromuscular blockade produced by dTc and succinylcholine.[307] Furosemide appears to inhibit the production of cyclic adenosine monophosphate. In addition, the breakdown of adenosine triphosphate is inhibited, which results in reduced output of acetylcholine. Acetazolamide antagonizes the effects of anticholinesterases in the rat phrenic-diaphragm preparation.[308] However, in one report, 1 mg/kg of furosemide facilitated recovery of the evoked twitch response after pancuronium.[309] Chronic furosemide treatment had no effect on either dTc- or pancuronium-induced neuromuscular blockade.[310]

In contrast, mannitol appears to have no effect on nondepolarizing neuromuscular blockade. Moreover, increasing urine output by the administration of mannitol or other osmotic or tubular diuretics has no effect on the rate at which dTc and presumably other neuromuscular blockers are eliminated in urine.[126] However, this lack of effect on the excretion of dTc should not be surprising. Urinary excretion of all neuromuscular blockers that are long acting depends primarily on glomerular filtration. Mannitol is an osmotic diuretic that exerts its effects by altering the osmotic gradient within the proximal tubules so that water is retained within them. An increase in urine volume in patients with adequate glomerular filtration, therefore, would not be expected to increase the excretion of neuromuscular blockers.

Interactions with Other Drugs

Dantrolene (see Chapter 37), a drug used for the treatment of malignant hyperthermia, prevents release of calcium from the sarcoplasmic reticulum and blocks excitation-contraction coupling. Although it does not block neuromuscular transmission, the mechanical response to stimulation will be depressed, with subsequent potentiation of the nondepolarizing neuromuscular blockade.[88]

Azathioprine, an immunodepressant drug used in patients undergoing renal transplantation, has a minor antagonistic action on muscle relaxant–induced neuromuscular blockade.[311]

Steroids antagonize the effects of nondepolarizing neuromuscular blockers in both humans[312] and animals.[313] Possible mechanisms for this interaction include facilitation of acetylcholine release because of the effect of steroids on the presynaptic motor nerve terminal[314] and channel blockade of the nAChR.[315] Endogenous steroids act noncompetitively on nAChRs.[316] Prolonged treatment with a combination of corticosteroids and neuromuscular blocking drugs can result in prolonged weakness in critical care patients (see the later section "Neuromuscular Blockers and Weakness Syndromes in the Critically Ill").

Antiestrogenic drugs such as tamoxifen appear to potentiate the effects of nondepolarizing neuromuscular blockers.[317]

Recovery From Neuromuscular Blockade

In the 1970s, Ali and colleagues[318] described a TOF ratio of 0.60 as indicating adequate recovery of neuromuscular strength. Nonetheless, in 1997 a TOF ratio of 0.70 in unanesthetized volunteers was associated with difficulty speaking and swallowing, weakness of the facial musculature, visual disturbances, and inability to sit up without assistance.[319] Also in human volunteers, TOF ratios of 0.6 to 0.7 were associated with decreased upper esophageal tone and decreased coordination of the esophageal musculature during swallowing.[320,321] Fluoroscopic examination of these individuals demonstrated significant pharyngeal dysfunction resulting in a fourfold to fivefold increase in the risk for aspiration. With recovery of the TOF ratio to 0.9, esophageal tone and pharyngeal coordination returned toward baseline.[320,321]

Residual paralysis also decreases the hypoxic ventilatory drive (Fig. 29-23),[322,323] which is due to inhibition of the carotid body's neural response to hypoxia.[324] Vecuronium decreases carotid sinus nerve activity in response to hypoxia in a dose-related fashion, presumably through its interaction with nicotinic chemotransduction of the carotid body.

After the administration of nondepolarizing neuromuscular blocking drugs, adequate return of normal neuromuscular function must be present. Whether that degree of recovery is a

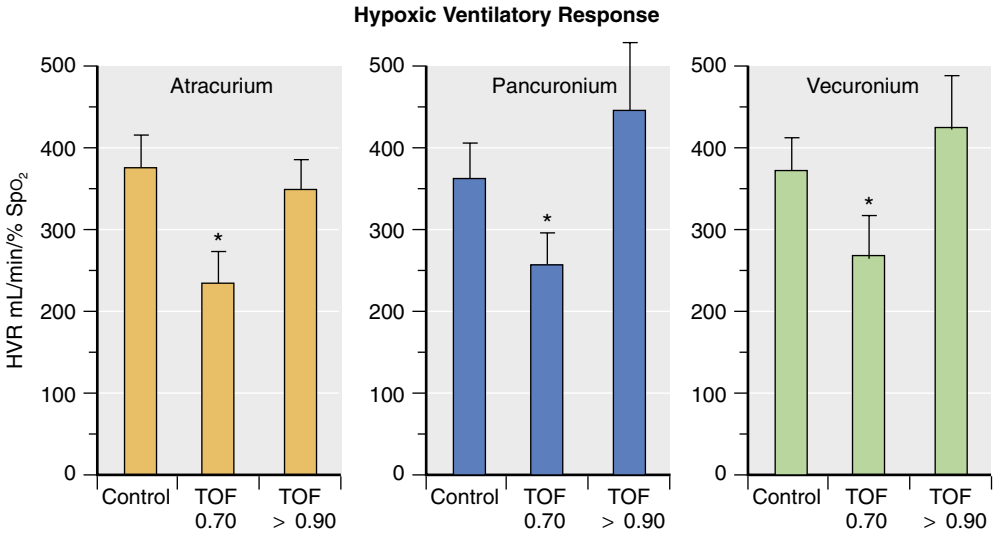

Figure 29-23 Hypoxic ventilatory response (HVR) before (control); during steady-state infusion (train-of-four [TOF] = 0.07) of atracurium, pancuronium, and vecuronium; and after recovery (TOF > 0.90). Data are presented as means ± SD. *$P < .01$. *(From Eriksson LI: Reduced hypoxic chemosensitivity in partially paralysed man. A new property of muscle relaxants? Acta Anaesthesiol Scand 40:520-523, 1996.)*

TOF ratio of 0.7, 0.8, or 0.9 has been an area of debate, and in a recent international guideline a TOF ratio of 0.9 was recommended as an end point for recovery from a nondepolarizing neuromuscular block. Certainly, the clinician's ability to quantify the degree of residual neuromuscular block is limited. Kopman and colleagues[319] work in volunteers demonstrated that when they could oppose their incisors to retain a tongue depressor, their TOF ratio was, on average, 0.8 and at least 0.68. This test of muscle strength, though, would have limited usefulness in tracheally intubated patients.

Recommendations for detection and prevention of residual neuromuscular blockade are summarized in Chapter 47.

Recovery from muscle relaxation caused by nondepolarizing neuromuscular blockers depends on several factors. Primarily, it depends on an increase in the acetylcholine concentration relative to that of the relaxant to overcome the competitive neuromuscular blockade. Although neostigmine will increase the acetylcholine concentration, ultimately, the muscle relaxant needs to be eliminated. The relative increase in acetylcholine concentration depends first on the ongoing movement of relaxant from the motor end plate into the central circulation and then on its elimination from the circulating blood volume so that it is not free to move into the synaptic cleft. Ultimately, recovery depends on elimination of the neuromuscular blocker from the body. Neuromuscular blockers may be eliminated through a host of mechanisms, including excretion as unchanged drug in urine, metabolism in the liver, enzymatic hydrolysis, and chemical breakdown. Although it has never been specifically examined, several groups of investigators have, through their ranges of recovery parameters, described wide interpatient variation in the spontaneous recovery of neuromuscular function.[325-327]

Several factors in addition to coexisting disease will affect the speed of spontaneous recovery of neuromuscular function. The presence of volatile anesthetics will potentiate any existing neuromuscular block and, presumably, cause recovery to be more prolonged.[328] If the anesthesiologist observes no or only minimal recovery of neuromuscular function in the presence of a volatile anesthetic, discontinuing or decreasing the concentration of that anesthetic should augment the recovery of neuromuscular function.

As will be discussed later in this section, acidosis, hypokalemia, hypothermia, and concomitant medications all potentiate residual neuromuscular blockade and render pharmacologic antagonism more difficult.

Antagonism of Residual Neuromuscular Blockade

Anticholinesterases act by inhibiting acetylcholinesterase (enzyme classification 3.1.1.7), which is a type B carboxylesterase. At the neuromuscular junction, acetylcholinesterase occurs in the asymmetric or A12 form and consists of three tetramers of catalytic subunits covalently linked to a collagen-like tail. Acetylcholinesterase has a powerful catalytic capacity: it can catalyze 4000 molecules of acetylcholine per active site per second. The active site lies deep inside the enzyme protein. Nearly half of the acetylcholine released is hydrolyzed across the synaptic cleft before reaching the nAChRs. For a detailed account of this enzyme, see the article by Soreq and Seidman.[329]

The active surface of acetylcholinesterase is best viewed as having two sites: the anionic site, which is concerned with binding and orienting the substrate molecule, and the esteratic site, which is responsible for the hydrolytic process. The existence of a second "anionic" site, known as the "peripheral" anionic site, has also been proposed. This topic has been reviewed by Silman and Sussman.[330]

Three anticholinesterases—neostigmine, pyridostigmine, and edrophonium—are used to antagonize residual neuromuscular blockade. They exert their effect primarily by inhibiting acetylcholinesterase and thus increasing the concentration of acetylcholine at the motor end plate. Neostigmine and pyridostigmine are oxydiaphoretic (acid-transferring) inhibitors of acetylcholinesterase. They transfer a carbamate group to acetyl-

cholinesterase and form a covalent bond at the esteratic site. Edrophonium is a prosthetic inhibitor that binds to the anionic site on the acetylcholinesterase by electrostatic attraction and to the esteratic site by hydrogen bonding. In addition, anticholinesterases may increase the release of acetylcholine from presynaptic nerve terminals, block neural potassium channels, and have a direct agonistic effect. For more details, see Bevan and colleagues.[331]

Major Determinants of the Speed and Adequacy of Recovery

Antagonism of nondepolarizing neuromuscular blockade is time dependent. Recovery occurs at a rate that depends primarily on five factors: (1) depth of the blockade when the antagonist is administered, (2) which anticholinesterase is administered, (3) dose of the anticholinesterase, (4) rate of spontaneous recovery from the neuromuscular blocker, and (5) concentration of inhaled anesthetic agent present during reversal.

Depth of the Blockade

Generally, more time is required to antagonize profound levels than lesser levels of blockade.[332] It is interesting that in a study by Bevan and coworkers,[333] antagonism of the blockade induced by doses of vecuronium or rocuronium that were 1.5 times the ED_{95} occurred at the same rate regardless of the timing of administration of 70 µg/kg of neostigmine. Neostigmine shortened the recovery time by approximately 40%, whether it was administered at the time of 1%, 10%, or 25% of spontaneous recovery. However, as shown in Figure 29-24, the time from administration of the neuromuscular blocker to TOF ratios of 0.7 and 0.9 did not decrease as the extent of spontaneous recovery at the time of neostigmine administration increased. Recovery to TOF ratios of 0.7 and 0.9 required, on average, 25 and 30 minutes, respectively. More specifically, should neostigmine be given during a profound (i.e., little or no response to peripheral nerve stimulation) neuromuscular block? Unfortunately, the answer is not clear. Thus, recommendations about the timing of administration of anticholinesterase are equivocal. Instinctively, many experts recommend not administering the anticholinesterase at the earliest degrees of recovery. Kirkegaard and associates[334] recently demonstrated that to recover to a TOF ratio of 0.7 within 10 minutes of administering neostigmine, three or four responses to TOF stimulation had to be present at the time of neostigmine administration. If only one response to TOF stimulation was present, recovery to a TOF ratio of 0.7 required up to 23 minutes.

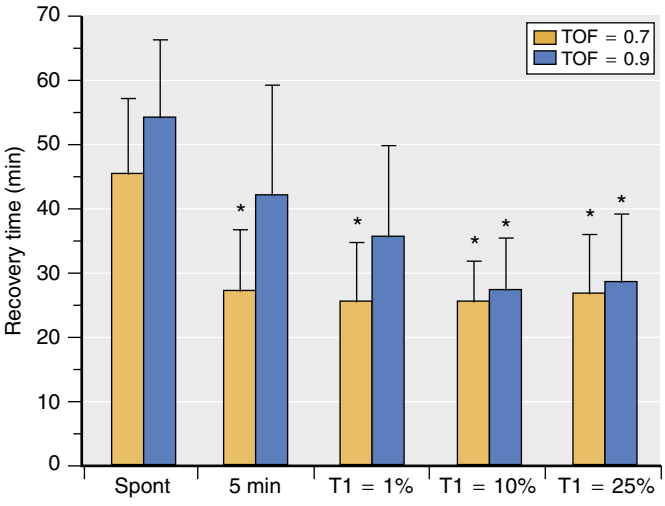

Figure 29-24 Recovery times (mean ± SD) after the administration of a single dose of 0.45 mg/kg (1.5 times the ED_{95}) rocuronium. In one group (Spont), spontaneous recovery was allowed. In the remaining groups, 70 µg/kg of neostigmine was administered 5 minutes after rocuronium or at 1%, 10%, and 25% recovery of the first twitch (T1) from its control value. *$P < .01$ versus spontaneous recovery. Note that the times to attain a train-of-four (TOF) ratio of 0.9 are significantly shorter when neostigmine was administered at T1 = 10% or 25% of control tension. *(From Bevan JC, Collins L, Fowler C, et al: Early and late reversal of rocuronium and vecuronium with neostigmine in adults and children. Anesth Analg 89:333-339, 1999.)*

The maximum antagonistic effect of neostigmine occurs in 10 minutes or less. If adequate recovery does not occur within this time, subsequent recovery is slow and requires ongoing elimination of the neuromuscular blocker from plasma. For profound vecuronium-induced blockade in which no twitch recovery has occurred, administration of 70 µg/kg of neostigmine produces an initial reversal that falls far short of adequate recovery.[327] Subsequent recovery occurs at the same rate as spontaneous recovery and is caused by the decrease in plasma concentration of vecuronium as the drug is eliminated.[327,335] Administration of a second dose of neostigmine has no further effect on recovery[327] because acetylcholinesterase is already maximally inhibited.

If the blockade at the time of neostigmine administration is sufficiently deep that adequate recovery does not occur within 10 minutes, the time at which full recovery of neuromuscular function will occur depends on the inherent duration of action of the neuromuscular blocker.[332] With drugs that have a long duration of action, this period of inadequate neuromuscular function can be 30 to 60 minutes or even longer, whereas with drugs that have an intermediate duration of action, it will be much shorter (e.g., 15 to 30 minutes).[336]

The Anticholinesterase Administered

Under the conditions of a moderate depth of blockade (such as two to three twitches palpable by TOF monitoring), the order of rapidity of antagonism of residual blockade by anticholinesterases is edrophonium > neostigmine > pyridostigmine.[337,338] For this reason and because of its lesser atropine requirement, edrophonium regained popularity as an antagonist during the 1980s.[327] However, Rupp and coworkers[339] found that edrophonium is not as effective as neostigmine in antagonizing profound blockade of more than 90% twitch depression (only one twitch palpable by TOF) whereas increasing the edrophonium dose from 0.5 to 1.0 mg/kg increased its efficacy. Neostigmine remains capable of more complete antagonism.[340] To be equivalent to 40 µg/kg of neostigmine as an antagonist of profound vecuronium blockade, 1.5 mg/kg of edrophonium must be administered.[330]

The relative potencies of edrophonium and neostigmine differ at various intensities of blockade (Fig. 29-25.).[341] Edrophonium becomes less potent relative to neostigmine as the depth of blockade becomes more intense. In other words, the dose-response curves are not parallel and become increasingly divergent as the depth of blockade intensifies. This difference indicates that edrophonium may be less effective than neostigmine when antagonizing very deep levels of blockade.

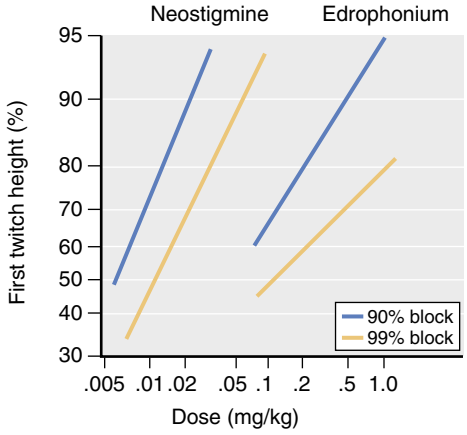

Figure 29-25 First twitch height (logit scale) versus dose (log scale) 10 minutes after the administration of neostigmine and edrophonium given at either 1% (99% block) or 10% (90% block) first twitch recovery. *(From Donati F, Smith CE, Bevan DR: Dose-response relationships for edrophonium and neostigmine as antagonists of moderate and profound atracurium blockade. Anesth Analg 68:13-19, 1989.)*

The Dose of Anticholinesterase

Larger doses of anticholinesterases should antagonize neuromuscular blockade more rapidly and more completely than smaller doses do. This relationship is true up to the point of the maximum effective dose, beyond which additional amounts of anticholinesterase will not produce any further antagonism. For neostigmine, this maximum effective dose is in the 60- to 80-µg/kg range,[327] and for edrophonium, it is in the 1.0- to 1.5-mg/kg range.[339,340]

Mixing or combining antagonists is not advisable. Neostigmine and edrophonium do not potentiate each other; in fact, their effects in combination may not even be additive.[342] Therefore, when inadequate reversal occurs, one should not be tempted to add a different anticholinesterase but should ensure only that the maximum dose of the original drug has been administered. Ventilation should then be supported until adequate neuromuscular function is achieved.

Rate of Spontaneous Recovery from the Neuromuscular Blocker

After administration of an anticholinesterase, two processes contribute to recovery of neuromuscular function. The first is the antagonism induced by the effect of the anticholinesterase at the neuromuscular junction; the second is the natural process of decrease in plasma concentration of the neuromuscular blocker (and hence its effect at the neuromuscular junction).[332,335] Therefore, the more rapid the elimination of the neuromuscular blocker, the faster the recovery of adequate neuromuscular function after the administration of an antagonist (Fig. 29-26).[343] A clear illustration of this principle is the difference in antagonism of the blockade induced by neuromuscular blockers with an intermediate duration of action versus those with a long duration. Plasma concentrations of drugs with an intermediate duration of action decrease more rapidly than those with a long duration of action,[141] and consequently, recovery of neuromuscular function is more rapid. Thus, the incidence of inadequate neuromuscular function in the postoperative period is less with intermediate-acting than with long-acting neuromuscular blockers.[336,344] This difference in speed of reversal between intermediate- and long-acting drugs is due to the effect of different rates of spontaneous recovery and not to a difference in response to neostigmine.[345] When neostigmine is administered to antagonize a stable level of blockade maintained by continuous infusion of either vecuronium or pancuronium, the rate and degree of recovery are similar to those achieved in the case of administration of each neuromuscular blocker alone.[345]

Even though mivacurium is no longer available in the United States, its pharmacology allows better understanding of basic pharmacology. The interaction between spontaneous recovery from and anticholinesterase-induced reversal of mivacurium's effect is more complex. The rate of spontaneous recovery from mivacurium-induced bockade is more rapid than that from any other nondepolarizing neuromuscular blocker. This is a result of its rapid hydrolysis by butyrylcholinesterase. Neostigmine-induced reversal of mivacurium is similar to or faster than that of atracurium.[184,346] During profound (<3% twitch recovery) mivacurium-induced blockade, the administration of neostigmine may prolong recovery.[347] Neostigmine has two major effects relevant to mivacurium. First, it inhibits acetylcholinesterase at the neuromuscular junction, thereby effectively increasing the acetylcholine concentration and facilitating recovery. Second, it inhibits butyrylcholinesterase, the enzyme responsible for metabolism of mivacurium, and slows the normally rapid decrease in the plasma concentration of mivacurium.[348] In contrast, edrophonium is a less potent inhibitor of butyrylcholinesterase[348] and should have little effect on the metabolism of mivacurium. Provided that there is 10% recovery of twitch response (one twitch in the TOF), either 20 to 40 µg/kg of neostigmine or 0.3 to 0.5 mg/kg of edrophonium will accelerate recovery from mivacurium.[346]

It has been suggested that routine administration of an anticholinesterase may often be omitted because spontaneous recovery from mivacurium's effect is so rapid. However, this strategy may lead to inadequate recovery and postoperative weakness unless at least 20 minutes is allowed for spontaneous recovery before the anticholinesterase is administered.[346]

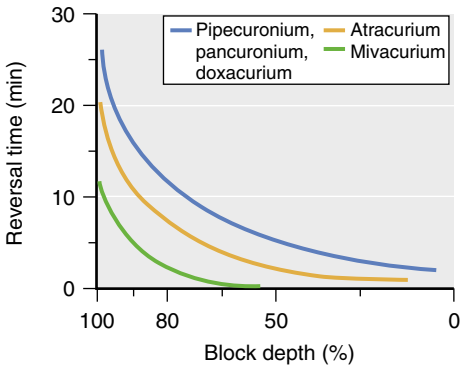

Figure 29-26 Comparative mean speed of antagonism by neostigmine of neuromuscular blockade induced by long-acting agents (doxacurium, pancuronium, pipecuronium), intermediate-acting drugs (atracurium and others), and the short-acting agent mivacurium. Antagonism is more rapid as processes of clearance increase (see text). *(From Savarese JJ: Reversal of nondepolarizing blocks: More controversial than ever?* In *Review Course Lectures, 67th Congress. Cleveland, OH, International Anesthesia Research Society, 1993.)*

Because mivacurium is metabolized by butyrylcholinesterase, administration of exogenous human butyrylcholinesterase can theoretically hasten recovery from mivacurium's effects. Administration of purified human cholinesterase does produce some antagonism of mivacurium-induced blockade,[349] but it is ineffective in profound blockade[348] and no better than edrophonium alone.[350] Administration of purified butyrylcholinesterase to patients who are genetically homozygous for atypical butyrylcholinesterase and have a prolonged blockade may be justified,[188] but this therapy is expensive and has not yet been tested adequately.

Concentration of Inhaled Anesthetic

Several studies have documented that antagonism of residual blockade is actually retarded by anesthetizing concentrations of anesthetic vapors.[351,352] For example, reversal of rocuronium by neostigmine under sevoflurane (and to a lesser extent, isoflurane) anesthesia occurred more slowly than under propofol anesthesia.[352] Sevoflurane may impede neostigmine-induced antagonism more than isoflurane does.[351] When compared with recovery from isoflurane anesthesia, recovery from that produced by desflurane or sevoflurane is prolonged.[343] Withdrawal of the anesthetic vapor at the end of surgery, with subsequent reduction of its enhancement of neuromuscular blockade, will speed pharmacologic reversal.[328]

Clinical Recommendations

When antagonizing deep levels of neuromuscular blockade (about 10% recovery or one twitch in response to TOF stimulation), larger doses of anticholinesterases (e.g., neostigmine, 35 µg/kg) should be administered and adequate time allowed for recovery of neuromuscular function. The time required for recovery to a TOF ratio of 0.7 will be approximately 60 minutes for the long-acting neuromuscular blocking drugs (pancuronium) and 30 minutes for the intermediate-acting ones (rocuronium). To antagonize lesser degrees of blockade, smaller doses of anticholinesterases may be administered, with additional anticholinesterase given if adequate recovery has not occurred in 10 minutes.

It is not advisable to administer additional anticholinesterase if maximal doses of edrophonium (1.5 mg/kg), neostigmine (70 µg/kg), or pyridostigmine (350 µg/kg) fail to antagonize the residual blockade.[340] Giving too much anticholinesterase to antagonize residual neuromuscular blockade may actually render patients weaker.[326,354,355] These doses inhibit acetylcholinesterase completely, and if they fail to fully antagonize the residual blockade, another likely cause of the inadequate antagonism should be sought. Some of these additional potential causes of inadequate antagonism of neuromuscular blockade are described in the following sections.

Acid-Base State

Both metabolic and respiratory acidosis may augment the blockade induced by a nondepolarizing neuromuscular blocker, but only respiratory acidosis prevents adequate antagonism.[338,356] The probability of achieving adequate antagonism of nondepolarizing neuromuscular blockade in the presence of significant respiratory acidosis (partial pressure of carbon dioxide in arterial gas >50 mm Hg) is low. Therefore, attempts to antagonize residual blockade may fail if a patient hypoventilates. Administration of narcotics to relieve pain may, by producing hypoventilation, increase the likelihood of this adverse event. Although metabolic acidosis might also be predicted to prevent antagonism by neostigmine, this hypothesis has not been substantiated.[338,356] Metabolic alkalosis, but not metabolic acidosis, prevents neostigmine's antagonism of dTc and pancuronium.[338,356,357] These results suggest that extracellular pH is not as important as changes in electrolyte concentrations and intracellular pH.

Electrolyte Imbalance

Few data are available on the effect of electrolyte imbalance on antagonism of a nondepolarizing neuromuscular blockade induced by neostigmine. Low extracellular concentrations of potassium enhance the blockade from nondepolarizing neuromuscular blockers and diminish the ability of neostigmine to antagonize the blockade. This effect is caused by the increase in end-plate transmembrane potential that results from a higher ratio of intracellular to extracellular potassium. Thus, a decrease in extracellular potassium causes hyperpolarization and produces resistance to depolarization. Patients with an imbalance in potassium may have other diseases or injuries that alter their response to neuromuscular blockers (e.g., patients with burns). In addition, severe dehydration will concentrate the neuromuscular blocker present in plasma, in effect decreasing the volume of distribution and increasing muscle relaxant activity. In an animal model of chronic hypokalemia, cats were given a diuretic without potassium supplementation for 15 days. Less pancuronium was required for neuromuscular blockade and more neostigmine was required for antagonism.[358] Even though the differences were small, the blockade was always antagonized completely. If we assume that this animal model approximates the clinical situation, changes in potassium appear to be of relatively minor consequence with respect to the clinical question of adequacy of reversal.

Other Factors

The calcium channel blocker verapamil will potentiate nondepolarizing neuromuscular blocking drugs and may render achieving adequate reversal difficult.[359,360] When attempting reversal of neuromuscular blockade in patients receiving verapamil, edrophonium may be more effective than neostigmine.[359,360] Other factors that may interfere with antagonism are hypothermia and the administration of antibiotics, particularly those of the aminoglycoside or polypeptide classes (see the section on drug interactions).[271] In the case of antibiotics, administration of an anticholinesterase may in fact deepen the blockade.

Side Effects of Anticholinesterases

Cardiovascular Effects

Because only the nicotinic effects of edrophonium, neostigmine, and pyridostigmine are desired, the muscarinic effects must be blocked by atropine or glycopyrrolate. Atropine induces its vagolytic effect much more rapidly than glycopyrrolate does. To minimize cardiovascular changes, atropine is better suited for administration with the rapid-acting edrophonium, and glycopyrrolate is better suited for administration with the slower-acting neostigmine and pyridostigmine.[361] In general, 7 to 10 µg/kg of atropine should be given with 0.5 to 1.0 mg/kg of edrophonium.[337] When cardiac dysrhythmias are a concern, glycopyrrolate may be

preferable to atropine,[362] and the anticholinesterases and anticholinergics should be administered more slowly (e.g., 2 to 5 minutes) to reduce the incidence and severity of disordered rhythm.

Nausea and Vomiting

Reports on the effect of anticholinesterase administration on postoperative nausea and vomiting are conflicting. Neostigmine has been implicated as a cause of postoperative nausea and vomiting,[363] but it has also been described as having antiemetic properties[364] and as having no effect on the incidence of postoperative nausea and vomiting.[365] A meta-analysis by Tramer and Fuchs-Bader[366] looked at the results of anticholinesterase administration in more than 1100 patients. They found a dose-response relationship for the incidence of nausea and vomiting after the administration of neostigmine: the highest incidence of vomiting after the administration of 1.5 mg of neostigmine was lower than the lowest incidence of vomiting after the administration of 2.5 mg of neostigmine. Discrepancies between the results of other studies may have been at least partly attributable to the use of different dosing regimens. Although vomiting occurs in 17% to 33% of patients after the administration of neostigmine, the authors did not recommend that all patients be allowed to recover spontaneously because of the risk for postoperative residual paralysis.[366] A more recent study demonstrated the hazards of not antagonizing residual neuromuscular blockade at least 2 hours after the administration of a dose twice the ED_{95} of vecuronium, rocuronium, or atracurium.[367]

Pharmacokinetics of Neostigmine, Pyridostigmine, and Edrophonium

The pharmacokinetics of edrophonium, neostigmine, and pyridostigmine is summarized in Table 29-12.[368-371] The data indicate several relevant clinical conclusions:

1. Pyridostigmine has a longer elimination half-life than that of the other anticholinesterases, which probably accounts for its longer duration of action.[368,369]
2. Comparison data on the elimination half-lives in patients with and without renal failure showed that renal excretion accounts for about 50% of the excretion of neostigmine and about 75% of the excretion of pyridostigmine and edrophonium. Renal failure decreases the plasma clearance of neostigmine, pyridostigmine, and edrophonium as much as, if not more than that of the long-acting neuromuscular blockers. Therefore, if proper doses of anticholinesterase drugs are given and overdoses of neuromuscular blockers are avoided, renal failure should not be associated with "recurarization."[368,369] This remote possibility is further diminished if the clinician restricts the relaxants used to the intermediate- or short-acting drugs in patients with renal failure.
3. Edrophonium was once thought to be an unsuitable antagonist in clinical practice because its duration of action was believed to be too short. However, when larger doses (e.g., 0.5 to 1.0 mg/kg) are given, sustained antagonism of nondepolarizing neuromuscular–induced blockade results.[372] In fact, the elimination half-life of edrophonium is similar to that of neostigmine and pyridostigmine (see Table 29-12).[370]

Mild hypothermia (i.e., 34°C to 35°C), which commonly occurs intraoperatively, affects the pharmacokinetics of neostigmine. Its clearance is decreased from 16.2 mL/kg/min at 36.5°C to 13.5 mL/kg/min at 34.5°C.[284] In addition, onset of the peak effect of neostigmine is delayed by mild hypothermia from 4.2 to 5.5 minutes.[284] If hypothermia has any influence on the efficacy of neostigmine-induced reversal, it is more likely to be due to the effect of temperature on the neuromuscular blocker (e.g., prolonged duration of action[273]) than to the pharmacology of neostigmine.

The pharmacokinetics of the anticholinesterases depends on several factors, including distribution, metabolism, and elimination. In the case of neostigmine, a carbamylated complex with acetylcholinesterase is formed, and it is the rate of dissociation of neostigmine from this complex (i.e., its metabolism) that is probably the major determinant of its duration of action. The decrease in the plasma concentration of neostigmine (i.e., its distribution and elimination) may not be as pertinent a determinant of its duration of action.

Table 29-12 Pharmacokinetics of Neostigmine (N), Pyridostigmine (P), and Edrophonium (E) in Patients without and with Renal Failure

	Without Renal Failure			With Renal Failure		
	N	P	E	N	P	E
Distribution half-life ($t_{½\alpha}$, min)	3.4	6.7	7.2	2.5	3.9	7.0
Elimination half-life ($t_{½\beta}$, min)	77	113	110	181	379	304
Volume of central compartment (L/kg)	0.2	0.3	0.3	0.3	0.4	0.3
Total plasma clearance (mL/kg/min)	9.1	8.6	9.5	4.8	3.1	3.9

Other Antagonists of Nondepolarizing Neuromuscular Blockade

Sugammadex

Sugammadex may be the most exciting drug in clinical neuromuscular pharmacology in the last 50 years. The combination of rocuronium and sugammadex could replace succinylcholine for rapid-sequence induction of anesthesia and completely eliminate residual paralysis in the postanesthetic recovery room.[373]

Sugammadex (ORG 25969) is the first selective relaxant binding agent (*su* refers to *su*gar, and *gammadex* refers to the structural molecule *gamma*-cyclo*dex*trin). A modified γ-cyclodextrin, sugammadex (Fig. 29-27) is a new type of reversal agent.[374] The three natural unmodified cyclodextrins consist of six, seven, and eight cyclic oligosaccharides (i.e., dextrose units joined through one to four glycosyl bonds) and are called α-, β-,

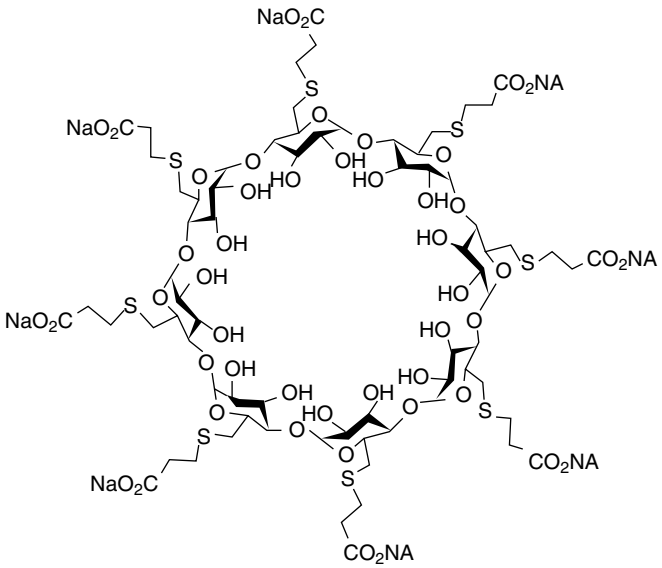

Figure 29-27 Structure of the synthetic γ-cyclodextrin sugammadex (ORG 25969).

and γ-cyclodextrin, respectively. Their three-dimensional structure resembles a hollow truncated cone or a doughnut. The structure has a hydrophobic cavity and a hydrophilic exterior because of the presence of polar hydroxyl groups. Hydrophobic interactions trap the drug in the cyclodextrin cavity (the "doughnut hole"), thereby resulting in the formation of a water-soluble guest-host complex. Although unmodified γ-cyclodextrin possesses a larger lipophilic cavity (7.5 to 8.3 Å) than any other cyclodextrin does, it is still not deep enough to accommodate the larger rigid structure of the rocuronium molecule. Therefore, the cavity was modified by adding eight side chains to extend it to 11 Å for better accommodation of the four hydrophobic steroidal rings of rocuronium and by adding negatively charged carboxyl groups at the end of the side chains to enhance electrostatic binding to the positively charged quaternary nitrogen of rocuronium (Fig. 29-28).[374,375] The stability of the rocuronium-sugammadex complex is the end result of an interplay of intermolecular forces (van der Waals forces), including thermodynamic (hydrogen bonds) and hydrophobic interactions.[376]

Sugammadex exerts its effect by forming very tight complexes in a 1 : 1 ratio with steroidal neuromuscular blocking agents (rocuronium > vecuronium ≫ pancuronium).[374] The guest-host complex exists in an equilibrium with a very high association rate and very low dissociation rate, so the complex is tight.[374] During rocuronium-induced neuromuscular blockade, intravenous administration of sugammadex results in rapid removal of free rocuronium molecules from plasma. This creates a concentration gradient favoring movement of the remaining rocuronium molecules from the neuromuscular junction back into plasma, where they are encapsulated by free sugammadex molecules. These molecules also enter tissues and form a complex with rocuronium. Therefore, the neuromuscular blockade of rocuronium is terminated rapidly by the diffusion of rocuronium away from the neuromuscular junction back into plasma. This results in an increase in the total plasma concentration of rocuronium (free and that bound to sugammadex).[377] Sugammadex therefore acts as a binding agent and has no effect on acetylcholinesterase or any receptor system in the body, thus eliminating the need for anticholinergic drugs and their undesirable side effects.

PHARMACOKINETICS. During an infusion of rocuronium to maintain a stable depth of neuromuscular blockade, administration of sugammadex increases the measured plasma concentration of rocuronium; the relaxant is redistributed from the effect compartment to the central compartment as it is encapsulated by sugammadex.[377] Recovery of muscle strength can occur despite increasing plasma concentrations of relaxant because the efficacy of sugammadex does not rely on renal excretion of the cyclodextrin-relaxant complex.[378]

When administered by itself to volunteers who had not received a neuromuscular blocking agent, 0.1 to 8.0 mg/kg of sugammadex had a clearance rate of 120 mL/min, an elimination half-life of 100 minutes, and a volume of distribution of 18 L.[379] Approximately 75% of a dose was eliminated in urine. The kinetics of sugammadex appears to be dose dependent in that clearance increases and the elimination half-life decreases as the dose of sugammadex increases from 0.15 to 1.0 mg/kg.[379]

In the absence of sugammadex, rocuronium is eliminated mainly by biliary excretion (>75%) and to a lesser degree by renal excretion (10% to 25%). Plasma clearance of sugammadex alone is approximately three times lower than that of rocuronium alone.[380] In volunteers, plasma clearance of rocuronium was decreased by a factor of greater than 2 after the administration of a 2.0-mg/kg or greater dose of sugammadex.[379] This decreased clearance occurs because the biliary route of excretion becomes unavailable for the rocuronium-sugammadex complex, and rocuronium clearance decreases to a value approaching the glomerular filtration rate (120 mL/min). Because of the soluble

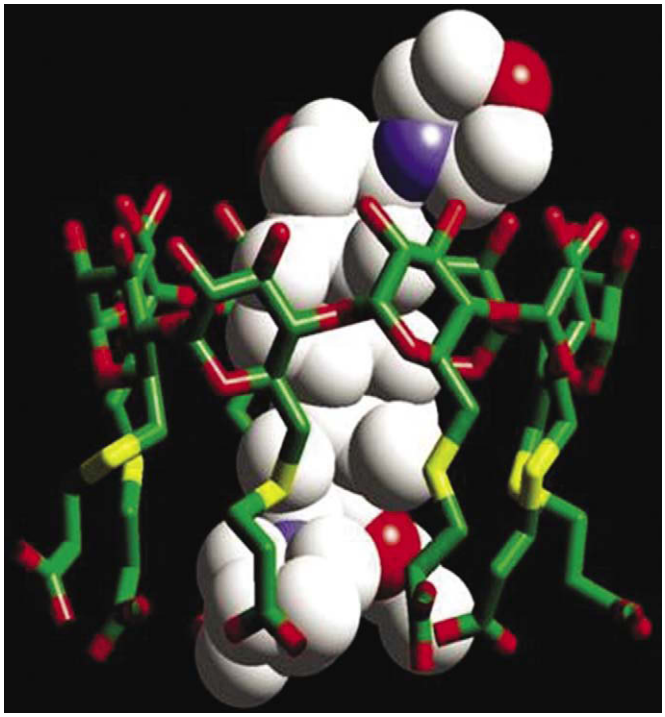

Figure 29-28 The sugammadex-rocuronium complex. *(From Bom A, Bradley M, Cameron K, et al: A novel concept of reversing neuromuscular block: Chemical encapsulation of rocuronium bromide by a cyclodextrin-based synthetic host. Angew Chem 41:266-270, 2002.)*

nature of the rocuronium-cyclodextrin complex, urinary excretion of the complex is the major route of elimination of rocuronium. Renal excretion of rocuronium is increased by more than 100% after the administration of 4 to 8 mg/kg of sugammadex.[380]

As noted earlier, after the administration of sugammadex, the plasma concentration of free rocuronium decreases rapidly, but the total plasma concentration of rocuronium (both free and that bound to sugammadex) increases.[377]

Pharmacodynamics. In male volunteers, administration of 8 mg/kg of sugammadex 3 minutes after the administration of 0.6 mg/kg of rocuronium resulted in recovery of the TOF ratio to 0.9 within 2 minutes.[379] Decreasing the dose of sugammadex to 4 mg/kg resulted in recovery of the TOF ratio to 0.9 in less than 4 minutes.[379] Additionally, in surgical patients who were anesthetized with total intravenous anesthetic agents and had received 0.6 mg/kg of rocuronium, different doses of sugammadex or placebo were administered at reappearance of the second twitch of the TOF response.[381] Sugammadex decreased the median recovery time in a dose-dependent manner from 21.0 minutes in the placebo group to 1.1 minutes in the group given 4.0 mg/kg of sugammadex.[381]

Administration of sugammadex when the TOF count had returned to two detectable responses resulted in a dose-dependent recovery from the neuromuscular blockade induced by either rocuronium (0.60 mg/kg) or vecuronium (0.10 mg/kg).[382] After a dose of 4.0 mg/kg of sugammadex, the mean time to recovery of the TOF ratio to 0.9 was 1.1 minutes and 1.5 minutes after rocuronium and vecuronium, respectively. A sugammadex dose of 0.5 mg/kg is considered to be grossly inadequate for antagonism.[382-384]

One of the features that make sugammadex so different pharmacodynamically from the available anticholinesterases is that it takes effect more quickly and reliably than either neostigmine or edrophonium.[385] In a trial by Sacan and colleagues,[385] patients received 0.6 mg/kg of rocuronium, and neuromuscular blockade was maintained with supplemental doses of rocuronium given at reappearance of the second twitch in the TOF. The reversal agent—70 μg/kg of neostigmine, 1 mg/kg of edrophonium, or 4 mg/kg of sugammadex—was administered at least 15 minutes after the last dose of rocuronium. A 4-mg/kg dose of sugammadex reversed the rocuronium-induced neuromuscular blockade more rapidly than neostigmine or edrophonium did. The average time to achieve a TOF ratio of 0.9 was 10 times longer after the administration of neostigmine than it was after sugammadex (1044 versus 107 seconds) and three times longer after the administration of edrophonium (331 seconds) than after sugammadex. Although 5 of 20 patients in the neostigmine group and 2 of 20 patients in the edrophonium group achieved a TOF ratio of 0.9, all 20 in the sugammadex group achieved this degree of recovery. Furthermore, 5 minutes after the administration of edrophonium, none of the patients who had received edrophonium and 5% of those who had received neostigmine had recovered to a TOF ratio of 0.9, but all the patients in the sugammadex group had.[385] Hence, sugammadex appears to allow more complete recovery of neuromuscular function than the anticholinesterases do, and it does so more quickly than the more conventional agents. Unlike the case with neostigmine or edrophonium,[328,351,353] the choice of anesthetic agent (e.g., propofol versus sevoflurane) does not appear to influence the ability of sugammadex to antagonize rocuronium-induced neuromuscular blockade.[386]

Whereas there is a ceiling effect to what anticholinesterases can do[332] in that they cannot effectively antagonize profound levels of neuromuscular blockade, sugammadex has been shown to do so in trials.[384,387] Deep neuromuscular blockade (post-tetanic count of <10) was maintained for at least 2 hours in patients anesthetized with propofol–nitrous oxide–opioid anesthesia.[387] After spontaneous recovery of the second twitch of the TOF, different doses of sugammadex were administered; increasing the sugammadex dose from 0.5 to 4.0 mg/kg shortened the average recovery time to a TOF of 0.9 from 6.8 minutes (range, 4.8 to 11.4 minutes) to 1.4 minutes (range, 0.95 to 2.3 minutes), respectively.[387] Unexpectedly, the recovery time was longer (2.6 minutes[388]) with a 6.0-mg/kg dose.[387] The reason for this deviation is unclear.

Sugammadex produces rapid and effective reversal of even more profound rocuronium-induced neuromuscular blockade. In one study, sugammadex or placebo was administered 5 minutes after the administration of 1.2 mg/kg of rocuronium.[389] Increasing the dose of sugammadex to 16 mg/kg decreased the mean recovery time to a TOF ratio of 0.9 from 122.1 minutes (spontaneous recovery) to less than 2 minutes.[389]

In another study, patients were randomized to receive an intubating dose of 1.2 mg/kg of rocuronium followed 3 minutes later by 16 mg/kg of sugammadex or an intubating dose of 1.0 mg/kg of succinylcholine.[390] The mean time to 90% recovery of first twitch was significantly faster in the rocuronium-sugammadex group than it was in the succinylcholine group. The mean (± SD) time to 90% recovery of first twitch from the start of sugammadex administration was 2.9 minutes (1.7 minutes).[390] Therefore, the use of rapid-sequence induction with rocuronium can be facilitated by the presence of sugammadex. Administration of 1.2 mg/kg of rocuronium followed 3 minutes later by 16 mg/kg of sugammadex seems to provide a faster onset-offset profile than that seen with 1.0 mg/kg of succinylcholine (Fig. 29-29).[391]

Sugammadex is ineffective against succinylcholine and benzylisoquinolinium neuromuscular blockers such as mivacurium, atracurium, and cisatracurium[392] because it cannot form inclusion complexes with these drugs. Therefore, if neuromuscular blockade must be reestablished after using sugammadex, one of the benzylisoquinolinium neuromuscular blockers should be considered.

Side Effects. The ability of sugammadex to form complexes with steroidal and nonsteroidal compounds such as cortisone, atropine, and verapamil is probably clinically insignificant and is 120 to 700 times less than that of rocuronium.[393] In phase I and II studies, the most frequently reported side effects have been hypotension, coughing, movement, nausea, vomiting, dry mouth, parosmia (an abnormal sense of smell), a sensation of a changed temperature, and abnormal levels of *N*-acetyl-glucosaminidase in urine.[379,381,387] Patient movement with the administration of sugammadex may have been due to the unmasking of inadequate anesthesia rather than an adverse response to the reversal agent. In one study, prolongation of the corrected QT interval was noted in five subjects who received placebo and in three who received sugammadex.[379]

Cysteine

Gantacurium undergoes rapid degradation in plasma by chemical hydrolysis and inactivation by cysteine adduction (see Fig. 29-10),[105] which is a novel chemical mechanism of inactivation. Exogenous administration of cysteine can accelerate the

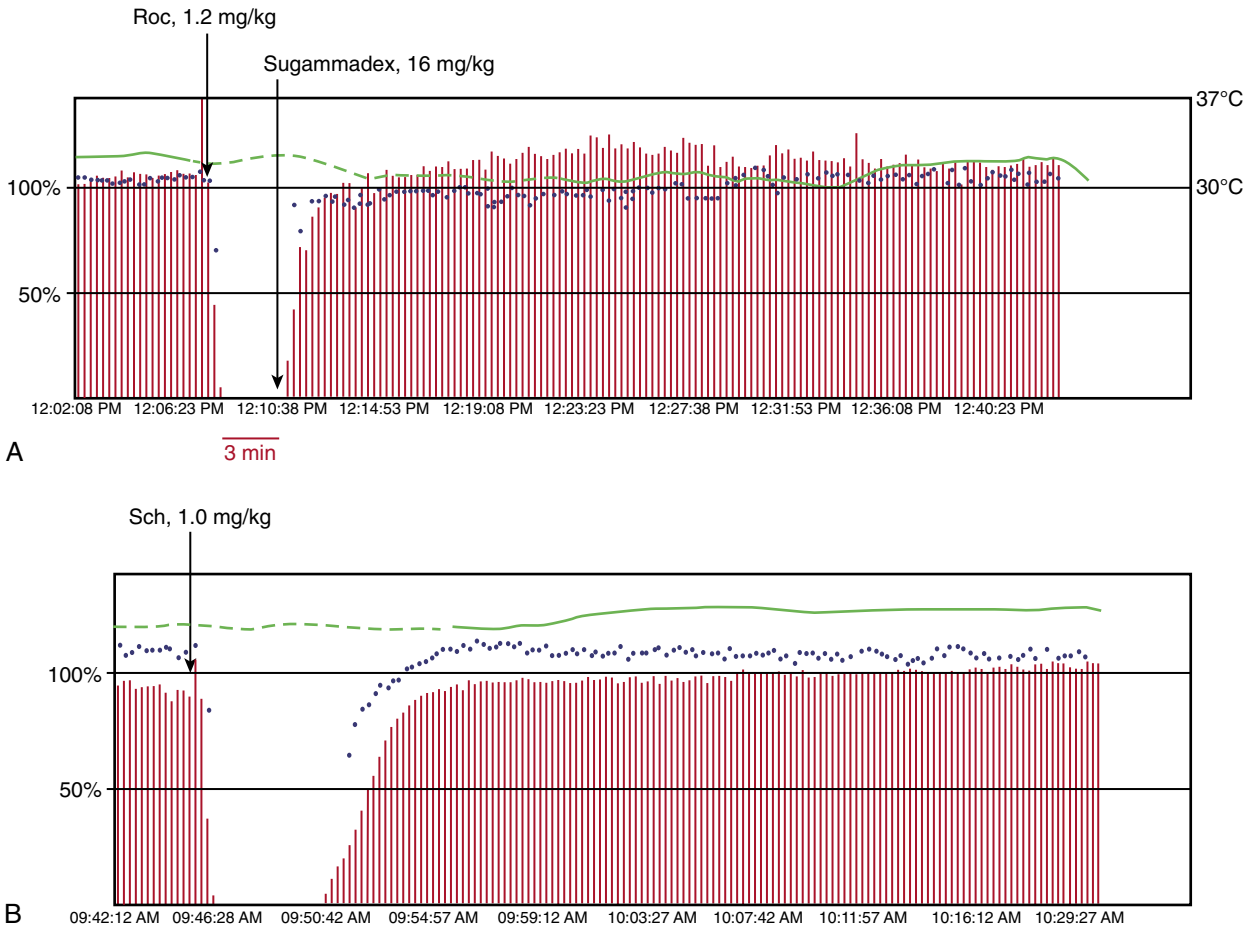

Figure 29-29 A, Recovery of twitch height and the train-of-four (TOF) ratio after the administration of 1.2 mg/kg of rocuronium, followed 3 minutes later by 16 mg/kg of sugammadex, both given intravenously. Recovery to a first twitch height (T1) of 90% and a TOF ratio of 0.94 occurred 110 seconds later. The onset-offset time with this sequence (i.e., time from the end of the injection of rocuronium until T1 recovery to 90%) was 4 minutes, 47 seconds. **B,** Effects of administering 1.0 mg/kg of succinylcholine (Sch) with spontaneous recovery to a T1 of 90% occurring after 9 minutes, 23 seconds. *(From Naguib M: Sugammadex: Another milestone in clinical neuromuscular pharmacology. Anesth Analg 104:575-581, 2007.)*

antagonism of gantacurium-induced neuromuscular blockade. As shown in Figure 29-30, after administration of a second 0.2-mg/kg dose of gantacurium, followed less than 1 minute later by 10 mg/kg of cysteine, complete recovery from neuromuscular blockade occurred within 4 minutes.

Special Populations

Pediatric Patients

Development of the neuromuscular junction is not complete at birth.[14] In humans, maturation of neuromuscular transmission probably occurs after the first 2 months of age. Nonetheless, neuromuscular blockers can be used safely in term and preterm infants.

Routine administration of succinylcholine to healthy children should be discontinued. In apparently healthy children, intractable cardiac arrest with hyperkalemia, rhabdomyolysis, and acidosis may occur after succinylcholine administration, particularly in patients with unsuspected muscular dystrophy of the Duchenne type.[394] In response to this report, the U.S. Food and Drug Administration and Glaxo-Wellcome have modified the package insert for succinylcholine to warn against the use of succinylcholine in children except for emergency control of the airway (see the section on complications of succinylcholine).

It is not apparent from older studies whether neonates are more sensitive than adults to nondepolarizing neuromuscular blockers.[395] More recent studies by Fisher and coworkers[137,396,397] on the pharmacokinetics and pharmacodynamics of neuromuscular blockers in infants, children, and adults, however, have made it possible to better understand the clinical pharmacology of these drugs in pediatric patients (see Chapter 82). Neonates and infants are more sensitive than adults to the neuromuscular blocking effects of dTc.[396] A lower plasma concentration of this neuromuscular blocker is required to achieve a desired level of neuromuscular blockade in these young patients. However, the dosage should not be decreased because infants have a larger volume of distribution. The increased volume of distribution and slower clearance (Fig. 29-31) contribute to a longer elimination half-life,[396,398]

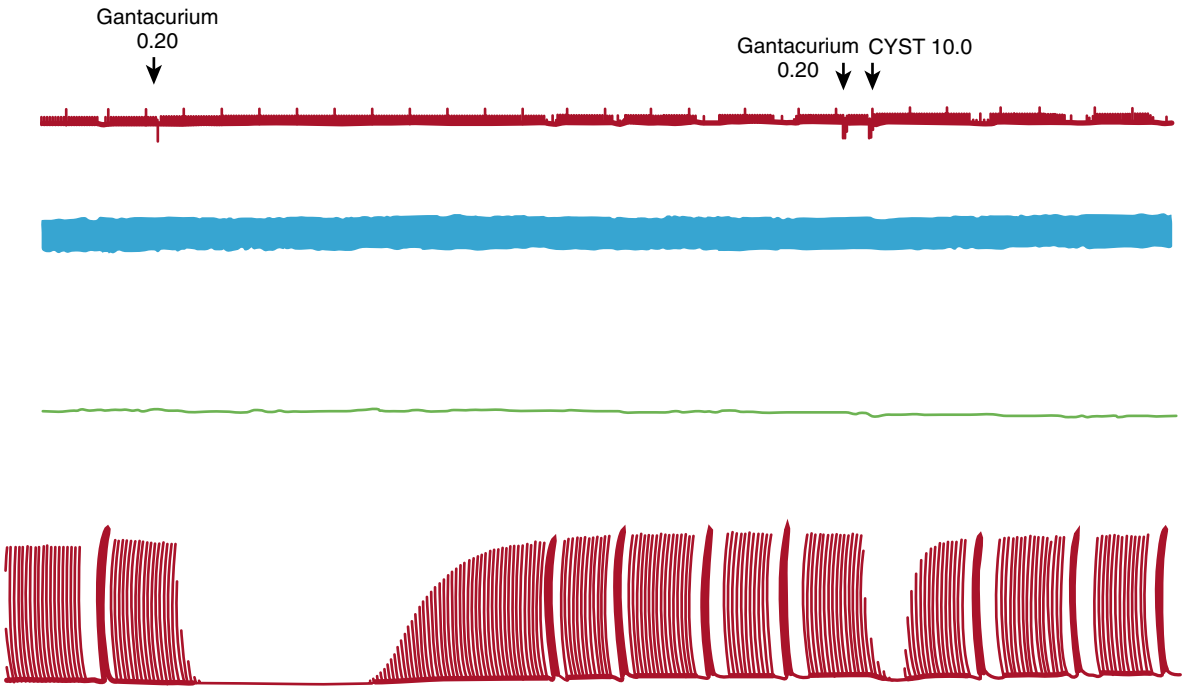

Figure 29-30 Twitch recording from a single monkey demonstrating complete spontaneous recovery from 3.2 times the ED_{95} of gantacurium, 0.2 mg/kg. Complete spontaneous recovery occurred within 10 minutes. Six minutes after complete recovery, a second dose of gantacurium, 0.2 mg/kg, was administered to this animal. Less than 1 minute later, 10 mg/kg of cysteine was administered. With cysteine administration, complete recovery occurred within 4 minutes of administering gantacurium. *(Courtesy of John J. Savarese.)*

which means that in infants, less frequent dosing (longer dosing intervals) of dTc may be required than in older children.

Atracurium, vecuronium, cisatracurium, rocuronium, and mivacurium are commonly administered to children. The popularity of these drugs in children most likely stems from the following points: minimal residual paralysis is seen in the postoperative period, and onset of action is faster in children than in adults.

Atracurium and vecuronium, in comparison, show very different kinetic and dynamic patterns in infants. As with the long-acting neuromuscular blockers, the sensitivity of infants to vecuronium is greater than it is in children (ED_{95} of 0.047 versus 0.081 mg/kg, respectively).[399] The increased duration of action in infants is most likely secondary to the increased volume of distribution of vecuronium because its clearance is unchanged.[397,398] Vecuronium therefore acts as a long-acting neuromuscular blocker in neonates.[397,398]

In contrast, the duration of action of atracurium is not significantly different in pediatric patients and adults.[400] As with vecuronium and dTc, the volume of distribution is increased in infants.[137] However, clearance of atracurium is also more rapid.[137] Therefore, the same dose (0.5 to 0.6 mg/kg) can be used in infants, children, and adults for tracheal intubation without any major difference between the three groups in its duration of action. In children, a dose of 0.1 mg/kg of cisatracurium has an onset of just over 2 minutes and a clinical duration of approximately 30 minutes during balanced or halothane anesthesia.[401] The calculated ED_{95} doses of cisatracurium in infants and children are 43

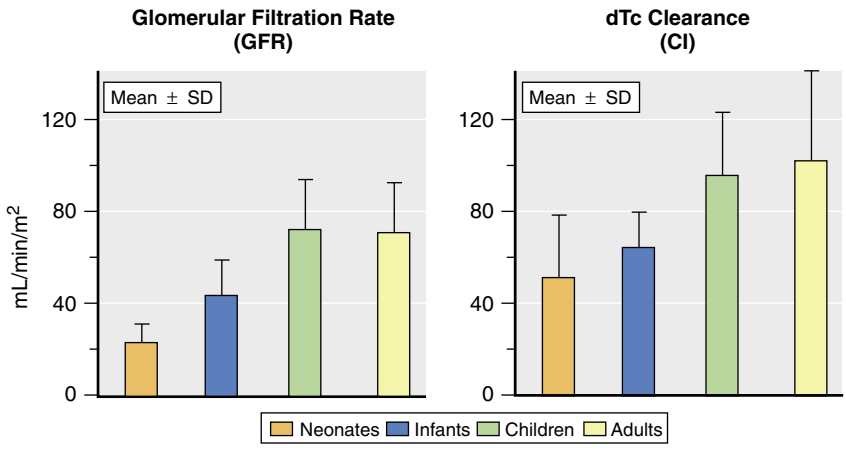

Figure 29-31 Correlation between age, glomerular filtration, and clearance of curare. *(From Fisher DM, O'Keeffe C, Stanski DR, et al: Pharmacokinetics and pharmacodynamics of d-tubocurarine in infants, children, and adults. Anesthesiology 57:203-208, 1982.)*

and 47 mg/kg, respectively.[402] The mean infusion rate necessary to maintain 90% to 99% neuromuscular blockade is also similar in infants and children.[402]

Rocuronium in adults is an intermediate-acting neuromuscular blocker with a fast onset of action, and this is also true in infants and children.[403,404] Its potency is greater in infants than in children, but its onset is faster in the latter age group.[404] In children, 0.6 mg/kg of rocuronium produces better conditions for rapid tracheal intubation than 0.1 mg/kg of vecuronium or 0.5 mg/kg of atracurium does.[403] As with adults, for rapid-sequence intubation (60 seconds) in the presence of a full stomach, a 1.2-mg/kg dose of rocuronium is suggested.

Antagonism of residual neuromuscular blockade in the case of the various nondepolarizers is similar in children and adults. Fisher and coauthors described some minor variations in the neostigmine and edrophonium dosage for pediatric patients. For example, the ED_{50} of neostigmine for antagonism of a dTc-induced 90% blockade of the adductor pollicis twitch was 22.9 μg/kg in adults versus 15.5 μg/kg in infants. In the case of edrophonium, the ED_{50} for antagonism of dTc-induced 90% blockade was 128 μg/kg in adults. In children, the ED_{50} was 233 μg/kg, and in infants it was 145 μg/kg.[405] The rate of recovery from intermediate- or short-acting neuromuscular blockers is faster than that from long-acting drugs in children.[333]

Neostigmine doses of 50 to 60 μg/kg or edrophonium doses of 500 to 1000 μg/kg should be used for antagonism of residual neuromuscular blockade in children. In all cases, tests of clinical recovery, such as head lift, leg lift, and cry, should be performed and documented for pediatric patients and adults.

Elderly Patients

The pharmacodynamics of neuromuscular blockers is altered in elderly patients (see Chapter 71). A number of physiologic changes that accompany the aging process, including decreases in total body water, increases in total body fat, decreases in hepatic and renal blood flow, and decreases in cardiac reserve, account for the altered responses of the elderly to neuromuscular blockers. A number of physiologic and anatomic changes at the neuromuscular junction also occur with aging. Such changes include an increase in the distance between the junctional axon and the motor end plate, flattening of the folds of the motor end plate, decreased concentration of acetylcholine receptors at the motor end plate, a reduction in the amount of acetylcholine in each vesicle in the prejunctional axon, and decreased release of acetylcholine from the preterminal axon in response to a neural impulse.[14] That is, the elderly and young adults have similar degrees of neuromuscular blockade at the same plasma concentration of a neuromuscular blocker. Rather, it appears that in the elderly, decreased splanchnic and renal blood flow, decreased glomerular filtration rate, and decreased hepatic function are responsible for the prolonged durations of action of most neuromuscular blockers. The greater depth of blockade with a given dose of relaxant in elderly patients than in young patients may also be due, in part, to altered volumes of distribution. The effect of aging alone, versus disease states often associated with the aging process, may be difficult to distinguish in identifying mechanisms of altered neuromuscular blocker action in the elderly.

Pancuronium,[406] vecuronium,[325,397] and rocuronium[208] all show altered pharmacodynamics and pharmacokinetics in elderly patients. Decreased clearance of each of these drugs from plasma explains their prolonged duration of action in these patients. These neuromuscular blockers depend on the kidney or the liver (or on both) for their metabolism and elimination.

In the case of drugs whose elimination is independent of hepatic or renal blood flow, pharmacokinetics and pharmacodynamics should be unaffected by age. This is true of atracurium, which depends on Hofmann elimination for its clearance.[138] Cisatracurium, which also undergoes Hofmann elimination, has a delayed onset of effect in elderly patients. The duration of action of the relaxant, however, appears to not be influenced by advanced age. The prolonged elimination half-life of the drug in the elderly is due to an increased volume of distribution. Clearance is not decreased with advanced age.

Butyrylcholinesterase activity in the elderly, though still in the normal range, is approximately 26% lower than it is in young adults.[407] Because mivacurium is metabolized by butyrylcholinesterase, its clearance is likely to be slightly reduced in the elderly; as a result, the duration of action of mivacurium is 20% to 25% longer in elderly patients,[408] and the infusion rate needed to maintain a stable depth of blockade is decreased.

In general, when maintaining neuromuscular blockade with nondepolarizing neuromuscular blockers in elderly patients, one can expect that with the exception of atracurium and cisatracurium, the dosing interval will be increased and fewer doses of neuromuscular blocker will be required to maintain the desired depth of neuromuscular blockade. The choice of drug and monitoring the depth of blockade are exceptionally important in this population because recovery of neuromuscular function is generally delayed in the elderly. Inadequate or incomplete recovery of muscle strength after the use of pancuronium is associated with an increased incidence of perioperative pulmonary complications in this patient population.[336]

Obese Patients

Reports on the effect of obesity on the pharmacodynamics of nondepolarizing neuromuscular blockade are conflicting. Although the duration of action of pancuronium is unaffected by a patient's weight,[409] obese patients recover more slowly from vecuronium-[410] or rocuronium-induced[411] neuromuscular blockade. These findings imply that elimination of these drugs is decreased. Recovery from atracurium-induced neuromuscular blockade, however, is not affected by obesity,[410] most likely because of lack of dependence on end-organ function for elimination.

Neuromuscular blockers should be administered to obese patients on the basis of about 20% more than lean body mass rather than on their actual body weight[412] to ensure that these patients are not receiving relative overdoses.

Severe Renal Disease

Renal failure influences the pharmacologic characteristics of nondepolarizing neuromuscular blockers either by decreased elimination of the drug or its metabolites via the kidney or by decreased activity of butyrylcholinesterase (Table 29-13). Consequently, the duration of action of neuromuscular blockers may be prolonged in patients with renal failure (see Chapters 65 and 67).

Table 29-13 Pharmacokinetics of Neuromuscular Blocking Drugs in Patients with Normal Renal Function or Renal Failure

Renal failure does not alter the sensitivity (dose-response relationship) of patients to the neuromuscular blocking action of pancuronium,[130] atracurium,[417] vecuronium,[418] or rocuronium.[419]

All long-lasting muscle relaxants are eliminated predominantly via the kidney, and renal failure is associated with reduced plasma clearance and an increased elimination half-life of these drugs as well.[107] As a consequence of these pharmacokinetic changes, the duration of neuromuscular blockade produced by these drugs is longer and more variable than in patients with normal renal function. Because of the potential for prolonged blockade and the availability of intermediate- and short-acting neuromuscular blockers, there is no longer any reason to recommend the use of the long-acting neuromuscular blockers in patients with renal failure.

The pharmacokinetics and duration of action of atracurium are unaffected by renal failure.[413,420] This lack of effect occurs in part because Hofmann elimination and ester hydrolysis[205] account for 50% of its total clearance.[191] The elimination half-life of laudanosine, the principal metabolite of atracurium, increases in renal failure.[413] Recent evidence suggests, however, that significant concentrations of laudanosine are not achieved during the administration of atracurium in the operating room setting.[413]

In patients with chronic renal failure, the duration of action of cisatracurium is not prolonged.[154] Hofmann elimination accounts for 77% of the total clearance of cisatracurium,[203] and renal excretion accounts for 16% of its elimination.[203] Clearance of the drug is slightly decreased (by 13%) in this patient population.

Vecuronium relies principally on hepatic, not renal, mechanisms for its elimination. However, its clearance is reduced and its elimination half-life is increased in patients with renal failure.[414,415] In one study, the duration of action of 0.1 mg/kg of vecuronium was both longer and more variable in patients with renal failure than in those with normal renal function.[415] In three other studies, the duration of action of 0.05 to 0.14 mg/kg of vecuronium was not prolonged by renal failure, but this result was probably due to the use of relatively small doses or inadequate sample sizes.[414] The principal metabolite of vecuronium, 3-desacetylvecuronium, has 80% of the neuromuscular blocking activity of vecuronium[177]; it may cause prolonged paralysis in patients with renal failure in the ICU.[179] In patients with renal failure, the duration of action and rate of recovery from vecuronium- or atracurium-induced neuromuscular blockade during surgery are similar.[421]

Plasma clearance of rocuronium may be decreased in patients with renal failure and its volume of distribution increased.[206] The duration of action of single and repeated doses, though, is not significantly affected.[419] When rocuronium is administered to patients with renal failure undergoing renal transplantation as opposed to patients with normal renal function, plasma clearance is unchanged (2.89 mL/kg/min), the volume of distribution is increased by 28%, and its elimination half-life is lengthened by 37% (see Fig. 29-16).[206]

Hepatobiliary Disease

Patients with hepatobiliary disease may exhibit prolonged blockade with pancuronium,[175] vecuronium,[127] rocuronium,[207,210] and mivacurium (see Chapters 66 and 67).[182] In the case of pancuronium,[175] vecuronium,[127] and mivacurium,[182] this prolonged action is associated with decreased plasma clearance of the drug. However, this relationship is not consistent, and many studies have described a reduction in clearance without a prolonged duration of action. In the case of atracurium, one study even demonstrated increased clearance in patients with cirrhosis, but the duration of action was normal.[193]

The influence of hepatobiliary disease on the pharmacokinetics of neuromuscular blockers is complex (Table 29-14). In

most studies, hepatic disease has been associated with an increased volume of distribution and, as a result, apparent resistance to the effect of dTc,[193] atracurium,[425] pancuronium,[423] and rocuronium.[426] The effect of hepatic disease on the pharmacokinetics of neuromuscular blockers (see Table 29-14) suggests that initial doses may need to be greater than those in patients with normal hepatic function but that once the desired level of blockade has been achieved, subsequent recovery may be slower. This is illustrated in the case of vecuronium, in which doses of up to 0.15 mg/kg have a normal duration of action[178,427] but a dose of 0.2 mg/kg results in prolonged action (see Fig. 29-14).[422]

Hepatic disease can alter the elimination of neuromuscular blockers by several mechanisms. The principal route of metabolism of pancuronium and vecuronium is deacetylation at the 3-position.[173] This metabolic process is presumed to occur in the liver because 10% to 20% of the total dose of pancuronium and 40% of that of vecuronium is found in the liver and bile as both parent drug and metabolite.[173] In hepatic disease, an increased plasma concentration of bile salts can reduce the hepatic uptake of pancuronium and vecuronium,[173] which may be an explanation for the decreased clearance of these drugs observed by some investigators.[174,175] Excretion of vecuronium is diminished in the presence of decreased hepatic function.[397] The duration of action of vecuronium is longer in these patients, and recovery is slower than in young healthy individuals.

Atracurium and cisatracurium share organ-independent modes of elimination.[189,202,203] As a consequence, their clearance should be little affected by hepatic disease. In fact and in contrast with that of all other neuromuscular blockers, plasma clearance of atracurium and cisatracurium is slightly increased in patients with liver disease (see Table 29-14).[193,211] Because elimination of atracurium and cisatracurium occurs outside of as well as from within the central compartment, it has been suggested that a larger volume of distribution should be associated with greater clearance.[203] In two studies,[193,211] the volume of distribution and clearance of the drugs increased with liver disease, thus lending support to this hypothesis.[203] The increased clearance of the relaxant in patients with liver disease is not reflected in a decrease in the drug's duration of action.[193,211]

One concern raised about administering atracurium to patients with hepatic disease was the possible accumulation of laudanosine. Although laudanosine relies principally on hepatic mechanisms for elimination, the concentrations encountered during liver transplantation are unlikely to be associated with clinical sequelae.[428]

In patients with hepatic disease (most commonly cirrhosis), the volume of distribution of rocuronium is increased,[207,209,210,426] and its clearance may be decreased.[210] The duration of action of rocuronium is prolonged in patients with hepatic disease,[207,210,426] and its onset may be prolonged.[207]

In patients with severe liver disease, butyrylcholinesterase activity is decreased because of decreased synthesis of the hepatic enzymes. Consequently, plasma clearance of the isomers of mivacurium is decreased by approximately 50% (see Table 29-14),[182] and its duration of action is prolonged and may be almost tripled.[182]

Burns

After a period of immobilization, burn injury causes upregulation of both fetal ($\alpha_2\beta\gamma\delta$) and mature ($\alpha_2\beta\varepsilon\delta$) nAChRs.[429] This upregulation of nAChRs is usually associated with resistance to nondepolarizing neuromuscular blockers and increased sensitivity to succinylcholine.[430] Causes of upregulation of nAChRs are listed in Box 29-1. A significant increase in the quantal content of evoked acetylcholine release is noted by 72 hours after scald injury in rats.[431] This also contributes to the resistance to nondepolarizing blockers in burn patients. In mice, thermal injury induces changes in diaphragm acetylcholinesterase with respect to total content and specific molecular forms.[432]

Resistance to the effects of nondepolarizing neuromuscular blocking drugs is usually seen in patients with burns over at least 25% of their total body surface area.[140,430] Recovery of neuromuscular function to preburn levels may take several months or even years after the burn injury.[433] The increase in serum potassium concentration that normally follows the administration of succinylcholine is markedly exaggerated in burned victims.[434] Potassium concentrations as high as 13 mEq/L have been reported to result in ventricular tachycardia, fibrillation, and cardiac arrest.[434] The magnitude of the hyperkalemic response does not appear to closely correlate with the magnitude of the burn injury. Potentially lethal hyperkalemia was seen in a patient with only an 8% total body surface area burn.[435] Succinylcholine has been safely administered within 24 hours of a burn injury. After this initial 24 hours, however, sufficient alteration in muscle response may have occurred, and the use of succinylcholine is best avoided.

The time course of abnormal muscle membrane function corresponds with that of the healing process. Once normal skin has regrown and any infection subsides, the normal acetylcholine receptor populations appear to return.[433] Normal responses to succinylcholine have been demonstrated in burn patients studied 3 years after injury.[433] The length of time during which a burn patient may be at risk for a hyperkalemic response is not well defined. A conservative guideline therefore would be to avoid the use of succinylcholine in patients 24 to 48 hours after a thermal injury and for at least 1 or 2 years after the burned skin has healed.

Box 29-1 Conditions Associated with Upregulation and Downregulation of Acetylcholine Receptors

Box 29-2 Reported Indications for the Use of Muscle Relaxants in the Intensive Care Unit

- Facilitate mechanical ventilation
  - Facilitation of endotracheal intubation
  - Enable patients to tolerate mechanical ventilation
  - High pulmonary inflation pressures, e.g., acute respiratory distress syndrome
- Hyperventilation for increased intracranial pressure
- Facilitate therapeutic or diagnostic procedures
- Tetanus
- Status epilepticus
- Reduce oxygen consumption
  - Abolish shivering
  - Reduce work of breathing

Neuromuscular Blockers and Weakness Syndromes in the Critically Ill

Neuromuscular blocking drugs are frequently used in conjunction with sedatives and analgesics in ICUs. Indications for the use of neuromuscular blockers in the ICU are outlined in Box 29-2. Few available data support their use, and evidence for a beneficial effect on pulmonary function or patient oxygenation is inconclusive.[436] Yet nondepolarizing neuromuscular blockers are commonly used for weeks in ICU patients, most of the time without monitoring and frequently at doses exceeding those used in the operating room.[437] The results of two surveys in the United States, including anesthesiologists and nurses with special certificates of competence in critical care, indicated that 98% of those surveyed use neuromuscular blocking drugs at least occasionally.[437]

Of particular concern in intensive care settings is the risk that paralyzed patients will receive inadequate analgesia and sedation.[438] This may be due to the fact that ICU nurses and physicians are unfamiliar with the pharmacology of neuromuscular blocking drugs.[437,438] For instance, pancuronium was thought to be an anxiolytic by 50% to 70% of ICU nurses and house staff, and 5% to 10% thought that it was an analgesic.[438] In the United Kingdom, the erroneous use of neuromuscular blockers as sedatives in intensive care was not uncommon in the 1980s.[439] Approximately 96% of ICU patients received neuromuscular blockers to aid mechanical ventilation in 1980. By 1986, their use had fallen to 16% of ventilated patients.[439] In the United States, neuromuscular blockers are used in less than 20% of all patients requiring mechanical ventilation.[437]

A prolonged ICU stay during critical illness is associated with disorders of neuromuscular function that contribute to morbidity, length of hospital stay, weaning difficulty, and prolonged rehabilitation.[440] Complications of long-term administration of

Box 29-3 Complications of Muscle Paralysis in the Intensive Care Unit

- Short-term use
  - Specific, known drug side effects
  - Inadequate ventilation in the event of ventilator failure or circuit disconnection
  - Inadequate analgesia and/or sedation
- Long-term use
  - Complications of immobility
    - Deep venous thrombosis and pulmonary embolism
    - Peripheral nerve injuries
    - Decubitus ulcers
  - Inability to cough
    - Retention of secretions and atelectasis
    - Pulmonary infection
- Dysregulation of nicotinic acetylcholine receptors
- Prolonged paralysis after stopping relaxants
  - Persistent neuromuscular blockade
  - Critical illness myopathy
  - Critical illness polyneuropathy
  - Combination of the above
- Unrecognized effects of drug or metabolites
  - Succinylcholine and metabolic acidosis/hypovolemia
  - 3-Desacetylvecuronium and neuromuscular blockade
  - Laudanosine and cerebral excitation

neuromuscular blockers in the ICU are outlined in Box 29-3. In the ICU, the duration of mechanical ventilation, sepsis, dysfunction of two or more organs, female sex, administration of steroids, and hypercapnia are known risk factors for the development of neuromuscular dysfunction. Syndromes of weakness in critically ill patients are relatively common and probably polymorphic in origin. In a retrospective study of 92 critically ill patients with clinically diagnosed weakness, electromyographic studies indicated that acute myopathy (critical illness myopathy) is three times as common as acute axonal neuropathy (critical illness neuropathy): 43% versus 13%, respectively.[440] The additional health care cost of one case of persistent weakness was estimated to be approximately $67,000.[441] Conditions to consider in the differential diagnosis of neuromuscular weakness in the ICU are listed in Box 29-4.

Critical Illness Myopathy

Lacomis and colleagues[442] suggested using the term "critical illness myopathy" (CIM) instead of the current terms used in the literature, such as acute quadriplegic myopathy,[443] acute (necrotizing) myopathy of intensive care, thick filament myopathy, acute corticosteroid myopathy, and critical care myopathy.

Most published reports of CIM in the ICU have focused on patients with status asthmaticus.[444] Affected individuals typically have been treated with corticosteroids and nondepolarizing neuromuscular blockers. Nevertheless, myopathy has also been documented in asthmatic patients and those with chronic lung disease without paralysis who received corticosteroids[445] and in critically ill patients with sepsis who received neither corticosteroids nor nondepolarizing neuromuscular blockers.[446] Animal studies have revealed that the number of cytosolic corticosteroid receptors is increased in immobilized muscles relative to contralateral controls.[447] It seems—at least in some patients—that prolonged immobility may be the key risk factor for myopathy in corticosteroid-treated patients[448] and that selective muscle atrophy is a result of changes in glucocorticoid sensitivity.[447]

Sepsis, immobility, and the catabolism associated with negative nitrogen balance may also result in myopathy.[14] Skeletal muscle hypoperfusion is noted in patients with severe sepsis despite normal or elevated whole blood oxygen delivery.[449] Antibodies to nAChRs have been demonstrated in a rodent model of sepsis.[450] Thus, myasthenia-like syndrome is also seen in critically

ill patients. Evidence of local immune activation by cytokine expression in skeletal muscle was reported in patients with CIM.[451]

The major feature of CIM is flaccid weakness that tends to be diffuse and sometimes also includes the facial muscles and diaphragm.[442] The clinical features of CIM overlap with those of critical illness polyneuropathy (CIP) and prolonged neuromuscular blockade.[442] Electrophysiologic studies and increases in serum creatine kinase concentration may differentiate neuropathy from myopathy.[442] Lacomis and coworkers[442] stated that "muscle biopsy should be considered if another myopathic process such as an inflammatory myopathy is suspected or if the histologic findings would affect management."

Critical Illness Polyneuropathy

The polyneuropathy seen in the critically ill has been termed "critical illness polyneuropathy (CIP)." It affects both sensory and motor nerves and occurs in 50% to 70% of patients with multisystem organ failure and systemic inflammatory response syndrome.[452] It has been postulated that systemic inflammatory response syndrome contributes to CIP by releasing cytokines and free radicals that damage the microcirculation of the central and peripheral nervous systems.[451] Dysregulation of the microcirculation may render the peripheral nervous system susceptible to injury.

No specific treatment of weakness syndromes in critically ill patients is available other than physical rehabilitation. Intravenous immunoglobulin and nerve growth factors appear to be promising in CIP syndrome. Recently, intensive insulin therapy during critical illness has been found to decrease the risk for CIP, and maintenance of blood glucose at or below 110 mg/mL in critically ill patients may reduce the risk for CIP.[453]

Outcomes after CIM and CIP appear to be similar.[440] The reported mortality rate of patients with CIP syndrome is about 35%. In one study, 100% (13 of 13) of the patients who survived had abnormal clinical or neurophysiologic findings 1 to 2 years after the onset of CIP syndrome, and quality of life was markedly impaired in all patients.[454]

Clinical Implications

Should Succinylcholine Be Used in ICU Patients?

It is likely that the upregulation of nAChRs induced by immobilization and by prolonged administration of nondepolarizing neuromuscular blockers contributes to (1) the higher incidence of cardiac arrest associated with the use of succinylcholine in ICU patients[455] and (2) increased requirements for nondepolarizing neuromuscular blockers in ICU patients.[456] Upregulation of nAChRs was noted in the muscles of deceased critically ill adults who had received long-term infusions of vecuronium.[455] Therefore, succinylcholine is best avoided in ICU patients in whom total body immobilization exceeds 24 hours.[14] In a survey in U.K. ICUs, 68.7% of respondents indicated that they would use succinylcholine in a clinical scenario suggestive of CIP.[457] This highlights the lack of awareness of the dangers associated with the use of succinylcholine in these patients.[457]

Should Nondepolarizing Neuromuscular Blockers Be Used in ICU Patients?

Nondepolarizing neuromuscular blocker–associated persistent weakness appears to be a distinct pathologic entity and is not simply a manifestation of weakness syndromes in the critically ill. In a prospective study, Kupfer and associates[458] showed a 70% incidence of persistent weakness in ICU patients who received neuromuscular blockers for more than 2 days versus a 0% incidence in similar ICU patients who did not receive a neuromuscular blocker. This is compelling evidence for the effects of nondepolarizing neuromuscular blockers in this complication.

Long-term weakness has been described after all commonly used nondepolarizing neuromuscular blockers.[179,459,460] The overall incidence of prolonged paralysis after long-term use of neuromuscular blockers is about 5%. Prolonged weakness developed in approximately 20% of patients who received neuromuscular blockers for more than 6 days,[459] in 15% to 40% of asthmatic patients who also received high-dose steroids,[444] and in 50% of patients with renal failure who received vecuronium.[179] Clinically, it appears that prolonged recovery from neuromuscular blockade occurs more frequently when steroidal neuromuscular blockers are used.[179,459]

However, prolonged weakness was also noted after the use of atracurium in ICU patients.[460] Furthermore, the use of atracurium has raised concern about its metabolite laudanosine. Laudanosine, also detected in the cerebrospinal fluid (CSF) of ICU patients given atracurium,[461] is an analeptic and can trigger seizures in animals.[462] The toxic dose in humans is not known, but there are case reports of patients having seizures while receiving atracurium, and laudanosine has not been ruled out as a cause of these seizures.[463-465] There is also evidence that laudanosine can activate neuronal nicotinic receptors.[466] Cisatracurium is a single isomer of atracurium, and because it is four to five times more potent than atracurium, it is given in smaller doses. Therefore, the risk of laudanosine-related adverse effects should be minimal.[199]

Nondepolarizing neuromuscular blockers are polar molecules and do not cross the blood-brain barrier readily, but vecuronium and its long-acting active metabolite 3-desacetylvecuronium have been detected in the CSF of patients in the ICU. The CNS effects of neuromuscular blockers and their metabolites in humans have not been well studied, but in rats, atracurium, pancuronium, and vecuronium injected into CSF will cause dose-related cerebral excitation culminating in seizures.[462] Cerebral excitation with consequent increased cerebral oxygen demand is undesirable in ICU patients at risk for cerebral ischemia. It has also been suggested that nondepolarizing neuromuscular blockers can gain access to nerves during systemic inflammatory response syndrome and thereby result in direct neurotoxicity.[462]

Combining corticosteroids and nondepolarizing neuromuscular blockers should be avoided. When nondepolarizing neuromuscular blockers are necessary, the use of a peripheral nerve stimulator is recommended, and periodic return of muscle function should be allowed. However, routine monitoring of neuromuscular function alone is insufficient in eliminating prolonged recovery and weakness syndromes in ICU patients.[467] Adjusting the dosage of neuromuscular blockers by peripheral nerve stimulation versus standard clinical dosing in critically ill patients reduces drug requirements, produces faster recovery of neuromuscular function, and results in a total cost savings of $738 per patient.[468] A recent study found that daily interruption of sedative-drug infusions decreases the duration of mechanical ventilation and length of stay in the ICU.[469] The effect of such an approach on weakness syndromes in ICU patients is unknown. When nondepolarizing neuromuscular blockers are used, the guidelines in Box 29-5 may help minimize the incidence of

Box 29-5 Recommendations for the Use of Neuromuscular Blockers in the Intensive Care Unit

Avoid the use of neuromuscular blockers by:
- Maximal use of analgesics and sedatives
- Manipulation of ventilatory parameters and modes

Minimize the dose of neuromuscular blocker:
- Use a peripheral nerve stimulator with train-of-four monitoring.
- Do not administer for more than 2 days continuously.
- Administer by bolus rather than infusion.
- Administer only when required and to achieve a well-defined goal.
- Continually allow recovery from paralysis.

Consider alternative therapies:
- Avoid vecuronium in female patients with renal failure.
- Use isoflurane in place of muscle relaxants in patients with severe asthma.
- Minimize the dose of steroid in patients with asthma.

complications. As stated in the clinical practice guidelines for sustained neuromuscular blockade in adult critically ill patients,[436] "*Independent of the reasons for using neuromuscular blockers, we emphasize that all other modalities to improve the clinical situation must be tried, using neuromuscular blockers only as a last resort.*"

30 Local Anesthetics

Key Points

1. Local anesthetics block voltage-gated sodium channels and thereby interrupt initiation and propagation of impulses in axons, but they have a wide variety of other biologic actions, desirable and undesirable.
2. Currently available local anesthetics are of two chemical classes: aminoesters and aminoamides.
3. The low potency and lack of specificity of available local anesthetics are due in part to the very weak structural constraints at their binding site on the sodium channel. Most of their features derive from the requirement for high solubility and rapid diffusion in both aqueous environments and the lipid phases of biologic membranes.
4. Reversible protonation of the tertiary amine group tends to make local anesthetics less charged at more basic pH and more charged at neutral or acidic pH; the neutral base forms are more soluble in lipid environments, whereas the charged acid forms are more soluble in aqueous environments.
5. Aminoesters are metabolized primarily by plasma esterases, and aminoamides are metabolized primarily by hepatic cytochrome P450–linked enzymes.
6. The principal systemic toxicities of local anesthetics involve the heart (including atrioventricular conduction block, arrhythmias, myocardial depression, and cardiac arrest) and the brain (including agitation, lethargy, seizures, and generalized central nervous system depression). Hypoxemia and acidosis exacerbate these toxicities. Resuscitation after bupivacaine overdose is particularly difficult. Therefore, prevention of intravascular injection or overdose is crucial, and major nerve blockade should involve incremental, fractionated dosing.
7. Local anesthetics are directly toxic to nerve at the concentrations supplied in commercial solutions. Intraneural concentrations during regional anesthesia are generally (but not always) below a threshold for toxicity because of spread of solutions through tissues and diffusion gradients from injection sites into nerve. Injection into a constrained tissue space increases the risk for local toxicity.
8. Optimal use of local anesthetics in regional anesthesia requires an understanding of (1) the individual patient's clinical situation; (2) the location, intensity, and duration of regional anesthesia and analgesia required; (3) anatomic factors affecting deposition of drug near nerves; (4) proper drug selection and dosing; and (5) ongoing assessment of clinical effects after administration of a local anesthetic.
9. Recent efforts have led to the development of several new formulations for topical anesthesia. Single-stereoisomer (as opposed to a racemic mixture) formulations have been developed in an effort to reduce systemic toxicity and improve sensory selectivity.
10. Local anesthetics are increasingly being used for postoperative infusions and via both local and systemic administration for the management of chronic pain. Further research and development may lead to safe, more selective agents that will facilitate more prolonged administration in the setting of acute or chronic pain.

Local anesthesia results from the blockade of nerve impulses to abolish sensation. All currently available, clinically useful agents are either aminoesters or aminoamides. These drugs, when applied in sufficient concentration at the site of action, prevent conduction of electrical impulses by the membranes of nerve and muscle. In addition to blockade of impulses, local anesthetics can inhibit various receptors, enhance release of glutamate, and depress the activity of certain intracellular signaling pathways. When local anesthetic agents are given systemically, the functions of cardiac, skeletal, and smooth muscle, as well as transmission of impulses in the central and peripheral nervous systems and within the specialized conducting system of the heart, may all be altered. Local anesthetics may abolish sensation in various parts of the body by topical application, injection in the vicinity of peripheral nerve endings and major nerve trunks, or instillation within the epidural or subarachnoid spaces. Toxicity may be local or sys-

temic. The central nervous and cardiovascular systems are most commonly involved in acute clinical toxicity.

Basic Pharmacology

Chemistry

The Local Anesthetic Molecule

The typical local anesthetic molecule, exemplified by lidocaine and procaine (Fig. 30-1), contains a tertiary amine attached to a substituted aromatic ring by an intermediate chain that almost always contains either an ester (—C(=O)—O—) or an amide (—NHC(=O)—) linkage; local anesthetics may therefore be classified as aminoester or aminoamide compounds. The aromatic ring system gives a lipophilic (membrane-liking) character to its portion of the molecule, whereas the tertiary amine end is relatively hydrophilic, particularly since it is partially protonated and thus bears some positive charge in the physiologic pH range (Fig. 30-2). The structures of commonly administered local anesthetics are given in Table 30-1 and their physicochemical properties in Table 30-2.

Structure-Activity Relationships and Physicochemical Properties

The intrinsic potency and duration of action of local anesthetics are clearly dependent on certain features of the molecule.

Lipophilic-Hydrophilic Balance

The lipophilic versus hydrophilic character of a local anesthetic depends on the size of alkyl substituents on or near the tertiary amine and on the aromatic ring. "Lipophilicity" expresses the tendency of a compound to associate with membrane lipids, a property usually approximated by equilibrium partitioning into a hydrophobic solvent such as octanol.[1] Although octanol-buffer partition coefficients are comparable to membrane-buffer partition coefficients for the uncharged species of local anesthetics, they severely underestimate membrane partitioning for the charged, protonated species, octanol being a poor model for the polar regions near the membrane surface where local anesthetics are concentrated.[2] Here we use the term "hydrophobicity," expressed as octanol-buffer partitioning, to describe a physicochemical property of local anesthetics.

Compounds with a more hydrophobic nature are obtained by increasing the size of the alkyl substituents. These agents are more potent and produce longer-lasting blocks than their less hydrophobic congeners do.[3-5] For example, etidocaine, which has three more carbon atoms than lidocaine does in the amine end of the molecule, is four times as potent and five times as long lasting when compared by impulse blockade in the isolated sciatic nerve.

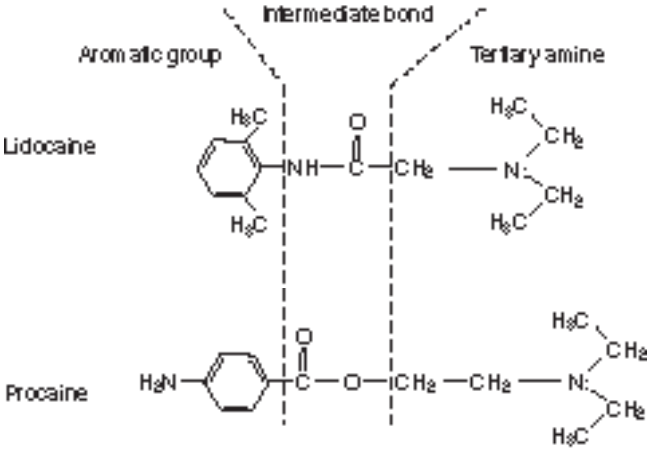

Figure 30-1 Structures of two local anesthetics, the aminoamide lidocaine and the aminoester procaine. In both drugs a hydrophobic aromatic group is joined to a more hydrophilic base, the tertiary amine, by an intermediate amide or ester bond.

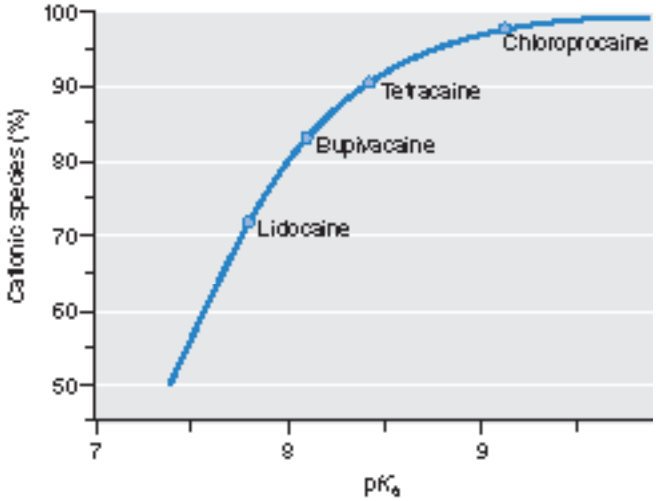

Figure 30-2 Fraction of local anesthetic in the protonated, cationic form of an aqueous solution at physiologic pH (7.4) as a function of the pK_a of the drug. Lidocaine, the drug with the lowest pK_a, has the smallest fraction of its molecules protonated, the largest in the neutral form, and vice versa for chloroprocaine, the local anesthetic with the highest pK_a. Individual drug molecules become protonated and deprotonated in thousandths of a second in solution.

Hydrogen Ion Concentration

Local anesthetics in solution exist in a very rapid chemical equilibrium between the basic uncharged form (B) and the charged cationic form (BH^+). At a certain hydrogen ion concentration ($\log_{10}^{-1}$ [–pH]) specific for each drug, the concentration of local anesthetic base in solution is equal to the concentration of charged cation. The logarithm of this hydrogen ion concentration is called pK_a. The relationship is defined by

$$\frac{[BH^+]}{[B]} = 10^{pK_a - pH} \quad (1)$$

pK_a values of local anesthetic agents in aqueous solution are listed in Table 30-2. The tendency to be protonated also

Table 30-1 Representative Local Anesthetics in Common Clinical Use

Generic* and Common Proprietary Name	Chemical Structure	Approximate Year of Initial Clinical Use	Main Anesthetic Use	Representative Commercial Preparation
Cocaine		1884	Topical	40 mg/mL solution
Benzocaine (Americaine)		1900	Topical	200 mg/mL
			Topical	200 mg/mL
Procaine (Novocain)		1905	Infiltration	10- and 20-mg/mL solutions
			Spinal	100-mg/mL solution
Dibucaine (Nupercaine)		1929	Spinal	0.667-, 2.5-, and 5-mg/mL solutions
Tetracaine (Pontocaine)		1930	Spinal	Niphanoid crystals—20- and 10-mg/mL solutions
Lidocaine (Xylocaine)		1948	Infiltration	5- and 10-mg/mL solutions
			Peripheral nerve blockade	10-, 15-, and 20-mg/mL solutions
			Epidural	10-, 15-, and 20-mg/mL solutions
			Spinal	50-mg/mL solution
			Topical	20 mg/mL jelly, viscous
			Topical	25, 50 mg/mL ointment
Chloroprocaine (Nesacaine)		1955	Infiltration	10-mg/mL solution
			Peripheral nerve blockade	10- and 20-mg/mL solutions
			Epidural	20- and 30-mg/mL solutions
Mepivacaine (Carbocaine)		1957	Infiltration	10-mg/mL solution
			Peripheral nerve blockade	10- and 20-mg/mL solutions
			Epidural	10-, 15-, and 20-mg/mL solutions

Table 30-1 Representative Local Anesthetics in Common Clinical Use—cont'd

Generic* and Common Proprietary Name	Chemical Structure	Approximate Year of Initial Clinical Use	Main Anesthetic Use	Representative Commercial Preparation
Prilocaine (Citanest)		1960	Infiltration	10- and 20-mg/mL solutions
			Peripheral nerve blockade	10-, 20-, and 30-mg/mL solutions
			Epidural	10-, 20-, and 30-mg/mL solutions
Bupivacaine (Marcaine)		1963	Infiltration	2.5-mg/mL solution
			Peripheral nerve blockade	2.5- and 5-mg/mL solutions
			Epidural	2.5-, 5-, and 7.5-mg/mL solutions
			Spinal	5- and 7.5-mg/mL solutions
Ropivacaine (Naropin)		1992	Infiltration	2.5- and 5-mg/mL solutions
			Peripheral nerve blockade	5- and 10-mg/mL solutions

*USP nomenclature.
Modified from Covino B, Vassallo H: Local Anesthetics: Mechanisms of Action and Clinical Use. Orlando, FL, Grune & Stratton, 1976.

depends on environmental factors, such as temperature and ionic strength, and on the medium surrounding the drug. In the relatively apolar milieu of a membrane, the average pK_a of local anesthetics is lower than in solution.[6] This is chemically equivalent to saying that the membrane concentrates the base form of the local anesthetic more than it concentrates the protonated cation form.

The pH of the medium containing the local anesthetic influences drug activity by altering the relative percentage of the base and protonated forms. For example, in inflamed tissues the pH is lower than normal, and local anesthetics are more protonated than in normal tissue and thus penetrate the tissue relatively poorly (see later).

The relationship between pK_a and the percentage of local anesthetic present in the cationic form is shown in Figure 30-2. As described later, there are dual effects of pH on clinical effectiveness, depending on where the local anesthetic is injected and the importance of the base form for tissue penetration.

Anatomy of the Peripheral Nerve

Each peripheral nerve axon possesses its own cell membrane, the axolemma. Nonmyelinated nerves, such as autonomic postganglionic efferent and nociceptive afferent C fibers, contain many axons encased in a single Schwann cell sheath. In contrast, all large motor and sensory fibers are enclosed in many layers of myelin, which consists of the plasma membranes of specialized Schwann cells that wrap themselves around the axon during axonal outgrowth. Myelin greatly increases the speed of nerve conduction by insulating the axolemma from the surrounding conducting salt medium and forcing the "action current" generated by an impulse to flow through the axoplasm to the nodes of Ranvier, which are periodic interruptions in the myelin sheath where the active impulse is regenerated (Fig. 30-3). The Na^+ channels that serve generation and propagation of impulses are highly concentrated at the nodes of Ranvier of myelinated fibers[7] but are

Table 30-2 Relative in vitro Conduction-Blocking Potency and Physiochemical Properties of Local Anesthetic Drugs

Drug	Relative Conduction-Blocking Potency*	Physiochemical Properties	
		pK_a†	Hydrophobicity†
Low Potency			
Procaine	1	8.9	100
Intermediate Potency			
Mepivacaine	1.5	7.7	130
Prilocaine	1.8	8.0‡	129
Chloroprocaine	3	9.1	810
Lidocaine	2	7.8	366
High Potency			
Tetracaine	8	8.4	5822
Bupivacaine	8	8.1	3420
Etidocaine	8	7.9	7320

*Data derived from C fibers of isolated rabbit vagus and sciatic nerve.
†pK_a and hydrophobicity at 36°C; hydrophobicity equals the octanol-buffer partition coefficient of the base. Values are ratios of concentrations.
‡Values at 25°C.
From Strichartz GR, Sanchez V, Arthur GR, et al: Fundamental properties of local anesthetics. II. Measured octanol : buffer partition coefficients and pK_a values of clinically used drugs. Anesth Analg 71:158-170, 1990.

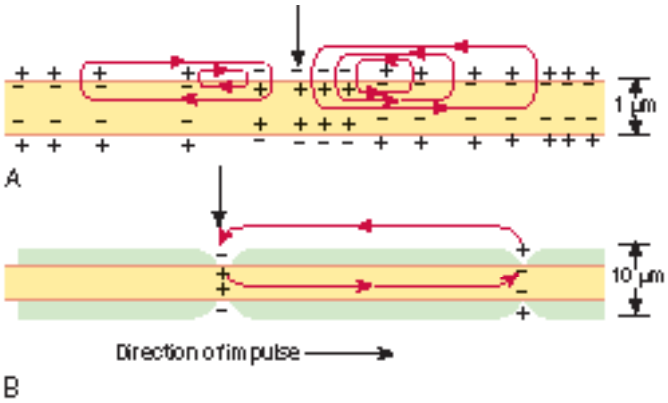

Figure 30-3 Pattern of "local circuit currents" flowing during propagation of an impulse in a nonmyelinated C fiber's axon (**A**) and a myelinated axon (**B**). During propagation of impulses, from left to right, current entering the axon at the initial rising phase of the impulse (*large vertical arrows*) passes through the axoplasm (local circuit current) and depolarizes the adjacent membrane. "Plus" and "minus" signs adjacent to the axon membrane indicate the polarization state of the axon membrane: negative inside at rest, positive inside during active depolarization under the action potential, and less negative in regions where local circuit currents flow. This ionic current passes relatively uniformly across the nonmyelinated axon, but in the myelinated axon it is restricted to entry at the nodes of Ranvier, several of which are simultaneously depolarized during a single action potential.

distributed all along the axon of nonmyelinated fibers (Fig. 30-3). A classification of peripheral nerves according to fiber size and physiologic properties is presented in Table 30-3.

A typical peripheral nerve consists of several axon bundles, or fascicles. Each axon has its own connective tissue covering, the *endoneurium*. Each fascicle of many axons is encased by a second connective tissue layer, the epithelial-like *perineurium*, and the entire nerve is wrapped in a loose outer sheath called the *epineurium* (Fig. 30-4). To reach the nerve axon, a local anesthetic molecule must traverse four or five layers of connective tissue or lipid membranous barriers, or both.

Structure of the Axonal Membrane

Biologic membranes consist of a molecular lipid bilayer containing proteins adsorbed on the surfaces, as well as embedded in or spanning the hydrocarbon core (Fig. 30-5). The character of the bilayer is determined by the phospholipids, which have long hydrophobic fatty acyl tails that lie in the center of the membrane, as well as by the polar hydrophilic head groups, which are usually composed of zwitterionic portions (containing positive and negative charges) that project into the cytoplasm or the extracellular

Table 30-3 Classification of Peripheral Nerves According to Anatomy, Physiology, and Function

Fiber Class	Subclass	Myelin	Diameter (µm)	Conduction Velocity (msec)	Location	Function	Susceptibility to Local Anesthetic Block
A	α	+	6-22	30-120	Efferent to muscles	Motor	++
	β	+	6-22	30-120	Afferent from skin and joints	Tactile, proprioception	++
	γ	+	3-6	15-35	Efferent to muscle spindles	Muscle tone	++++
	δ	+	1-4	5-25	Afferent sensory nerves	Pain, cold temperature, touch	+++
B		+	<3	3-15	Preganglionic sympathetic	Various autonomic functions	++
C	sC	–	0.3-1.3	0.7-1.3	Postganglionic sympathetic	Various autonomic functions	++
	dC	–	0.4-1.2	0.1-2.0	Afferent sensory nerves	Various autonomic functions Pain, warm temperature, touch	+

Modified From Bonica JJ: Principles and Practice of Obstetric Anesthesia and Analgesia. Philadelphia, FA Davis, 1967.

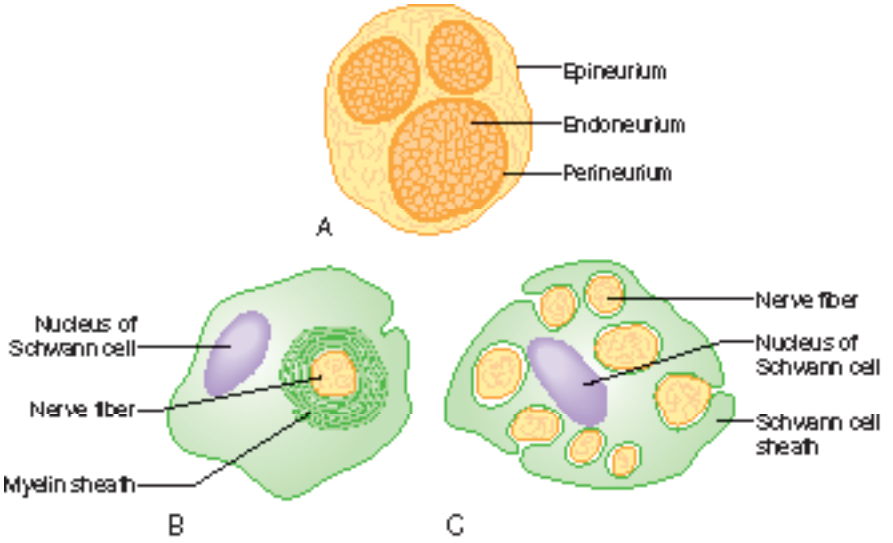

Figure 30-4 Transverse sections of a peripheral nerve (**A**) showing the outermost epineurium; the inner perineurium, which collects nerve axons in fascicles; and the endoneurium, which surrounds each myelinated fiber. Each myelinated axon (**B**) is encased in the multiple membranous wrappings of myelin formed by one Schwann cell, each of which stretches longitudinally more than approximately 100 times the diameter of the axon. The narrow span of axon between these myelinated segments, the node of Ranvier, contains the ion channels that support action potentials. Nonmyelinated fibers (**C**) are enclosed in bundles of 5 to 10 axons by a chain of Schwann cells that tightly embrace each axon with but one layer of membrane.

fluid. Within the membrane there is both lateral and rotational diffusion, which allows lipids and certain proteins to migrate in a fluid mosaic, but most membrane proteins are fixed within specific regions of a membrane, anchored by connections to specific proteins of the cell's cytoskeleton.[7]

A dynamic interaction exists between the cell's membrane and cytoplasm. Although we focus here on the channel-blocking actions of local anesthetics, it is noteworthy that many other cellular activities, including both metabolic and signal transduction pathways, are inhibited by these drugs.

Physiology of Nerve Conduction

The neural membrane is able to maintain a voltage difference of −60 to −90 mV between the intracellular medium and the cell's outside because at rest it is relatively impermeable to sodium ions but selectively permeable to potassium ions. The Na^+/K^+ pump, an active, energy-dependent mechanism, sustains the ion gradients that drive this potential difference by constant extrusion of sodium from within the cell in exchange for a net uptake of potassium, with adenosine triphosphate used as an energy source. Although the membrane is relatively permeable to potassium ions, an intracellular-to-extracellular potassium ratio of 150 to 5 mM, or 30:1, is maintained by active removal of potassium as it leaks passively across the plasma membrane.

The nerve at rest behaves largely as a "potassium electrode," according to the Nernst equation:

$$E_m \approx E_K = \left(\frac{-RT}{F}\right) \ln\left(\frac{[K^+]_i}{[K^+]_o}\right) \quad (2)$$

where E_m is the membrane potential, E_K is the potassium equilibrium potential, R is the gas constant, T is temperature (Kelvin), F

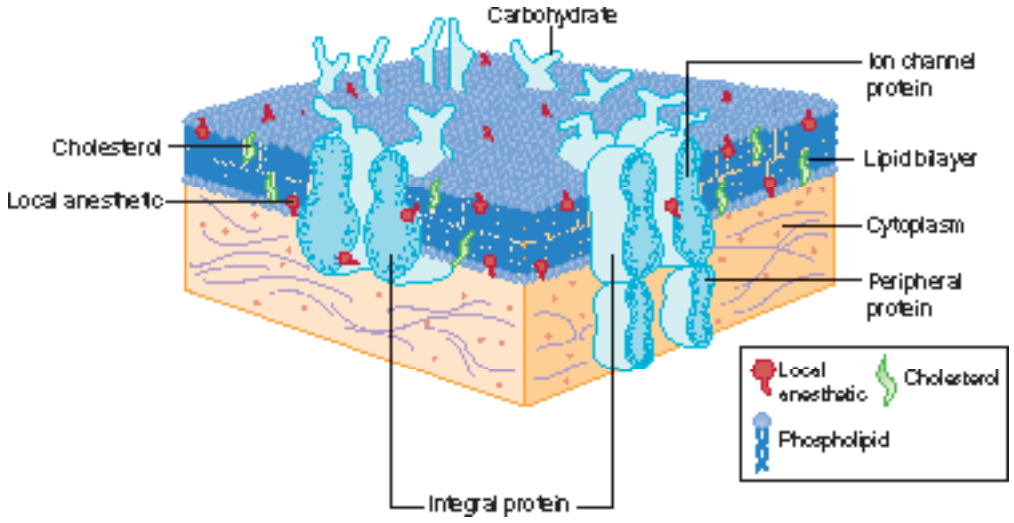

Figure 30-5 A typical plasma membrane has at its core the lipid bilayer, composed of phospholipids and cholesterol molecules (in about a 5:1 ratio) embedding the membrane integral proteins, which are most often glycosylated by extracellular carbohydrates and include receptors and ion channels essential for intercellular communication. "Peripheral proteins" regulate the functions of membrane proteins, chaperone them to the plasma membrane, and stabilize them in the cell through interactions with both the cytoskeleton and the extracellular matrix. Probable membrane locations and protein sites for local anesthetics are also shown.

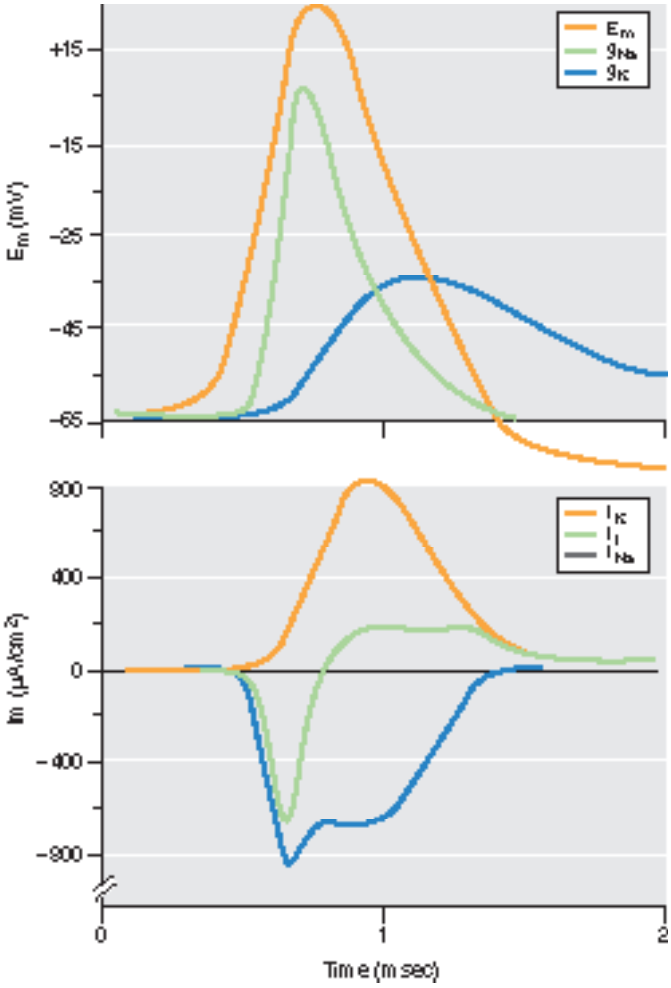

Figure 30-6 Membrane potential (E_m) and the voltage-gated ionic conductance of sodium (g_{Na}) and potassium (g_K), which determine the corresponding membrane currents Im (I_{Na} and I_K) during a propagated action potential. Modeled from the original studies of Hodgkin and Huxley on the squid giant axon (see Hodgkin[8]), these relationships hold for almost all invertebrate and vertebrate nerve fibers. The direction of the total ionic current (i_t), which is the sum of I_{Na} and I_K, is inward (negative values) for the depolarizing phase of the action potential and outward (positive values) for the repolarizing phase.

is Faraday's constant, and $[K^+]$ is the potassium ion concentration inside (i) and outside (o) the cell. For potassium, therefore,

$$E_K = -58 \log 30, \text{ or } -85.7 \text{ mV}$$

An opposite situation exists for Na^+, which is at higher concentration outside the cell and has a Nernst potential, E_{Na}, of about +60 mV. During an action potential, the nerve membrane transiently switches its higher permeability from K^+ to Na^+, thereby changing the membrane potential from negative to positive, and back again.[8] The progress of this potential change and the underlying events are graphed in Figure 30-6. They provide a basis for understanding local anesthetic conduction block.

Permeation of ions through membranes occurs via specialized proteins called ion channels.[9] The conformation of these channels is often sensitive to the membrane potential; both Na^+ and K^+ channels in nerve membranes are activated to an "open" conformation by membrane depolarization. Sodium channels, in addition, close to an "inactivated" conformation after their initial activation. A small membrane depolarization extending along an axon from a region of excited membrane, for example, will begin to open both Na^+ and K^+ channels. The Na^+ channels open faster, however, and the inwardly directed Na^+ current (see Fig. 30-6) depolarizes the membrane further, thereby leading to opening of more Na^+ channels and increasing the inward Na^+ current even further (Fig. 30-7). This sequence of events continues during the *depolarizing phase* until some of the Na^+ channels have become inactivated and enough of the K^+ channels have opened to change the balance of current and result in a net outward current that produces membrane *repolarization* (see Fig. 30-7). After one action potential, the concentrations of Na^+ and K^+ have changed little for the large myelinated fibers but by as much as 10% for the small, nonmyelinated axons. The Na^+ ions entering and K^+ ions leaving the cell as a result of this process are restored by the Na^+/K^+ pump.

Depolarizations too weak to activate enough Na^+ channels to produce a net inward current are below the membrane's excitability *threshold*. The precise value of the threshold varies in different regions of the cell and also changes with time. For example, directly after an impulse, when some Na^+ channels are still inactivated and some K^+ channels are still activated, the threshold is above its "resting" value and the membrane is "refractory" to stimulation. Over time, however, as Na^+ inactivation decays and K^+ channels return to their closed conformation, the original resting threshold value is restored.

The action potential is a wave of depolarization that is propagated along the axon by continuous coupling between excited and nonexcited regions of membrane. Ionic current (the action current) enters the axon in the excited, depolarized region and then flows down the axoplasm and exits through the surrounding membrane, thereby passively depolarizing this adjacent region (see Fig. 30-3). Although this *local circuit current* spreads away from the excited zone in both directions, the region behind the impulse, having just been depolarized, is absolutely refractory and propagation of impulses is thus unidirectional.

The local circuit current spreads rapidly along a length of insulated internode in a myelinated axon (see Fig. 30-3), and

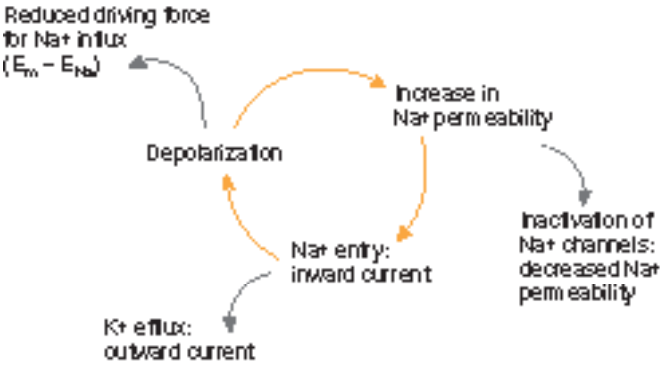

Figure 30-7 The action potential can be understood in terms of the cyclic relationships between factors contributing to the regenerative, depolarizing phase and the passive, repolarizing phase. *Positive* factors (*yellow arrows*) increase the rate of depolarization in a "positive-feedback loop," each element in the cycle favoring the subsequent one. *Negative* factors (*gray arrows*) decrease the depolarization rate by reducing or opposing the related positive factor, with efflux of K^+ eventually dominating the ionic flow and repolarizing the membrane.

many nodes of Ranvier in sequence are depolarized to threshold with little intervening delay. Single impulses do not jump from node to node as separate, discrete events; instead, active depolarization occurs simultaneously along several centimeters of the largest axons (see Fig. 30-3). Indeed, the local circuit current is so robust that it can skip past two completely nonexcitable nodes (e.g., blocked by local anesthetic) and successfully stimulate a third node. If excitability is partially reduced, such as by inhibition of some of the Na^+ channels, the amplitude of impulses in successive nodes falls decrementally, a process that can continue for many centimeters.[10,11] This situation probably occurs during certain phases of local anesthesia, as discussed later. However, when enough of the Na^+ channels are blocked, local circuit current fails to bring the adjacent resting region to threshold, and the impulse is fully extinguished.

Mechanism of Action of Local Anesthetics (Pharmacodynamics)

Active Form

Local anesthetic bases are poorly to sparingly soluble in water but are quite soluble in relatively hydrophobic organic solvents. Therefore, as a matter of chemistry (and to optimize shelf life), most of these drugs are formulated as hydrochloride salts. The pK_a of the drug and tissue pH determine the amount of drug that exists in solution as free base or as positively charged cation when injected into living tissue (see earlier). Furthermore, uptake of the drug by tissue, largely via lipophilic adsorption, will also alter its activity, both by shifting the effective pK_a downward, thereby favoring the neutral base form, and by limiting diffusion of the anesthetic away from the site of injection. Moderately hydrophobic local anesthetics block faster than either hydrophilic or highly hydrophobic ones, delivered at the same concentration, for the following reasons. Moderately hydrophilic molecules, such as lidocaine, are less bound to tissues than very hydrophobic drugs are (e.g., tetracaine) but are still more membrane permeant than very hydrophilic ones (e.g., 2-chloroprocaine). The highly hydrophobic local anesthetics, having higher intrinsic potencies (see Table 30-2), are therefore used in lower concentrations and their diffusion-controlled rate of onset is correspondingly reduced.

Which form of the local anesthetic, charged cation or neutral base, is actually responsible for blockade of impulses? More alkaline solutions of local anesthetics block nerve conduction more effectively. On sheath-free nerves, the rate of inhibition by tertiary amine anesthetics is greater at alkaline than at neutral external pH[12] because membrane permeation, favored by the base over the cationic species, determines the rate of access to the binding site. Direct control of axoplasmic pH (or internal perfusion with permanently charged quaternary amine homologs) shows that the dominant potency derives from the cationic species acting from the cytoplasmic surface.[13,14] The uncharged base also has intrinsic pharmacologic activity, however, which explains the effectiveness of benzocaine as a topical local anesthetic.

Electrophysiologic Effect of Local Anesthetics

The resting membrane potential of nerve is little affected by local anesthetics. As the concentration of local anesthetic applied to the nerve is increased, a decrease in the rate of depolarization and in the peak amplitude of the action potential occurs until the impulse is abolished. It is not possible, however, to derive data on the binding of local anesthetics to Na^+ channels from measurement of the changes in nerve impulses.

By using a "voltage-clamp" procedure, Na^+ currents and their inhibition by local anesthetics can be directly assayed (Fig. 30-8A). When the membrane of isolated neurons is rapidly depolarized to a constant value, the time course of ionic currents is observed. Sodium currents during one initial depolarization are reduced by subclinical doses of local anesthetic (e.g., 0.2 mM lidocaine) and totally abolished by clinical doses (e.g., 1% lidocaine, ≈40 mM). If the test depolarization is applied repeatedly, for example, at frequencies higher than 5 Hz (five pulses per second), the partially depressed (*tonically* inhibited) Na^+ current is further reduced incrementally for each pulse until a new steady-state level of inhibition is reached.[15,16] This frequency-dependent inhibition, also called *phasic inhibition*, is reversed when stimulation is slowed or stopped, and currents return to the level of tonic inhibition observed in the resting nerve. Paralleling the phasic inhibition of Na^+ currents in voltage-clamped membranes is a "use-dependent" blockade of action potentials during normal physiologic function (see Fig. 30-8B).

The potency of local anesthetics to produce tonic and phasic inhibition is similarly dependent on their structure, hydrophobicity, and pK_a. At its simplest, there appears to be a single binding site for local anesthetics on the Na^+ channel, with a "tonic" affinity at rest and increased "phasic" affinity occurring as a result of depolarization. The phasic blocking phenomenon can thus be used to reveal the true kinetics of binding of local anesthetic to the functional receptor, the Na^+ channel itself.

Phasic actions are a manifestation of the selective affinity of local anesthetics for conformations of the Na^+ channel that result from depolarization. Both "open" and "inactivated" states of the channel bind local anesthetics more avidly than the resting state does. Repeated depolarization thus increases the fraction of drug-bound channels; dissociation of these bound drug molecules is usually a slower process than the normal recovery from inactivation (see earlier) and results in the use-dependent accumulation of channels in the blocked condition and the phenomenon of phasic block.

By its selective binding to a channel state, the local anesthetic stabilizes that state. During phasic block, therefore, more inactivated channels become drug bound, and reciprocally, less activation can occur. This relationship between state-dependent affinities and modification of transitions among states through drug binding is known as the "modulated receptor" model.[17] Overall binding of anesthetic is increased by membrane depolarization for two reasons: *more binding sites become accessible* during activation (the "guarded receptor" model) and drug *dissociation* from inactivated channels *is slower* than from resting channels (the modulated receptor model).

The specific binding rates and affinities for the different conformations of the sodium channel depend on the particular local anesthetic drug. When the details of this dependence are

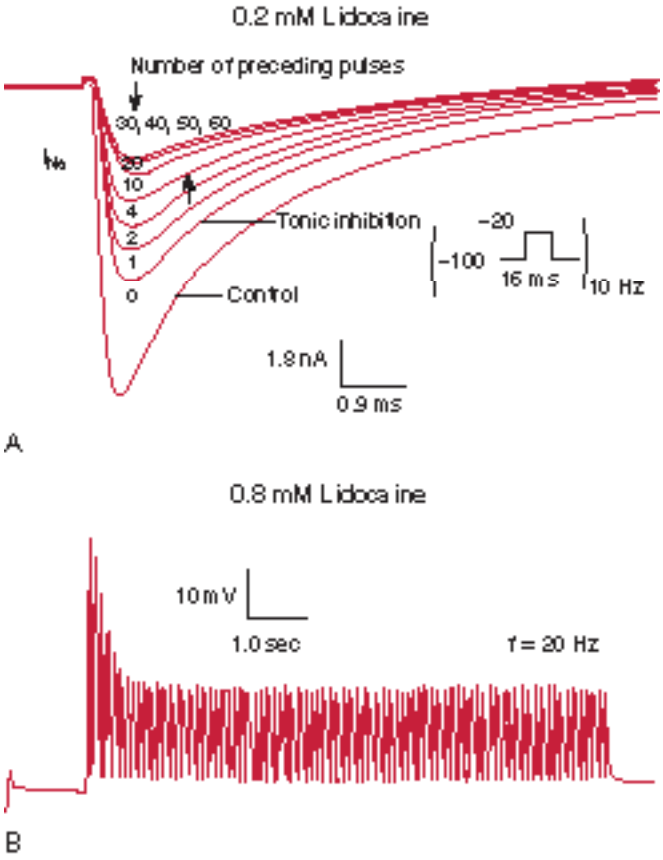

Figure 30-8 "Use-dependent" actions of local anesthetics on excitable membrane properties. **A,** Ionic Na^+ currents measured by a voltage-clamping technique are transiently activated by brief steps of depolarization applied infrequently ("tonic" test) or in a train at 10 times per second ("phasic" test, see E_m pattern in parentheses). After equilibration with 0.2 mM (0.005%) lidocaine, the currents measured tonically are reduced by about 30% from the control currents. Application of the "phasic" train of depolarizations results in a dynamic reduction of currents after each depolarization, with a steady-state value of phasic inhibition reached during the train of 75% of control currents. Recovery of currents to the tonic value occurs within a few seconds when phasic testing stops (not shown). **B,** Action potentials are also inhibited in a phasic manner by local anesthetics. After equilibration with 0.8 mM lidocaine (0.02%), the action potential is tonically reduced by about 20% from its amplitude in drug-free solution (not shown). Stimulation by a train at 20 stimuli per second induces a phasic inhibition that further reduces the amplitude by about 70% from the control value. As with the ionic currents (**A**), phasic inhibition of the action potential recovers rapidly when high-frequency stimulation stops.

correlated with the physicochemical properties of the drug and with the experimental conditions, they provide insight into the molecular features of the local anesthetic binding site.

The Nature of the Local Anesthetic Binding Site

Intentional mutation of specific amino acids of the Na^+ channel has allowed definition of regions that interact directly with local anesthetics. The major functional protein of the Na^+ channel (the α-subunit) is composed of four homologous "domains" (DI to DIV), each of which contains six helical regions (S1 to S6) that span the core of the membrane (Fig. 30-9A). Each domain also has a loop, termed the "P region," that links the extracellular ends of its S5 and S6 transmembrane segments; the P regions extend inward between the transmembrane regions such that when the α-subunit folds together, each P loop contributes a quarter of the cylindrical ion "selectivity pore," the narrowest passage of an open channel (see Fig. 30-9B). Voltage sensitivity derives from the positive charges located on S4 segments, which slide or swing "outward" in response to membrane depolarization. By linkages still unknown, this movement of S4 results in a conformational rearrangement of the S6 segments, which form the inner, cytoplasmic entry to the channel. Closed-to-open channel gating results from movement of the S6 segments, whereas inactivation gating results from binding of the cytoplasmic loop located between D-3 and D-4 to the cytoplasmic opening of the channel.

Local anesthetics bind in the "inner vestibule" of the closed Na^+ channel (see Fig. 30-9C). Amino acid mutations in the S6 segments of D-1, D-3, and D-4 all modify local anesthetic action, thus suggesting either that these regions form a "pharmocophore" small enough to simultaneously contact the drug at three surfaces or that the local anesthetic molecule moves rapidly among these three segments.

The rate constant for binding of local anesthetic to the closed Na^+ channel is larger for the more hydrophobic molecules, which suggest that drug molecules can reach the binding site (and depart from it) through a "hydrophobic" pathway. This path could be movement from the membrane phase laterally, into the channel, or through hydrophobic amino acid residues that limit access through a pathway in the closed pore. The slow block of closed and inactivated channels appears to use such a hydrophobic access and thus accounts for tonic inhibition.

The charged species of local anesthetics dissociates much more slowly from closed and inactivated Na^+ channels than the neutral form does, which suggests that an ionic bond may be involved in drug binding or that the charged molecule moves only slowly along the hydrophobic pathway.

In brief, hydrophobicity delivers the drug to the receptor and charge keeps it there.

Neurophysiologic Aspects of Phasic Inhibition

Different fiber types in the nerve are affected differently during local anesthesia. At least part of this difference arises from pharmacokinetic factors. At the onset of and during recovery from clinical block, in particular, longitudinal and radial diffusion of drug will produce concentration variations within and along the nerve. This variation is superimposed on the dynamic use-dependent inhibition to provide variable propagation, which depends on a fiber's geometry, position within the nerve, and functional as well as electrophysiologic properties.

Different fiber types are also differentially sensitive to local anesthetic blockade. In vivo experiments in which continuous superperfusion of peripheral nerve allows equilibration with drug and experiments in which a drug bolus is delivered by percutaneous injection,[18] analogous to clinical peripheral nerve block, show unequivocally that small myelinated axons (Aγ motor and Aδ sensory fibers) are the most susceptible to impulse annihilation. Next in order of block are the large myelinated (Aα and Aβ) fibers, and the least susceptible are the small, nonmyelinated C

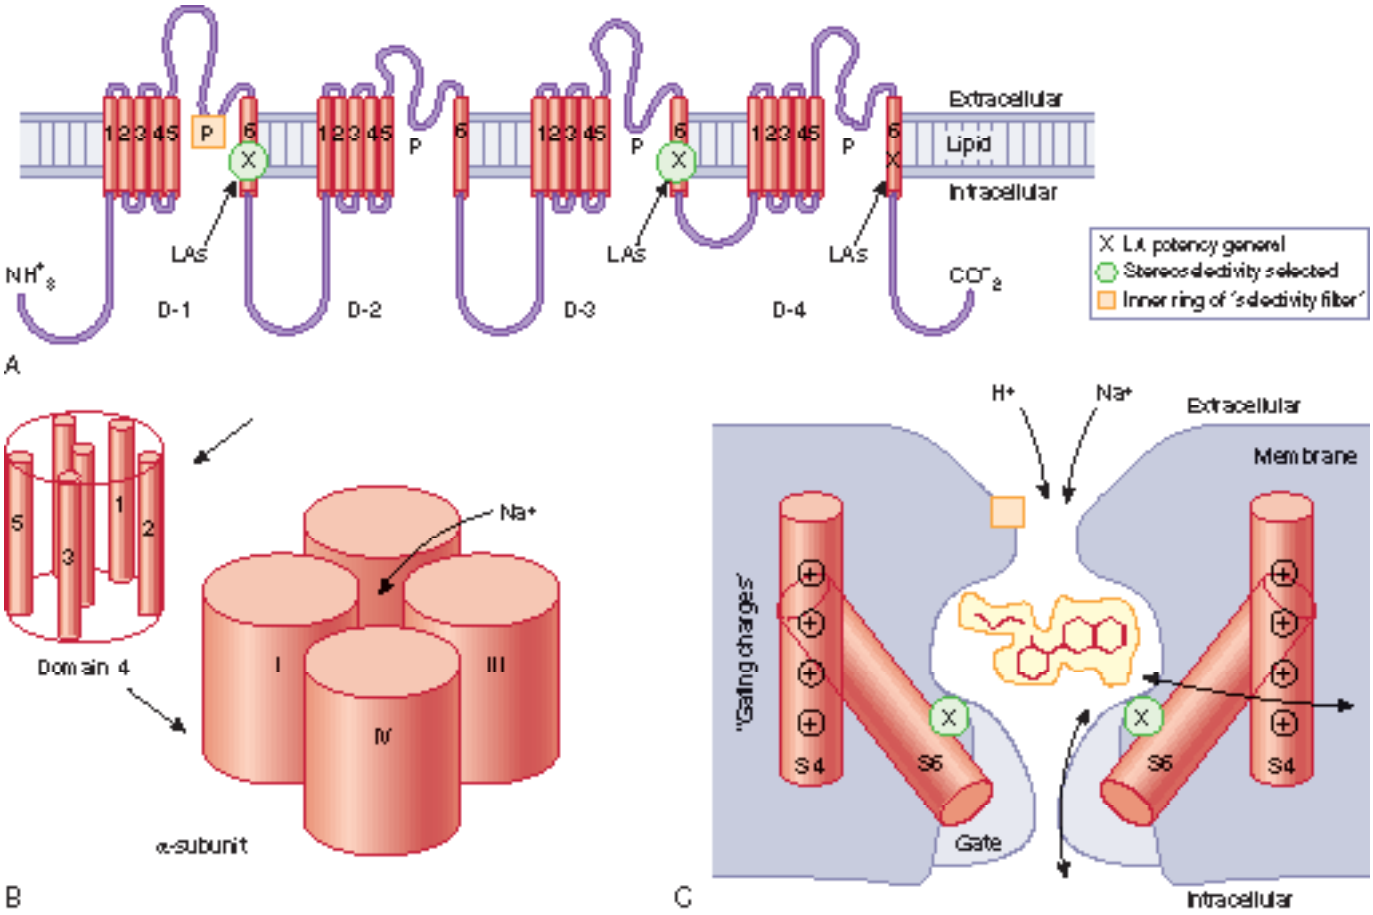

Figure 30-9 Structural features of the Na^+ channel that determine local anesthetic (LA) interactions. **A,** Consensus arrangement of the single peptide of the Na^+ channel α-subunit in a plasma membrane. Four domains with homologous sequences (D-1 through D-4) each contain six α-helical segments that span the membrane (S1 to S6). Each domain folds within itself to form one cylindrical bundle of segments, and these bundles converge to form the functional channel's quaternary structure (**B**). Activation gating leading to channel opening results from primary movement of the positively charged S4 segments in response to membrane depolarization (see panel **C**). Fast inactivation of the channel follows binding to the cytoplasmic end of the channel of part of the small loop that connects D-3 to D-4. Ions travel through an open channel along a pore defined at its narrowest dimension by the P region formed by partial membrane penetration of the four extracellular loops of protein connecting S5 and S6 in each domain. Intentional, directed mutations of different amino acids on the channel indicate residues that are involved in LA binding in the inner vestibule of the channel (X on S6 segments), at the interior regions of the ion-discriminating "selectivity filter (*square* on the P region), and also are known to influence stereoselectivity for phasic inhibition (*circle*, also on S6 segments). **C,** Schematic cross section of the channel speculating on the manner in which S6 segments, forming a "gate," may realign during activation to open the channel and allow entry and departure of a bupivacaine molecule by the "hydrophilic" pathway. The closed (inactivated) channel has a more intimate association with the LA molecule, whose favored pathway for dissociation is no longer between S6 segments (the former pore) but now, much more slowly, laterally between segments and then through the membrane, the "hydrophobic" pathway. Na^+ ions entering the pore will compete with the LA for a site in the channel, and H^+ ions, which pass very slowly through the pore, can enter and leave from the extracellular opening, thereby protonating and deprotonating a bound LA molecule and thus regulating its rate of dissociation from the channel.

fibers. In fact, in this last group, impulses in the slowest conducting population (conduction velocity of 0.5 to 0.8 msec) are the most resistant to local anesthetic.[18] The generalized notion that local anesthetics block the smallest fibers first or most is clearly wrong.

Selective Susceptibility of Na^+ Channel Isoforms

Ten different Na^+ channels have been physiologically identified and biochemically sequenced. At least four of them are found in peripheral neurons, some exclusively associated with nociceptive afferents. Obviously, it would be clinically advantageous to selectively inhibit these channels and thus prevent or reduce pain while sparing other functions. Although selective channel blockade has been attained with naturally occurring small peptide toxins,[19] relatively little selective blockade by local anesthetics has been reported,[20] probably because the local anesthetic pharmacophore is too similar among the different channel isoforms and the local anesthetic molecules themselves have several rotational axes, which makes them poor structural templates for selecting among static binding pockets.

Sodium Channel Isoforms in Human Diseases Characterized by Pain or Pain Insensitivity. Mutations in sodium channel isoform $Na_V1.7$ can produce disease states with either spontaneous pain[21,22] or profound and selective impairment of pain sensitivity.[23] Erythromelalgia is characterized by episodes of severe burning pain, predominantly in the feet and hands. In these subjects, pain is exacerbated by heat and relieved by cold. This disorder may occur as an isolated problem or can coexist

with certain rheumatologic disorders. In a small subgroup of these patients the disorder has a clear familial pattern with an autosomal dominant pattern of inheritance. A second autosomal dominant disorder characterized by spontaneous pain is known initially as "familial rectal pain disorder" or "paroxysmal extreme pain disorder." Recent molecular studies have shown that these disorders involve several distinct types of mutations in $Na_V1.7$ sodium channels.[21,22] When these channels are inserted into cells that lack sodium channels, they generate spontaneous, temperature-sensitive inward currents.

Perhaps even more remarkable is the recent report of several consanguineous families in Pakistan in which certain members exhibit profound insensitivity to pain while being neurologically normal in almost all other respects.[23] Genetic, biochemical, and electrophysiologic studies have demonstrated an autosomal recessive pattern of inheritance. Molecular studies have shown that these mutations are of the nonsense type and generate functionally impaired $Na_V1.7$ sodium channels; when placed into cell membranes in vitro, they fail to generate inward currents in response to depolarizing stimuli.

On the other hand, aberrant impulses, which are often considered the hallmarks of various diseases of excitable membranes such as abnormal repetitive firing in neuropathic pain or in certain types of inherited skeletal myotonia, are abolished by systemic lidocaine in doses that do not block normal propagating impulses. Conditions for the sensitivity of such impulses to local anesthetics, such as lidocaine, appear to result from the patterns of impulse spikes superimposed on slow membrane depolarizations caused by abnormal expression of Na^+ channels rather than from selective sensitivity of certain subtypes of channels to these drugs.[24]

Summary of Local Anesthetic Mechanisms

Impulse blockade by local anesthetics may be summarized by the following chronology[4]:

1. Solutions of local anesthetic are deposited near the nerve. Removal of free drug molecules away from this locus is a function of tissue binding, removal by the circulation, and local hydrolysis of aminoester anesthetics. The net result is penetration of the nerve sheath by the remaining free drug molecules.
2. Local anesthetic molecules then permeate the nerve's axon membranes and reside there and in the axoplasm. The speed and extent of these processes depend on a particular drug's pK_a and on the lipophilicity of its base and cation species.
3. Binding of local anesthetic to sites on voltage-gated Na^+ channels prevents opening of the channels by inhibiting the conformational changes that underlie channel activation. Local anesthetics bind in the channel's pore and also occlude the path of Na^+ ions.
4. During onset of and recovery from local anesthesia, impulse blockade is incomplete and partially blocked fibers are further inhibited by repetitive stimulation, which produces an additional, use-dependent binding to Na^+ channels.
5. One local anesthetic binding site on the Na^+ channel may be sufficient to account for the drug's resting (tonic) and use-dependent (phasic) actions. Access to this site may potentially involve multiple pathways, but for clinical local anesthetics, the primary route is the hydrophobic approach from within the axon membrane.
6. The clinically observed rates of onset and recovery from blockade are governed by the relatively slow diffusion of local anesthetic molecules into and out of the whole nerve, not by their much faster binding and dissociation from ion channels. A clinically effective block that may last for hours can be accomplished with local anesthetic drugs that dissociate from Na^+ channels in a few seconds.

Clinical Pharmacology

Successful use of regional anesthesia requires knowledge of the pharmacologic properties of the various local anesthetic drugs, as well as technical skill in performance of the nerve block. Local anesthetic requirements vary considerably, depending on factors such as the type of block, surgical procedure, and physiologic status of the patient.

Commonly used aminoester local anesthetics include procaine, chloroprocaine, tetracaine, and cocaine. Commonly used aminoamides include lidocaine, mepivacaine, prilocaine, bupivacaine (racemic and its levo-enantiomer), ropivacaine, and etidocaine. The ester and amide local anesthetics differ in their chemical stability, locus of biotransformation, and allergic potential. Amides are extremely stable, whereas esters are relatively unstable in solution. Aminoesters are hydrolyzed in plasma by cholinesterase enzymes, but the amides undergo enzymatic degradation in the liver. Two exceptions to this trend include cocaine, an ester that is metabolized predominantly by hepatic carboxylesterase,[25] and articaine, an amide local anesthetic widely used in dentistry that is inactivated by plasma carboxylesterase-induced cleavage of a methyl ester on the aromatic ring.

p-Aminobenzoic acid is one of the metabolites of ester-type compounds that can induce allergic-type reactions in a small percentage of patients. The aminoamides are not metabolized to *p*-aminobenzoic acid, and reports of allergic reactions to these agents are extremely rare.

General Considerations

Clinically important properties of the various local anesthetics include potency, speed of onset, duration of anesthetic action, and differential sensory/motor blockade. As previously indicated, the profile of individual drugs is determined by their physicochemical characteristics (see Table 30-2).

Anesthetic Potency

Hydrophobicity appears to be a primary determinant of intrinsic anesthetic potency[5] because the anesthetic molecule must penetrate into the nerve membrane and bind at a partially hydrophobic site on the Na^+ channel. Clinically, however, the correlation between hydrophobicity and anesthetic potency is not as precise as in an isolated nerve. For example, etidocaine is more potent than bupivacaine in an isolated nerve, whereas etidocaine is actually less potent than bupivacaine in vivo. Differences between in

vitro and in vivo potency may be related to a number of factors, including local anesthetic charge and hydrophobicity (which influence partitioning into and transverse diffusion across biologic membranes) and vasodilator or vasoconstrictor properties (which influence the initial rate of vascular uptake from injection sites into the central circulation).

Onset of Action

The onset of conduction block in isolated nerves is related to the physicochemical properties of the individual agents. In vivo latency is also dependent on the dose or concentration of local anesthetic used. For example, 0.25% bupivacaine possesses a rather slow onset of action, but increasing the concentration to 0.75% results in a significant acceleration of its anesthetic effect.[26] Chloroprocaine demonstrates a rapid onset of action in humans despite the fact that its pK_a is approximately 9, its proportion of charged molecules is high (97%), and thus its onset of action in isolated nerves is relatively slow. However, the low systemic toxicity of this agent allows its use in high concentrations (e.g., 3%). Therefore, the rapid onset of chloroprocaine in vivo may be related simply to mass diffusion because of the large number of molecules placed in the vicinity of peripheral nerves. In humans, 1.5% lidocaine produces a more rapid onset of epidural anesthesia than 1.5% chloroprocaine does[27]; however, 3% chloroprocaine results in more rapid onset than 2% lidocaine does.

Duration of Action

The duration of action of the various local anesthetics differs markedly. Procaine and chloroprocaine have a short duration of action. Lidocaine, mepivacaine, and prilocaine produce a moderate duration of anesthesia, whereas tetracaine, bupivacaine, ropivacaine, and etidocaine have the longest durations. For example, with procaine, the duration of brachial plexus blockade is 30 to 60 minutes, but up to approximately 10 hours of anesthesia (or at least analgesia) is common for brachial plexus blockade with bupivacaine or ropivacaine.[28]

In humans, the duration of anesthesia is markedly influenced by the peripheral vascular effects of the local anesthetic drugs. Many local anesthetics have a biphasic effect on vascular smooth muscle; at low concentrations these agents tend to cause vasoconstriction, whereas at higher, clinically administered concentrations, they cause vasodilation.[29] However, differences exist in the degree of vasodilator activity of the various drugs. For example, lidocaine is a more potent vasodilator than mepivacaine or prilocaine is. The effects of local anesthetics on vascular tone and regional blood flow are complex and vary according to concentration, time, and the particular vascular bed near the site of application, among other factors. As a practical example, the topical local anesthetic formulation EMLA (eutectic mixture of the local anesthetics lidocaine and prilocaine) vasoconstricts cutaneous vessels initially and through most of the first hour of application, but vasodilation is observed after 2 or more hours of application.

Differential Sensory/Motor Blockade

Another important clinical consideration is the ability of local anesthetic agents to cause differential inhibition of sensory and motor activity. Bupivacaine became popular in the 1980s for epidural blocks because it was better than the previously available long-acting agents (e.g., etidocaine) in producing adequate antinociception without profound inhibition of motor activity, particularly when dilute solutions are used. Bupivacaine is widely used epidurally for obstetric analgesia and postoperative pain management because it can provide acceptable analgesia with only mild muscle weakness, particularly when used for infusions in concentrations of 0.125% or less (also see Chapters 51, 69 and 87). When given by epidural bolus dosing, bupivacaine produces more effective sensory than motor blockade over a concentration range from 0.25% to 0.75%, whereas etidocaine produces almost equally effective sensory and motor blockade over this concentration range. Additional observations on the sensory selectivity of newer local anesthetics are detailed later in the section on chiral local anesthetics.

Traditional texts often state that small-diameter axons, such as C fibers, are more susceptible to local anesthetic block than larger-diameter fibers are. However, when careful measurements are made of single-impulse annihilation in individual nerve fibers, exactly the opposite differential susceptibility is noted (see earlier).[30,31] Repetitive stimulation, such as occurs during propagation of trains of impulses, produces a further, phasic inhibition of excitability, but it is unclear how this will affect a functionally selective failure of impulses. The length of drug-exposed nerve in the intrathecal space, imposed by anatomic restrictions, can perhaps explain clinically documented differential spinal or epidural blockade,[32] with longer drug-exposed regions yielding block by lower concentrations of local anesthetic.[33] However, this reasoning does not explain the functionally differential loss from peripheral nerve block. Other factors may include actual spread of the drug along the nerve or its selective ability to inhibit Na^+ channels over K^+ channels,[34] which in itself can produce a differential block because these channels are present in very different proportions in different types of nerves. As a result of these confounding factors, clinicians should be discouraged from making conclusions about fiber-type involvement in chronic pain syndromes based on the dose or concentration requirement for pain relief in diagnostic nerve blockade.[35]

Factors Influencing Anesthetic Activity in Humans

Dosage of Local Anesthetic

As the dosage of local anesthetic is increased, the probability and duration of satisfactory anesthesia increase and the time to onset of block is shortened. The dosage of local anesthetic can be increased by administering either a larger volume or a more concentrated solution. For example, increasing the concentration of epidurally administered bupivacaine from 0.125% to 0.5% while maintaining the same volume of injectate (10 mL) resulted in shorter latency, an improved incidence of satisfactory analgesia, and a longer duration of sensory analgesia.[36] The volume per se of anesthetic solution probably influences the spread of anesthesia. For example, 30 mL of 1% lidocaine administered into the epidural space produced a level of anesthesia that was 4.3 dermatomes higher than that achieved when 10 mL of 3% lidocaine was given.[37]

In selecting the volume and concentration for a specific block in a particular patient, clinicians must balance the risk of adverse effects from excessive dosing (systemic toxicity, excessive motor or autonomic blockade, etc.) against the increased risk of

block failure if an inadequate volume or concentration is chosen. The degree to which additional volume can compensate for imprecise needle placement varies among different blocks.

With the advent of very precise needle placement using ultrasound-guided blockade, it has become clear that the median effective volume for obtaining successful blockade can be achieved with smaller volumes than have been recommended from some previous clinical series based on traditional methods of needle localization. For example, in a recent dose-finding randomized trial for femoral nerve blockade, the median volumes for 50% or 95% success in obtaining dense sensory and motor block at 30 minutes under ultrasound guidance were 57% and 54% of the corresponding volumes with the use of nerve stimulation.[38] Interested readers will note the very wide confidence intervals found in this study and are encouraged to read recent work on some statistical design issues for dose-response studies involving all types of anesthetics.[39] As limited by toxicity considerations, the aim in most clinical situations should be to choose doses that provide high success rates; that is, a dose effective in 95% of patients (ED_{95}) is generally a more relevant guide to dose selection than an ED_{50} dose. We should not aim for failure 50% of the time.[40]

Addition of Vasoconstrictors

Vasoconstrictors, usually epinephrine (5 μg/mL or 1:200,000), are frequently included in local anesthetic solutions to decrease the rate of vascular absorption, thereby allowing more anesthetic molecules to reach the nerve membrane and thus improve the depth and duration of anesthesia, as well as to provide a marker for inadvertent intravascular injection.[41] Test dosing with epinephrine can generate false negatives and false positives. Some of these sources of error have been described for specific patient groups, such as adults and children under general anesthesia, parturients in labor, and patients receiving β-blockers. Despite these limitations, test dosing has utility in a wide range of clinical situations.[42]

Epinephrine in a concentration of 1:200,000 has been reported to provide the optimal degree of vasoconstriction when used with lidocaine for epidural or intercostal blockade.[43] Other vasoconstrictor agents, such as norepinephrine and phenylephrine, have been used but do not appear to be superior to epinephrine.

The extent to which epinephrine prolongs the duration of anesthesia depends on the specific local anesthetic used and the site of injection. Epinephrine will significantly extend the duration of both infiltration anesthesia and peripheral nerve blockade with shorter-duration agents (e.g., lidocaine); epinephrine produces mild intensification of blockade but only most modest prolongation of epidural or peripheral blocks with bupivacaine.[44] α_2-Adrenergic receptors in the spinal cord are known to activate endogenous analgesic mechanisms, and the increased depth of analgesic action produced by epinephrine and the α_2-agonist clonidine[45] with both epidural and intrathecal local anesthetics may arise from this pharmacodynamic mechanism and from the pharmacokinetic (vasoconstrictive) action.

Site of Injection

The most rapid onset but the shortest duration of action occurs after intrathecal or subcutaneous administration of local anesthetics. The longest latencies and durations are observed after brachial plexus blocks. For example, intrathecal bupivacaine will usually produce anesthesia within 5 minutes that will persist for 3 to 4 hours. However, when bupivacaine is administered for brachial plexus blockade, the onset time is approximately 20 to 30 minutes, and the duration of anesthesia (or at least analgesia) averages 10 hours.[28] These differences in the onset and duration of anesthesia and analgesia are due in part to the particular anatomy of the area of injection, which will influence the rate of diffusion and vascular absorption and, in turn, affect the amount of drug used for various types of regional anesthesia. In the subarachnoid space, for example, the lack of a nerve sheath around the spinal cord and deposition of the local anesthetic solution in the immediate vicinity of the spinal cord are responsible for the rapid onset of action, whereas the relatively small amount of drug used for spinal anesthesia probably accounts for the short duration of conduction block.

In contrast, the onset of brachial plexus blockade is slow because the anesthetic agent is usually deposited at some distance from the nerve and must diffuse through various tissue barriers before reaching the nerve membrane. The prolonged block with brachial plexus blockade may be related to several factors, including comparatively slow rates of vascular absorption from the brachial plexus sheath, larger doses of drug required for this regional anesthetic technique, and comparatively long segments of nerves exposed to local anesthetic.

Carbonation and pH Adjustment of Local Anesthetics

The addition of sodium bicarbonate to a solution of local anesthetic applied to an isolated nerve accelerates the onset and decreases the minimum concentration (C_m) required for conduction blockade.[46] Although the effect of carbon dioxide on local anesthetic activity is easily demonstrable in isolated nerve, controversy exists concerning the clinical utility of carbonated local anesthetic solutions.[47]

The addition of sodium bicarbonate to local anesthetic solutions has also been reported to decrease the onset time of conduction blockade.[47] An increase in the pH of the local anesthetic solution increases the amount of drug in the uncharged base form, which should enhance the rate of diffusion across the nerve sheath and nerve membrane and result in a more rapid onset of anesthesia. Alkalinization of solutions of bupivacaine or lidocaine accelerated the onset of brachial plexus and epidural blockade in some studies[47] but not others.[48]

Mixtures of Local Anesthetics

Mixtures of local anesthetics for regional anesthesia are sometimes used in an effort to compensate for the short duration of action of certain rapidly acting agents such as chloroprocaine and lidocaine and the long latency of longer-acting agents such as tetracaine and bupivacaine. Mixtures of chloroprocaine and bupivacaine theoretically offer significant clinical advantages because of the rapid onset and low systemic toxicity of chloroprocaine and the long duration of action of bupivacaine; however, clinical results in studies of combinations have been mixed.[49] In addition, the use of catheter techniques for many forms of regional anesthesia makes it possible to begin with a rapid-onset local anesthetic such as lidocaine, mepivacaine, or chloroprocaine and then follow with an infusion of either a shorter-acting or longer-acting local anesthetic thereafter. Conversely, clinicians should be cautioned to not use maximum doses of two local anesthetics in combination in the mistaken belief that their toxicities are independent.[50]

In the absence of additional data, the toxicities should be presumed to be additive.

Pregnancy

The spread and depth of epidural and spinal anesthesia are greater in pregnant than in nonpregnant women (also see Chapter 69). The effects of pregnancy on local anesthetic potency may reflect a combined effect of mechanical factors associated with pregnancy (i.e., dilated epidural veins decrease the volume of the epidural and subarachnoid spaces) and direct effects of hormones, especially progesterone, on the susceptibility of nerves to conduction blockade by local anesthetics per se.[51] Hormonal alterations are probably the more important of these two factors because greater spread of epidural anesthesia occurs during the first trimester of pregnancy,[52] before any gross change in vascular dimensions within the epidural or subarachnoid spaces. The dosage of local anesthetics should probably should be reduced in patients in all stages of pregnancy.

Choice of Local Anesthetic for Various Regional Anesthetic Procedures

On the basis of anatomic considerations, regional anesthesia may be divided into infiltration anesthesia, intravenous regional anesthesia, peripheral nerve blockade (including plexus blockade), central neural blockade, and topical anesthesia (also see Chapters 51, 52 , 53, 69, 70, 81, and 87). An additional method of local anesthetic injection, tumescent anesthesia, is included because it is widely used in office plastic surgery practice.

Infiltration Anesthesia

Any local anesthetic may be used for infiltration anesthesia. Onset of action is almost immediate for all agents after intradermal or subcutaneous administration; however, the duration of anesthesia varies (Table 30-4). Epinephrine will prolong the duration of infiltration anesthesia by all local anesthetic drugs, although this effect is most pronounced when epinephrine is added to lidocaine. The choice of a specific drug for infiltration anesthesia largely depends on the desired duration of action.

The dosage of local anesthetic required for adequate infiltration anesthesia depends on the extent of the area to be anesthetized and the expected duration of the surgical procedure. When large surface areas have to be anesthetized, large volumes of dilute anesthetic solutions should be used. These considerations are particularly important when performing infiltration anesthesia in infants and smaller children. As an example, consider a 4-kg infant receiving infiltration anesthesia with the maximum safe dose of lidocaine, 5 mg/kg. Dosing to 5 mg/kg × 4 kg permits 20 mg, which is 1 mL of a 2% solution or 4 mL of a 0.5% solution. Lidocaine is effective for infiltration in concentrations as dilute as 0.3% to 0.5%, so the more dilute solution can be used more safely to anesthetize a larger area.

Patients frequently experience pain immediately after subcutaneous injection of local anesthetic solutions, in part because of the acidic nature of these solutions. For example, neutralization of lidocaine solutions by the addition of sodium bicarbonate immediately before injection reduces pain on skin infiltration[53] and may improve onset (see earlier).

Intravenous Regional Anesthesia

Intravenous regional anesthesia involves the intravenous administration of a local anesthetic into a tourniquet-occluded limb (i.e., Bier block) (see Chapter 70).[54] The local anesthetic diffuses from the peripheral vascular bed to nonvascular tissue such as axons and nerve endings. Both the safety and the efficacy of this regional anesthetic procedure depend on interruption of blood flow to the involved limb and gradual release of the occluding tourniquet. Intravenous regional anesthesia has been used primarily for surgical procedures on the upper limbs. Shorter procedures on the foot can also be successfully performed under intravenous regional anesthesia. If a lower leg tourniquet is used, it should be applied well below the fibular neck to avoid pressure

Table 30-4 Infiltration Anesthesia

	Plain Solution			Epinephrine-Containing Solution	
Drug	**Concentration (%)**	**Max Dose (mg)**	**Duration (min)**	**Max Dose (mg)**	**Duration (min)**
Short Duration					
Procaine	1-2	500	20-30	600	30-45
Chloroprocaine	1-2	800	15-30	1000	30
Moderate Duration					
Lidocaine	0.5-1	300	30-60	500	120
Mepivacaine	0.5-1	300	45-90	500	120
Prilocaine	0.5-1	350	30-90	550	120
Long Duration					
Bupivacaine	0.25-0.5	175	120-240	200	180-240
Ropivacaine	0.2-0.5	200	120-240	250	180-240

over the superficial peroneal nerve; in general, use of an upper leg tourniquet is preferred over lower leg tourniquets.[55]

Lidocaine has been the drug used most frequently for intravenous regional anesthesia. Prilocaine, mepivacaine, chloroprocaine, procaine, bupivacaine, and etidocaine have also been used successfully. One might suppose a safety advantage with the aminoester-linked compounds because of their hydrolysis in blood; however, thrombophlebitis has been reported in several patients with chloroprocaine. Cardiovascular collapse has occurred after the use of bupivacaine for intravenous regional anesthesia, and this use of bupivacaine is discouraged.[56]

In general, approximately 3 mg/kg (40 mL of a 0.5% solution) of preservative-free lidocaine without epinephrine is used for upper extremity procedures. For surgical procedures on the lower limbs, 50 to 100 mL of a 0.25% lidocaine solution has been used.

Peripheral Nerve Blockade

Regional anesthetic procedures that inhibit conduction in fibers of the peripheral nervous system can be classified together under the general category of peripheral nerve blockade (also see Chapters 52 and 53). This form of regional anesthesia has been arbitrarily subdivided into minor and major nerve blocks. Minor nerve blocks are defined as procedures involving single nerve entities such as the ulnar or radial nerve, whereas major nerve blocks involve the blockade of two or more distinct nerves or a nerve plexus or the blockade of very large nerves at more proximal sites (i.e., the femoral and sciatic nerves).

Most local anesthetic drugs can be used for minor nerve blocks. The onset of blockade is rapid with most drugs, and the choice of drug is determined primarily by the required duration of anesthesia. A classification of the various drugs according to their duration of action is shown in Table 30-5. The duration of both sensory analgesia and motor blockade is prolonged significantly when epinephrine is added to the various local anesthetic solutions in some, but not all applications.[57]

In 1986, a technique of interpleural regional analgesia was described as an alternative to multiple intercostal nerve blocks.[58] This procedure involves the administration of local anesthetic solution into the pleural space, either by percutaneous placement or by placement through the open chest by the surgeon during thoracotomy. The risk of pneumothorax has varied in published case series. Although interpleural analgesia appears to be useful for unilateral postoperative analgesia after cholecystectomy, mastectomy, and nephrectomy, its efficacy for post-thoracotomy pain is doubtful.[59] This technique has been associated with extremely high plasma concentrations of anesthetic, with an associated risk of convulsions. Interpleural analgesia has also been used to provide analgesia for chronic pain conditions as diverse as upper extremity complex regional pain syndromes, pancreatitis, and cancer of the thorax and abdomen. In many centers, interpleural analgesia has largely been supplanted by thoracic epidural analgesia for the majority of thoracic and abdominal procedures.

Two related approaches for unilateral somatic blockade in the thorax are continuous extrapleural catheters[60] (placed by the surgeon through the chest dorsal to the parietal pleura) and continuous thoracic paravertebral somatic blockade.[61] One advantage of these two approaches over interpleural analgesia is that very little of the administered solution leaks out of the chest into chest tubes.

Brachial plexus blockade for upper limb surgery is the most common major peripheral nerve block technique. A significant difference exists between the onset times of various agents when these blocks are used (Table 30-6). In general, agents of intermediate potency exhibit a more rapid onset than the more potent compounds do. Onset times of approximately 14 minutes for lidocaine and mepivacaine have been reported versus approximately 23 minutes for bupivacaine. A variety of approaches to the brachial plexus are available; the choice among these approaches is dictated by several factors, including the site of surgery and the ability of the patient to tolerate spillover to other nerves, including the phrenic nerve; these considerations are detailed in Chapters 52, 53, and 70. Similarly, the lumbar plexus can be approached via several routes, including a posterior approach, an anterior perivascular "3 in 1" approach, and an anterior fascia iliaca compartment approach.[62]

The variation in duration of anesthesia after brachial plexus blockade is also considerably greater than that observed with other types of conduction block. For example, durations of anesthesia varying from 4 to 30 hours have been reported for bupivacaine. It is prudent to warn patients before a major nerve block about the possibility of prolonged sensory and motor block in the involved region, particularly when agents such as bupivacaine, levobupivacaine, and ropivacaine are used.

Table 30-5 Minor Nerve Blocks

		Plain Solutions		Epinephrine-Containing Solutions	
Drug	**Usual Concentration (%)**	**Usual Volume (mL)**	**Dosage (mg)**	**Average Duration (min)**	**Average Duration (min)**
Procaine	2	5-20	100-400	15-30	30-60
Chloroprocaine	2	5-20	100-400	15-30	30-60
Lidocaine	1	5-20	50-200	60-120	120-180
Mepivacaine	1	5-20	50-200	60-120	120-180
Prilocaine	1	5-20	50-200	60-120	120-180
Bupivacaine	0.25-0.5	5-20	12.5-100	180-360	240- 420
Ropivacaine	0.2-0.5	5-20	10-100	180-360	240-420

Also see Chapter 52.
Doses refer to 70-kg adults. For pediatric doses, see Chapter 81.

Table 30-6 Major Nerve Blocks

Drug with Epinephrine 1:200,000	Usual Concentration (%)	Usual Volume (mL)	Maximal Dose (mg)	Usual Onset (min)	Usual Duration (min)
Lidocaine	1-2	30-50	500	10-20	120-240
Mepivacaine	1-1.5	30-50	500	10-20	180-300
Prilocaine	1-2	30-50	600	10-20	180-300
Bupivacaine	0.25-0.5	30-50	225	20-30	360-720
Levobupivacaine	0.25-0.5	30-50	225	20-30	360-720
Ropivacaine	0.2-0.5	30-50	250	20-30	360-720

Also see Chapter 52. Doses listed refer to 70-kg adults receiving epinephrine-containing solutions. Doses should be reduced, as detailed in Chapter 81, for children, for patients with specific risk factors, and when non–epinephrine-containing solutions are used.

Central Neural Blockade

Any of the local anesthetic drugs may be used for epidural anesthesia (Table 30-7), although procaine and tetracaine are rarely used because of their long onset times (also see Chapter 51). Drugs of intermediate potency produce surgical anesthesia of 1 to 2 hours' duration, whereas long-acting drugs usually produce 3 to 4 hours of anesthesia. The duration of short- and intermediate-acting drugs is significantly prolonged by the addition of epinephrine (1:200,000), but the duration of long-acting drugs is only minimally affected by epinephrine. The onset of lumbar epidural anesthesia occurs within 5 to 15 minutes after the administration of chloroprocaine, lidocaine, mepivacaine, and prilocaine. Bupivacaine has a slower onset of action.

Bupivacaine bolus doses at a concentration of 0.125% produce adequate analgesia in many clinical settings with only mild motor deficits.[63] Continuous epidural infusions of bupivacaine as dilute as 0.0625% to 0.1% are useful for labor epidural analgesia, especially when administered in combination with opioids and other additives. Bupivacaine 0.25% may be used for more intense analgesia (particularly during combined epidural–light general anesthesia cases) with moderate degrees of motor block. Bupivacaine at concentrations of 0.5% to 0.75% is associated with a more profound degree of motor block, which makes these solutions most suitable for major surgical procedures, particularly when epidural anesthesia is not combined with general anesthesia. It should be emphasized that although high concentrations of local anesthetics may be appropriate for episodic bolus dosing for surgery, these concentrations (i.e., >0.2% for bupivacaine) should generally be avoided for continuous epidural infusions. Bolus injections produce much more cephalocaudad spread than infusions do. When concentrated bupivacaine solutions are used for infusions, they have the potential for excessive local effect with an associated risk for unwanted and very prolonged motor blockade. Etidocaine produces adequate sensory analgesia and profound, long-lasting motor block. Use of etidocaine has decreased in recent years, and at present it is primarily restricted to surgical procedures for which profound muscle relaxation is required.

Drugs available for subarachnoid administration are shown in Table 30-8.

Although lidocaine has long been used for spinal anesthesia as a 5% solution, recent studies of local anesthetic neurotoxicity have led some to question this practice; this issue is discussed later in the chapter in the section on the neurotoxicity of local anesthetics.

Tetracaine is available both as crystals and as a 1% solution, which may be diluted with 10% glucose to obtain a 0.5% hyperbaric solution. Hypobaric solutions of tetracaine (tetracaine in sterile water) may be used for specific operative situations, such as anorectal or hip surgery. Isobaric tetracaine obtained by mixing 1% tetracaine with cerebrospinal fluid or normal saline is useful for lower limb surgical procedures.

Bupivacaine is widely used as a spinal anesthetic, either as a hyperbaric solution at a concentration of 0.75% with 8.25% dextrose or by using the nearly isobaric 0.5% solution. Intrathecal

Table 30-7 Epidural Anesthesia

Drug with Epinephrine 1:200,000	Usual Concentration (%)	Usual Volume (mL)	Total Dose (mg)	Usual Onset (min)	Usual Duration (min)
Chloroprocaine	2-3	15-30	300-900	5-15	30-90

*Dosing refers to a 70-Kg adult. Dosing may be reduced in pregnancy (see Chapter 69) and with advancing age (see Chapter 71). Pediatric dosing is detailed in Chapter 81.

bupivacaine possesses an anesthetic profile similar to that of tetracaine.[64]

The addition of vasoconstrictors may prolong the duration of spinal anesthesia; for example, the addition of 0.2 to 0.3 mg of epinephrine to lidocaine, tetracaine, or bupivacaine solutions will produce a 50% or greater increase in duration.[65,66] The duration of spinal anesthesia produced by tetracaine can also be increased to a similar extent by adding 1 to 5 mg of phenylephrine. The addition of epinephrine to bupivacaine or lidocaine may be more effective in prolonging the duration of spinal anesthesia in lumbosacral segments than in thoracic segments.

Topical Anesthesia

A number of local anesthetic formulations are available for topical anesthesia (Table 30-9), lidocaine, dibucaine, tetracaine, and benzocaine being the drugs used most commonly. In general, these preparations provide effective but relatively short durations of analgesia when applied to mucous membranes or abraded skin. Lidocaine and tetracaine sprays are commonly used for endotracheal anesthesia before intubation or for mucosal analgesia for bronchoscopy or esophagoscopy.

A variety of topical local anesthetic formulations have been developed to penetrate intact skin. EMLA, which is a eutectic mixture of 2.5% lidocaine base and 2.5% prilocaine base, is widely used for venipuncture, intravenous cannulation, skin grafting, and a range of other uses, including circumcision.[67-69] This preparation must be applied under an occlusive bandage for 45 to 60 minutes to obtain effective cutaneous anesthesia; longer application times increase the depth and reliability of skin analgesia. EMLA appears to be quite safe in neonates, and methemoglobinemia with the use of prilocaine is exceedingly uncommon. EMLA is more effective for newborn circumcision than placebo is but less effective than dorsal penile nerve block.[69,89] Several alternative topical local anesthetic formulations also are in use, including tetracaine gel[70] and liposomal lidocaine.[71] Physical methods to accelerate local anesthetic transit across skin, including iontophoresis, local heating, electroporation, and a variety of forms of needle-less pressure injection, may lead to more rapid onset of cutaneous analgesia.[72] Synera (originally studied as S-Caine) is a formulation of lidocaine and tetracaine that was developed with a heating element (activated by opening the package to initiate an oxygen-dependent exothermic reaction). This formulation has a rapid onset and evokes vasodilatation.[73]

Topical anesthesia through cut skin is commonly used in pediatric emergency departments for liquid application into lacerations that require suturing. Historically, this had been provided by a mixture of tetracaine, epinephrine (adrenaline), and cocaine, known as TAC.[74] TAC is usually supplied as tetracaine 0.5%, epinephrine 1:2000, and cocaine 10% to 11.8%, although studies suggest that more dilute concentrations may be almost equally effective and less likely to cause toxicity. The generally recommended safe maximum dose is 3 to 4 mL for adults or 0.05 mL/kg for children. TAC is ineffective through intact skin; in contrast, its rapid absorption from mucosal surfaces can lead to toxic, even fatal reactions.

Because of concerns regarding cocaine toxicity and the potential for diversion and abuse, several groups have investigated alternative cocaine-free topical preparations. Non–cocaine-containing formulations, especially lidocaine-epinephrine-tetracaine (LET) and tetracaine-phenylephrine, have largely supplanted TAC.[75] Similarly, otolaryngologists previously administered cocaine routinely as a solution or aerosol into the nasal passages to provide mucosal analgesia and vasoconstriction. In recent years, cocaine has increasingly been replaced for nasal application by the combined use of an α_1-adrenergic agonist (oxymetazoline or phenylephrine) and a local anesthetic such as 2% to 4% lidocaine, with more dilute solutions being recommended for infants and children (see Chapter 81). Systemic absorption of phenylephrine can cause severe hypertension and reflex bradycardia; oxymetazoline is associated with much less

Table 30-9 Various Preparations Intended for Topical Anesthesia

Anesthetic Ingredient	Concentration (%)	Pharmaceutical Application Form	Intended Area of Use
Benzocaine	1-5	Cream	Skin and mucous membrane
	20	Ointment	Skin and mucous membrane
	20	Aerosol	Skin and mucous membrane
Cocaine	4	Solution	Ear, nose, throat
Dibucaine	0.25-1	Cream	Skin
	0.25-1	Ointment	Skin
	0.25-1	Aerosol	Skin
	0.25	Solution	Ear
	2.5	Suppositories	Rectum
Cyclonine	0.5-1	Solution	Skin, oropharynx, tracheobronchial tree, urethra, rectum
Lidocaine	2-4	Solution	Oropharynx, tracheobronchial tree, nose
	2	Jelly	Urethra
	2.5-5	Ointment	Skin, mucous membrane, rectum
	2	Viscous	Oropharynx
	10	Suppositories	Rectum
	10	Aerosol	Gingival mucosa
Tetracaine	0.5-1	Ointment	Skin, rectum, mucous membrane
	0.5-1	Cream	Skin, rectum, mucous membrane
	0.25-1	Solution	Nose, tracheobronchial tree
EMLA	Lidocaine, 2.5 Prilocaine, 2.5	Cream	Intact skin
TAC	Tetracaine, 0.5 Epinephrine, 1:200,000 Cocaine, 11.8	Solution	Cut skin
LET	Lidocaine, 4% Epinephrine, 1:20,000 Tetracaine, 0.5%	Solution	Cut skin

EMLA, eutectic mixture of lidocaine and prilocaine; LET, lidocaine-epinephrine-tetracaine; TAC, tetracaine-epinephrine-cocaine.
Modified from Covino B, Vassallo H: Local Anesthetics: Mechanisms of Action and Clinical Use. Orlando, FL, Grune & Stratton, 1976, with permission.

systemic effect and has a considerably wider margin of safety. In our view, there is no clinical setting for which the benefits of cocaine clearly outweigh the potential risks when compared with alternative approaches involving combined administration of a local anesthetic and a topical vasoconstrictor such as oxymetazoline.

Tumescent Anesthesia

A technique of local anesthesia most commonly used by plastic surgeons during liposuction procedures involves the subcutaneous injection of large volumes of dilute local anesthetic in combination with epinephrine and other agents. Total doses of lidocaine ranging from 35 to 55 mg/kg have been reported to produce safe plasma concentrations, which may peak more than 8 to 12 hours after infusion.[76] Despite these seemingly huge doses, very good outcomes have been reported in several case series.[77] Conversely, there have been several case series of cardiac arrest and death during plastic surgical procedures in which multiple risk factors, including high local anesthetic concentrations and concomitant use of sedatives, may have contributed to the patients' instability and deterioration.[78] Factors governing uptake and clearance from this method of local anesthetic delivery deserve further study. Clinicians should exercise great caution when administering additional local anesthetics by infiltration or other routes for at least 12 to 18 hours after the use of this technique.

Systemic Local Anesthetics for Neuropathic Pain

A broad variety of local anesthetics, antiarrhythmics, anticonvulsants, and other Na^+ channel blockers are administered intravenously, orally, or both to relieve a number of forms of neuropathic pain (see Chapter 58).[79] Clinical results are unpredictable. Although successful responses from intravenous lidocaine are often taken as a positive indication for oral mexiletine, many patients find mexiletine difficult to tolerate. When the signs of neuropathic pain are reversed by lidocaine infusion, normal nociception and other sensory modalities are unaffected, suggesting that the neurophysiologic correlate of the disease has an unusually high susceptibility to these drugs, present in plasma at concentrations 50 to 100 times lower than that required to block normal impulses in peripheral fibers. Laboratory studies suggest

that ectopic impulse activity arising at a site of injury or elsewhere, such as the dorsal root ganglion, contributes to the neuropathic pain and that such impulses are particularly sensitive to use-dependent Na^+ channel blockers. It is noteworthy that relief of preexisting neuropathic pain, both clinically and in animal models,[80] can in some cases persist for days, weeks, or months after a single intravenous infusion of drug (e.g., lidocaine), far beyond the lifetime of the drug in vivo or any nerve block that it might affect. The mechanism of this remarkable action remains a mystery.

Pharmacokinetics

The concentration of local anesthetics in blood is determined by the amount injected, the rate of absorption from the site of injection, the rate of tissue distribution, and the rate of biotransformation and excretion of the specific drug.[81-83] Patient-related factors such as age, cardiovascular status, and hepatic function influence the physiologic disposition and resultant blood concentration of local anesthetics.

Absorption

The systemic absorption of local anesthetics is determined by the site of injection, dosage and volume, addition of a vasoconstrictor agent, and the pharmacologic profile of the agent itself.[81-83] Comparison of the blood concentration of local anesthetics after various routes of administration reveals that the anesthetic drug level is highest after intercostal nerve blockade, followed in order of decreasing concentration by injection into the caudal epidural space, lumbar epidural space, brachial plexus, and subcutaneous tissue.[83] When a local anesthetic solution is exposed to an area of greater vascularity, a greater rate and degree of absorption occur. This relationship is of clinical significance because use of a fixed dose of a local anesthetic agent may be potentially toxic in one area of administration but not in others. For example, the use of 400 mg of lidocaine without epinephrine for an intercostal nerve block results in an average peak venous plasma level of approximately 7 µg/mL, which is sufficiently high to cause symptoms of central nervous system (CNS) toxicity in some patients. By comparison, this same dose of lidocaine used for a brachial plexus block yields a mean maximum blood level of approximately 3 µg/mL, which is rarely associated with signs of toxicity.[83]

The maximum blood concentration of local anesthetic drugs is related to the total dose of drug administered for any particular site of administration. For most drugs there is a proportionality between the amount of drug administered and the resultant peak anesthetic blood concentration.

Local anesthetic solutions frequently contain a vasoconstrictor agent, usually epinephrine, in concentrations varying from 5 to 20 µg/mL. Epinephrine decreases the rate of vascular absorption of certain agents from various sites of administration and thus lowers their potential systemic toxicity. A 5-µg/mL concentration of epinephrine (1:200,000) significantly reduces the peak blood levels of lidocaine and mepivacaine irrespective of the site of administration. Peak blood levels of bupivacaine and etidocaine are minimally influenced by the addition of a vasoconstrictor after injection into the lumbar epidural space. However, epinephrine will significantly reduce the rate of vascular absorption of these drugs when they are used for peripheral nerve blocks such as brachial plexus blockade.

Differences also exist in the rate of absorption of various local anesthetics. In some studies, absorption of local anesthetics from the epidural space has appeared to involve both rapid and slow processes, as described by two-compartment models.[84]

Distribution

The systemic distribution of local anesthetics can be described sufficiently by a two-compartment model.[85] The rapid disappearance phase is believed to be related to uptake by rapidly equilibrating tissues (i.e., tissues that have high vascular perfusion). The slower phase of disappearance from blood is mainly a function of the particular compound.[85]

Local anesthetic drugs are distributed throughout all body tissues, but the relative concentration in different tissues varies. In general, more highly perfused organs show higher concentrations of local anesthetic drug than less well perfused organs do. Because local anesthetics are rapidly extracted by lung tissue, the whole blood concentration of local anesthetics decreases markedly as they pass through the pulmonary vasculature.[86]

Biotransformation and Excretion

The pattern of metabolism of local anesthetic agents varies according to their chemical classification. The ester, or procaine-like, drugs undergo hydrolysis in plasma by the pseudocholinesterase enzymes; clearance of chloroprocaine is especially rapid.[87,88]

The aminoamide drugs undergo enzymatic degradation primarily in the liver. Lidocaine is metabolized somewhat more rapidly than mepivacaine, which in turn is more rapidly metabolized than bupivacaine.[89-91]

Excretion of the metabolites of amide-type local anesthetics occurs via the kidney. Less than 5% of the unchanged drug is excreted via the kidney into urine.

Pharmacokinetic Alterations by Patient Status

Patient age may influence the physiologic disposition of local anesthetics (see Chapters 71 and 81). The half-life of lidocaine after intravenous administration averaged 80 minutes in human volunteers varying in age from 22 to 26 years, whereas volunteers 61 to 71 years of age demonstrated a significantly prolonged lidocaine half-life that averaged 138 minutes.[92]

Newborn infants have immature hepatic enzyme systems and hence prolonged elimination of lidocaine, bupivacaine, and ropivacaine.[93-95] Bupivacaine, for example, has a terminal elimination half-life in adults that averages around 3.5 hours. In neonates and some younger infants, terminal elimination half-lives may be as long as 8 to 12 hours. Prolonged elimination is particularly an issue for continuous infusions of local anesthetics in infants, and seizures have been associated with high bupivacaine infusion rates.[96] Based on analysis of these cases, a maximum infusion rate of 0.4 mg/kg/hr for prolonged bupivacaine infusions has been proposed for children and adults, whereas prolonged infusion

rates for neonates and young infants should not exceed 0.2 mg/kg/hr.[97] Even at 0.2 mg/kg/hr, plasma bupivacaine concentrations were found to be rising toward a toxic range in some younger infants after 48 hours.[98] Similarly, prolonged lidocaine infusions in neonates should not exceed 0.8 mg/kg/hr. The potential for toxicity with lidocaine infusions in neonates is also increased by the accumulation of its principal metabolite, monoethylglycinexylidide (MEGX), which can cause seizures. Chloroprocaine may offer unique advantages for epidural infusion in neonates in that it is rapidly cleared from plasma, even in preterm neonates.[99]

Decreased hepatic blood flow or impaired hepatic enzyme function can produce a substantial elevation of blood levels of the aminoamide local anesthetics. An average lidocaine half-life of 1.5 hours was reported in volunteers with normal hepatic function, whereas patients with liver disease demonstrated an average half-life of 5.0 hours.[100] The rate of disappearance of lidocaine from blood has also been shown to be markedly prolonged in patients with congestive heart failure.[101]

Toxicity

Local anesthetic drugs are relatively safe if administered in an appropriate dosage and in the correct anatomic location. However, systemic and localized toxic reactions can occur, usually as a result of accidental intravascular or intrathecal injection or administration of an excessive dose. In addition, specific adverse effects are associated with the use of certain drugs, such as allergic reactions to the aminoester drugs and methemoglobinemia after the use of prilocaine.

Systemic Toxicity

Systemic reactions to local anesthetics primarily involve the CNS and the cardiovascular system (also see Chapters 51 to 53 and 81). In general, the CNS is more susceptible to the actions of systemic local anesthetics than the cardiovascular system is, and thus the dose or blood level of local anesthetic required to produce CNS toxicity is usually lower than that resulting in circulatory collapse.

Central Nervous System Toxicity

The initial symptoms of local anesthetic–induced CNS toxicity are feelings of lightheadedness and dizziness followed frequently by visual and auditory disturbances such as difficulty focusing and tinnitus. Other subjective CNS symptoms include disorientation and occasional feelings of drowsiness. Objective signs of CNS toxicity are usually excitatory in nature and include shivering, muscular twitching, and tremors initially involving muscles of the face and distal parts of the extremities. Ultimately, generalized convulsions of a tonic-clonic nature occur. If a sufficiently large dose or rapid intravenous injection of a local anesthetic is administered, the initial signs of CNS excitation are rapidly followed by a state of generalized CNS depression. Seizure activity ceases, and respiratory depression and ultimately respiratory arrest may occur. In some patients CNS depression is seen without a preceding excitatory phase, particularly if other CNS depressant drugs have been administered.

CNS excitation may be the result of an initial blockade of inhibitory pathways in the cerebral cortex by local anesthetic drugs[102] but can also result from the net stimulation of release of glutamate, an excitatory amino acid neurotransmitter. Blockade of inhibitory pathways allows facilitatory neurons to function in an unopposed fashion, which results in an increase in excitatory activity leading to convulsions. A further increase in the dose of local anesthetic leads to inhibition of activity of both the inhibitory and facilitatory circuits, which results in a generalized state of CNS depression.

In general, a correlation exists between potency of the local anesthetic and intravenous CNS toxicity.[103] Convulsions caused by an inadvertent intravenous bolus of local anesthetic can generally be terminated by small intravenous doses of a benzodiazepine, such as midazolam, or by small intravenous doses of thiopental.

Respiratory or metabolic acidosis increases the risks for CNS toxicity from local anesthetics.[104]

Elevated $Paco_2$ enhances cerebral blood flow and thus the anesthetic is delivered more rapidly to the brain. In addition, diffusion of carbon dioxide into neuronal cells decreases intracellular pH, which facilitates conversion of the base form of the drugs to the cationic form. The cationic form does not diffuse well across the nerve membrane, so ion trapping will occur, which will increase the apparent CNS toxicity of local anesthetics.

Hypercapnia and acidosis also decrease the plasma protein binding of local anesthetic agents.[105] Accordingly, an elevation in $Paco_2$ or a decrease in pH will increase the proportion of free drug available for diffusion into the brain. On the other hand, acidosis increases the cationic form of the local anesthetic, which should decrease the rate of diffusion through lipoid barriers.

The clinical implication of this effect of hypercapnia and acidosis on toxicity deserves emphasis. Seizures produce hypoventilation and a combined respiratory and metabolic acidosis, which further exacerbates the CNS toxicity. In the setting of local anesthetic toxic reactions, it is essential to provide prompt assisted ventilation and circulatory support as needed to prevent or correct hypercapnia and acidosis and to prevent or correct hypoxemia, which also exacerbates CNS toxicity. Based on the preceding discussion, it should be apparent that clinicians performing major conduction blockade should make a routine practice of having the following ready at hand: monitoring equipment; an oxygen tank or wall oxygen outlet; airway equipment, including at minimum, a bag-mask circuit for delivery of positive-pressure ventilation; and drugs to terminate convulsions, such as midazolam, lorazepam, diazepam, or thiopental.

Cardiovascular System Toxicity

Local anesthetics can exert direct actions on both the heart and peripheral blood vessels, as well as indirect actions on the circulation by blockade of sympathetic or parasympathetic efferent activity.

Direct Cardiac Effects

The primary cardiac electrophysiologic effect of local anesthetics is a decrease in the rate of depolarization in the fast conducting tissues of Purkinje fibers and ventricular muscle.[106] This reduction in rate is believed to be due to a decrease in the availability of fast sodium channels in cardiac membranes. Action potential duration and the effective refractory period are also decreased by local anesthetics.

The electrophysiologic effects of various agents differ qualitatively. Bupivacaine depresses the rapid phase of depolarization (Vmax) in Purkinje fibers and ventricular muscle to a greater extent than lidocaine does. In addition, the rate of recovery from a use-dependent block is slower in bupivacaine-treated papillary muscles than in lidocaine-treated muscles. This slow rate of recovery results in incomplete restoration of Na^+ channel availability between action potentials, particularly at high heart rates. These differential effects of lidocaine and bupivacaine have been advanced as explanations of the antiarrhythmic properties of lidocaine and the arrhythmogenic potential of bupivacaine.

Electrophysiologic studies have shown that high blood levels of local anesthetics will prolong conduction time through various parts of the heart, as indicated on the electrocardiogram (ECG) by an increase in the PR interval and duration of the QRS complex. Extremely high concentrations of local anesthetics depress spontaneous pacemaker activity in the sinus node, thereby resulting in sinus bradycardia and sinus arrest.

All local anesthetics exert dose-dependent negative inotropic action on cardiac muscle[107]; the depression of cardiac contractility is roughly proportional to conduction blocking potency. Thus, bupivacaine and tetracaine are more potent cardiodepressants than lidocaine is.

Local anesthetics may depress myocardial contractility by affecting calcium influx and triggered release from the sarcoplasmic reticulum,[108] as well as by inhibiting cardiac sarcolemmal Ca^{2+} currents and Na^+ currents.

Direct Peripheral Vascular Effects

Local anesthetics exert biphasic effects on peripheral vascular smooth muscle.[109] Low concentrations of lidocaine and bupivacaine produced vasoconstriction in the cremaster muscle of rats, whereas high concentrations produced vasodilation in both isolated tissue models and in vivo.

Cocaine is the only local anesthetic that consistently causes vasoconstriction at all concentrations because of its ability to inhibit the uptake of norepinephrine by premotor neurons and thus to potentiate neurogenic vasoconstriction.

Comparative Cardiovascular Toxicity

All local anesthetics, but especially bupivacaine, can cause rapid and profound cardiovascular depression (also see Chapters 51 to 53 and 81). The cardiotoxicity of bupivacaine appears to differ from that of lidocaine in the following manner:

1. The ratio of the dosage required for irreversible cardiovascular collapse (CC) and the dosage that will produce CNS toxicity (convulsions) (i.e., the CC/CNS ratio) is lower for bupivacaine and etidocaine than for lidocaine.[110]
2. Ventricular arrhythmias and fatal ventricular fibrillation may occur more often after the rapid intravenous administration of a large dose of bupivacaine but far less frequently with lidocaine.[111,112] The CNS effects of local anesthetics may contribute to the generation of arrhythmias (see Chapter 61).[113]
3. A pregnant animal or patient may be more sensitive to the cardiotoxic effects of bupivacaine than a nonpregnant animal or patient[114] (see also Chapter 69). The 0.75% solution of bupivacaine is no longer recommended for use in obstetric anesthesia in the United States.
4. Cardiac resuscitation is more difficult after bupivacaine-induced cardiovascular collapse, and acidosis and hypoxia markedly potentiate the cardiotoxicity of bupivacaine.[115]

Many resuscitation drugs, including atropine, epinephrine, bretylium, lidocaine, amrinone, and phenytoin, have been used in animal studies and occasionally in humans for the treatment of bupivacaine overdose and cardiovascular collapse. In our view, beyond the established uses of epinephrine, vasopressin, and atropine in their designated steps in the advanced cardiac life support (ACLS) protocol[116] and beyond the use of Intralipid as detailed later, there is no established role for antiarrhythmic drugs or other traditional resuscitation drugs in the setting of bupivacaine-induced cardiac arrest. It is *not* recommended that bupivacaine-induced ventricular arrhythmias be treated with lidocaine or amiodarone.

The clinical implications for cardiac resuscitation after intravascular injection or overdose of local anesthetic are the following:

1. No medications are uniformly effective in facilitating resuscitation from bupivacaine-induced cardiac arrest or severe ventricular tachycardia (despite our recommendations regarding Intralipid later). Basic principles of cardiopulmonary resuscitation should be emphasized first, including attention to securing the airway, providing oxygenation and ventilation, and performing chest compressions if needed.
2. Because resuscitation after local anesthetic–induced circulatory collapse is so difficult, prevention of massive intravascular injection or excessive dosing is crucial.
3. Negative aspiration of the syringe does not always exclude intravascular placement. Incremental, fractionated dosing should be the rule for all patients undergoing major conduction blockade. Although changes on the ECG are not always present before circulatory collapse, they often are, and continuous attention to the ECG (including changes in QRS morphology, rate, rhythm, or ectopy) may be lifesaving by terminating injection before a lethal dose is administered.
4. Based on animal studies[117] and a growing number of human case reports,[118-120] we recommend that hospitals and clinics that perform major conduction blockade keep available for emergency use a supply of Intralipid 20%. If a patient experiences profound cardiovascular depression or circulatory arrest after the administration of bupivacaine, ropivacaine, or by extrapolation, other local anesthetics, then along with initiation of basic life support and the ACLS protocol we support the recommendation of Weinberg and colleagues[120] that a rapid bolus of Intralipid 20%, 1.5 mL/kg (or roughly 100 mL in adults), be administered without delay, followed if necessary by an infusion of 0.25 mL/kg/min for the next 10 minutes.

Chiral Local Anesthetics: Ropivacaine and Levobupivacaine

Commercial bupivacaine is a racemic mixture of (*R*)- and (*S*)-stereoisomers. In response to the problem of cardiovascular toxicity as a result of accidental intravenous injection of bupivacaine,

single enantiomers were developed in the hope that they would be potentially safer local anesthetics. Ropivacaine (Naropin)[121] and levo-(*S*)-bupivacaine (Chirocaine)[122] were formulated to exploit this stereoselectivity. Ropivacaine is a single (*S*)-stereoisomer that differs from levobupivacaine in the substitution of a propyl for the butyl group on the piperidine ring (see Fig. 30-2). With these designed changes in molecular structure, it was hoped that ropivacaine and levobupivacaine would be less intrinsically cardiotoxic. Conversely, it appears that the (*S*)-enantiomers of mepivacaine and bupivacaine are metabolized by the liver more slowly than the corresponding (*R*)-enantiomers, which would lead to somewhat greater systemic accumulation with prolonged infusions.[123]

The cardiovascular toxicity of local anesthetics is complex and involves direct effects on the myocardium, on vascular tissue (both smooth muscle and its neuronal supply), and on the central innervation of the heart. The very slow reversal of Na^+ channel blockade after a cardiac action potential, which is a hallmark of bupivacaine, is considerably faster with ropivacaine. In addition to these electrical differences, the negative inotropic potency of ropivacaine on isolated cardiac tissue appears to be considerably less than that of bupivacaine.[124,125] Both electrical and mechanical differences in the toxic profiles may arise from the selective inhibition of Ca^{2+} currents by bupivacaine.

Do the data support the claim of a greater therapeutic index for ropivacaine than bupivacaine, particularly with regard to cardiotoxicity? In clinical studies comparing potencies of ropivacaine and bupivacaine administered for brachial plexus[126] or lumbar epidural block,[127] the anesthetic profiles of the drugs were almost identical. A third study comparing lumbar epidural 0.5% bupivacaine with 0.75% ropivacaine also found no significant differences in motor or sensory effects between the drugs at these different concentrations.[128] Overall, it appears that ropivacaine is slightly less potent than (1:1.3 to 1:1.5) or equally potent as bupivacaine for regional anesthesia. In some laboratory animal studies and in some human studies, ropivacaine also produced blocks of shorter duration than those induced by bupivacaine. Other studies in animals and humans have found equal durations of sensory and motor block for the two drugs.

At the projected equipotent doses for nerve block, are the drugs equally toxic? The overall impression is that ropivacaine is less cardiotoxic than bupivacaine. Studies in animals have generally found that bupivacaine more readily produces conduction disturbances, cardiac collapse, or ventricular fibrillation than ropivacaine does and that aggressive cardiac resuscitation after an intentional intravenous bolus in dogs leads to effective reversal of the toxic effects far more frequently with ropivacaine than with bupivacaine.[129]

The greater safety of ropivacaine than bupivacaine may be related both to the reduced toxicity of the single (*S*)-isomer and to the difference between the propyl- and butyl-*N*-piperidine substituent. In contrast to bupivacaine, the cardiotoxic profile of ropivacaine in pregnant ewes is the same as the corresponding profile in nonpregnant ewes.[130]

Levobupivacaine has been studied in a range of clinical settings and sites of administration.[131-133] Although a number of publications have compared levobupivacaine with racemic bupivacaine and ropivacaine,[132,133] conclusions differ among studies regarding the relative potency and duration of block of these three drugs at different sites of administration with respect to sensory and motor end points. Clinicians should note that levobupivacaine is formulated as a weight percentage with regard to its free base content, whereas the weight percentage of most other local anesthetics is calculated on the basis of the hydrochloride salt.[134]

Acidosis and Hypoxia

As with CNS toxicity, hypercapnia, acidosis, and hypoxia potentiate the negative chronotropic and inotropic actions of lidocaine and bupivacaine in isolated cardiac tissue, and the combination of hypoxia and acidosis markedly potentiates the cardiodepressant effects of bupivacaine.[135] Hypoxia and acidosis also increased the frequency of cardiac arrhythmias and the mortality rate in sheep after the intravenous administration of bupivacaine. Hypercapnia, acidosis, and hypoxia occur very rapidly in some patients after seizure activity caused by the rapid accidental intravascular injection of local anesthetic agents.[136] Thus, the cardiovascular depression observed in some patients after the accidental intravenous injection of bupivacaine may be related in part to the effect of seizures producing acidosis and hypoxia and thereby leading to an exacerbation of bupivacaine's intrinsic cardiotoxicity.

Indirect Cardiovascular Effects

High levels of spinal or epidural blockade can produce severe hypotension. A follow-up study of closed claims of patients who suffered perioperative cardiac arrest confirmed previous reports of a series of cardiac arrests involving generally healthy patients undergoing spinal or epidural anesthesia.[137] These events frequently occurred in conjunction with high dermatomal levels of blockade, liberal use of sedatives, and progression to cardiac arrest after a period of hypotension accompanied by bradycardia, often involving delays in recognition of the problem, delays in instituting airway support (particularly in sedated patients), and delays in administration of direct-acting combined α- and β-adrenergic agonists, such as epinephrine. Whereas mild to moderate degrees of hypotension generally respond well to indirect-acting sympathomimetics such as ephedrine or incremental dosing of phenylephrine, the combination of severe hypotension and severe bradycardia under spinal anesthesia should in most clinical settings be treated promptly with incremental dosing of epinephrine, initially at doses of 0.1 to 1 μg/kg, or roughly 20- to 200-fold below those used in the ACLS cardiac arrest algorithm.

Methemoglobinemia

A unique systemic side effect associated with a specific local anesthetic is the development of methemoglobinemia after the administration of large doses of prilocaine.[138] In general, 600-mg doses are required for the development of clinically significant levels of methemoglobinemia in adults. Hepatic metabolism of prilocaine generates *O*-toluidine, which oxidizes hemoglobin to methemoglobin. Methemoglobinemia, if severe, may be treated by the intravenous administration of methylene blue. Standard dosing of the topical local anesthetic EMLA (a mixture of lidocaine and prilocaine) in term newborns produced minimal amounts of methemoglobin, and EMLA should be regarded as very safe in

the great majority of newborns. Risk may be increased in newborns with rare metabolic disorders or after the concomitant administration of other drugs that impair reduction of methemoglobin.

Allergies

Even though patients receiving local anesthetics may experience a range of local and systemic symptoms, prospective studies indicate that very few of these reactions are confirmed as allergic reactions.[139] Aminoester drugs such as procaine may produce allergic-type reactions more commonly than the aminoamides do, although even with aminoesters, the vast majority of reactions are not allergic. Aminoesters, unlike aminoamides, are derivatives of *p*-aminobenzoic acid, which is known to be allergenic. Some aminoamide solutions may contain a preservative, methylparaben, whose chemical structure is similar to that of *p*-aminobenzoic acid, but for most aminoamides, preservative-free solutions are available. Contamination of vials with latex antigen has been suspected in some allergic reactions, although it has been difficult to confirm. In the very rare patient for whom confirmed allergy to both aminoamides and aminoesters precludes their use for spinal anesthesia, meperidine can be considered as an alternative.[140]

Local Tissue Toxicity

All the clinically used aminoamide and aminoester local anesthetics can produce direct toxicity to nerves if they achieve sufficiently high intraneural concentrations. Conversely, in the great majority of clinical applications, no damage to nerves occurs. Although local anesthetics are usually packaged and injected at concentrations well above their physiologically effective range, in the process of delivery they are generally diluted sufficiently that no harm is done. If such dilution does not occur, however, long-term or permanent neural deficits do result. Thus, the application of 5% (200 mM) lidocaine in viscous, dense solutions through narrow intrathecal catheters has been associated with a high frequency of transient or longer-term radicular symptoms or even cauda equina syndrome.[141] Laboratory investigations have shown that such high concentrations of local anesthetics alone applied directly to bare nerve fibers produce an irreversible conduction block in less than 5 minutes.[142] Indeed, previous studies on ensheathed peripheral nerves in vivo had shown neurologic and histologic changes after infiltration of the space surrounding the nerve with local anesthetics at concentrations as low as 1% to 2%. Clinicians should be aware that the concentrations of formulated local anesthetic solutions are neurotoxic per se and that their dilution, in situ or in tissue, is essential for safe use. A recently published randomized trial has renewed interest in continuous spinal anesthesia,[143] and it may have a favorable risk-benefit ratio for selected high-risk patients.

In the late 1970s and early 1980s, prolonged sensory and motor deficits were reported in some patients after the epidural or subarachnoid injection of large doses of chloroprocaine.[144] Studies in animals have proved somewhat contradictory regarding the potential neurotoxicity of chloroprocaine.[145,146] Some studies suggest that the combination of low pH, sodium bisulfite, and inadvertent intrathecal dosing is responsible in part for the neurotoxic reactions observed after the use of large amounts of chloroprocaine solution; other studies have disputed this claim and note that chloroprocaine itself at high concentrations can also be neurotoxic,[145,146] but these concentrations are probably rarely achieved during properly positioned epidural anesthesia, as opposed to inadvertent spinal anesthesia. The currently available commercial solutions of chloroprocaine do not contain sodium bisulfite. This was initially replaced by ethylene glycol-bis-(β-aminoethyl ether)-*N*,*N*-tetraacetic acid (EGTA), a preservative and high-affinity calcium chelator that was occasionally reported to cause local muscle spasms after epidural administration. More recently, chloroprocaine has become available in an entirely preservative-free preparation. Chloroprocaine has unique utility in situations in which rapid plasma clearance is required to prevent excessive systemic accumulation of local anesthetic. Chloroprocaine has been given by epidural infusion to neonates and young infants in settings in which lidocaine and bupivacaine may not provide an effective therapeutic index,[99] and it has also recently become popular as a short-duration spinal anesthetic.

Single-shot spinal anesthesia with commonly recommended doses and concentrations of many different local anesthetics can produce more limited and transient neurologic symptoms (back pain, paresthesias, radicular pain, or hypoesthesia).[147] Some studies and systematic reviews have found that mepivacaine and lidocaine at a range of dilutions cause more frequent symptoms than bupivacaine and prilocaine do.[148] The risk of transient neurologic symptoms after spinal anesthesia was not diminished by dilution of lidocaine from 5% to 1%-2%. Differences in study design, method of questioning, and criteria for inclusion may be partially responsible for differences in the prevalence of radicular sequelae in various studies. Despite these differences in study design, a meta-analysis concluded that the pooled relative risk for transient neurologic symptoms after spinal anesthesia with lidocaine was 6.7-fold higher than with bupivacaine and 5.5-fold higher than with prilocaine.[148] The addition of vasoconstrictors to local anesthetic solutions may also increase risk.[149] Neurotoxicity appears to be unrelated to conduction block because tetrodotoxin, a highly potent blocker of sodium channels, can produce intense conduction blockade without histologic or behavioral signs of nerve injury.[150]

Intraoperative positioning also appears to be a risk factor. Patients undergoing surgery in the lithotomy position appear to be at increased risk for neurologic symptoms after either spinal or epidural anesthesia. It is unknown at present why this association produces increased risk; nerve compression or stretch or reduced perfusion pressure in the vasa nervorum may possibly exacerbate the toxicity from local anesthetics. The lithotomy position can produce neurologic sequelae and lower extremity compartment syndrome, particularly with prolonged surgery and use of the Trendelenburg position.[151]

Skeletal muscle changes have been observed after the intramuscular injection of local anesthetic agents such as lidocaine, mepivacaine, prilocaine, bupivacaine, and etidocaine. In general, the more potent, longer-acting agents bupivacaine and etidocaine appear to cause more localized skeletal muscle damage than the less potent, shorter-acting agents lidocaine and prilocaine do. This

effect on skeletal muscle is reversible, and muscle regeneration occurs rapidly and is complete within 2 weeks after the injection of local anesthetic agents. Local anesthetic–induced myotoxicity may involve actions on mitochondria.[152]

Prolonged Infusions of Local Anesthetics and the Development of Long-Duration Local Anesthetics

Local anesthetics are increasingly being administered by continuous infusion for several days after surgery or for periods of weeks to months for the treatment of chronic malignant and nonmalignant pain (see also Chapters 58 and 87). With prolonged infusions there is the potential for delayed systemic accumulation and toxicity. Continuous bupivacaine infusions of up to 30 mg/hr in adults for as long as 2 weeks produced no overt CNS or cardiac toxicity despite total plasma bupivacaine concentrations in the range of 2 to 5 μg/mL in several patients.[153]

Several methods for producing long-duration nerve blockade are under investigation. Liposomal encapsulation can prolong nerve blockade, depending on the dose and the physical properties of the liposome (surface charge, size, lamellar structure).[154-156] Local anesthetics can be incorporated into biodegradable polymer microspheres for sustained release.[157] These preparations produce peripheral nerve blockade in animal models and human volunteers[158] ranging from 2 to 8 days, depending on the dose, site, and species. Because of the intrinsic neurotoxicity of all aminoamide and aminoester local anesthetics, there is likely to be some irreducible potential for neurotoxicity with most of these approaches to controlled release of aminoamide and aminoester local anesthetics in proximity to major nerve trunks. Thus, these formulations will have the most favorable risk-benefit ratio when used in nonprotective locations, such as intercostal nerve blockade, where prolonged numbness may be a benefit rather than a complication of the intervention. This risk is also likely to be less clinically important for infiltration analgesia.

Prolonged-duration local anesthesia also appears to be feasible with the use of site 1 sodium channel toxins in combination with either local anesthetics or adrenergics.[159] Other site 1 toxins have been used in humans in preliminary case series.[160] A combination of site 1 toxins with either local anesthetics or adrenergics results in prolongation of blockade and improvement in the therapeutic index.[159] Theoretically attractive features of site 1 toxins include their apparent lack of local tissue toxicity on nerves[150] or muscles[161] and their minimal effects on cardiac sodium channels.

Other drugs have been examined for use as local anesthetics, including tricyclic antidepressants,[162] although neurotoxicity may limit the clinical utility of this group of drugs.

It remains to be determined whether prolonged-duration local anesthetics will gain widespread use in clinical practice. If they prove to be safe and effective, they may have potential utility in intercostal blockade and wound infiltration, particularly for surgery on the thorax and abdomen, where protective sensation is comparatively less important than for limb surgery. If agents can be developed that last for weeks or longer, they may have additional applications in the management of chronic pain and cancer pain.

Biologic Mechanisms of Local Anesthetic Failure: Inflammation, Hyperalgesia, Tachyphylaxis, and Genetic Variants

Failure of local anesthesia is commonly ascribed to technical failure of delivery, insufficient volume or concentration of drug, or erroneous clinical decisions in selection of techniques. However, there are a number of clinical situations in which biologic processes contribute to failed local anesthesia, even with proper technique and drug selection. For example, in patients going to the dentist with infections such as a tooth abscess or severe pulpitis, failure rates of standard doses of local anesthetic have been reported to be as high as 70%. Local anesthetic failure at a site of inflammation appears to reflect a combination of pharmacokinetic factors and pharmacodynamic factors. Pharmacokinetic factors include (1) increased local blood flow leading to accelerated removal of drug from perineural injection compartments; (2) local tissue acidosis leading to a greater proportion of the drug in the hydrochloride form, which diffuses more poorly across biologic membranes; and (3) local tissue edema, which increases diffusion distances for drug into nerves. Pharmacodynamic factors include the effects of inflammation on both peripheral sensitization of nerves and central sensitization.[163,164] It is noteworthy that in the setting of an infected mandibular tooth, inferior alveolar nerve block (performed proximally at a site presumably remote from the infected area) also has an unexpectedly high failure rate.

Local anesthetics and regional anesthesia, in turn, can suppress components of inflammatory responses by a complex interplay of local, spinal, and systemic mechanisms.[165,166]

Apparent reductions in the effectiveness of local anesthetic infusions over time may be due to a number of causes unrelated to tolerance per se, including dislodgement of catheters and changes in the dermatomal origin or intensity of nociceptive input. In obstetric patients receiving epidural bolus injections, recurrence of pain before the next injection resulted in a reduction in the intensity and duration of blockade, whereas repeat injection before the return of pain prevented this rapidly occurring form of tolerance, or tachyphylaxis.[167] In postoperative patients, coadministration of systemic opioids prevented regression of segmental block in patients receiving thoracic epidural bupivacaine infusions.[168] Studies in rats suggest that both pharmacokinetic and pharmacodynamic mechanisms are involved. In a rat model, tachyphylaxis was linked to the development of hyperalgesia,[169] and drugs that inhibit hyperalgesia, including *N*-methyl-D-aspartate receptor antagonists and nitric oxide synthase inhibitors,[170] also prevented tachyphylaxis. Conversely, repeated sciatic injections of lidocaine resulted in reduced intraneural lidocaine content along with reduced duration of block.[171]

Occasional patients report that "local anesthetics don't work for me." Although this claim may reflect previous technical failures or a variety of other processes and patient- or procedure-specific factors, it is possible that in some cases these failures may involve genetic variation in local anesthetic responsiveness. For example, a subgroup of patients with the connective tissue disorder Ehlers-Danlos syndrome appears to have diminished responses to topical local anesthesia.[172]

31 Nitric Oxide and Inhaled Pulmonary Vasodilators

Key Points

1. Endogenous nitric oxide (NO) is produced from oxygen and L-arginine by a group of enzymes called nitric oxide synthases with L-citrulline as a by-product.
2. Most of the effects of NO on the cardiovascular system are mediated by activation of the enzyme soluble guanylate cyclase, which catalyzes formation of the second messenger cyclic guanosine monophosphate (cGMP) from guanosine 5′-triphosphate. NO stimulates soluble guanylate cyclase to synthesize cGMP, which in turn activates cGMP-dependent protein kinase and thereby leads to vascular relaxation.
3. Because NO binds rapidly to hemoglobin with high affinity, the vasodilatory effect of inhaled NO is limited to the lung.
4. NO can be safely inhaled when delivered by facemask, nasal cannula, or an endotracheal tube.
5. According to a survey in 2000, 94% of pediatric cardiologists consider inhaled NO to be a clinically proven agent to test pulmonary vasoreactivity in the cardiac catheterization laboratory.[66]
6. Several clinical trials of inhaled NO in patients with acute lung injury demonstrated no effect on mortality or the duration of mechanical ventilation; however, the frequency of progression to severe respiratory failure from milder respiratory failure was decreased by inhaled NO in one study.[78]
7. Inhaled NO has been reported to ameliorate the postoperative pulmonary hypertension of congenital heart disease[91,92] and decrease the need for postoperative extracorporeal membrane oxygenation.[93]
8. The vasodilatory response to inhaled NO is variable in patients with valvular heart disease.[86,95] The variability in dilator response is likely to be related to the balance between pulmonary vascular remodeling and active vasoconstriction.
9. In contrast to therapy with intravenous vasodilators, which often cause systemic hypotension, inhaled NO has been shown in a small group of patients to selectively reduce peripheral vascular resistance and enhance right ventricular stroke work after cardiac transplantation.[98]
10. A trial of inhaled NO is recommended before consideration of implantation of a right ventricular assist device because this invasive procedure may be avoided if there is a salutary response to inhaled NO.[102]
11. Inhaled NO can combine with hemoglobin to form nitrosylhemoglobin, which is rapidly oxidized to methemoglobin. The enzyme methemoglobin reductase rapidly converts methemoglobin to hemoglobin in the red blood cell. Because neonates have reduced activity of this enzyme, they are at greater risk than adults for the development of significant methemoglobinemia after the inhalation of high levels of NO for a prolonged period.[142]

Pulmonary hypertension often complicates patient care intraoperatively, as well as in intensive care units (ICUs). Severe acute pulmonary hypertension may produce right ventricular (RV) failure. Pulmonary hypertension and RV failure may reduce left ventricular (LV) filling, decrease cardiac output, and lead to systemic hypotension. Decreased arterial blood pressure may compromise RV coronary perfusion at a time when RV end-diastolic pressure and RV myocardial oxygen consumption are increased because of increased RV wall tension, thereby leading to RV ischemia.[1] RV ischemia will exacerbate RV failure and cause a further reduction in cardiac output and blood pressure (Fig. 31-1). This vicious cycle may continue unless pulmonary artery pressure is reduced to permit increased RV ejection. Unfortunately, treatment of pulmonary hypertension with intravenous vasodilators may worsen the systemic hypotension. Inhalation of nitric oxide (NO) produces selective pulmonary vasodilation without reducing systemic arterial pressure in patients with acute or chronic pulmonary hypertension. Addi-

tionally, there are now a number of other experimental inhaled pulmonary vasodilators described in the literature that may provide potential alternatives to inhaled NO. In this chapter the theoretical background, current uses, and future therapeutic potential of inhaled NO and other inhaled pulmonary vasodilators are discussed.

Inhaled Nitric Oxide

Since recognition of NO as a key endothelial-derived vasodilator molecule in 1987, the field of NO research has expanded to encompass many areas of biomedical research. It is now well established that NO is an important signaling molecule throughout our body. Endogenous NO is produced from oxygen and L-arginine by a group of enzymes called nitric oxide synthases (NOSs) with L-citrulline as a by-product. Most of the effects of NO on the cardiovascular system are mediated by activation of the enzyme-soluble guanylate cyclase (sGC), which catalyzes formation of the second messenger cyclic guanosine monophosphate (cGMP) from guanosine 5′-triphosphate. Studies also indicate that NO may directly modulate other signaling systems. For example, recent evidence suggests that NO is directly involved in post-translational protein modification, including nitrosylation of proteins (Fig. 31-2).

A therapeutic potential for inhaled NO to act as a selective pulmonary vasodilator was demonstrated by Frostell and colleagues in 1991, who showed that breathing NO gas resulted in rapid and profound pulmonary vasodilation in an awake lamb model of pulmonary hypertension produced by infusion of a stable thromboxane analog (Fig. 31-3).[2] Because NO binds rapidly to hemoglobin (Hb) with high affinity, the vasodilatory effect of inhaled NO is limited to the lung. This is in sharp contrast to intravenously infused vasodilators, which often cause systemic vasodilation and lead to systemic arterial hypotension. This unique ability of inhaled NO to cause highly selective pulmonary vasodilation has prompted a large number of preclinical and clinical studies. The early pilot studies also demonstrated that inhaled NO therapy rapidly improves oxygenation without causing systemic hypotension in critically ill newborns with acute pulmonary hypertension (see Chapter 84).[3,4] Subsequently, the efforts of many research groups studying animals and patients led to approval of inhaled NO by the U.S. Food and Drug Administration in 1999 and by the European Medicine Evaluation Agency and European Commission in 2001.[5-8]

A number of studies now indicate that inhaled NO may play an important role in treating pulmonary hypertension in pediatric and adult patients with respiratory and cardiac failure, in determining the vasodilatory capacity of the pulmonary vas-

cular bed, and perhaps in preventing the development of chronic lung disease in infants with lung injury.

Inhaled Nitric Oxide: Physical Properties, Methods of Administration, and Mechanism of Action

Chemistry of Nitric Oxide Gas

NO is a colorless and odorless gas that is only slightly soluble in water.[9] Atmospheric concentrations of NO usually range between 10 and 500 parts per billion by volume (ppb) but can exceed 1.5 parts per million (ppm) in areas of heavy traffic or lightning.[10] In the inhaled smoke of a burning cigarette, NO is produced by oxidation of nitrogen from the atmosphere and nitrogen-containing compounds in tobacco and can reach levels of 1000 ppm.[11] NO is unstable in air and undergoes spontaneous oxidation to form the more toxic nitrogen oxides (NO_2, N_2O_4, etc.). NO is therefore stored in cylinders diluted in an inert gas, usually nitrogen.

Delivery and Monitoring of Inhaled Nitric Oxide

NO can be safely inhaled when delivered by facemask, nasal cannula, or an endotracheal tube. It is important to carefully regulate the concentration of NO and its length of exposure to oxygen, which can be achieved with several commercially available systems. Although NO and NO_2 are more accurately measured by chemiluminescence devices, electrochemical detectors have proved adequate for the measurement of inhaled NO and are integrated components of several clinical delivery systems. Despite concern that ICU workers would passively inhale NO, this has not become a problem because levels of NO in ICU air remain quite low.[12]

Nitric Oxide/Cyclic Guanosine Monophosphate Signal Transduction System

After inhalation, NO diffuses rapidly across the alveolar-capillary membrane into the subjacent smooth muscle of pulmonary vessels (Fig. 31-4). NO stimulates sGC to synthesize cGMP, which in turn activates cGMP-dependent protein kinase and thereby leads to vascular relaxation. The physiologic actions of cGMP are limited by its hydrolysis to GMP and by export from the cell. A family of cyclic nucleotide phosphodiesterases (PDEs) is known to hydrolyze cyclic nucleotides. Of the 11 reported PDE isozymes, PDE5 is considered to be the most active cGMP-hydrolyzing PDE in smooth muscle (for review, see Rybalkin and associates[13]). PDE5 has high affinity for cGMP and is selectively inhibited by PDE inhibitors such as zaprinast, sildenafil, and verdenafil. In addition to its pulmonary vasodilating effects, inhaled NO has several other effects in the lung. For instance, inhaled NO has been shown to cause bronchodilation[14,15] and to possess anti-inflammatory[16] and antiproliferative[17] effects. NO can also elicit effects via cGMP-independent mechanisms, including interactions with heme-containing molecules (in addition to sGC) and with proteins containing reactive thiol groups.[18] NO interacts with the superoxide radical (O_2^-), which limits the bioavailability of NO and results in formation of the potent oxidant peroxynitrite ($ONOO^-$). In the presence of oxygenated Hb, NO is rapidly metabolized to nitrate with the formation of methemoglobin (MetHb). Within red blood cells, electron donors rapidly convert MetHb back to ferrous Hb.

Enhancement of Ventilation-Perfusion Matching by Inhalation of Nitric Oxide

The intrapulmonary distribution of blood flow and ventilation (ventilation-perfusion [$\dot{V}/\dot{Q}$] distribution) is a major determinant of the efficiency of transpulmonary oxygenation and determines the partial pressure of oxygen in arterial blood (Pao_2). In a normal, healthy lung, the majority of ventilated areas are well perfused (see also Chapter 15). The shunt from the right to the

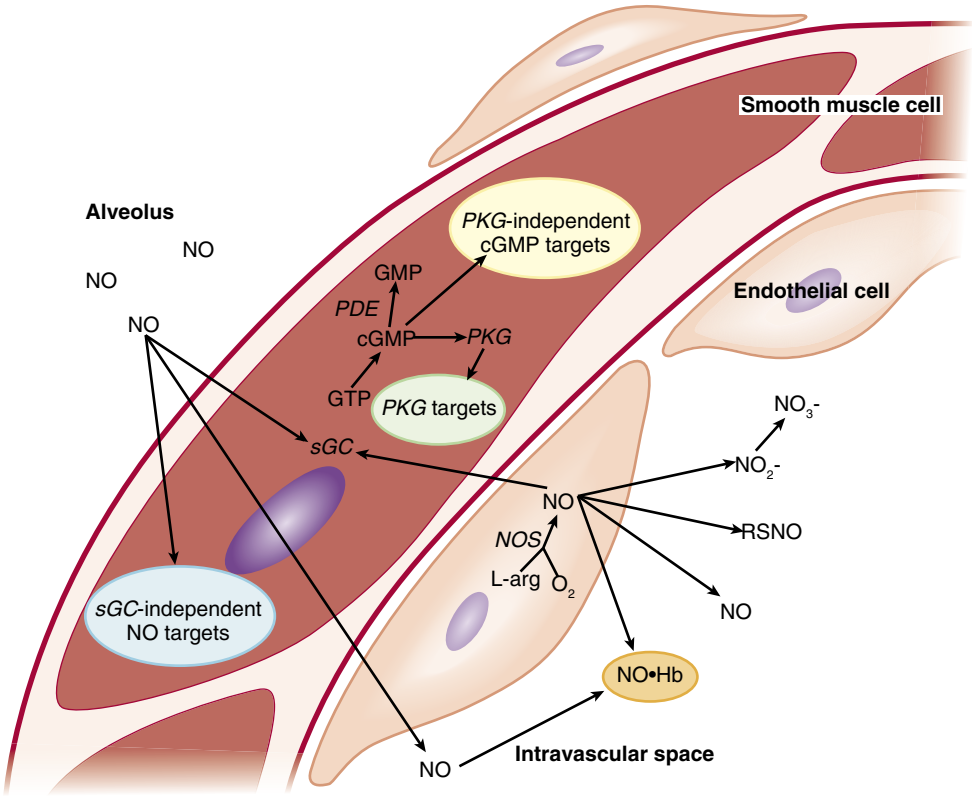

Figure 31-4 Schematic of the nitric oxide (NO) signaling pathway in the lung. NO, formed by endothelial cells or administered by inhalation, diffuses to vascular smooth muscle cells. Numerous targets of NO contribute to the wide variety of effects of this molecule on the cardiovascular system. One of the primary targets for NO is soluble guanylate cyclase (sGC). NO binds to the heme moiety of sGC and stimulates synthesis of the intracellular second messenger cyclic guanosine monophosphate (cGMP). cGMP interacts with a variety of targets, including ion channels, cGMP-regulated phosphodiesterases (PDEs), and cGMP-dependent protein kinases (PKGs). PKGs have been shown to phosphorylate various proteins in vascular smooth muscle cells. cGMP is metabolized to GMP by PDEs. On arrival in the bloodstream, the majority of NO rapidly binds to hemoglobin with high affinity, but small amounts of NO may remain to react with other molecules, including proteins. GTP, guanosine triphosphate; NOS, nitric oxide synthase; RSNO, S-nitrosothiol. *(From Ichinose F, Roberts JD, Zapol WM: Inhaled nitric oxide, a selective pulmonary vasodilator, current uses and therapeutic potential. Circulation 109:3106-3111, 2004, with permission.)*

left side of the circulation is mainly extrapulmonary (e.g., bronchial veins) and is less than 5% to 8% of cardiac output.[19] In a normal lung, local alveolar hypoxia constricts the vascular bed adjacent to hypoxic regions and redistributes blood flow toward lung regions with better ventilation and higher intra-alveolar Po_2. It has been proposed that inhaled NO amplifies this mechanism by increasing blood flow to well-ventilated lung areas, which may, in some diseases, cause increased vasomotor tone. This inhaled vasodilatory effect is in marked contrast to the effect of intravenously administered vasodilators, which produce diffuse dilation of the pulmonary vasculature, increase blood flow to areas of nonventilated lung, and thereby increase intrapulmonary shunting and reduce Pao_2. In contrast, inhaled NO should selectively improve the perfusion of ventilated regions and hence reduce intrapulmonary shunting and improve arterial oxygenation (Fig. 31-5). These beneficial effects of inhaled NO on intrapulmonary shunting and oxygenation have been demonstrated in some adult and pediatric patients with acute respiratory distress syndrome (ARDS).[20,21] Unfortunately, this effect can at times be transient.[22]

Clinical Use of Inhaled Nitric Oxide

Perinatal and Pediatric Uses of Inhaled Nitric Oxide

Nitric Oxide Is an Important Regulatory Molecule in the Perinatal Lung. Several studies indicate that NO has an important role in modulating pulmonary vascular resistance (PVR) at birth. For example, in the developing lungs of several animals, NOS and sGC expression and signaling increase late in gestation, are maximal in the postnatal period, and decrease in adults.[23-25] Moreover, because NOS inhibitors attenuate the reduction in PVR at birth,[26,27] it is likely that NO signaling plays a critical role in transition from the fetal to the newborn pulmonary circulatory system.

Many forms of newborn and infant lung disease are associated with endothelial cell injury and decreased NO/cGMP signaling. Studies in newborns suggest that premature constriction of the ductus arteriosus, septic mediators, and meconium aspiration all cause pulmonary endothelial cell injury. For example, in utero ligation of the ductus arteriosus in the fetal lamb causes flow-

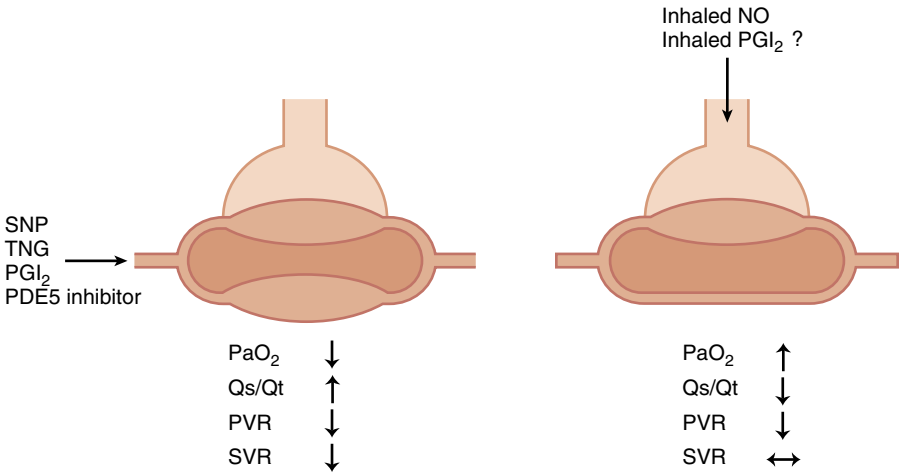

Figure 31-5 Diagram illustrating the differing pathophysiologic effects of inhaled pulmonary vasodilators and intravenous vasodilators. induced endothelial cell dysfunction and decreases the expression of endothelial NOS (NOS3)[28] and vasorelaxation caused by NO.[29] Moreover, cardiac lesions, such as atrial and ventricular septal defects, atrioventricular canals, persistent ductus arteriosus, and transposition of the great vessels without a ventricular septal defect, cause endothelial cell injury, decrease NO-mediated pulmonary vasorelaxant activity, and lead to pulmonary hypertension.[30]

Accumulating evidence suggests that NO/cGMP signaling has an important role in regulating lung development. For example, in mildly hypoxemic newborn NOS3-deficient mice, alveolar development is severely inhibited in a manner that can be improved by inhalation of NO.[31,32] Furthermore, in perinatal models of pulmonary vascular disease, in which NO activity has been observed to be decreased, inhaled NO improves the development of peripheral pulmonary arteries.[33]

Experimental Studies of the Selective Pulmonary Vasodilator Effects of Inhaled Nitric Oxide in the Newborn. Several investigations in newborn animals have demonstrated that inhaled NO decreases pulmonary hypertension. For example, in fetal lambs with an intact placental circulation, inhaled NO decreased PVR.[34] Similarly, in newborn lambs with pulmonary vasoconstriction associated with hypoxemia, inhaled NO was observed to decrease PVR and increase lung cGMP levels in a manner that was not modified by acidosis.[35] Importantly, in the latter study inhaled NO did not cause systemic vasodilation, and breathing up to 80 ppm NO did not decrease either systemic vascular resistance or blood pressure.

Inhaled NO also reversed vasoconstriction in newborn animals with pulmonary vascular remodeling. In newborn lambs with pulmonary vascular disease induced by premature ligation of the ductus arteriosus and associated with muscularization of peripheral arteries in the lung periphery, inhaled NO caused dose-dependent vasodilatation and improved systemic oxygenation and survival rates.[36] Moreover, in lambs with lung hypoplasia caused by congenital diaphragmatic hernia, NO improved systemic oxygenation when inhaled after exogenous surfactant treatment or during partial liquid ventilation.[37] These latter findings suggest that lung volume recruitment is required for inspired NO to effectively reduce pulmonary vasoconstriction in models associated with lung hypoplasia.

Inhaled Nitric Oxide Can Attenuate Pulmonary Disease in Newborn Animals. In newborn rats, lung injury caused, for example, by sustained hypoxia or exposure to endothelial toxins results in pulmonary artery muscularization and hypertension similar to that observed in patients with pulmonary artery hypertension (PAH) and many forms of congenital heart disease. In these models, prolonged inhalation of NO has been reported to attenuate pulmonary vascular remodeling and RV hypertrophy in chronically hypoxic newborns.[33] Importantly, it appears that breathing NO can inhibit pulmonary vascular remodeling even in the absence of pulmonary hypertension. Roberts and colleagues reported that in newborn rats with monocrotaline-induced endothelial injury, inhaled NO decreased the abnormal proliferation of cells in the walls of pulmonary arteries and prevented abnormal pulmonary vascular remodeling even before the development of pulmonary hypertension.[17] These findings suggest that inhaled NO may play an important role in modifying the abnormal vascular development and secondary pulmonary hypertension of the injured newborn lung.

Lung injury decreases alveolar and pulmonary microvascular development in premature lambs and baboons and in newborn mice and rats.[38] Accumulating experimental evidence suggests that inhaled NO promotes the development of the injured maturing lung. For example, prolonged NO inhalation has been observed to increase alveologenesis in chronically ventilated premature baboons[39] and lambs.[40] Moreover, inhaled NO improves alveolar development in mice after hyperoxic lung injury.[41] The mechanisms responsible for the protective effects of inhaled NO in alveologenesis are unknown. Because studies suggest that the pulmonary vasculature importantly regulates alveolar development[42] and inhaled NO protects newborn lung vessels from injury,[33] it is possible that inhaled NO protects the lung via its effects on the microvasculature. This concept is supported by the observation that inhaled NO improves alveolarization in rat pups that have decreased microvascular development.[43] However, it is also possible that NO regulates the homeostasis of other cells or might modulate other signaling systems regulating or contributing to lung development.

Inhaled Nitric Oxide Increases Systemic Oxygenation in Hypoxemic Newborns with Pulmonary Hypertension. Pilot studies revealed that inhalation of NO increases systemic oxygenation in severely hypoxemic newborns with pulmonary hypertension (see Chapter 84).[3,4] The ability of inhaled NO to increase systemic oxygen levels was confirmed in several multicenter randomized controlled studies of term and near-term

babies with hypoxemia and pulmonary hypertension.[6,8,44] In one study, systemic oxygenation was observed to increase in nearly half of patients with severe persistent pulmonary hypertension of the newborn who received inhaled NO.[6] Importantly, the magnitude of the increase in oxygen levels in babies treated with inhaled NO was directly proportional to the degree of hypoxia before NO inhalation, and the increased systemic oxygenation of the NO-breathing infants was maintained in 75% of the patients. In another study, the optimal concentration of inhaled NO level was investigated[45]; although the maximum increase in systemic oxygenation was observed in babies breathing 80 ppm NO, as little as 5 to 20 ppm NO increased arterial oxygen levels above those measured in babies not breathing NO. Several studies have reported that inhaled NO decreases the need for extracorporeal membrane oxygenation (ECMO), an invasive procedure requiring systemic heparinization.[6,8,44]

Inhaled Nitric Oxide in Bronchopulmonary Dysplasia. Bronchopulmonary dysplasia (BPD) is an important chronic lung disease of prematurely born infants that results, in part, from the inhibition or disruption of normal pulmonary alveolar and microvascular development as a result of oxygen- and ventilator-induced lung injury.[46] Although an early study suggested that inhaled NO does not decrease the incidence of BPD,[47] a subsequent single-center trial involving 207 premature infants conducted by Schreiber and colleagues suggested that inhaled NO decreases the incidence of BPD and death in prematurely born infants.[48] These observations were supported by results from a later multicenter trial in which inhaled NO was noted to decrease the rate of BPD and death in premature infants with a birth weight of less than 1000 g.[49] In a more recent study of 793 newborns 34 weeks of gestational age or less, Kinsella and coauthors reported that inhaled NO decreased the incidence of BPD in the subset of 129 infants with a birth weight of at least 1000 g.[50] Furthermore, in another multicenter study of 582 premature infants with a birth weight of 1250 g or less in whom inhaled NO was commenced 7 to 21 days after birth, Ballard and coworkers reported that inhalation of NO improved survival and reduced the incidence of BPD.[51] Although these results are encouraging when considered together, additional studies need to be performed before the role of inhaled NO in preventing BPD can be defined.

Safety of Inhaled Nitric Oxide in the Newborn. Even though studies in newborns and infants suggest that prolonged inhalation of NO is safe,[52] the long-term pulmonary and extrapulmonary effects of inhaled NO are unknown. In particular, the effects of chronic NO inhalation on normal pulmonary cell proliferation and differentiation, as well as on alveolar and microvascular development, are unknown.

NO can increase cGMP levels in platelets and inhibit their function (reviewed by Schwarz and colleagues[53]). The potential of inhaled NO to alter platelet function[54] is of particular concern for immature infants because abnormal hemostatic activity might increase the incidence or evolution of intraventricular hemorrhage (IVH) and associated neurologic injury. In one study, breathing NO was associated with increased mortality and rates of IVH in infants weighing 1000 g or less.[49] Nevertheless, data from several other studies suggest that inhaled NO does not increase the incidence or severity of IVH in premature babies.[47,48,51] In fact, in one very large study of premature infants, inhaled NO was reported to decrease the frequency of IVH and its sequelae.[50]

It is uncertain whether the improvement in pulmonary disease in some premature babies who breathed NO is associated with improved neurologic development. In a European multicenter trial of nearly 100 premature babies, inhaled NO was not observed to affect the incidence of death or severe disability at 1 year corrected for postnatal age.[55] On the other hand, a more rigorous evaluation of older premature babies treated in another trial suggested that inhaled NO can improve neurologic outcomes.[56]

Uses of Inhaled Nitric Oxide in Adult Patients with Cardiopulmonary Diseases

Pulmonary Vasoreactivity Testing in the Cardiac Catheterization Laboratory. Demonstration of a positive response to vasodilating agents in patients with pulmonary hypertension correlates with an improved long-term clinical outcome and has been used to guide medical therapy (see Chapter 60).[57] Although a number of vasodilators, including intravenous prostacyclin and calcium channel blockers, have been used for diagnostic testing during cardiac catheterization, such circulating agents produce systemic vasodilation and increase intrapulmonary right-to-left shunting.[58] In contrast, recent studies indicate that inhaled NO is a safe and effective agent to determine the pulmonary circulation's capacity for vasodilation in pediatric[59] and adult patients[60,61] with pulmonary hypertension. In these patients, selective pulmonary vasodilation during NO breathing correlates with a subsequent response to oral and systemically active vasodilators.[62,63] Preoperative hemodynamic evaluation with oxygen and inhaled NO as opposed to a test with oxygen alone is suggested to more accurately identify patients with pulmonary hypertension who will be the most appropriate candidates for corrective cardiac surgery or transplantation.[64] In 1998, inhaled NO was the primary vasodilator used to test pulmonary vascular responsiveness in 32% of U.S. tertiary hospitals.[65] According to a survey in 2000, 94% of pediatric cardiologists consider inhaled NO to be a clinically proven agent to test pulmonary vasoreactivity in the cardiac catheterization laboratory.[66]

Treatment of Chronic Pulmonary Hypertension with Inhaled Nitric Oxide. Even though continuous administration of intravenous prostacyclin (epoprostenol) is associated with improved survival and exercise tolerance,[67] indwelling central venous catheters carry the risk of bacteremia. The feasibility of an ambulatory NO delivery system has been reported in a small number of patients with primary pulmonary hypertension.[68,69] The safety and efficacy of long-term domiciliary NO inhalation require investigation in larger patient populations. On the other hand, clinical trials with newer orally active vasodilators (bosentan,[70] beraprost,[71] and sildenafil[72]) in patients with primary pulmonary hypertension have reported promising results. Although these orally active medications are more convenient for ambulatory patients than intravenous or inhalation therapies are, inhaled NO may prove more effective than these agents. In addition, because these agents may cause systemic hypotension, inhaled NO may prove safer.

Treatment of Cardiogenic Shock Caused by Right Ventricular Myocardial Infarction. RV injury and dysfunction may complicate inferior myocardial infarction (MI) caused by right coronary artery occlusion. If coronary revascularization is delayed, cardiogenic shock may develop despite preserved LV function and is associated with a high frequency of mortality. In a small series of patients with cardiogenic shock

caused by right ventricular myocardial infarction (RVMI), Inglessis and colleagues reported that unloading the right ventricle by breathing 80 ppm NO acutely improved the cardiac index by approximately 25%.[73] In RVMI patients with a patent foramen ovale, treatment with inhaled NO markedly reduced right-to-left shunting and improved systemic oxygenation. Further studies are required to determine whether NO inhalation will decrease the morbidity and mortality associated with RVMI.

Acute Respiratory Distress Syndrome in Adults. In clinical studies of patients with severe ARDS, inhaled NO has been shown to produce selective pulmonary vasodilation,[20] decrease pulmonary capillary pressure[74] and pulmonary transvascular albumin flux,[75] and improve oxygenation (see Chapters 92 and 93).[20] Although these clinical studies, as well as a number of studies in animal models of acute lung injury, have demonstrated a physiologic benefit of inhaled NO therapy, subsequent clinical trials reported disappointing results. Two pilot trials were conducted in the United States. Both were randomized, unblinded, controlled, single-center studies with small sample sizes ($n = 40$ and $n = 30$) and demonstrated only transient improvements in oxygenation during the first 24 hours of treatment but no effect of inhaled NO on the mortality rate.[22,76] Subsequently, a randomized, double-blind, placebo-controlled trial of 177 patients (average entry $Pao_2/Fio_2 \approx 129$ mm Hg) treated with various concentrations of inhaled NO (1.25 to 80 ppm) versus placebo failed to find a difference in either the mortality rate or the number of days alive and off mechanical ventilation.[77] A prospective, randomized, unblinded European multicenter trial of inhaled NO in patients with acute lung injury ($n = 286$, average entry $Pao_2/Fio_2 \approx 105$ mm Hg) also demonstrated no effect on mortality or the duration of mechanical ventilation; however, the frequency of progression to severe respiratory failure from milder respiratory failure was decreased by inhaled NO.[78] Although renal failure was identified as a possible adverse effect of NO inhalation in the European trial, this finding remains unexplained and has not been confirmed in other clinical trials.

Several possible explanations why the physiologically beneficial effects of inhaled NO in ARDS were not translated into clinical outcome benefits have been offered: (1) because the majority of patients dying of ARDS suffer from multiple organ failure, the beneficial effects of a lung-selective therapy such as inhaled NO (e.g., improvement in gas exchange and reduced pulmonary artery pressure) may not alter the overall survival rate; (2) the beneficial effects of NO inhalation may be offset by toxic effects such as the formation of peroxynitrite in the presence of inflammation-produced superoxide; and (3) inhalation of NO has a narrow therapeutic range, and the effective dose may have changed over time as patients and their disease states vary.[79] Whether the subgroup of severely hypoxemic ARDS patients will respond more favorably to inhaled NO and have an improved clinical outcome has not yet been conclusively resolved.[80]

Chronic Obstructive Pulmonary Disease. Severe chronic obstructive pulmonary disease (COPD) is frequently complicated by pulmonary hypertension and hypoxemia. Systemic hypoxemia in COPD is primarily caused by ventilation-perfusion mismatching and not by intrapulmonary right-to-left shunting (as in ARDS). Hypoxic pulmonary vasoconstriction diverts venous blood flow to better ventilated lung regions, thereby improving arterial oxygenation. Although inhaled NO is a more potent pulmonary vasodilator than oxygen in patients with COPD, breathing inhaled NO admixed with air may produce vasodilation of poorly ventilated regions of the obstructed lung without receiving sufficient oxygen replenishment. Increasing blood flow with inhaled NO to these hypoventilated lung areas can reduce the transcutaneous arterial oxygen tension[81] and Pao_2.[82] However, when NO gas is breathed in combination with modest oxygen enrichment (1 L/min via facemask),[83] Pao_2 is increased to a greater extent than with oxygen therapy alone. Along these lines, a recent controlled, prospective randomized trial demonstrated that the combined use of supplemental oxygen and inhaled NO for a period of 3 months via a portable inspiratory pulsing device caused greater improvement in pulmonary hemodynamics than supplemental oxygen alone did without worsening the oxygenation of COPD patients.[84] Further studies are needed to determine the effect of long-term ambulatory breathing of pulsed NO and oxygen on the quality of life and mortality rate of patients with severe COPD.

Treatment of Perioperative Pulmonary Hypertension with Inhaled Nitric Oxide

Coronary Artery Bypass Grafting. Pulmonary hypertension often complicates the management of patients during and after cardiac surgery involving cardiopulmonary bypass (CPB) (see Chapter 60). A number of uncontrolled studies have demonstrated that 20 to 40 ppm inhaled NO effectively decreases pulmonary artery pressure after coronary artery bypass grafting (CABG), even in patients without significant preoperative pulmonary hypertension.[85-87] Although these results suggest a role for inhaled NO in treating transient pulmonary hypertension after CPB, whether inhaled NO can improve the clinically important outcomes of patients undergoing CABG is unknown. A large prospective randomized trial would be needed to define a role for inhaled NO in this patient population.

Congenital Heart Disease. Postoperative pulmonary hypertensive crises are an important cause of morbidity and mortality after congenital heart surgery[88,89] and may be precipitated by diminished NO bioavailability because of endothelial dysfunction.[30,90] PAH and subsequent heart failure are associated with certain types of congenital heart defects, particularly those characterized by increased pulmonary blood flow (e.g., ventricular septal defect and atrioventricular canal). Inhaled NO has been reported to ameliorate the postoperative pulmonary hypertension of congenital heart disease[91,92] and decrease the need for postoperative ECMO.[93] In a randomized double-blind study, Miller and colleagues examined the effects of the prophylactic use of inhaled NO in high-risk infants undergoing congenital heart surgery.[94] One hundred twenty-four patients were randomized before surgery, and inclusion in the study did not depend on the presence of pulmonary hypertension. They reported that when compared with placebo, infants who inhaled 10 ppm NO continuously after surgery until just before extubation had fewer pulmonary hypertensive crises and a shorter time to eligibility for extubation. These studies indicate that inhaled NO safely decreases postoperative pulmonary hypertension in patients after surgery for congenital heart disease. Further studies are needed to test if inhaled NO should be used in all patients after CPB for congenital heart disease surgery to decrease their perioperative morbidity and mortality.

Valvular Heart Disease. Patients with chronic mitral valve disease may have preoperative pulmonary hypertension caused by retrograde transmission of elevated left atrial pressure (see Chapter 60). After mitral valve repair or replacement,

pulmonary vascular remodeling and vasoconstriction may persist or slowly decrease. It has been reported that the vasodilatory response to inhaled NO is variable in patients with valvular heart disease.[86,95] The variability in dilator response is likely to be related to the balance between pulmonary vascular remodeling and active vasoconstriction. Treatment with inhaled NO after repair of valvular heart disease can relieve the vasoconstrictor component of pulmonary hypertension in these patients.[96] Whether inhaled NO can alter the clinical outcome of patients after valvular heart surgery is unknown.

Cardiac Transplantation. Pulmonary hypertension in cardiac transplant recipients is a major cause of right heart failure and early death. Goals in the management of acute RV failure include preservation of coronary perfusion through maintenance of systemic blood pressure and reduction of RV afterload by decreasing PVR.[97] In contrast to therapy with intravenous vasodilators, which often cause systemic hypotension, inhaled NO has been shown in a small group of patients to selectively reduce PVR and enhance RV stroke work after cardiac transplantation.[98] A positive pulmonary vasodilator response to inhalation of NO has been used as a criterion to select patients for cardiac transplantation.[99]

Insertion of Left Ventricular Assist Devices. RV dysfunction occurs in 20% to 50% of patients after insertion of a left ventricular assist device (LVAD).[100] The ability of the right ventricle to pump sufficient quantities of blood to the LVAD is critically related to the intrinsic contractility of the right ventricle and RV afterload, which is influenced by PVR. PVR is usually elevated in long-standing congestive heart failure and can be further increased in the early postoperative period by the effects of CPB. Inhaled NO has been shown to effectively decrease PVR in the setting of RV dysfunction after LVAD insertion.[101] A trial of inhaled NO is recommended before consideration of implantation of an RV assist device because this invasive procedure may be avoided if there is a salutary response to inhaled NO.[102] In a randomized, double-blind trial, Argenziano and coworkers demonstrated the hemodynamic benefits of inhaled NO (decreased pulmonary artery pressure and increased LVAD flow) in LVAD recipients with pulmonary hypertension.[103]

Treatment of Pulmonary Ischemia-Reperfusion Injury. Ischemia-reperfusion (I-R) injury is one of the major causes of early graft failure after lung transplantation. Adhesion and sequestration of activated leukocytes by activated pulmonary endothelium is believed to be an important mechanism of I-R injury. NO possesses anti-inflammatory properties, and inhaled NO has been shown to attenuate pulmonary I-R injury in preclinical studies.[104] Although two uncontrolled clinical studies suggested that inhaled NO may prevent lung I/R injury,[105,106] a small randomized, placebo-controlled study demonstrated that inhaling 20 ppm NO commencing 10 minutes after reperfusion did not affect the physiologic or clinical outcome of patients after lung transplantation.[107] Additional studies are required to define the therapeutic role of inhaled NO in patients in whom I-R injury develops after lung transplantation.

Experimental Methods to Improve the Efficacy of Inhaled Nitric Oxide

In an important fraction of patients, inhalation of NO fails to reduce PVR, improve oxygenation, or both. Moreover, because the pulmonary vasodilator effects of inhaled NO disappear after NO is discontinued, continuous therapy is required. Use of the lowest effective concentration of NO may decrease the risk for methemoglobinemia, augment matching of ventilation and perfusion, and theoretically, minimize lung toxicity. Based on an understanding of the NO/cGMP signal transduction system, several research groups have developed strategies to augment or prolong the efficacy of inhaled NO (or both). For example, inhibition of PDE5, the cGMP-specific PDE, by intravenous administration of zaprinast prolonged the pulmonary vasodilator effects of NO inhalation in awake adult lambs with U46619-induced pulmonary hypertension[108] and augmented the effects of inhaled NO in perinatal lambs with pulmonary hypertension induced by prenatal ligation of the ductus arteriosus.[109] Delivery of PDE5 inhibitors by inhalation also augmented and prolonged the efficacy of inhaled NO in adult lambs.[110,111] Steinhorn and colleagues have reported that reduction of NO scavenging by superoxide via superoxide dismutase can augment the efficacy of inhaled NO in neonatal pulmonary hypertension.[112] In studies of awake adult lambs with U46619-induced pulmonary hypertension, Evgenov and coauthors reported that agents that sensitize sGC to NO can augment and prolong the pulmonary vasodilator effects of inhaled NO.[113,114]

These observations in animal models have been extended to patients with pulmonary diseases. For example, sildenafil augmented and prolonged the pulmonary vasodilator effects of inhaled NO in patients with PAH secondary to pulmonary vascular disease[115] or congestive heart failure.[116] Importantly, sildenafil was also found to attenuate the pulmonary vascular rebound associated with discontinuing NO inhalation[117] and may facilitate weaning from NO gas in patients with cardiovascular instability.

Extrapulmonary Effects of Breathing Nitric Oxide

Because breathing NO decreased PVR without altering systemic blood pressure, it was initially proposed that the action of inhaled NO was limited to the lungs. It was hypothesized that any NO reaching the bloodstream would be rapidly scavenged by oxygenated Hb and lead to the production of nitrate and MetHb.[2] However, as early as 1993, evidence began to accumulate that inhalation of NO could inhibit platelet function.[54] Subsequently, studies describing a wide range of systemic effects of breathing NO were published, as summarized recently by McMahon and Doctor[118] and highlighted in Table 31-1. In this section, the ability of NO inhalation to decrease I-R injury is reviewed, and circumstances in which breathing NO can modulate systemic vascular tone are discussed. In addition, potential mechanisms by which inhaled NO may exert its systemic effects are outlined.

Inhaled Nitric Oxide and Platelet Function

The ability of NO-donor compounds to inhibit platelet function is well known, but the therapeutic application of their antithrombotic effects is limited by systemic hypotension. In 1993, Hogman and colleagues first reported that breathing NO (30 ppm) could prolong the bleeding time in rabbits and healthy human subjects.[54] Subsequent reports from multiple research groups presented conflicting data, with some investigators reporting that breathing NO increases the bleeding time in neonates and adults

Table 31-1 Biological Effects of Breathing Nitric Oxide with Selected Physiologic Impacts and Potential Therapeutic Applications

Biologic Effect	Impact	Therapeutic Application	References*
Pulmonary vasodilation	Reduction in pulmonary artery pressure	Pulmonary arterial hypertension	2
	Decrease in extrapulmonary right-to-left shunting and improved systemic oxygenation	Pulmonary hypertension of the newborn and congenital heart disease	3, 4, 91
	Decrease in RV afterload	RV failure after LVAD placement	103
		RVMI complicated by cardiogenic shock	73
		RV failure after cardiac surgery	85
Improved matching of lung ventilation and perfusion	Increased systemic oxygenation	Acute lung injury/pneumonia	20, 77, 78
		Chronic pulmonary disease	84
Pulmonary vascular and alveolar development	Decreased vascular SMC hyperplasia and increased alveolarization in the injured developing lung	Prevent or ameliorate pulmonary hypertension in infants with congenital heart disease and chronic lung disease in premature infants	32, 33, 39, 40
Systemic effects of breathing NO	Platelet inhibition	Decrease thrombosis after coronary thrombolysis (dogs)	54, 119
	Leukocyte inhibition	Improve mesenteric blood flow after ischemia and reperfusion (cats)	120
		Decrease infarct size in cardiac ischemia-reperfusion injury	121, 122
	Oxidization of extraerythrocytic hemoglobin	Decrease hemolysis-induced vasoconstriction and renal dysfunction (dogs)	123

and others reporting that NO inhalation does not alter either the bleeding time or platelet function. Prolongation of the bleeding time raised the possibility of increased hemorrhagic complications in patients treated with inhaled NO, particularly neonates at increased risk for intracranial hemorrhage. On the other hand, the observation that breathing NO could decrease platelet function led other investigators to examine in animal models whether NO inhalation could be used to treat vascular diseases associated with platelet activation. For example, Semigran's group reported that in a canine model of coronary thrombosis after thrombolysis, breathing 20 and 80 ppm NO decreased platelet-mediated thrombosis,[119] an effect that was augmented by coadministration of inhibitors of type 5 PDE.[124] In addition, Lee and coworkers observed that breathing 80 ppm NO for 1 or 2 weeks decreased neointimal formation in rat carotid arteries subjected to balloon injury.[125] In both models, breathing NO did not prolong the bleeding time or cause systemic hypotension.

Inhaled Nitric Oxide and Ischemia-Reperfusion Injury of Extrapulmonary Organs

Observations that NO can form stable, biologically active adducts with protein thiol constituents led Kubes' group to examine whether inhaled NO could be used to deliver NO to peripheral tissues.[120] Studying postcapillary venules from cats subjected to intestinal I-R, these investigators observed that breathing 80 ppm NO, but not 20 ppm, prevented the reduction in blood flow, the increase in leukocyte activation (rolling, adherence, and migration), and vascular leakage. The investigators also observed that breathing NO prevented the arteriolar constriction and neutrophil activation induced by the administration of N^G-nitro-L-arginine methyl ester (L-NAME), a NOS inhibitor. Interestingly, because inhaled NO did not alter neutrophil activation or vascular leakage in endotoxin-challenged cats, the investigators proposed that inhaled NO does not affect peripheral tissues with abundant NO (produced by inducible NOS). In contrast, Neviere and coauthors reported that breathing NO (10 ppm) decreased adhesion of leukocytes to the mesenteric venular endothelium of endotoxin-challenged rats.[126] Furthermore, breathing NO prevented endotoxin-induced cardiac dysfunction and leukocyte accumulation. In a subsequent report, Kubes and associates reported that in contrast to NO-donor compounds, inhaled NO did not prevent the increase in mucosal permeability induced by intestinal I-R and suggested that the effects of breathing NO were limited to the vascular compartment.[127]

Based on these observations, Guery and colleagues evaluated the ability of breathing NO to preserve cardiac function after myocardial I-R injury.[128] Hearts from rats that had breathed air with or without 10 ppm NO for 4 hours were isolated and perfused. Coronary perfusion was stopped for 30 minutes, followed by reperfusion for 40 minutes. The investigators observed that pretreatment with inhaled NO led to improved systolic and diastolic function after ischemia and reperfusion. These findings were extended by Hataishi and colleagues, who examined the ability of breathing NO to decrease cardiac I-R injury in intact mice.[121] They observed that breathing NO for the final 20 minutes of ischemia and for 24 hours after reperfusion decreased MI size and improved systolic and diastolic function. Breathing 80 ppm NO decreased MI size similarly after 30, 60, or 120 minutes of ischemia. Breathing 40 and 80 ppm NO decreased myocardial I-R injury equally, but 20 ppm was not effective. Breathing NO decreased cardiac neutrophil accumulation, and leukocyte depletion prevented the beneficial effects of NO on MI size. Observations in rodents have recently been extended to a clinically relevant porcine model of cardiac I-R injury; Liu and colleagues reported that in pigs subjected to 50 minutes of cardiac ischemia and 4 hours of reperfusion, breathing 80 ppm NO decreased MI

size and improved myocardial perfusion.[122] The ability of inhaled NO to decrease cardiac I-R injury is further suggested by the observation that breathing NO decreased the release of cardiac enzymes in a small series of patients undergoing CPB.[129] Taken together with the observations of Fox-Robichaud and coworkers,[120] these results suggest that when inhaled, the concentrations of NO required to elicit systemic effects (in vivo) are greater than those required to directly elicit pulmonary vascular effects. Based on these considerations, a randomized clinical trial has been initiated to test whether breathing 80 ppm can decrease MI size in patients with ST-segment elevation MI.

Inhaled Nitric Oxide and Systemic Vascular Tone

Whether breathing NO can modulate systemic vascular tone remains controversial. Clinically significant systemic hypotension has not been observed in adults and babies with a wide variety of disorders treated with NO concentrations of up to 80 ppm. However, breathing 80 ppm NO has been reported to attenuate the ability of L-NAME to increase blood pressure in cats.[127] Cannon and colleagues reported that breathing 80 ppm NO increased forearm blood flow in healthy subjects treated by intrabrachial artery infusion of the NOS inhibitor L-NMMA.[130] In contrast, Hataishi and colleagues observed that breathing NO did not decrease SVR in L-NAME–treated mice or in mice congenitally deficient in NOS3.[131]

The ability of inhaled NO to decrease SVR is perhaps clearest in the case of the endothelial dysfunction associated with hemolysis. Studying dogs with free water–induced hemolysis, Minneci and associates observed that the presence of Hb in plasma induced hypertension and decreased creatinine clearance, probably via scavenging of endothelium-derived NO.[123] Breathing 80 ppm NO attenuated the hemolysis-induced hypertension and renal dysfunction by oxidizing free Hb to MetHb and preventing the scavenging of endogenous NO. The authors proposed that inhalation of NO may attenuate the hypertension, vascular disease, and prothrombotic state characteristic of diseases associated with hemolysis, such as sickle cell anemia.

How Does Inhaled Nitric Oxide Exert Its Systemic Effects?

With the exception of the case of hemolysis, the mechanisms by which NO, once inhaled, is able to induce responses in the periphery remain incompletely understood. One hypothesis is that during NO inhalation, blood cells, including white blood cells and platelets, are exposed to NO before scavenging of the gas by red blood cells and that NO-exposed blood cells are responsible for the systemic effects of inhaled NO. For example, exposure of platelets to NO in the pulmonary circulation may inhibit their activation at the site of vascular injury. However, this hypothesis does not fully account for the dilator effects of breathing NO seen in some vascular beds or the observations of Fox-Robichaud and coworkers,[120] who reported that inhaled NO did not alter the ability of feline blood leukocytes to bind to immobilized platelet monomers ex vivo.

An alternative hypothesis is that some of the inhaled NO escapes scavenging by Hb and is carried in a stable, bioavailable form to the periphery. Loscalzo's group proposed that endogenously synthesized NO reacts with low- and high-molecular-weight thiols in blood, including serum albumin.[132,133] These *S*-nitrosothiols can deliver NO to tissues distant from the site of its synthesis. Stamler and colleagues[132] observed that NO reacts with the thiol group on Cys93 of the Hb β-chain and that *S*-nitrosylation of Hb (SNO-Hb) is dependent on the oxygen tension enabling erythrocytes to load Hb in the rich oxygen environment of the lungs and release low-molecular-weight *S*-nitrosothiols in the relatively hypoxic periphery (reviewed by McMahan and Doctor[118]). NO can be oxidized in blood to nitrite, which regenerates NO in the presence of nitrite reductases, including deoxyhemoglobin (reviewed by Gladwin and colleagues[134]). Erythrocyte SNO-Hb and nitrite have both been implicated as potential mediators of the systemic vasodilation induced by tissue hypoxia. NO may also react with other plasma species that are subsequently capable of regenerating NO, including *N*-nitrosamines, iron-nitrosyls, and nitrated lipids.

Even before it was appreciated that breathing NO could selectively dilate the pulmonary vasculature, several research groups examined the metabolic fate of inhaled NO. In 1975, Oda and colleagues reported that inhalation of NO led to the formation of nitrosyl-Hb in the blood of mice, rats, and rabbits.[135] In 1987, Yoshida and Kasama reported that breathing ^{15}NO (145 ppm for 123 minutes) led to the formation of nitrosyl-Hb, nitrite, and nitrate.[136] More recently, Cannon and coworkers found that in healthy adults breathing 80 ppm NO, nitrosyl-Hb concentrations increased markedly, whereas nitrite increased modestly.[130] Arterial concentrations of both products were greater than venous levels, thus suggesting consumption in peripheral tissues. Cannon and colleagues did not detect an increase in plasma *S*-nitrosothiols or SNO-Hb. In contrast, Ng and coauthors reported that in cats, breathing 80 ppm NO increased plasma levels of *S*-nitrosoalbumin and nitrite, both of which were further increased in the setting of intestinal I-R.[137] Arterial levels of *S*-nitrosoalbumin were higher than venous levels, whereas the converse was true for nitrite levels, which suggested that *S*-nitrosoalbumin was consumed in the periphery and nitrite was generated.

The potential importance of nitrite as a mediator of inhaled NO's impact on I-R injury was highlighted in recent studies of Duranski and colleagues.[138] They observed that small increases in blood nitrite levels were sufficient to decrease I-R injury in the liver and heart. Moreover, in studies of murine I-R injury, Hataishi and coauthors[121] reported that breathing NO increased nitrite concentrations in plasma and blood to levels similar to those demonstrated to be effective by Duranski and associates.

Controversy regarding the identity of the circulating NO-derived products whose levels increase during inhalation of NO may be attributable to differences in the methods used to detect these products. Nonetheless, there appears to be a consensus that bioavailable NO derivatives contribute to the effects of breathing NO on the periphery. However, many questions remain, including the following: Do NO-derived products accumulate in tissues during the inhalation of NO? Are cGMP-dependent or cGMP-independent mechanisms responsible for the systemic effects of inhaled NO?

Safety Issues and Method of Administration

Prolonged inhalation of low levels of NO appears to be safe. The major clinical toxicity is due to the formation of NO_2 and methemoglobinemia. Nitrogen dioxide is rapidly converted to nitric acid in aqueous solution (acid rain) and is highly toxic to the respiratory tract. Increased airway reactivity has been reported

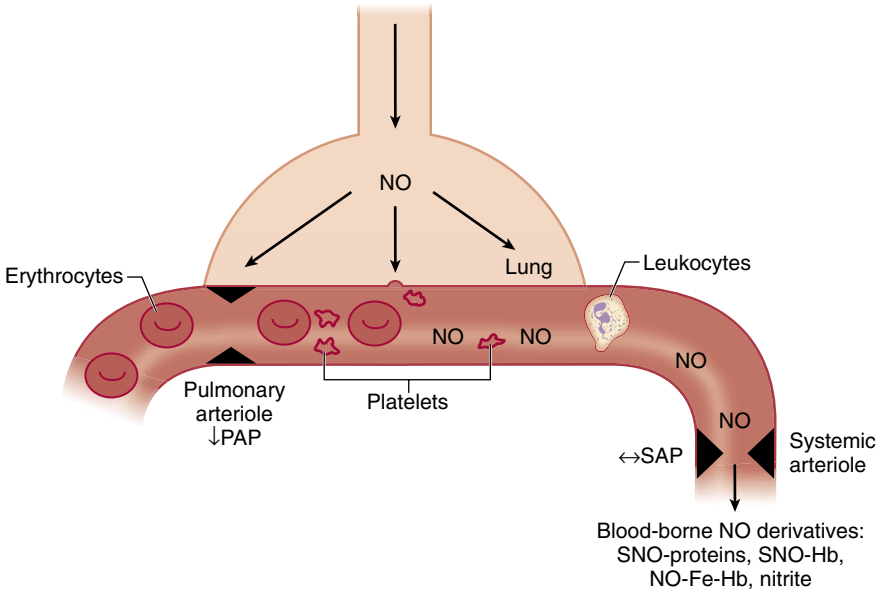

Figure 31-6 Inhaled nitric oxide (NO) is a selective pulmonary vasodilator with actions on the systemic vasculature. A schematic of an alveolar-capillary unit is presented in which the ability of inhaled NO to dilate pulmonary arterioles and reduce pulmonary artery pressure (PAP) is highlighted. Although inhaled NO does not dilate systemic arterioles or alter systemic arterial pressure (SAP) under normal conditions, inhaled NO does have systemic effects (described in text) that may be mediated by circulating cells exposed to NO in the lungs and blood-borne NO derivatives: SNO-proteins or *S*-nitroso proteins including SNO-albumin; SNO-Hb or S-nitroso-Hb (nitrosylated on Cys93 of the β-chain); NO-Fe-Hb or nitrosyl-Hb; and nitrite. *(From Bloch KD, Ichinose F, Robert JD, Zapol WM: Inhaled NO as a therapeutic agent. Cardiovasc Res 75:339-348, 2007, with permission.)*

in humans after exposure to as low as 1.5 ppm NO_2.[139] At higher inhaled NO_2 concentrations, pulmonary edema is the major toxicologic effect[140] and can result in rapid death after inhalation.[141]

Inhaled NO can combine with Hb to form nitrosyl-Hb, which is rapidly oxidized to MetHb. Rates of uptake and release of NO from ferrous (Fe^{2+}) Hb are 10^5- to 10^6-fold greater than those of oxygen. Tissue hypoxia can be produced at excessive circulating MetHb concentrations. In general, cyanosis does not appear until MetHb levels approach 15% to 20%, and clinical symptoms of hypoxia (such as fatigue and dyspnea) become significant at MetHb levels above 30% of the Hb concentration.[142] The enzyme MetHb reductase rapidly converts MetHb to Hb in red blood cells. Because neonates have reduced activity of this enzyme, they are at greater risk than adults for the development of significant methemoglobinemia after the inhalation of high levels of NO for prolonged periods.[142] Blood MetHb concentrations and inspired NO_2 concentrations were frequently monitored in clinical trials of inhaled NO in adults and neonates.[6,77,143,144] In a large number of adult (n = 120) and newborn patients (n = 351) pooled from several clinical trials, significant methemoglobinemia or NO_2 formation was uncommon in patients breathing NO at doses ranging from 1.25 to 80 ppm (see the summary table in the article by Steudel and coworkers).[19] If MetHb or NO_2 levels increased above predetermined limits, the concentration of inhaled NO was decreased. Discontinuation of NO administration because of excessive NO_2 or MetHb formation was necessary in only 3 of 471 patients (0.6%).

Inhaled NO has been demonstrated to be a selective pulmonary vasodilator in heart failure patients, although breathing NO can be accompanied by an elevation in LV filling pressure in patients with severe LV dysfunction.[58,145] Taken together with the in vitro experimental evidence of a direct negative inotropic action of NO,[146,147] these clinical observations led to concern that inhaled NO may exert clinically important negative inotropic effects in patients with impaired LV function. However, investigators learned that the elevation in LV filling pressure that occurs with breathing NO is due to the augmentation of filling into a relatively noncompliant left ventricle and is not caused by a negative inotropic effect.[148] This concept is supported by an observation in heart failure patients with mechanical LV assistance that inhaled NO increases LV filling pressure only when cardiac output is not assisted.[149] Nonetheless, it is important to be aware of the possibility that inhaled NO can produce pulmonary vasodilation and may overwhelm a failing left ventricle, thereby producing pulmonary edema.

Other Inhaled Pulmonary Vasodilators

Successful clinical use of inhaled NO as a selective pulmonary vasodilator prompted the search for other alternatives, at least in part because of the significant cost of inhaled NO therapy (e.g., $3000/day with a $12,000 monthly cap) in the United States.[150] A wide variety of intravenous vasodilators were clinically tested via the inhaled route, including prostacyclin (prostaglandin I_2 [PGI_2]),[151] milrinone,[152] nitroglycerin,[153] sodium nitroprusside,[154] PGE_1,[155] and iloprost, a stable analog of PGI_2.[156] It was expected that inhalation of intravenous vasodilators would maximize drug levels in the lung while minimizing their systemic effects (Fig. 31-6). Although encouraging results have been reported by some studies, especially with inhaled PGI_2 and iloprost, at the time of this writing, the efficacy and safety profile of these inhaled vasodilators have not been established. For instance, even though very brief exposure to inhaled PGI_2 has been reported to decrease PVR similar to inhaled NO,[157,158] PGI_2 is known to cause hypotension when large doses are inhaled.[158] The plasma half-life of PGI_2 is sufficiently long (5 minutes) to allow systemic effects, and systemic arterial levels of an active metabolite have been measured during the inhalation of even small doses of PGI_2. Furthermore, PGI_2 must be dissolved in a highly viscous and basic glycine diluent (pH = 10.5) that is associated with tracheitis,[159] interstitial pneumonia,[160] and ventilator valve malfunction.[161] Finally, although the drug cost associated with inhaled PGI_2 is claimed to be lower than that of inhaled NO, a robust cost comparison taking

into account the impact of prolonged therapy on overall cost has not been done. For example, if one therapy reduces ICU stay by 1 day or the need for an RV assist device or ECMO perfusion, the difference in drug cost would be incidental. Further studies appropriately designed to address these issues are needed to better define the role of other "less selective" inhaled pulmonary vasodilators.

Conclusion

Inhaled NO is the first vasodilator to produce truly selective pulmonary vasodilation. It is characterized by pulmonary vasoselectivity and it also raises arterial oxygenation and enhances pulmonary ventilation-perfusion matching by increasing blood flow to ventilated regions of the lung. A large number of laboratory and clinical research studies have been performed to delineate its biochemistry, physiology, side effects, and clinical efficacy in various diseases of children and adults. Nearly simultaneously, the clinical use of inhaled NO has become widespread. It is estimated that twenty thousand patients are treated with inhaled NO annually in the United States. During the past 16 years, inhaled NO has been used to treat pulmonary hypertension and hypoxemia in more than a hundred thousand pediatric and adult patients worldwide. For many it is lifesaving. The experimental use of inhaled NO continues to be a unique and fascinating approach to studying and treating diseases as diverse as acute rejection of a transplanted lung and sickle cell crisis. In evaluating this complex field, it is critical that our view not become colored by a single study of a particular disease state. As with most medical advances, it is the accumulation of a wide-ranging body of clinical research that will eventually determine the place of NO inhalation therapy in our therapeutic armamentarium for many diseases.

32 Complementary and Alternative Therapies

Key Points

1. Despite lack of federal oversight, herbal medication use has increased dramatically in the overall population and particularly in preoperative patients.
2. Patients may not volunteer information unless they are specifically queried about herbal medication use.
3. Many commonly used herbs have side effects that affect drug metabolism, bleeding, and neuronal function.
4. Although stopping the use of herbal medication up to 2 weeks preoperatively can eliminate many of these problems, patients often arrive for surgery without a preoperative visit 2 weeks before surgery. Knowledge of specific interactions and metabolism of these herbs can provide practical guidelines to facilitate care.
5. Other complementary therapies, including acupuncture and music therapy, have become increasingly popular, although less is known about their effectiveness.

Complementary and alternative medicine (CAM) has implications for physicians in general but has particular importance for perioperative physicians because of complications associated with the use of certain therapies and their roles as anesthesia adjuvants. In 2002, 35% of Americans used CAM therapies.[1] Visits to CAM practitioners exceed those to American primary care physicians,[2] and CAM is even more widely used in Europe, where herbal medicines are more frequently prescribed than conventional drugs in many situations. Of particular relevance for anesthesiologists is that patients undergoing surgery appear to use CAM more than the general population does.[3,4]

Despite the public enthusiasm for CAM, scientific knowledge in this area is still incomplete and often confusing for practitioners and patients. One recent study confirmed poor knowledge of this subject among physicians.[5] Recommendations for clinicians are often based on small clinical trials, case reports, animal studies, predictions derived from known pharmacology, and expert opinion. Research is essential because CAM therapies are often widely adopted by the public before adequate data are available to support their safety and efficacy. In 1991, Congress established the Office of Alternative Medicine, which became the National Center for Complementary and Alternative Medicine within the National Institutes of Health in 1998. In 2006, more than twice as many CAM-related English-language research articles were published as in 1996.

Practices encompassed by CAM are heterogeneous and evolving as CAM therapies are integrated into conventional medicine (e.g., diet, exercise, behavioral medicine). CAM practices can be classified into five general categories (Box 32-1).[6] This chapter is not intended as a comprehensive review of CAM. Specific therapies relevant to anesthesia are discussed, and we focus primarily on herbal medicines. Nonherbal dietary supplements, acupuncture, and music are also examined.

Herbal Medicines

Preoperative use of herbal medicines has been associated with adverse perioperative events.[3] Surveys estimate that 22% to 32% of patients undergoing surgery use herbal medications.[7-9] As pharmacologically active agents, herbal medicines may affect the perioperative period through several mechanisms: direct effects (i.e., intrinsic pharmacologic effects), pharmacodynamic interactions (i.e., alteration of the action of conventional drugs at effector sites), and pharmacokinetic interactions (i.e., alteration of the absorption, distribution, metabolism, and elimination of conventional drugs). Because approximately 50% of herbal medicine users take multiple herbs concomitantly[8] and 25% of herbal medicine users take prescription drugs,[10] adverse effects are difficult to predict and attribute. For example, PC-SPES, a commercially available combination of eight herbs used by patients with prostate cancer, has been associated with thrombotic (i.e., deep venous thrombosis and pulmonary embolism) and hemorrhagic (i.e., anticoagulation from phytocoumarins) complications.[11]

Herbal medicines are associated with problems not usually found with conventional drugs.[12] Because herbal medicines are classified as dietary supplements, they are not subject to

Box 32-1 Five Major Categories of Complementary and Alternative Medicine

1. Alternative medical systems (e.g., homeopathic medicine, naturopathic medicine, traditional Chinese medicine, ayurveda)
2. Mind-body interventions (e.g., meditation; prayer; art, music, or dance therapy)
3. Biologically based treatments (e.g., herbal medicines, dietary supplements)
4. Manipulative and body-based methods (e.g., chiropractic manipulation, osteopathic manipulation, massage)
5. Energy therapies (e.g., acupuncture, electromagnetic fields, reiki, qi gong)

Adapted from the National Center for Complementary and Alternative Medicine. Available at http://nccam.nih.gov/health/whatiscam/ Accessed August 15, 2003.

preclinical animal studies, premarketing controlled clinical trials, or postmarketing surveillance. Under current law, the burden is shifted to the U.S. Food and Drug Administration (FDA) to prove products unsafe before they can be withdrawn from the market. Commercial herbal medicine preparations may have unpredictable pharmacologic effects resulting from inaccurate labeling, misidentified plants, adulterants, variations in natural potency, and unstandardized processing methods.

In this chapter we discuss the preoperative assessment and management of patients who use herbal medicines and examine nine herbal medicines that have the greatest impact on perioperative patient care: echinacea, ephedra, garlic, *Ginkgo biloba*, ginseng, kava, saw palmetto, St. John's wort, and valerian (Table 32-1). These nine account for 50% of the herbal medicines sold in the United States (Box 32-2).[13] Print and Internet resources for additional information on herbal medicines are provided in Table 32-2.

Preoperative Assessment and Management

Preoperative assessment should address the use of herbal medicines (see Chapter 34). However, 90% of anesthesiologists do not routinely ask about herbal medicine use.[14] Moreover, more than 70% of patients are not forthcoming about their herbal medicine use during routine preoperative assessment.[8] When a positive history of herbal medicine use is elicited, one in five patients is unable to properly identify the preparation being taken.[15] Patients should be asked to bring their herbal medicines and other dietary supplements with them at the time of the preoperative evaluation. A positive history of herbal medicine use should also prompt anesthesiologists to suspect the presence of undiagnosed disorders causing symptoms leading to self-medication. Patients who use herbal medicines may be more likely than those who do not to avoid conventional diagnosis and therapy.[16]

In general, herbal medicines should be discontinued preoperatively. When pharmacokinetic data for the active constituents in an herbal medication are available, the timeframe for preoperative discontinuation can be tailored. For other herbal medicines, 2 weeks is recommended.[17] However, in clinical practice because many patients require nonelective surgery, are not evaluated until the day of surgery, or are noncompliant with instructions to discontinue herbal medications preoperatively, they may take herbal medicines until the day of surgery. In this situation, anesthesia can usually proceed safely at the discretion of the anesthesiologist, who should be familiar with commonly used herbal medicines to avoid or recognize and treat complications that may arise. For instance, recent use of herbal medicines that inhibit platelet function (e.g., garlic, ginseng, *Ginkgo biloba*) may warrant specific strategies for procedures with substantial intraoperative blood loss (e.g., platelet transfusion) and those that alter the risk-benefit ratio of using certain anesthetic techniques (e.g., neuraxial blockade).

Preoperative discontinuation of all herbal medicines may not eliminate complications related to their use. Withdrawal of regular medications is associated with increased morbidity and mortality after surgery.[18] Alcoholics who abstain from drinking alcohol preoperatively may have poorer postoperative outcomes than those who continue drinking preoperatively.[19] The danger of abstinence after long-term use may be similar with herbal medicines such as valerian, which has the potential to produce acute withdrawal after long-term use.

Echinacea

Three species of echinacea, a member of the daisy family, are used for the prophylaxis and treatment of viral, bacterial, and fungal infections, particularly those of upper respiratory origin, although its efficacy in the latter is doubtful.[20] A recent meta-analysis

Table 32-1 Clinically Important Effects, Perioperative Concerns, and Recommendations for Perioperative Discontinuation of Nine Commonly Used Herbal Medicines

Herbs (Common Names)	Pharmacologic Effects	Perioperative Concerns	Discontinue before Surgery
Echinacea (purple coneflower root)	Activation of cell-mediated immunity	Allergic reactions Decreases effectiveness of immunosuppressants Potential for immunosuppression with long-term use	No data
Ephedra (ma huang)	Increases heart rate and blood pressure through direct and indirect sympathomimetic effects	Risk of myocardial ischemia and stroke from tachycardia and hypertension Ventricular arrhythmias with halothane Long-term use depletes endogenous catecholamines and may cause intraoperative hemodynamic instability Life-threatening interaction with MAO inhibitors	24 hours
Garlic (ajo)	Inhibits platelet aggregation (may be irreversible) Increases fibrinolysis Equivocal antihypertensive activity	May increase risk of bleeding, especially when combined with other medications that inhibit platelet aggregation	7 days
Ginkgo (duck-foot tree, maidenhair tree, silver apricot)	Inhibits platelet-activating factor	May increase risk of bleeding, especially when combined with other medications that inhibit platelet aggregation	36 hours
Ginseng (American ginseng, Asian ginseng, Chinese ginseng, Korean ginseng)	Lowers blood glucose Inhibits platelet aggregation (may be irreversible) Increased PT/PTT in animals	Hypoglycemia May increase risk of bleeding May decrease anticoagulant effect of warfarin	7 days
Kava (awa, intoxicating pepper, kawa)	Sedation Anxiolysis	May increase sedative effect of anesthetics Increase in anesthetic requirements with long-term use unstudied	24 hours
Saw palmetto (dwarf palm, sabal)	Inhibits 5α-reductase Inhibits cyclooxygenase	May increase risk of bleeding	No data
St. John's wort (amber, goat weed, hardhay, hypericum, Klamath weed)	Inhibits neurotransmitter reuptake MAO inhibition unlikely	Induction of cytochrome P450 enzymes; affects cyclosporine, warfarin, steroids, and protease inhibitors; may affect benzodiazepines, calcium channel blockers, and many other drugs Decreased serum digoxin levels Delayed emergence	5 days
Valerian (all heal, garden heliotrope, vandal root)	Sedation	May increase sedative effect of anesthetics Benzodiazepine-like acute withdrawal May increase anesthetic requirements with long-term use	No data

MAO, monoamine oxidase; PT, prothrombin time; PTT, partial thromboplastin time.

showed echinacea's benefit in decreasing the incidence and duration of the common cold.[21] Its pharmacologic activity cannot be attributed to a single compound, although the lipophilic fraction, which contains alkylamides, polyacetylenes, and essential oils, appears to be more active than the hydrophilic fraction.

Echinacea had a number of immunostimulatory effects in preclinical studies.[22] Although no studies have specifically addressed interactions between echinacea and immunosuppressive drugs, expert opinion generally warns against the concomitant use of echinacea and these drugs because of the probability of diminished effectiveness.[22,23] Therefore, patients who may require perioperative immunosuppression, such as those awaiting organ transplantation, should be counseled to avoid echinacea. In contrast to its immunostimulatory effects with short-term use, long-term use of more than 8 weeks is accompanied by the potential for immunosuppression[23] and a theoretically increased risk for certain postsurgical complications such as poor wound healing and opportunistic infections.

Echinacea has also been associated with allergic reactions, including one reported case of anaphylaxis.[24] Therefore, echinacea should be used with caution in patients with asthma, atopy, or allergic rhinitis. Concern for potential hepatoxicity has also been raised, although documented cases are lacking.[25] In the absence of definitive information, patients with preexisting liver

dysfunction should be cautious in using echinacea. Furthermore, because the pharmacokinetics of echinacea have not been studied, it may be prudent to discontinue this herb as far in advance of surgery as possible when compromise in hepatic function or blood flow is anticipated.

Ephedra

Ephedra, known as ma huang in Chinese medicine, is a shrub native to central Asia. It is used to promote weight loss, increase energy, and treat respiratory conditions such as asthma and bronchitis. Ephedra contains alkaloids, including ephedrine, pseudoephedrine, norephedrine, methylephedrine, and norpseudoephedrine.[26] Commercial preparations may be standardized to a fixed ephedrine content. Publicity about adverse reactions to this herb prompted the FDA to bar its sale in 2004, but ephedra is still widely available via the Internet.

Ephedra causes dose-dependent increases in blood pressure and heart rate. Ephedrine, the predominant active compound, is a noncatecholamine sympathomimetic that exhibits α_1, β_1, and β_2 activity directly at adrenergic receptors and indirectly by releasing endogenous norepinephrine (noradrenaline). These sympathomimetic effects have been associated with more than 1070 reported adverse events, including fatal cardiac and central nervous system complications.[27]

Although ephedrine is widely used as first-line therapy for intraoperative hypotension and bradycardia, the unsupervised preoperative use of ephedra raises certain concerns. Vasoconstriction and, in some cases, vasospasm of coronary and cerebral arteries may cause myocardial infarction and thrombotic stroke.[28] Ephedra may also affect cardiovascular function by causing hypersensitivity myocarditis characterized by cardiomyopathy with myocardial lymphocyte and eosinophil infiltration.[29] Long-term use results in tachyphylaxis from depletion of endogenous catecholamine stores and may contribute to perioperative hemodynamic instability. In these situations, direct-acting sympathomimetics may be preferred as first-line therapy for intraoperative hypotension and bradycardia. Concomitant use of ephedra and monoamine oxidase inhibitors can result in life-threatening hyperpyrexia, hypertension, and coma. Finally, continuous ephedra use has been documented as a very rare cause of radiolucent kidney stones.[30]

The pharmacokinetics of ephedrine has been studied in humans.[31,32] Ephedrine has an elimination half-life of 5.2 hours, with 70% to 80% of the compound excreted unchanged in urine. Based on the pharmacokinetic data and the known cardiovascular risks associated with ephedra, including myocardial infarction, stroke, and cardiovascular collapse from catecholamine depletion, this herb should be discontinued at least 24 hours before surgery.

Garlic

Garlic is one of the most extensively researched medicinal plants. It has the potential to modify the risk for atherosclerosis by reducing blood pressure, thrombus formation, and serum lipid and cholesterol levels.[33] These effects are primarily attributed to its sulfur-containing compounds, particularly allicin and its transformation products. Commercial garlic preparations may be standardized to a fixed alliin and allicin content.

Garlic inhibits platelet aggregation in vivo in a dose-dependent fashion. The effect of one of its constituents, ajoene, appears to be irreversible and may potentiate the effect of other platelet inhibitors such as prostacyclin, forskolin, indomethacin, and dipyridamole.[34] Although these effects have not been consistently demonstrated in volunteers, there is one case in the literature of an octogenarian in whom a spontaneous epidural hematoma developed that was attributed to continuous garlic use.[35] In addition to bleeding concerns, garlic has the potential to decrease systemic and pulmonary vascular resistance in laboratory animals, but this effect is marginal in humans.[36]

Although there are insufficient pharmacokinetic data on garlic's constituents, the potential for irreversible inhibition of platelet function may warrant discontinuation of garlic at least 7

days before surgery, especially if postoperative bleeding is a particular concern or other anticoagulants are given.

Ginkgo

Ginkgo is derived from the leaf of *Ginkgo biloba* and has been used for cognitive disorders, peripheral vascular disease, age-related macular degeneration, vertigo, tinnitus, erectile dysfunction, and altitude sickness. Studies have suggested that ginkgo may stabilize or improve cognitive performance in patients with Alzheimer's disease and multi-infarct dementia[37] but not in healthy geriatric patients.[38] The compounds believed to be responsible for its pharmacologic effects are the terpenoids and flavonoids. The two ginkgo extracts used in clinical trials are standardized to ginkgo-flavone glycosides and terpenoids.

Ginkgo appears to alter vasoregulation, act as an antioxidant, modulate neurotransmitter and receptor activity, and inhibit platelet-activating factor (PAF). Of these effects, inhibition of PAF raises the greatest concern for the perioperative period. Clinical trials in a small number of patients have not demonstrated bleeding complications, but four reported cases of spontaneous intracranial bleeding,[39-42] one case of spontaneous hyphema,[43] and one case of postoperative bleeding after laparoscopic cholecystectomy[44] have been associated with ginkgo use.

Terpenoids are highly bioavailable when administered orally. Glucuronidation appears to be part of the metabolism of flavonoids.[45] The elimination half-lives of the terpenoids after oral administration are between 3 and 10 hours.[46] Based on the pharmacokinetic data and the risk of bleeding in the surgical population, ginkgo should be discontinued at least 36 hours before surgery.

Ginseng

Among the several species used for their pharmacologic effects, Asian ginseng and American ginseng are the most commonly described. Ginseng has been labeled an "adaptogen" because it reputedly protects the body against stress and restores homeostasis.[47,48] Most pharmacologic actions are attributed to the ginsenosides, a group of compounds known as steroidal saponins. Commercially available ginseng preparations may be standardized to ginsenoside content.

Ginseng has a broad but incompletely understood pharmacologic profile because of the many heterogeneous and sometimes opposing effects of different ginsenosides.[49] The underlying mechanism appears to be similar to that classically described for steroid hormones. A potential therapeutic use for this herb lies in its ability to lower postprandial blood glucose in both type 2 diabetics and nondiabetics,[50] an effect that may create unintended hypoglycemia in patients who have fasted before surgery. There is concern about ginseng's effect on coagulation pathways. Ginsenosides inhibited platelet aggregation in vitro[51,52] and prolonged both the thrombin time and the activated partial thromboplastin time in rats.[53] One early study suggested that the antiplatelet activity of panaxynol, a constituent of ginseng, may be irreversible in humans.[54] Although ginseng may inhibit the coagulation cascade, in one case its use was associated with a significant decrease in warfarin anticoagulation.[55] A recent study in volunteers confirmed its ability to interfere with warfarin-induced anticoagulation.[56] Because warfarin is often used after orthopedic or vascular procedures, this drug interaction is more than theoretical in nature.

Studies of the pharmacokinetics of the ginsenosides Rg1, Re, and Rb2 in rabbits found elimination half-lives between 0.8 and 7.4 hours.[57] These data suggest that ginseng should be discontinued at least 24 hours before surgery. Because platelet inhibition by ginseng may be irreversible, it is probably prudent to discontinue ginseng use at least 7 days before surgery.

Kava

Kava is derived from the dried root of the pepper plant *Piper methysticum*. Kava has gained widespread popularity as an anxiolytic and sedative. The kavalactones appear to be the source of kava's pharmacologic activity.[58]

Because of its psychomotor effects, kava was one of the first herbal medications expected to interact with anesthetics. The kavalactones have dose-dependent effects on the central nervous system, including antiepileptic, neuroprotective, and local anesthetic properties. Kava may act as a sedative-hypnotic by potentiating inhibitory neurotransmission of γ-aminobutyric acid (GABA). The kavalactones increased barbiturate sleep time in laboratory animals.[59] This effect may explain the mechanism underlying the report of a coma attributed to an alprazolam-kava interaction.[60] Although kava has abuse potential, whether long-term use can result in addiction, tolerance, and acute withdrawal after abstinence has not been satisfactorily investigated. Continuous kava use may elevate γ-glutamyl transpeptidase levels, thus raising concern about hepatotoxicity.[61] With continuous use, kava produces "kava dermopathy," characterized by reversible scaly cutaneous eruptions.[62]

Peak plasma levels occur 1.8 hours after an oral dose, and the elimination half-life of kavalactones is 9 hours.[58] Unchanged kavalactones and their metabolites undergo renal and fecal elimination.[63] Pharmacokinetic data and the possibility for potentiation of the sedative effects of anesthetics suggest that kava should be discontinued at least 24 hours before surgery. Earlier discontinuation should be considered when surgical procedures are expected to compromise hepatic function or blood flow.

Saw Palmetto

Saw palmetto, which is used by more than 2 million men in the United States to treat symptoms associated with benign prostatic hypertrophy, is ineffective for this purpose.[64] The major constituents of saw palmetto are fatty acids and their glycerides (i.e., triacylglycerides and monoacylglycerides), carbohydrates, steroids, flavonoids, resin, pigment, tannin, and volatile oil. The pharmacologic activity of saw palmetto has not been attributed to a single compound.

The mechanism of action of saw palmetto is not known, but multiple mechanisms have been proposed.[65] In vitro data suggest that saw palmetto extract, like finasteride, inhibits 5α-reductase. However, results of in vivo studies have been inconsistent.[65] Other proposed mechanisms are inhibition of estrogen and androgen receptors, binding of autonomic receptors, blocking of prolactin receptor signal transduction, interference

with fibroblast proliferation, induction of apoptosis, inhibition of α_1-adrenergic receptors, and anti-inflammatory effects.

In a patient undergoing craniotomy, saw palmetto was associated with excessive intraoperative bleeding that required termination of the procedure.[66] This complication was attributed to saw palmetto's anti-inflammatory effects, specifically the inhibition of cyclooxygenase and subsequent platelet dysfunction. Because there are no pharmacokinetic data for saw palmetto, specific recommendations for preoperative discontinuation cannot be made.

St John's Wort

St John's wort is the common name for *Hypericum perforatum*. A multicenter clinical trial concluded that St John's wort is not effective in the treatment of major depression.[67] The compounds believed to be responsible for its pharmacologic activity are hypericin and hyperforin.[68] Commercial preparations are often standardized to a fixed hypericin content of 0.3%.

St John's wort exerts its effects by inhibiting reuptake of serotonin, norepinephrine, and dopamine.[69] Concomitant use of this herb with or without serotonin reuptake inhibitors may create a syndrome of central serotonin excess.[70] Although early in vitro data implicated monoamine oxidase inhibition as a possible mechanism of action, a number of later investigations have demonstrated that monoamine oxidase inhibition is insignificant in vivo.[71]

Use of St John's wort can significantly increase the metabolism of many concomitantly administered drugs, some of which are vital to the perioperative care of certain patients. There is induction of the cytochrome P450 3A4 isoform, with approximate doubling of its metabolic activity.[72] Interactions with substrates of the 3A4 isoform, including indinavir sulfate,[73] ethinylestradiol[74] and cyclosporine, have been documented. In one series of 45 organ transplant patients, St John's wort was associated with an average 49% decrease in blood cyclosporine levels.[75] Another group reported two cases of acute heart transplant rejection associated with this particular pharmacokinetic interaction.[76] Other P450 3A4 substrates commonly used in the perioperative period include alfentanil, midazolam, lidocaine, calcium channel blockers, and 5-hydroxytryptamine receptor antagonists. In addition to the 3A4 isoform, the cytochrome P450 2C9 isoform may also be induced. The anticoagulant effect of warfarin, a substrate of the 2C9 isoform, was reduced in seven reported cases.[74] Other 2C9 substrates include the nonsteroidal anti-inflammatory drugs. Furthermore, the enzyme induction caused by St John's wort may be more pronounced when other enzyme inducers, which could include other herbal medications, are taken concomitantly. St John's wort also affects digoxin pharmacokinetics.[77] A recent study in the rat showed that St John's wort could markedly alter intracellular accumulation of irinotecan and its major metabolite (SN-38) in hepatocytes and glucuronidation of SN-38.[78]

The single-dose and steady-state pharmacokinetics of hypericin, pseudohypericin, and hyperforin has been determined in humans.[79,80] After oral administration, peak plasma levels of hypericin and hyperforin are achieved in 6.0 and 3.5 hours, respectively, and their median elimination half-lives are 43.1 and 9.0 hours, respectively. Long half-life and altered metabolism of many drugs make concomitant use of St John's wort a particular risk in the perioperative setting. Pharmacokinetic data suggest that this herbal medication should be discontinued at least 5 days before surgery. Discontinuation is especially important in patients awaiting organ transplantation or in those who may require oral anticoagulation postoperatively. Moreover, these patients should be advised to avoid taking St John's wort postoperatively.

Valerian

Valerian (*Valeian officinalis*) is an herb native to temperate regions of the Americas, Europe, and Asia. It is used as a sedative, particularly in the treatment of insomnia, and virtually all herbal sleep aids contain valerian.[81] Valerian contains many compounds acting synergistically, but the sesquiterpenes are the primary source of valerian's pharmacologic effects. Commercially available preparations may be standardized to valerenic acid.

Valerian produces dose-dependent sedation and hypnosis.[82] These effects appear to be mediated through modulation of GABA neurotransmission and receptor function.[83] Valerian increased barbiturate sleep time in experimental animals.[84] In one patient, valerian withdrawal appeared to mimic an acute benzodiazepine withdrawal syndrome characterized by delirium, cardiac complications after surgery, and attenuation of the symptoms by administration of a benzodiazepine.[85] Based on these findings, valerian should be expected to potentiate the sedative effects of anesthetics and adjuvants that act at the GABA receptor, such as midazolam.

The pharmacokinetics of valerian's constituents has not been studied, although their effects are thought to be short lived. Abrupt discontinuation in patients who may be physically dependent on valerian risks benzodiazepine-like withdrawal. In these individuals, it may be prudent to taper this herbal medication with close medical supervision over the course of several weeks before surgery. If tapering is not feasible, physicians can advise patients to continue taking valerian up until the day of surgery. Based on the mechanism of action and a reported case of efficacy,[85] benzodiazepines can be used to treat withdrawal symptoms should they develop in the postoperative period.

Summary

Although the American Society of Anesthesiologists has no official standards or guidelines on the preoperative use of herbal medications, public and professional educational information released by this organization suggests that herbals be discontinued at least 2 to 3 weeks before surgery.[17,86] Our review of the literature favors a more targeted approach because in practice, evaluating patients 2 to 3 weeks before elective surgery may be impossible. Moreover, some patients require nonelective surgery or are noncompliant with instructions to discontinue herbal medications preoperatively. These factors and the extensive use of herbal medicines may mean that herbal medications are taken until the time of surgery. Pharmacokinetic data on selected active constituents indicate that some herbal medications are eliminated quickly and may be discontinued closer to the time of surgery.

Evidence-based estimates of herbal safety in the perioperative period are limited. One recent study of 601 patients who used traditional Chinese herbal medications suggested a low rate of potential serious complications.[87] Clinicians should be familiar

with commonly used herbal medications to recognize and treat any complications that may arise. Table 32-1 summarizes the clinically important effects, perioperative concerns, and recommendations for preoperative discontinuation of the nine herbal medications discussed in this chapter.

Nonherbal Dietary Supplements

Herbal medicines fall into the broader category of dietary supplements that also includes vitamins, minerals, amino acids, enzymes, and animal extracts. Data on the safety of these agents in the perioperative period are scant. High-dose vitamin use, particularly of the fat-soluble vitamins (i.e., A, D, E, and K), can be associated with acute and chronic toxicity. Glucosamine and chondroitin sulfate, which are used for joint disorders by many patients undergoing orthopedic procedures, have not been associated with perioperative complications, although chondroitin sulfate, which belongs to the same group of glycosaminoglycan molecules as heparin, may have minor anticoagulant effects.[88] Whether long-term chondroitin sulfate use can cause thrombocytopenia is unknown. Creatine, a dietary supplement used by athletes to enhance performance, has been associated with renal dysfunction in at least one case.[89] There are preliminary data that exogenous melatonin, a hormone produced by the pineal gland, may be useful in preventing and treating postoperative delirium.[90]

Acupuncture

Mechanism and General Practice

There has been interest in using acupuncture as an aid in diminishing preoperative anxiolysis to reduce intraoperative anesthetic requirements, in supporting cardiovascular function, in controlling postoperative pain, and in reducing postoperative ileus, nausea, and vomiting.[91]

Acupuncture is the stimulation of anatomic locations on the skin by a variety of techniques that can be classified as invasive (e.g., needles, injections) or noninvasive (e.g., transcutaneous electrical stimulation, pressure, laser). Needles inserted into the skin can be stimulated by manual manipulation, moxibustion (i.e., burning a substance to produce heat), pressure, laser, and electricity. There are Chinese, Japanese, Korean, French, and other acupuncture systems for identifying acupuncture points, but little research has compared these different systems. As a result, there are no standard or optimal acupuncture points. Practitioners consider acupuncture an art as much as a science.

The traditional theory of acupuncture is that it corrects disruptions in the flow of energy (i.e., qi) and restores the balance of dual forces (i.e., ying-yang) in the body. Data suggest that there is a scientific basis for acupuncture. Acupuncture stimulates high-threshold, small-diameter nerves leading to the activation of spinal cord, brainstem (i.e., periaqueductal gray area), and hypothalamic (i.e., arcuate) neurons, which trigger endogenous opioid mechanisms.[92] The effect of acupuncture analgesia can be reversed by naloxone.[93] Other mechanisms such as modulation of immune function,[94] inhibition of the inflammatory response,[95] regulation of neuropeptide gene expression,[96] and alterations in hormonal levels[97] have been proposed. The development of neuroimaging tools, such as positron emission tomography (PET)[98] and functional magnetic resonance imaging (fMRI),[99,100] make noninvasive studies of acupuncture's effects on human brain activity possible. Studies using PET have demonstrated that the thalamic asymmetry present in patients suffering from chronic pain was reduced after the patients underwent acupuncture treatment. Other studies, using fMRI, have pointed to relationships between particular acupoints and activation of the visual cortex.[101]

Many of the clinical acupuncture studies that have been published are of poor quality and suffer from insufficient sample size, high dropout rates, inadequate follow-up, and poorly defined illnesses, enrollment criteria, and outcome measures.[92] Acupuncture studies suffer from inherent methodologic problems, including difficulties in blinding patients and acupuncturists, using placebo or sham acupuncture, and choosing between different acupuncture techniques. One of the most promising indications for acupuncture is to prevent postoperative nausea and vomiting (PONV).

Acupuncture for Postoperative Nausea and Vomiting

PONV remains a significant problem that results in patient dissatisfaction, delayed discharge, unanticipated hospital admission, and the use of resources (see Chapter 86). Pharmacologic agents, the mainstay of management, have limited effectiveness, are associated with adverse effects, and can be costly. There is considerable interest in acupuncture for its potential to prevent PONV with minimal adverse effects and expense.

The evidence available suggests that when compared with placebo (e.g., sham acupuncture, no treatment), acupuncture prevents PONV.[91] Acupuncture appears to prevent PONV to approximately the same extent as pharmacologic agents do, including metoclopramide, droperidol, prochlorperazine, and ondansetron. A meta-analysis of studies published before 1998 showed that acupuncture and related techniques prevented PONV in adults, not children, with a calculated absolute reduction in risk of 20% to 25% (i.e., for every four or five patients treated, one case of PONV is avoided).[102] Several subsequent randomized, controlled trials suggested that acupuncture may also prevent PONV in the pediatric population[103-106]; another meta-analysis found that acupuncture was not useful for PONV prophylaxis in children after tonsillectomy.[107] P6 acupressure did not reduce PONV in women who underwent cesarean delivery with spinal anesthesia.[108]

Most PONV acupuncture studies use the P6 (i.e., Nei-Nuan or pericardium) acupuncture point, which is located between the palmaris longus and flexor carpi radialis muscle tendons, 4 cm proximal to the distal wrist crease and 1 cm below the skin (Fig. 32-1). Korean hand acupuncture may be equally effective.[109] Studies often differ on the acupuncture method: duration and timing of stimulation, unilateral versus bilateral stimulation, and type of stimulation (i.e., needles with or without additional stimulation, acupressure, transcutaneous electrical stimulation, cutaneous laser stimulation, injection of a 50% dextrose solution, or capsicum plaster). Data to compare the effectiveness, safety, and costs of different methods of stimulation are inadequate. It is

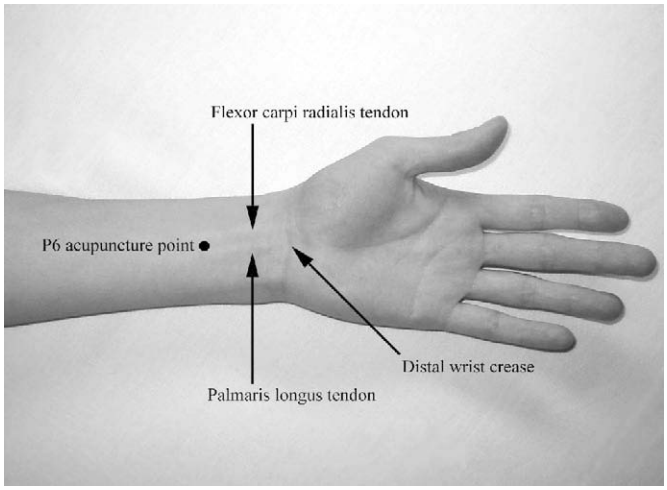

Figure 32-1 The P6 acupuncture point is located between the palmaris longus and flexor carpi radialis muscle tendons, 4 cm proximal to the distal wrist crease and 1 cm below the skin.

typically recommended that stimulation of the acupuncture point be initiated before induction of anesthesia.[110] However, some evidence suggests that postoperative stimulation may be just as or more effective.[111] In children, stimulation immediately before emergence and in the recovery room has been effective. Some anesthesiologists anecdotally report tapping a small needle cap or other piece of smooth plastic over the P6 point as an effective means of acupressure stimulation.

Music Therapy

Music may decrease preoperative anxiety, reduce intraoperative sedative and analgesic requirements, and increase patient satisfaction. Patient-selected music reduced patient-controlled sedative requirements during spinal anesthesia and analgesic requirements during lithotripsy.[112] Music in the preoperative area reduced anxiety without affecting physiologic measures of stress.[113] Music may be part of a low–sensory stimulation strategy to reduce anxiety and increase cooperation in children undergoing induction of anesthesia.[114] Music increased patient satisfaction and reduced systolic blood pressure during cataract surgery performed under a retrobulbar block.[115]

Conclusion

One of the fastest changing aspects of health care is the growing public and scientific interest in CAM. When taken preoperatively, some herbal medicines may adversely affect patient care. Surgery and anesthesia can usually proceed safely if potential complications are predicted and can be avoided. Preliminary data suggest that acupuncture and music may be useful adjuncts in the perioperative period. Although medical schools are beginning to incorporate CAM into their curricula, it is important for anesthesiologists already in practice to stay informed about these alternative therapies.

33 Risk of Anesthesia

Key Points

1. Perioperative risk is multifactorial and depends on the interaction of anesthesia-, surgery-, and patient-specific factors.
2. Anesthesia-related (and surgery-related) risk includes morbidity and mortality within 30 days, although shorter periods may be relevant, depending on the extent of surgery.
3. Anesthesia and the actions of anesthesiologists may completely or partially cause perioperative morbidity and mortality, but the actions of the anesthesiologist may also decrease or modify risk related to patient disease.
4. In the literature on anesthesia-related risk, rates of morbidity and mortality depend on the wide variety of definitions found.
5. Studies of anesthesia-related risk have found that postanesthesia respiratory depression is the major cause of death and coma totally attributable to anesthesia; this finding prompted the development of postanesthesia care units.
6. Research into anesthesia-related cardiac arrest has found it to be attributable to medication administration, airway management, and technical problems of central venous access.
7. Multivariate modeling using logistic regression equations can be used to determine factors associated with increased risk in the cohort and in individuals and has been used to develop risk indices such as the Cardiac Risk Index.
8. Surveys of maternal mortality suggest that the absolute rate of complications by anesthesia type has not decreased but that the increased use of regional anesthesia has led to improvements in outcome.
9. Medication-related and cardiovascular causes of cardiac arrest were the most common causes in the Pediatric Perioperative Cardiac Arrest Registry.
10. With increases in outpatient surgery, increased surveillance is required to ensure that appropriate procedures are performed in appropriate locations.

Much attention has been focused on the risks associated with anesthesia—surgery-related risks to the patient and occupational risks to the anesthesiologist. From the patient's perspective, it is important to provide an accurate assessment of the probability of complications and to study perioperative morbidity and mortality as a means of quality assurance to improve outcome. Numerous studies have attempted to define the probability of morbidity and mortality, with widely variable results. Risk indices have been developed to identify patients who have a higher probability of complications developing, and it has become evident that individual genetic makeup can affect outcome. In all these areas, as well as in clinical discussions with patients, the key issue is what risk are we attempting to define.

To determine the risk associated with anesthesia, multiple factors have to be entered into the equation. A myopic perspective could include only the morbidity and mortality that occur intraoperatively. From a quality assurance perspective, any death within 48 hours after the use of an anesthetic is evaluated for potential relevancy. Other investigators have evaluated 30-day morbidity and mortality as part of their estimation of anesthesia- and surgery-related risks. However, an important question is the period after anesthesia and surgery at which baseline risk returns to normal, although it is increasingly being recognized that events that take place during the perioperative period may have implications for quite a long time. From the perspective of a shorter timeframe, patients undergoing ambulatory surgery have been shown to have the lowest risk of death the day of surgery as opposed to 1 month later.[1] At the opposite end of the spectrum, asymptomatic release of cardiac enzyme in the perioperative period can have implications for months to years.[2,3] It is therefore important to define the time perspective when evaluating such studies (Table 33-1).

It is also important to differentiate the potential risk that is solely attributable to the administration of anesthesia from the risks that anesthesia may modify. Anesthesia has been touted as the one area of medicine that has achieved very low rates of

Table 33-1 Time Perspective of Anesthetic Morbidity and Mortality Studies

Study	Study Year	Time Perspective
Beecher and Todd	1954	All deaths on the surgical services
Dornette and Orth	1956	Deaths in the operating room or after failure to regain consciousness
Clifton and Hotten	1963	Any death under, attributable to, or without return of consciousness after anesthesia
Harrison	1978	Death within 24 hours
Marx, et al.	1973	Death within 5 days
Hovi-Viander	1980	Death within 3 days
Lunn and Mushin	1982	Death within 6 days
Tiret and Hatton	1986	Complications within 24 hours
Mangano, et al.	1996	Death within 2 years
Monk, et al.	2005	Death within 1 year

medical error and complications when the rate of death directly attributable to anesthesia is considered. However, from a quality assurance perspective, a patient with coronary artery disease who experiences a perioperative myocardial infarction would have the primary cause of morbidity assigned to the disease, but tight heart rate control might have prevented the adverse outcome. In this situation, the perioperative infarction might be considered attributable to patient disease rather than the anesthesia, alternatively, it can be considered an event that is partially preventable by anesthesia care. Anesthesiologists must view perioperative organ protection as part of their goals to provide the highest quality of care and reduce perioperative risk. Another example is the use of regional anesthesia to reduce graft thrombosis in patients undergoing infrainguinal arterial reconstruction.[4,5] The importance of anesthesia care on perioperative risk may also be a reflection of the local risk associated with the surgery. For example, benefit from regional anesthesia was found in only two studies; the third study had a much lower rate of graft thrombosis that was not influenced by the type of anesthesia, suggesting that the benefit may be manifested only if the rate of complications is sufficiently large. Assessment of risk therefore depends on the rate of complications.

Traditionally, anesthesiologists and investigators have focused on issues of death and major morbidity such as myocardial infarction, pneumonia, and renal failure. It is becoming increasingly important to include outcomes that affect economic issues, quality of life, and satisfaction for the patient (Table 33-2). For example, a delay in or prevention of discharge home by nausea and vomiting is important from the perspective of economics and quality of life. Readmission to the hospital after outpatient surgery is an important component of outcome studies. Overall satisfaction with care is increasingly being included as an outcome. Further research is required to assess the influence of anesthesia care for nonmorbid outcomes and the importance of these outcomes from a patient-oriented perspective.

Many studies have also looked at what some investigators describe as surrogate end points. For example, nausea and vomiting that do not require treatment or do not delay discharge do not have the same impact as episodes that do affect these outcomes. Myocardial ischemia on the electrocardiogram is another example of a surrogate outcome that may not lead directly to overt morbidity. In determining the risk attributable to anesthesia, it is important to define the outcome of greatest significance.

Finally, many investigators as well as insurers, such as the Centers for Medicare and Medicaid Services, are now evaluating process measures. Examples of process measures include antibiotic timing (did the patient receive antibiotic within 1 hour before surgical incision). These measures are not the outcomes of interest, but there is sufficient evidence that improvement in compliance with these measures should decrease morbidity (e.g., surgical site infections) to warrant measurement and potentially payment for the action. Importantly, compliance with these measures are now publicly reported on websites such as www.hospitalcompare.hhs.gov.

Framework of Perioperative Risk

Perioperative risk is multifactorial and depends on the interaction of anesthesia-, patient-, and surgery-specific factors (Fig. 33-1). With respect to anesthesia, the effects of the agents and the skills of the practitioner are important. Similarly, the surgeon's skills and the surgical procedure itself affect perioperative risk. From the patient's perspective, the question remains whether coexisting disease raises the probability of complications to a level such that the benefit of the surgery is outweighed by the risk. Anesthesiologists frequently have focused on perioperative risk, but the patient is most concerned with management of the disease process. As the specialty focuses on its role in the 21st century, it is important to acknowledge the patient's perspective and desire to undergo procedures that prolong life or improve quality of life. Increasing the ability of the anesthesiologist to affect the decision-making process and overall risk is the future challenge.

Given these various goals, perspectives, and influences, this chapter attempts to define the current state of knowledge in this area. With the increasing interest in evidence-based medicine, it

Table 33-2 Examples of Common Outcome Measures

Outcome	Example
Mortality

Patient satisfaction	
Quality of life	

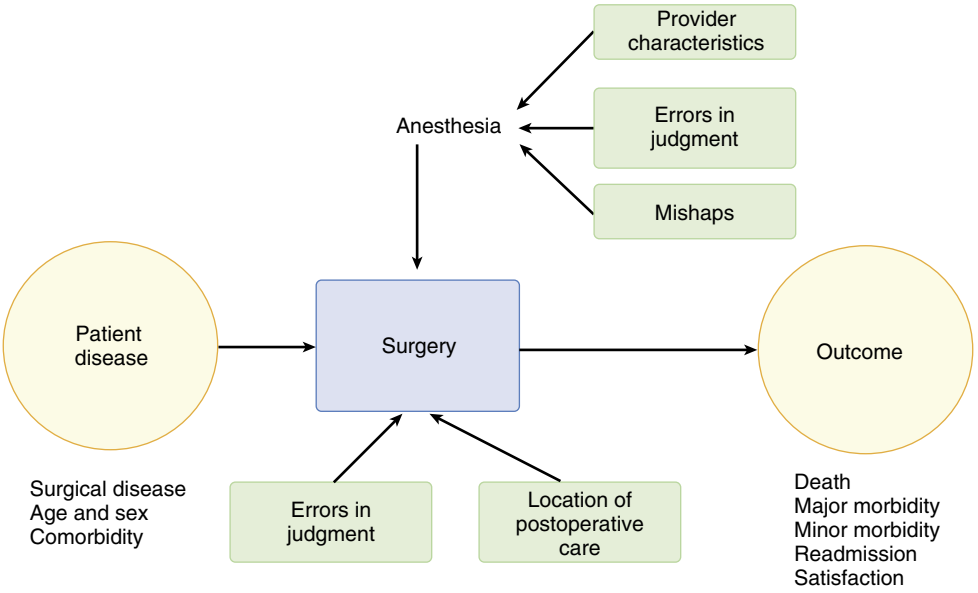

Figure 33-1 Representation of the influences of various components on poor perioperative outcomes. Surgical, anesthetic, and patient characteristics all contribute to outcome. Anesthesia-related contributions can include issues of judgment and mishaps, as well as characteristics of the provider. The surgical procedure itself affects outcome, as does the location of intraoperative and postoperative care.

is important to define what is known and not known. Because it would be unethical to compare operations performed with the use of an "ideal anesthetic" with those using a less ideal or no anesthetic, virtually all studies looking at the factors that contribute to perioperative mortality involve evaluations of large cohorts of patients. However, since the 1990s there have been several well-designed, randomized clinical trials to evaluate different anesthesia regimens, which has advanced the field. This chapter also reviews the literature, with an emphasis on the strength of the evidence for the conclusions.

Issues Related to Study Design

Types of Studies

To interpret the literature, it is important to understand the strengths and limitations of the various study designs. Prospective cohort studies involve the identification of a group of subjects who are monitored over time for the occurrence of an outcome of interest. The goal is to identify patients in whom the outcome develops. For studies of perioperative mortality, individual cases can be reviewed to determine the cause of mortality. Alternatively, data on all patients in the cohort can be obtained, and factors associated with the development of morbidity or mortality can be discerned. An example of a prospective cohort study to identify factors associated with perioperative cardiac morbidity and mortality is that of Goldman and colleagues,[6] which led to development of the Cardiac Risk Index.

Another example of a prospective cohort study is one in which patients with a known disease are studied for the development of predefined outcomes. Such studies provide the natural history of the disease. For example, studies of patients who have sustained a myocardial infarction could be important in determining optimal timing between occurrence of the infarct and surgery.

Although prospective cohort studies have important value in identifying risk factors for the outcome of interest, there are significant limitations. Selection of the cohort of interest can significantly affect the results obtained. The larger the cohort, the more the results can be generalized. A second bias is that many patients may be lost to follow-up. In perioperative studies, this may not be an important issue for short-term outcomes. The importance of a risk factor depends on the completeness of the data. For example, if the presence of severe angina were not included in the database, it could not be considered a risk factor, and other factors may appear to be more important.[6]

A specific example of a prospective cohort study is the randomized clinical trial. Randomized clinical trials represent the standard for evidence of causation. They have defined inclusion and exclusion criteria, treatment protocols, and outcomes of interest. They are usually single- or double-blinded (to patient and physician) studies and are designed to test the effect of a new drug or intervention. They are rarely used as a means of identifying risk, but they may be used to determine whether a risk factor is truly linked by a causal relationship or is simply an association. For example, hypothermia in the perioperative period has been associated with an increased incidence of perioperative ischemia, a surrogate marker for morbidity.[7] In a randomized clinical trial, the use of forced-air warming to maintain normothermia was associated with a significantly lower incidence of perioperative morbid cardiac events.[8] Randomized clinical trials directed at interventions that reduce the frequency of a given risk factor in the population are frequently performed after the results of a prospective cohort study to confirm the findings of an association between poor outcome and that factor.

Randomized clinical trials derive their strength from an evidence-based perspective because of their high degree of internal validity; the randomization scheme and the use of placebo (or accepted alternative treatments) provide strong evidence that the

results are related to the intervention. Importantly, these trials have a lower degree of external validity because the intervention may not behave in the same manner when it is diffused in a more heterogeneous population in which treatment is not defined. Additionally, low-risk complications in specific subsets of patients may not be detected in smaller randomized trials. For example, the cardiovascular complications of cyclooxygenase-2 inhibitors were not initially detected in the randomized trials.

Retrospective studies involve identification of patients who have sustained an outcome and definition of risk factors associated with the outcome. An example of a retrospective design is a case-control study. Case-control studies identify patients with the outcome of interest. Frequently, these patients are included as part of a prospective cohort study. The prevalence of a risk factor in patients with the outcome (i.e., cases) is compared with the prevalence of the risk factor in matched controls to maximize the efficiency and power of the results. The ratio of cases to controls can be varied to yield greater power with an increasing number of controls.

Case-control studies are subject to several biases. The exact definitions of cases and controls can influence the analysis. Frequently, patients are matched for age and gender, but other factors may play an important role. It is critical that the exposure precede the outcome, and a dose-response gradient further confirms the relationship.

Problems Inherent in Studying Anesthesia-Related Risk

Several issues related to studying anesthesia-related risk can affect the findings. For example, multiple definitions of perioperative mortality exist. In particular, the timeframe in which a death can be attributed to the surgery and delivery of anesthesia varies. Because in-hospital stays have shortened, many events related to surgery may occur after discharge. For this reason, the National Surgical Quality Improvement Project (NSQIP) requires 30-day follow-up on all patients to develop robust risk-adjusted models of morbidity and mortality. The issue of the time horizon is particularly important with ambulatory or short-stay surgery, for which recovery from anesthesia occurs at home. As we continue to monitor our patients for safety, it will be important to extend follow-up care beyond the traditional hospital setting, and many recent studies have included such an approach.

A major problem in any study of risk is the actual rate of complications in the population of interest. There are multiple sources of data for studying perioperative risk. Although some of the original studies used data from only one or a small group of institutions, such approaches may not be practical in the current era. As demonstrated throughout this chapter, most individuals believe that risk related to anesthesia has decreased over time, although this premise has been questioned.[9] For example, the rate of anesthesia-related mortality described in the Confidential Enquiry into Perioperative Deaths (CEPOD) of 1987 was 1 in 185,000 patients as opposed to the 1 in 2680 cases reported by Beecher and Todd about 30 years earlier.[10,11] In view of the current rate, any study would have to be enormous to detect anesthesia-related mortality. Such a study would require information from a large number of sites or data covering multiple years from a single institution. Because of concern in the United States regarding confidentiality and legal liability, a multicenter study of risk in unselected patients would be difficult to undertake. Such problems may not be inherent in other countries.

Another issue is the effect of the act of studying outcome. As in any study of risk, the actual rate of complications decreases as a result of increased observation. This is frequently observed as a lower than expected rate of complications in the placebo arm of a randomized, controlled trial.

An alternative approach is to identify bad outcomes and study them for patterns of error. For example, Cheney and colleagues[12] developed the American Society of Anesthesiologists (ASA) Closed Claims Study (ACCS). By obtaining the records of major events that led to legal litigation, they were able to identify factors that contributed to bad outcomes. With this methodology, selected morbidities that lead to litigation can be identified. The limitation of this methodology is that the actual rates of complications are not known; only the number of closed legal claims is identified. Cases that do not result in litigation are not included in the database.

Several attempts have been made to establish large epidemiologic databases. One example of such an approach has been the work of Mangano and the Multicenter Study of Perioperative Ischemia group with regard to cardiac surgery. This group used their database to evaluate issues such as the rate and importance of atrial fibrillation after cardiac surgery and the use of aspirin.[13,14] Other approaches include the development of cardiac surgery databases by the Society of Thoracic Surgeons, the U.S. Veterans Administration NSQIP, and the New England Collaborative Project.[15-18] These databases are used to define risk factors for poor outcome, to compare local with national complication rates, and as educational tools. Such databases currently include little or no information regarding anesthesia practice, although many anesthesia specialty societies are in discussion to develop independent databases or join with surgical groups to develop more robust databases. Even though these databases may provide extremely important information to improve care, the ability to generalize results to centers that do not have sufficient infrastructure to participate in such projects (e.g., smaller hospitals) is unknown.

This final issue—the institutional site of the surgery—may have other implications related to the pattern of care at a particular hospital. Although studies frequently categorize risk as related to anesthesia, surgery, or patient disease, postoperative care may have a profound impact on risk. For example, risk for pulmonary embolism may be related to nursing care and the frequency of patient ambulation after surgery.[19] The presence of an intensivist who makes daily rounds and higher nurse staffing ratios may also affect outcome.[20] Variations in the total care provided by a hospital, including anesthesiologists and surgeons, may significantly affect outcomes.

One advance in determining local complication rates is the development of hospital information systems. The use of computer databases in the assessment of risk began with Marx and colleagues[21] in the 1970s. These information systems are now nearly a requirement for survival of the hospital. The ability to query these systems will make large-scale studies of institutional risk much less burdensome in the future. Anesthesia information systems are increasingly becoming common. Reich and coworkers[22] used one such system to identify intraoperative hemodynamic abnormalities, including pulmonary hypertension, hypotension during cardiopulmonary bypass, and pulmonary

diastolic hypertension after cardiopulmonary bypass, as independent predictors of mortality, stroke, and perioperative myocardial infarction beyond the effects of other preoperative risk factors.

When extremely large sample sizes are needed, administrative databases may be among the most cost-effective approaches to this issue. Examples of administrative databases include Medicare claims files, private insurance company claims, and hospital electronic records. These databases include a small number of data points for an extremely large number of subjects. For example, the Medicare database includes financial data, disease codes (International Classification of Diseases, 9th revision [ICD-9]), and procedure codes (Current Procedural Terminology [CPT]) for each patient. It also includes information regarding the location of care and provider type. The Medicare claims file is being extensively used to provide benchmarks for rates of mortality and major complications after coronary bypass surgery.[23] Hospitals can compare their rates with those of neighboring and competing hospitals and may use these data as markers for quality of hospital care.[24,25] Silber and associates[26] took an alternative approach to the use of Medicare databases and evaluated perioperative factors that influence failure to rescue. Failure to rescue is the concept whereby the actual rate of complications associated with death is studied rather than the overall death and complication rate.[26] The underlying assumption is that higher quality of care results in a lower rate of fatal outcomes, even among patients who sustain complications. Importantly, the use of administrative databases to study outcomes should be considered as hypothesis generating rather than simply answering specific questions in the same manner as randomized controlled trials.

Mortality Related to Anesthesia

The first report of the delivery of anesthesia (ether) for an operative procedure took place in 1846. Only 2 years later, a death attributable to anesthesia was reported.[27] In that report, Hannah Greener died on induction with chloroform. Since that time there have been numerous investigations into the cause of anesthesia-related deaths. The first formal investigation of anesthesia-related deaths was published by John Snow in 1858.[28] Snow analyzed 50 deaths that occurred during chloroform anesthesia. At that time, mortality occurred principally in healthy patients undergoing minor procedures, suggesting that anesthesia was the principal cause of the mortality. Subsequent studies reported deaths of patients with significant comorbid conditions who were undergoing major surgical procedures; in these cases the cause of mortality was frequently multifactorial.

Surgery Without Anesthesia

Surgical procedures were carried out before the introduction of anesthetics. The key to success was the speed of the procedure, with successful amputations lasting only 30 seconds. Strong assistants and restraints were frequently required. Alternatively, decreased cerebral perfusion by means of bilateral carotid compression was used to decrease sensation during the procedure. Surgical procedures were associated with a significant risk of death and, at a minimum, were associated with severe pain. The development of anesthesia has been heralded as one of the great advances of modern medicine because it allowed surgery to advance.

Early Studies of Anesthesia-Related Mortality

One of the earliest systematic approaches to anesthesia-related risk occurred in 1935, when Ruth[29] helped establish the first anesthesia study commission to analyze perioperative deaths (Table 33-3). The commissioners relied on voluntary submission of cases and determined the cause of death by majority vote. Both

these methodologies were deemed inadequate in subsequent years.

From a pragmatic standpoint, determining the cause of anesthesia-related mortality is important if information from the analysis can be used to improve subsequent care. This concept was best voiced by Sir Robert MacIntosh in 1948.[30] He stated that many anesthesia-related deaths were preventable and that improved education was the best means to avoid unnecessary mortality. He went so far as to suggest that all development of new drugs be halted for 5 years to direct more attention to training young anesthetists. He attempted to focus attention on postoperative care by suggesting that more deaths occurred after patients were returned to the ward than intraoperatively. His final comments were related to the need to establish a formal inquiry mechanism for determining the cause of any death because such an analysis could lead to improved practice. In many ways, the CEPOD was the culmination of such a philosophy.

A major advance in the analysis of anesthesia-related risk was the 1954 report by Beecher and Todd[10] of anesthesia-related deaths at 10 institutions. Their study included 599,548 anesthesia procedures. The overall chance of mortality from any cause was 1 per 75 cases. Anesthesia was the primary cause of mortality in 1 in 2680 procedures, and it was a primary or contributory cause of mortality in 1 in 1560 procedures. Surgical error in diagnosis, judgment, or technique was the primary cause of death in 1 in 420 cases, and patient disease was the primary cause in 1 in 95 cases.

Dornette and Orth[31] reported on deaths occurring in the operating room at their institution during a 12-year period from 1943 through 1954. The rate of mortality totally attributable to anesthesia was 1 in 2427 cases, and the rate of mortality totally or partially attributable to anesthesia was 1 in 1343 cases.

Dripps and colleagues[32] at the University of Pennsylvania surveyed their experience during the 10-year period from 1947 through 1957. They identified 1285 operative deaths (i.e., death within 30 days) in approximately 120,000 anesthesia procedures, for a gross mortality rate of 1.1%. This definition includes late deaths, in contrast to many studies that focused on the intraoperative period or the first 48 postoperative hours. After review of hospital records, the investigators determined whether anesthesia was definitely or possibly contributory to each death. Among patients who underwent spinal anesthesia, mortality definitely related to anesthesia occurred in 1 in 1560 procedures, and mortality definitely or possibly related to anesthesia occurred in 1 in 780 procedures. Among those who underwent general anesthesia, mortality was definitely related to anesthesia in 1 in 536 cases and definitely or possibly related in 1 in 259 cases. Mortality was correlated with physical status with use of the ASA physical status classification scoring system. The higher mortality figures than in other reports may be related to the higher physical acuity at this hospital. Importantly, deaths attributable to anesthesia did not occur in any of the 16,000 patients with ASA class 1 physical status.

Dripps and colleagues compared their data with those of Beecher and Todd. The principal intraoperative complications were hypotension and hypoxia. Virtually all patients who underwent spinal anesthesia had intraoperative complications, but postoperative complications were rare in this group. The investigators believed that anesthesia-related mortality had improved since the start of the study, mainly because of improvements in cardiac resuscitation, more rational transfusion therapy, standard use of recovery rooms, and efficient use of mechanical ventilators.

There were a number of reports from individual hospitals or a small group of hospitals during the subsequent 2 decades.[33] The Baltimore Anesthesia Study Committee[34] reviewed 1024 deaths occurring on the day of or the day after a surgical procedure to determine the potential contribution of anesthesia. This short period of observation (48 hours) contrasts with the 30-day period used by Dripps and coworkers. For each case reviewed, the committee determined whether anesthesia was the principal cause or one of several contributing factors. In 196 cases (19.2%), the committee voted that anesthesia management contributed to the death of the patient. Anesthesia was the principal cause of death in approximately one third of the cases (64 of 196), with one half of them being related to improper management of the anesthetic. The researchers estimated that operative mortality occurred in 4 per 10,000 operations by using these data and applying rates of surgery from the National Health Survey. In more than 50% of all cases studied, death occurred in the patient's room, which led the investigators to emphasize the need for routine use of postanesthesia care areas. In an attempt to educate practitioners and prevent duplication of preventable causes of death, each of the perioperative deaths was discussed.

Schapira and coauthors[35] reported on mortality occurring within 24 hours after surgery between the years 1952 and 1956 at Montefiore Hospital in New York. They ascribed 27 deaths to anesthesia, including 18 in which anesthesia was a primary cause and 9 in which it was contributory. The overall prevalence of death partially or totally attributable to anesthesia was 1 in 1232 procedures.

Clifton and Hotton[36] reported 162 deaths associated with anesthesia in 205,640 operations performed at the Royal Prince Alfred Hospital in Sydney, Australia, between 1952 and 1962. They calculated that the incidence of mortality totally attributable to anesthesia was 1 in 3955, that attributable to surgery was 1 in 2311, and that attributable to patient disease was 1 in 1996 procedures. One cause of postoperative mortality was respiratory insufficiency. The researchers argued that many of these complications would have been prevented by the use of a recovery unit. The potential safety advantages of a postanesthesia care unit (PACU) constituted a general theme in reports from the 1960s.

Dinnick[37] reported 600 deaths associated with anesthesia as part of a series of investigations sponsored by the Association of Anaesthetists in London. This represents the second report from this group since a committee was established to collect clinical data in 1949. The first report included a review of 1000 fatalities and concluded that "in the majority of the reports there were departures from accepted practice." The initial report, published in 1956, found that regurgitation or vomiting was the main factor leading to death, whereas the second report, published in 1964, found that low blood volume was more important. Underventilation was the second most common finding and it accounted for 25% of deaths.

Bodlander[38] provided a follow-up report of anesthesia-related mortality at the Royal Prince Alfred Hospital for the years 1963 to 1972. The incidence of mortality totally attributed to anesthesia decreased to 1 in 1702 cases, whereas anesthesia contributed to mortality in 1 in 502 cases as compared with 1 in 1208 for the years 1952 to 1962. The reduction in anesthesia-related deaths was attributed to an increase in the number of qualified staff and the degree of supervision.

Marx and colleagues[21] evaluated the incidence of death within 7 days after surgery in 34,145 consecutive patients at the Bronx Municipal Hospital Center between 1965 and 1969. A total of 645 patients died, and a death report form based on that developed by a committee of the New York Academy of Medicine was constructed. The deaths were then analyzed in relation to perioperative data available from a computer system. The patient's preexisting disease was considered to be the primary cause of death in 83% of cases, surgery in 10%, and anesthesia in only 4% (1 of 1265 cases). Although mortality rose progressively with age, physical status correlated best with the incidence of mortality.

Marx and colleagues also determined the relationship between type of anesthesia and mortality. Regional anesthesia was associated with the lowest incidence of death, local anesthesia with the highest; the incidence for general anesthesia was intermediate. Although this relationship was significantly different between groups, the difference appeared to be related to patient risk factors, a finding supported by a study by Cohen and coworkers.[39]

Farrow and associates[40,41] studied hospital mortality after 108,878 anesthesia procedures in Cardiff, Wales, between 1972 and 1977. The crude mortality rate was 2.2 per 100 patients. Mortality was greatest in patients older than 65 years. The mortality rate also increased with the severity of disease and the need for emergency operations.

Harrison[42] evaluated mortality associated with 240,483 anesthesia procedures performed between 1967 and 1976 at Groote Schuur Hospital in Cape Town, South Africa. Data were collected prospectively, beginning in 1956. Anesthesia was the cause of death or a major contributory factor in 0.22 cases per 1000 procedures, as opposed to 0.33 per 1000 operations in the previous 10 years. Anesthesia contributed to 2.2% of all the deaths associated with surgery. The most common causes of anesthesia-related mortality, in order of frequency, were hypovolemia, respiratory inadequacy after neuromuscular blockade, complications of tracheal intubation, and inadequate postoperative care. Although the improvement in anesthesia-related mortality could not be directly attributed to specific improvements in care, four specific changes did occur: continuing improvement in routine monitoring, an increase in the ratio of consultants to registrars (British system residents), a decrease in the case load per anesthesiologist, and the introduction of recovery rooms and intensive care units (ICUs).

Studies before 1980 demonstrated steady improvements in anesthesia-related mortality. Studies performed throughout the world focused on identifying causative factors for perioperative mortality. Several general themes emerged. Anesthesia represents a small but significant cause of perioperative mortality, perioperative respiratory complications represent a major complication, and elucidation of the causes of perioperative mortality and education about these causes should lead to improved outcomes.

Anesthesia-Related Mortality Studies after 1980

Whereas studies conducted before 1980 typically focused on one institution or a small group of institutions, studies since then have frequently been performed on a national basis. Improvements in anesthesia-related and overall mortality have made analysis of a single institution inadequate because of the small sample size. For example, Holland[43] reported deaths occurring within 24 hours after an anesthesia procedure in New South Wales, Australia. A committee of six anesthesiologists, three surgeons, an obstetrician, a general practitioner, and a medical administrator was established in 1960 and reviewed all such cases except those that occurred during a 3-year period between mid-1980 and mid-1983. Four categories were established to define the relationship of anesthesia to operative morbidity and mortality (Table 33-4). Between 1960 and 1985, information was available on 92% to 96% of all cases. The incidence of anesthesia-attributable deaths decreased from 1 in 5500 procedures performed in 1960 to 1 in 10,250 in 1970 and then to 1 in 26,000 in 1984. Based on these estimates, the investigators asserted that it was at least five times safer to undergo anesthesia in 1984 than in 1960, particularly for healthy individuals. A subsequent follow-up report stated that factors under the control of the anesthesiologist caused or contributed to perioperative mortality at a rate of 1 in 20,000 operations.[44] The latter study demonstrated a preponderance of male over female patients (1.7 : 1). The reason for this finding is unclear, although it confirms other reports. Importantly, 64% of the deaths were deemed inevitable, suggesting that only one third were preventable.

Table 33-4 Edwards Classification of the Relationship of Anesthesia to Operative Morbidity and Mortality

Category	Definition
I	When it is reasonably certain that the event or death was caused by the anesthetic agent or technique of administration or in other ways coming directly within the anesthetist's province
II	Similar to type I cases, but ones in which there is some element of doubt about whether the agent or technique was entirely responsible for the result
III	Cases in which the patient's adverse event or death was caused by the anesthetic and the surgical technique
IV	Events entirely referable to surgical technique

From Holland R: Anaesthetic mortality in New South Wales. Br J Anaesth 59:834, 1987.

The New South Wales study of anesthesia-related mortality evaluated the contribution of the anesthetist to perioperative mortality. Four groups of providers were identified: specialists, nonspecialists, certified registered nurse anesthetists (CRNAs), and residents. The absolute number of anesthesia-related deaths decreased in all groups but was most pronounced for nonspecialists. During the period 1960 through 1969, the resident medical officer frequently provided anesthesia. During this same period it was found that residents contributed significantly to the mortality observed in "good-risk" patients, which led to phasing out of the resident medical officer as a member of the anesthesia workforce.

Under the direction of the French Ministry of Health, Tiret and colleagues[45] carried out a prospective survey of complications associated with anesthesia in France between 1978 and 1982 from a representative sample of 198,103 anesthesia procedures chosen at random from hospitals throughout the country. The sample included a survey of 460 public and private hospitals. The investigators evaluated the occurrence of death or coma within 24

Table 33-5 Incidence of Complications Partially or Totally Related to Anesthesia

hours after surgery. The opinion of the participating anesthesiologists and the National Committee of Assessors was determined, and the latter was accepted if there was disagreement. In the group studied, 268 patients had major complications, 67 patients died, and 16 patients suffered persistent coma. Death was totally related to anesthesia in 1 in 13,207 procedures and partially related in 1 in 3810 (Table 33-5). Sixty-two percent of the coma cases were deemed totally attributable to anesthesia, with the remainder being partially attributable to anesthesia. The French survey confirmed previous findings that major complications occur more frequently in older patients, those undergoing emergency operations, and those with more extensive comorbid conditions as measured by the ASA physical status classification.

One of the most important findings of the survey was that postanesthesia respiratory depression was the leading cause of death and coma that were totally attributable to anesthesia. Almost all the patients who had respiratory depression leading to a major complication had received narcotics and muscle relaxants that had not been reversed. They also reported a high incidence of anaphylactoid shock, which the investigators contended was caused primarily by the use of Althesin and succinylcholine. There was no category of drug overdose, which might have been a more appropriate label for some of these cases.

The study by Tiret and colleagues had the advantage of collecting data prospectively, thereby allowing more accurate estimation of overall mortality than many of the other studies completed. A major limitation of the study was that only deaths occurring within 24 hours after surgery were included, thus ignoring late deaths that were the direct result of intraoperative complications.

Tikkanen and Hovi-Viander[46] studied deaths associated with anesthesia and surgery in Finland and compared the results in 1986 with those collected in 1975. Mortality related to anesthesia decreased during the 9-year period; the incidence of anesthesia-related mortality was 0.15 per 10,000 procedures in 1986.

Lunn and coworkers[47-50] published two reports on anesthesia-related surgical mortality in the United Kingdom. When a death occurred in a hospital within 6 days after surgery, a questionnaire was sent to the patient's anesthetist and surgeon. For 59.3% of the 4034 reported deaths, both the surgeon and the anesthetist returned the forms. The replies were reviewed anonymously by two assessors, and differences of opinion were determined by arbitration. After review, further details were obtained if the reply indicated that anesthesia was at least partly responsible for the death. The second report was based on an analysis of 197 reports of death within 6 days after anesthesia during 1981. In this report, 43% of the deaths were found by the assessors to have nothing to do with anesthesia, 41% were partly attributable to anesthesia, and 16% were totally attributable to anesthesia. Of the 32 cases for which death was totally attributable to anesthesia, most were caused by faulty anesthesia technique or postoperative respiratory failure.

The pioneering work of Lunn and others led to the development of CEPOD, which assessed almost 1 million cases of anesthesia during a 1-year period in 1987 in three large regions of the United Kingdom. Unique to this study was the establishment of "crown privilege" by the government to allow total confidentiality:

> *The Secretary of State is satisfied that the disclosure of documents about individual cases prepared for the Enquiry into Perioperative Deaths would be against the public interest and would undermine the whole basis of a confidential study. The data or information sent to the Confidential Enquiry into Perioperative Deaths is therefore protected from subpoena …*

Deaths occurring within 30 days after surgery were included in the study. There were 4034 deaths in an estimated 485,850 operations, for a crude mortality rate of 0.7% to 0.8%. Surgery contributed totally or partially in 30% of all cases. Progression of the present disease contributed to death in 67.5% of the cases, and progression of an intercurrent disease was relevant in 44.3%. Anesthesia was considered the sole cause of death in only three individuals, for a rate of 1 in 185,000 cases, and anesthesia was contributory in 410 deaths, for a rate of 7 in 10,000 cases (Table 33-6).

There are several potential causes for the improvement in mortality between the CEPOD study and previous studies, including cases from the same group. One explanation is that improvement in care led to improvement in outcome. Many of the deaths that would previously have been classified as "anesthesia totally contributory" were later classified as "anesthesia partially contributory."

An important aspect of the CEPOD study was that it established anesthesia- and surgery-related factors that contributed to mortality. The five most common causes of death are shown in Table 33-7. Of the 410 perioperative deaths, there were 9 cases of aspiration or vomiting and 18 cases of cardiac arrest. A large proportion of elderly women had fractures of the femoral neck. The death rate was inversely related to the seniority of the operating surgeon and to preoperative preparation. The operating surgeon was a consultant in only 19% of the orthopedic cases as compared with 47% overall.

The CEPOD study also provided important information regarding anesthesia practice. Patients were seen preoperatively

Table 33-6 Death Totally Attributable to Each Component of Risk in the Confidential Enquiry into Perioperative Deaths

Component	Mortality Rate Contribution
Patient	1:870
Operation	1:2860
Anesthetic	1:185,056

in more than 80% of the cases but postoperatively in less than 50%. Although the electrocardiogram was monitored in 97% of cases, core temperature was assessed in only 7%. Muscle relaxants were used in more than 50% of the cases, but a nerve stimulator was used in only 14%.

The assessors concluded that avoidable factors were present in about 20% of the perioperative deaths. Contributing factors for anesthesiologists and surgeons tended to be failure to act appropriately with existing knowledge (rather than lack of knowledge), equipment malfunction, and fatigue. However, the researchers suggested that inadequate supervision was a problem and that no operation on a patient with an ASA physical status of class 4 or 5 should be performed without direct consultation with the appropriate anesthesia or surgical authority (Table 33-8).

Several large national studies have been published since the CEPOD. Pedersen and colleagues[51] performed a series of studies in the late 1980s in Denmark to look at factors attributable to anesthesia that led to serious morbidity or mortality. They performed a prospective study of 7306 anesthesia procedures. In a method similar to that used in earlier studies, three anesthetists reviewed the records of complications and determined whether the cause was attributable to anesthesia (no distinction was made between totally and partially contributing factors). Complications attributable to anesthesia occurred in 43 patients (1 in 170), and 3 patients (1 in 2500) died. Complications in the 43 patients, in order of incidence, included cardiovascular collapse in 16 (37%), severe postoperative headache after regional anesthesia in 9 (21%), and awareness under anesthesia in 8 (19%). The researchers determined that 37% of the anesthesia-related morbidity was preventable. The three deaths occurred in severely ill patients (ASA class 3 or greater physical status), and two of these deaths were judged to be preventable.

Cohen and coworkers[39] developed a methodology for studying the outcome of anesthesia in four teaching hospitals in Canada. They developed a new anesthesia record to serve as a data collection instrument. Research nurses reviewed all inpatient records within 72 hours after surgery, conducted interviews of the patients with a standardized instrument, and conducted a telephone survey of most of the outpatients. Assessment of the contribution of anesthesia to each complication was determined by using the classification of the New South Wales Committee on Anaesthesia Mortality (see Table 33-4). In a total of 6914 anesthesia procedures in adults, no deaths were directly attributable to anesthesia.

Lagasse[9] reviewed perioperative deaths (i.e., deaths occurring within 2 days after surgery) at a suburban university hospital network between 1992 and 1994 and an urban university hospital network between 1995 and 1999. There were a total of 347 deaths in 184,472 cases. Anesthesia-related mortality (i.e., death to which error by an anesthesia practitioner contributed) occurred in 1 in every 12,641 procedures in the suburban setting and in 1 in 13,322 procedures in the urban setting. Mortality increased with increasing ASA physical status (Fig. 33-2). In reviewing data over the previous decade, the investigators estimated that anesthesia-related mortality had remained stable at approximately 1 death per 13,000 procedures, with wide variation making it impossible to detect trends in anesthesia safety.

The Thai Anesthesia Incidents Study (THAI Study) consists of a prospectively defined cohort of patients who underwent anesthesia from February 1, 2003, to January 31, 2004 (N = 163,403).[52] The incidence of 24-hour perioperative death, death directly related to anesthesia, and death partially related to anesthesia per 10,000 anesthetics was 28.2 (95% confidence interval [CI], 25.7 to 30.8), 1.7 (95% CI, 1.1 to 2.3), and 4.0 (95% CI, 3.1 to 5.0), respectively. Of 462 deaths, 28 cases (6.1%) were directly related to anesthesia, 66 (14.3%) were partially related to anesthesia, 61 (3.3%) were related to surgery, 399 (86.4%) were

related to patient disease, and 104 (22.5%) were related to the system or management.

Analysis of Intraoperative Cardiac Arrest

Rather than studying perioperative mortality associated with anesthesia, several studies have evaluated intraoperative fatal and nonfatal cardiac arrest (Table 33-9). In this situation there are sufficient numbers of complications to perform an analysis at a single institution. Keenan and Boyan[53] studied the incidence and causes of cardiac arrest related to anesthesia at the Medical College of Virginia during a 15-year period. A total of 27 cardiac arrests occurred during 163,240 procedures, for an incidence of 1.7 per 10,000 cases. Fourteen patients died, for an incidence of 0.9 per 10,000 cases. Pediatric patients had a threefold higher risk of arrest than adults did; emergency cases had a sixfold greater risk. Specific errors in anesthesia management could be identified in 75% of the cases, most commonly inadequate ventilation and absolute overdose of an inhaled anesthetic. The time of day did not appear to influence the rate of anesthesia-related cardiac arrest. From an educational perspective, the investigators identified progressive bradycardia preceding all but one arrest, suggesting that early identification and treatment may prevent complications.

*Because pulse oximetry was introduced in 1984, no "preventable respiratory" cardiac arrests have occurred.
Adapted from Brown DL: Anesthesia risk: A historical perspective. *In* Brown DL (ed): Risk and Outcome in Anesthesia, 2nd ed. Philadelphia, JB Lippincott, 1992.

Olsson and Hallen[54] studied the incidence of intraoperative cardiac arrest at the Karolinska Hospital in Stockholm, Sweden, from 1967 to 1984. A total of 170 arrests occurred in 250,543 anesthesia procedures performed. Sixty patients died, for a mortality rate of 2.4 per 10,000 procedures. After elimination of cases of inevitable death (e.g., rupture of a cerebral aneurysm, trauma), the rate of mortality caused by anesthesia was 0.3 per 10,000 procedures. The most common causes of anesthesia-related cardiac arrest were inadequate ventilation (27 patients), asystole after succinylcholine (23 patients), and postinduction hypotension (14 patients). The incidence of cardiac arrest increased with increasing severity of comorbid disease, as assessed by the ASA physical status classification. In evaluating the incidence of intraoperative cardiac arrest over time, there was a considerable decline between 1967 and 1984, coincident with the increased number of anesthesia specialists employed at the clinic.

Biboulet and colleagues[55] studied fatal and nonfatal cardiac arrests encountered during anesthesia and during the first 12 postoperative hours in the PACU or ICU in a single hospital in France. Eleven cardiac arrests related to anesthesia were identified in 101,769 anesthesia procedures (1.1 per 10,000). The mortality rate related to anesthesia was 0.6 per 10,000 cases. The major causes of death were anesthetic overdose, hypovolemia, and hypoxemia; 10 of the 11 cases had at least one human error, and all were classified as avoidable.

Newland and associates[56] reported anesthesia-related cardiac arrests during 72,959 procedures over a 10-year period in a teaching hospital in the United States. They judged that 15 of the 144 cardiac arrests were related to anesthesia (0.69 per 10,000 procedures), and in an additional 10 cases, anesthesia was considered contributory, for a total rate of 1.37 per 10,000 procedures (95% CI, 0.52 to 2.22). The risk of death from perioperative cardiac arrest that was attributable to anesthesia was 0.55 per 10,000 procedures. Most of the arrests were related to medication administration, airway management, or technical problems of central venous access.

Kawashima and colleagues sent confidential questionnaires to all Japan Society of Anesthesiologists Certified Training Hospitals every year from 1994 through 1998.[57] A total of 2,363,038 cases were documented over a 5-year period. The average yearly incidence of cardiac arrest during surgery that was totally attributable to anesthesia was 1.00 (95% CI, 0.88 to 1.12) per 10,000 cases. The average mortality per year in the operating room or within 7 postoperative days that was totally attributable to anesthesia was 0.21 (0.15 to 0.27) per 10,000 cases. The two principal causes of cardiac arrest totally attributable to anesthesia were drug overdose or selection error (15.3%) and serious arrhythmia (13.9%). Preventable human errors caused 53.2% of cardiac arrests and 22.2% of deaths in the operating room that were totally attributable to anesthesia. The outcomes of cardiac arrests totally attributable to anesthesia are shown in Table 33-10.

Sprung and colleagues studied patients who experienced cardiac arrest in the operating room, during transport to the PACU or ICU, or in the PACU after noncardiac surgery between 1990 and 2000.[58] Cardiac arrest occurred in 223 of 518,294 anesthesia procedures (4.3 per 10,000) during the study period. The frequency of arrest in patients receiving general anesthesia

Reproduced with permission from Kawashima Y, Takahashi S, Suzuki M, et al: Anesthesia-related mortality and morbidity over a 5-year period in 2,363,038 patients in Japan. Acta Anaesthesiol Scand 47:809-817, 2003.

decreased over time (7.8 per 10,000 during 1990 to 1992; 3.2 per 10,000 during 1998 to 2000). The frequency of arrest during regional anesthesia (1.5 per 10,000) and monitored anesthesia care (0.7 per 10,000) remained consistent (Fig. 33-3). The hospital survival rate was 34.5%. Twenty-four patients (0.5 per 10,000) had cardiac arrest related primarily to anesthesia, 19 of whom (79.2%) survived to hospital discharge. The in-hospital mortality attributable to anesthetic-related cardiac arrest was 0.1 per 10,000 anesthetics. Given the small number of events, no relationship between the type of anesthesia and anesthetic-related cardiac arrest could be determined.

Braz and coworkers studied perioperative cardiac arrest that occurred during 53,718 anesthetics performed between 1996 and 2005 in a Brazilian teaching hospital.[59] One hundred eighty-six cardiac arrests (34.6 per 10,000) and 118 deaths (21.97 per 10,000) were reported. Major risk factors for cardiac arrest were neonates, children younger than 1 year and the elderly, male patients with ASA 3 or poorer physical status, emergency surgery, and general anesthesia. There were 18 anesthesia-related cardiac arrests (3.35 per 10,000), 10 totally attributed (1.86 per 10,000) and 8 partially related to anesthesia (1.49 per 10,000). There were six anesthesia-related deaths (1.12 per 10,000), three totally attributable and three partially related to anesthesia (0.56 per 10,000 in both cases). The main causes of anesthesia-related cardiac arrest were respiratory events (55.5%) and medication-related events (44.5%).

Perioperative Mortality and Morbidity in Outpatient Surgery

It is estimated that 60% of all surgical procedures are performed on an outpatient basis, and this percentage is increasing annually. The type and extent of surgical procedures performed in an outpatient setting are constantly changing, and procedures associated with greater perioperative risk are increasingly being performed on an outpatient basis (see Chapter 78). The value of overnight observation in a hospital setting as opposed to immediate discharge home has been studied for a number of surgical procedures. One of the first procedures advocated to be performed on an ambulatory basis was tonsillectomy. In 1968, a case series of 40,000 outpatient tonsillectomies with no deaths was reported.[60] Details on patient selection and length of postoperative monitoring were vague. Based on insurance company and state mandates, performance of tonsillectomy on an outpatient

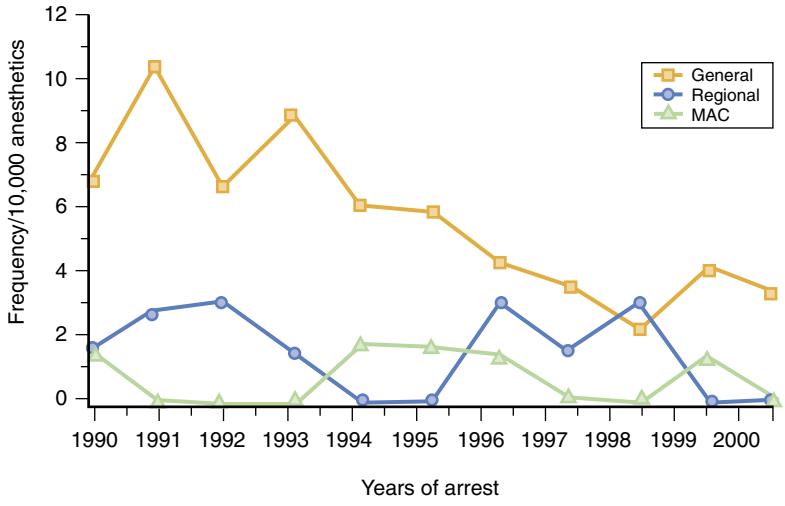

Figure 33-3 Frequency of cardiac arrest by calendar year and type of anesthesia. MAC, monitored anesthesia care. *(From Sprung J, Warner ME, Contreras MG, et al: Predictors of survival following cardiac arrest in patients undergoing noncardiac surgery: A study of 518,294 patients at a tertiary referral center. Anesthesiology 99:259-269, 2003.)*

basis became routine.[61] Beginning in the mid-1980s and continuing in the 1990s, a number of articles evaluated the risk associated with early discharge. For example, Carithers and colleagues[62] at Ohio State University analyzed 3000 tonsillectomies and argued that early discharge might be hazardous and economically unwarranted. The rate of readmission for active bleeding between 5 and 24 hours after surgery was reported to be between 0.2% and 0.5%.[63-66] Although the absolute rate of readmission is low, it represents a substantial risk for children. Whether the benefits of early discharge outweigh the risks is a decision society will have to make.

Another procedure being performed on an outpatient basis is mastectomy. An analysis of Medicare claims demonstrated that the rate of outpatient mastectomy increased from only two procedures reported to Medicare in 1986 to 10.8% of the mastectomies performed in this population in 1995.[67] The investigators compared the rate of readmission within 7 days after surgery for those who had the procedure performed on an inpatient basis versus those treated on an outpatient basis, with adjustment for the severity of disease. Simple mastectomies performed on an outpatient basis had a significantly higher rate of readmission than 1-day stays did, with an adjusted odds ratio (OR) of 1.84. There were 33.8 readmissions per 1000 cases for the outpatient surgeries as compared with 24.2 readmissions for surgeries with 1-day length of hospital stay. When compared with the group treated on an outpatient basis, there were significantly lower rates of readmission after 1-day stays for infection (4.1 versus 1.8 per 1000 cases), nausea and vomiting (1.1 versus 0 per 1000 cases), and pulmonary embolism or deep venous thrombosis (1.1 versus 0 per 1000 cases). Similarly, modified radical mastectomies performed on an outpatient basis had a significantly higher rate of readmission than 1-day stays did, with an adjusted OR of 1.72. The researchers suggested that patients who undergo the procedure on an outpatient basis may wait longer at home until seeking medical care and therefore may have more advanced symptoms initially.

Warner and colleagues[68] at the Mayo Clinic studied major morbidity and mortality occurring within 1 month after ambulatory surgery in 38,598 patients (see Chapter 78). Four patients died, two of myocardial infarction and two in an automobile accident (Fig. 33-4). The two deaths from myocardial infarction occurred at least 1 week after surgery and were not directly attributable to anesthesia. In view of the rate of mortality directly related to anesthesia described in the CEPOD study, no deaths would be expected in a study of this size.

Fleisher and coworkers[1] performed a claims analysis of patients undergoing 16 different surgical procedures in a nationally representative (5%) sample of Medicare beneficiaries for the years 1994 through 1999. A total of 564,267 procedures were studied, with 360,780 in an outpatient hospital, 175,288 in an ambulatory surgery center (ASC), and 28,199 in an office. On the day of surgery, no deaths occurred in the office, but 4 deaths occurred in the ASC (2.3 per 100,000) and 9 deaths occurred in the outpatient hospital (2.5 per 100,000). The 7-day mortality rate was 35 per 100,000 in the office setting, 25 per 100,000 in the ASC, and 50 per 100,000 in the outpatient hospital. The rate of admission to an inpatient hospital within 7 days was 9.08 per 1000 in the office, 8.41 per 1000 in the ASC, and 21 per 1000 in the outpatient hospital.

Fleisher and colleagues analyzed data from operations performed in hospital-based and freestanding ASCs in New York during 1997 that were obtained from the Agency for Healthcare Research and Quality's Healthcare Cost & Utilization Project.[69] Of the 783,558 patients eligible for inclusion in this study, 4351 were discharged directly for short-term hospitalization (1 in 180), and 19 died (1 in 41,240).

Chukmaitov and colleagues compared quality outcomes between ASCs and hospital-based outpatient departments in the state of Florida between the years 1997 and 2004.[70] They used 7- and 30-day mortality and unexpected hospitalization as the outcomes of interest in 12 surgical procedures. The importance of location of care varied by surgical procedure and the number of comorbid conditions included in the analysis. They postulated that the difference in outcomes between the two locations may be related to variations in organizational structure, processes, and strategies. The study, however, is flawed because of extreme selection bias and huge differences in available data between the ASC and hospital-based outpatient department setting. The differences in data sets were evaluated with a limited set and a set using all available data (which differed between settings). Not surprisingly, the results between settings changed with the two types of data.

Interest in performing surgery and providing anesthesia in office-based settings is increasing. There are no good data to determine the safety of such practice, although a number of high-profile cases have occurred in which patients have died during plastic surgery and during dental office procedures. Anesthesia and sedation are frequently provided by individuals other than anesthesiologists or nurse anesthetists in these settings, with reports of office nurses or even clerical help administering anesthetic agents.

There has been an attempt to quantify the incidence of complications in an office-based setting. The American Association for Ambulatory Plastic Surgery Facilities mailed a survey to their members to determine the incidence of complications occurring in office facilities.[71] The overall response rate was 57%. The findings showed that 0.47% of patients had at least one complication, including bleeding, hypertension, infection, and hypotension, and 1 in 57,000 patients died. Assuming that these are very minor procedures performed only on healthy individuals, a rate of mortality that is three times the current estimate for anesthesia-related complications is a concern. Further research and quality assurance mechanisms need to be in place before this practice is generalized. One of the problems inherent in an office-based setting is the inability to perform quality assurance reviews. For example, few surgeons or anesthesiologists would be willing to allow their "competitors" to review their complication rate unless mandated to perform such a review.

Vila and colleagues reviewed all adverse incident reports to the Florida Board of Medicine for procedure dates April 1, 2000, to April 1, 2002.[72] The numbers of office procedures performed during a 4-month period were used to estimate the total number of procedures. Adverse incidents occurred at a rate of 66 and 5.3 per 100,000 procedures in offices and ASCs, respectively. The death rate per 100,000 procedures performed was 9.2 in offices and 0.78 in ASCs. The relative risk for injury and death for procedures performed in the office versus ASCs was 12.4 (95% CI, 9.5 to 16.2) and 11.8 (95% CI, 5.8 to 24.1), respectively. The authors concluded that if all office procedures had been performed in ASCs, approximately 43 injuries and 6 deaths per year could have been prevented. In contrast, Coldiron and colleagues studied office-based surgery in Florida and showed that the greatest danger to patients lies not with surgical procedures in office-based settings per se but with cosmetic procedures that are

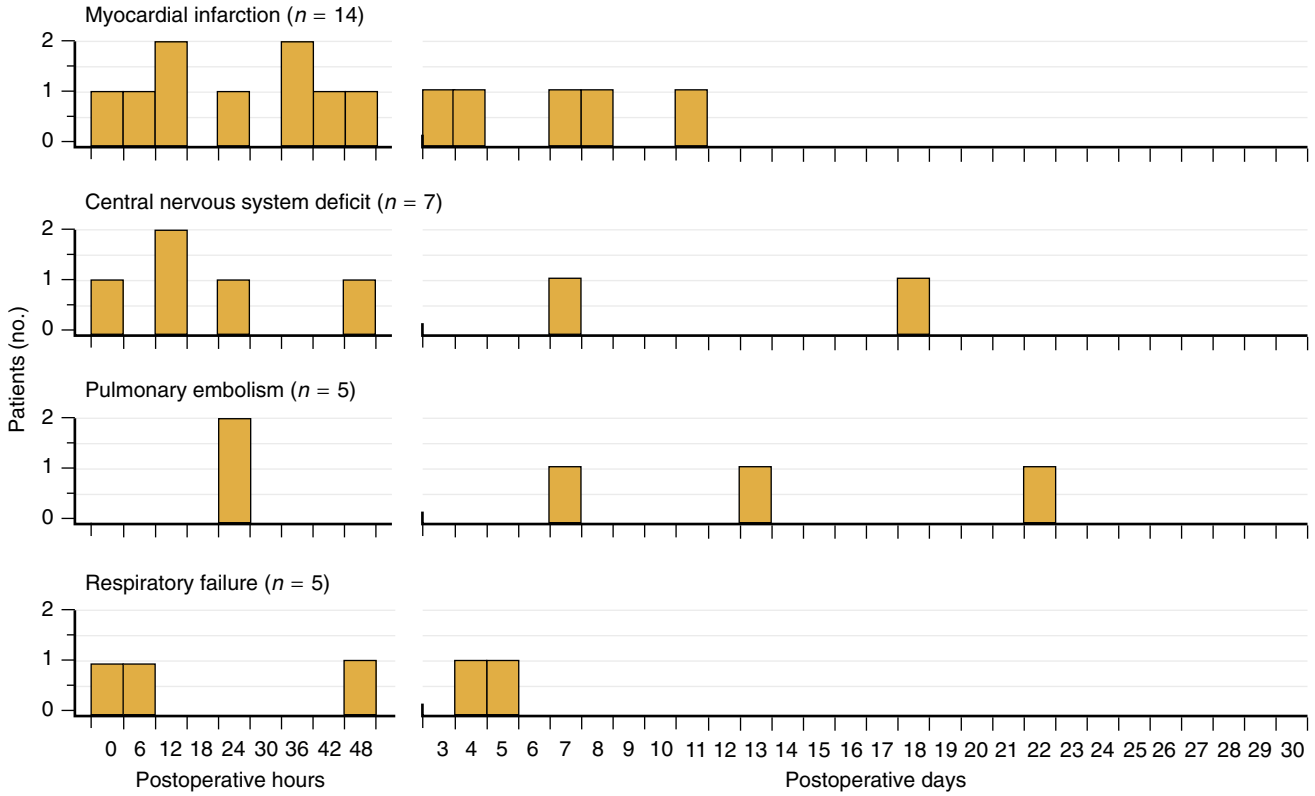

Figure 33-4 Timing of perioperative events in patients undergoing ambulatory surgery. Many of the events occurring within the first 48 hours are probably related to the stress of surgery. A subset of events occurring after this period may be related to background event rates. The overall rate of morbidity was lower than expected for a similar cohort of age-matched nonsurgical patients. *(From Warner MA, Shields SE, Chute CG: Major morbidity and mortality within 1 month of ambulatory surgery and anesthesia. JAMA 270:1437, 1993.)*

performed in office-based settings, particularly when under general anesthesia.[73] Several other groups have analyzed the Florida data and have been unable to document the increased risk in the office setting.[74,75]

Problems in evaluating the risk associated with outpatient surgery include the lack of any large database compiled from a diverse group of settings and the lack of uniform standards for quality assurance. Even though the Joint Commission accredits ASCs, as do two other organizations, accreditation is still not widespread and remains optional. Although ASCs have led the way in performing appropriate follow-up of their patients at home, such follow-up is not uniformly complete. As of 1998, only three states had established regulations for office-based settings, and these regulations vary greatly. The implications of the lack of regulation are unclear, but issues related to emergency plans and resuscitation equipment may be left to the discretion of the local personnel, potentially placing patients at risk.

The decision to perform a procedure in an ambulatory setting is based on the surgeon's preference and the insurance company's mandates. Frequently, a case series by a surgeon or review by an insurance company demonstrates that otherwise healthy individuals can undergo a given procedure safely in an outpatient setting. The need for subsequent medical attention or use of resources at home is not necessarily taken into account. This may lead to insurance company mandates that the procedure be performed in all patients in an ambulatory setting. The generalization from healthy individuals to patients with comorbid disease may not be justified in the absence of data to demonstrate its safety. As an advocate for the patient, the anesthesiologist should continue to evaluate the safety of such practices and determine when the risks of ambulatory surgery outweigh any potential benefits. It is also important to determine whether the insurance companies are in essence transferring the risk of undergoing surgery from the medical system to the patient.

Use of Anesthesia Information Management Systems

Use of computer databases has enhanced the ability of investigators to identify perioperative complications (see Chapter 4). In one of the earliest computer analyses of postanesthesia deaths, Marx and associates[21] identified 645 individuals who died within 7 days after surgery out of a total cohort of 34,145 consecutive surgical patients. More recently, anesthesia information systems have been installed in many operating rooms. The advantage of these systems is the ability to query very large sets of data; however, the limitation is that many of these systems do not link with data from outside the operating room or the PACU. Therefore, the risk related to anesthesia for most of these studies is restricted to intraoperative events. Currently, there are several initiatives to try to link these data, including linking multiple institutions, with validated postoperative data from the NSQIP or Society of Thoracic Surgeons database.

One of the first such analyses was performed by Sanborn and colleagues,[76] who used a computer anesthesia record to iden-

tify intraoperative incidents with high sensitivity and specificity. They were able to demonstrate that perioperative deaths occurred more frequently in patients who sustained an intraoperative incident than in those who did not.

Reich and colleagues used computerized anesthesia records to evaluate hemodynamic variables.[22] Among 2149 patients, there were 50 mortalities, 51 strokes, and 85 perioperative myocardial infarctions. By multivariate analysis they identified pulmonary hypertension, hypotension during cardiopulmonary bypass, and post–cardiopulmonary bypass pulmonary diastolic hypertension as independent predictors associated with mortality, stroke, and perioperative myocardial infarction over and above the effects of other preoperative risk factors.

Tremper's group at the University of Michigan used their home-grown information system to identify predictors of perioperative risk. For example, they queried 22,660 attempts at mask ventilation.[77] Limited or severely limited mandibular protrusion, abnormal neck anatomy, sleep apnea, snoring, and a body mass index of 30 kg/m^2 or greater were independent predictors of grade 3 or 4 mask ventilation and difficult intubation. In another publication, a total of 15,102 patients had a normal preoperative creatinine clearance and were undergoing noncardiac surgery.[78] Acute renal failure developed in 121 patients (0.8%), and 14 required renal replacement therapy (0.1%). Seven independent preoperative predictors were identified: age, emergency surgery, liver disease, body mass index, high-risk surgery, peripheral vascular occlusive disease, and chronic obstructive pulmonary disease necessitating chronic bronchodilator therapy. They found that acute renal failure was associated with increased 30-day, 60-day, and 1-year all-cause mortality.

Given the growth in the use of anesthesia information management systems and the ease of collecting large quantities of data and linking them to outcome, it is likely that many more studies documenting associations with outcome will be published.

Other Approaches to Discern the Root Cause of Morbidity and Mortality

The accumulating data clearly demonstrate that risk directly attributable to anesthesia has declined over time (see Chapter 5). The cause of this reduction in mortality is unclear. Numerous factors have been implicated in the improved outcome, including new monitoring modalities, new anesthetic drugs, and changes in the anesthesia workforce. However, it is difficult to document reduced risk related to any one factor (issues related to manpower are addressed later). Although the use of newer monitoring modalities, particularly pulse oximetry, would be expected to improve outcomes, no randomized trial has been able to document such a conclusion. This limitation supports the need for continued monitoring of complications and their root cause with studies such as the ACCS.

Studies similar to the CEPOD have not been performed in the United States, most likely because of the legal system, and information related to perioperative mortality must be obtained from other sources. The Professional Liability Committee of the ASA conducted a nationwide survey of closed insurance claims for major anesthesia mishaps. In the ACCS, fatal and nonfatal outcomes were reviewed. Among the fatal events, unexpected cardiac arrest during spinal anesthesia was observed in 14 healthy patients from the initial 900 claims.[79] The cases were analyzed in detail to identify patterns of management that might have led to the event. Two patterns were identified: oversedation leading to respiratory insufficiency and inappropriate resuscitation of high spinal sympathetic blockade.

Tinker and coworkers[80] queried the ACCS to determine the role of monitoring devices in the prevention of anesthesia mishaps. They reviewed 1097 anesthesia-related claims and determined that 31.5% of the negative outcomes could have been prevented by the use of additional monitors, primarily pulse oximetry and capnography. Injuries that were deemed preventable with additional monitoring resulted in dramatically more severe injury and cost of settlement than did those judged nonpreventable with additional monitoring. In nearly 90% (305 of 346) of the preventable cases, at least one clinical sign of abnormality was identified by the existing monitors.

Caplan and colleagues[81] reviewed the ACCS for respiratory events (Table 33-11). These claims represented the single largest class of injury (34%), with death or brain damage occurring in 85% of cases. They identified inadequate ventilation, esophageal intubation, and difficult tracheal intubation as the primary causes of respiratory events. Most of the outcomes were thought by the investigators to be preventable with better monitoring (Fig. 33-5). Although no randomized trial has demonstrated the value of pulse oximetry or capnography, an analysis of claims supports the value of such monitoring. This analysis also formed part of the basis for the guidelines and algorithm endorsed by the ASA Task Force on Management of the Difficult Airway.

The closed claims analysis has recently focused on such topics as monitored anesthesia care.[82] More than 40% of 121 claims associated with monitored anesthesia care involved death or permanent brain damage. Respiratory depression, after an absolute or relative overdose of sedative or opioid drugs, was the most common (21%, $n = 25$) of the complications.

A similar registry was developed by the Danish Patient Insurance Association.[83] For the period 1996 to 2004, 1256 files were related to anesthesia and 24 deaths were considered to be a result of the anesthetic procedure: 4 deaths were related to airway management, 2 to ventilation management, 4 to central venous catheter placement, 4 as a result of medication errors, 4 from infusion pump problems, and 4 after complications from regional blockade. Severe hemorrhage caused one death, and in one case the cause was uncertain.

Table 33-11 Distribution of Adverse Respiratory Events in the American Society of Anesthesiologists Closed Claims Study

Event	No. of Cases	Percentage of 522 Respiratory Claims
Inadequate ventilation	196	38
Esophageal intubation	94	18
Difficult tracheal intubation	87	17
Inadequate inspired oxygen concentration	11	2

From Caplan RA, Ward RJ, Posner K, Cheney FW: Unexpected cardiac arrest during spinal anesthesia: A closed claims analysis of predisposing factors. Anesthesiology 68:5, 1988.

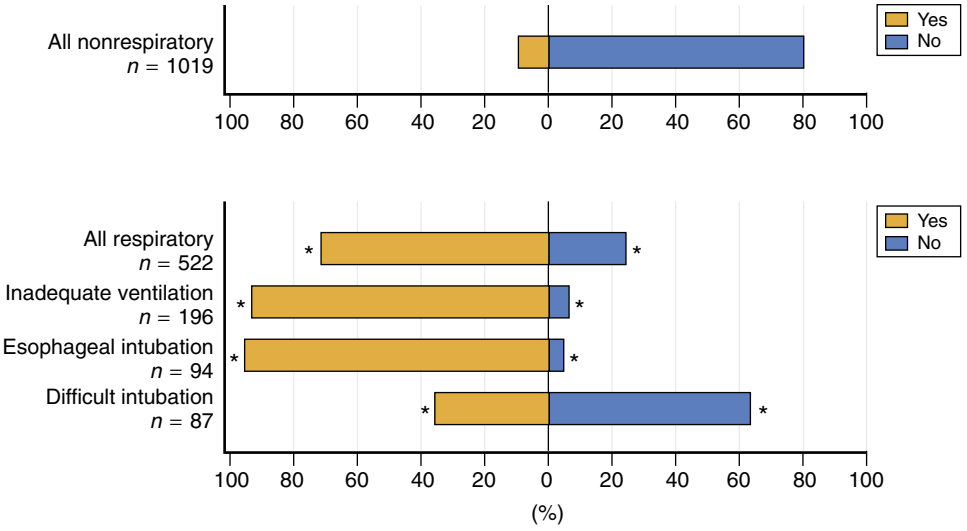

Figure 33-5 Relationship between adverse events in the American Society of Anesthesiologists Closed Claims Study and preventable complications. Preventable events related to respiratory complications were significantly more common than those related to all nonrespiratory complications. Of the respiratory complications, difficult intubation had the least number of preventable complications (*$P < .05$ versus nonrespiratory claims). *(From Caplan RA, Posner KL, Ward RJ, Cheney FW: Adverse respiratory events in anesthesia: A closed claims analysis. Anesthesiology 72:828, 1990.)*

Cooper and colleagues[84-86] approached the problem of sample size for determining perioperative morbidity by identifying critical incidents, which were defined as those that were preventable but could lead to undesirable outcomes. This definition included events that led to no or only transient effects in the patient. The investigation involved collecting data on anesthesia-related human errors and equipment failures from anesthesiologists, residents, and nurse anesthetists. In a series of reports, the authors identified frequent incidents, such as disconnections in breathing circuits, and causes of discovery of errors, such as intraoperative relief. They confirmed that equipment failure was a small cause of anesthesia mishaps (4%), whereas human error was dominant. They suggested that future studies of anesthesia-related mortality and morbidity should classify events according to a strategy for prevention rather than outcome alone.

The Australian Incident Monitoring Study was developed by the Australian Patient Safety Foundation and has been in existence since the early 1990s. It is a method of reporting and analyzing critical incidents so that corrective strategies can be implemented. Similar to the ACCS, there is no rate of occurrence, only an analysis of reported cases. Numerous reports have looked at the cause of critical incidents, including problems with ventilation, with vascular access, and in the PACU.[87-89]

Buffington and coworkers[90] studied the ability of attendees of an anesthesia meeting to identify five faults intentionally created in a standard anesthesia machine. A survey was distributed, and the answer sheets were scored with respect to the number of correct answers. Only 3.4% of the respondents found all five faults. The average number of faults detected was 2.2. The professional background of the participants did not influence the ability to find the faults; distributions were similar between physicians and CRNAs. There was a small improvement in fault-finding ability in those with more than 10 years of experience. Studies such as these highlight the problem of the practitioner's ability to identify conditions that may lead to anesthesia mishaps. Whether improved technology or education can reduce some basal level of mishaps is unknown.

Issues Associated with Anesthesia-Related Mortality

Most of the studies have focused on in-hospital and short-term mortality, but perioperative complications may be the events that directly lead to death. For example, a perioperative stroke or myocardial infarction may lead to death after the period of analysis. Even small myocardial infarctions or unstable angina during the perioperative period has been associated with worse long-term survival in several studies.[91,92] Should these "late" deaths be attributed to anesthesia complications for the purpose of such analyses? Results from several studies add to the dilemma. For example, Mangano and colleagues[93] performed a randomized clinical trial in which 7 days of perioperative β-blockade was compared with placebo in high-risk patients undergoing noncardiac surgery. They reported significantly improved survival at 6 months, which remained significant during the 2 years of follow-up. In a subsequent report regarding this trial, Wallace and coworkers[94] demonstrated that the improved survival in the group receiving β-blockade was associated with a significantly lower incidence of perioperative myocardial ischemia but no difference in perioperative cardiac events. The authors of the original study suggested that atenolol administration led to better plaque stabilization during the perioperative period, which resulted in improved long-term survival. If the hyperdynamic perioperative state is not well controlled, this theory suggests that more plaque becomes destabilized and progresses to acute occlusion and sudden death. If atenolol is not used and patients die within 6 months of surgery, should this be attributed to an error in anesthesia and perioperative management? Part of the answer relies on the strength of this study to support the conclusion that routine use of atenolol does result in improved long-term survival.

The potential effects of anesthesia on long-term survival were suggested by Monk and colleagues.[95] Multivariate Cox proportional hazards modeling identified three variables as signifi-

cant independent predictors of mortality: patient comorbidity (relative risk, 16.116), cumulative deep hypnotic time (bispectral index <45) (relative risk, 1.244/hr), and intraoperative systolic hypotension (relative risk, 1.036/min). They reported that cumulative deep hypnotic time and intraoperative hypotension were significant, independent predictors of increased mortality. Further work is required to determine whether these results reflect a true pathophysiologic link between perioperative management and long-term outcome or a simple statistical association.

Risks Related to the Patient

Perioperative morbidity and mortality increase with increasing patient comorbidity. The original ASA physical status scoring system was proposed in 1941 and included six categories.[96] It was intended to standardize terminology and allow statistical analysis of outcomes between sites.[97] The original classification avoided the inclusion of surgical variables and was restricted to preoperative patient characteristics. It was revised in 1961 by Dripps and colleagues[32] to five categories, which were then adopted by the ASA.

The simplest example of such a relationship is the incidence of mortality correlated with ASA physical status. In their original study of perioperative mortality, Dripps and coworkers demonstrated that mortality increased as the severity of comorbid disease increased, as assessed by the ASA physical status classification. Several investigators have re-evaluated the relationship between operative mortality and ASA physical status. Studies by Pedersen and Tiret and their colleagues demonstrated such relationships. Vacanti and coworkers[98] also demonstrated the relationship between increasing mortality and decreasing physical status in 68,388 cases.

In Canada, Cohen and colleagues[99] analyzed 100,000 anesthesia procedures and determined mortality within 7 days of surgery by using governmental vital statistics mortality data between the years 1975 and 1984. They established a computer database for each procedure that included age, preoperative conditions, ASA physical status, anesthesia technique, monitors, and other factors. The overall 7-day mortality rate was 71.04 deaths per 10,000 procedures. The mortality rate increased with advanced age, and it showed a marked increase in those older than 80 years. Rates were low for normal, healthy individuals and for those undergoing minor procedures. The investigators developed a multiple logistic regression model to determine the independent predictors of mortality. Significant risk markers for increasing mortality were advanced age, male gender, increasing physical status score, major or intermediate surgery, emergency procedure, having a complication in the operating room, narcotic anesthesia techniques, and having received only one or two anesthetic drugs (Table 33-12).

In an attempt to look at each of the categories of contributing factors independently, Cohen's group constructed receiver-operator characteristic curves. There was no increment in prediction of mortality beyond that based on characteristics of the patient plus surgery. Plots including "other" or anesthesia-related factors showed almost complete overlap with curves including only patient- and surgery-specific factors.

One of the limitations of the ASA physical status classification is that ranking is a subjective measure conferred by the practitioner rather than an objective measure determined by the presence of specific disease states. Owens and coworkers[100] evaluated this hypothesis by asking 255 anesthesiologists to classify 10 hypothetical patients. In six of the cases there was general agreement among the practitioners about classification of the patient; in the other four cases, opinion diverged. The key finding of this study was that the ASA physical status classification is "useful but suffers from a lack of scientific precision."

Rather than evaluating the risk of overall mortality, many studies have attempted to define the patient characteristics associated with morbidity and mortality related to a particular organ system. In evaluating the risk directly related to the patient's condition, it is important to understand the limitations of the methodology. All such studies evaluate the predictive value of a clinical

Table 33-12 Risk Factors Associated with Increased Odds of Dying within 7 Days for All Cases

Variable	All Procedures: Relative Odds of Dying within 7 Days	95% Confidence Limits
Patient Related		
Age (yr)		
60-79/<60	2.32	1.70-3.17
80+/<60	3.29	2.18-4.96
Sex (F/M)	0.77	0.59-1.00
Physical status score (3-5/1-2)	10.65	7.59-14.85
Surgery Related		
Major/minor	3.82	2.50-5.93
Intermediate/minor	1.76	1.24-2.5
Length of anesthesia (≤2 hr/<2 hr)	1.08	0.77-1.50
Emergency/elective	4.44	3.38-5.83
Other Factors		
Year of surgery (1975-1979/1980-1984)	1.75	1.32-2.31
Had a complication in the operating or recovery room (yes/no)	1.42	1.06-1.89
Anesthesia Related*		
Experience of the anesthetist (>600 procedures for ≥8 yr/<600 procedures for <8 yr)	1.06	0.82-1.37
Inhalation with narcotic/inhalation alone	0.76	0.51-1.15
Narcotic alone/inhalation alone	1.41	1.01-2.00
Narcotic with inhalation/inhalation alone	0.79	0.47-1.32
Spinal/inhalation alone	0.53	0.29-0.98
No. of anesthetic drugs (1-2/3+)	2.94	2.20-3.84

or laboratory risk factor for a defined perioperative complication. In this approach, a cohort of individuals of interest is defined. In the optimal state the study is performed prospectively, and the outcome of interest is assessed in a rigorous, blinded fashion. Unfortunately, many of the studies focus on selected patients and include a retrospective design, methods that greatly limit their generalizability and validity. For example, many studies evaluating risk factors in vascular surgery patients include only patients who are referred for diagnostic testing rather than a consecutive series of patients.

Many studies have adopted the approach of defining a cohort of individuals, determining their clinical and laboratory risk factors, and using multivariate modeling to determine the factors associated with increased risk. Frequently, perioperative risk is used to define intraoperative and postoperative complications. A major limitation in the use of multivariate modeling for this purpose is the assumption that the intraoperative period is a "black box" and that care is not modified by knowledge of the risk factor (Fig. 33-6). However, anesthesiologists do modify their intraoperative care of high-risk patients in an attempt to reduce the risk. Changes in medical care over time and better knowledge about high-risk patients should result in a reduction of the risk related to specified clinical factors. For this reason, many of the indices developed previously may no longer have clinical validity.

In designing a multivariate risk index for perioperative morbidity and mortality, only factors that are included in the analysis and in the patient population of interest can be included in the final model. For example, if the population studied represents a unique referral bias, some risk factors may be overrepresented, and others may not be present in sufficient quantity to study. An example is unstable angina in the original Cardiac Risk Index developed by Goldman and colleagues.[6] Because patients with unstable angina are typically seen only for emergency surgery, that risk factor is rarely represented in many indices.

There are numerous specific disease states that increase perioperative risk. Cardiovascular disease has been the most extensively studied, with the goal of identifying patients at greatest risk for fatal and nonfatal myocardial infarction. One of the earliest attempts to define cardiac risk was performed by Goldman and colleagues at the Massachusetts General Hospital. They studied 1001 patients older than 45 years who were undergoing noncardiac surgery, excluding those who underwent transurethral resection of the prostate under spinal anesthesia. Using multivariate logistic regression, they demonstrated nine clinical factors associated with increased morbidity and mortality. Each of these risk factors was associated with a given weight in the logistic regression equation, which was converted into points in the index. An increasing number of points was associated with increasing perioperative cardiac morbidity or mortality.

There have been several attempts to validate the Goldman Cardiac Risk Index. Zeldin[101] prospectively determined the Cardiac Risk Index for 1140 surgical patients and reported that the overall accuracy of the index was as high as in the original study, although the rate of complications in the highest-risk group was less than originally reported. Larsen and coworkers[102] also found that the Cardiac Risk Index demonstrated good accuracy in 2609 consecutive unselected patients older than 40 years. Domaingue and colleagues[103] studied patients undergoing various vascular surgery procedures and reported a higher probability of major cardiac complications than that reported by Goldman and associates; however, they also demonstrated a higher rate of complications with increasing cardiac risk class. The validity of the Cardiac Risk Index is more controversial for vascular surgery patients. Jeffrey and colleagues[104] evaluated the rate of cardiac complications in 99 patients undergoing elective abdominal aortic surgery and demonstrated a similar pattern of increased overall complication rates with increasing cardiac risk. A higher percentage (7%) of patients in the lowest category in their study sustained a cardiac complication. White and associates[105] demonstrated the value of the Goldman Cardiac Risk Index for long-term survival after vascular surgery. Several other studies, however, were unable to demonstrate any relationship between the Cardiac Risk Index and perioperative cardiac complications, with a high incidence of complications found in patients with a Cardiac Risk Index of I or II.[106,107] When the ASA physical status classification was compared with the Goldman Cardiac Risk Index in a cohort of 16,277 patients undergoing noncardiac surgery,[108] both indices demonstrated predictive value, although the objective Goldman Cardiac Risk Index had little increased value over the more subjective ASA physical status classification.

Other investigators have attempted to develop risk indices. Detsky and coworkers[109] studied a cohort of individuals who were referred to an internal medicine service for preoperative evaluation. Many of the factors identified by Goldman were confirmed or slightly modified in the Detsky index, and angina was added to the risk factors. The researchers advocated the calculation of a pretest probability of complications based on the type of surgery, after which the Detsky Modified Risk Index is applied with the use of a nomogram. In this manner, the overall probability of complications can be determined as a function of the surgical procedure and patient disease. The Detsky index was advocated as the starting point for risk stratification in the American College of Physicians guidelines on preoperative evaluation.[110] In an

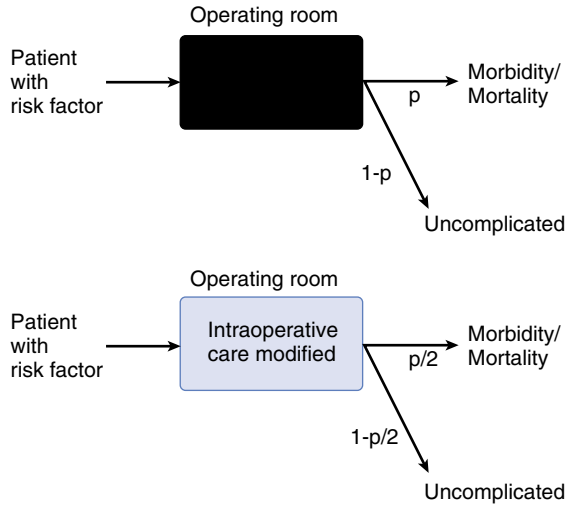

Figure 33-6 The concept of the black box for risk indices. In developing a risk index, patients with a specific risk factor enter the operating room and have a complication at a rate (p). If the anesthesiologist is aware of the importance of the risk factor and can modify care to reduce such risk (p/2), the risk factor may no longer be significant. If the risk factor is ignored, complications may again occur in such patients.

attempt to update the original index, Lee and colleagues[111] at the Brigham and Women's Hospital studied 4315 patients 50 years or older who were undergoing elective major noncardiac procedures in a tertiary care teaching hospital. Six independent predictors of complications were identified and included in a Revised Cardiac Risk Index: high-risk type of surgery, history of ischemic heart disease, history of congestive heart failure, history of cerebrovascular disease, preoperative treatment with insulin, and preoperative serum creatinine level higher than 2.0 mg/dL. The rate of major cardiac complications increased with the number of risk factors.

Numerous risk indices for cardiac surgery have been developed. The goal has been to identify patients who are at greatest risk for adverse perioperative outcomes, not specifically anesthesia-related risk. Many of these indices focus on anatomic considerations for perioperative risk. They are extremely useful in risk adjustment to assess rates of mortality. For example, the state of New York annually publishes data on mortality rates associated with coronary bypass grafting by surgeon and by hospital.[112-114] For comparison of rates across institutions, risk figures must be adjusted so that institutions that perform predominantly high-risk surgery are not penalized.

Vanzetto and coworkers[115] performed a prospective evaluation in which an expanded number of clinical variables were identified in a cohort of patients undergoing major vascular surgery. Cardiovascular morbidity and mortality were determined prospectively in this population. An increasing number of clinical variables was associated with increasing perioperative risk. Most importantly, dipyridamole-thallium imaging was performed only in the subset of patients with two or more clinical variables, and the results of the test were not made available to the clinicians caring for the patients. In this well-performed study, the presence of thallium redistribution identified a cohort who had an incrementally greater perioperative risk than did those with negative scan results and a similar number of clinical variables.

As part of their study of anesthesia-related mortality, Pedersen and colleagues[51] evaluated the occurrence of cardiovascular and pulmonary complications. For a total of 7306 anesthesia procedures, they reported a 6.3% incidence of intraoperative or postoperative cardiovascular complications and a 4.8% incidence of intraoperative or postoperative pulmonary complications. Acute myocardial infarction occurred in 0.16% of the patients. The investigators evaluated a number of characteristics, including gender, age, presence of ischemic heart disease, duration of anesthesia, and type of surgery, and assessed their relationship to cardiovascular and pulmonary complications and overall mortality in the hospital (Table 33-13). Cardiopulmonary complications were associated with advanced age (>70 years), preoperative signs of ischemic heart disease with recent myocardial infarction, chronic heart failure, chronic lung disease, and abdominal surgery, particularly of an emergent nature. They observed that the use of pancuronium was associated with worse perioperative outcome, a finding reminiscent of the curare-related deaths of the 1940s and 1950s.

Numerous studies have evaluated the importance of single variables such as hypertension on perioperative risk. Goldman and Caldera[116] evaluated a cohort of patients undergoing noncardiac surgery under general anesthesia. Hypertension did not denote a group with increased perioperative risk, although the number of patients with diastolic blood pressure greater than 110 mm Hg was insufficient to draw any conclusions. This study highlighted the problems related to generalization of results in that many subsequent researchers have suggested that surgery be delayed in patients with a diastolic blood pressure greater than 110 mm Hg. In one of the few studies to demonstrate a relationship, Hollenberg and coworkers[117] identified hypertension and the presence of left ventricular hypertrophy as predictors of perioperative ischemia, but they did not consider their independent relationship to perioperative major morbidity.

Examples of prospective cohort studies to identify the risk associated with a particular clinical factor include studies of the rate of perioperative reinfarction in patients who had previously sustained a myocardial infarction. Traditionally, risk assessment for noncardiac surgery was based on the time interval between the myocardial infarction and surgery. Multiple studies have demonstrated an increased incidence of reinfarction if the myocardial infarction occurred within 6 months of surgery. With improvements in perioperative care, this difference has decreased.

The previous example of assessing risk illustrates the issue of changes in management over time. The importance of the intervening time interval may no longer be valid in the current era of thrombolytics, angioplasty, and risk stratification after acute myocardial infarction. Although many patients with myocardial infarction continue to have myocardium at risk for subsequent ischemia and infarction, in others, the critical area of coronary stenosis is totally occluded or widely patent. Patients should be evaluated from the perspective of their risk for ongoing ischemia. In their Guidelines for Perioperative Evaluation of Noncardiac Surgery, the American Heart Association/American College of Cardiology Task Force on Assessment of Diagnostic and Therapeutic Cardiovascular Procedures[118] proposed that patients who have experienced a myocardial infarction within less than 30 days be considered the group at highest risk; after that period, risk stratification is based on disease severity and exercise tolerance.

Special Patient Groups

Obstetrics

Maternal mortality is rare, and the anesthesia-related component of maternal delivery represents only a small fraction of all maternal deaths, thus making study of this problem difficult or impossible in any one institution (see Chapter 69). A series of studies were performed between 1974 and 1985 to determine the rate of complications in the United States and England. One of the first reports included the period 1974 to 1978. Kaunitz and coauthors[119] reported an anesthesia-related death rate of 0.6 per 100,000 births with data from all 50 states. Endler and coworkers[120] studied births in Michigan between 1972 and 1984 and reported 15 maternal deaths in which anesthesia was the primary cause and 4 deaths in which anesthesia was contributory. This resulted in a rate of 0.82 anesthesia-related deaths per 100,000 live births. Eleven of the 15 deaths were associated with cesarean section. Obesity and emergency surgery were risk factors in many patients. Complications related to regional anesthesia were problems during the early part of the study, whereas failure to secure a patent airway was the primary cause of mortality in later years. There were no anesthesia-related maternal deaths in the final 2 years of the study. The incidence of anesthesia-related death was

markedly higher in black women, which the investigators suggested might have been related to an inability to detect cyanosis. Rochat and colleagues[121] studied 19 areas of the United States between 1980 and 1985 and reported 0.98 anesthesia-related deaths per 100,000 live births. They observed that maternal mortality did not decrease over the time of the study.

The Confidential Enquiry into Maternal Deaths in England and Wales has been assessing maternal deaths since 1952.[122] Records of all maternal deaths are sent to a district medical officer, who sends an inquiry form to all health practitioners involved in the care of these patients. These forms are evaluated by a senior obstetrician and an anesthesia assessor. Morgan[122] reported the maternal deaths from anesthesia between 1952 and 1981 (Table 33-14). The total maternal mortality rate decreased over time, but the percentage of deaths related to anesthesia increased, although the absolute number of deaths associated with anesthesia decreased. During the early years of the study, endotracheal intubation was rarely performed during obstetric anesthesia. Later reports advocated the use of endotracheal intubation after thiopental-suxamethonium, and technical difficulties with intubation were identified. The other major finding of this study was that the experience of the anesthetist in obstetric anesthesia was the most important factor in anesthesia-related maternal mortality.

From Morgan M: Anaesthetic contribution to maternal mortality. Br J Anaesth 59:842, 1987.

Several studies have attempted to define the cause of anesthesia-related maternal deaths. Insight into the cause of maternal mortality can also be elicited from the ACCS. In 1991, Chadwick and coauthors[123] published a report of closed malpractice claims related to 190 obstetric cases—127 cesarean sections and 63 vaginal deliveries. The most frequent complications were maternal death and brain damage in the newborn. There were 15 maternal deaths in patients who underwent regional anesthesia and 26 in patients who had general anesthesia. Because the absolute number of patients who underwent each type of anesthesia was unknown, the risk attributable to anesthesia could not be determined, unlike the subsequent report from Hawkins and coworkers.[124]

Hawkins and associates[124] obtained data from the ongoing National Pregnancy Mortality Surveillance System of the Centers for Disease Control and Prevention. Using state data on births and fetal deaths from 1979 through 1990, three obstetric anesthesiologists reviewed the records to determine the possible risk related to anesthesia. A total of 129 women died of anesthesia-related causes during the study period, most (82%) during cesarean section, and the incidence decreased over time (Table 33-15). The decreased mortality rate appeared to be related to increased use of regional anesthesia. The primary cause of mortality was related to the type of anesthesia. For general anesthesia, 73% of the deaths were related to airway problems. Unlike the Confidential Enquiry into Maternal Deaths in England, the U.S. study lacked the extensive detail for each event, and the absolute cause of mortality therefore remained somewhat in doubt. In particular, the researchers acknowledge that general anesthesia may be used more often in patients with a higher acuity of disease, which may account for the higher mortality rate associated with its use. The availability of national databases should allow accurate tracking of mortality to ensure that appropriate quality assurance and quality improvement systems are in place.

Panchal and colleagues[125] conducted a retrospective case-control study using patients' records from a state-maintained anonymous database of all nonfederal Maryland hospitals that performed deliveries between 1984 and 1997 (Fig. 33-7). Variables studied included patient demographics and ICD-9 (Clinical Modification) diagnosis and procedure codes. Of the 822,591 hospital admissions for delivery during the 14-year study period, there were 135 maternal deaths. The most common diagnoses associated with mortality during hospital admission for delivery were preeclampsia or eclampsia (22.2%); postpartum hemorrhage or obstetric shock (22.2%); pulmonary complications (14%); blood clot or amniotic embolism, or both (8.1%); and anesthesia-related complications (5.2%).

Gibbs and coworkers[126] surveyed 1200 hospitals in 1981 and sent questionnaires to the chiefs of anesthesia and obstetrics. Anesthesiologists were available for obstetric anesthesia in only 21% of all hospitals and at night and on the weekends in just 15%. Hospitals with fewer than 500 deliveries per year had the most

Anesth Analg 93:134, 2001.)*

striking deficiencies in anesthesia personnel. Even for cases in which general anesthesia was provided for cesarean section, an anesthesiologist was involved in care only 44% of the time, whereas hospitals with greater than 1500 deliveries per year had an anesthesiologist present 85% of the time. The researchers did not evaluate the relationship between outcome and staffing models. The survey was performed again in 1992.[127] When compared with 1981, the researchers found a marked increase in the availability of labor analgesia and a decrease in the use of general anesthesia. In more than half of the anesthesia procedures for cesarean section, care was provided by nurse anesthetists without medical direction by an anesthesiologist. How these trends in staffing have affected maternal mortality requires further evaluation.

Mhyre and colleagues reviewed maternal mortality in Michigan between 1985 and 2003.[128] Of 855 pregnancy-associated deaths, 8 were related to anesthesia, and anesthesia was considered to be contributory in 7. All anesthesia-related deaths from airway obstruction or hypoventilation took place during emergence and recovery, not during induction of general anesthesia. Lapses in postoperative monitoring and inadequate supervision by an anesthesiologist seemed to contribute to more than half of the deaths.

Bloom and associates studied anesthesia-related morbidity and mortality as part of a prospective observational study conducted in women ($N = 37,142$) with singleton gestations undergoing cesarean delivery in the centers forming the National Institute of Child Health and Human Development Maternal-Fetal Medicine Units Network.[129] There was one maternal death, caused by failed intubation, in which the anesthetic procedure was directly implicated. Importantly, 93% received regional anesthesia.

Pediatrics

There are few studies of anesthesia-related risk in the pediatric population (see Chapters 81 to 84). Two themes emerge from these studies: very young infants are at increased risk, and anesthesia-related risk is reduced in centers with specialized pediatric anesthesia facilities. In the report by Beecher and Todd,[10] there was a "disproportionate number" of anesthesia-related deaths in children younger than 10 years.

Graff and colleagues[130] from the Baltimore Anesthesia Study Committee reported 335 operative deaths in the pediatric age group. Of these, 58 were thought to be primarily or partially attributable to anesthesia. The percentage of operative deaths attributable to anesthesia was relatively constant among age groups at 16.6% to 21.7%. The estimated anesthesia-associated mortality rate was 3.3 deaths per 10,000 operations for those younger than 15 years versus 0.6 for those between 15 and 24 years of age and 11.7 for those older than 64 years. More than half of the patients were categorized as ASA physical status class 1 or 2, suggesting that the majority of deaths occurred in children with good anesthesia risk. Most deaths occurred during tonsillectomy, which probably reflects the fact that tonsillectomy is the most common operation in this age group. The investigators attempted to determine the phase of the operation that was associated with highest risk. Improper management of the anesthetic accounted for approximately half of the cases. Respiratory complications (e.g., underventilation, aspiration of vomitus or blood) were apparent in 82% of the anesthesia-related deaths. The investigators suggested that female patients have a lower operative risk than male patients in all age groups.

Tiret and coauthors[131] published a study of pediatric anesthesia risk in 1988. They prospectively studied major anesthesia-related complications in pediatric patients in 440 hospitals in France between 1978 and 1982. There were 27 major complications in 40,240 cases, which included 12 cardiac arrests and 1 death. The incidence of major complications and cardiac arrest was significantly higher in infants than in older children. The rate of cardiac arrest related to anesthesia was highest in infants (19 per 10,000) and lowest in children (2.1 per 10,000). Most complications in infants involved the respiratory system and consisted predominantly of airway problems and aspiration. Older children experienced respiratory and cardiac complications, which occurred most frequently during induction and recovery.

Cohen and colleagues[132] studied 29,220 anesthesia procedures at the Winnipeg Children's Hospital. Data were collected

Table 33-16 Summary of Perioperative Events by Age Group*

	<1 Month (*n* = 361)	1-12 Months (*n* = 2544)	1-5 Years (*n* = 13,484)	6-10 Years (*n* = 7184)	11+ Years Event (*n* = 5647)

from mid-1982 to 1987 and stored in a databank. Data on patients' coexisting medical conditions and postoperative follow-up were obtained within 72 hours. Complications included death, cardiac arrest, drug reactions, airway obstruction, and minor complications such as nausea and vomiting, arrhythmias, and sore throat. Neonates underwent a higher percentage of major vascular or cardiac and intra-abdominal procedures, and older children had a higher incidence of extremity procedures. Intraoperative cardiac arrest occurred most frequently in patients younger than 1 year (4 in 2901 procedures). Postoperatively, minor events such as nausea and vomiting were more common in older children, whereas respiratory events were more common in infants and younger children (Table 33-16). When compared with adult patients, children experienced different complications, which frequently extended well into the postoperative period. In a comparison of 2-year periods between 1982 and 1987, rates of intraoperative events were found to be stable, and the rate of postoperative complications decreased. The researchers suggested that identification of these problems could lead to changes in management that result in improved outcomes.

Flick and associates[132a] studied patients younger than 18 years who underwent surgery at the Mayo Clinic and experienced perioperative cardiac arrest between November 1, 1988, and June 30, 2005, A total of 92,881 anesthetics were administered during the study period, 4242 of which (5%) were for repair of congenital heart malformations. The incidence of perioperative cardiac arrest during noncardiac procedures was 2.9 per 10,000, and the incidence during cardiac procedures was 127 per 10,000. The incidence of perioperative cardiac arrest attributable to anesthesia was 0.65 per 10,000 anesthetics. The incidence of cardiac arrest and mortality was highest in neonates (0 to 30 days of life) undergoing cardiac procedures (incidence, 435 per 10,000; mortality, 389 per 10,000).

Investigators at the Children's Hospital of Boston used an established data registry that included all cardiac arrests from January 2000 through December 2005 related to surgery for congenital heart disease.[133] There were 41 cardiac arrests in 40 patients during 5213 anesthetics over the time period, for an overall frequency of 0.79%. Eleven cardiac arrests (26.8%) were classified as either likely ($n = 6$) or possibly related ($n = 5$) to anesthesia (21.1 per 10,000 anesthetics), but with no mortality; 30 were categorized as being related to the procedure.

In 1994, the Pediatric Perioperative Cardiac Arrest (POCA) Registry[134] was formed to determine the clinical factors and outcomes associated with cardiac arrest in anesthetized children. Institutions included in the registry submitted standardized data from each cardiac arrest occurring in an anesthetized child 18 years or younger. A total of 289 cardiac arrests occurred in the 63 institutions in the database during the first 4 years of the registry, 150 of which were judged to be related to anesthesia (1.4 per 10,000 anesthesia procedures), with a 26% mortality rate. Medication-related causes and cardiovascular causes of cardiac arrest were most common. Anesthesia-related cardiac arrest occurred most often in patients younger than 1 year and in patients with severe underlying disease. The goal of the registry is similar to that of the closed claims studies—to identify the causes in this unique population and thereby formulate preventive strategies.

An update from the POCA Registry was published in 2007.[135] From 1998 to 2004, 193 arrests (49%) were related to anesthesia. Medication-related arrests accounted for 18% of all arrests. Cardiovascular causes of cardiac arrest were the most common (41% of all arrests), with hypovolemia from blood loss and hyperkalemia from transfusion of stored blood being the most common identifiable cardiovascular causes (Fig. 33-8). Among respiratory causes of arrest (27%), airway obstruction from laryngospasm was the most common. Vascular injury incurred during placement of central venous catheters was the most frequent equipment-related cause of arrest. Cardiovascular and respiratory causes occurred most commonly in the surgical and postsurgical phases, respectively.

Geriatrics

Numerous studies have documented the importance of advanced age to perioperative risk (see Chapter 71). In many of the original studies on factors associated with perioperative mortality, the highest rates of death after surgery occurred in the youngest and the oldest patients. Age was implicated as one of the factors in the

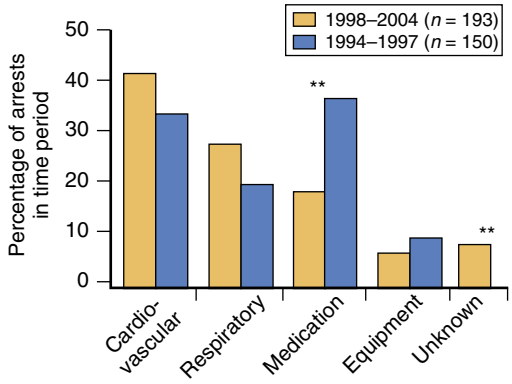

Figure 33-8 Causes of anesthesia-related cardiac arrest in in the Pediatric Perioperative Cardiac Arrest Registry from 1998 to 2004 versus 1994 to 1997. (**$P < .01$ 1998-2004 vs. 1994-1997 by Z test). *(From Bhananker SM, Ramamoorthy C, Geiduschek JM, et al: Anesthesia-related cardiac arrest in children: Update from the Pediatric Perioperative Cardiac Arrest Registry. Anesth Analg 105:344-350, 2007.)*

risk indices developed by Goldman, Detsky, and Pedersen. Age is predominantly analyzed as a dichotomous variable, with many studies focusing on age older than 70 years.

One of the issues regarding mortality rates in the geriatric population is the definition of this group. Multiple definitions have been used for advanced age, including patients older than 65, 70, 80, or 90 years. Denney and Denson[136] evaluated risk associated with surgery in patients older than 90 years. They suggested that the prevailing philosophy in 1972—that surgery might not be appropriate in this cohort in view of their high perioperative risk—was without objective supporting data. They reported 272 patients undergoing 301 operations at the University of Southern California Medical Center and found, contrary to their expectation, that the risk was more than justified in at least 70% of the nonagenarians. They reported that serious bowel obstruction was the only underlying comorbid condition associated with a prohibitive perioperative mortality rate (63%).

Djokovic and Hedley-Whyte[137] studied outcome after surgery in 500 patients older than 80 years at the Harvard University medical system. They found that mortality was predicted by ASA physical status classification, with greater comorbid conditions associated with increasing risk. Myocardial infarction was the leading cause of postoperative death. Patients without significant comorbid diseases (ASA class 1) had a mortality rate of less than 1%. The data suggest that surgery is safe in this cohort and that risk is not a function of age but of coexisting disease.

Del Guercio and Cohn[138] investigated the value of preoperative invasive monitoring in obtaining hemodynamic and cardiopulmonary variables for predicting operative risk in the elderly. A total of 148 consecutive patients older than 65 years were studied preoperatively in an ICU. Only 13.5% had normal physiologic measurements. Advanced and uncorrectable functional deficits were found in 63% of patients, and all in this group who underwent the planned operation died. This further supports the contention that coexisting disease, not age, is the risk.

An elderly patient presents a difficult issue for the anesthesiologist. Atherosclerosis increases with advancing age, and the heart muscle itself ages. Further preoperative evaluation in the elderly usually focuses on the identification of comorbid disease. Based on the accumulating evidence, these factors influence perioperative risk.

Risks Directly Related to the Anesthetic Drug

Numerous studies have evaluated the influence of the choice of anesthetic on outcome, a question that is discussed throughout this book. From a global perspective, there does not appear to be one best anesthesia technique. In a multivariate analysis by Cohen and coworkers[99] of 100,000 anesthesia procedures performed in Canada, the choice of drug did not provide any additional prognostic information for predicting mortality beyond that of patient disease and the surgical procedure. In univariate analysis, monitored anesthesia care did appear to be associated with worse outcomes, but this was attributable to its use in sicker patients (see Table 33-12).

One question that has plagued the anesthesia literature is the issue of inherent toxicity of anesthetics (see Chapter 24). There are important distinctions between undesirable side effects of anesthesia and true toxicity. In the initial reports of the mid-20th century, there was much concern about curare toxicity. Recent discussions of anesthetic toxicity have focused on halothane and sevoflurane. The issues for halothane were fulminant hepatic necrosis and death. The issue for sevoflurane was whether its metabolite compound A was nephrotoxic. After several case reports of hepatic necrosis after halothane anesthesia, a retrospective study of 856,500 anesthesia procedures at 34 institutions was undertaken.[139-141] In all but nine cases, hepatic necrosis could be explained by other causes. Of the remaining nine cases, only seven received halothane. Halothane could be associated with hepatitis and hepatic failure, but the incidence was very low.

Despite concern about the renal toxicity of sevoflurane (see Chapter 24), the overall safety of this drug has been sufficiently established for the U.S. Food and Drug Administration to allow its continued sale in the United States. Some laboratory studies have supported the contention that sevoflurane reacts with soda lime to form compound A and that this metabolite can lead to renal toxicity.[142,143] However, clinical studies have been unable to confirm this potentially detrimental effect.[144,145]

Numerous studies have attempted to define the "safest" anesthetic for high-risk patients. In the late 1980s, there was particular concern that isoflurane caused coronary steal in patients with coronary stenosis and collaterals and that this could result in myocardial ischemia.[146,147] A series of studies were conducted to evaluate the rate of perioperative cardiac morbidity and mortality in patients undergoing coronary artery bypass grafting to determine the importance of the agent used for general anesthesia.[148-151] All these studies demonstrated no difference in outcome, thus supporting the contention that there is no one safest anesthesia technique.

A series of randomized trials demonstrated improved outcome with regional rather than general anesthesia.[152] For lower extremity and pelvic surgery, regional anesthesia was associated with a lower incidence of graft thrombosis and deep venous thrombosis, as well as decreased bleeding. For vascular surgery patients, the primary finding was a lower incidence of graft thrombosis and need for reoperation in patients undergoing infrainguinal bypass surgery; however, the largest of these studies was unable to demonstrate any difference in outcome based on anesthesia technique.[4,153,154] The rate of this complication was low

in the total cohort in the largest trial, which made it impossible to detect any difference based on technique.

Rodgers and coworkers[152] published a large meta-analysis of regional versus general anesthesia. Neuraxial blockade was found to reduce postoperative mortality and other serious complications. The magnitude of some of these benefits remained uncertain. Discussion of regional versus general anesthesia is presented in Chapters 51 and 52.

Risks Related to Surgery

The surgical procedure itself significantly influences perioperative risk. In virtually every study performed, emergency surgery is associated with additional risk. For example, in the study of Goldman and colleagues,[6] emergency surgery was associated with the second highest weight (i.e., number of points) after active signs of congestive heart failure. In the same study, intrathoracic and abdominal procedures were determined to have higher risk.

In some cases, the risk related to surgery is a function of the underlying disease processes and the stress related to the surgical procedure. Cardiovascular surgery is associated with the highest risk of any procedure. The risks related to cardiac surgery are reviewed in Chapter 60. Vascular surgery is among the highest-risk group of noncardiac procedures. Although aortic reconstructive surgery has traditionally been considered the procedure with highest risk, infrainguinal procedures have shown a similar rate of cardiac morbidity in several studies.[155,156] In an attempt to analyze the cause of the high complication rate with a relatively peripheral procedure, L'Italien and associates[156] demonstrated that the extent of coronary artery disease is higher in patients undergoing infrainguinal procedures and most likely accounts for the excess morbidity and mortality.

Ashton and colleagues[157] evaluated perioperative morbidity and mortality in a cohort of patients at a Veterans hospital. Although vascular surgery was among the highest-risk procedures, amputation was associated with the highest in-hospital cardiac complication rate within this subgroup. This finding most likely represents the more severe nature of the cardiovascular disease in these patients and the prolonged hospitalization needed to facilitate recuperation. As in the study by Goldman and coworkers,[6] intra-abdominal, thoracic, and orthopedic procedures were associated with increased risk. In another report, Ashton and colleagues[158] evaluated the rate of perioperative myocardial infarction in patients undergoing transurethral resection of the prostate. Despite the high frequency of coronary artery disease in this population, the incidence of perioperative myocardial infarction was only 1%.

Numerous studies have evaluated the perioperative complication rate related to superficial procedures. Backer and associates[159] evaluated the rate of perioperative myocardial reinfarction in patients undergoing ophthalmologic surgery. They demonstrated that the rate of perioperative cardiac morbidity after ophthalmologic surgery was extremely low, even in patients with recent myocardial infarction. Virtually all studies have confirmed that ophthalmologic surgery is very safe under anesthesia.[160] Warner and colleagues[161] studied patients undergoing ambulatory surgery and reported no anesthesia-related deaths in more than 45,000 cases. A more complete discussion of the risk of anesthesia in the outpatient setting is provided earlier.

Eagle and associates[162] evaluated the contribution of coronary artery disease and its treatment to perioperative cardiac morbidity and mortality by surgical procedure. They evaluated patients enrolled in the Coronary Artery Surgery Study who had documented coronary artery disease and received medical therapy or coronary revascularization and then underwent noncardiac surgery during the subsequent 10-year period. Rates of perioperative myocardial infarction and death were determined, and the surgical procedures were divided into three broad categories. Major vascular surgery was associated with the highest risk, with a combined incidence of morbidity and mortality of greater than 5%. Procedures associated with a combined complication rate of 1% to 5% included intra-abdominal, thoracic, and head and neck operations. In all these cases, patients who had previously undergone coronary artery bypass grafting had a significantly lower combined morbidity and mortality rate than did those in the medically treated group. Low-risk procedures included breast, skin, urologic, and orthopedic surgery. These broad groups of surgical procedures were the basis for the definitions of surgical risk published in the guidelines on perioperative cardiovascular evaluation for noncardiac surgery by the American Heart Association/American College of Cardiology Task Force on Assessment of Diagnostic and Therapeutic Cardiovascular Procedures.[163]

Risks Related to the Location of Surgery and Postoperative Monitoring

Perioperative risk varies among hospitals for major procedures such as coronary artery bypass grafting and abdominal aortic aneurysm repair (see Chapters 60 and 62).[164,165] Multiple studies have documented a relationship between surgical volume and mortality. Although surgical skill most certainly plays a role in the rate of complications and mortality, local factors may also play an important role. For example, low surgical volume may lead to less skilled anesthesia and postoperative care. The influence of each of these factors on overall morbidity and mortality is unknown.

Although the value of postoperative monitoring and care in an ICU has never been documented in a randomized clinical trial, many investigators have suggested that such care is one of the primary reasons for the improved morbidity and mortality in recent years. For patients undergoing major vascular surgery, several investigators have suggested that more intense postoperative monitoring could obviate the need for preoperative cardiac testing and revascularization.[163] One potential value of risk assessment is identification of patients who could benefit from referral to centers with more extensive perioperative resources. Patients with a low probability of perioperative morbidity and mortality could have surgery performed locally, and individuals at higher risk could receive benefit from transfer to a larger center.

Risks Related to the Anesthesia Provider

The added risk associated with the provider of anesthesia is an emotionally charged issue, particularly in the United States. Over the history of the specialty, various individuals have provided anesthesia, including anesthesiologists, general medical officers, residents, and CRNAs.

The importance of the anesthesiologist to outcome is best illustrated by the work of Slogoff and Keats.[166] They studied the association of perioperative myocardial ischemia and cardiac morbidity in patients undergoing coronary artery bypass grafting and found that perioperative myocardial infarction occurred significantly more frequently in patients with ischemia before the bypass operation. They then reported the rate of ischemia and infarction by anesthesiologist (identified by number). Anesthesiologist no. 7 had a significantly higher rate of complications than the average for the rest of the group. Operator technique or experience may affect risk. This observation parallels similar findings that surgical volume (and presumably experience) is associated with outcome.[167]

Arbous and coauthors reported a case-control study of major morbidity (coma) and mortality affecting a total of 869,463 procedures over a 1-year period in the Netherlands.[168] Eight hundred seven cases of coma or death within 24 hours of anesthesia were identified and matched by age and sex to randomly selected controls who underwent anesthesia temporally in close proximity to the matched case. The Hospital Characteristics Questionnaire, Procedure Questionnaire, and anesthesia and recovery records were used to examine the intraoperative and postoperative characteristics of cases and controls. Anesthesia practice in the Netherlands is described as a "flexible" system with one-on-one anesthesiologist coverage of induction and emergence, assisted by a nurse anesthetist or resident, and a two-on-one system during maintenance anesthesia, with a nurse or resident present in the room and an anesthesiologist in the vicinity. The authors elected to use multivariate analysis on data sets rather than match cases and controls for anesthesia/physical risk categories or the type of surgical procedure (or both).

Included in analysis were 807 cases and 883 controls. Cases and controls, however, were not comparable for ASA classification, and controls were more likely than cases to have undergone minor elective procedures during regular working hours. Cases more frequently underwent cardiac and major vascular procedures, and controls more often underwent orthopedic, urologic, and ophthalmologic procedures. Of 807 cases, 95% died within 24 hours, and 5% remained comatose, all of whom eventually died in the hospital. Postoperative mortality was 8.8% per 10,000 anesthetics, and postoperative coma occurred in 0.5% of 10,000 anesthetics. Confounding factors were, expectedly, ASA status, type of procedure, anesthetic technique, and hospital. Independent variables that were associated with decreased risk for coma and death in 24 hours were (1) anesthesia equipment check performed with a checklist (OR, 0.61); (2) direct availability of an anesthesiologist during maintenance anesthesia by phone, beeper, or walkie-talkie (OR, 0.46); (3) no change of anesthesiologist during the case (OR, 0.46); (4) presence of a full-time nurse anesthetist versus part-time anesthetist during maintenance anesthesia (OR, 0.41); (5) presence of two persons (anesthesiologist plus resident or nurse anesthetist) versus one person during emergence (OR, 0.69); (6) reversal of muscle relaxant (OR, 0.1); and (7) reversal of muscle relaxant and opioids (OR, 0.29).

This study is one of very few to attempt to identify practice characteristics rather than specific drugs or techniques that have an impact on anesthesia outcomes. The size of this study and the nonambiguity of outcomes followed are important characteristics. The study suffers from several significant problems, however. Study groups were not comparable in very important ways. The estimated incidence of underreporting of coma and death was 13% to 47%, and selective underreporting could have occurred. The finding that a change of anesthesiologist during maintenance anesthesia adversely affected patient outcomes contradicts findings in previous studies and requires further explanation. Confounding variables associated with a change of anesthesiologist during maintenance anesthesia could include case length and the time of day in which cases are performed. An intriguing finding is that practitioner characteristics affect outcomes (better outcomes with more availability of an anesthesiologist and better outcomes when nurse anesthetists practice full-time rather than part-time), and this finding warrants further follow-up.

Several studies have attempted to evaluate the complication rates and risks associated with various care provider models. Bechtoldt,[169] as a member of the North Carolina Anesthesia Study Committee, evaluated 900 perioperative deaths that occurred in an estimated 2 million anesthesia procedures performed in North Carolina between 1969 and 1976. Data were obtained from the medical examiner's report, routine death certificates, and a questionnaire completed by the person who administered the anesthetic. The committee concluded that 90 of these deaths were related to anesthesia. About half of the anesthesia-related deaths took place in the operating room, including 19 that occurred on induction. With information attained from a survey of hospitals, they then determined the relationship between mortality and anesthesia provider based on the total number of procedures administered by each group. The lowest rate of anesthesia-related deaths (1 per 28,166 procedures) occurred in patients who received anesthesia from an anesthesia care team (physician anesthesiologist and CRNA), and the highest rate (1 per 11,432 procedures) was associated with anesthesia administered by a dentist (1 per 11,432); the rate for the nurse anesthetist–only cohort was intermediate (1 per 20,723). The large number of cases in which the care provider was unknown and reliance on hospital estimates of the number of cases performed by each group made interpretation of this study difficult.

The Stanford Center for Health Care Research[170] also evaluated the impact of provider on outcome of care. They prospectively collected data from 8593 patients undergoing 15 surgical procedures over a 10-month period (May 1973 through February 1974). Using a risk adjustment methodology, the actual patient outcome was compared with that predicted by the patient's health status and operative procedure. The investigators reported that death plus severe morbidity was 11% higher than predicted in patients who received their care in a nurse anesthetist–only setting, 3% lower than predicted for physician-only care, and 20% lower than predicted for an anesthesia care team environment. Because of the small sample size, these findings did not reach statistical significance between groups.

The differences in outcome among anesthesia providers are extremely difficult to study from a methodologic standpoint. The impact of specific provider types may be greatest in specific situ-

ations. For example, there may be no difference in outcome for healthy individuals, particularly if no complications occur. In contrast, patients with significant comorbid diseases and those who sustain perioperative complications may benefit from having providers with specific skill sets. One way to study such issues is to evaluate the rate of survival after complications. Silber and colleagues[26] at the University of Pennsylvania studied the medical records of 5972 surgical patients randomly selected from 531 hospitals. They evaluated patient and hospital characteristics, including the number and type of physicians, board certification status, and ratio of care providers. The 30-day mortality rate correlated with patient characteristics. Failure to rescue (i.e., prevent death) after an adverse event was inversely associated with the proportion of board-certified anesthesiologists on staff in each facility. Improved perioperative survival was significantly associated with the presence of an increased number of board-certified anesthesiologists.

As a follow-up to this study, Silber and colleagues[171] used an administrative data set to compare the outcomes of surgical patients for whom anesthesia care was or was not personally performed or medically directed by an anesthesiologist. They analyzed all elderly patients in Pennsylvania who underwent general surgical or orthopedic procedures between 1991 and 1994. The 30-day mortality rate and the mortality rate after complications (i.e., failure to rescue) were lower when anesthesiologists directed anesthesia care, even after adjustment for patient and hospital characteristics. Interpretation of the study was limited because the undirected group was small and included a large percentage of procedures in which there was no bill submitted for anesthesia services, thus questioning the validity of the classification. Administrative data sets, such as Medicare claims, allow the investigator to study a large number of patients, but there are significant limitations related to the robustness of the data and potential uncontrolled confounding factors. Therefore, most investigators suggest that such studies are best at generating hypotheses rather than defining best practices.[172]

Silber and colleagues[173] used similar methodology to determine the importance of board certification on perioperative risk. Adjusted ORs for death (1.13; 95% CI, 1.00 to 1.26; $P < .04$) and for failure to rescue (1.13; 95% CI, 1.01 to 1.27; $P < .04$) were greater when care was delivered by noncertified, midcareer anesthesiologists.

Pine and coworkers evaluated mortality after eight specific surgical procedures.[174] Procedure-specific risk adjustment models (including institutional and geographic factors) were derived by stepwise logistic regression. Observed and predicted values by type of provider were not statistically significantly different. Hospitals without anesthesiologists had results similar to those where anesthesiologists provided or directed anesthesia care. The authors did not evaluate failure to rescue or cause of mortality.

Smith and associates[175] performed a systematic review of the available published studies through 2004 on the influence of anesthesia providers. They identified four studies, two smaller observational studies and the two previously described studies using administrative data sets. They concluded that all of the studies had potential confounding factors that limited the validity of the results and that the paucity of high-level primary evidence made it impossible to draw a conclusion regarding differences in patient safety as a function of provider type. Therefore, the relationship of patient outcomes to the type of anesthesia provider has not been conclusively demonstrated. Nurse anesthetists and other nonphysician providers are vital to the delivery of anesthesia care in the United States and elsewhere, and differences, if present, are small or restricted to specific situations.

Risks to the Anesthesiologist

Several potential risks to the anesthesiologist are related to the provision of care (see Chapter 101), including medicolegal risk, the risk of an allergic reaction, and the risk of a needlestick injury and transmission of disease from the patient to the practitioner. Medicolegal risks are described in Chapter 10.

It is increasingly becoming apparent that anesthesiologists are at risk for latex allergy, which can lead to a life-threatening reaction. Many anesthesiologists realize that they are sensitized to latex and apply appropriate precautions. The problem is that many sensitized individuals are asymptomatic. Brown and coworkers[176] studied 168 eligible anesthesiologists and nurse anesthetists working in the anesthesia department of The Johns Hopkins Hospital. The prevalence of latex allergy with clinical symptoms was 2.4% and that of latex sensitization without clinical symptoms was 10.1%. The prevalence of irritant or contact dermatitis was 24%. These data suggest that latex is an important problem to the anesthesiologist and that there is a need to transform the hospital to a latex-free environment.

There has always been concern that anesthesiologists are at risk for contracting a disease from a patient. In the past the risk was primarily hepatitis, but human immunodeficiency virus (HIV) is a greater concern today. In a review of the literature, Berry and Greene[177] reported that at least 20 different pathogens have been transmitted through accidental needlestick injuries.

Among anesthesia personnel in several studies conducted in the United States, hepatitis B seropositivity ranged from 12.7% to 48.6%, a rate at least four times greater than that in the general population.[178-180] The risk of hepatitis B infection after percutaneous exposure to antigen-positive blood is estimated to be 27% to 43%.[181] Development of the hepatitis B vaccine has substantially reduced this risk. Hepatitis C virus has been identified as a major cause of post-transfusion hepatitis. There have been several reports of occupationally acquired hepatitis in health care workers.[182] Because signs of chronic liver infection develop in up to 50% of infected individuals, this represents a potentially serious problem.

Among the greatest fears of health care workers is HIV infection. The risk of acquiring HIV is approximately 0.4% from a single percutaneous exposure to blood or bloody fluid from an HIV-infected patient.[183] There has been at least one case report of an anesthesiologist who was infected with HIV from a needlestick injury during insertion of a central venous catheter into an HIV-positive patient.[184]

Several strategies have been developed to reduce the transmission of communicable diseases (see Chapter 101). Although anesthesiologists traditionally think of the risk to the patient, they must now include the risk to themselves. Widespread adoption of universal precautions should reduce the rate of infection; however, anesthesiologists have not accepted these recommendations widely. In a study of nine hospitals, 59% of the contaminated percutaneous injuries were preventable.[185] In a theoretical model of the risk for HIV infection, it was estimated that the 30-year occupational risk was 0.10% to 0.22% in low-prevalence areas and

8.26% to 13% in high-prevalence areas.[186] The researchers suggested that double-gloving practices may lead to reduced risk.

Improving Anesthesia Safety

Over the past several decades there have been major initiatives to improve the safety of anesthesia. In 1984, Cooper, Kitz, and Ellison hosted the first International Symposium on Preventable Anesthesia Mortality and Morbidity in Boston. Approximately 50 anesthesiologists from around the world attended the meeting and, after much debate, established a series of definitions of outcome, morbidity, and mortality (Box 33-1). These meetings have been held every 2 years since the first symposium. The Anesthesia Patient Safety Foundation was established as a result of the Boston meeting. The society has been active in publishing widely circulated newsletters and awarding annual grants. Similar societies have been established in countries outside the United States, and a National Patient Safety Foundation has been created on the same model.

Starting with the ACCS, there has been much interest in establishing guidelines for the best and safest practice. Practice policies or guidelines are summations by clinicians of the available evidence about the benefits and risks of particular treatment plans. Guidelines are a method of codifying recommendations regarding the use of a given technology. Several types of recommendations fall into the general category of a practice parameter. A standard implies that a therapy or practice should be performed for patients with a particular condition. Standards are approved only if an assessment of the probabilities and utilities of the group indicate that the decision to choose the treatment or a strategy would be virtually unanimous. If a particular therapy or strategy is considered a standard, it is a cost-effective measure for those for whom it is being recommended. Standards are intended to be applied rigidly. The ASA has established standards for intraoperative monitoring, which were developed from safety guidelines adopted by the Harvard University hospital system. Guidelines are intended to be more flexible than standards, but they should be followed in most cases. Depending on the patient, the setting, and other factors, guidelines can and should be tailored to fit individual needs. Like standards, guidelines should be cost-effective methods. A number of specific guidelines have been adopted by the ASA for diverse issues such as a difficult airway,[187] use of the pulmonary artery catheter,[188] and use of blood components.[189] The goal is to define the evidence on which optimal practice can be based.

There is much interest in the use of anesthesia simulators to train and test individuals and their ability to react to simulated crises.[190-194] Standardized scenarios have been developed for making comparisons among individuals. Further research is required to determine how best to use this technology in anesthesia training and recertification. Further discussion of this topic can be found in Chapters 5, 6, and 7.

Box 33-1 Proposed Definitions from the 1994 International Symposium on Preventable Anesthesia Morbidity and Mortality

- Outcome
  - Normal
  - Abandoned procedure
  - Morbidity
  - Death
- Morbidity
  - An unplanned, unwanted, undesirable consequence of anesthesia
- Mortality
  - Death that occurs before recovery from the effects of a drug or drugs given to facilitate a procedure
  - Death that occurs during an attempt to relieve the pain of a condition
  - Death that results from an incident that occurs while the drugs are effective

Adapted from Pierce EC Jr: The 34th Rovenstine Lecture: 40 years behind the mask: Safety revisited. Anesthesiology 84:965, 1996.

Future Directions in Perioperative Risk

The impact of genetics on perioperative risk has been well known since elucidation of the inheritance pattern of malignant hyperthermia. With malignant hyperthermia, there is a clear link between the autosomal dominant disease and an adverse outcome after administration of an anesthetic.[195] Interest in evaluating the impact of genetic polymorphism on overall perioperative outcome is increasing, even if the link to anesthesia is less well defined. For example, apolipoprotein E_4 has been shown to modulate neurologic injury and recovery after a variety of acute ischemic insults, including coronary artery bypass grafting.[196] Polymorphism of the glycoprotein IIIa constituent of the platelet integrin receptor has also been correlated with postoperative cognitive decline.

Summary

The risks related to anesthesia have dramatically decreased over the past several decades. It is clear that death totally attributable to anesthesia is rare. Patient disease and the type and perhaps the location of surgical procedures have a greater effect on overall outcome. With these changes in risk, the anesthesiologist must now focus on nonmorbid outcomes, and there must be continued vigilance to maintain the high standards of hospital-based anesthesia in nonhospital settings. Finally, anesthesiologists should play a role in systems-based thinking to improve all aspects of care.

34 Preoperative Evaluation

Key Points

1. The anesthesia preoperative evaluation is the clinical foundation and framework of perioperative patient management and can potentially reduce operative morbidity and enhance patient outcomes.
2. The fundamental purpose of preoperative evaluation is to obtain pertinent information regarding the patient's current and past medical history and to formulate an assessment of the patient's intraoperative risk and requisite clinical optimization.
3. Basic and complex medical diseases and syndromes that can potentially affect anesthesia perioperative management require the anesthesiologist to be clinically knowledgeable and current in many aspects of internal medicine.
4. Patients require preoperative diagnostic and laboratory studies that are consistent with their medical history, the proposed surgical procedure, and the potential for intraoperative blood loss. Routine preoperative testing cannot be justified and is costly and clinically inappropriate.
5. Preoperative patient education and individual discussion can significantly reduce patient anxiety and fears of the perioperative anesthesia process.
6. Under the clinical directorship of an anesthesiologist, the anesthesia preoperative evaluation clinic can enhance operating room efficiency, decrease day-of-surgery cancellations and delays, reduce hospital costs, and enhance the quality of patient care.
7. New and updated preoperative evaluation consensus and evidence-based guidelines published by multiple medical specialties have led to evaluation protocols for preparing patients for anesthesia and surgery.
8. Increasing regulatory and reporting requirements involving preoperative issues by agencies such as the Joint Commission on Accreditation of Healthcare Organizations require awareness and compliance by anesthesiologists.
9. Information technology and decision support systems in preoperative evaluation can enhance the quality of patient care and clinical management through electronic integration and standardization of patient data.
10. The anesthesiologist is the perioperative medical specialist and the only preoperative evaluation physician who can truly evaluate the risks associated with anesthesia, discuss these risks with the patient, and manage them intraoperatively.

Virtually every practicing anesthesiologist has experienced and contributed to the evolution of anesthesia's involvement in perioperative care. Furthermore, the rapid transformation from admission of the patient to the hospital the night before surgery to the morning of surgery has necessitated that preoperative evaluation be conducted in a different manner. Although the historical basic concept of preoperative evaluation and an anesthesia clinic is not new to anesthesia, what has occurred in this specialty is unique, remarkable, and revolutionary. Many anesthesiologists have essentially taken back from multiple medical specialties the primary responsibility, coordination, and recognition for assessment and optimization of preoperative risk in patients being prepared for surgery.

Some anesthesiologists have evolved into perioperative medical specialists by demonstrating their unique qualification of focused knowledge and experience to evaluate and successfully manage medical complexities related to anesthesia and surgery.[1,2] Anesthesia care is no longer limited to the operating room. Many departments of anesthesiology have even changed their official departmental titles to include anesthesia and "perioperative care."

This chapter on preoperative evaluation is intended to provide the reader with a comprehensive discussion of the basics and fundamental practice of preoperative assessment, as well as provide a review of new concepts, regulatory requirements, consensus guidelines, medical-legal responsibilities, and clinical options.

The Evolution in Preoperative Evaluation

Preoperative evaluation of a surgical patient for anesthesia increases the practitioner's awareness of the patient's medical condition and becomes the foundation of the individual patient's perioperative management plan. The fundamental purpose in preoperative evaluation is to obtain pertinent information regarding the patient's current and past medical history and to formulate an assessment of the patient's intraoperative risk.

Anesthesiologists preoperatively perform focused clinical examinations, develop a plan of medical intervention and optimization, reduce the patient's (and family's) anxiety and fears through education, discuss perioperative care and options for postoperative pain control, determine the appropriate laboratory tests and diagnostic studies to perform, discuss anesthesia risks, and obtain informed consent. The anesthesia preoperative evaluation can decrease surgical morbidity, minimize expensive delays and cancellations on the day of surgery, and increase perioperative efficiency. The practice of preoperative evaluation for anesthesia has changed. Fewer patients are admitted to the hospital before surgery unless their medical condition is unstable and requires optimization. Currently, approximately 80% of surgeries in the United States are performed on an outpatient or same-day admission basis, even including major neurosurgical, cardiac, and radical cancer procedures. The previous process of admitting the majority of patients to the hospital at least the day before is no longer financially supported or justified.

Although patients are still assessed for the first time by the anesthesiologist just before surgery, the trend toward preparing and evaluating patients in a preoperative program or "clinic" before the surgical date has increased. This has been especially important in patients with multiple medical risks and comorbid conditions. In other settings, the preoperative evaluation is completed for many patients by the surgeon (or designee) or primary care physician, and only patients at highest risk are referred for consultation by an anesthesiologist. In such circumstances, the anesthesia department must interact with the surgical departments to establish general protocols for acquiring the information needed to safely perform anesthesia or there could be a potential for an increased incidence of delays or cancellations at the time of surgery to obtain additional information or evaluation.

A change in the procedure and manner of preoperative evaluation requires the anesthesiologist to achieve a high level of efficiency and accuracy in assessment of the patient's history, physical examination, differential diagnosis, and planning of management. It presents the anesthesiologist with a formidable challenge from both an organizational and a clinical perspective because of a decreased amount of time available to evaluate often medically complex patients. Providing consistent quality and cost-effective preoperative preparation of patients is an important issue in perioperative patient management.

Both The Joint Commission (TJC) and the American Society of Anesthesiologists (ASA) have developed standards and requirements for preoperative anesthesia evaluation.[3] Recent and updated preoperative evaluation guidelines published by multiple medical specialties have led to protocols for evaluation in preparing patients for anesthesia and surgery. Several of the current practice guidelines challenge the historical manner of practicing anesthesia.

These guidelines require objective review, reasonable consideration, and possibly changes in the manner of customary anesthesia practice.[4] For example, the routine "nothing by mouth" (NPO) after midnight or 6 hours before surgery has been redefined by the ASA Task Force on Preoperative Fasting.[5] The American College of Cardiologists/American Heart Association (ACC/AHA) preoperative evaluation guidelines, recently updated in 2007, recommend proceeding with elective surgery in certain patients who have experienced a myocardial infarction (MI) in terms of weeks rather than months. Both these and other changes and challenges in anesthesia practice are reviewed and the implications discussed in this chapter.

If anesthesia and surgery were not associated with perioperative risk or adverse patient outcome, anesthesia preoperative evaluation and management would not be required. Although the incidence of patient morbidity and mortality has decreased in the past decades, many patients still have an abundance of fear and anxiety regarding anesthesia risk. We begin this preoperative chapter with a current review and identification of the concepts, evaluation, and goals in assessment of patient risk.

Preoperative Risk Assessment

The current ASA risk classification system was developed in 1941 by Meyer Saklad at the request of the ASA (Table 34-1). This classification was the first attempt to quantify the risk associated with anesthesia and surgery. Neither the type of anesthesia nor the location of the procedure or operation was considered in the development or as components of this risk classification. The system attempts to give a subjective and relative risk based only on the patient's preoperative medical history (i.e., no consideration of diagnostic studies). ASA physical status (ASA-PS) 2

Table 34-1 American Society of Anesthesiologists Physical Status Classification

ASA 1	Healthy patient without organic, biochemical, or psychiatric disease
ASA 2	A patient with mild systemic disease, e.g., mild asthma or well-controlled hypertension. No significant impact on daily activity. Unlikely to have an impact on anesthesia and surgery
ASA 3	Significant or severe systemic disease that limits normal activity, e.g., renal failure on dialysis or class 2 congestive heart failure. Significant impact on daily activity. Probable impact on anesthesia and surgery
ASA 4	Severe disease that is a constant threat to life or requires intensive therapy, e.g., acute myocardial infarction, respiratory failure requiring mechanical ventilation. Serious limitation of daily activity. Major impact on anesthesia and surgery
ASA 5	Moribund patient who is equally likely to die in the next 24 hours with or without surgery
ASA 6	Brain-dead organ donor

"E" added to the classification indicates emergency surgery.
Available from www.asahq.org.

patients are at higher risk than ASA-PS 1 patients, but only if undergoing the *same* operation. Most importantly, there is no attempt to *quantify* the risk, which hampers the ability to use this risk assessment tool for communicating meaningful expectations to patients and other caregivers.

Despite these limitations, some studies have corroborated an association of mortality and morbidity with ASA-PS scores. Studies have also shown a correlation between ASA-PS and unanticipated intensive care unit admissions, longer hospital stays for some procedures, and adverse cardiopulmonary outcomes. No correlation has been shown between ASA-PS class and cancellations, cost, unplanned admissions, and other perioperative complications, and traditionally, surgical risk has been considered more important than anesthetic risk. However, few studies have evaluated the effect of combining the risk inherent in the surgical procedure and the ASA-PS score. Among the first was the Johns Hopkins Risk Classification System, but this system focuses only on surgical risk. As surgery has evolved with innovations in minimally invasive and endoscopic techniques, a general anesthetic requiring instrumentation of the airway with associated significant physiologic perturbations may pose a significant and greater risk than the surgery itself to some extremely fragile individuals.

Even the location of the procedure may alter the risk. A study of ambulatory surgery in Medicare beneficiaries older than 65 years found no deaths on the day of surgery when the procedure was performed in a physician's office; 2.3 deaths per 100,000 performed in a freestanding ambulatory surgical center; and 2.5 deaths per 100,000 performed at an outpatient hospital. The 7-day mortality was 35 per 100,000, 25 per 100,000, and 50 per 100,000, respectively. Age older than 85 years, significant comorbidity, and the type of procedure predicted adverse events.[6]

Other specialties have developed risk assessment tools for patients undergoing anesthesia and surgery. One of the first was Goldman, who further advanced risk assessment by identifying risk factors and cardiac complications in patients undergoing noncardiac surgery. Several studies followed, culminating in one of the most widely used guidelines for assessment of the common, significant perioperative complication of cardiac morbidity and mortality associated with noncardiac surgery. The joint ACC/AHA guideline was first published in 1996 and updated in 2007.[7] This guideline combines patient and surgical risk but is specific only for cardiac complications. There is no comprehensive risk assessment tool available at the time of this writing.

The concept of risk associated with anesthesia (see Chapter 33) is unique in that rarely does the anesthetic itself offer benefit but merely allows others to do things that potentially offer benefit. The goals in assessing risk are to inform patients so that they can weigh their options and to identify opportunities to alter that risk. Analysis of the Australian Incident Monitoring Study (AIMS) database showed that 11.6% of reports identified inadequate or incorrect preoperative *assessment* (478 of 6271) or preoperative *preparation* (248/6271).[8] Of adverse events, 3.1% (197) were indisputably related to inadequate or incorrect preoperative assessment or preparation. Of these 197 patients, major morbidity occurred in 23, and 7 patients died. The investigators concluded that patient factors contributed only 1% of the time. More than half of the incidents were preventable; an additional 21% were possibly preventable. Unpreventable events accounted for just 5% of cases. Almost a quarter of the time, communication failure was cited as the most significant factor. Analysis of the first 2000 reports submitted to AIMS found a sixfold increase in mortality in patients who were inadequately assessed preoperatively.[9] In a different study of anesthetic-related perioperative deaths, 53 of 135 deaths involved inadequate preoperative assessment and management.

Many anesthesiologists perform preoperative evaluations, review diagnostic studies (chosen and ordered by someone else), discuss anesthetic risks, and obtain informed consent moments before patients undergo major, potentially life-threatening or disfiguring procedures. This choice offers little opportunity to optimize comorbid conditions or alter risk. The effects of extensive disclosure are stressful for patients and families at a time when they may be ill prepared to consider the implications rationally. An increase in preoperative anxiety probably affects postoperative outcomes because increased anxiety correlates with increased postoperative analgesic requirements and prolonged recovery and hospital stay. Anxiety impairs retention of information, with attendant medicolegal implications because of inadequate communication or discussion of the risks associated with anesthesia.

Some assessment of risk is important to prepare for anesthesia and the surgical procedure. Patients have a right to be informed during the consent process of possible complications and, if possible, be given some estimate of the chance of complications occurring. Identified modifiable risk factors such as poorly controlled hypertension or unstable ischemic heart disease should be addressed. Risk assessment is useful to compare outcomes, control costs, allocate compensation, postpone surgery until interventions improve risk, or assist in the difficult decision of canceling or recommending that a procedure not be done when the risks are too high. The need for special techniques, postoperative care in the intensive care unit, and special monitoring must be considered and planned for. Yet risk assessment, at its best, is hampered by individual patient variability.

Detecting Disease in Preoperative Evaluation

Several studies have proved the utility of the history and physical examination in determining diagnoses. A study of general medical clinic patients found that 56% of correct diagnoses were made with the history alone, which increased to 73% with the addition of physical examination. In patients with cardiovascular disease, the history establishes the diagnosis two thirds of the time, and physical examination contributes to a quarter of diagnoses. Diagnostic tests such as chest radiographs and electrocardiograms (ECGs) helped with only 3% of diagnoses, and special tests (e.g., exercise ECG) assisted with 6%. In patients with respiratory, urinary, and neurologic conditions, the history has also been shown to be the most important diagnostic method. The skill of performing a clinical examination derives from pattern recognition learned by listening to and seeing patients and assimilating the stories and outcomes of their illnesses. The diagnostic acumen of the physician is a result of the ability to integrate and develop an overall impression rather than just reviewing a compilation of facts.

Importance of the Preoperative Medical History

The variability of the medical history and the words that both patients and physicians use to describe symptoms is a common problem. Using lay language and recording symptoms in ordinary words leads to greater interobserver agreement between practitioners and can lessen communication errors, which are common obstacles in medical care. Common errors occur when diagnostic labels such as "angina" are written in the record when the patient actually complained of "chest pain." Conversely, true angina or cardiac ischemia/infarction is rarely described by a patient as chest *pain*. More likely, the patient will have complaints of tightness or squeezing, often in the upper part of the abdomen, shoulder, or neck. Therefore, medical interviewers should not be surprised that patients may deny ever having chest *pain* if this is the only noun used when inquiring about symptoms to elicit a history, thus missing a history of angina. Obtaining the patient's history is not simply asking questions but asking the right questions, frequently in a variety of ways, and interpreting and carefully recording the answers. Complete and thorough histories assist in planning appropriate and safe anesthesia care and are more accurate and cost-effective in establishing diagnoses than screening laboratory tests are.

Components of the Preoperative Medical History

The important components of the anesthesia history are shown in Figure 34-1. The form can be completed by the patient in person (paper or electronic version), via Web-based programs, through a telephone interview, or by anesthesia staff.

The classic "history of present illness, or HPI," as it relates to evaluation for anesthesia starts with the reason that the patient is having surgery and the planned procedure. Often one needs to inquire further about how the surgical condition developed and any previous therapies related to this problem. Current and past medical problems, previous surgeries and types of anesthesia, and any anesthesia-related complications need to be noted. Rarely is simply a notation of diseases or symptoms such as hypertension, diabetes mellitus, coronary artery disease (CAD), shortness of breath, or chest pain sufficient. Equally important in identifying the presence of a disease is to establish the severity, current or recent exacerbations, the stability, and previous treatment of the condition or planned interventions. The extent, degree of control, and activity-limiting nature of the problems are equally important. The patient's medical problems, previous surgeries, and response to questions will elicit further inquiry to establish a complete history.

Prescription and over-the-counter medications, including supplements and herbals, should be carefully recorded, along with dosages and schedules. Any recent but currently interrupted medications should be included because this may lead to recognition of important issues. It is necessary to inquire about allergies to drugs and substances such as latex or radiographic dye, with special emphasis on the specifics of the patient's response to the exposure. Frequently, patients claim an allergy to a substance when in reality the reaction was a common, expected side effect (e.g., nausea or vomiting with narcotics). Use of tobacco, alcohol, or illicit drugs should be documented. Quantitatively documenting tobacco exposure by pack-years (number of packs of cigarettes smoked per day times the number of years of smoking) is best. For example, if one has smoked two packs of cigarettes daily for the last 10 years, this is recorded as 20 pack/years of tobacco use.

A history of malignant hyperthermia (MH) or a suggestion of it (hyperthermia or rigidity during anesthesia) in either a patient or family member should be clearly documented to allow appropriate arrangements to be made before the day of surgery. A personal or family history of pseudocholinesterase deficiency should be identified preoperatively. Records from previous anesthesia may clarify an uncertain history.

A screening review of systems is especially useful to uncover symptoms that may lead to the establishment of previously undiagnosed conditions. During the review of systems for anesthesia purposes, special emphasis needs to be placed on airway abnormalities; a personal or family history of adverse events related to anesthesia; and cardiovascular, pulmonary, hepatic, renal, endocrine, or neurologic symptoms. Questioning the patient about snoring and daytime somnolence may suggest undiagnosed sleep apnea, which has implications for anesthesia management (see the section "Preoperative Evaluation of Patients with Obstructive Sleep Apnea" and Chapter 64). The presence of any two of the following increases the chance that a patient has sleep apnea:

- Snoring
- Daytime sleepiness
- Hypertension
- Obesity

A significant history of heartburn, especially with associated reflux or after a period of fasting comparable to what will occur preoperatively, is important. Women of childbearing age need to be prompted to recall their last normal menstrual period and their likelihood of being pregnant. This history is more reliable if the woman, especially if a minor child, is questioned in privacy.

Determination of the patient's cardiorespiratory fitness or functional capacity is useful in guiding additional preanesthetic evaluation and predicting outcome and perioperative complications.[7,10] Exercise or work activity can be quantified in metabolic equivalents of the task (METs), which refers to a measure of the volume of oxygen consumed during an activity (Table 34-2). One's ability to exercise is two-pronged in that better fitness decreases mortality through improved lipid and glucose profiles and reductions in blood pressure (BP) and obesity. Lack of exercise increases the risk for development of cardiac disease. Conversely, an inability to exercise may be the result of cardiopulmonary disease. Patients with peripheral vascular disease (PVD) will be limited by claudication, and those with ischemic heart disease may complain of shortness of breath or chest discomfort with exertion. Patients may not volunteer this information until asked why they cannot walk more than a certain distance or climb stairs. Several studies have shown that inability to perform average levels of exercise (4 to 5 METs) identifies patients at risk for perioperative complications (see Table 34-2).[7]

One should inquire about chest discomfort (pain, pressure, tightness), duration of the discomfort, precipitating factors, associated symptoms, and methods of relief. One should note diagnoses, diagnostic tests, therapies, and names of treating physicians.

Shortness of breath with exertion or when lying flat (orthopnea) or peripheral edema is important to note. Patients are asked about a history of heart murmurs and what diagnostic studies have been performed to evaluate a murmur. The cardinal symptoms of severe aortic stenosis are angina, heart failure, and syncope, although patients are much more likely to complain of a decrease in exercise tolerance and exertional dyspnea.

A general examination of all organ systems needs to be performed. For example, asking patients whether they have ever had problems with their heart, lungs, kidneys, liver, or nervous system, whether they have had cancer, anemia, or bleeding problems, or whether thay have ever been hospitalized for any reason will often prompt recall of medical problems. Similarly, obtaining a complete listing of previous surgeries can help complete the medical history. Finally, a review of records from primary care physicians, specialists, or the hospital can reveal issues that the patient may not recall.

The Preoperative Physical Examination

At a minimum, the preanesthetic examination should include vital signs (e.g., BP, heart rate [HR], respiratory rate, oxygen saturation), height, and weight. Body mass index (BMI) is calculated from height and weight and is more accurate than weight in establishing obesity. Online BMI calculators can be found at

Figure 34-1, cont'd

http://www.cdc.gov/nccdphp/dnpa/bmi/index.htm or http://www.nhlbisupport.com/bmi/. Formulas for calculating BMI are as follows:

English formula:

$$\text{BMI} = \left(\frac{\text{Weight in pounds}}{(\text{Height in inches}) \times (\text{Height in inches})} \right) \times 703$$

Metric formula:

$$\text{BMI} = \frac{\text{Weight in kilograms}}{(\text{Height in meters}) \cdot (\text{Height in meters})}$$

or

$$\text{BMI} = \left(\frac{\text{Weight in kilograms}}{(\text{Height in centimeters}) \times (\text{Height in centimeters})} \right) \times 10{,}000$$

A BMI of 40 or greater defines extreme obesity, obesity is defined as a BMI of 30 to 39.9, and an overweight person has a BMI of 25 to 29.9. An increased BMI is predictive of airway difficulties in some studies and one of many factors associated with the development of chronic diseases such as heart disease, cancer, and diabetes.[11]

Table 34-2 Metabolic Equivalents of Functional Capacity

MET	Functional Levels of Exercise
1	Eating, working at a computer, dressing
2	Walking down stairs or in your house, cooking
3	Walking 1-2 blocks
4	Raking leaves, gardening
5	Climbing 1 flight of stairs, dancing, bicycling
6	Playing golf, carrying clubs
7	Playing singles tennis
8	Rapidly climbing stairs, jogging slowly
9	Jumping rope slowly, moderate cycling
10	Swimming quickly, running or jogging briskly
11	Skiing cross country, playing full-court basketball
12	Running rapidly for moderate to long distances

From Jette M, Sidney K, Blumchen G: Metabolic equivalents (METs) in exercise testing, exercise prescription, and evaluation of functional capacity. Clin Cardiol 13:555-565, 1990.
MET, metabolic equivalent of the task. 1 MET = consumption of 3.5 mL O_2/min/kg of body weight.

Not infrequently, patients will have increased BP during the preoperative visit, even without a history of hypertension. This may be due to anxiety or missing doses of drugs because patients often do not take their medications before an appointment or procedure. This reading is probably not reflective of their usual control. Repeating the BP measurement, especially after the administration of anxiolytics if this is planned, obtaining previous readings from either medical records or asking patients what their "usual" BP measurements are, can be informative.

Inspection of the airway may be the single most important component of the physical examination from an anesthesiologist's perspective. Without specialized training in airway evaluation and management, including advanced techniques such as fiberoptic intubation, it is unlikely that nonanesthesiologists will be capable of performing an adequate assessment. See Box 34-1 for components of the airway examination.

All patients should have thorough documentation of an airway examination, whether in a preoperative evaluation clinic or immediately before surgery (see Chapter 50). The Mallampati classification is performed by having patients open the mouth widely and protruding the tongue completely forward. A tongue depressor is not used. In class I, the soft palate, fauces, entire uvula, and pillars are visualized; in class II, the soft palate, fauces, and a portion of the uvula; in class III, the soft palate and base of the uvula; and in class IV, the hard palate only. The evaluation should also document the status of teeth, range of motion of the neck, neck circumference (increasing size predicts difficulty with laryngoscopy), thyromental distance, body habitus, and pertinent deformities.[12] Because of the relatively high incidence of dental injuries during anesthesia, thorough documentation of preexisting tooth abnormalities is useful. A good time to discuss with patients variant options of airway management or techniques other than general anesthesia when applicable and prepare patients for possible awake fiberoptic intubation is after examination of the airway. When challenging airways are identified, advance planning ensures that the necessary equipment and skilled personnel are available.

Evaluation of the heart, lungs, and skin is necessary, as well as further focus on the organ systems involved with disease as reported by the patient. Auscultation of the heart and, when indicated, inspection of the pulses and peripheral and central veins and assessment for the presence of edema in the extremities may aid in developing a perioperative plan. One should auscultate for murmurs, rhythm disturbances, and signs of volume overload. Physical findings should focus on examination for third or fourth heart sounds, rales, jugular venous distention, ascites, hepatomegaly, and edema.

Observing whether the patient can walk up one to two flights of stairs can predict a variety of postoperative complications, including pulmonary and cardiac events and mortality, and aid in decisions regarding the need for further specialized testing such as pulmonary function tests (PFTs) or noninvasive cardiac stress testing.[13] This is frequently not practical, and a report by the patient is often sufficient.

The pulmonary examination should include auscultation for wheezing and decreased or abnormal breath sounds and notation of cyanosis or clubbing, use of accessory muscles, and effort of breathing.

A basic neurologic examination to document deficits in mental status, speech, cranial nerves, gait, and motor and sensory function may be indicated, depending on the surgical procedure and patient's history. For selective patients (e.g., those with deficits or disease or undergoing neurosurgery), a more extensive or focused neurologic examination is necessary to document specific preexisting abnormalities that may aid in diagnosis or interfere with positioning. Establishing a baseline allows comparison postoperatively for evaluation of new deficits and can aid in defense of potential malpractice claims of adverse events.

Obesity, hypertension, and large neck circumference (>17 inches in men, >16 inches in women, or >60 cm in anyone) predict an increased incidence of obstructive sleep apnea (OSA).[14] These same neck measurements also predict difficulty with mask ventilation and intubation. Intravenous access sites should be

Box 34-1 Components of the Airway Examination

- Length of the upper incisors
- Condition of the teeth
- Relationship of the upper (maxillary) incisors to the lower (mandibular) incisors
- Ability to protrude or advance the lower (mandibular) incisors in front of the upper (maxillary) incisors
- Interincisor or intergum (if edentulous) distance
- Tongue size
- Visibility of the uvula
- Presence of heavy facial hair
- Compliance of the mandibular space
- Thyromental distance with the head in maximum extension
- Length of the neck
- Thickness or circumference of the neck
- Range of motion of the head and neck

noted. If this is limited, one should discuss possible central line placement with the patient or arrange for assistance from interventional radiology. Auscultation for bruits is important in patients with a history of head and neck irradiation, stroke, or transient ischemic attack.

Preoperative Evaluation of Patients with Coexisting Disease

Many of these concerns and conditions, including intraoperative and postoperative anesthesia management, are discussed in greater detail in other chapters of this text. This section briefly reviews specific medical conditions that are commonly seen in preoperative evaluation and for which preoperative assessment and intervention are important. Identification of patients with these comorbid conditions often presents an opportunity for the anesthesiologist to intervene to lower risk. The following conditions are best managed before the day of surgery, which allows ample time for thoughtful evaluation, consultation, and planning of anesthesia care.

Cardiovascular Disease

Cardiovascular complications are the most common serious perioperative adverse event (see Chapter 33). It is estimated that cardiac morbidity will occur in 1% to 5% of unselected patients undergoing noncardiac surgery. In specific circumstances, perioperative interventions have been shown to modify cardiovascular morbidity and mortality.[7,15-17]

Hypertension

Hypertension, defined as two or more BP readings greater than 140/90 mm Hg, affects 1 billion individuals worldwide and increases with age. In the United States, 25% of adults and 70% of patients older than 70 years have hypertension, less than 30% are adequately treated, and 30% are undiagnosed. The degree of end-organ damage and morbidity and mortality correlate with the duration and severity of hypertension. Ischemic heart disease is the most common type of organ damage associated with hypertension. Each 20–mm Hg incremental elevation in systolic BP or 10–mm Hg incremental elevation in diastolic BP above 115/75 doubles the lifetime risk for cardiovascular disease in individuals 40 to 70 years of age. The odds ratio for an association between hypertension and perioperative cardiac risk is 1.31.[7,18] However, there is little evidence of an association between a preoperative BP reading of less than 180/110 mm Hg and perioperative cardiac risk. Heart failure, renal insufficiency, and cerebrovascular disease are common in hypertensive patients.

Preoperative evaluation identifies causes of hypertension, other cardiovascular risk factors, end-organ damage, and therapy. Paroxysmal hypertension or hypertension in young individuals should prompt a search for causes such as coarctation, hyperthyroidism, pheochromocytoma, or even illicit drug use such as cocaine, amphetamines, or anabolic steroids. (See the section "Pheochromocytoma" for further evaluation guidelines.) Physical examination focuses on the cardiovascular system, pulses, vital signs (BP needs to be repeated and previous records obtained to establish long-term values), the thyroid gland, and signs of volume overload. Asking about episodic tachycardia, palpitations, and syncope, measuring BP in both arms, listening for bruits, and assessing the pulses in both the upper and lower extremities are necessary if there is concern the patient may have more than essential hypertension. Testing should be determined by the history and physical examination. Patients with long-standing, severe (often based on the number and dosages of prescribed antihypertensive medications), or poorly controlled hypertension need an ECG and determination of blood urea nitrogen (BUN) and creatinine, depending on the surgical procedure. Those taking diuretics should have an evaluation of electrolytes. Patients with significant left ventricular hypertrophy (LVH), especially those with a strain pattern on the ECG, which is indicative of chronic ischemia, should have a careful assessment of symptoms and other risk factors for CAD. In the presence of heart failure or dyspnea of unknown origina, an echocardiogram may provide additional information that will modify management. LVH independently increases the risk for perioperative cardiac morbidity. Patients suspected of having hyperthyroidism require thyroid function tests.

It is generally recommended that elective surgery be delayed for severe hypertension (diastolic BP >115 mm Hg, systolic BP >200 mm Hg) until BP is less than 180/110 mm Hg. If severe end-organ damage is present, the goal should be to normalize BP *as much as possible* before surgery.[18] A careful history and physical examination to determine cardiac, neurologic, or renal disease is important (see appropriate sections of this chapter). Effective lowering of risk may require 6 to 8 weeks of therapy to allow regression of vascular and endothelial changes, but too rapid or extreme lowering of BP may increase cerebral and coronary ischemia; therefore, the benefits of delaying surgery for treatment must be weighed against the risks. The Antihypertensive and Lipid Lowering Treatment to Prevent a Heart Attack Trial (ALLHAT) showed that effective treatment of hypertension is not simply a matter of decreasing BP.[19] Thus, if surgery cannot be postponed, the goal is to not decrease chronically increased BP too rapidly. Severely elevated BP should be lowered over a period of several weeks. Studies suggest that hypotension intraoperatively is far more dangerous than hypertension.[18] For a BP lower than 180/110 mm Hg, there is no evidence to justify cancellation of surgery, although interventions preoperatively are appropriate. It is important to identify patients who have undiagnosed hypertension (although typically three separate occasions of increased BP in nonstressful situations are required to diagnosis true hypertension) and differentiate those who have poorly controlled hypertension from those who have episodic increased BP because of pain, anxiety, or stress.

Because the perioperative period is an excellent opportunity to alter the long- and short-term consequences of diseases, appropriate referral for future management is vital. Guidelines suggest that cardioselective β-blocker therapy is the best treatment preoperatively because of a favorable profile in lowering cardiovascular risk, although the Perioperative Ischemia Evaluation (POISE) trial has recently questioned the safety of starting these agents acutely.[7] The optimal time to start β-blocker therapy to achieve its benefit while minimizing risk is unknown. Even though diuretics are first-line therapies in most circumstances, starting them in the preoperative period is not generally a good idea because of the alterations in potassium (both hypokalemia and hyperkalemia) that may occur and the need for close moni-

toring and replacement. Calcium channel blockers (e.g., amlodipine, 5 to 10 mg daily) can be very effective. Frequently, anxiety increases BP, and therefore antianxiolytics can be used as adjunctive therapy. BP should not be lowered too rapidly. Continuation of antihypertensive treatment preoperatively is critical.

Ischemic Heart Disease

The goals of preoperative evaluation are to

- Identify the risk for heart disease based on risk factors (Fig. 34-2, Box 34-2)
- Identify the presence and severity of heart disease from symptoms, physical findings, or diagnostic tests
- Determine the need for preoperative interventions
- Modify the risk for perioperative adverse events

The basis of cardiac assessment is the history, physical examination, and ECG. Risk factors for CAD are as important or more important than symptoms of ischemia because CAD is not diagnosed in 40% of men and 65% of women before an acute coronary syndrome (unstable angina, acute MI, or sudden death) occurs. The traditional risk factors for CAD, such as smoking, hypertension, age, male gender, hypercholesterolemia, and family history, are not the same risk factors that are associated with an increased incidence of perioperative cardiac events (see Fig. 34-2 and Box 34-2). However, traditional risk factors are important in assessing the significance of chest pain, dyspnea, or an abnormal ECG. The Revised Cardiac Risk Index (RCRI; Box 34-2) has been validated in several studies as the best scoring system to predict

Box 34-2 Revised Cardiac Risk Index

High-risk surgery (intraperitoneal, intrathoracic, or suprainguinal vascular procedures)*
Ischemic heart disease (by any diagnostic criteria)
History of congestive heart failure
History of cerebrovascular disease
Diabetes mellitus requiring insulin†
Creatinine >2.0 mg/dL

*This risk factor is not considered a clinical predictor in the ACC/AHA 2007 guidelines for perioperative cardiac evaluation for noncardiac surgery.[7]
†This risk factor has been changed to simply diabetes mellitus in the ACC/AHA 2007 guidelines for perioperative cardiac evaluation for noncardiac surgery.[7]
From Lee TH, Marcantonio ER, Mangione CM, et al: Derivation and prospective validation of a simple index for prediction of cardiac risk of major noncardiac surgery. Circulation 100:1043-1049, 1999.

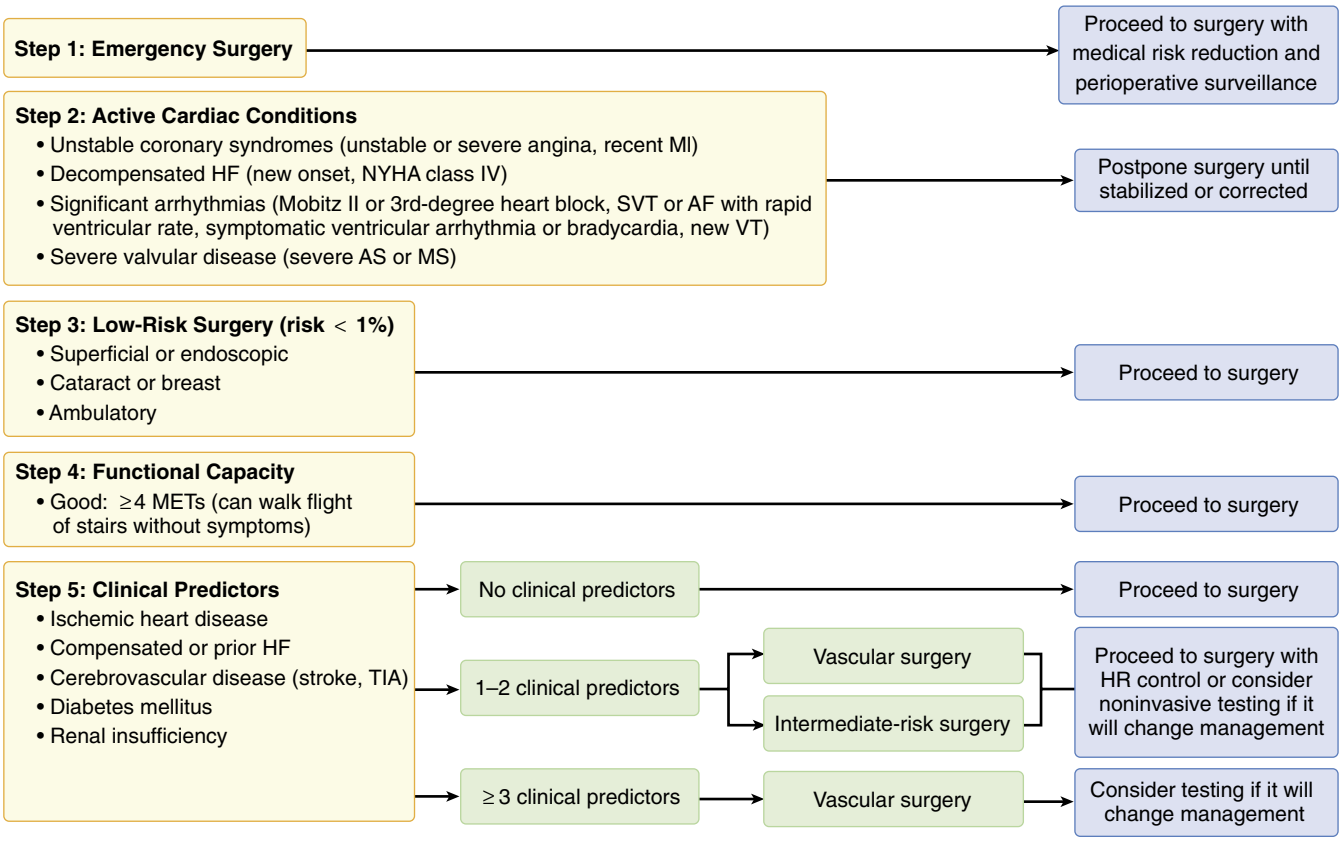

Figure 34-2 Simplified cardiac evaluation for noncardiac surgery. AF, atrial fibrillation; AS, aortic stenosis; HF, heart failure; HR, heart rate; METs, metabolic equivalents of the task; MI, myocardial infarction; MS, mitral stenosis; NYHA, New York Heart Association; SVT, supraventricular tachycardia; TIA, transient ischemic attack; VT, ventricular tachycardia. *(From Fleisher LA, Beckman JA, Brown KA, et al: ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery. J Am Coll Cardiol 50:e159-e241, 2007. Available at http://www.acc.org/qualityandscience/clinical/guidelines/Periop_/ Accessed September 28, 2007.)*

perioperative cardiac risk in patients undergoing noncardiac surgery.[20] The most important risk factors for adverse events are a history of ischemic heart disease, heart failure, diabetes, cerebrovascular disease, and renal insufficiency; advanced age; and high-risk surgery, especially open vascular procedures.

One should inquire about chest discomfort (pain, pressure, tightness), the duration of the discomfort, precipitating factors, associated symptoms, and methods of relief. Regardless of symptoms, the most important prognostic indicators of heart disease and perioperative adverse events are risk factors. Shortness of breath with exertion is a common angina-equivalent. Dyspnea is nonspecific and can be a result of deconditioning, pulmonary disease, or heart failure. Dyspnea in patients with risk factors for CAD (see Fig. 34-2 and Box 34-2) may necessitate an investigation for ischemic heart disease. Women are particularly likely to have atypical symptoms of ischemic heart disease. One should note diagnoses, diagnostic tests, therapies, and names of treating physicians.

Patients with risk factors for CAD or symptoms suggestive of ischemia, including atypical ones such as dyspnea, need an ECG. Tait and colleagues suggested that routine preoperative ECGs are not indicated in patients without a history of cardiovascular disease and no significant risk factors.[21] An abnormal ECG is found in 62% of patients with known cardiac disease, in 44% of those with strong risk factors, but in only 7% of individuals younger than 50 years with no risk factors. Additionally, the specificity of an abnormality on the ECG in predicting postoperative cardiac adverse events is only 26%, and a normal ECG does not exclude cardiac disease.[22]

An ECG should not be ordered simply because of advanced age (see Chapter 71). Recommendations for age-based testing are derived from the high incidence of abnormalities found with advancing age. The frequency of Q-wave infarctions found only by ECG in men 75 years or older is about 0.5%. In an ambulatory surgical population, 43% of patients had an abnormal ECG, but only 1.6% had an adverse perioperative event and the preoperative ECG was of potential value in just half of those who had a complication. Only certain abnormalities on the ECG are important in preoperative assessment (e.g., Q waves, especially if recent; conduction abnormalities and arrhythmias), and one study found that just 2% of patients had one or both if a previous ECG did not show these abnormalities. Establishing a baseline for comparison is the most important reason to obtain an ECG preoperatively. However, if the rate of probable events is infrequent or the ECG is likely to be normal preoperatively, the yield lessens. If a previous ECG is available and there has been no change in symptoms or risk factors and no new physical findings, it is unlikely that a repeat ECG will be useful. The 2007 ACC/AHA guidelines on perioperative cardiovascular evaluation provide additional recommendations for preoperative resting ECGs (Box 34-3).[7]

Review of medical records and previous diagnostic studies, especially stress tests and catheterization results, should be performed if possible. In our experience, many patients are unaware of abnormalities or results not requiring revascularization. Frequently, a phone call to the primary care physician or cardiologist will yield important information and obviate the need for further testing or consultation. Consultation initiated by the preoperative physician should seek specific advice regarding diagnosis and status of the patient's condition. Asking specific questions such as "*Does this patient have CAD?*" or "*Is this patient optimized for planned radical nephrectomy?*" is the first step. Letters or notes stating "*cleared for surgery*" are not sufficient to design a safe anesthetic plan. A letter summarizing the medical problems and therapies, along with the results of diagnostic tests, should be requested.

Box 34-3 Recommendations for Preoperative Resting 12-Lead Electrocardiogram

Class I

A preoperative resting 12-lead ECG is recommended for patients with at least one clinical risk factor* who are undergoing vascular surgical procedures

A preoperative resting 12-lead ECG is recommended for patients with known congestive heart failure, peripheral arterial disease, or cerebrovascular disease who are undergoing intermediate-risk surgical procedures

Class IIa

A preoperative resting 12-lead ECG is reasonable in persons with no clinical risk factors who are undergoing vascular surgical procedures

Class IIb

A preoperative resting 12-lead ECG may be reasonable in patients with at least one clinical risk factor who are undergoing intermediate-risk operative procedures

Class III

Preoperative and postoperative resting 12-lead ECGs are not indicated for asymptomatic persons undergoing low-risk surgical procedures

Class I recommendations: the procedure *should* be performed; class IIa: it is reasonable to perform the preocedure; class IIb: the procedure may be considered; class III: the procedure should *not* be performed because it is not helpful.

*Clinical risk factors are listed in Box 34-2.

Adapted from Fleisher LA, Beckman JA, Brown KA, et al: ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery. J Am Coll Cardiol 50:e159-e241, 2007. Available at http://www.acc.org/qualityandscience/clinical/guidelines/Periop_Fulltext_2007.pdf/ Accessed September 28, 2007.

The goal is to identify patients with heart disease who are at high risk for perioperative cardiac morbidity or mortality or those with modifiable conditions or risk. The guidelines for cardiac evaluation before noncardiac surgery published by the ACC/AHA have become the national standard of care. These guidelines were recently revised with a marked reduction in recommendations for preoperative noninvasive stress testing and revascularization.[7]

Step 1 in this guideline algorithm is to determine the urgency of the surgery. If emergency surgery does not allow further assessment, the focus needs to be placed on perioperative surveillance (e.g., serial ECGs, enzymes, monitoring) and risk reduction (e.g., HR control, statins, pain management). Clinical predictors, functional or exercise capacity, and level of surgical risk guide further diagnostic and therapeutic interventions.

Step 2 is to determine whether the patient has an active cardiac condition, such as acute MI, unstable or severe angina, decompensated heart failure, severe valvular disease (e.g., severe

aortic stenosis), or significant arrhythmias (e.g., ventricular tachycardia or atrial fibrillation with a rapid rate), that warrants postponement of all except lifesaving emergency procedures (e.g., ruptured aneurysms). After evaluating and treating these conditions according to the AHA/ACC guidelines, surgery may be considered if the benefits outweigh the risks. Traditionally, patients who experienced an MI within 3 to 6 months were considered high risk and surgery was delayed. More recent evidence and the ACC/AHA guidelines suggest that *acute* MI, defined as occurring within the past 7 days, should still be considered high risk and elective surgeries postponed. A *recent* MI, defined as occurring within the past 30 days (but more than 7 days) *with evidence of myocardium at risk* (generally based on persistent symptoms or results of stress testing), is also a high-risk condition. However, a recent (8 to 30 days previously) MI *without evidence of myocardium at risk* is considered an active cardiac condition and equivalent to any history of CAD.

Step 3 involves determination of the surgical risk or severity. Patients without active cardiac conditions who are undergoing low-risk surgery (reported cardiac risk generally <1%; endoscopic or superficial procedures, cataract, breast, or ambulatory surgeries) can proceed to surgery without further cardiac testing other than an ECG within 3 months.

Step 4 assesses the patient's functional capacity (see Table 34-2). Asymptomatic patients who are highly functional can proceed to surgery. The 2007 ACC/AHA guidelines use the RCRI (see Box 34-2) derived from a cohort study showing an incidence of major cardiac events of 0.4%, 0.9%, 7%, and 11% in patients with zero, one, two, or three risk predictors, respectively.[20] The RCRI medical conditions have been confirmed in independent studies as valid predictors of risk.[15]

Step 5 is the last and most complicated determination for patients with poor or indeterminate functional capacity. The presence and number of clinical predictors as shown in Box 34-2 drive the recommendations for and probable benefit of further cardiac testing. Patients with no clinical predictors proceed to surgery. Those undergoing vascular surgery with three or more clinical risk factors are the group most likely to benefit from further testing, but the ACC/AHA guidelines recommend further testing only "if it will change management." Patients with one or more clinical predictors undergoing intermediate-risk surgery (1% to 5% risk for cardiac complications, including orthopedic, intraabdominal, and intrathoracic procedures) or those with one or two risk factors undergoing vascular surgery can either proceed to surgery with HR control or undergo noninvasive testing if it will change management.

Chronic inflammatory conditions (e.g., rheumatoid arthritis, systemic lupus erythematosus [SLE]), chronic steroid use, and chest irradiation) increase the risk for CAD but have not been shown to be significant predictors of perioperative cardiac complications.[23,24] The substantial pullback of ACC/AHA recommendations advocating noninvasive stress testing and coronary revascularization before noncardiac surgery is due to the general lack of definitive benefit and risk reduction with this approach. The only randomized prospective study of revascularization (coronary artery bypass grafting [CABG] or percutaneous coronary intervention [PCI] with stenting) versus medical management failed to show a difference in outcome. This study was performed in intermediate- to high-risk patients with known CAD undergoing major vascular surgery.[25] Numerous retrospective and observational studies have failed to show a benefit of coronary revascularization before noncardiac surgery. Noncardiac surgery soon after revascularization (CABG or PCI with or without stents) is associated with high rates of perioperative cardiac morbidity and mortality.[26] Factors to consider are the urgency of the noncardiac surgery (e.g., patients with cancer) and the potential long-term benefits of revascularization. Patients who need noncardiac surgery within the next year are not good candidates for implantation of drug-eluting stents, and if revascularization is absolutely necessary, these patients need to be considered for either CABG or PCI without stenting or with a bare metal stent.[27] See the section on recent coronary stents and antiplatelet agents.

Stress testing identifies CAD and its severity, but the positive predictive value for perioperative cardiac complications is generally only 5% to 25%.[28] The negative predictive value of noninvasive tests for predicting perioperative events generally approaches 100%, so these tests are typically more informative about a patient who will *not* have an event than one who will. However, studies of the predictive value of noninvasive testing predated the era of drug-eluting stents and the risk of perioperative acute thrombosis with these stents. Cardiac catheterization, which some consider the gold standard for evaluation of coronary lesions, does not absolutely risk-stratify patients.[29] This lack of prognostic value is partly due to the approximately 50% incidence of plaque rupture (with intermediate-sized plaque of 40% to 70% being most vulnerable to rupture) as the causative event during the perioperative period combined with the hypercoagulable state and the typical withdrawal of antiplatelet agents.

Exercise treadmill testing can be ordered for patients with normal ECGs who can exercise and are likely to achieve an adequate HR response (68% to 81% sensitivity and 66% to 77% specificity for finding ischemia).[7] Prognostic information such as functional capacity and the workload at which ischemia occurs predict outcome. The test result is adequate when the patient can exercise to at least greater than 85% of the target HR (the target HR is defined as 220 − age). The individual's ability to exercise and symptoms that limit activity, such as dyspnea, have long-term prognostic implications, even in those without evidence of ischemia.

Pharmacologic tests such as dobutamine echocardiography or nuclear perfusion imaging are necessary for patients unable to exercise, those with pacemakers or significant bradycardia, or those taking high-dose β-adrenergic blockers.[7]

A combination of exercise and imaging can be used in patients able to exercise who have significant abnormalities on the ECG that may interfere with the interpretation of ischemia via the ECG (e.g., LVH with a strain pattern, ST-T wave changes, or left bundle branch block [LBBB]). Exercise combined with perfusion imaging in patients with LBBB results in a high incidence of false-positive tests because of septal perfusion defects not caused by CAD.[7] For most patients, the choice of which pharmacologic test is immaterial. Dobutamine uncovers ischemia by increasing contractility, HR, and BP and may therefore not be the best test in patients with pacemakers, significant bradycardia, aortic or cerebral aneurysms, or poorly controlled hypertension. Adenosine radionucleotide imaging (one of the most common methods of nuclear stress testing) uses the vasodilatory properties of adenosine (stenotic vessels are maximally vasodilated at rest) and uptake of the radioisotope by viable myocardium. This type of test is not dependent on the HR response but may exacerbate bronchospasm in patients taking theophylline or reduce preload,

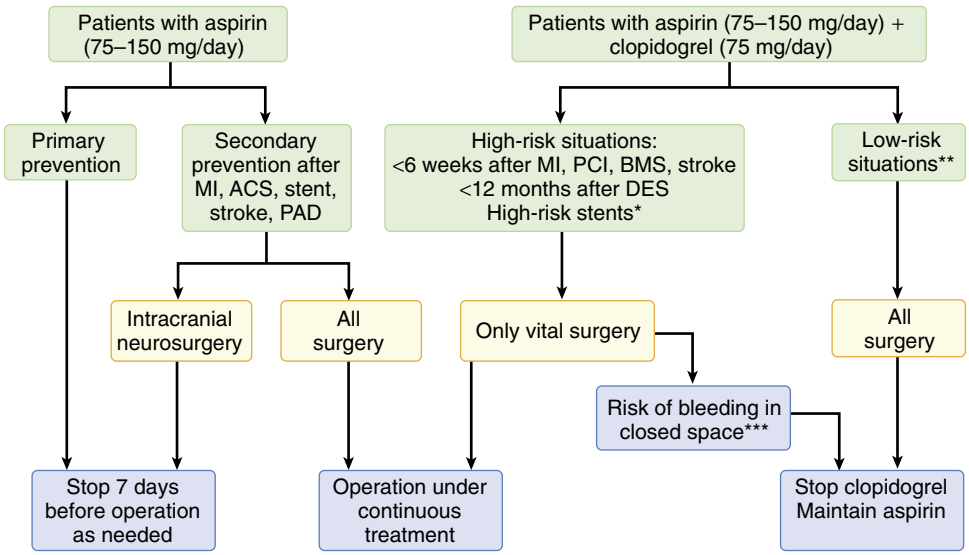
which may be dangerous in patients with severe aortic stenosis, hypertrophic cardiomyopathy (HCM), or carotid stenosis.

Echocardiography, combined with exercise or a pharmacologic agent, is used to look for wall motion abnormalities. Abnormalities present at rest (baseline) indicate scar tissue from previous infarction. Areas of myocardium that are normal at rest but show abnormalities with increased isotropy and chronotropy are consistent with stenotic lesions and limited blood flow. Similarly, nuclear imaging perfusion abnormalities at rest are consistent with infarction. Normal coronary arteries vasodilate with adenosine or exercise, and uptake of isotope is normal. Myocardium with limited blood flow will be normal at rest but show decreased uptake of isotope with exercise or administration of adenosine. Perioperative cardiac risk increases with increasing amounts of at-risk myocardium. If a patient has undergone a specific test in the past, it is most useful to obtain the same test for comparison.

Patients with ischemic heart disease require a complete blood count (CBC), and transfusion for anemia should be considered. In nonoperative settings but in populations with critical illness or chronic disease states associated with known CAD or risk factors for CAD, hemoglobin levels higher than 13.5 g/dL are associated with adverse outcomes.[30] A recent study suggests that even mild preoperative anemia increases postoperative mortality and cardiac morbidity in men but not in women.[31] Individuals with preoperative hematocrits between 39% and 51% had the lowest risk of adverse outcomes in this Veteran's Administration surgical population.

A thorough discussion of the optimal perioperative medical treatment of patients with ischemic heart disease can be found in Chapter 35. In brief, patients already taking statins and β-blockers need to have these drugs continued without interruption throughout the perioperative period. Those already taking β-blockers need their dosages adjusted to achieve an HR lower than 70 beats/min if at all possible. The optimal use of β-blockers in patients who are at significant risk for perioperative cardiac events and are currently not taking them in accord with national guidelines is controversial and discussed more fully in Chapter 35. Strong consideration should be given to continuing aspirin perioperatively or discontinuing for the shortest duration possible if used for secondary prevention of vascular events (Fig. 34-3).

By applying the ACC/AHA recommendations or using the predictive value of the RCRI and developing practice guidelines as shown in Figure 34-2, anesthesiologists in preanesthetic clinics are well positioned to risk-stratify patients, thus obviating the need for cardiac consultation. The preoperative period is an opportunity to identify patients with CAD who will benefit from long-term risk modification with statins, aspirin, exercise, and diet adjustment. Patients with symptoms consistent with ischemia (but without a diagnosis of CAD) or significant risk factors



*High-risk stents: long (>36 mm), proximal, overlapping, or multiple stent implantation, stents for chronic total occlusions, stents in small vessels or bifurcated lesions.
**Examples of low-risk situations: >3 months after BMS, stroke, uncomplicated MI, PCI without stenting.
***Risk of bleeding in closed space: intracranial neurosurgery, intra-medullary canal surgery, posterior eye chamber ophthalmic surgery. In these situations, the risk/benefit ratio of upholding vs withdrawing aspirin must be evaluated for each case individually; in case of aspirin upholding, early postoperative re-institution is important.

Figure 34-3 Algorithm for preoperative management of patients receiving antiplatelet therapy. ACS, acute coronary syndrome; BMS, bare metal stent; DES, drug-eluting stent; MI, myocardial infarction; PAD, peripheral arterial disease; PCI, percutaneous coronary intervention. *(From Chassot P-G, Delabays A, Spahn DR: Perioperative antiplatelet therapy: The case for continuing therapy in patients at risk of myocardial infarction. Br J Anaesth 99:316-328, 2007. Available at http://bja.oxfordjournals.org.)*

without medical management such as statins and aspirin may benefit from evaluation by a cardiologist regardless of whether they are having surgery. Preoperative evaluation should not simply focus on perioperative risk.

Heart Failure

Heart failure affects 4 to 5 million people (2% of the population) in the United States and is a significant risk factor for postoperative adverse events (see Chapter 60).[32] One in 100 individuals between 50 and 59 years of age has a 5% to 7% risk of perioperative cardiac complications, but those with decompensated failure have a 20% to 30% incidence. Heart failure may be due to systolic dysfunction (decreased ejection fraction because of abnormal contractility), diastolic dysfunction (elevated filling pressure because of abnormal relaxation but normal contractility and ejection fraction), or a combination. Diastolic failure accounts for almost half of all cases, but there is little science to guide perioperative care of these individuals. Hypertension is a cause of diastolic dysfunction, and LVH on an ECG should raise suspicion. Ischemic heart disease is the most common cause of systolic dysfunction in the United States (50% to 75% of cases). Cardiomyopathies occur from a variety of causes, including infectious causes (human immunodeficiency virus [HIV], coxsackievirus, influenza virus, adenovirus, Chagas' or Lyme disease), ischemia, stress, toxins, alcohol, the peripartum period, drugs (doxorubicin [Adriamycin], cocaine), muscular dystrophies, and idiopathic causes, which can be familial and inherited in an autosomal dominant or X-linked autosomal recessive pattern.

The preoperative evaluation history and physical examination focus on identifying and minimizing the effects of heart failure. Recent weight gain, complaints of shortness of breath, fatigue, orthopnea, paroxysmal nocturnal dyspnea, nocturnal cough, peripheral edema, hospitalizations, and recent changes in management are all significant. Patients with decompensated heart failure feel as though they are "suffocating" or have "air hunger."[33] Angina or a history of CAD may indicate heart failure.

The physical examination focuses on finding third or fourth heart sounds, tachycardia, a laterally displaced apical pulse, rales, jugular venous distention, ascites, hepatomegaly, or peripheral edema. Classifying the patient's medical status according to the New York Heart Association (NYHA) categories is useful.[34]

NYHA Classification

Class I: no limitation of physical activity; ordinary activity does not cause fatigue, palpitations, or syncope
Class II: slight limitation of physical activity; ordinary activity results in fatigue, palpitations, or syncope
Class III: marked limitation of physical activity; less than ordinary activity results in fatigue, palpitations, or syncope; comfortable at rest
Class IV: inability to perform any physical activity without discomfort; symptoms at rest

Decompensated heart failure is considered a high-risk cardiac condition, and elective surgery should be postponed (see Fig. 34-2).[7] Brain naturetic peptide (BNP), which is released from the ventricles of the heart, can be useful in evaluating patients suspected of having decompensated heart failure.[35] In an emergency room study of patients with dyspnea, a plasma BNP level higher than 100 pg/mL diagnosed heart failure with a sensitivity, specificity, and predictive accuracy of 90%, 76%, and 83%, respectively. The plasma concentration of BNP correlated with NYHA functional class, with BNP levels ranging from 244 to 817 pg/mL corresponding to classes I to IV.[36] In patients undergoing noncardiac surgery, preoperative BNP levels predict cardiac complications and death.[37] An N-terminal pro-BNP level elevated to greater than 450 pg/mL in patients younger than 50 years and to greater than 900 pg/mL in patients 50 years or older is highly sensitive and specific for the diagnosis of acute failure. An N-terminal pro-BNP level less than 300 pg/mL has a 99% negative predictive value for acute heart failure. A study of patients undergoing vascular surgery showed that preoperatively elevated levels of N-terminal pro-BNP predicted cardiac events and mortality.[38]

A preoperative ECG plus determination of electrolytes, BUN, creatinine, and possibly BNP is indicated in all patients with or suspected of having heart failure. Digoxin levels should not be routinely measured unless toxicity under treatment or noncompliance is suspected. One should determine *trough* levels of digoxin, which is not always possible in a preoperative evaluation setting. Paroxysmal atrial tachycardia with a 2:1 atrioventricular (AV) block is pathognomonic of digoxin toxicity. Junctional tachycardia, ventricular ectopic beats, bigeminy, second-degree AV block, nausea, lethargy, altered color perception, and mental status changes or agitation are symptoms of digoxin toxicity. Chest radiography is useful in those suspected of pulmonary edema or decompensation. An objective measure of the left ventricular ejection fraction (LVEF), ventricular performance, and diastolic function with echocardiography is helpful if not previously performed, especially in patients with NYHA class III or IV heart failure. Normal LVEF is greater than 50%, mildly diminished is 41% to 49%, moderately diminished is 26% to 40%, and severely diminished is less than 25%. In patients with class III or IV heart failure, cardiology consultation would be useful before the patient undergoes general anesthesia or any intermediate- or high-risk procedure. Minor procedures under monitored anesthesia care may proceed as long as the patient's condition is stable.

Medical therapy, including β-blockers, hydralazine, nitrates, and digoxin, needs to be optimized and continued preoperatively. Angiotension-converting enzyme inhibitors (ACEIs), angiotensin receptor blockers (ARBs), diuretics (including aldosterone antagonists such as spironolactone), and anticoagulants may be beneficial, even on the day of surgery. Selectively continuing or discontinuing these drugs depends on the volume and hemodynamic status of the patient, the degree of cardiac dysfunction, and the anticipated surgery and volume challenges. Continuing all medications for patients with severe dysfunction who are scheduled for minor procedures is probably best. The other extreme occurs when patients with well-compensated NYHA class I failure are scheduled for lengthy high-risk procedures with projected significant blood loss or fluid requirements; in this case it is best to discontinue potent diuretics on the morning of surgery. Short-acting calcium channel antagonists depress left ventricular function, worsen symptoms, and increase the risk for death. Some patients will have pacemakers or implantable cardiac defibrillators, which have special considerations perioperatively (see the section on devices for management of cardiac rhythm for recommendations and Chapter 43).

Unless truly an emergency and life preserving, surgery should be postponed in patients with decompensated or untreated heart failure. There is no consensus on how long after an acute

exacerbation patients remain at risk. Severely affected individuals or those with decompensation are best managed in concert with a heart failure specialist and may benefit from preoperative hospitalization for interventions designed to improve function.

Murmurs and Valvular Abnormalities

The quandary in the preoperative clinic is to determine the cause of cardiac murmurs and to distinguish between significant murmurs and clinically unimportant ones (see Chapter 60).[39] Functional murmurs occur as a result of turbulent flow across the aortic or pulmonic outflow tracts. These benign murmurs occur with high-outflow states such as hyperthyroidism, pregnancy, or anemia. However, noncardiologists or even cardiologists often cannot distinguish benign from pathologic murmurs. In elderly patients and those with risk factors for heart disease, other abnormal heart sounds, a history of rheumatic fever or anorectic drug use, evidence of volume overload, pulmonary disease, cardiomegaly, or an abnormal ECG, echocardiography should be considered (Box 34-4).[40] Although echocardiography may be useful in the diagnosis of many of these murmurs, the evaluation may not be required preoperatively if the information will not change management.

Diastolic murmurs are always pathologic and require further evaluation. Regurgitant disease is tolerated perioperatively much better than stenotic disease is. Heart failure in concert with any valvular disease is associated with a 20% risk of decompensation in the perioperative period. Murmurs are graded according to loudness: grade I, a faint murmur that can be heard with difficulty; grade II, faint but easily heard; grade III, moderately loud without a thrill; grade IV, loud with a palpable thrill; grade V, very loud but still needs a stethoscope (thrill present); and grade VI, murmur heard without a stethoscope. However, the usefulness of this distinction is debatable because severe lesions can be associated with soft murmurs and vice versa. The location of the murmur and changes in intensity with maneuvers guide diagnosis (Table 34-3). A Valsalva maneuver decreases filling of the right and left heart chambers and reduces the intensity of most murmurs, except those associated with mitral valve prolapse (MVP) and HCM. Standing will also increase the intensity of murmurs of MVP and HCM. Squatting increases venous return and afterload and therefore increases most murmurs, except those related to MVP and HCM. Asking the patient to repeatedly perform a handgrip will increase HR and afterload (increases BP) and will augment murmurs of mitral regurgitation and stenosis and aortic insufficiency but decrease aortic stenosis and HCM murmurs. All patients with murmurs require an ECG. In patients with significant abnormalities found by history, physical examination, or ECG, further evaluation by echocardiography or by a cardiologist should be considered (see Box 34-4).

Box 34-4 ACC/AHA Guideline Summary—Echocardiography in Asymptomatic Patients with Cardiac Murmurs*

Class I—There is evidence or general agreement (or both) that echocardiography is useful in asymptomatic patients with the following cardiac murmurs:

- Diastolic murmurs
- Continuous murmurs
- Late systolic murmurs
- Murmurs associated with ejection clicks
- Murmurs that radiate to the neck or back
- Grade 3 or louder systolic murmurs

Class IIa—The weight of evidence or opinion is in favor of the usefulness of echocardiography in asymptomatic patients with the following cardiac murmurs:

- Murmurs associated with other abnormal physical findings on cardiac examination
- Murmurs associated with an abnormal electrocardiogram or chest radiograph

Class III—There is evidence or general agreement (or both) that echocardiography is not useful in asymptomatic patients with the following murmurs:

- Grade 2 or softer midsystolic murmurs considered innocent or functional by an experienced observer

*These are indications for general evaluation but do not necessarily need to be performed preoperatively.

From Bonow, RO, Carabello, BA, Chatterjee, K, et al: ACC/AHA 2006 guidelines for the management of patients with valvular heart disease. A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the 1998 Guidelines for the Management of Patients with Valvular Heart Disease). J Am Coll Cardiol 48:e1, 2006.

Table 34-3 Descriptions of Murmurs Associated with Cardiac Abnormalities

Lesion	Location	Timing	Description
Aortic stenosis	Second parasternal interspaces	Midsystolic	Crescendo-decrescendo, radiates to the carotids; ± S_3, S_4; Valsalva and sustained handgrip exercise decrease intensity
Aortic insufficiency	Third and fourth parasternal interspaces	Holodiastolic	Decrescendo, blowing, high pitched, radiates to the carotids; Austin-Flint rumble at the apex; squatting, handgrip exercise, and leaning forward increase intensity
Mitral stenosis	Apex	Mid-diastolic	Opening snap; low-pitched rumble radiates to the axilla; squatting and handgrip exercise increase intensity
Mitral regurgitation	Apex	Holosystolic	High pitched, blowing, radiates to the axilla; loud S_3; standing decreases intensity; squatting and handgrip exercise increase intensity
Mitral valve prolapse	Apex	Late systolic	Crescendo, midsystolic click; Valsalva and standing increase intensity; squatting decreases intensity
Hypertrophic cardiomyopathy	Apex, lower left sternal border	Midsystolic	S_4, single S_2; Valsalva and standing increase intensity; squatting, passive leg raising, and handgrip exercise decrease intensity

Aortic Stenosis

Aortic stenosis, the most common valvular lesion in the United States, affects 2% to 4% of adults older than 65 years; severe stenosis is associated with high risk for perioperative complications.[7] Once considered a degenerative lesion associated with age or a congenital bicuspid valve, aortic stenosis is now thought to have much in common with ischemic heart disease and is an independent marker of CAD.[41] In patients with bicuspid valves, stenosis typically develops at a younger age (fourth and fifth decades of life); those with stenosis of the tricuspid valves are usually older than 60 years, but there is overlap.

Aortic *sclerosis*, which also causes a systolic ejection murmur similar to that of aortic stenosis, is present in 25% of people 65 to 74 years of age and in almost half of those older than 84 years.[41] Aortic sclerosis is associated with a 40% increase in risk for MI and a 50% increase in risk for cardiovascular death in patients without a history of CAD.[42] There is no hemodynamic compromise with aortic sclerosis.

The cardinal symptoms of severe aortic stenosis are angina, heart failure, and syncope, although patients are much more likely to complain of a decrease in exercise tolerance and exertional dyspnea. Aortic stenosis causes a systolic ejection murmur, best heard in the right upper sternal border and often radiating to the neck. There is delayed carotid upstroke and a paradoxically split S_2, and exercise will increase HR and decrease an aortic stenosis murmur. Patients with a previously undiagnosed murmur need an ECG, and an echocardiogram should be considered in patients with an abnormality on the ECG (see Box 34-4). Such abnormalities may consist of LVH, often with a strain pattern (ST-T wave changes), left axis deviation, or LBBB.

Aortic stenosis severity is based on the mean transvalvular pressure gradient and valve area (Table 34-4). The pressure gradient falls if the left ventricle begins to fail. Current guidelines recommend echocardiography annually for patients with severe aortic stenosis, every 2 years for moderate stenosis, and every 5 years for mild stenosis.[40] Patients with aortic stenosis are at risk for sudden death from arrhythmias, heart failure, and myocardial ischemia and infarction from concomitant CAD (high incidence) or a supply-demand mismatch. Patients with aortic sclerosis or stenosis need evaluation for CAD regardless of other risk factors. Those with severe or critical stenosis should not undergo noncardiac surgery (unless emergency and lifesaving) without a cardiology evaluation and careful consideration of risks or until valve replacement. Patients with moderate to severe aortic stenosis have an increased risk of bleeding (especially from gastrointestinal angiodysplasia). The cause appears to be an acquired von Willebrand syndrome resulting from mechanical disruption of von Willebrand multimers during turbulent blood flow through a narrowed valve. See the section "von Willebrand's Disease" for more details. An activated partial thromboplastin time (aPTT) is indicated. Prophylaxis for infective endocarditis in patients with aortic stenosis is no longer recommended.[43]

Table 34-4 Severity of Aortic Stenosis

Grade	Velocity of Aortic Jet (m/sec)	Mean Pressure Gradient (mm Hg)	Valve Area (cm^2)
Mild	<3	<25	≥1.5
Moderate	3-4	25-40	1.0-1.5
Severe	4-4.5	40-50	0.7-1.0
Critical	>4.5	>50	<0.7

Aortic Insufficiency

Insufficiency of the aortic valve occurs with true valvular disease affecting the leaflets, from aortic root dilation, or as a result of both. Rheumatic heart disease, a bicuspid valve, collagen vascular diseases, and endocarditis can all lead to valvular disease. Aortic root dilation can complicate ankylosing spondylitis, osteogenesis imperfecta, syphilis, hypertension, age-related degeneration, Marfan's syndrome, and collagen vascular diseases. Acute insufficiency with pulmonary edema and hypertension can occur with trauma, infection, or aortic dissection and is an emergency. The murmur of aortic insufficiency is described in Table 34-3. The intensity of the murmur does not correlate with the severity of regurgitation.[44] Patients typically have a widened pulse pressure (normal or elevated systolic BP and low diastolic BP) manifested as Corrigan's or water-hammer pulses (bounding carotid pulse with a rapid downstroke). de Musset's sign is a head bob with each heartbeat, Duroziez's sign is a systolic and diastolic bruit heard over the femoral artery when it is partially compressed, Quincke's pulses are capillary pulsations in the fingertips or lips, and Müller's sign is systolic pulsations of the uvula.

An ECG is needed and an echocardiogram should be considered if finding could change management (see Box 34-4); a chest radiograph may be useful. LVH with ST- and T-wave changes as a result of volume overload or underlying chronic ischemia may be present. Left atrial hypertrophy and left axis deviation along with premature atrial and ventricular contractions are not uncommon. Generally, chronic insufficiency is well tolerated in the perioperative period. Patients with good functional status and preserved left ventricular systolic function have a low risk of complications with anesthesia. Prophylaxis for infective endocarditis is no longer recommended.[43]

Mitral Stenosis

Mitral stenosis is much less common than aortic stenosis and is usually associated with a history of rheumatic heart disease. It can occur with aortic valvular disease or mitral regurgitation. A normal mitral valve has an area of 4 to 6 cm^2; stenosis is mild when the mitral valve area is 1.5 to 2.5 cm^2, moderate with an area of 1.1 to 1.5 cm^2, and critical when the area is 0.6 to 1.0 cm^2. A resting mean transvalvular gradient greater than 10 mm Hg also denotes severe stenosis. Symptoms typically occur 10 to 20 years after acute rheumatic fever and are often precipitated by pregnancy or illness. Unrecognized mitral stenosis is included in the differential diagnosis of pulmonary edema.

Preoperative evaluation includes determining whether the patient has a history of dyspnea, fatigue, orthopnea, pulmonary edema, and hemoptysis. These findings result from elevated left atrial pressure and decreased cardiac output. Atrial fibrillation can be due to a dilated left atrium, which can acutely precipitate failure and chronically cause thrombosis. Patients with atrial fibrillation require anticoagulation to avoid a left atrial thrombus. Tachycardia decreases cardiac output. Pulmonary hypertension and right heart failure may occur with significant stenosis. A loud S_2 suggests pulmonary hypertension. The characteristics of the murmur are described in Table 34-3. Sustained handgrip exercise increases HR and BP and may increase the murmur. Examination should look for rales and signs of right heart failure such as

jugular venous distention, peripheral edema, hepatomegaly, right ventricular heave, and ascites.

A preoperative ECG is necessary and an echocardiogram should be considered if it will change management (see Box 34-4). A chest radiograph should also be considered. β-Blockers are used to control HR, and antiarrhythmics prevent or control atrial fibrillation. These medications have to be continued preoperatively because HR needs to be controlled before surgery. Anticoagulation is managed in conjunction with the treating cardiologist and surgeon. Prophylaxis for infective endocarditis is no longer recommended.[43]

Mitral Regurgitation

Mitral regurgitation can be acute in the setting of ischemia or infarction or can be chronic and associated with mitral stenosis, mitral valve prolapse, collagen vascular diseases, or cardiomyopathies. The course is typically very gradual, and symptoms develop late and only after the development of left ventricular dysfunction. Preoperative symptoms are vague and often attributed to other causes. Fatigue, dyspnea, and atrial fibrillation can be present. Description of murmurs is presented in Table 34-3. A loud murmur associated with a thrill (grade ≥4) has a specificity of 91% for severe regurgitation but a sensitivity of 24%.[44] Severe regurgitation is rarely present with a grade 1 to 2 murmur; however, there is a wide range of severity with a grade 3 murmur. Chronic mitral regurgitation is generally well tolerated perioperatively unless other valvular lesions (e.g., mitral or aortic stenosis) or left ventricular dysfunction coexist. Prophylaxis for infective endocarditis is no longer recommended.[43]

Mitral Valve Prolapse

Also known as click-murmur or floppy valve syndrome, mitral valve prolapse is commonly diagnosed in young women during evaluation for atypical chest pain, palpitations, or syncope. Whether these symptoms are truly related is questionable. Interestingly, men older than 55 years with mitral valve prolapse are more likely to have regurgitation complications and are at greatest risk for infective endocarditis. The important issue preoperatively is to differentiate patients with clinically significant mitral valve degeneration and regurgitation from those with an incidental finding of prolapse or a click, which does not warrant further evaluation or change in management. Patients taking β-blockers for control of palpitations or atypical chest pain continue these medications perioperatively. Prophylaxis for infective endocarditis is no longer recommended.[43]

Tricuspid Regurgitation

Tricuspid regurgitation is a relatively common abnormality, but because it is usually asymptomatic and not audible on physical examination, it is most commonly noted by echocardiography performed for other reasons. A small degree of tricuspid regurgitation is present in approximately 70% of normal adults. Tricuspid regurgitation is most commonly caused by dilatation of the right ventricle and the tricuspid annulus. Right ventricular dilatation is caused by conditions that directly involve the right ventricle (ischemia, cardiomyopathy) or is due to pulmonary hypertension and elevated right ventricular systolic pressure. Tricuspid and mitral regurgitation often occurs together. Tricuspid regurgitation is less often due to processes that directly affect the tricuspid valve, such as Ebstein's anomaly (a congenital malformation), infective endocarditis, rheumatic fever, carcinoid syndrome, connective tissue disorders (Marfan's syndrome), myxomatous degeneration or prolapse (occurs in as many as 40% of patients with mitral valve prolapse), or injury from a pacemaker, central line, or implantable cardioverter-defibrillator (ICD) lead. Drugs such as the anorectics fenfluramine and phentermine and the dopamine agonist pergolide may cause tricuspid regurgitation by a mechanism similar to that seen with carcinoid syndrome. The aforementioned drugs are no longer available in the United States.

Tricuspid regurgitation is classically associated with a holosystolic murmur that is best heard at the right or left midsternal border or at the subxiphoid area. When the right ventricle is very enlarged, the murmur may even be appreciated at the apex. There is usually little radiation of the murmur, and a thrill is not palpable. However, the murmur of tricuspid insufficiency is often soft or absent, even when regurgitation is severe. Interventions that result in an increase in venous return (leg raising, exercise, hepatic compression) will augment the murmur of tricuspid regurgitation. The murmur may also become louder after a premature beat and prolonged diastole. In contrast, reducing venous return (by standing or with amyl nitrate) will diminish the intensity of the murmur. In patients with pulmonary hypertension, the intensity of the murmur may change with alterations in pulmonary artery pressure and therefore the right ventricle. Patients with (or suspected of having) pulmonary hypertension need to be managed in conjunction with a pulmonary hypertension specialist (see the section "Pulmonary Hypertension"). Prophylaxis for infective endocarditis is no longer recommended.[43] An echocardiogram should be considered if it will change management.

Hypertrophic Cardiomyopathy

Previously known as hypertrophic obstructive cardiomyopathy and before that as idiopathic hypertrophic subaortic stenosis, HCM can be familial. Patients with hypertrophic obstructive cardiomyopathy are often young and male and may be asymptomatic without murmurs. An ECG and echocardiogram should be considered if there is a personal or family history of syncope with exertion or sudden death or when a murmur consistent with this disorder is detected. Characteristics of the murmur are described in Table 34-3. A maneuver that decreases diastolic volume or increases contractility increases the intensity of the murmur. Passive leg raising and squatting decrease the intensity, and a Valsalva maneuver increases it. In an otherwise healthy nonhypertensive patient with LVH and ST-segment and T-wave abnormalities on an ECG, an echocardiogram should be considered.

Patients are at risk for sudden cardiac death probably from arrhythmias (see Box 34-4). Holter monitoring may be useful in some patients. Many patients are treated with β-blockers to decrease contractility; these medications are continued perioperatively. ICDs may be in place to prevent sudden death; see discussion in the appropriate section of this chapter. Prophylaxis for infective endocarditis is no longer recommended.[43]

Prosthetic Heart Valves

In patients with prosthetic valves, the most important issues preoperatively are determination of the underlying condition requiring replacement, the type of prosthesis, the need for anticoagulation, and the planned management of such patients in the perioperative period. Occasionally, patients will have valve-related hemolysis. The risk for thrombosis is greatest with multiple prosthetic

valves, followed by valves in the mitral position and then aortic valve replacements. Caged-ball valves (Starr-Edwards) have the highest risk, single tilting-disk valves (Björk-Shiley, Medtronic-Hall, Omnicarbon) have an intermediate risk, and the lowest risk is seen with bileaflet tilting-disk prostheses (St. Jude, CarboMedics, Edwards Duromedics). Bioprosthetic valves such as Carpentier-Edwards (porcine heterograft or pericardial) or Hancock (porcine) brands generally do not require long-term anticoagulation. The decision to stop anticoagulants, the duration off anticoagulants, and the need to "bridge" with a shorter-acting drug and the type of bridging agent (intravenous heparin or low-molecular-weight heparin [LMWH]) need to be made in conjunction with the treating cardiologist and surgeon. See the section on anticoagulation for a discussion of bridging.

Rhythm Disturbances and Electrocardiographic Abnormalities

Arrhythmias and conduction disturbances are common in the perioperative period (see also Chapter 42). Supraventricular and ventricular arrhythmias are associated with a greater risk of perioperative adverse events because of the arrhythmia itself and because they are markers for cardiopulmonary disease. Uncontrolled atrial fibrillation and ventricular tachycardia are high-risk clinical predictors, and elective surgery should be postponed until evaluation and stabilization are complete.[7] New-onset atrial fibrillation, symptomatic bradycardia, or high-grade heart block (second or third degree) identified in the preoperative clinic warrant consideration of postponement of elective procedurest and referral to cardiology for further evaluation. First-degree AV block is defined as a PR interval longer than 0.20 msec with an HR of 50 to 100 beats/min and is generally benign. Second-degree heart block occurs when the PR interval is prolonged greater than 0.20 msec, and eventually the atrial beat is blocked, which results in a dropped or missing QRS complex after a P wave. Two types of second-degree block exist. A Mobitz type I or Wenckebach block is more benign, rarely progresses to complete heart block, and responds to atropine. It is characterized by a progressive lengthening of the PR interval until the dropped beat occurs and is usually due to AV nodal delay. Mobitz type II results from an infranodal block, can progress to complete heart block, and is generally treated with a pacemaker unless secondary to a reversible cause such as ischemia or drugs. It is characterized by a fixed, prolonged PR interval that does not change before the dropped QRS complex. Third-degree or complete heart block is complete dissociation between the atrial and ventricular beats (P waves and QRS complexes) and requires a pacemaker unless a reversible source is identified. The ventricular beats in a patient with complete heart block are independent of the atria and should not be depressed. Two general factors are considered when determining the need for a pacemaker: an arrhythmia associated with symptoms and the location of the conduction abnormality. Syncope or near syncope associated with bradycardia or conduction delays is generally an indication for placement of a pacemaker. Disease below the AV node, in the His-Purkinje system, is more ominous and is suggested by a normal or minimally prolonged PR interval, a Mobitz type II block, and QRS abnormalities (bundle branch block, fascicular block, or both). Because disease in the His-Purkinje system is generally less stable, permanent pacemaker placement is likely to be beneficial. The indications for a pacemaker perioperatively are the same as those in nonsurgical patients (Box 34-5).[45]

Box 34-5 Indications for a Pacemaker

Class I Indications

- Sinus bradycardia with symptoms clearly related to the bradycardia (usually with a heart rate <40 beats/min or frequent sinus pauses)
- Symptomatic chronotropic incompetence
- Complete (third-degree) AV block*
- Advanced second-degree AV block (block of ≥2 consecutive P waves)
- Symptomatic Mobitz I or II second-degree AV block
- Mobitz II second-degree AV block with a widened QRS or chronic bifascicular block, regardless of symptoms

Class II Indications

- Sinus bradycardia (heart rate <40 beats/min) with symptoms suggestive of bradycardia but without a clear association between bradycardia and symptoms
- Sinus node dysfunction with unexplained syncope
- Chronic heart rates <30 beats/min in an awake patient

Class I conditions are those in which permanent pacing is definitely beneficial and effective, provided that the condition is not due to a transient cause. Class II conditions are those in which permanent pacing may be indicated but there is conflicting evidence or divergence of opinion (or both).

*Controversy exists concerning complete atrioventricular (AV) block without symptoms. The current ACC/AHA guidelines classify asymptomatic third-degree AV block with average awake ventricular rates of 40 beats/min or greater as a class IIa indication, although others recommend definite pacemaker placement.

From Gregoratos, G, Abrams, J, Epstein, AE, et al: ACC/AHA/NASPE 2002 guideline update for implantation of cardiac pacemakers and antiarrhythmia devices: Summary article. A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (ACC/AHA/NASPE Committee to Update the 1998 Pacemaker Guidelines). Circulation 106:2145-2161, 2002.

Bundle branch blocks are complete or incomplete and either right (RBBB) or left (LBBB). They result from aging or fibrosis of the conducting system, ischemia, pulmonary disease, radiation, or cardiomyopathies or can be normal variants. Traditionally, LBBB has been considered more ominous and has been shown to be associated with CAD and heart failure.[46,47] LBBB is strongly associated with CAD, and in a patient with a recent onset or no previous evaluation of LBBB, stress testing or cardiology consultation may be warranted. Obtaining a previous ECG for comparison can establish the stability. RBBB is likely to be congenital, a result of calcification and degeneration of the conduction system or secondary to pulmonary disease. Brugada's syndrome is a congenital disease characterized by RBBB with ST-segment elevation in the right precordial leads and is associated with a risk for sudden death and lethal arrhythmias. If the history and physical examination do not suggest significant pulmonary, congenital, or ischemic heart disease or Brugada's syndrome, no further evaluation is warranted because of an isolated RBBB. An RBBB in a patient with pulmonary symptoms (including pulmonary hypertension) may be suggestive of severe respiratory or vascular compromise and may warrant pulmonary evaluation and echocardiography if intermediate- or high-risk surgery is planned. If congenital heart disease, pulmonary hypertension (see the appropriate section in this chapter), or Brugada's

syndrome is suspected, cardiology consultation is indicated. LVH and ST-segment depression on a preoperative ECG are associated with a greater risk for MI and cardiac death perioperatively.[48] LVH may be associated with diastolic dysfunction and poorly controlled hypertension. Prolonged QT intervals should prompt an evaluation of electrolytes, magnesium, and calcium and a search for potentiating drugs. In a patient with a prolonged QT interval and syncope, near syncope, or a family history of sudden death, further evaluation should be considered.

Atrial Fibrillation

Atrial fibrillation occurs in elderly patients and those with thyrotoxicosis, valvular disease, and ischemic heart disease. It can be intermittent (paroxysmal), persistent (able to be cardioverted), or permanent (unable to be converted). Evidence suggests that rate control is more important than rhythm control. Patients with rapid ventricular rates (>100 beats/min) require control before elective surgery.[7] Patients with slow ventricular rates not caused by rate-controlling medications are at risk for sick sinus syndrome, need a careful history to uncover syncopal or near-syncopal episodes, and may need a Holter monitor. Most patients with atrial fibrillation will require long-term anticoagulation, which becomes an issue in the perioperative period. If they are being treated with only prophylactic therapy (no history of emboli or left atrial thrombi), bridging perioperatively is not cost-effective. Patients with atrial or ventricular thrombi or a previous history of thromboembolic events are at higher risk, and anticoagulant therapy is managed on a case-by-case basis in concert with the treating physician. β-Blockers, digoxin, and calcium channel blockers taken chronically to control rate or rhythm need to be continued perioperatively.

Supraventricular Arrhythmias

Supraventricular tachycardias result from rapidly firing ectopic atrial foci with rapid conduction via the AV node or from a reentry mechanism via accessory pathways. With a reentry mechanism the cycle self-perpetuates because conduction occurs down one pathway and up the other, with both the AV node–Purkinje system and the accessory pathway or pathways being involved. Various degrees of AV block may slow the ventricular rate. Wolff-Parkinson-White (WPW) syndrome is a classic supraventricular tachycardia with an accessory pathway but unique in that impulses can travel both retrograde and antegrade. Antegrade conduction over the accessory pathway results in a short PR interval (<0.12 msec) and slurring of the upstroke of the QRS, termed a delta wave. AV nodal–blocking drugs such as β-blockers, calcium channel blockers, and digoxin can paradoxically increase conduction over the accessory pathway and cause ventricular fibrillation. Lidocaine and procainamide are the preferred drugs to slow the tachycardia in patients with WPW syndrome. Certain patients may require ablation for long-term management of WPW syndrome, and this should be performed before elective surgery.

Ventricular Arrhythmias

Ventricular ectopics can be differentiated from atrial ectopics by a widen QRS (>0.12 msec) and lack of a P wave. The traditional grading system of Lown, organized by morphology (unifocal or multifocal), frequency (less than or greater than 30 beats/min), and other characteristics (couplets, R on T phenomenon), is limited in its ability to stratify risk. Classifying ventricular arrhythmias according to the type of rhythm disturbance and the presence of coexisting heart disease better predicts the risk for sudden death.

- Benign: isolated ventricular premature beats (VPBs) without heart disease
  - No need for further evaluation
  - No risk of sudden cardiac arrest
- Potentially lethal: greater than 30 VPBs/hr or nonsustained ventricular tachycardia with underlying heart disease
  - Requires cardiology evaluation with possible echocardiography, stress testing, catheterization, or electrophysiologic testing
  - Moderately high risk of sudden cardiac arrest; may benefit from an ICD
- Lethal: sustained ventricular tachycardia, ventricular fibrillation), syncope, or hemodynamic compromise associated with VPBs with underlying heart disease and often depressed cardiac function
  - Requires cardiology evaluation with possible stress testing, echocardiography, catheterization, or electrophysiologic testing
  - High risk of sudden cardiac arrest; likely to benefit from an ICD

Preoperative evaluation focuses on reversible causes such as hypokalemia, ischemia, acidosis, hypomagnesemia, drug toxicity, and endocrine dysfunction, which should be further evaluated and treated. Patients taking amiodarone are at risk for hypothyroidism and require thyroid function tests before surgery. Antiarrythmics should be continued perioperatively.

Cardiac Rhythm Management Devices: Pacemakers and Implantable Cardioverter-Defibrillators

More than 100,000 new cardiac rhythm management devices are implanted yearly in the United States. A complete discussion of the perioperative management of these devices can be found in Chapter 43.

Peripheral Vascular Disease

Also called peripheral arterial disease, PVD refers to aneurysmal or occlusive arterial disease of the extremities, visceral organs, head, neck, and brain. Many of these patients have disease secondary to tobacco abuse, diabetes, hyperlipidemia and hypertension, or combinations of these causes. Patients with Marfan's or Ehlers-Danlos syndrome may have aneurysmal disease without other risk factors. Renal insufficiency and cerebrovascular disease are frequent in this cohort of patients. Up to 75% of patients with PVD have CAD. In a study of 1000 consecutive patients scheduled for major vascular surgery, almost 60% had critical stenosis in at least one major coronary vessel. In addition, undiagnosed PVD (e.g., patients who smoke, are of increased age, have diabetes, or have cerebrovascular disease) should be considered when assessing patients scheduled for major surgery. Because claudication often limits functional capacity, symptoms of ischemic heart disease are often not apparent.

Determination of BP in both upper extremities and the presence or absence of peripheral pulses is important. Listening for bruits over the abdomen and femoral arteries or palpating for abdominal masses is part of the vascular examination but is rarely necessary preoperatively. BUN and creatinine should be determined before procedures involving injection of radiocontrast dye

(see the section "Contrast-Induced Nephropathy" for management to reduce risk). Many patients take aspirin or dipyridamole, a vasodilator with some antiplatelet effects that are reversible on discontinuation; its elimination half-life is approximately 10 hours. Therefore, stopping this drug 48 hours before surgery eliminates the antiplatelet effect. However, because dypyridamole is often combined with aspirin (Aggrenox), this drug must be stopped 5 to 7 days before surgery if complete reversal of its antiplatelet effects is desired, although the risks related to stopping antiplatelet medications must also be considered.

Pulmonary Disorders (See Chapter 59)

Asthma

Asthma is a chronic inflammatory disease characterized by obstruction of the airways that is partially or completely reversible with treatment or spontaneously.[49] Bronchoconstriction is precipitated by irritants (smoke), allergens, infections, medications, or instrumentation of the larynx, trachea, or bronchi. Asthma is classified as intermittent (mild) or persistent (mild, moderate, or severe) based on how frequently symptoms occur and whether they are sporadic or constant. Patients with mild, well-controlled asthma have no greater risk associated with anesthesia and surgery than normal individuals do.

Reporting of asthma should prompt further questioning about shortness of breath, chest tightness, coughing (especially nocturnal), recent exacerbations, therapy (especially the use of steroids, particularly within the previous year) or oxygen use, hospitalizations, and intubations. The patient's best exercise level is important information for assessment of risk. A history of previous exacerbations with anesthesia should be elicited. Patients with asthma are quite good at estimating their current status and breathing capacity when asked about what percentage they are presently at (100% being normal). Adequate and appropriate medical therapy must be determined. The quality of breath sounds, quantity of air movement, and degree of wheezing are important. The degree of wheezing does not always correlate with the severity of bronchoconstriction. With severe obstruction, airflow is dangerously restricted and wheezing diminishes. Observing the degree of accessory muscle use often gauges the severity of the bronchoconstriction. Determination of oxygen saturation by pulse oximetry is useful. Arterial blood gas analysis is not generally necessary unless the patient is having a severe acute exacerbation. Patients taking oral steroids need blood glucose checked and may require perioperative steroid supplementation.

Wheezing is a common symptom in asthmatics but is not specific for this disease. Patients with chronic obstructive pulmonary disease (COPD), gastroesophageal reflux disease, vocal cord dysfunction, tracheal or bronchial stenosis, cystic fibrosis, allergic bronchopulmonary aspergillosis, and heart failure may wheeze. Spirometry is the preferred diagnostic test, but a normal result does not exclude asthma. A methacholine challenge test or a trial of bronchodilator therapy is indicated if spirometry is normal but there is still a strong suspicion of asthma. PFTs have no perioperative predictive value but in rare instances may be useful to gauge the severity of disease or the adequacy of therapy. Typical findings on PFTs are reduced forced expiratory volume in 1 second (FEV_1) and normal to increased functional residual capacity (FVC).

A preoperative chest radiograph is necessary only for evaluation of infections or pneumothorax. Bronchodilators, inhaled and oral steroids, and antibiotics (if taken) need to be continued on the day of surgery. β-Agonists are the most useful prophylactic intervention to lower the risk for bronchospasm on induction of anesthesia. A short course of steroids (20 to 60 mg of prednisone daily for 3 to 5 days) preoperatively may be useful in any patient who is not at baseline and surgery must proceed.

Chronic Obstructive Pulmonary Disease

COPD includes chronic bronchitis and emphysema and is characterized by obstruction to airflow that is not fully reversible. It is often due to exposure to pollutants such as cigarette smoke or substances in the environment (air pollution, allergens, grain, dust, and coal), α_1-antitrypsin deficiency, chronic infections, and long-standing asthma. Chronic bronchitis is the presence of symptoms on most days for at least 3 months for 2 successive years or recurrent excessive sputum that severely impairs expiratory airflow. Dyspnea, coughing, wheezing, and sputum production are common features. An acute exacerbation is defined as an increase in symptoms that requires a change in management.

The preoperative history and physical examination for patients with COPD are similar to that for patients with asthma, but with additional emphasis on the change in amount of sputum, color, or other signs of infection. A barrel chest and pursed-lip breathing suggest advanced disease. Typically, FEV_1 is reduced because of obstructed airflow, but FVC is increased because of reduced airflow, loss of elasticity, and overexpansion. Diffusing capacity (D_{LCO}) is typically decreased, and its severity often correlates with the degree of hypoxia and hypercapnia, which in turn can predict the presence of pulmonary hypertension. However, PFTs have not been shown to predict perioperative outcome. Determination of oxygen saturation by pulse oximetry is appropriate to establish a baseline. Patients found to be hypoxic or using oxygen may benefit from further testing, including arterial blood gas determination. A chest radiograph is useful only when infection is suspected. An ECG may demonstrate right axis deviation, RBBB, or peaked P waves, which suggest pulmonary hypertension and possibly right ventricular changes in response to the chronic lung disease (see the section "Pulmonary Hypertension").

Restrictive Pulmonary Disorders

Restrictive lung disease is distinguished by a reduction in total lung capacity. Both pulmonary and extrapulmonary conditions cause restrictive disease. Pulmonary conditions include idiopathic interstitial pneumonia, interstitial lung disease related to connective tissue disease, lung resection, and pulmonary fibrosis. Extrapulmonary disorders are caused by chest wall limitations (kyphoscoliosis, obesity, ankylosing spondylitis), muscle dysfunction (muscular dystrophies, myasthenia gravis, paralyzed diaphragm), or pleural disease (mesothelioma, effusion, pneumothorax).

The preoperative medical history of associated diseases or symptoms prompts the directed evaluation. A chest radiograph and PFTs may be indicated to establish a diagnosis or evaluate acute or progressive worsening but are not routinely necessary preoperatively. FEV_1 and FVC are reduced proportionally, so the ratio is normal. These patients are at risk for pulmonary hypertension, which may not be diagnosed or communicated to caregivers because of overlapping symptoms with restrictive lung disease. See the section "Pulmonary Hypertension" for more details.

Dyspnea

Dyspnea is a subjective experience of breathing discomfort. It is a symptom of deconditioning, obesity, and disorders of ventilation, cardiac function, perfusion, and oxygen delivery. Dyspnea is associated with cardiac, pulmonary, hematologic, and neuromuscular diseases.

Patients with an insidious onset may not seek attention until quite late, and frequently they and their caregivers assume that the dyspnea is due to being "out of shape," although this should be a diagnosis of exclusion. The majority of patients with chronic dyspnea of unclear etiology have one of four diagnoses: asthma, COPD, interstitial lung disease, or cardiac dysfunction.

The important facts to determine are the onset, progression, precipitating factors, type and level of provocative activity, associated symptoms (chest pain, leg edema, syncope or near syncope, fatigue), other conditions (arthritis, connective tissue disease, cardiac disease, smoking), and drug or toxin exposure. Asking about the quality of dyspnea can differentiate causes. Dyspnea secondary to deconditioning is usually described as "heavy breathing," and one can often determine that the patient is actually describing fatigue more than true dyspnea. The bronchoconstriction in exacerbations of asthma is more commonly described as "tightness" or "air hunger," whereas patients with COPD complain of "not being able to take a deep breath" or "an increased effort to breathe." Patients with heart failure feel as though they are "suffocating" or have "air hunger."[33] Orthopnea (dyspnea while recumbent) suggests heart failure or sleep apnea. Coughing can be a symptom of heart failure, asthma, or COPD. Angina or a history of CAD may indicate heart failure. Anorexic drugs can cause pulmonary hypertension or valvular abnormalities. Connective tissue disease is associated with interstitial lung disease. On physical examination one should look for pallor, cyanosis, a "barrel" chest, rales, wheezing, crackles, murmurs, abnormal heart sounds or rhythms, an enlarged heart, tachycardia, jugular venous distention, joint involvement, clubbing, fibrotic skin changes, and edema. Patients with severe airflow obstruction may have pursed lips and a slow deep breathing pattern, and those with interstitial fibrosis or kyphoscoliosis typically have rapid shallow breathing.

The preoperative history and physical examination lead to accurate diagnoses in two thirds of cases. Initial testing may include an ECG, hematocrit (to exclude anemia), arterial blood gas analysis, thyroid function tests, a chest radiograph, spirometry, and oximetry at rest and while walking several feet. BNP levels may be useful. Most dyspnea patients with heart failure have BNP values higher than 400 pg/mL, whereas left ventricular dysfunction without exacerbation, pulmonary embolism, and cor pulmonale should be considered in dyspnea patients with plasma BNP concentrations between 100 and 400 pg/mL. Other testing depends on findings on these tests and is directed by the history and physical examination. Computed tomography scans and cardiopulmonary exercise testing are rarely necessary but can be useful if the aforementioned tests are not diagnostic.

Patients with Risk Factors for Postoperative Pulmonary Complications

Postoperative pulmonary complications develop in 5% to 10% of patients undergoing nonthoracic surgery and in 22% of high-risk patients. As many as one in four deaths occurring within a week of surgery are related to pulmonary complications, thus making it the second most common serious morbidity after cardiovascular adverse events.[50,51]

Established risk factors for an increased risk for pulmonary complications include the following[52]:

- History of cigarette use (current or >40 pack-years)
- ASA-PS scores higher than 2
- Age >70 years
- COPD
- Neck, thoracic, upper abdominal, aortic, or neurologic surgery
- Anticipated prolonged procedures (>2 hours)
- Planned general anesthesia (especially with endotracheal intubation)
- Albumin less than 3 g/dL
- Exercise capacity of less than two blocks or one flight of stairs
- BMI greater than 30

Surprisingly absent predictors in this list are asthma and results from arterial blood gas analysis or PFTs. The risk for complications is surprisingly low in patients with well-controlled asthma or those treated preoperatively with corticosteroids.[53] The risk is greater in asthmatics with recent exacerbations or a history of postoperative pulmonary complications or recent hospitalization or intubation for asthma. Arterial blood gas analysis is useful in predicting pulmonary function after lung resection surgery but does not predict risk for complications. The degree of airway obstruction, measured by FEV_1, is not predictive of pulmonary complications.[54] PFTs, arterial blood gas analysis, or chest radiographs should not be used routinely to predict the risk for postoperative pulmonary complications. PFTs may be indicated to diagnose disease (dyspnea caused by lung disease or heart failure?) or to assess management (can dyspnea or wheezing be improved further?) but should *not* be used as a risk assessment tool or to deny a beneficial procedure.[54]

Laboratory results and patient- and procedure-related determinants of risk for perioperative pulmonary complications have recently been reviewed in the literature.[55] Some of these factors can be modified to alter risk. The pulmonary status of patients with recent exacerbations or infections should be improved whenever possible. Prescriptions for antibiotics, bronchodilators, and steroids, referral to pulmonologists or internists, and postponing surgery are important in patients at high risk. Training patients preoperatively in lung expansion maneuvers, such as deep-breathing exercises and incentive spirometry, reduces pulmonary complications more than training postoperatively does. Additionally, a change in perioperative management, including altering the planned surgical procedure if possible, discussing alternatives to general anesthesia, especially when peripheral nerve blocks are an option, and educating the patient about the benefits of epidural pain management, may provide effective measures to decrease pulmonary complications.[56]

Patients Scheduled for Lung Resection

Most patients scheduled for lung resection surgery have underlying lung disease, and PFTs may be useful in predicting risk or excluding patients who may not have adequate pulmonary reserve after resection. This topic is covered more fully in Chapter 59.

Pulmonary Hypertension

Pulmonary hypertension may occur in isolation or with associated medical conditions and is classified into five groups (Box 34-6) according to the World Health Organization. Idiopathic

Box 34-6 Classification of Pulmonary Hypertension

Pulmonary Arterial Hypertension
Primary pulmonary hypertension
- Sporadic
- Familial

Associated with
- Collagen vascular disease
- Congenital shunts
- Portal hypertension
- Human immunodeficiency virus infection
- Drugs/toxins
- Persistent pulmonary hypertension of the newborn

Pulmonary Venous Hypertension
Left-sided heart disease

Extrinsic compression of central pulmonary veins

Pulmonary veno-occlusive disease

Pulmonary Hypertension Related to Lung Disease or Hypoxemia
Chronic obstructive pulmonary disease

Interstitial lung disease

Sleep-disordered breathing

Neonatal lung disease

Chronic exposure to high altitude

Pulmonary Hypertension Caused by Chronic Thromboembolic Disease
Pulmonary thrombosis or embolism

Sickle cell disease

Pulmonary Hypertension from Disorders Directly Affecting the Pulmonary Vasculature
Schistosomiasis

Sarcoidosis

Available from http://www.who.int/ncd/cvd/pph.html.

pulmonary arterial hypertension, formerly called primary pulmonary hypertension, is rare, but other forms are more common and occur with a variety of diseases, including cardiac, pulmonary, liver, thromboembolic, and collagen vascular disease. Pulmonary hypertension is associated with HIV infection, exposure to anorexics such as fenfluramine, chronic liver disease, especially if portal hypertension is present, and collagen vascular diseases, including scleroderma, SLE, and rheumatoid arthritis. Pulmonary hypertension is defined as a persistent elevation in mean pulmonary artery pressure greater than 25 mm Hg with a pulmonary artery occlusion pressure of less than 15 mm Hg. Occult pulmonary hypertension is more problematic than fully recognized disease because symptoms may be attributed to other diseases and perioperative decompensation may occur unexpectedly.

The manifestation of pulmonary hypertension is usually nonspecific, insidious, and associated with delayed diagnosis. Dyspnea is the initial symptom in 60% of patients but is present in 98% by the time of diagnosis. Dyspnea is nonspecific and associated with a multitude of conditions (see the section "Dyspnea"). Near syncope or syncopal episodes suggest severe disease. Hypoxia, hypercapnia, vasoconstrictors, and increased sympathetic tone (even from anxiety) increase pulmonary vascular resistance and lead to acute decompensation with right heart failure.

Patients with pulmonary arterial hypertension have a high rate of perioperative morbidity and mortality.[57] Mild pulmonary hypertension rarely affects anesthetic management, but moderate to severe disease increases the risk for right heart failure. Signs and symptoms of disease severity include[58]

- Dyspnea at rest
- Metabolic acidosis
- Hypoxemia
- Right heart failure (peripheral edema, hepatomegaly, jugular venous distention)
- History of syncope

Physical examination may reveal a split S_2 with a loud second component, right ventricular heave, a murmur of tricuspid regurgitation, ascites, hepatomegaly, jugular venous distention, and peripheral edema.

An echocardiogram is the screening test of choice and can used to estimate pulmonary artery pressure, assess right ventricular function, and identify left heart failure and valvular or congenital heart disease.[59] Patients with significant findings may require right and left heart catheterization, although the need for catheterization preoperatively depends on the surgical procedure. An ECG, chest radiograph, and echocardiogram are useful in patients with more than mild disease. Findings on the ECG include right axis deviation, RBBB, right ventricular hypertrophy, and tall R waves in leads V_1 and V_2. Right atrial hypertrophy and "P pulmonale" may be present in severe pulmonary hypertension, with peaked P waves most apparent in leads II, III, aVF, and V_1. Enlargement of the main pulmonary artery and a globular heart shape with loss of the retrosternal air space as a result of right ventricular dilation can be seen on the chest radiograph. Evaluators should inquire about a history of OSA, which can also be the cause of pulmonary hypertension.[60] A CBC with platelets, electrolytes, BUN, creatinine, and liver function tests (LFTs; may be elevated as a result of congestion or the use of bosentan) are needed.

Preoperatively, patients may be treated with diuretics, anticoagulants, calcium channel blockers, supplemental oxygen, sildenafil (a phosphodiesterase inhibitor), endothelin receptor antagonists (bosentan), and prostanoids (iloprost, epoprostenol). Some of these agents are given by continuous intravenous infusion, and even momentary interruption of therapy can be catastrophic. All drugs need to be continued preoperatively. Management of these patients in conjunction with a pulmonary hypertension specialist is advised.

Smokers and Those Exposed to Second-Hand Smoke

Exposure to tobacco, directly or through "second-hand" smoke, increases the risk for many perioperative complications. Smokers are more likely to experience wound infections, respiratory or airway complications (including oxygen desaturation), and severe coughing.[61] Smoking decreases macrophage function, negatively affects coronary flow reserve, and causes vascular endothelial dysfunction, hypertension, and ischemia. Smokers require longer hospital stays than nonsmokers do and often need postoperative intensive care admission.

The greatest benefit of smoking abstinence is probably realized only after several months of cessation. In studies reporting greater perioperative risk in recent quitters than in smokers, selection bias may have contributed to the results. Patients who were motivated to stop or advised to quit smoking may have been at greater risk because of health status. Soon after a patient quits smoking, carbon monoxide levels decrease, which improves oxygen delivery and utilization. Cyanide levels decrease, which benefits mitochondrial oxidative metabolism. Lower nicotine levels improve vasodilation, and many toxic substances that impair wound healing decrease. Patients without a history of ischemic heart disease who smoked shortly before surgery had significantly more episodes of rate-pressure product–related ST-segment depression than did nonsmokers, former smokers, or chronic smokers who did not smoke in the immediate preoperative period.[62]

A preoperative smoking cessation intervention in patients who underwent knee and hip replacement decreased rates of surgical site infection (SSI) from 23% in the conventional group to 4% in those who stopped smoking. The U.S. Public Health Service recommends that "*all* physicians should strongly advise every patient who smokes to quit because evidence shows that physician advice to quit smoking increases abstinence rates."[63] Nearly 70% of smokers want to quit.

Effective interventions include medical advice and pharmacotherapy, such as nicotine replacement therapy, which is safe in the perioperative period (see Chapter 35). Nicotine patches, gum, and lozenges are available without a prescription; nasal spray and buproprion (Wellbutrin) require prescriptions. Clonidine is also effective. Buproprion or clonidine should be started 1 to 2 weeks before an attempt at quitting; nicotine replacement therapy is effective immediately.[64] Individual and group counseling may increase rates of long-term abstinence. Many hospitals, insurance companies, and communities offer smoking cessation programs. Excellent resources are available on the Internet and from the U.S. government. Advice and guidelines are available at http://www.surgeongeneral.gov/tobacco/default.htm. Tobacco intervention training during medical school and residency can significantly improve the quality of physician counseling and rates of abstinence.

Endocrine Disorders (See also Chapter 35)

Diabetes Mellitus

Type 1 diabetes is an autoimmune disease that results in destruction of pancreatic insulin-producing (beta) cells; patients have an absolute deficiency of insulin but normal sensitivity to insulin, are at risk for ketoacidosis, and generally have an onset of disease at a younger age. Because of the often-difficult nature of control and the long duration of disease, by the time that these individuals reach adulthood, they are at increased risk for premature vascular disease, especially myocardial ischemia, even in the second decade of life. Type 2 diabetes is initially a result of insulin resistance, which with time can result in pancreatic "burnout," and is usually found in older, overweight adults. Using terms such as insulin dependent, non–insulin dependent, or adult onset is confusing and not recommended.

In the United States, approximately 20 million persons have diabetes, with 1 million new cases diagnosed each year. In as many as a third of patients, the disease is diagnosed only after significant diabetes-related complications develop. Unfortunately, the symptoms of diabetes are nonspecific, so the history, other than a family history of the disease, is not reliable in screening for the disease. However, patients who are overweight, have excessive abdominal fat (even if their BMI is normal), take steroids, or have polycystic ovarian syndrome are at increased risk. Certain ethnic groups (Native American, non-Hispanic black, Hispanic, and Asian American) have a higher incidence. Diabetes develops in females twice as commonly as in males.

Diabetics are at risk for multiorgan dysfunction, with renal insufficiency, stroke, peripheral neuropathy, autonomic dysfunction, and cardiovascular disease being most prevalent. Delayed gastric emptying, retinopathy, and reduced joint mobility occur in these patients. Diabetes is considered a CAD equivalent and an intermediate risk factor for perioperative cardiac complications, on a par with angina or a previous MI.[7] Diabetic patients without known coronary stenosis or angina have the same risk of myocardial ischemia or cardiac death as a nondiabetic with a previous MI.[65] Autonomic neuropathy is the best predictor of silent ischemia. Erectile dysfunction has been shown to be a strong predictor as well. Poorly controlled blood glucose and longer duration of disease also correlate with cardiac risk. See the section "Ischemic Heart Disease" and Figure 34-2 for further guidance on this topic.

Heart failure is twice as common in men and five times as common in women with diabetes as in those without diabetes. Poor glycemic control is associated with an increased risk for heart failure, and both systolic and diastolic dysfunction may be present. Diabetics are at increased risk for renal failure perioperatively and for postoperative infections. Recent studies suggest that tighter perioperative control may be warranted. Patients with poor preoperative management of glucose are likely to be more out of control intraoperatively and postoperatively. Aggressive management of hyperglycemia decreases postoperative complications.

Chronic kidney disease is usually asymptomatic until quite advanced. Diabetes is responsible for almost half of the patients requiring dialysis in the United States. The combination of hypertension, diabetes, and age older than 55 years accounts for more than 90% of patients with renal insufficiency. "Screening" for kidney disease is accepted practice in patients with diabetes. Patients with poorly controlled diabetes are at risk for the development of stiff joint syndrome with reduced cervical mobility, which may influence airway management.

The preoperative evaluation should focus on assessing organ damage and control of blood sugar. Cardiovascular, renal, and neurologic systems need close evaluation. Ischemic heart disease is often asymptomatic in diabetics. Inquiring about early satiety, erectile dysfunction, numbness in the hands and feet, and postprandial vomiting is important. Documenting pulses, skin breakdown, a sensory examination, and orthostatic vital signs (BP and HR both lying and standing) are important in most diabetics, especially those with long-standing disease or poor control. Patients with autonomic dysfunction or hypovolemia will have greater than a 20–mm Hg drop in systolic or greater than a 10–mm Hg decrease in diastolic BP pressure when assuming an upright position from recumbency.

A preoperative ECG plus determination of electrolytes, BUN, creatinine, and blood glucose is recommended for all diabetic patients. Frequently, patients are not fasting when evaluated in a preoperative clinic, and relying on reported glucose values is

problematic. If patients bring a diary of multiple glucose values at varying times of the day (preprandial and postprandial), one can estimate the adequacy of therapy. However, patients often will only randomly check AM fasting blood glucose, which is likely to be lower because of an overnight fast than glucose values obtained later in the day. The glycosolated hemoglobin (HbA_{1c}) level is not influenced by fasting and, if available, can identify those with poor control. The American Diabetes Association recommends a target HbA_{1c} of less than 7%. Suggestions for hypoglycemic medication management on the day of surgery are discussed in Chapter 35. The goals of perioperative diabetic management include avoidance of hypoglycemia and marked hyperglycemia. The American College of Endocrinologists position statement recommends a target fasting glucose level of less than 110 mg/dL in noncritically ill hospitalized patients.[66]

Thyroid Disease

Thyroid hormones are important for metabolism and its regulation. Mild to moderate dysfunction probably has minimal impact perioperatively. Significant hyperthyroidism or hypothyroidism appears to increase perioperative risk. Hyperthyroid patients may have tachycardia, arrhythmias, palpitations, tremors, weight loss, and diarrhea. Hypothyroid patients may be hypotensive, bradycardic, and lethargic and exhibit weight gain, depressed cardiac function, pericardial effusions, and an impaired ventilatory response to hypoxia and hypercapnia. Symptoms and findings of both hypothyroidism and hyperthyroidism can be subtle and nonspecific, especially in the elderly. Patients may have goiters with related symptoms such as dysphagia, dyspnea, wheezing, and orthopnea. Grave's ophthalmopathy or proptosis is more common in smokers. Patients taking amiodarone are at risk for hypothyroidism and require evaluation of thyroid function before surgery.

Determination of medical therapy is important. Patients with a history of chronic thyroid disease need thyroid function tests before surgery. If symptomatology and therapy have not changed, tests within the 6 month before surgery are generally adequate. Thyroid-stimulating hormone (TSH) assays are best to evaluate for hypothyroidism. Measuring both *free* triiodothyronine (T_3) and thyroxine (T_4) and TSH is useful in hyperthyroid patients and avoids the confusion of protein-binding effects seen with total hormone levels. Elective surgery should be postponed until patients are euthyroid. Surgery, stress, or illness can precipitate myxedema or thyroid storm in patients with untreated or severe thyroid dysfunction. Preoperative consultation with an endocrinologist should be considered if surgery is urgent in patients with clinical thyroid dysfunction. Hyperthryoid patients should be treated with β-blockers, antithyroid medications, and steroids if surgery is urgent. Chest radiography or computed tomography is useful to evaluate tracheal or mediastinal involvement by a goiter. Continuation of medications (thyroid replacement and antithyroid drugs such as propylthiouracil) on the day of surgery is important.

Parathyroid Disease

Parathyroid hormone regulates calcium, and most cases of hyperparathyroidism are discovered when an elevated calcium level is found incidentally during diagnostic testing. Primary hyperparathyroidism is caused by a primary disorder of the parathyroid glands (adenomas or hyperplasia). Secondary hyperparathyroidism is hyperplasia of the parathyroid gland caused by hyperphosphatemia and hypocalcemia from chronic renal failure. Tertiary hyperparathyroidism occurs when the parathyroid hyperplasia in secondary hyperparathyroidism functions autonomously and results in hypercalcemia. Hypercalcemia from parathyroid disease is associated with osteoporosis and bone loss. Rarely, the parathyroid glands can become so enlarged that they compromise the airway. Hypoparathyroidism is rare but can result from total parathyroidectomy. Hypercalcemia and hypocalcemia are discussed in the section on calcium disorders.

Hypothalamic-Pituitary-Adrenal Disorders

Corticotropin-releasing hormone is released by the hypothalamus and regulates adrenocorticotropic hormone (ACTH) from the anterior pituitary gland, which in turn regulates cortisol from the adrenal cortex. A key component is the negative-feedback suppression by endogenous or exogenous glucocorticoids. Cortisol secretion varies with the circadian rhythm, being highest in the morning and with stress, fever, hypoglycemia, and surgery. Surgery is one of the most potent activators of the hypothalamic-pituitary-adrenal (HPA) axis. ACTH concentrations increase with incision and during surgery, but the greatest secretion of ACTH occurs during reversal of anesthesia, during extubation, and in the immediate postoperative period.

Excess adrenal hormone results from glucocorticoid treatment of disorders such as asthma or inflammatory diseases or from pituitary or adrenal tumors. Cushing's disease denotes the constellation of findings associated with a pituitary tumor; Cushing's syndrome refers to the same findings resulting from either an adrenal tumor or hyperplasia, ectopic ACTH from neoplasms, or exogenous steroids.

Preoperative findings on evaluation include significant hypertension, weight gain, myopathy, diabetes, moon facies, and a buffalo hump, which can influence airway management. Striae, virilization in females, and easy bruising are common. Exogenous steroids will suppress the adrenals, and the normal hypersecretion expected from stress or surgery will be blunted. Therefore, patients at risk will need "steroid coverage," which is discussed in Chapter 35. An ECG and electrolyte and glucose levels should be obtained preoperatively for most surgical procedures. Despite bruising easily, patients have normal coagulation profiles.

Adrenal insufficiency results from destruction of the pituitary or adrenal glands or from long-term administration of exogenous glucocorticoid. Tuberculosis and HIV infection can cause primary hypoadrenalism. Prednisone or its equivalent in doses of greater 20 mg/day for longer than 3 weeks suppresses the HPA axis. The HPA axis is not suppressed with doses of less than 5 mg/day of prednisone or its equivalent. Intermediate doses of steroids taken for longer than 3 weeks have equivocal effects on the HPA axis. The risk remains for up to 1 year after cessation of steroids. Patients with adrenal insufficiency exhibit weakness, weight loss, hypotension, orthostasis, hypovolemia, hyperpigmentation, and electrolyte abnormalities. Electrolytes and orthostatic vital signs should be evaluated.

Serum cortisol and plasma ACTH can establish the diagnosis and cause of adrenal insufficiency in most cases. If the serum cortisol concentration is inappropriately low and a simultaneous plasma ACTH concentration is very high, primary adrenal insufficiency (primary adrenal disease) is the cause. Secondary (pituitary disease) or tertiary (hypothalamic disease) insufficiency is the diagnosis if both the serum cortisol and plasma ACTH concentrations are inappropriately low. However,

in more urgent situations one may not be able to wait for the ACTH results, so an ACTH stimulation test can be performed unless the diagnosis has been ruled out by a basal serum cortisol value in the upper end of the reference range or higher.[67] Cosyntropin is synthetic ACTH and can be administered in either a high-dose or a low-dose test. The time of day is not important because in patients with adrenal insufficiency, the response to cosyntropin is the same in the morning and afternoon. A normal response to the high-dose (250 μg as an intravenous bolus) ACTH stimulation test is a rise in serum cortisol concentration, measured after 30 to 60 minutes, to a peak of 18 to 20 μg/dL or greater. Low-dose (1-μg intravenous bolus) ACTH causes a rise in cortisol of 17 to 22.5 μg/dL or greater after 20 to 30 minutes. For both tests, a subnormal response confirms the diagnosis of adrenal insufficiency, but further studies are necessary to establish the type and cause.

Preoperative electrolytes should be evaluated and an ECG obtained if appropriate. Patients continue steroids on the day of surgery and may need supplementation with additional doses (see the section on medication).

Aldosterone, which is produced by the adrenal cortex, regulates volume and electrolytes (absorption of sodium and chloride, secretion of potassium and hydrogen ions) and is controlled by renin-angiotensin, not the HPA axis.

Multiple Endocrine Neoplasia Syndromes

The multiple endocrine neoplasia (MEN) syndromes are rare, but recognition is important both for treatment and for evaluation of family members.[68] MEN type II (MEN II) is subclassified into three distinct syndromes: MEN IIA, MEN IIB, and familial medullary thyroid cancer. Inheritance of MEN I and II is autosomal dominant.

Hyperparathyroidism is the most common manifestation of MEN I, with almost 100% penetrance by 40 to 50 years of age. Hypersecretion of gastrin in MEN I in association with Zollinger-Ellison syndrome is often manifested as multiple peptic ulcers. The *MEN1* gene has been identified, and therefore testing for *MEN1* mutations is possible. There is little evidence that early, presymptomatic detection reduces morbidity or mortality in MEN I. Screening of asymptomatic family members can also be done by measurement of serum calcium because of the high penetrance of hyperparathyroidism in MEN I.

An undiagnosed pheochromocytoma can cause substantial morbidity or even death during surgery. It is important to consider this preoperative diagnosis as a component of possible MEN II and, if present, remove the tumor before eliminating other endocrine tumors. Extra-adrenal pheochromocytoma is rare in MEN II, but bilateral adrenal disease is common. It is unusual for pheochromocytoma to precede the development of medullary thyroid carcinoma or be the initial manifestation of MEN II.

Hyperparathyroidism in MEN IIA is often clinically occult. DNA testing is the optimal test in MEN II syndromes. In contrast to MEN I, in which the long-term benefit of early diagnosis by genetic screening is not well established, early diagnosis by screening of at-risk family members in MEN II kindreds is essential because medullary thyroid carcinoma is a life-threatening disease that can be cured or prevented by early thyroidectomy.

Please refer to the appropriate sections in this chapter for discussion of the preoperative evaluation of patients with thyroid, hyperparathyroid, and pituitary diseases and pheochromocytomas.

Pheochromocytoma

Tumors that arise from chromaffin cells of the adrenal medulla and sympathetic ganglia and secrete catecholamines are referred to as pheochromocytomas and extra-adrenal catecholamine-secreting paragangliomas (extra-adrenal pheochromocytomas), respectively.[69] The term "pheochromocytoma" is often used for both types of tumors because of similar clinical findings and therapies. Pheochromocytomas are discovered when patients have symptoms, a family history, or discovery of an incidental adrenal mass. Approximately 3% to 10% of adrenal incidentalomas prove to be pheochromocytomas. The classic triad of symptoms is episodic headache, sweating, and tachycardia. Paroxysmal hypertension occurs in half of the patients. Many of the rest have what appears to be essential hypertension. Approximately 5% to 15% of patients have normal BP.

Preoperative evaluation may demonstrate paroxysmal hypertension, which is a classic sign of pheochromocytoma; however, patients with this finding rarely have the disorder. Headache, which is variable in severity and duration, occurs in up to 90% of symptomatic patients. Sweating occurs in up to 60% to 70% of patients. Other symptoms include palpitations, dyspnea, weakness, and panic attacks (particularly with pheochromocytomas that produce an increase in epinephrine). Pallor, orthostatic hypotension, blurred vision, weight loss, polyuria, polydipsia, hyperglycemia, psychiatric disorders, cardiopulmonary dysfunction (especially with the initiation of β-adrenergic blockers), and dilated cardiomyopathy are due to excess catecholamines. Marked hypertension has also been reported.

Pheochromocytoma should be suspected in patients who have one or more of the following:

- Hyperadrenergic spells (nonexertional palpitations, diaphoresis, headache, tremor, pallor)
- Difficult-to-control hypertension
- A familial syndrome that includes catecholamine-secreting tumors (MEN II, neurofibromatosis 1, von Hippel-Lindau disease), often with bilateral disease
- A family history of pheochromocytoma
- An incidentally discovered adrenal mass
- Unusual BP response during anesthesia, surgery, or angiography
- Hypertension at a young age (e.g., <20 years old)
- Idiopathic dilated cardiomyopathy
- A history of gastric stromal tumor or pulmonary chondromas (Carney's triad)

Preoperative measurements of urinary and plasma fractionated metanephrines and catecholamines generally establishes the diagnosis. The history and physical examination focus on the cardiovascular system and evaluation of vital signs, orthostatic BP, and findings of heart failure. An ECG and determination of electrolytes, BUN, creatinine, and glucose should be performed in all patients. Computed tomography, echocardiography, and cardiac consultation may be useful. A complete discussion of the anesthetic implications can be found in Chapter 35.

Renal Disease

The type and degree of impairment are important. Patients with renal dysfunction have many associated comorbid conditions that

are generally related to the accompanying vasculopathy (see Chapters 18 and 45). Hypertension, cardiovascular disease, and electrolyte disturbances are most common. Chronic kidney disease (CKD) is defined as a decreased glomular filtration rate (GFR <60 mL/min/1.73 m^2) for at least 3 months or significant proteinuria. Chronic renal failure is defined as a GFR of less than 15 mL/min/1.73 m^2; acute renal failure (ARF) is a sudden decrease in renal function with a urine output of less than 0.5 mL/kg/hr. End-stage renal disease (ESRD) is loss of renal function for 3 or more months. Diabetes accounts for almost half of all cases of ESRD, hypertension for more than a quarter, and the combination of these plus age older than 55 years predicts more than 90% of cases. Polycystic kidney disease (autosomal dominant 90% of the time) is the causative factor in 10% of cases of ESRD and can be associated with intracranial aneurysms and mitral valve prolapse.

ARF may be reversible if precipitating factors are identified and corrected. Dividing ARF into prerenal, renal, and postrenal categories allows a systematic approach. Prerenal causes can often be differentiated by calculating the BUN-creatinine ratio. A ratio of 20 or greater suggests a prerenal cause, with hypovolemia or hypotension being most common. Fractional excretion of sodium (FE_{Na}) of less than 1% also suggests prerenal azotemia and can be calculated by the following formula:

$$FE_{Na} = \frac{P_{Cr}/U_{Cr}}{P_{Na}/U_{Na}}$$

Obstruction will result in dilated ureters and enlarged kidneys and is always in the differential diagnosis of ARF. Prompt identification with ultrasound leads to attempts to decompress the outflow tract. Rhabdomyolysis can cause ARF and is treatable.

GFR decreases with age, and the renal reserve of a normal 80-year-old is less than half that of a 40-year-old. The creatinine level is often not an accurate indicator of renal function, especially in elderly individuals. A doubling of serum creatinine from 0.8 to 1.6 mg/dL represents a halving of the GFR. The GFR can be reduced 50% or more without a rise in creatinine. Creatinine does not exceed the normal limits until the GFR has fallen below 50 mL/min. The Cockcroft-Gault formula can be used to estimate GFR:

$$\text{Creatinine clearance} = \frac{(140 - \text{Age}) \times \text{Weight (kg)} \times (0.85 \text{ if female})}{72 \times \text{Serum creatinine (mg/dL)}}$$

Online calculators to estimate renal function are available at www.nephron.com. Calculation of an eGFR can be done in elderly patients, those with an elevated serum creatinine, or individuals with other risk factors for CKD.

Chronic renal disease is a significant risk factor for cardiovascular morbidity and mortality and is an ACC/AHA intermediate cardiac risk factor considered to be equal to angina, MI, or a history of known CAD. The annual incidence of death from CAD in patients with both diabetes and ESRD who require hemodialysis is 8.2%. A creatinine concentration of 2.0 mg/dL or higher should trigger an assessment of cardiac risk under the ACC/AHA guidelines, simplified in Figure 34-2.[7] See the section "Ischemic Heart Disease" for a more detailed discussion of these guidelines. Pericarditis, pericardial effusions, and diastolic and systolic dysfunction can be present. Valvular heart disease is common in patients undergoing maintenance dialysis. Abnormalities include valvular and annular thickening and, most significantly, calcification of the heart valves resulting in regurgitation or stenosis (or both).[70] Mitral and aortic valve calcifications (40% and 55% of patients, respectively) and stenosis (11% to 13%) occur. Valvular calcifications progress to stenosis at an accelerated rate in dialysis patients.[71] Systemic hypertension is almost ubiquitous but is generally easier to manage with initiation of dialysis. Pulmonary hypertension and increased cardiac output occur in many patients with an arteriovenous fistula.

Renal failure results in anemia from lack of erythropoietin production by the kidneys, but in the present era of aggressive erythropoietin replacement, many of these patients have normal or high hematocrits, which actually increases morbidity and vascular events.[30] Patients with CKD can have platelet dysfunction and increased bleeding despite a normal platelet count, prothrombin time (PT), and aPTT. Once on dialysis, patients are more prone to hypercoagulable states. Chronic metabolic acidosis is common but usually mild and compensated for by chronic hyperventilation. Patients may exhibit electrolyte and calcium abnormalities, pulmonary and peripheral edema, anemia, hypercholesterolemia, and hypoalbuminemia. Hyperkalemia is the most serious electrolyte disturbance. Hypocalcemia is common with dialysis, and eventually secondary and tertiary hyperparathyroidism develops. Chronically elevated troponin and creatine kinase levels are common in patients maintained on dialysis. Worsening renal function should be suspected in diabetics who have improved glycemic control or unexpected hypoglycemia because insulin is metabolized by the kidneys and has a prolonged duration of action with progressive renal dysfunction. Autonomic and peripheral (sensory and motor) neuropathies can occur.

Patients at risk for perioperative renal failure include those with preexisting renal insufficiency (the single strongest predictor) or diabetes, especially in combination, and those undergoing procedures with the administration of contrast medium. If all three conditions are present, the risk of renal failure may be as high as 12% to 50%. Preoperative identification of at-risk patients alters management, such as hydration, administration of sodium bicarbonate, a change in the type of contrast medium, and avoidance of hypovolemia (see Chapter 65). This may require admission preoperatively. Nonsteroidal anti-inflammatory drugs (NSAIDs) and cyclooxygenase (COX-2) inhibitors interfere with autoregulation of renal perfusion and should be avoided or discontinued in patients with or at risk for renal insufficiency. Cyclosporine and aminoglycoside antibiotics can cause renal insufficiency. ACEIs and ARBs prevent deterioration in patients with diabetes or renal insufficiency but may worsen function during hypoperfusion states.

Many drugs are metabolized or cleared by the kidneys. Drugs with particular implications for anesthesia and surgery are the LMWHs because there is no easy method of monitoring their anticoagulation effects. All the LMWHs available in the United States are cleared by the kidneys and are not removed during dialysis. Therefore, LMWH has a prolonged duration of action in patients with CKD. The risk of significant bleeding or hematomas with centroneuraxial anesthesia may be increased.

Preoperative evaluation of patients with renal insufficiency or failure should focus on the cardiovascular and cerebrovascular systems, fluid volume, and electrolyte status. The early stages of

CKD typically cause no symptoms. Inquiring about the cardiovascular systems (chest pain, orthopnea, paroxysmal nocturnal dyspnea), urine output, associated comorbid conditions, medications, and dialysis schedules is vital. Understanding changes in patient weight is one method of assessing volume status.

In patients with or at risk for renal disease (especially those with two of the following: diabetes, poorly controlled hypertension, advanced age), an ECG and determination of electrolytes, calcium, glucose, albumin, BUN, and creatinine should be performed if the results will have an impact on management. LVH (from hypertension), peaked T waves (hypokalemia), flattened T waves, and prolonged PR and QT intervals (hypokalemia) prompt further evaluation. A chest radiograph (infection or volume overload), echocardiogram (for murmurs or heart failure), and stress testing (see ACC/AHA guidelines) may be indicated in certain patients. Many of these patients will benefit from cardiology evaluation based on these tests as discussed earlier. Venous access or blood draws from the brachial, cephalic (antecubital), and central veins in the nondominant upper extremity should be avoided in patients who may need fistulas for dialysis in the future.

Preoperative renal replacement therapy (dialysis) schedules should be determined, with scheduling of surgery ideally within 24 hours after dialysis. In elective cases, dialysis is best performed within 24 hours of surgery but not immediately before because of acute volume depletion and electrolyte alterations. Dialysis is associated with fluid and electrolyte (sodium, potassium, magnesium, phosphate) imbalance and shifting of electrolytes between the intracellular and extracellular compartments. Dialysis should be performed to correct volume overload, hyperkalemia, and acidosis. Coordinating the scheduling of dialysis and elective surgery is an important aspect of preoperative care.

Contrast-Induced Nephropathy

Contrast-induced nephropathy is defined as a 25% rise in creatinine above baseline after the administration of a radiocontrast agent (see Chapter 79). Patients with diabetes and CKD are at greatest risk, although radiocontrast media causes a transient decrease in the GFR in most individuals. Renal failure requiring dialysis after contrast-induced nephropathy is associated with less than a 20% 2-year survival rate, and a third of patients die during the initial hospitalization.

Hepatic Disorders

Liver disease can affect hepatocytes, the biliary system, or both (see Chapters 17 and 66). Liver disease affects protein synthesis, including coagulation factors and albumin, drug and toxin metabolism, and bile regulation. Hepatocellular diseases, including viral, alcoholic, and autoimmune hepatitis or hepatocellular carcinoma, affect hepatocytes and synthetic function of the liver. Obstructive disorders, including choledocholithiasis and bile duct tumors (extrahepatic), primary biliary cirrhosis (intrahepatic), or primary sclerosing cholangitis (extrahepatic and intrahepatic), cause bile stasis. Most drug-induced liver disease and some forms of viral hepatitis affect both hepatocytes and the biliary system.

Hepatitis

Hepatitis is a term used to describe inflammation of hepatocytes and can be caused by drugs, alcohol, viruses (hepatitis A, B, C, D, and E), or autoimmune diseases. All of these conditions have acute and chronic phases that can progress to cirrhosis, which is irreversible fibrosis of the liver. Risk factors for hepatitis are alcohol use, sexual activity (multiple partners, sex industry workers, sex with sex industry workers, or men who have sex with men), intravenous drug use, blood transfusions before 1992, travel to underdeveloped countries, obesity, tattoos, and body piercing. Hepatitis A is caused by contaminated food or water or contact with an infected person and rarely progresses beyond the acute illness. A remote history of hepatitis A has no significance perioperatively. Hepatitis B is transmitted by sexual activity or contact with blood (rarely from transfusions since screening was implemented in 1986). It varies in severity but is much less common since the widespread use of vaccination against this virus. Hepatitis C is caused primarily by blood exposure (blood has been screened since 1992), most often in intravenous drug users. Many patients are unaware of infection because the acute phase is frequently asymptomatic but can advance to cirrhosis. Hepatitis D occurs only with hepatitis B, and hepatitis E is rare in developed countries. Alcoholic hepatitis generally occurs after at least 10 years of daily moderate to heavy alcohol intake (>3 drinks/day for women; >5/day for men) and may progress to cirrhosis. Autoimmune hepatitis primarily affects young women and has no known cause. Virtually any drug, as well as herbals and over-the-counter preparations, can cause hepatitis, including statins, isoniazid, and acetaminophen.

Obstructive Jaundice

Extrahepatic bile duct obstruction is caused by gallstones, tumors (pancreatic, gallbladder, bile duct, ampulla of Vater), or scarring. Patients may have jaundice, pruritus, and abdominal pain. Predictors of surgical mortality are a preoperative hemocrit of less than 30%, bilirubin concentration greater than 11 mg/dL, and malignancy, and death may occur in as many as 60% if all three are present.[72] Renal failure develops in up to 8% of these patients postoperatively, which may be lessened with administration of bile salts or lactulose.[73]

Miscellaneous Liver Diseases

Wilson's disease, hemochromatosis, and α_1-antitrypsin deficiency are less common than hepatitis, are hereditary, and commonly occur in members of the same family. Obesity can result in nonalcoholic steatohepatitis, also known as "fatty liver," which causes abnormal LFT results and can progress to fibrosis. Primary biliary cirrhosis is an autoimmune disorder that results in intrahepatic biliary obstruction; it occurs most frequently in middle-aged women and is associated with antimitochondrial antibodies. Primary sclerosing cholangitis destroys bile ducts, is most frequent in young males, is associated with inflammatory bowel disease but can be idiopathic, and may progress to cirrhosis. Acute illnesses such as sepsis, surgery, and anesthesia can cause hepatic dysfunction. Gilbert's syndrome is a benign familial disorder with mildly elevated bilirubin and has no perioperative significance.

Remote History of "Hepatitis"

Patients may recount a history of "having hepatitis" many years before but little other information is known. One must take a careful preoperative history to determine circumstances surrounding the onset (e.g., transfusions, travel, exposure to risky situations) and whether any sequelae of chronic liver disease are present. It is important to clarify whether the episode occurred

during or soon after surgery. Although halothane is rarely used in adults in the United States today, those who previously had halothane hepatitis may be at risk for cross-sensitivity to other fluorinated volatile agents with trifluoroacetyl metabolites (enflurane, isoflurane, desflurane).

Cirrhosis

Cirrhosis is the end result of most hepatotoxic conditions. Portal hypertension with splenomegaly, varices, ascites, and pleural effusions occur. The liver fails to synthesize proteins and clotting factors or clear toxins and drugs. Patients may have encephalopathy, bleeding, thrombocytopenia, and a prolonged PT and are at risk for renal insufficiency or failure. Pulmonary shunting may cause hypoxemia and pulmonary hypertension. Hepatorenal syndrome is the occurance of renal insufficiency in patients with hepatic disease in the absence of primary renal disease and may be related to hypoperfusion. Jaundiced patients are at particular risk for hepatorenal syndrome. Spontaneous bacterial peritonitis may develop in patients with ascites and increases perioperative mortality.

The Child-Turcotte-Pugh classification (Table 34-5) can predict perioperative morbidity and mortality. The Model for End-Stage Liver Disease (MELD) formula, which factors bilirubin, the international normalized ratio (INR), creatinine, and the cause of the liver disease, is used to select patients for transplantation, may be useful to predict risk for other surgery, and may do so better than the Child class.[74] Online calculators to determine MELD can be found at www.unos.org. Higher scores indicate more severe disease. One study showed that a MELD score lower than 14 predicted 77% of patients with poor outcomes.[74] Anemia increases postoperative mortality in patients with obstructive jaundice. One study did show that a serum albumin concentration of less than 2.1 mg/dL was a strong predictor of mortality in veterans undergoing major noncardiac surgery.[75]

Unexpected Increased Liver Function Test Values

Elevated alanine aminotransferase (ALT) and aspartate aminotransferase (AST) reflect damage to hepatocytes, bilirubin measures the liver's ability to conjugate or excrete bile (or both), alkaline phosphatase rises with degradation of hepatic excretion (also from bone turnover and thus nonspecific for liver disease), and albumin and PT measure synthetic function of the liver. Only 1 in 700 preoperative patients is unexpectedly found to have liver disease, and the vast majority are not severe disorders. However, if abnormal LFT values are unexpectedly found, further testing or referral may be warranted. In patients with elevations in ALT or AST, screening for hepatitis with hepatitis A IgM antibody, hepatitis B surface and core antigens, hepatitis B surface antibody, and hepatitis C antibody can help in establishing a diagnosis. Elevated alkaline phosphatase or bilirubin with normal or mildly to moderately increased transaminases suggests obstruction of the biliary system, and abdominal ultrasound, computed tomography, and endoscopic retrograde cholangiopancreatography can establish a diagnosis.

Table 34-5 Child-Turcotte-Pugh Classification

	Points (For Each with a Maximum of 15)		
Parameter	**1**	**2**	**3**
Ascites	Absent	Slight	Moderate
Bilirubin (mg/dL)	<2	2-3	>3
Albumin (g/dL)	>3.5	2.8-3.5	<2.8
Prothrombin time (seconds over control)	<4	4-6	>6
Encephalopathy	None	Grade 1-2	Grade 3-4

Class A: <7 points; Class B: 7-9 points; Class C: >9 points.

All Forms of Liver Disease

The preoperative history often uncovers the cause of the liver disease, therapies, and associated complications. Important issues to explore include the cause and degree of hepatic dysfunction. Patients with liver disease may be asymptomatic or complain of fatigue, weight loss, dark urine, pale stools, pruritus, right upper quadrant pain, bloating, and jaundice. Weight and vital signs, including oxygen saturation, are needed. Physical examination may reveal jaundice, bruising, ascites, pleural effusions, peripheral edema, or hypoxia. The presence of encephalopathy, coagulopathy, ascites, volume overload, and infectivity needs to be determined and explored preoperatively. The bilirubin level is generally higher than 2.5 mg/dL before icterus can be seen in mucous membranes and sclerae. Examination may reveal hepatomegaly, splenomegaly, and altered mental status. New-onset or worsening encephalopathy prompts an evaluation for precipitating factors such as worsening liver disease, infection, drug effects, bleeding, or electrolyte disturbances.

In selected patients, preoperative evaluation may warrant further testing consisting of an ECG, CBC with platelet count, electrolytes, BUN, creatinine, LFTs, albumin, and PT. An ammonia level may be helpful in patients with encephalopathy. A chest radiograph may identify effusions. Coagulopathy can be a result of vitamin K deficiency caused by an inability to secrete bile (cholestatic disorders), deficiency of coagulation factors because of loss of synthetic function as a result of cirrhosis, or thrombocytopenia secondary to splenomegaly and portal hypertension.

Therapy to correct coagulopathy is directed at the cause. Vitamin K, fresh frozen plasma, or platelets are used to correct deficiencies. Vitamin K, 1 to 5 mg orally or subcutaneously daily for 1 to 3 days, may correct a prolonged PT and carries minimal risk. However, the coagulopathy in patients with synthetic failure will probably not correct with such measures, and performing a type and screen will prepare the patient for platelet and fresh frozen plasma transfusions with the goal of achieving a platelet count higher than 50,000/mm^3 and an INR less than 1.5, respectively. Correction of anemia is controversial but may limit renal dysfunction. Lactulose (30 mL orally every 6 hours for 3 days before surgery with the last dose given within 12 hours of surgery) or oral bile salts with intravenous hydration beginning the night before surgery may reduce perioperative progression of renal disease in patients at risk.[76] Reduction of ascites preoperatively may decrease the risk of wound dehiscence and improve pulmonary function. Sodium restriction (in diet and intravenous solutions), diuretics (especially spironolactone, which inhibits aldosterone), and even paracentesis are useful. If fluid is aspirated, it is important to analyze it for infection. Encephalopathy is frequently caused by an acute insult such as infection, gastrointestinal bleeding, hypovolemia, or sedatives. It is important to determine reversible factors and treat accordingly. Lactulose, 30 mL every 6 hours orally, is first-line therapy. Addressing nutritional deficiencies with enteral or parenteral supplementation

may have benefit, especially in alcoholic patients. Patients who abuse alcohol are at risk for neurologic deterioration if thiamine, folate, and vitamin B_{12} supplements are not provided, particularly when nutrition or glucose is given. These patients are also at risk for alcohol withdrawal syndromes (see the appropriate section).

Delaying elective surgery until after an acute episode of hepatitis or an exacerbation of chronic disease has resolved or until a diagnosis is established if hepatic dysfunction is newly detected is appropriate.[74] Elective surgery is contraindicated in patients with acute or fulminant liver disease, including alcoholic (mortality >55%), viral (mortality >10%), or undefined hepatitis. Perioperative risk in patients with chronic hepatitis or cirrhosis is predicted by its histologic severity (bridging or multilobular necrosis on biopsy), impairment of the synthetic and excretory functions of the liver, and portal hypertension (ascites, varices, bleeding).

Patients with severe liver disease have increased perioperative morbidity and mortality.[77] Perioperative management is discussed in Chapter 66. The most common adverse events are bleeding, infection, liver failure, and hepatorenal syndrome (renal failure in patients with portal hypertension but otherwise normal kidneys).

Hematologic Disorders

Anemia

Anemia may be a known problem or a suspected possibility based on a patient's history of underlying medical conditions or the reason for surgery. It is useful to determine the etiology, duration, and stability of the anemia, related symptoms, and therapy (especially transfusions), although the evaluation needs to consider the extent and type of surgery, the anticipated blood loss, and the patient's comorbid conditions that may influence oxygenation or be affected by hypoxia, such as pulmonary, cerebrovascular, or cardiovascular disease. Inquiring about a personal or family history of anemia is important.

The World Health Organization defines anemia as a hemoglobin level lower than 13 g/dL in adult men and less than 12 g/dL in adult women. The consequences of moderate levels of anemia and hemoglobin levels of 6.0 g/dL or higher in patients without CAD are minimal. The ASA Task Force on Blood Component Therapy concluded that red blood cells should not be transfused solely because of a hemoglobin level but rather because of risk for complications from inadequate oxygenation (see Chapter 55).[78] A recent Veteran's Affairs study suggests that even mild preoperative anemia increases postoperative mortality and cardiac morbidity, but only in men.[31] This study found that individuals with hematocrits between 39% and 51% had the lowest risk for adverse outcomes.

Preoperative patients at risk for anemia include those with a history of colon cancer, gastrointestinal or genitourinary bleeding, metrorrhagia, chronic infections, inflammatory diseases, nutritional deficiencies (including gastric bypass recipients), and a host of other conditions. Anemia is the most common preoperative hematologic disorder. An important component of the history and physical examination includes asking about palpitations, fatigue, chest pain, black or bloody stools, weight loss, pallor, murmurs, hepatospenomegaly, or lymphadenopathy.

Preoperative evaluation of patients with anemia or suspected anemia will benefit from a CBC. Generally, further evaluation should be done by a primary care physician or hematologist, but initial studies include a peripheral smear, determination of mean corpuscular volume (MCV), a reticulocyte count, and further testing such as iron studies, vitamin B_{12}, or folate levels, depending on the findings on the smear and the MCV. MCV, iron, and ferritin are low and total iron-binding capacity (TIBC) is high in iron deficiency anemia. MCV and TIBC are low or normal and iron and ferritin are normal or high in anemia associated with chronic disease. MCV is high and vitamin B_{12} or folate levels are low in macrocytic anemia associated with these deficiencies. Type and screening and preoperative transfusion may be necessary, depending on the level of anemia and anticipated surgical blood loss.

In special circumstances, such as a patient's refusal of perioperative blood transfusion or elective procedures with expected significant blood loss in anemic patients, postponement of surgery to treat with recombinant human erythropoietin and iron may be warranted.

Sickle Cell Disease

Sickle cell disease, a hereditary hemoglobinopathy with vaso-occlusion, is responsible for most of the associated complications. Patients homozygous for hemoglobin S (HbS) have disease and are at risk for major morbidity and a shortened life expectancy. Patients with SC disease have both HbS and HbC and a much less severe clinical course with moderate anemia. Heterozygous patients (HbS and HbA) have sickle cell trait and rarely have any consequences related to this condition. Preoperative assessment should focus on identification of organ dysfunction and acute exacerbations.[80] Patients may have renal insufficiency, splenomegaly, pulmonary hypertension and infarction, cerebrovascular accidents, and heart failure. They are at increased risk for infection because of splenic infarction. Frequent hospitalizations or a recent increase in hospitalizations, advanced age, preexisting infections, and pulmonary disease are predictive of perioperative vaso-occlusive complications.[79]

The preoperative history and physical examination should focus on the frequency, severity, and pattern of vaso-occlusive crises and the degree of pulmonary, cardiac, renal, and central nervous system damage. Pulse oximetry, hematocrit, measurement of BUN and creatinine, an ECG, and a chest radiograph should be considered. Additional testing (e.g., echocardiogram, arterial blood gases) may be needed in rare instances. Prophylactic transfusion may be beneficial, especially before intermediate- to high-risk cases. Preoperative prophylactic transfusion is controversial, and the decision to transfuse should be made in concert with a hematologist familiar with the disease. The Cooperative Study of Sickle Cell Disease concluded that preoperative transfusion was beneficial, although patients undergoing low-risk surgery had few complications even without transfusion.[80] Another study showed that a conservative transfusion regimen (decreasing HbS to <60% and hemoglobin to 10 g/dL) was as effective as a more traditional approach (transfusing to decrease HbS to <30% and hemoglobin to 10 g/dL). Additional benefits included fewer transfusion-related complications.[81]

Glucose-6-Phosphate Dehydrogenase Deficiency

Glucose-6-phosphate dehydrogenase deficiency is an X-linked hereditary Coombs-positive hemolytic anemia. Hemolysis occurs with exposure to drugs (antipyretics, nitrates, sulfonamides), infections, hypoxia, hypothermia, blood products, or stress. The

severity of the hemolysis varies among patients and the offending agent or condition. Steroids are usually effective. The preoperative history focuses on previous episodes of hemolysis, identification of predisposing factors, and determination of the current hematocrit.

Coagulopathies

Hypocoagulable states are either inherited disorders such as the hemophilias and thrombocytopenia or are acquired disorders secondary to liver disease, malnutrition, or drug exposure. To determine the diagnosis and risk of bleeding, one inquires about known diagnoses, tests, treatments, previous bleeding episodes, and family history. Asking about excessive bruising, prolonged bleeding after cuts, heavy menstrual cycles, and bleeding gums is sensitive but not specific. A *change* in one of these factors is more meaningful than a chronic history becauses what one individual considers excessive may actually be normal.

The preoperative evaluation inquires into excessive bleeding after previous procedures or childbirth, especially if transfusions were unexpectedly required; such bleeding is more definitive but not diagnostic. Petechiae, multiple bruises, hematomas, jaundice, and frank bleeding are important findings. Diagnostic testing may include a platelet count, CBC, PT, and aPTT. *Routine* screening for coagulopathies with a PT, aPTT, or a bleeding time without an indication is not indicated. If specific causes of bleeding are suspected or known, such as liver disease or malnutrition, targeted testing with liver enzyme, protein, and albumin levels and a PT is needed.

In the case of a prolonged PT without a history of warfarin use, the most common cause is laboratory error, liver disease, or malnutrition. One should first repeat the test. If the test is abnormal again, referral to a hematologist or the primary care physician or evaluation of liver enzymes and a hepatitis panel may be warranted, depending on the surgery. A trial of vitamin K (1 to 5 mg orally once a day for 3 days) can be initiated. A prolonged aPTT can result from both hypocoagulable and hypercoagulable conditions. The first step is to repeat the test and ascertain exposure to heparin. Even small amounts of heparin present in indwelling catheters, especially if the blood is drawn from that site, can prolong the aPTT. The most common cause of a prolonged aPTT other than heparin exposure is von Willebrand's disease (vWD), but other hemophilias discussed later can prolong the aPTT. Factor V Leiden, anticardiolipin antibody, and lupus anticoagulants, which result in increased clotting, cause prolongation of the aPTT. Further testing for a prolonged aPTT includes a repeat aPTT; an aPTT mixing study; lupus anticoagulant; evaluation of coagulation factors VII, IX, XI, and XII; and checking von Willebrand factor (vWF) antigen and ristocetin cofactor levels. A mixing study, in which normal blood is mixed with the subject's blood, will detect factor deficiencies (the aPTT will correct with this test) or inhibitors (the aPTT will not correct).

Hemophilias

Hemophilia A (factor VIII deficiency) and hemophilia B (or Christmas disease) are X-linked recessively inherited disorders that occur almost exclusively in males. Hemophiliacs have a prolonged aPTT and normal PT. The severity of bleeding varies among individuals but tends to be similar in relatives and is directly related to the degree of factor deficiency. Even mild trauma can result in significant hemorrhage. Orthopedic procedures account for 50% of operations in hemophiliacs because recurrent bleeding destroys joints. Hemophilia A accounts for 85% of all cases of hemophilia.

A hematologist should be involved in the perioperative care of these patients. A detailed plan to monitor and replace deficient factors is paramount. Typically, factors VIII and IX are maintained at 75% to 100% in the immediate perioperative period and then at 50% until any risk of bleeding is past. Each unit of recombinant or purified factor concentrate raises the factor level by 2% per kilogram. Intramuscular injections are to be avoided.

Von Willebrand's Disease

vWD is an inherited disorder of factor VIII and vWF that affects both genders. It is the most common congenital coagulopathy and is estimated to occur in 1% of individuals.[82] Several types (1, 2A, 2B, 2M, and 2N) are autosomal dominant, and type 3 is recessive. Factor VIII and vWF circulate as a complex, and vWD results from both quantitative and qualitative deficiencies. Most patients have a prolonged aPTT, but those with mild disease may have a normal aPTT. The most common cause of a prolonged aPTT in patients not taking heparin is vWD. vWD is diagnosed by measuring ristocetin cofactor (a functional assay for vWF that causes platelet aggregation in the presence of ristocetin), vWF antigen, and factor VIII. vWF is an acute-phase reactant that increases with certain conditions such as stress or surgery, which sometimes makes the diagnosis difficult. Most patients with vWD will have a history of bleeding, but in some the diagnosis will not be made until a second challenge to coagulation occurs, including major surgery or exposure to drugs such as aspirin or NSAIDs.

Involvement of a hematologist in the care of these patients is beneficial. Desmospressin (1-desamino-8-D-arginine vasopressin [DDAVP]) increases release of factor VIII, vWF, and plasminogen activator from endothelial cells. An intravenous dose of 0.3 μg/kg (given over a period of 15 to 30 minutes to avoid hypotension, flushing, and tachycardia) typically raises vWF threefold to fourfold. However, there is considerable variation among individuals, so vWF and factor VIII levels must be monitored. Desmopressin is available as a nasal spray and should not be given more frequently than every 48 hours to avoid depletion of endothelial stores. To avoid release of plasminogen activator by desmopressin, ε-aminocaproic acid or tranexamic acid is given. Desmopressin is contraindicated in patients with type 2B because it increases abnormal vWF and may result in thrombocytopenia. Cryoprecipitate or factor VIII concentrates containing vWF will replace abnormal vWF.

Thrombocytopenia

Thrombocytopenia is a platelet count lower than 150,000/mm^3 and results from decreased production, increased destruction, or sequestration. Malignancies, drugs, autoimmune disorders, preeclampsia, hereditary disease, and disseminated intravascular coagulation can cause thrombocytopenia. In patients found to have low platelet counts unexpectedly, first repeat the test, examine the peripheral smear, and collect blood for a platelet count in a tube without ethylenediaminetetraacetic acid (EDTA). EDTA is a chelating agent added to tubes commonly used for determination of the CBC because it prevents clotting. However, in some patients it causes clumping of platelets resulting in pseudothrombocytopenia.

Recent exposure to heparin raises the issue of heparin-induced thrombocytopenia (HIT), which generally occurs within

5 to 10 days after exposure to heparin.[83] HIT is an immune-mediated disorder with antibodies directed against platelets and can result in arterial or venous thrombosis, stroke, amputations, and death in up to 30% of patients. Immediate discontinuation of heparin and testing for heparin-induced platelet antibodies are indicated. LMWH is less likely than unfractionated heparin to cause HIT but is contraindicated in patients with HIT. Alternative anticoagulants are danaparoid sodium, lepirudin, and argatroban. Idiopathic thrombocytopenic purpura is a chronic autoimmune disorder with autoantibodies against platelets that results in increased destruction. Patients are treated with corticosteroids and splenectomy (to eliminate the major site of platelet removal). Patients often have minimal bleeding at even very low platelet levels, probably because of increased turnover and a predominance of young platelets.

Surgery can be performed safely in patients with platelet counts higher than 50,000/mm^3. The risk of bleeding is inversely related to platelet counts lower than 50,000/mm^3. Anemia, fever, infections, and drugs that affect platelet function increase bleeding at any platelet level. Centroneuraxial anesthesia is safe with platelet counts higher than 100,000/mm^3.[84] Patients with newly discovered thrombocytopenia may benefit from hematology consultation before elective surgery. One unit of platelets transfused typically raises the count by 10,000/mm^3.

Thrombocytosis

Thrombocytosis is a platelet count greater than 500,000/mm^3 and may be physiologic (exercise, pregnancy), primary (myeloproliferative disorder), or secondary (iron deficiency, neoplasm, surgery, chronic inflammation). Platelet counts greater than 1,000,000/mm^3 place patients at risk for thrombotic events such as stroke, MI, pulmonary and mesenteric emboli, and peripheral arterial and venous clots. Patients with primary thrombocytosis (essential thrombocythemia) have a bleeding tendency that is worsened by exposure to drugs such as aspirin. Older patients and those with a previous history of bleeding or thrombosis may be at increased risk. Hydroxyurea, anagrelide (these drugs decrease production, so 7 to 10 days is needed), or plasmapheresis (removes platelets, so the effect is immediate) may be used to lower the platelet count. Treatment of the underlying disorder of secondary causes of thrombocytosis usually results in normalization of the platelet count.

Polycythemia

Polycythemia is a hematocrit greater than 54% and can be primary (polycythemia vera) or secondary to chronic hypoxia (COPD, high altitude, congenital heart disease). A steep increase in blood viscosity, which is thrombogenic, occurs with hematocrits higher than 50%. High hematocrits are associated with increased atherosclerosis (carotid stenosis, stroke) and cardiovascular disease (heart failure, MI). There are contradictory reports on whether polycythemia increases perioperative risk. A recent study showed an increase in postoperative mortality in men but not women with hematocrits higher than 51%.[31] However, an earlier report found no increased perioperative complications in patients with secondary polycythemia.

The preoperative evaluation (history and physical examination) focuses on the pulmonary and cardiovascular systems. Examination for cyanosis, clubbing, wheezing, and murmurs is necessary. Oxygen saturation, an ECG, and possibly arterial blood gas analysis and a chest radiograph are needed in patients with polycythemia. An unexpected preoperative finding of polycythemia should prompt an investigation to find the cause and, if not readily apparent, the possibility of polycythemia vera.

Risk of Thromboembolism or Pulmonary Emboli

Fatal pulmonary embolism occurs in 0.1% to 0.8% of patients undergoing elective general surgery, 2% to 3% of patients having elective hip replacement, and 4% to 7% of patients undergoing repair of a fractured hip who do not receive prophylaxis. The risk for venous thrombosis is increased in patients with previous venous thromboembolism, obesity, varicose veins, diabetes, cancer, heart failure, pregnancy, paralysis, the presence of an inhibitor deficiency state, or age younger than 50 years.[85] Factor V Leiden is the most common cause of inherited thrombophilia (40% to 50% of cases). The prothrombin gene mutation and deficiencies in protein S, protein C, and antithrombin account for most of the remaining cases. The risk of perioperative venous thromboembolism depends on the surgical procedure (e.g., degree of invasiveness, trauma, and immobilization) and patient-related variables (e.g., inflammatory bowel disease, acute illness, smoking, malignancy, obesity, increasing age, previous thromboembolism, estrogen use, hypercoagulable state).[86] Primary thromboembolic prophylaxis is beyond the scope of this chapter, but it is important to risk-stratify patients preoperatively so that appropriate measures can be implemented on the day of surgery. Because of the high risk of thromboembolism in patients undergoing elective lower extremity joint replacement, these patients are often given a dose of warfarin the night before surgery. American Society of Regional Anesthesiologists guidelines specifically state that if a single dose of warfarin has been administered within the previous 24 hours, it is safe to perform neuraxial anesthesia.[87]

Recent arterial or deep venous thromboembolism (DVT) requires perioperative interventions or postponement of nonlifesaving procedures. Without anticoagulation, the risk for recurrent DVT within 3 months of a proximal DVT is approximately 50%. A month of warfarin treatment reduces the risk to 10%, and 3 months reduces it to 5%. Patients with a hereditary hypercoagulable state (e.g., antithrombin III or protein C or S deficiency, prothrombin gene mutation, Factor V Leiden), cancer, or multiple episodes of DVT are at higher risk indefinitely. Patients with nonvalvular atrial fibrillation who have had a previous cerebral embolism are also at higher risk. Patients with mechanical heart valves, especially multiple valves, are at risk for embolism. Risk is greater with mitral than with aortic valves. Surgery increases the risk for DVT, but there is no such evidence that surgery increases the risk for arterial embolism in patients with atrial fibrillation or mechanical valves.[84]

Preoperative evaluation determines whether "bridging" with either unfractionated heparin intravenously or LMWH subcutaneously as an outpatient (or not to bridge) is warranted for patients with mechanical heart valves or previous episodes of thromboembolism secondary to atrial fibrillation. The decision needs to be made in concert with the treating physician or a cardiologist.

The authors believe that elective surgery should be postponed in the first month after an episode of venous or arterial thromboembolism. If postponement is not possible, the patient should receive preoperative heparin while the INR is below 2.0.[84] Ideally, 3 months of anticoagulation is recommended before elective surgery. Typically, withholding warfarin for 5 days will allow

the PT/INR to fall to normal if the INR is chronically maintained between 2.0 and 3.0, the usual therapeutic targets. It may be necessary to withhold more doses if the INR is more prolonged or fewer doses if subtherapeutic. Therefore, it is necessary to check the INR during the preoperative visit to guide cessation of therapy. During the time without warfarin, patients may be at risk for recurrent thromboembolism, but the risk is relatively small in all but the highest-risk patients. It is controversial whether patients require "bridging" or heparin during this period. Previously, the only option was hospital admission for intravenous heparin therapy, which is costly. However, with the availability of LMWH, patients can receive subcutaneous (usually self-administered) LMWH at home without the need for monitoring.

Neurologic Disease

In patients with neurologic disease, a detailed history is required with a focus on recent events, exacerbations, or evidence of poor control of the medical condition. Information about previous investigations or therapy is important. A basic preoperative neurologic examination documenting deficits in mental status, speech, cranial nerves, gait, and motor and sensory function is important. This baseline determination allows comparison of new deficits postoperatively.

Cerebrovascular Disease

If a stroke or transient neurologic deficit has not been fully evaluated or has occurred recently, elective surgery should be considered pending complete evaluation because a history of stroke or symptoms of cerebrovascular insufficiency are strong predictors of perioperative stroke.[88] High-quality data are lacking on how soon after an event anesthesia and surgery are safe. The etiology and treatment guide further perioperative management. An embolic stroke from a patent foramen ovale (PFO) may require correction of the PFO or strict attention to avoidance of air emboli. A left atrial or ventricular thrombus or an embolic stroke secondary to atrial fibrillation or mechanical heart valves requires a minimum of 1 month and preferably 3 months of anticoagulation and possible bridging with short-acting anticoagulants for elective surgery.[84] Atrial fibrillation (either chronic or new onset) is a common cause of perioperative stroke, especially those occurring postoperatively, the most common time for stroke.[89]

Asymptomatic Bruit

A newly discovered carotid bruit requires a careful searching for symptoms of cerebral ischemia or transient ischemic attack, especially if the procedure is likely to involve manipulation of the neck or the patient has a potentially difficult airway. Frequently, patients will not have volunteered pertinent symptoms until specifically probed, especially if they were transient. Patients with risk factors for carotid atherosclerosis, including those who have undergone head and neck irradiation, especially at a younger age, need to be questioned specifically about amaurosis fugax, dysphagia, dysarthria, and other symptoms of cerebovascular insufficiency. One of the authors met a college professor in the preoperative clinic who was scheduled for an abdominal procedure and had a history of Hodgkin's lymphoma as a teenager. After a carotid bruit was ausculated, the patient confirmed receiving mantle irradiation for her lymphoma, but it took much probing to elicit a history of two transient episodes of slurred speech within the previous month. The patient was found to have 99% occlusion of her left internal carotid artery.

In patients who have truly asymptomatic bruits, significant carotid lesions are present 40% to 60% of the time, the risk of stroke in this group is 1% to 2% per year, and most strokes are preceded by transient symptoms.[90] A significant prospective, randomized multicenter trial found that patients with asymptomatic carotid stenosis of 60% or greater benefited from revascularization if they were considered good risk and the surgeon had a 3% or lower perioperative morbidity and mortality rate.[91] However, after reviewing the published data, a more recent Symposium on Cerebrovascular Diseases concluded that because progression rates are extremely slow and patients with carotid stenosis are at substantial risk for MI and vascular death, revascularization should be contemplated only in centers with low complication rates for medically stable patients, those expected to live at least 5 years with 80% or greater stenosis.[90] There is no evidence that truly asymptomatic bruits increase the risk for perioperative stroke. Carotid Doppler ultrasound studies are simple effective tools to evaluate at-risk patients who might benefit from further evaluation. Significant abnormalities on Doppler studies should prompt referral to a vascular surgeon or neurologist.

Seizure Disorder

The type and frequency of seizures (e.g., grand mal or absence) and the specifics of symptoms such as staring or focal findings are important to ascertain and document. Absence (previously petit mal) seizures may be particularly difficult to recognize because they lack generalized motor signs. More typical symptoms such as staring and obtundation may be misinterpreted as residual anesthetic effects in the postoperative period. Brain tumors, aneurysms, arteriovenous malformations (AVMs), classic epilepsy, drug toxicity, electrolyte disorders, infections, and vascular disease from arteriosclerosis, stroke, sickle cell disease, or SLE can all cause seizures.

Preoperative evaluation and documentation of anticonvulsants and the adequacy of seizure control are necessary. Routinely ordering tests for serum drug levels of anticonvulsant medications is not indicated unless toxicity is a concern or the patient is having breakthrough seizures. Patients with good control of seizures may have levels outside the therapeutic range, and the results may be confounded if the timing of administration of the drugs in relation to when the blood is drawn is not considered. Generally, trough levels are necessary for accurate interpretation. Medications to control seizures have multiple side effects (bone marrow suppression, macrocytic anemia, leukopenia, hyponatremia), and testing should be directed at suspected abnormalities. A CBC with a platelet count and electrolyte levels are most commonly obtained. Poorly controlled or new-onset seizures require consultation with a neurologist before proceeding with anything other than emergency surgery. Continuation of anticonvulsants in the perioperative period is necessary.

Multiple Sclerosis

Multiple sclerosis is thought to be an inflammatory immune disorder with two general patterns of disability: exacerbating-remitting and chronic progressive.[92] Symptomatology can include ataxia, motor weakness, sensory deficits, autonomic dysfunction, emotional lability, bladder or bowel dysfunction, and visual disturbances. Exacerbations can be triggered by stress, infections, the peripartum, and elevated temperatures. Varieties of treatments

have been evaluated, including steroids, immunosuppressants, monoclonal antibodies, plasmapheresis, benzodiazepines, and baclofen. Preoperatively, it is important to document the history and pattern of disease, including symptoms and physical deficits, with special emphasis on respiratory compromise. Medications and previous triggers are important. There has been no documented association with the type of anesthetic or particular anesthetic agents and exacerbation of disease. Regional anesthesia may offer advantages for patients with respiratory compromise or cognitive dysfunction. Detailed documentation of preexisting neurologic deficits is important. Determination of oxygen saturation is needed. Testing is directed toward possible medication effects (e.g., azathioprine can suppress bone marrow and affect liver function, cyclophosphamide may cause electrolyte abnormalities, and steroids can cause hyperglycemia) and associated disturbances (e.g., chest radiography and white blood cell count if pulmonary infection is suspected). Patients with minor, stable disease require no special testing. Medications are continued on the day of surgery.

Aneurysms and Arteriovenous Malformations

Cerebral and spinal vascular lesions consist of aneurysms and AVMs, which may be intact or ruptured, symptomatic, or an incidental finding (see Chapter 63). Patients with polycystic kidney disease, fibromuscular dysplasia, type IV Ehlers-Danlos syndrome, or a family history of aneurysms are at increased risk for aneurysms. An AVM may be large enough to cause a mass effect. Pregnancy increases the risk for aneurysmal and possibly AVM bleeding. Before rupture, most patients will have minimal symptoms other than headache or seizures, but it is important to document complaints in all patients. With rupture, altered mental status, syncope, increased intracranial pressure with the typical signs and symptoms, inappropriate secretion of antidiuretic hormone, and hemodynamic perturbations are common. Bradycardia, tachycardia, ectopic beats, and ST-T wave changes, often mimicking those seen with ischemia, are common. Significant cardiac dysfunction with depressed contractility and wall motion abnormalities can be present on echocardiography. Preoperatively, concomitant CAD or preexisting cardiomyopathy should be considered and it not be assumed that these changes are related only to the bleeding. A preoperative ECG with determination of electrolytes, glucose, BUN, and creatinine is necessary. Chest radiography and echocardiography may also be helpful.

Parkinson's Disease

Parkinson's disease is a degenerative disorder of the basal ganglia in which failure of dopamine secretion results in diminished inhibition of the extrapyramidal motor system.[93] Preoperative patients typically have diminution of spontaneous movements, rigidity (cogwheel rigidity is classic), resting tremor, masked facies, difficulty speaking and walking, and frequently depression and dementia. Autonomic dysfunction with orthostatic hypotension, excessive salivation, and difficulty regulating temperature also occurs.

Patients are at risk for pulmonary complications because of difficulty swallowing and altered mental status and have an increased risk of aspiration and dysfunction of ventilatory muscles. Replacement of dopamine with levodopa, often combined with carbidopa, anticholinergic agents, bromocriptine, amantadine, and selegiline, is standard treatment. Levodopa can cause dyskinesias (dystonic and myoclonic involuntary movements). Pergolide, a dopamine receptor agonist, was recalled in early 2007 because of an increased risk for mitral and aortic regurgitation.[94] Patients exposed to this drug need a careful examination for murmurs and, if present, require an ECG and may require an echocardiogram. Selegiline is a monoamine oxidase inhibitor that inhibits dopamine degradation. Metoclopramine, phenothiazines, and butyrophenones may exacerbate symptoms by interfering with dopamine.

Preoperative evaluation focuses on the pulmonary system and degree of disability, especially dysphagia and dyspnea. Determination of room-air saturation and orthostatic BP and HR is important. Significant pulmonary symptoms, especially symptoms of infection or if worsening, may require a chest radiograph, pulmonary consultation, and delay of the procedure for improvement. Patients who have taken pergolide need auscultation for murmurs and, if present, may benefit from an ECG and echocardiogram. Deep brain stimulators need to be deactivated before procedures in which electrocautery will be used. All parkinsonian medications are continued. Abrupt withdrawal of levodopa may exacerbate symptoms, epecially dysphagia and chest wall rigidity, or result in neuroleptic malignant syndrome (NMS). NMS is characterized by autonomic instability, altered mental status, rigidity, and fever.

Neuromuscular Junction Disorders

Myasthenia gravis is an autoimmune disorder of skeletal muscle neuromuscular junctions that is due to antibodies against nicotinic acetylcholine receptors.[95] It is characterized by muscle weakness that worsens with activity and improves with rest.

Preoperative evaluation determines whether the patient has clinical or progressive weakness that can be exacerbated by stress, infections, hypokalemia, medications (aminoglycoside antibiotics, propranolol, ciprofloxacin, clindamycin), and surgery. Cardiac and smooth muscles are unaffected. Thymic hyperplasia and tumors may be present. The thymus is located in the anterior mediastinum and, when enlarged, has implications related to anesthesia (see "Mediastinal Masses"). Cranial nerve and bulbar involvement is common with pharyngeal and laryngeal muscle weakness, which increases the risk for aspiration. Ocular symptoms (diplopia, ptosis) are usually present and are frequently the initial or only complaints. Ventilatory function can be compromised. Preoperative PFTs are indicated for severely affected individuals and may be useful in predicting who may require postoperative ventilation.[96] PFTs may be particularly helpful if patients are being considered for ambulatory surgery, especially in freestanding surgical centers. Other autoimmune diseases such as rheumatoid arthritis, polymyositis, and thyroid disorders are common in myasthenics. See the appropriate sections of this chapter for discussion of these topics.

Patients are treated by thymectomy and with anticholinesterase and immunosuppressant medications. Worsening symptoms may be due to deteriorating disease (a myasthenic crisis) or excessive anticholinesterase treatment (a cholinergic crisis). By using a short-acting anticholinesterase (edrophonium), the two can be distinguished; only a myasthenic crisis will improve with more anticholinesterase. Plasmapheresis and intravenous immunoglobulins have been used to treat myasthenic crises or prepare patients for surgery but require several days to weeks for improvement.

Preoperative patients taking azathioprine require a CBC and LFTs because of the bone marrow suppression and liver dysfunction associated with this drug. Patients treated with steroids

need an ECG and glucose determination and may require higher doses in the perioperative period. Even though anticholinesterases may cause bradycardia (necessitating a preoperative ECG) and salivation and alter the effects of neuromuscular blocking and reversal agents, they need to be continued to prevent a myasthenic crisis. Documentation of dosages and schedules and continuation of these medications up until the time of surgery are paramount. Avoidance of drugs that can exacerbate myasthenic symptoms is necessary. Management with a neurologist is important.

Lambert-Eaton syndrome is similar to myasthenia gravis and consists of muscle weakness, including oculobulbar involvement, and dysautonomia. It is caused by antibodies against voltage-gated calcium channels, which results in a decrease in acetylcholine. It is not associated with thymic abnormalities but is most common with malignancies; small cell lung cancer is the most frequent cause, but it also occurs with gastrointestinal tumors. The other distinguishing feature is that the muscle weakness classically improves with activity and is worse after inactivity. Therapies similar to that used for myasthenia, along with 3,4-diaminopyridine, a selective potassium channel blocker, are used and continued perioperatively. Preoperative evaluation and management are similar to that for myasthenia gravis.

Muscular Dystrophies and Myopathies

Muscular dystrophies and myopathies are inherited disorders of the neuromuscular junction (see Chapter 14). They share many similarities but have a few differences. Progressive skeletal muscle weakness commonly leading to respiratory failure and no effective therapy are the hallmarks of these disorders. Many have associated cardiomyopathies and possibly an association with MH. Duchenne's and Becker's muscular dystrophies are X-linked recessive disorders that occur in males. Patients have elevated creatine phosphokinase levels, often detected before the onset of symptoms. Males with a family history of Duchenne's or Becker's muscular dystrophy who have not been tested are considered at risk and require similar precautions as those with diagnosed disease. Cardiomyopathy and respiratory failure are common causes of death. Otherwise, normal female carriers may have dilated cardiomyopathy.

Preoperative evaluation for symptoms such as palpitations, dyspnea, chest pain, syncope, orthopnea, edema, aspiration, and pneumonia is important. Physical examination focuses on the cardiopulmonary system. An ECG, PFTs, and echocardiography are important in the preoperative evaluation.

Fascioscapulohumeral dystrophy is autosomal dominant, affects both genders, and causes a slowly progressive weakness of muscles of the shoulders and face. Cardiomyopathy is much less frequent than in the other dystrophies, but arrhythmias have been reported. Limb-girdle dystrophies have a variable inheritance and primarily affect the muscles of the shoulders and pelvis. Conduction abnormalities are present in some patients, although frank cardiomyopathies are less frequent. Inquiring about palpitations, syncope, and cardiac symptoms, examining patients as noted earlier for Duchenne's muscular dystrophy, and obtaining an ECG preoperatively are important.

Myotonic Dystrophies

Myotonia is prolonged contraction and delay of relaxation of muscles. It is a common symptom of several dystrophies, including classic myotonic dystrophy, congenital myotonic dystrophy, myotonia congenita, and central core disease. Myotonic dystrophy is the most common of these conditions and is an autosomal dominant inherited disorder that affects both genders. Congenital myotonic dystrophy is a severe form of this disease that is noted in infancy, often in the offspring of mothers with myotonic dystrophy.

Preoperative classic findings are severe muscle wasting, typically involving the face, hands, diaphragm, and pharyngeal, laryngeal, and pretibial muscles. Cold can trigger myotonia. The severity of disease is variable and it may not be apparent until the second to third decades of life, so a family history is important. Cardiomyopathies, arrhythmias, and conduction abnormalities are common, and some patients have cardiac valvular abnormalities. Cardiac involvement may not correlate with skeletal muscle atrophy or weakness. Patients require pacemakers once any evidence of second- or third-degree AV block develops, even if the patient is asymptomatic, because there may be unpredictably rapid progression of AV conduction disease. As a result of this potential for rapid progression, pacemaker placement is considered in these patients even with a first-degree AV block, regardless of symptoms. Aspiration with pneumonia and respiratory or cardiac failure are common. An increased risk for pulmonary complications postoperatively has been reported.[97]

Central core disease is a rare disorder consisting of a deficiency of mitochondrial enzymes. The name derives from the pathology of muscle biopsy specimens in which "cores" of abnormalities are apparent. Patients have proximal muscle weakness and scoliosis and may have cardiomyopathies. They are at risk for respiratory failure and aspiration, much like patients with myotonic dystrophy. Myotonia congenita is a hereditary disorder involving only skeletal muscles, is less severe, and does not cause cardiac abnormalities.

Patients with myotonia may be at increased risk for MH, although this is controversial. They may have similar findings as those with MH as a result of uncontrolled myotonic contraction with elevated metabolism and rhabdomyolysis.

Steroids, quinine, and procainamide may relieve myotonic contractions, but there is no cure for these diseases. These medications need to be continued perioperatively. The history and physical examination focus on the cardiopulmonary systems with special emphasis on findings of pulmonary infection, heart failure, palpitations, syncope, and conduction and valvular abnormalities. Preoperative testing includes an ECG and echocardiogram (except for patients with myotonia congenita), as well as a chest radiograph if acute symptoms of pulmonary disease are present. Any conduction abnormality on the ECG may benefit from cardiology consultation.

Central Nervous System Tumors

Pituitary tumors may be functioning (associated with endocrine abnormalities) or nonfunctioning and benign (adenomas are the most common pituitary lesion) or malignant (see Chapter 63).

Preoperative evaluation determines whether symptoms related to a mass effect of the tumor are present (e.g., headaches, visual field defects) or symptoms related to elevations in intracranial pressure are present (e.g., gait disturbances, vomiting, cranial nerve deficits, or bladder or bowel incontinence). Symptoms may be related to pituitary insufficiency (hypoadrenalism, hypothyroidism, or infertility being most common) or overactivity (Cushing's syndrome from tumors secreting ACTH; acromegaly from growth hormone secretion; hyperthyroidism from TSH production; gynecomastia, lactation, and sex hormone–

related changes from secretion of prolactin and gonadotropin [follicle-stimulating and luteinizing hormone]). These hormones are all produced by the anterior lobe of the pituitary and controlled via a feedback loop by the hypothalamus. The posterior pituitary stores and secretes vasopressin and oxytocin, which are synthesized in the hypothalamus. Cushing's syndrome results from excess cortisol production by the adrenals (stimulated by ACTH from the pituitary) and is discussed in the metabolic section of this chapter.

Acromegaly is caused by excess growth hormone and results in enlargement of connective tissue, bone, and visceral organs. On the preoperative physical examination, patients classically have an enlarged jaw (macrognathia), nose, feet, hands, and pharyngeal and laryngeal tissues, including the epiglottis and tongue (macroglossia). Patients have an increased incidence of both central sleep apnea and OSA, neuropathies from nerve entrapment, hypertension, LVH, diastolic dysfunction, and valvular abnormalities. CAD, heart failure, diabetes, hypothyroidism, and difficulty with mask ventilation, laryngoscopy, and intubation occur.

Preoperative solicitation and documentation of symptoms such as chest pain, dyspnea, snoring, numbness, polydipsia, headaches, and visual disturbances are important. Physical examination focuses on BP, airway features, murmurs, neurologic findings, and edema. Planning for difficult airway management plus discussion with the patient of possible awake fiberoptic intubation is necessary. An ECG, echocardiogram, electrolyte and glucose determination, and thyroid function tests are usually obtained.

TSH increases production of thyroid hormones (T_3 and T_4) by the thyroid gland. See the section "Thyroid Disease."

Posterior pituitary tumors result in failure to secrete vasopressin, also known as antidiuretic hormone, which regulates excretion of water by the kidneys. Deficiency of antidiuretic hormone results in excessive urine output from failure to reabsorb water and causes diabetes insipidus. These patients need estimation of volume status with orthostatic BP and HR measurement and electrolyte, BUN, and creatinine determination. Patients may have hypernatremia and volume depletion unless maintained on DDAVP.

Prolactin- and gonadotropin-secreting tumors have little impact on anesthetic management, but associated symptoms may alert clinicians to an undiagnosed pituitary tumor.

Patients with tumors or postpartum hemorrhage that cause pituitary insufficiency or those who have undergone resection of a pituitary tumor may require hormonal replacement such as steroids, thyroid medications, or DDAVP. It is important that these medications not be interrupted during the perioperative period. The preoperative history and physical examination should determine whether patients are adequately treated. Determining electrolyte, BUN, and creatinine levels and performing thyroid function tests and an ECG are necessary.

Intracranial tumors include gliomas (45% of tumors), such as glioblastoma multiforme, astrocytoma, ependymoma, medulloblastoma, and oligodendrocytoma, which are malignant and highly lethal. Benign meningiomas (15%) arise from the dura or meninges. Metastatic lesions (6%) are associated with virtually all types of malignancies. Schwannomas, craniophyaryngiomas, and dermoid tumors also occur. Most intracranial tumors are detected when symptoms related to a mass effect develop, patients have seizures, or they are found incidentally. Symptoms include headaches, stroke-like symptoms, vomiting, visual disturbances, altered cognitive function, and ataxia. If intracranial pressure becomes elevated, hypertension, bradycardia, arrhythmias, ECG abnormalities, and risk of brainstem herniation develop.

Careful questioning and documentation of neurologic deficits and symptomatology are important. For patients with metastatic lesions, issues pertaining to the primary malignancy or previous treatment need to be clarified. Continuation of steroids to decrease brain edema and anticonvulsant medications is essential.

Preoperative Evaluation of Patients with Psychiatric Disorders

Key issues in the preoperative assessment of patients with psychiatric disorders include assessing cognitive capacity, obtaining an accurate psychiatric history, evaluating the patient's capacity to give informed consent, and assessing the impact of psychotropic medications.[98]

Cognition is usually unimpaired in patients suffering from illnesses such as depression or schizophrenia and impaired in those suffering from disorders such as delirium, dementia, and autism. Orientation and memory should be assessed by the preoperative clinician to ensure that cognition is sufficient to obtain an accurate history and consent. Basic orientation to person, place, and time can be determined during the preoperative conversation or by looking at the way the patient has answered questions on forms. Mild cognitive impairment is frequently associated with mild dementia in elderly patients, who are at risk for postoperative delirium. More severe cognitive impairment raises issues regarding the reliability of the history and ability to obtain informed consent. Family members can aid by providing the history and countersigning consent forms.

Musculoskeletal and Connective Tissue Diseases

Deformities and chronic inflammation are key components of many of these disorders. The deformities need to be determined because of potential challenges in airway and regional anesthesia management. Chronic inflammation and associated vasculopathy with diseases such as rheumatoid arthritis, SLE, and scleroderma or systemic sclerosis often result in multiorgan dysfunction. The cardiovascular, pulmonary, renal, hematologic, integumentary, gastrointestinal, central, and peripheral nervous systems can all be involved.

Rheumatoid Arthritis

Rheumatoid arthritis affects up to 1% of the population (females more than males) and is a chronic autoimmune disorder primarily affecting the joints but often multiple systems.[99] Both large and small joints become inflamed, and severe deformity is possible, although the disease course varies dramatically. The temporomandibular joints and cricoarytenoid cartilage can be involved and result in limited mouth opening and hoarseness. Atlantodens subluxation and cervical spine instability can occur.

Subluxation is caused by laxity of the ligaments, not joint disease, and may be present in as many as 46% of patients.[100] Cervical spine diseases can occur without symptoms. Vasculitis or entrapment results in peripheral neuropathy. CAD, pericardial effusion, aortic regurgitation, and conduction abnormalities are frequently present.[101] The often severely limited functional status in these patients masks ischemic symptoms. Dyspnea, which can be an anginal equivalent, especially in women, may be confused with pulmonary symptomatology. Restrictive lung disease from decreased thoracic mobility, interstitial fibrosis, and pleural effusions may occur. Patients have an increased incidence of renal dysfunction from both vasculitis and chronic use of NSAIDs. Anemia, leukocytosis, and both thrombocytosis (from chronic inflammation) and thrombocytopenia (from splenomegaly) can be found. Rheumatoid nodules occur subcutaneously, usually over extensor joints, or in the lungs.

The preoperative history and physical examination are performed to document symptoms related to the many organ systems affected by rheumatoid arthritis (refer to appropriate sections of this chapter). Special detail needs to be given to the airway and to the neurologic, pulmonary, and cardiovascular systems. A careful history may elicit neurologic deficits, neck and upper extremity pain, and a crunching sound with neck movement. Patients who have neurologic deficits or symptoms or long-standing, severely deforming disease or who are scheduled to undergo procedures requiring manipulation of the cervical spine or special positioning, such as turning prone, require anteroposterior and lateral cervical spine radiographs with special flexion, extension, and open-mouth odontoid views.[100] Significant abnormalities (anterior atlas-dens interval >9 mm or posterior interval <14 mm) may benefit from consultation with a neurologist or neurosurgeon. However, the duration, severity, or symptoms of the disease do not correlate with cervical spine subluxation.

Preoperative documentation of deformities and neurologic deficits is important to establish a baseline level of function. For patients with significant hoarseness, referral to an otolaryngologist to assess mobility of the vocal cords and the degree of cricoarytenoid arthritis may be of benefit.[102] Acute or worsening pulmonary symptoms may trigger a need for pulse oximetry, chest radiographs, PFTs, or a pulmonary consultation (see the section "Pulmonary Disorders"). An ECG is always indicated, and abnormalities may prompt further testing or referral to a cardiologist, or both. Muffled heart sounds, pericardial rubs, and an enlarged heart detected by examination or on a chest radiograph together with low voltage on an ECG suggest a pericardial effusion, which can be evaluated with an echocardiogram. Many murmurs, especially if new, would benefit from further investigation (see Table 34-4 and Box 34-4). A CBC with a platelet count and determination of BUN and creatinine are indicated, except for the most minor of procedures.

Advanced planning for the management of identified or potential difficult airways is important. Discussion of regional anesthetic options and awake fiberoptic intubation is necessary. Continuation of steroids and chronic pain medications is optimal, but drugs with antiplatelet effects are generally discontinued and immunosuppressants may have to be temporarily stopped to allow normalization of blood counts. Patients with complex regimens and severe disease are best managed in concert with their rheumatologist or primary physician.

Ankylosing Spondylitis

Ankylosing spondylitis is a progressive inflammatory arthropathy that affects mainly the spine and sacroiliac joints.[103] It occurs primarily in males and can be accompanied by uveitis, peripheral arthritis, and vasculitis causing aortitis and aortic insufficiency. Restrictive lung disease can result from pulmonary fibrosis or poor chest wall movement secondary to joint fixation and kyphosis. Kyphosis can be so extreme that patients cannot face forward and are extremely difficult to intubate or even mask ventilate.

Preoperative evaluation by history and physical examination focuses on the skeletal and cardiopulmonary systems. A murmur warrants an ECG and may benefit from an echocardiogram. If ventilatory compromise is suspected or present, room-air pulse oximetry and a chest radiograph are necessary, as well as PFTs when appropriate. Acute processes must be managed preoperatively.

Patients taking NSAIDs require determination of BUN and creatinine levels, and a CBC with a platelet count and LFTs are indicated for those treated with leflunomide. Planning for airway management and discussion with the patient about the possibility of awake fiberoptic intubation are important. Peripheral nerve blocks are options, but centroneuraxial anesthesia is often unsuccessful because of severe spinal involvement.

Systemic Lupus Erythematosus

SLE is a systemic autoimmune disease predominately caused by vasculitis; it has a variable course, often with remissions punctuated by flares.[104] SLE affects mainly females and is typically more severe in African Americans than in other groups.

Preoperative evaluation determines whether the patient has chronic fatigue, weakness, respiratory compromise, fevers, and migratory arthritis affecting primarily the small joints of the hands and feet, which is common. Fevers may be a result of the disease itself or the frequent infections that develop because of the immune dysfunction and immunosuppressants used to treat the disease. Many patients have dermatologic conditions, including alopecia, the typical "butterfly rash" across the cheeks and nose, and photosensitivity. Vasospasm of the digits, dubbed Raynaud's phenomenon or disease, often with atrophy of the nails and fingernails, makes it difficult to obtain pulse oximetry readings.

Preoperative evaluation for interstitial lung disease, pleural effusions, frequent infections, and pulmonary hypertension is important and presents a significant concern. Pulmonary hypertension can result from interstitial lung disease, recurrent pulmonary emboli, or cardiomyopathy and carries a high risk of perioperative complications (see "Pulmonary Hypertension"). Cardiac involvement includes premature coronary artery arteriosclerosis, pericarditis, myocarditis, aseptic endocarditis, and pleural effusions.

Coronary vasculitis and cardiomyopathy may occur. Hypertension, frequently difficult to control, is almost ubiquitous. Neuropsychiatric manifestations consisting of cerebral vasculitis, stroke, cognitive dysfunction, seizures, peripheral neuropathy, headache, affective disorders, and carotid artery disease are common. Lupus nephritis is a common morbidity with a poor prognosis that frequently results in renal failure. Patients with SLE often have anemia and may have leukopenia and thrombocytopenia.

Antiphospholipid antibodies occur frequently and can result in a coagulopathy with recurrent episodes of venous and arterial thrombosis, including pulmonary emboli and stroke. Typically, the aPTT is prolonged in these patients. Antinuclear antibodies are present in most cases and can help establish a diagnosis, especially with atypical manifestations.

The preoperative history and physical examination must evaluate all major organ systems and identify medications. Patients with severe disease, exacerbations, or infections are best managed along with the physicians primarily responsible for their care or a rheumatologist. Detailed questioning regarding neurologic symptoms, coughing, dyspnea, chest pain, orthopnea, fever, the course of disease, and medications is paramount. Any history of thromboembolic events is important, but recent events regarding precipitating factors, type and duration of treatment, and severity of the event (e.g., pulmonary embolus or DVT) must be detailed so that one can plan discontinuation of anticoagulants and need for bridging. Because of the significant incidence of both cerebrovascular and coronary artery lesions in these patients, careful questioning about exercise capacity, atypical symptoms of ischemia, and any previous diagnostic studies such as computed tomography, magnetic resonance imaging, echocardiography, or stress testing may be revealing.

Systemic Sclerosis

Systemic sclerosis, previously known as scleroderma, is an autoimmune disease characterized by excessive fibrosis that occurs more commonly in females.[105] Raynaud's phenomenon is the most common occurrence besides skin thickening. Localized scleroderma involves just the skin without involvement of other organs. Limited cutaneous systemic sclerosis is "limited" to the skin of the face and upper extremities as the cutaneous manifestation, but with systemic involvement, the gastrointestinal tract (dysphagia, reflux) and lungs (interstitial lung disease, pulmonary hypertension) can be affected. Pulmonary hypertension is associated with a poor prognosis and increases perioperative risk (see "Pulmonary Hypertension").[106] Diffuse cutaneous systemic sclerosis causes generalized skin thickening and multiple end-organ damage. Myocardial fibrosis, pericarditis, heart failure, and coronary artery fibrosis or spasm can occur. Patients often have severe hypertension, renal failure, dysphagia, fatigue, weight loss, reflux, and right heart failure.

The preoperative history and physical examination focus on the organ systems as outlined in the section "Systemic Lupus Erythematosus," with special attention paid to signs or symptoms of pulmonary hypertension (see "Pulmonary Hypertension"). A careful history to elicit symptoms of pulmonary disease (cough, dyspnea) or cardiac disease (dyspnea, orthopnea, chest pain) is vital. A murmur of tricuspid regurgitation and a split second heart sound are suggestive of pulmonary hypertension. Because of the thickened and fibrosed skin, microstomia, limited neck mobility, poor dentition, and oropharyngeal lesions, airway examination and planning for management are essential. Dermal thickening, scarring, edema, and contractures make venous access and regional anesthesia challenging. Discussing central venous access, even arranging for interventional radiology to place intravenous lines, and explaining the possibility for awake fiberoptic intubation will help on the day of surgery.

Preoperatively, patients with systemic sclerosis need an ECG and determination of BUN and creatinine levels. A CBC with a platelet count is indicated in those taking immunosuppressants. A chest radiograph and PFTs can be useful when evaluating patients with symptoms (cough, dyspnea) or signs (rales, hypoxemia) of possible interstitial lung disease or pulmonary fibrosis. Echocardiography is useful to screen for pulmonary hypertension in patients suspected of having this significant end-organ complication. Calcium channel blockers to treat Raynaud's phenomenon, antihypertensive agents, and immunosuppressants need to be continued preoperatively.

Inherited Connective Tissue Disorders

Ehlers-Danlos syndrome, a disorder of collagen synthesis, consists of several subtypes that have various manifestations, but almost all are characterized by joint hypermobility. Type IV is one of the most serious because those affected may have vascular and skin fragility and are at risk for vascular and visceral rupture and pneumothorax. Patients with type VI Ehlers-Danlos syndrome have muscle weakness, scoliosis, ocular and skin fragility, and osteopenia.

Marfan's syndrome is characterized by tall stature, arachnodactyly (long digits), scoliosis, pectus excavatum, ascending aortic dilatation and even dissection, valvular disease (aortic insufficiency, mitral valve prolapse, mitral regurgitation), and arrhythmias. Ocular (ectopia lentis, strabismus, glaucoma) and pulmonary (blebs, spontaneous pneumothorax) complications can occur.[107] Patients may have retrognathia and high arched palates. Careful auscultation for the diastolic murmur of aortic insufficiency is important (see Table 34-3). An ECG, echocardiogram, and chest radiograph should be obtained if a murmur is detected and management will be changed.

The most distinguishing feature of osteogenesis imperfecta is the propensity of patients for fractures from extremely fragile bones. Patients may have blue sclerae, short stature, scoliosis, joint hypermobility, hearing loss, pulmonary complications, muscle weakness, mitral valve prolapse, aortic insufficiency, and platelet dysfunction. An ECG and echocardiogram are necessary if a murmur is detected.

Epidermolysis bullosa is distinguished by blistering, skin fragility, and scarring because of abnormal epidermal-dermal anchoring. Even obtaining a BP reading may cause skin blistering and breakdown.

Kyphoscoliosis

Kyphoscoliosis is a curvature of the spine both laterally and anteriorly and may involve the thoracic or lumbar regions, or both. It occurs alone as as a manifestation of other diseases, including collagen vascular disorders, Marfan's syndrome, neurofibromatosis, muscular dystrophies, and cerebral palsy, among others. Therefore, the preoperative evaluation is aimed at identifying coexisting abnormalities. Pulmonary and cardiac compromise can occur with severe thoracic deformity. Restrictive lung disease, pulmonary hypertension, tracheobronchial and cardiac compression, and heart failure are possible.
